A typical HTF system consists of a heater, heat exchangers to transfer heat to the process fluid(s), a storage reservoir and an expanse tank. The storage vessel may double as a discharge vessel or there may be a separate discharge vessel. There may be an emergency cooler. Flow diagrams of HTF systems are given in the IChemE *Guide* and the CCPS *Guidelines*.

The heat input is provided by a heater, except for smaller units where electrical heating is used. It follows that an HTF system is subject to the various problems of fired heaters and that the precautions applicable to fired heaters in general, described in Chapter 12, are required for those in HTF systems. They include on the heater tubes trips on high temperature and low flow.

In contrast to most fired heaters, the fluid in an HTF system is recirculated. The conditions created by this combination of fired heating and recirculation are severe and fluid degradation is characteristic of HTF systems. One consequence can be coking and plugging of the heater tubes.

Heat transfer fluids tend to be 'searching' and HTF plants have a history of leaks, particularly at flanges. Ignition occurs where the leaking fluid is above its autognition temperature. Another problem due to leaks is saturation of the lagging, resulting in lagging fires.

Pressure relief valves on HTF systems have not always been well located, so that fluid has been discharged and has then found a source of ignition. Experience also shows that both out-leak of the HFT and in-leak of another fluid may occur. Precautions include the installation of a low level trip and a high level alarm on the expanse tank.

The need for security of supply of the hot fluid varies. A reliable system may be necessary, for example, in an application where heat is required to prevent a process fluid going solid in the plant.

11.10.17 Heat transfer media: refrigerants

Refrigerants are used to cool process fluids to temperatures lower than those achievable using cooling water. Accounts of refrigeration are given in the *ASHRAE Refrigeration Handbook* by the American Society of Heating, Refrigerating and Air-conditioning Engineers (ASHRAE, 1990/3). Other relevant ASHRAE publications are the *ASHRAE Thermodynamic Properties of Refrigerants* (ASHRAE/2) and the *ASHRAE Handbook of Fundamentals* (ASHRAE, 1993/7).

Basic methods of obtaining refrigeration are Joule–Thomson expansion, work expansion, evaporation refrigeration and absorption refrigeration. Joule–Thomson and work expansion may be used within the process to effect direct cooling of process fluids. Evaporation and absorption refrigeration sets are used to provide indirect cooling.

A variety of refrigerants are available, including: ammonia (R717); carbon dioxide; ethylene (R170), ethane (R1150), propylene (R1270) and propane (R290); and chlorofluorohydrocarbons (CFCs) such as dichlorodifluoromethane (R12) and chlordifluoromethane (R22). In selecting a refrigerant it is necessary to consider the general properties, the safety features and the environmental features.

Relevant general properties are the normal boiling point and refrigerant service temperature, the latent heat and the coefficient of performance (COP). Safety features include flammability and toxicity, in conjunction with the inventory required. The main environmental feature is the ozone depletion potential.

The replacement of materials with noxious properties such as ammonia (toxic) and ethylene (flammable) with non-toxic, non-flammable CFCs has been arrested by the environmental harm which the latter cause. The production and use of CFCs is restricted by the Montreal Protocols. New refrigerants to replace CFCs comprise an active area of development.

In some applications it may be necessary to consider other properties of the refrigerant, such as its interaction with the process fluid in the event of a pinhole leak.

A summary of general and environmental properties of refrigerants is given in the IChemE *Guide* and more detailed information in the ASHRAE handbooks. These publications also deal with refrigeration cycles and with package refrigeration sets.

Use is sometimes made in the process industries of systems in which a refrigerated heat transfer fluid is circulated between a refrigeration set and the process. A typical refrigerated fluid used in such applications is ethylene glycol.

11.10.18 Contamination hazards

Many of the services described are fluids. Hazards can arise from contamination of process materials by service fluids or contamination of service fluids by process materials. The contamination may occur through pipes and valves or by leakage in equipment.

Accidental entry of water, including steam, into the plant can have serious consequences. The water may vaporize, giving a large increase in pressure, or it may cause an oil–water 'slopover'. It may react violently with the process materials, it may ruin catalysts or adsorbents, it may give rise to very rapid corrosion and it may freeze and cause blockages. With accidental air ingress the main hazard is the formation of a flammable mixture.

In order to prevent unwanted entry of water and air into the plant through the pipework, it is necessary to provide positive isolation. This may require the use of double block and bleed valves rather than single valves. There need to be equally effective measures to prevent operational errors.

Contamination can also occur due to leakage of equipment. In particular, steam vaporizers and reboilers often develop pinhole leaks. If the consequences of such a leak might be serious, consideration should be given to the use of an alternative means of heating such as a heat transfer fluid.

The entry of process materials into lines carrying service fluids can have equally serious results. Toxic materials may enter the water supply, flammable vapours may pass into the air lines, or air may get into the nitrogen supply. In all these cases the hazard is obvious. It is essential, therefore, to check whether flow reversals into the service fluids could occur which might create a hazardous situation and to take any appropriate measures.

There is a particular obligation to ensure that the public water supply is not contaminated. If water is drawn from this for process use, positive means such as a break tank should be provided to prevent backflow and possible contamination.

11.11 Particular Chemicals

Accounts of the properties, manufacture and use of chemicals are given in the *Kirk–Othmer Encyclopaedia of Chemical Technology* (Kirk and Othmer, 1963–, 1978–, 1991–) and in *Ullmann's Encyclopaedia of Chemical Technology* (Ullmann, 1969–, 1985–). Selected references on particular chemicals and their hazards are given in Table 11.8.

The number of chemicals used in the process industries is very large. The few principal chemicals considered here are selected because they are important in their own right and because they illustrate the type of factors which have to be taken into account. The chemicals are:

(1) hydrocarbons;
(2) acetylene;
(3) acrylonitrile;
(4) ammonia;
(5) chlorine;
(6) ethylene dichloride;
(7) ethylene oxide;
(8) hydrogen;
(9) hydrogen fluoride;
(10) oxygen;
(11) phosgene;
(12) vinyl chloride.

Table 11.8 *Selected references on particular chemicals and their hazards*

Notes: (a) The former Manufacturing Chemists Association (MCA) SD series, given in the first edition of this book, is not included. (b)The FPA Compendium of Fire Safety Data, vol.4, H series is denoted by the H number. (c) Company materials safety data sheets are now a much improved source of detailed information.

Deterioration of chemicals
Crowl and Louvar (1990); Kletz (1992a)

The emission and dispersion characteristics of materials are treated in Chapter 15 and flammability, explosibility and toxicity in Chapters 16–18, whilst storage, transport and emergency planning are treated in Chapters 22–24, respectively.

The accounts of particular chemicals given in the table are based mainly on the codes of practice and other guidance documents of the Chemical Industries Association (CIA) and the HSE. An overview of some principal topics covered in these publications is given in Table 11.9. Storage is dealt with in all the publications to some degree and in several it is the main content. It is convenient, if somewhat arbitrary, to cover it separately in Chapter 22. The treatment of the individual chemicals given here is intended to highlight their characteristic features; it is not a detailed summary of the codes and guidance. For LPG, there are codes issued by the Liquefied Petroleum Gas Association (LPGA) in the United Kingdom and the National Fire Protection Association (NFPA) in the United States.

Toxic limits are given in *Occupational Exposure Limits* (HSE, 1994 a,b EH 40/94). The normal limit is the long-term time-weighted average (TWA), but the limit given is in some cases the maximum exposure limit or the short-term exposure limit (STEL). Alternatively, the substance may be classed as an asphyxiant. The HSE has also given guidance on toxicity in relation to major hazards for several of the materials, namely acrylonitrile, ammonia, chlorine and hydrogen fluoride, as described in Chapter 18.

One topic treated in most of the publications mentioned is pressure relief and relief of thermal expansion of liquids. Overall, the treatments are broadly similar, but contain differences of detail, the reasons for which are not always clear. In the treatments given below some mention is made of such reliefs, but only to highlight certain points particular to the chemical in question. An account of pressure relief and thermal relief for chlorine systems, which contains many typical features, is given in Chapter 12.

Guidance on safety cases under the Control of Industrial Major Accident Hazards Regulations 1984 (CIMAH) and on quantitative risk assessment is available, from different sources, for several of the materials, as described in Chapter 9. These include LPG, ammonia, chlorine and oxygen.

11.11.1 Hydrocarbons, LPG and LNG

Some of the principal hydrocarbons processed in the petrochemical industry are as follows:

	Normal boiling point (°C)
Methane	−161.4
Ethane	−88.6
Propane	−42.2
n-Butane	−0.6
Ethylene	−103.9
Propylene	−47.7

Methane is the main component of natural gas, which in liquefied form is known as liquefied natural gas (LNG). Propane and butane are referred to as liquefied petroleum gas (LPG). LNG and LPG are treated more fully in Section 11.12.

The hydrocarbons listed above are all gases at normal temperature and pressure, but can all be liquefied with a greater or lesser degree of difficulty. All are handled industrially in the liquid phase by the use of low temperatures, high pressures or both.

In many cases these materials are held not only under pressure but also at the high temperatures necessary for processing. The handling of hydrocarbons in this way means that if containment is lost, dispersion may be quite rapid. In particular, a material held under pressure and above its normal boiling point will flash off when let down to atmospheric pressure.

The use of extremes of temperature, both high and low, creates difficulties in materials of construction. Some of these are discussed in Chapter 12. In particular, there are problems of brittle fracture at low temperature and of creep at high temperature. The use of low temperatures also means that there is continual heat in-leak into the plant, which can become a problem if there is an interruption to processing or if insulation is lost. The hydrocarbons are flammable and can therefore give rise to the hazards both of fire and of explosion.

In addition to their use in the process industries, several of these hydrocarbons are widely used as fuels. In particular, propane and butane enjoy widespread use as fuels in the form of LPG supplied from self-contained storage installations. Natural gas, which is mainly methane, is transmitted by high pressure pipeline to the public distribution system for industrial and domestic users. It is also transported and stored as LNG. Natural gas liquids (NGLs), which are mainly ethane, propane and butane, are also transported by pipeline. Again there are hazards of fire and explosion associated with these materials. Fire and explosion hazards of hydrocarbons are considered in detail in Chapters 16 and 17, respectively.

11.11.2 Acetylene

Accounts of acetylene are given in *Acetylene – Its Properties, Manufacture and Use* (S.A. Miller, 1964), *Acetylene Manufacture and Uses* (Hardie, 1965), *Acetylene by the*

***Table 11.9** Some topics covered in certain Codes of Practice, and guidance for particular chemicals*[a]

[a] The publications referred to are as follows: acrylonitrile (CIA, 1978 PA11); ammonia (HSE, 1986 HS(G) 30); chlorine (HSE, 1986 HS(G) 28); ethylene dichloride (CIA, 1975 PA13); ethylene oxide (CIA, 1992 RC14); hydrogen fluoride (CIA, 1978 PA14); phosgene (CIA, 1975 CPP5); vinyl chloride (CIA, 1978 PA15). The numbers in the body of the table refer to the page numbers of these publications. Storage is considered separately in Chapter 22.

[b] Special properties: ammonia (oxygen); chlorine (nitrogen trichloride); ethylene oxide (decomposition, polymerization); phosgene (decomposition in water, reaction with lubricating oils); vinyl chloride (polyperoxides).

Compressed Gas Association (CGA, 1990 G-l) and *Acetylene Transmission for Chemical Synthesis* (CGA, 1970 G-1.3) and by Sargent (1957), S.A. Miller and Penny (1960), Schmidt (1971), Manyik (1978), P.J.T. Morris (1983), Passler *et al.* (1985) and Hort and Taylor (1991).

Codes for the handling of acetylene in the United Kingdom are issued by the British Compressed Gases Association (BCGA, 1986 CP 5, 1986 CP 6), the successor to the British Acetylene Association.

Acetylene is produced from calcium carbide or by the cracking or oxidation of hydrocarbons. Acetylene is highly reactive due to its triple carbon–carbon bond and was for many years the basis of a whole branch of the chemical industry, including in particular products derived from the intermediate tetrachloroethane, and of vinyl chloride. Acetylene chemistry has always been particularly strong in Germany. Thus, in 1958 the production of calcium carbide in West Germany, East Germany, the United States and the United Kingdom was 979,000, 815,000, 805,000 and 145,000 ton, respectively. Since the 1960s acetylene has been largely replaced by ethylene as the raw material for these products. Production peaked in the United States in 1960 at 480,000 ton/year and in Germany in the 1970s at 350,000 ton/year. New processes have been developed for the manufacture of acetylene, but these have not arrested its decline. However, there is some evidence that this decline has slowed, partly because acetylene has always been the main route for some chemicals such as 1,4-butanediol and special vinyl esters, and partly because in Europe the relative cost of oil to natural gas feedstock rose.

In the United Kingdom, acetylene was brought under the provisions of the Explosives Act 1875 by an Order in Council in 1897. For pressures exceeding 24 psig the installation came under the control of the Explosives Inspectorate. The legal requirements associated with this regime are described in *The Law Relating to Petroleum Mixtures, Acetylene, Calcium Carbide, etc.* (H. Watts, 1956). Legislation on acetylene is discussed in Chapter 3.

Acetylene is a gas. It is a flammable and explosively unstable material. For occupational exposure it is classed as an asphyxiant. Acetylene undergoes explosive decomposition at any pressure and temperature and even without the presence of oxygen. Acetylene decomposition may be initiated by shock, temperature or reactive substances. The decomposition may range from a harmless puff of flame to a violent explosion.

In particular, acetylene reacts violently with substances such as chlorine. Thus in the production of vinyl chloride by the reaction of acetylene with hydrogen chloride, where the latter is produced by burning hydrogen and chlorine, it is essential to ensure that there is no free chlorine in the hydrogen chloride. On the other hand, acetylene and chlorine are bubbled into liquid tetrachloroethane in the process for the manufacture of the latter product.

The explosion hazard with pure acetylene is most severe in pipelines. Here a deflagration may travel down a pipe until it becomes a detonation, which is much more destructive. This is a well-known effect in pipeline explosions, but acetylene presents a particularly severe problem in this regard. Further information on acetylene decomposition in equipment and pipelines is given by Schmidt (1971) and by Carver, Smith and Webster (1972). Despite this hazard, long-distance acetylene pipelines have been developed in Germany. Precautions against explosions include the earthing of pipes against static electricity and the use of flame arresters. There are no long-distance acetylene pipelines in the United Kingdom.

The usual material of construction for plant handling acetylene is mild steel. It is necessary in such plant to eliminate copper and brass, which can give rise to the formation of the highly explosive compound copper acetylide.

In some processes, traces of acetylene may be present in the effluent gases. These gases are sometimes cooled to condense out other components. In such cases, consideration should be given to the possibility of forming solid acetylene. Although the literature suggests that pure solid acetylene is not hazardous, this may not be the case if the material is impure.

Bulk acetylene is stored in gasholders. Holders with a capacity of 1000 m^3 have been used in the United Kingdom. Acetylene is stored and distributed in cylinders containing acetone and is widely used in this form, particularly for oxyacetylene welding.

11.11.3 Acrylonitrile

A relevant code for acrylonitrile is the *Codes of Practice for Chemicals with Major Hazards: Acrylonitrile* (the Acrylotnitrile Code) by the CIA (1978). Accounts are also given in *Acrylonitrile* (Dalin, Kolchin and Serebryakov, 1971) and by Langvardt (1985) and Brazdil (1991).

Acrylonitrile is a liquid with a normal boiling point of 77°C. It has moderate solubility in water. It is flammable, the flammable range being 3–17% and the flashpoint −1°C. It is toxic and has a long-term maximum exposure limit of 2 ppm.

Acrylonitrile is liable to polymerize and thus in storage needs to be stabilized. Stabilizers used are methyl ether of hydroquinone (MEHQ), ammonia and water.

Materials of construction for acrylonitrile plants are carbon steel, and for polymerization plants stainless steel. Copper and its alloys should not be used, since they cause contamination which inhibits subsequent polymerization.

Pumps used for transfer may be of the centrifugal or positive displacement types. For centrifugal pumps located outdoors a single mechanical seal is usually adequate, but indoors consideration should be given to double mechanical seals. At normal pumping rates of about 3 m/s the generation of static electricity by acrylonitrile should be minimal, but plant handling this chemical should be earthed.

In relief systems for acrylonitrile, consideration should be given to possible condensation in the relief line.

11.11.4 Ammonia

There is no single code of practice applicable to ammonia, but there are several codes covering particular aspects. These include *Storage of Anhydrous Ammonia under Pressure in the United Kingdom* (HSE, 1986a–c HS(G) 30), *Anhydrous Ammonia – Guidance for the Large Scale Storage, Full Refrigerated, in the United Kingdom* (CIA, 1993 RC40) and *Code of Practice for the Safe Handling and Transport of Anhydrous Ammonia by Rail* (CIA, 1975 PA1). Accounts are also given in *Ammonia* (Slack and James, 1973) and by Bakemeier *et al.* (1985) and Czuppon, Knez and Rounes (1992).

Ammonia is produced by the reaction of hydrogen and nitrogen in converters at high pressure, as described in Section 11.12. Much of the largest use is for fertilizers, in the form of ammonium sulfate and ammonium nitrate and in anhydrous liquid form. It is used to make nitric acid and, in part via this, a range of plastics and fibres such as nylon, urea–formaldehyde resins, urethane, acrylonitrile and melamine. It is also used in the manufacture of explosives, hydrazine, amines, amides, nitriles and dyestuff intermediates and of urea, sodium cyanide and sodium carbonate.

Ammonia has a normal boiling point of −33.4°C and is therefore a gas. The vapour pressure at 20°C is 8.6 bar. It is frequently handled as a liquefied gas, either under pressure or refrigerated. Pressurized liquefied ammonia gives on release a flashing liquid.

Ammonia is flammable, but not readily so. The flammability range is 15–28%. The minimum ignition energy, however, is 100 mJ, which is high. The flammability and explosibility of ammonia is discussed by Kletz (1988a). The incident at Jonova (Case History A124) illustrates the flammability of ammonia.

Ammonia is a toxic irritant. Its long-term occupational exposure standard is 25 ppm. A concentration of about 1700 ppm can be fatal for a half-hour exposure. Its odour is detectable by most people at about 5 ppm.

After a large release of chlorine, a release of ammonia is potentially one of the worst toxic hazards from the common bulk chemicals in the chemical industry.

Ammonia is fully miscible with water. This creates the hazard that if there is water in a vessel containing ammonia vapour, the latter may dissolve, so that a vacuum is formed and the vessel collapses inwards.

Materials of construction for ammonia depend on the operating temperature. While mild steel may be used at ambient temperatures, special steels are necessary at low temperatures to avoid embrittlement. Materials for ammonia processes are discussed in Section 11.12.

Ammonia is corrosive even in trace amounts to copper, zinc, silver and many of their alloys. It is necessary, therefore, in handling ammonia to avoid the use of valves and other fittings which contain these metals. Under certain conditions ammonia can react with mercury to form explosive compounds (Comings, 1956):

> 'Under pressure, mercury forms a compound with ammonia consisting of several molecules of ammonia per atom of mercury. This compound is apparently not explosive. However, as the pressure is lowered, the ratio of ammonia to mercury decreases and a compound similar to a fulminate is formed. This has been known to detonate and is a serious hazard. The hazard is greatest when a system containing mercury and ammonia is being depressured.'

Impurities in liquid anhydrous ammonia, such as air or carbon dioxide, can cause stress corrosion cracking of mild steel. This is largely inhibited, however, if the ammonia contains 0.2% water and this water content is therefore specified for some applications. This aspect is considered further in Chapters 22 and 23.

The production, storage and transport of ammonia are considered in Section 11.12, and Chapters 22 and 23, respectively, the toxic release hazard is discussed in Chapter 18 and emergency planning in Chapter 24.

11.11.5 Chlorine

Chlorine is treated in Chlorine (Sconce, 1972) and it is the subject of *Safety Advice for Bulk Chlorine Installations* (HSE, 1986a–c HS(G) 28). This code is based on an earlier CIA code and is the code now listed by the CIA; the earlier code *Codes of Practice for Chemicals with Major Hazards: Chlorine* (the *Chlorine Code*) by its predecessor, the British Chemical Industry Safety Council, (BCISC, 1975/1) is no longer listed. Further information is given in the *Chlorine Manual* (Chlorine Institute, 1986 Pamphlet 1). Accounts are also given by Schmittinger (1986) and Curlin, Bommaraju and Hansson (1991).

Chlorine is produced by the electrolysis of brine in mercury or diaphragm cells, with the co-products sodium hydroxide and hydrogen. It is used mainly for the manufacture of a wide range of organic and inorganic chlorine compounds and for the chlorination of water and for bleaching. Some principal organic compounds are chlorinated paraffins such as methyl chloride, methylene chloride, chloroform and carbon tetrachloride from methane and hexachlorobutadiene and hexachloropentadiene from butane and pentane, respectively. The main single organic chloride product is ethylene dichloride which is obtained by chlorination of ethylene and is used mainly to make vinyl chloride. Chlorination of ethylene also gives trichloroethylene and perchloroethylene. Products obtained via chlorination of propylene include propylene oxide, propylene glycol, carbon tetrachloride, glycerine and epoxy resins and synthetic rubber. Aromatic products of chlorination include monochlorobenzene, dichlorobenzene and hexachlorobenzene.

Chlorine has a normal boiling point of −34°C and is therefore a gas. The vapour pressure at 20°C is 6.7 bar. It has a very low solubility in water. Chlorine is frequently handled as a liquefied gas under pressure. In this condition liquefied chlorine gives on release a flashing liquid. Chlorine is not flammable in air, but is itself an oxidant. Chlorine is a toxic irritant. Its long-term occupational exposure standard is 0.5 ppm.

A large chlorine release is potentially one of the most severe hazards from a common bulk chemical presented by the chemical industry. As an oxidant chlorine is in many ways comparable with oxygen. Organic compounds may have flammability limits in chlorine rather similar to those which they have in oxygen. Reactions between organic compounds and chlorine are generally highly exothermic and tend to go to complete chlorination, often with some violence.

Chlorine also forms flammable mixtures with hydrogen. This is important in chlorine production, where both gases are evolved from the electrolysis cells. Hydrogen and chlorine may also be reacted together to produce hydrogen chloride.

Usually, liquid chlorine contains the impurity nitrogen trichloride, which decomposes explosively. Therefore, it is necessary when handling chlorine to prevent the accumulation of this substance. For example, a chlorine vaporizer should not be allowed to boil dry so that the nitrogen trichloride is concentrated and may explode.

Mild steel is a suitable material of construction for use with chlorine unless the water content or temperature renders it unsuitable. Wet chlorine corrodes mild steel rapidly. Mild steel should only be used if the chlorine is dry. For wet chlorine gas, ebonite-lined mild steel is commonly used.

There are both low and high temperature limitations on the use of mild steel with chlorine. Special steels are required at low temperatures to avoid embrittlement. At high temperatures, mild steel burns in chlorine and again special materials have to be used. Chlorine attacks mild steel significantly above 200°C and rapidly above 230°C. In order to prevent reaction, it is normal to limit the operating temperatures with mild steel. The *Chlorine Code* quotes a limit of 120°C.

The design of pressure systems for handling chlorine incorporates a number of special features. Many of these are generally applicable to the handling of a very toxic substance. They are discussed in Chapter 12. In view of the toxicity of chlorine, it is not appropriate to vent large quantities to atmosphere. Plants producing chlorine therefore require emergency gas absorption facilities. Chlorine from pressure relief devices should go to an expanse tank or to gas absorption plant.

Storage and transport of chlorine are treated in Chapters 22 and 23, respectively, the toxic release hazard in Chapter 18, and emergency planning in Chapter 24.

11.11.6 Ethylene dichloride

A relevant code for ethylene dichloride, or 1,2-dichloroethane, is the *Code of Practice for Chemicals with Major Hazards: Ethylene Dichloride* (CIA, 1975 PA13). Accounts are also given by V.L. Stevens (1979) and Rossberg *et al.* (1986).

Ethylene dichloride is made by the liquid phase chlorination of ethylene. It is used principally for the manufacture of vinyl chloride by cracking the ethylene dichloride to vinyl chloride and hydrogen chloride. Usually, the latter is then reacted in an oxychlorination process to produce more vinyl chloride.

Ethylene dichloride is a liquid with a normal boiling point of 84.4°C. It has a low solubility in water. Ethylene dichloride is flammable, the flammable range being 6–16%. The flash point is 13°C (closed cup) or 18°C (open cup).

Ethylene dichloride is toxic. It has a long-term maximum exposure limit of 5 ppm and carries the 'Skin' notation. Concentrations of about 3% can produce nausea, drowsiness and stupor. It is detectable by odour at a concentration of 50–100 ppm. The decomposition products of ethylene dichloride in a fire include hydrogen chloride, which is toxic.

Plant handling ethylene dichloride is usually constructed in mild steel. Mild steel is suitable for dry ethylene dichloride and also for wet saturated ethylene dichloride below 50°C, provided the aqueous phase is alkaline. But at temperatures above 80°C wet ethylene dichloride undergoes hydrolysis, forms acid and rapidly corrodes mild steel. Transfer of ethylene dichloride may be effected by pumping or inert gas padding.

11.11.7 Ethylene oxide

Ethylene oxide is the subject of the *Guidelines for Bulk Handling of Ethylene Oxide* (CIA, 1992 RC14) (the *CIA Ethylene Oxide Guidelines*), the earlier *Code of Practice for Chemicals with Major Hazards: Ethylene Oxide by the Chemical Industry Safety and Health Council* (CIHSC, 1975/1) (the *Ethylene Oxide Code*) is no longer listed. Accounts are also given by Cause *et al.* (1980), Ozero and Procelli (1984), Rebsdat and Mayer (1987), Ondrey (1992) and Siwek and Rosenberg (1993).

Ethylene oxide is produced by the vapour phase oxidation of ethylene. There are various processes; some use air and some use oxygen, but otherwise the processes are broadly similar. It is used primarily for the production of ethylene glycol, which in turn is used in roughly equal proportions as antifreeze and for production of polyesters. Other products obtained via ethylene oxide are ethanolamines, glycol ethers and surfactants.

Ethylene oxide is a toxic, flammable and explosively unstable material. Therefore it exhibits a rather unusual combination of hazards. The properties of ethylene oxide have been the subject of a series of investigations by Burgoyne and co-workers (e.g. Burgoyne and Burden 1948, 1949; Burden and Burgoyne, 1949; Burgoyne, Bett and Muir, 1960).

Ethylene oxide has a normal boiling point of 10.5°C. At atmospheric pressure it may therefore be a gas or a liquid, depending on the temperature, and in handling it may be treated as a liquefied gas. At higher ambient temperatures, a liquid leak undergoes a degree of flashing to vapour. This feature of a normal boiling point close to ambient temperature tends to increase the hazard.

Ethylene oxide is fully miscible with water. In contrast to other flammables such as hydrocarbons, therefore, liquid spills can readily be diluted with water to reduce the hazard of fire.

The lower flammability limit of ethylene oxide is 3%. There is no upper flammability limit as normally conceived, since at high concentrations up to pure ethylene oxide combustion is replaced by explosive decomposition. The flashpoint (open cup) is −17.8°C. The autoignition temperature in air is 429°C.

Ethylene oxide is toxic and has a long-term maximum exposure limit of 5 ppm. The odour of pure ethylene oxide is not detectable by many people below about 700 ppm, and whilst impurities present in the industrial material reduce the odour threshold considerably, odour is not a reliable guide to its presence, and artificial means are necessary. Ethylene oxide liquid or aqueous solution affect the skin.

Ethylene oxide vapour decomposes explosively even in the absence of air, if ignited or heated above about 560°C. The liquid is stable to decomposition.

Liquid ethylene oxide is very susceptible to polymerization. This may be initiated at ambient temperatures by acids, bases and anhydrous chlorides of iron and of some other metals. Also, iron rust is a moderate initiator, so that equipment should be substantially rust free. At around 100°C purely thermal initiation starts, and once this happens iron becomes a promoter. The polymerization is highly exothermic and can result in explosive decomposition. Slow polymerization can also occur, producing a solid polymer which does not decompose explosively.

Mild steel and stainless steel are used as materials of construction for plant handling ethylene oxide, but mild steel must be rust free. The internal surfaces of plant equipment for handling ethylene oxide should be carefully prepared before use and free from foreign matter which could cause slow polymerization such as welding slag, rust and debris. Cleaning may be by shot blasting or by chemical means. If shot blasting is used, it must be possible to remove the dust and debris created; otherwise chemical methods must be used. The stages of acid cleaning are: (1) degreasing, (2) acid pickling, using hydrochloric acid for mild steel and citric acid for stainless steel and (3) for mild steel, atmospheric passivation.

Flanged joints should have stainless steel, spiral wound, polytetrafluoroethene (PTFE) filled joint rings or trapped Fluon rings. Natural rubber joint rings should not be used. Compressed asbestos fibre (CAF) is suitable for use only below 25°C and is therefore not generally recommended. Joints should be kept to a minimum consistent with enabling lines to be opened for polymer clearance.

In order to avoid polymerization, pipework for handling liquid ethylene oxide should be laid out so that it can be completely drained during a shut-down. There should be facilities for blowing through with nitrogen. Lines of less than 25 mm (1 in) bore should not be used. Pipework should be designed to minimize the trapping of ethylene oxide between closed valves or in stagnant pockets. Relief is not normally required on in-plant pipework, but each case should be considered individually.

Ethylene oxide liquid has a high electrical conductivity, of the order of 10^6 pS/m ($1\ S = 1/\Omega^{-1}$). Since experience shows that buildup of electrostatic charge does not occur in a liquid with a conductivity greater than 300 pS/m, it is not necessary to take the usual precautions against the static electricity hazard, such as limitation of pipeline velocities and avoidance of splash filling. However, in order to maintain consistency with practice for flammable liquids generally, transport containers should be earthed during loading and discharge.

Transfer of liquid ethylene oxide may be by gravity, inert gas padding or pumping. For small quantities it may be preferable to use the first two methods. If a pump is used, it is essential for there to be no conditions which can cause an abnormal temperature rise. This requirement can be met by the use of a recycle system from the pump delivery to the suction when the pump is operating, with cooling of the recycle. The recycle system should be sized to handle all the heat which can be generated by the pump when operating against a closed delivery. If the recycle is to the suction tank, the latter acts as a thermal reservoir. If dead-heading can occur, the pump should be fitted with a high temperature trip, which should shut the pump down if the temperature reaches 10°C above normal.

An in-line centrifugal pump with mechanical seals is the preferred type. It should be fitted with a single seal with a restrictor brush or a double seal flushed with water, which should be analysed regularly to detect leaks. A canned pump should not be used. If a reciprocating pump has to be used, it should be fitted with a double diaphragm seal with suitable sealant and rupture indication.

Refrigerant fluids used for direct heat exchange with ethylene oxide should not react with it and should not contain polymerization initiators.

Vaporizers for liquid ethylene oxide should be designed as once-through systems so as to prevent the accumulation of hazardous residues. The heating medium should be such as to keep the temperature well below that of decomposition. Direct flame or electrical heating should not be used.

Measures are required to prevent contamination of ethylene oxide in storage by backflow from consumer plants, by contamination of inert gas supplies or by flow from the loading terminal. Protection against backflow from the plant should be effected by means of two separate trip systems, the first based on the pressure difference between the ethylene oxide storage outlet and the supply line to the consumer plant and the second on that between the supply line and the inlet of the plant.

Prevention of contamination of the supply of inert gas, typically nitrogen, is ideally effected by the use of separate supplies for storage and process. The measures necessary where the supply is common are detailed in the *Ethylene Oxide Guidelines*.

Ethylene oxide should be stored separately from other flammable liquids. Terminals for loading and unloading ethylene oxide should also be segregated. Storage and transport of ethylene oxide are considered in Chapters 22 and 23, respectively, the toxic release hazard in Chapter 18 and emergency planning in Chapter 24.

11.11.8 Hydrogen

Hydrogen is the subject of the codes NPFA 50A: 1989 Gaseous Hydrogen Systems at Consumer Sites and NFPA SOB: 1989 Liquefied Hydrogen Systems at Consumer Sites and of Hydrogen by the CGA (1974 G-3). Accounts are also given in *Hydrogen* (K.E. Cox and Williamson, 1977–) and *Hydrogen* (W.N. Smith and Santangelo, 1980) and by Donakowski (1981), Mandelik and Newsome (1981), J.D. Martin (1984), Haussinger, Lohmuller and Watson (1989) and Johansen, Raghuraman and Hackett (1992).

Hydrogen is produced by steam reforming or partial oxidation of hydrocarbons or from a hydrogen-rich stream from a low temperature section of a petroleum plant or a coke oven plant or from a chlorine cellroom. It is used in many large-scale processes, notably in ammonia synthesis, refinery hydrogenation processes, and methanol synthesis, and in hydrogenation of coal and hydrogasification of coal to synthetic natural gas (SNG). It is also used in: hydroformylation of olefins, the Oxo synthesis; organic hydrogenations; and hydrogenation of fats and oils.

Hydrogen has a normal boiling point of −252.5°C and is therefore a gas. Hydrogen has a wide flammable range of 4–75%, a low minimum ignition energy of about 0.019 mJ and a high burning velocity. It is therefore easily ignited and burns rapidly. For occupational exposure hydrogen is classed as an asphyxiant.

In consequence of its flammability, hydrogen presents an explosion hazard and it is necessary to take suitable precautions. As far as the hazard of an open air explosion is concerned, hydrogen gas has a low density and tends to rise and dissipate rapidly unless it is very cold. Nevertheless, vapour cloud explosions of hydrogen have occurred. They are discussed in more detail in Chapter 17.

Hydrogen gas may burn in air, but hydrogen flames have low heat radiation, about one-tenth that of propane, and tend, therefore, to be less hazardous. The gap through which a hydrogen flame can travel is much smaller than with most other gases. It is therefore more difficult to make electric motors sufficiently flameproof for operation in atmospheres which may contain a flammable hydrogen–air mixture.

Hydrogen at elevated pressures and temperatures attacks mild steel severely, causing hydrogen decarburization and embrittlement, and it is necessary, therefore, to use special alloy steels in hydrogen service.

Leakage of hydrogen constitutes a problem. The pressures in plant handling hydrogen are commonly high and the gas diffuses readily through small holes. Hydrogen exhibits a reverse Joule–Thomson effect, so that leaking gas heats up and may ignite. Since the flame is non-luminous, it may not be visible. An operator may walk unawares into a hydrogen leak flame.

Hydrogen can also diffuse through solid metal. It can pass, for example, into a thermocouple pocket and thence through the connecting leads into the control room. Where this risk exists, therefore, it is good practice to arrange the connections so that there is no flow path for the hydrogen.

Liquid hydrogen is used in certain special applications, notably aerospace work. This is effectively a separate technology. It is described in *Handbook for Liquid Hydrogen Handling Equipment* (AD. Little Inc., 1960), and by Cassut, Madocks and Sawyer (1964), Stoll (1965) and Scharle (1965).

11.11.9 Hydrogen fluoride

A relevant code for hydrogen fluoride is *Guide to Safe Practice in the Use and Handling of Hydrogen Fluoride* (CIA, 1978 PA14) (the CIA *Hydrogen Fluoride Guide*). Accounts are also given by Gall (1980) and Aigueperse *et al.* (1988).

Hydrogen fluoride is used industrially both as anhydrous hydrogen fluoride and as solution of hydrogen fluoride in water; the *Guide* recommends that the term ‘hydrofluoric acid’ be reserved for the latter. It is the former, anhydrous hydrogen fluoride, which is of interest here.

Hydrogen fluoride is produced by the reaction of sulfuric acid on fluorspar in a rotary furnace. There are a number of processes, broadly similar but with variations, involving mainly pre-heaters, pre-reactors and recycle. The main uses are for the manufacture of fluorocarbons and of aluminium fluoride and synthetic cryolite used in the aluminium industry. It is also used in refinery processes.

Anhydrous hydrogen fluoride has a normal boiling point of 19.5°C. At atmospheric pressure, it may therefore be a gas or a liquid, depending on the temperature and in handling it is conventionally treated as a liquefied gas. At higher ambient temperatures, a liquid leak undergoes a degree of flashing to vapour.

Hydrogen fluoride is fully miscible with water. This creates the hazard that if there is water in a vessel containing hydrogen fluoride vapour, the latter may dissolve, so that a vacuum is formed and the vessel collapses inwards; the like hazard with ammonia has already been mentioned.

Hydrogen fluoride is toxic. It has a short–term occupational exposure standard of 3 ppm (as fluorine). It is detectable by odour at about 2–3 ppm, but reliance should not be placed on this. Aqueous solutions of hydrogen fluoride, anhydrous hydrogen fluoride liquid or, to a lesser extent vapour, affect the skin and eyes.

Hydrogen fluoride is highly corrosive, but its corrosivity depends on the water content. Mild steel is resistant to corrosion down to concentrations in water of about 70% hydrogen fluoride. Plant for the manufacture of hydrogen fluoride is largely made of mild steel, but is designed to allow for the foreseeable presence of water. Mild steel is also the material used for the storage and transport of anhydrous hydrogen fluoride. Mild steel becomes decreasingly suitable as the temperature increases. The *Guide* states that the upper limit is usually given as 50–65°C and recommends that this be observed. Silica and silica-containing materials, including metal slags, are attacked by hydrogen fluoride and welds should be such as to avoid slag inclusions.

Special process conditions, such as those that occur in the manufacture of hydrogen fluoride, may require the use of other materials of construction. The *Guide* gives a list of other materials which may be used for hydrogen fluoride. Pipework for hydrogen fluoride should have flanged or butt-welded joints. The range of materials which can be used for joint rings is narrow and measures are needed to ensure that only suitable materials are used.

Transfer of liquid hydrogen fluoride may be by gas padding or pumping. If pumping is used, measures are needed to prevent cavitation and leaks. A pump with double diaphragm or a canned pump may be used. Padding gas is usually dry air or nitrogen. Unless it is from a source which is inherently dry, the gas should be monitored for water content. The gas supply should have its own pressure control and pressure relief systems, and should not be subject to contamination by hydrogen fluoride.

A vent system is required to handle both normal process and emergency vent flows. The vent gases should pass to a gas absorption system. Water is generally used for absorption, with neutralization by lime slurry.

Methods of relief disposal mentioned in the *Guide* include: returning the relief flow back to a suitable point in the process, which in hydrogen fluoride production is often possible; the use of an expanse tank; and the use of a gas absorption system.

Since with hydrogen fluoride a pressure relief valve is liable to become corroded, the primary relief device used is a platinum bursting disc. A further relief device may be located after the disc to control the relief flow. The design of the relief system ducting should allow for the erosive effect of high velocity hydrogen fluoride gas on mild steel.

Storage and transport of hydrogen fluoride are considered in Chapters 22 and 23, respectively, the toxic release hazard in Chapter 18 and emergency planning in Chapter 24.

11.11.10 Oxygen

Relevant codes for oxygen are *Bulk Liquid Oxygen at Production Plants* (BCGA, 1990 Code 20) and *Bulk Liquid Oxygen at Users' Premises* (BCGA, 1992 Code 19). Oxygen is the subject of NFPA 50: 1990 Bulk Oxygen Systems at Consumer Sites. Accounts are also given by A.H. Taylor (1981) and Kirschner (1991).

Oxygen is produced by the liquefaction and separation of air. It is used in bulk quantities in iron and steel making and in chemical processes. It is also used in oxyacetylene welding.

Oxygen is the constituent in the air which supports combustion of fuels and other materials, and in the pure form it supports combustion even more effectively. Combustible materials of all kinds, ranging from hydrocarbons in chemical reactors to workmen's clothing, undergo combustion much more readily in oxygen-enriched air or in pure oxygen. The enhancement of flammability in oxygen-enriched atmospheres is described in Chapter 16.

Oxygen has a normal boiling point of −183°C (90.2 K) and is therefore a gas. It is frequently handled as a liquefied gas under pressure. In this condition liquefied oxygen gives on release a flashing liquid.

Oxygen is odourless and therefore gives no indication of its presence. Short exposure to air with some degree of oxygen enrichment does not appear to be harmful. Oxygen is used in breathing apparatus. The main hazard of an oxygen-enriched atmosphere is the enhancement of flammability.

The effect of a large release of oxygen would be to increase the combustibility of materials in the oxygen cloud. Such materials might include not only people's clothing but even steel equipment on the plant, since steel will burn in oxygen. A possible source of ignition in such circumstances might be a lagging fire. There appears, however, to be no recorded case of any such incident.

Air separation plants are discussed in Section 11.12.

11.11.11 Phosgene

A relevant code for phosgene is *Code of Practice for Chemicals with Major Hazards: Phosgene* (CIHSC, 1975/3) (the CIA *Phosgene Code*), but this code is no longer listed by the CIA. Accounts are also given by Hardy (1982) and Schneider and Diller (1991).

Phosgene is manufactured by passing carbon monoxide and chlorine over activated carbon. It is used mainly to make isocyanates, particularly toluene diisocyanate. It is also used for chloroformic esters, urea azo dyes, carbonate esters and Friedel Crafts acylations. There are available small tonnage phosgene plants which may be installed at a user's site and which avoid the need to transport and store large quantities of the material.

Phosgene has a normal boiling point of 8.2°C. It is not flammable. It is highly toxic and has a long-term occupational exposure standard of 0.02 ppm, which is a five-fold downwards revision from the previous value of 1 ppm and is very low indeed.

In contact with water phosgene undergoes slow decomposition to hydrochloric acid and carbon dioxide. It is essential, therefore, to keep plant handling phosgene dry in order to prevent such decomposition. Phosgene also reacts with most lubricating oils to form a black sludge.

For dry phosgene, carbon steel has proved a satisfactory material of construction, for both vessels and pipework. Where other substances are also present, it may be necessary to use other materials. The *Code* cautions against the use of non-metallic materials for pipework.

The *Code* gives detailed requirements for the design of storage vessels for liquid phosgene. Process vessels handling more than one tonne of liquid phosgene in normal operation should be designed to a standard similar to that for storage vessels.

For the pipework on a phosgene plant seamless tubes are preferred to seam-welded ones. The pipework should take into account both the maximum and minimum temperatures which may occur. Stress relieving heat treatment may be required. The pipework arrangement should have a good degree of natural flexibility, but bellows should not be used. Joints should preferably be welded, but otherwise flanged. Butt-welded joints should be radiographed. Compressed asbestos fibre gaskets have been used satisfactorily.

Liquid phosgene may be transferred by pumping or inert padding gas. For pumping, glandless pumps should be used. These are suitable for phosgene concentrations down to 5% and for lower concentrations also. Particular attention should be paid to avoidance of cavitation and provision of sufficient net positive suction head (NPSH).

Due to its high solubility in liquid phosgene, nitrogen may be unsuitable as a padding gas. Any gas used should be dry, with a dewpoint less than −30°C. Measures should be taken to prevent contamination of the padding gas supply, preferably by the use of a supply exclusive to the phosgene plant.

Reciprocating compressors are used to compress phosgene vapour, but it is necessary to take special measures to prevent contact between phosgene and lubricating oil. Use is also made in phosgene systems of fans and vacuum pumps.

Relief disposal should be to an expanse tank or to a gas absorption system, but not to atmosphere.

A phosgene plant should normally have two separate gas absorption systems, one to handle process vents and one for emergency reliefs. The former should be designed for flows with high concentrations of inerts but low concentrations of phosgene and the latter for flows with higher concentrations of phosgene. The use of a dedicated absorption system for relief flows guards against corrosion and blockage of the relief lines by materials vented from the process. The phosgene content of gas leaving the gas absorption system should be monitored.

With regard to relief devices, pressure relief valves and carbon bursting discs both have some disadvantages for phosgene duties, but either is suitable with good design. A bursting disc alone risks imposing a sudden high load on the gas absorption system. An acceptable arrangement is a bursting disc followed by a pressure relief valve with an alarm on the intermediate space to detect disc failure.

For pipelines an alternative relief device is an expansion bottle. These bottles are fitted to the top of the pipeline at regular intervals and each is isolated from it by a bursting disc. There should be an alarm on the bottle space to detect disc failure.

The use of water or steam in direct heat exchange with phosgene should be avoided due to the possibility that water will leak into the phosgene stream.

Liquid phosgene may be stored under pressure or refrigerated. The *Code* states that plant for handling and storage of phosgene should be kept simple, even if this means storing liquid phosgene under pressure, that storage vessels for liquid phosgene should be pressure vessels and that the contents of a pressure storage vessel should be kept below 8°C in order to reduce the risk of overloading the gas absorption system due to flash-off if pressure has to be reduced.

11.11.12 Vinyl chloride

Vinyl chloride (VC), or vinyl chloride monomer (VCM), is the subject of *Precautions against Fire and Explosion: Vinyl Chloride* (CIA, 1978 PA15) (the *CIA Vinyl Chloride Guide*). The toxicity of vinyl chloride is treated in *Vinyl Chloride: Toxic Hazards and Precautions* (HSE, 1992 a−d EH 63). Accounts are also given in *Vinyl Chloride and PVC Manufacture* (Sittig, 1978) and by Cowfer and Magistro (1983).

Vinyl chloride was originally produced by the gas phase reaction of acetylene and hydrogen chloride. It is now made almost entirely by the cracking of ethylene dichloride and oxychlorination of ethylene. These two processes are generally operated in combination, with the hydrogen chloride from the cracking of ethylene dichloride being reacted with air or oxygen in the oxychlorination process to produce more vinyl chloride. Vinyl chloride is polymerized to polyvinyl chloride (PVC) and also used to make copolymers.

Vinyl chloride has a normal boiling point of −13.9°C. It is frequently handled as a liquefied gas under pressure. In this condition, liquefied vinyl chloride gives on release a flashing liquid. Vinyl chloride is flammable, the flammable range being 3.6−33%.

Vinyl chloride is toxic and has a long-term maximum exposure limit of 7 ppm. The toxicity of vinyl chloride was not fully appreciated until the mid-1970s. The discovery of its toxicity, and in particular its carcinogenic properties, presented the industry with a problem which, although quite different in nature, was of the same order of magnitude as that caused by the vapour cloud explosion at Flixborough. The decomposition products of vinyl chloride in a fire include hydrogen chloride and phosgene, which are both toxic, particularly the latter. As its full title indicates, the *Vinyl Chloride Guide* deals with the fire and explosion but not the toxic hazards of vinyl chloride.

In the handling of vinyl chloride, it is necessary to ensure that air is excluded. Air can cause the formation of vinyl chloride polyperoxides, which appear as a yellow oil or rubbery solid and which detonate on mild impact. Oxygen also catalyses the polymerization of vinyl chloride. Vinyl chloride can be stored unstabilized if air is excluded, but addition of inhibitor should be considered if this cannot be assured. On the other hand, in the absence of other substances, water in vinyl chloride does not constitute any special hazard, although it may cause contamination of the product with rust.

Change of phase, either condensation or boiling, of vinyl chloride can be hazardous. One hazard is a sudden pressure rise, another concentration of impurities and a third polymerization. The *Code* details measures for safeguarding against these hazards.

Materials of construction for vinyl chloride plants are mild steel and for polymerization plants stainless steel. Other materials which may be used where other substances are present in addition are described in the *Code*. Joints on pipework should be welded or flanged.

Liquid vinyl chloride may be transferred by pumping or inert padding gas. Pumps with fine clearances should be avoided as these can give trouble due to polymerization. Particular attention should be paid to avoidance of cavitation and provision of sufficient NPSH and to the pump seals. For padding, the gas normally used is nitrogen.

Compressors used for the compression of vinyl chloride vapour should be such as to ensure exclusion of air.

Relief flows may be sent to a gas absorption system, a flare or an atmospheric vent, if permitted. Both combustion at a flare and combustion following accidental ignition of a vent generate hydrogen chloride, which is toxic.

A suitable relief device for vinyl chloride is a bursting disc followed by a pressure relief valve, or possibly a second bursting disc. The design should allow for the possibility of polymerization in the pipework leading to the relief device and at the device itself.

Plant handling vinyl chloride should preferably be located outdoors, but where it has to be indoors with the attendant hazard of an indoor release of flammable material, consideration should be given to requirements for ventilation and explosion relief of the building.

Storage of vinyl chloride may be in pressure or refrigerated storage.

11.11.13 Some other chemicals

Some other leading inorganic chemicals are covered in *Bromine and Its Compounds* (Qolles, 1966) and *Nitric Acid and Fertiliser Nitrates* (Keleti, 1985). Accounts of some principal organic chemicals include *Propylene Oxide* (Jefferson Chemical Company, 1963), *Propylene and its Industrial Derivatives* (Hancock, 1973), *Benzene and its Industrial Derivatives* (Hancock, 1975), *Benzene* (Cheremisinoff and Morresi, 1979), *Toluene, the Xylenes and their Industrial Derivatives* (Hancock, 1982), *Maleic Anhydride* (Trivedi and Culbertson, 1982), and *Formaldehyde* (Clary, Gibson and Waritz, 1983).

Polymers are treated in *Encyclopaedia of PVC* (Nass, 1976–), *Vinyl Chloride and PVC Manufacture* (Sittig, 1978), *Encyclopaedia of PVC* (Nass and Heiberger, 1986), *Encyclopaedia of Polymer Science and Engineering* (Mark *et al.*, 1989) and *Handbook of Polyolefins* (Vasile and Seymour, 1993).

11.12 Particular Processes and Plants

The chemical and petrochemical industries operate a great variety of processes and plants, many of them highly interconnected. There are certain processes and plant which have particular hazards, which feature prominently in the safety and loss prevention literature and which are appropriate to consider here. These are:

(1) air and oxygen plants;
(2) ammonia plants;
(3) ammonium nitrate plants;
(4) methanol plants;
(5) olefins plants;
(6) LPG and LNG installations;
(7) petroleum refineries and gas processing plants.

Descriptions of the first three types of plants and the associated hazards and precautionary measures are given in *Operating Practices in Air and Ammonia Plants* (1961–62/27–28), in the series *Safety in Air and Ammonia Plants* (1960–69/17–26) and *Ammonia Plant Safety and Related Facilities* (1970–1994/31–52), in *Survey of Operating Practices in Thirty-one Ammonium Nitrate Plants* (AIChE, n.d./15), and in *Safe Operation of Ammonia and Ammonium Nitrate Plants* by the American Oil Company (Amoco/9).

Selected references on particular processes and plants and their hazards are given in Table 11.10 and selected references on ammonia, urea and ammonium nitrate plants and their hazards are given in Table 11.11.

11.12.1 Air separation plants

In addition to the references just given, there are accounts of air separation plants by Newton (1979), A.H. Taylor (1981) and Kirschner (1991).

Air separation plants can produce both oxygen and nitrogen. Each of these products may be in either gaseous or liquid form. Large amounts of oxygen are used in the chemical industry in oxidation processes and in the steel industry in both the blast furnace and steel-making processes. Nitrogen is used in large quantities as a synthesis gas and for gas washing, inerting and purging.

An air separation plant is an integral part of an ammonia plant where the hydrogen for the synthesis gas is obtained from a hydrogen-rich stream or by partial oxidation of hydrocarbons. Hydrogen from partial oxidation or from processes such as coke ovens, catalytic reformers or electrolysis plants is purified by washing in liquid nitrogen, which removes hydrocarbons and carbon monoxide. Nitrogen is then added to the hydrogen to form synthesis gas. The oxygen and nitrogen for these processes are obtained from an air separation plant.

Air separation is carried out by compression, liquefaction and distillation of air. If the products are gases near ambient temperature, the refrigeration required is small and is principally to cover heat inefficiencies and losses, but if they are liquids, there is a much larger refrigeration requirement. This refrigeration is produced by compressing the air and then expanding it through a valve, using the Joule–Thomson effect, or in an expansion engine. The plant is contained in an insulated cold box.

Low pressure plants operate in the approximate pressure range 5–10 bar and intermediate pressure range 10–45 bar. The temperatures are low with nitrogen being separated at about −190°C.

There are two main hazards in an air separation plant. These are that: (1) liquid oxygen reacts with any combustible material with explosive violence and (2) hydrocarbons may accumulate in the liquid oxygen and give an explosive reaction. Combustible materials with which liquid oxygen may react violently include wood, lubricating oils, greases and graphite.

Impurities which may enter the plant and accumulate in the liquid oxygen in the distillation column reboiler include methane, ethane, ethylene and acetylene. These hydrocarbons have a very low solubility in oxygen and therefore tend to precipitate out as solids. The solubility of acetylene in liquid oxygen, for example, is only 7 ppm. The solid hydrocarbons are then liable to react explosively with the oxygen. If nitrogen oxides, especially nitric oxides, are present, they catalyse this reaction.

Precautions which are necessary in liquid air plants, therefore, include the elimination of combustibles, both in the construction and operation of the plant, use of clean air and purification of this air, avoidance of build-up of contaminants in the liquid oxygen and safe disposal of the liquid oxygen.

In order to eliminate the combustible materials, equipment is degreased before installation. Grease and graphite materials are not used for pipe joints and gaskets containing graphite are not used for pipe flanges. Every effort is made to ensure that items such as wood, clothing or rags are not left inside the plant. Measures are taken to reduce the risk of hydrocarbon lubricating oils being carried into the low temperature section from the main compressors. Non-flammable lubricants are used for applications such as liquid oxygen pump seals.

Air is taken from an area which is not contaminated by hydrocarbons or nitrogen oxides. Methods of purifying the air in the air intake include catalytic combustion of

hydrocarbons and adsorption of hydrocarbons and nitrogen oxides.

Build-up of contaminants in the liquid oxygen is minimized by the avoidance of pockets where liquid oxygen accumulates, by running oxygen reboiler tube plates always flooded and by continuous blowdown of liquid oxygen into an auxiliary vaporizer.

If the air supply becomes contaminated, it may be necessary to stop air supply to the plant. Under these conditions heat leaks into the plant and causes liquid oxygen to

evaporate and contaminants to concentrate. There is therefore a certain time period after which hazardous concentrations of contaminants may accumulate. Thus there need to be arrangements for the discharge of the plant liquids.

Contaminants which accumulate in the plant may be removed by regular cleaning. This involves heating up the plant with warm air, which vaporizes the contaminants. The accumulation of contaminants is reduced if the insulation is efficient. The cold box is kept at a positive pressure by air, so that water vapour does not enter and freeze in the insulation, thus making it less effective. The air used has to be free of hydrocarbons.

The small bore instrument and sampling pipework inside the cold box is vulnerable to fracture when insulation is being put in. A suitable precaution is to do this work with the lines under a low nitrogen pressure so that a fracture can be detected by a fall in pressure. A further hazard is the twisting of the tubing when work is being done on tubing which extends through the cold box wall. The likelihood of this may be reduced by the use of back-up wrenches.

Materials of construction used in air separation plants include aluminium, copper and stainless steel. Mild steel is not used in applications where it may undergo low temperature embrittlement or may oxidize as a result of a liquid oxygen leak. This applies to its use not only in vessels and pipework but in supports also.

Tarmacadam road surfaces are avoided in areas where liquid oxygen may spill. Oily or greasy clothing is also avoided.

11.12.2 Ammonia plants

Treatments of ammonia and ammonia plants have been referenced in Section 11.11. Additional accounts of ammonia manufacture are given in *Technology and Manufacture of Ammonia* (Strelzoff, 1981) and by Bakemeier *et al.* (1985) and Czuppon, Knez and Rounes (1992).

Large tonnages of ammonia are used directly in liquid form as a fertilizer and as a chemical raw material for the production of other fertilizers such as ammonium sulfate, ammonium nitrate and ammonium phosphate, of explosives such as ammonium nitrate, of inorganic chemicals such as nitric acid and hydrogen cyanide and of organic chemicals such as acrylonitrile. Other uses are described in Section 11.11. The basic ammonia synthesis reaction is:

$$N_2 + 3H_2 \rightarrow 2NH_3$$

There are a number of processes for ammonia synthesis. The differences between these are partly in the source of hydrogen and partly in the operating conditions and synthesis converter design.

As already described, hydrogen is generally produced by steam reforming of natural gas or naphtha or partial oxidation of fuel oil or from a hydrogen-rich stream from the low temperature separation section of a petroleum or coke oven plant, or from a chlorine cell-room. Nitrogen is normally obtained either from an air separation plant or from air which has been burned to remove the oxygen. Some 75–80% of ammonia production worldwide uses steam reforming and of this some 65–70% is based on a natural gas feedstock.

In the steam reforming of natural gas, the principal process steps are feedstock purification, primary and secondary reforming, shift conversion, carbon dioxide removal, synthesis gas purification, synthesis gas compression, ammonia synthesis and recovery.

Following purification, the natural gas is reacted with steam in a primary reformer, which consists of a tubular reactor placed vertically in the furnace and packed with nickel catalyst. The reaction, which takes place in the temperature range approximately 700–800°C, is strongly endothermic, requires a substantial heat input and produces a mixture of hydrogen, carbon dioxide and carbon monoxide:

$$2CH_4 + 3H_2O \rightarrow 7H_2 + CO_2 + CO$$

Air is injected into this gas as it enters the secondary reformer, which is an internally insulated vessel filled with nickel catalyst operating at a temperature above 1100°C. Combustion of the air provides the heat for completion of the reaction and nitrogen to form the synthesis mixture. The air flow is adjusted to give this correct synthesis gas composition. The gas is then passed through a shift converter to assist the reaction of steam and carbon monoxide to hydrogen and carbon dioxide:

$$H_2O + CO \rightarrow H_2 + CO_2$$

Carbon dioxide and carbon monoxide are removed from the gas by various purification processes. The synthesis gas then passes to the compression section.

In the ICI LCA process a variation is introduced in which the primary reformer can be greatly reduced in size or even eliminated by waste heat reforming, in which part of the reforming is carried out in a reforming heat exchanger utilizing waste heat from the secondary reformer.

In partial oxidation, a similar hydrocarbon feed and oxygen from an air separation plant are preheated separately and reacted in non-catalytic gas generators at a temperature above 1100°C. The reaction is:

$$2CH_4 + O_2 \rightarrow 4H_2 + 2CO$$

The gas is cooled, followed by the shift reaction and purified of carbon dioxide and carbon monoxide by processes similar to those used in steam reforming. It is then cooled and washed with liquid nitrogen to remove traces of impurities. The gas is then adjusted in composition by addition of further nitrogen and passes to the compressors.

If the hydrogen is the off-gas from a refinery reformer, it is purified, dried and then washed with liquid nitrogen. After adjustment of the gas composition by further nitrogen addition, this synthesis gas enters the compressors.

The synthesis gas is then compressed. Whereas reciprocating compressors were a feature of earlier ammonia plants, on modern plants centrifugal compressors are used for compression of the synthesis gas. They are usually driven by steam turbines.

Following compression, the synthesis gas enters the ammonia converters, which on large plants are multiple-bed. There are a variety of designs which differ in respect of the flow pattern, the method of temperature control and the reaction heat recovery. The reaction takes place on an iron catalyst, is exothermic and gives a conversion of about 25%. The ammonia formed is condensed out by cooling the exit gases, which are recycled to the converter.

The ammonia synthesis is one of the classic high pressure processes, but the pressure at which ammonia converters operate has tended to fall. In plants designed before the mid-1960s synthesis converters operated at pressures up to about 340 bar (5000 psi), but the operating pressure in large plants is now of the order of 150 bar (2200 psi).

Up to about 1960, ammonia plants were of relatively low capacity operating at high pressures obtained using reciprocating machines. The early 1960s saw the introduction of the Kellogg single-stream ammonia plant using centrifugal compression and with an output of 544 t/day. This involved a step change in the scale and technology of ammonia plants and was one of the first examples of the large, single-stream plant. By the 1970s single-stream ammonia plants with a capacity of 1500 t/day were becoming common.

The hazards which are encountered in an ammonia plant depend somewhat on the process. But they include those of the chemicals (ammonia and hydrogen), of the operating conditions (high pressure, high temperature and low temperature), and of the pressure system components (furnaces and compressors).

The hazards of and the precautions necessary with ammonia and hydrogen were considered in Section 11.11. Those associated with extreme operating conditions were discussed in Section 11.9 and those associated with pressure systems are dealt with in Chapter 12.

11.12.3 Ammonium nitrate plants

Ammonium nitrate is the subject of NFPA 490: 1986 Storage of Ammonium Nitrate. Accounts of ammonium nitrate plants are given by Zapp (1985) and Weston (1992).

Ammonium nitrate is used in large quantities as an agricultural fertilizer. It is also used as an explosive. Some of the worst disasters in the chemical industry have been ammonium nitrate explosions. These include the explosion at Oppau in 1921, which killed 561 people, and that in Texas City in 1947, in which 522 died. Further details are given in Case Histories A5 and A16, respectively.

Despite these occurrences, ammonium nitrate is widely used. It is manufactured by neutralizing nitric acid with ammonia. The nitric acid is made by oxidation of anhydrous ammonia by air on a platinum–rhodium gauze catalyst. The reaction gases are cooled and absorbed in water to give about 56–60% nitric acid. The temperature of the ammonia entering this converter needs to be kept above 60°C in order to prevent liquid ammonia reaching the gauze and generating high temperatures, which may cause an explosion. The chloride content of the water entering the absorber has to be kept low to prevent formation of hydrochloric acid, and thus aqua regia, which is highly corrosive to stainless steel, and to avoid the catalysis by chloride of thermal decomposition of ammonium nitrate. Nitric acid is extremely corrosive and may react explosively with carbonaceous materials, so leaks require to be repaired promptly.

The nitric acid is neutralized with ammonia vapour. The reaction is exothermic and the heat liberated vaporizes water to produce 83–86% ammonium nitrate solution. Solutions of higher concentrations may be produced by further vaporization of water in evaporators. Concentrated ammonium nitrate solutions are blended with ammonia, additional water or urea as required to give ammonium nitrate–ammonia solutions. Alternatively, solid ammonium nitrate is produced by spray drying in a prilling tower or by concentrating to dryness and spraying the molten nitrate.

It is necessary to control closely the temperatures in ammonium nitrate neutralizers and evaporators. Although pure ammonium nitrate does not decompose rapidly below 200°C, impurities can cause a significant reduction in the decomposition temperature. The temperature in the neutralizers and evaporators is therefore generally kept below 135°C. In operating this plant, it is important not to produce dry ammonium nitrate, which can become hazardous if then heated further.

Limitation of impurities is equally essential, since they increase the tendency of the ammonium nitrate to decompose. Impurities which sensitize decomposition include copper and zinc as well as nitric acid and chlorides. Solid ammonium nitrate is very hygroscopic and tends to cake into a large mass which is difficult to handle. This is overcome by the use of a surface coating such as diatomaceous earth.

Addition of carbonaceous materials to ammonium nitrate can turn it into a blasting agent. It is necessary, therefore, to keep materials such as hydrocarbons away from ammonium nitrate. The sensitizing effect of hydrocarbon surface coatings used to prevent caking is partly responsible for some of the worst explosions which have occurred in the past. Other serious accidents have occurred from the former use of explosives to loosen caked ammonium nitrate, as at Oppau. This is no longer done.

The extent to which ammonium nitrate should be regarded as a high explosive was for some time a matter of debate. The matter was brought to a head when NFPA 490 was first adopted in 1963. A distinction was drawn between fertilizer grade and explosive grade ammonium nitrate, the latter containing some 1% of organic material. In effect, the former was treated in the code as not being a high explosive (W.H. Doyle, 1980). Furthermore, under certain circumstances ammonium nitrate exposed to fire can explode. For some time, the conditions necessary for an explosion were not well defined. Accounts of work on both these problems have been given by van Dolah (1966 BM RI 6903) and van Dolah *et al.* (1966 BM RI 6743, 1966 BM RI 6773).

If ammonium nitrate is heated to about 200°C, it begins to decompose and give off heat. This temperature may be lower if there are impurities present. Up to about 260°C the reaction is well behaved, but about this temperature decomposition becomes much more rapid. In a fire ammonium nitrate burns freely and does not explode. Thus over one three-year period records showed that 13 freight cars containing ammonium nitrate had burnt without explosion. Similarly, there have been several fires which have destroyed without explosion some five million pounds of ammonium nitrate stored in warehouses. But an explosion may occur if there is substantial confinement, so that high temperature and pressure can develop. The risk may be minimized by providing adequate spacing and ventilation in storages.

There are certain precautions which should be taken in the storage, transport and handling of ammonium nitrate. For aqueous solutions, the hazard is mainly that of evaporation of water to give a more concentrated solution. Precautions include limits on the strength of solutions stored and facilities for water addition. For bagged solids, the precautions required include spacing and ventilation, elimination of explosives and oxidizing materials, and avoidance of heat and ignition. In both cases, there should be prompt clearing up of spills.

Ammonium nitrate fires should be fought by the application of large volumes of water. Steam should not be used on an ammonium nitrate fire. The nitrate itself can supply enough oxygen, so that steam does not smother the fire, but only increases the temperature and the degree of hazard. Water sprinklers, fog nozzles and fire extinguishants such as foam or dry powder tend to be ineffective. In contrast to the situation with other fires in confined spaces, it may be advisable with ammonium nitrate fires to provide ventilation, so as to the reduce the chance of pressure and temperature build-up.

11.12.4 Methanol plants

Accounts of methanol production processes are given by Wade *et al.* (1981) and Fielder *et al.* (1990). Methanol is used in the production of a large range of organic chemicals, notably formaldehyde, methyl-*t*-butyl ether (MTBF), acetic acid, methyl methacrylate (MM) and dimethyl terephthalate. It is also finding use as a fuel, for which it has considerable potential. The basic methanol synthesis reactions are:

$$CO + 2H_2 \rightarrow CH_3OH$$

$$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O$$

There are a number of processes for methanol synthesis. All are based on the conversion of hydrogen, carbon monoxide and carbon dioxide to methanol in the presence of a catalyst. The main differences lie in the source of hydrogen and in the catalyst and operating pressure of the synthesis stage.

Sources of hydrogen were discussed above in the context of ammonia synthesis. For methanol, hydrogen is obtained mainly from natural gas, petroleum residues and naphtha. In 1980, some 70% of methanol production worldwide was based on steam reforming of natural gas.

The principal reactions occurring in steam reforming are for methane:

$$CH_4 + H_2O \rightarrow CO + 3H_2$$

and for heavy hydrocarbons

$$C_nH_{(2n+2)} + (n-1)H_2 \rightarrow nCH_4$$

and the water gas shift reaction

$$CO + H_2O \rightarrow H_2 + CO_2$$

The reaction is strongly endothermic, requires a substantial heat input and produces a mixture of hydrogen, carbon monoxide and carbon dioxide.

Steam reforming gives a hydrogen content higher than that required for the methanol reaction and processes differ in the way this feature is handled. In some, the hydrogen is burned whilst in others, an addition of carbon dioxide is made. The synthesis gas is then compressed by centrifugal compressors.

At the synthesis stage, the pressure required depends on the activity of the catalyst used and these are the main sources of difference between processes. Three pressure ranges are distinguished: low pressure (50–100 bar), medium pressure (100–250 bar) and high pressure (250–350 bar).

Up to the mid-1960s, methanol processes utilized relatively high pressures of the order of 350 bar obtained using reciprocating compressors. In 1966, ICI began operation of a low pressure methanol plant operating at 50 bar with an output of 400 t/day using all-rotating compression equipment. This plant set the pattern for subsequent developments. By 1980, a typical methanol plant was a single-stream plant, operating in the low–medium pressure range, using all-rotating compression equipment and with an output of 1000–2000 t/day.

11.12.5 Olefins plants

An account of olefins production processes is given in *Ethylene* (Kniel, Winter and Storck, 1980) and by Kniel, Winter and Chung-Hu Tsai (1980), Pike (1981) and Granton and Roger (1987). Olefins plants produce not only ethylene but other major co-products, including propylene and butadiene, and are the key units of a petrochemical works.

The main hazard on an olefins plant is that of the flammable hydrocarbons. This hazard is simply stated, but has many aspects. The hydrocarbons are processed under pressure at both low and high temperatures, which increase the risk both of loss of containment and of formation of a vapour cloud which may cause a fire or explosion.

Many aspects of olefins plants are discussed in Chapters 10, 12, 20 and 22, which deal with plant layout, pressure system design, plant operation and storage, respectively. A review of the evolution of safety aspects of olefins plants has been given by Barker, Kletz and Knight (1977), who consider in particular the following aspects: (1) plant layout, (2) plant equipment, (3) pressure relief and (4) leak control. The authors discuss these features in relation to differences of practice on ICI's successive olefins plants, particularly the then most recent plants, Nos 4 and 5. In the account given below, 'policy' refers to thinking described as 'current' in the paper by Barker, Kletz and Knight.

On plant layout the policy is to space units so that an expected leak does not find a source of ignition (rather than to use rules-of-thumb), to increase the number of fire breaks and to put more equipment at grade level, where it is more accessible to inspection and to fire fighting.

Electrical and instrument cables are vulnerable to flash fires and damage to cabling can cause extensive downtime. Whereas on No. 4 plant no special attention was paid to this aspect, on No. 5 plant in high risk areas cables are run in asbestos/galvanized steel troughs on the cable racks. Policy is to develop preformed reinforced concrete troughs.

Defects in the drainage systems of early olefins plants were that insufficient care was taken in siting low points and gullies and that drains did not have sufficient capacity to carry away fire water. These deficiencies were rectified on the No. 5 plant, in which the high and low points and the drains are located so as to avoid pools of liquid under equipment and the drains are sized to take the quantities of water used to cool major vessels in and near a fire area. The plant, however, has conventional luted drains and some drains from roads and pebbled areas do not pass through the oil–water separator. The policy is to use fully flooded drains with no vapour space in which explosion can occur and with no lutes which can choke, to make extensive use of paving, and to take all drainage from roads and pebbled areas to the oil–water separator.

With regard to process equipment, the early olefins plants had multiple reciprocating or spared centrifugal compressors. Current plants have single unspared machines. This requires the highest standard of design and operation. But it is very effective in reducing leaks.

Another area where leaks can occur is on cold pump glands. The use of O-rings and the elimination of routine pump changeovers have greatly reduced such leaks. Leakage has been further reduced by the use of brazed aluminium plate fin heat exchangers instead of tubular heat exchangers on cold duties. It is necessary, however, to provide these finned tube exchangers with special protection against fire damage.

Developments in pressure relief include the reduction of the total amount of material to be released, reduction of the probability that hydrocarbons will be discharged to the atmosphere unburnt and improvements in the safety of unburnt discharges.

Measures which can be taken to reduce discharge to the flare system include the more extensive use of trip systems and of higher design pressures for vessels such as low pressure catchpots.

The No. 5 plant has two separate flare systems, and this practice would be repeated. One system is for wet streams and the other for cold, dry streams. Process gas can be dumped to either flare or via a process gas transfer system to the fuel gas system or to other flare systems.

Various measures have been developed to reduce and control leaks. Both plants No. 4 and 5 have a leak detection system using Sieger detectors. There is a total of 140 detectors on the two units. Both plants are also provided with a steam curtain to dilute any vapour cloud which may escape from the plant. Extensive use is made of emergency isolation valves. The valves on No. 5 plant have been individually listed and justified by Kletz (1975b).

The possibility of hydrocarbons entering steam or condensate systems is investigated and potential routes are classed as high or low risk. On high risk routes the risk is either eliminated completely or at least is reduced. Thus a tubular heat exchanger is high risk if it may be subjected to conditions such as low temperature, high pressure, vibration or intermittent use. If, for example, a steam-heated heat exchanger might reach subzero temperatures during plant upsets, the practice would be to fit the steam supply with a check valve and the condensate system with a trip valve closed as appropriate by low level and/or low temperature.

The authors list the following safety reviews which are made on olefins plants: (1) piping and instrument diagram, (2) electrical distribution, (3) relief and blow-down, (4) layout, (5) paving and drainage, (6) cable routing and protection, (7) means of escape from structures and buildings, (8) fire fighting and (9) fire protection.

The foregoing is a necessarily brief summary of the hazards of olefins plants and of some of the measures developed to deal with them. Many of the aspects mentioned are considered in more detail in other chapters.

A further account of loss prevention in an ethylene plant has been given by Olivo (1994a).

11.12.6 LPG and LNG installations

Propane and butane are stored in liquid form as LPG. They play an important part in the oil and chemical industries, which have large LPG storages.

LPG is treated in *An Introduction to Liquefied Petroleum Gas by the LPG Industry Technical Association* (LPGITA, n.d.) and are the subject of a set of codes of practice, notably Installation and Maintenance of Fixed Bulk LPG Storage at Consumer Premises (LPGITA, 1991 LPG Code pt 1); the LPGITA is now renamed the Liquefied Petroleum Gas Association (LPGA). LPG is also covered in Storage of LPG at Fixed Installations (HSE, 1987a–d HS(G) 34) and in the Liquefied Petroleum Gas Safety Code (IP, 1987 MCSP Pt 9). It is the subject of NFPA 58: 1989 Storage and Handling of Liquefied Petroleum Gases (also published as the *Liquefied Petroleum Gases Handbook*) and NFPA 59: 1989 Storage and Handling of Liquefied Petroleum Gases at Utility Plants. Further accounts of LPG are given by Selim (1981) and S.M. Thompson (1990).

LPG is widely used as a fuel in general manufacturing industry, which therefore has a large number of LPG storage installations of various sizes. In general, these industries are not as well versed in the hazards of flammable materials as the chemical industry.

Natural gas, which is mainly methane, has replaced coal gas as the gas supplied to industrial and domestic users by British Gas. Most of the gas is obtained from the North Sea, but some is imported as LNG. In contrast to LPG, the number of LNG installations is very small, but the quantities stored are large. There is sophisticated management of the hazard.

LNG is the subject of *NFPA 59A: 1990 Production, Storage and Handling of Liquefied Natural Gas and of LNG Materials and Fluids* by the National Bureau of Standards (NBS, 1978), *Liquefied Energy Gases Safety* by the General Accounting Office (GAO, 1978), *Liquefied Natural Gas: Safety, Siting and Policy Concerns* (US Senate, 1978) and *Liquefied Gas Handling Principles on Ships and in Terminals* (McGuire and White, 1986). Further accounts of LNG are given by Boesinger, Nielsen and Albright (1980) and Hammer *et al.* (1991). Selected references on LPG and on LNG and their hazards are given in Tables 11.12 and 11.13 respectively.

LPG and LNG installations present the hazards of fire and explosion. In view of the scale involved, the siting of a large LNG installation is a major planning matter, which is likely to involve a public inquiry.

LNG is shipped to the storage terminals by specially designed vessels. The shipping of LNG involves the hazard that LNG may be spilled on the sea, may evaporate rapidly and may give a vapour cloud fire or explosion. This hazard has been a matter of much concern and has been the subject of considerable investigation. It is considered further in Chapters 16 and 17.

Storages of LPG and LNG are among the installations which have been of particular concern in relation to interactions between hazardous plants. Thus, for example, LPG storages, if poorly sited, are a possible threat to nuclear reactors and LNG storages may be hazarded by other plants. The British Gas LNG terminal at Canvey was one of the installations investigated in the *Canvey Report*, which is described in Appendix 7.

Closely related are synthetic fuels, or synfuels, including SNG. An account is given in *Handbook of Synfuels Technology* (Meyers, 1984).

11.12.7 Petroleum refineries and gas processing plants

Petroleum refining and gas processing involve the handling of hydrocarbons in very large quantities. This industry has faced many of the classic problems in SLP and has contributed much to their solutions.

Accounts of petroleum refining include *The Petroleum Handbook* (Shell International Petroleum Company, 1933–), *Modern Petroleum Technology* (Hobson and Pohl, 1975), *Our Industry Petroleum* (British Petroleum Company, 1977), *Petroleum Refining Technology and Economics* (Gary and Handwerk, 1984) and *Handbook of Petroleum Refining Processes* (Meyers, 1986b).

Gas processing is treated in *Gas Encyclopaedia* (L'Air liquide, 1976), *Handbook of Industrial Gas Utilization* (Pritchard, Guy and Connor, 1978) and *Natural Gas* (Melvin, 1988).

Reference to petroleum refining and gas processing is made throughout this book.

11.13 Operational Deviations

An important aspect of process design is consideration of possible deviations of operating parameters from their design values. Some of these deviations are listed in Table 11.14. A further list of deviations is given in the checklist for hazard and operability (hazop) studies shown in Figure 8.24.

The causes of deviation of a process variable are mostly specific to that variable, but there are some general causes of deviation. One is the deterioration or failure of equipment. Another is the maloperation of the control system, including in this the process operator.

The effects of deviations and the measures which may be taken to prevent them are also specific. But there are certain devices which are generally provided to give protection against extreme deviations, particularly of pressure and temperature. These are considered in the discussion of pressure systems and of control systems in Chapters 12 and 13, respectively. A further discussion of operating deviations is given by Wells, Seagrave and Whiteway (1976).

When a plant has been designed, it should be checked by some method such as a hazop study, as described in Chapter 8. Again this technique is based on consideration of operational deviations.

11.13.1 Pressure deviations

Pressure deviations can occur as a result of: changes in action of pumping equipment (e.g. failure of a pump or compressor), changes in flow (e.g. closure of a valve or pump outlet), changes of heat input (e.g. heat from sun or fire), changes in heat output (e.g. loss of condenser cooling), contacting of materials (e.g. hot oil and water), thermal expansion and contraction (e.g. liquid density changes in a pipeline), and chemical reaction and explosion (e.g. runaway reaction).

Effects of pressure deviations include overpressure and underpressure of equipment and changes of temperature, flow and level. Measures should be taken as appropriate to reduce the pressure deviations. In addition, it is essential to provide protective devices which prevent overpressure and underpressure.

11.13.2 Temperature deviations

Some causes of temperature deviations are: changes in heat input (e.g. loss of fuel), changes in heat output (e.g. loss of cooling), changes in heat transfer (e.g. fouling of heat exchangers), generation of heat (e.g. runaway reaction), changes of flow (e.g. flow to a reactor), changes of pressure (e.g. pressure reduction causing liquid flashing), thermal lags (e.g. lags in heat exchangers), hot spots (e.g. machinery in distress).

Table 11.14 *Some deviations of operating parameters from design conditions (after Wells, Seagrave and Whiteway, 1976) (Courtesy of the Institution of Chemical Engineers)*

Process variables	Pressure, temperature, flow, level, concentration
Pressure system	Mechanical stress, loading, expansion, contraction, cycling effects, vibration, cavitation, resonance, hammer; corrosion, erosion, fouling
Chemical reactions	Reactions in reactors: nature and rate of main reactions and side reactions Catalyst behaviour reaction, regeneration, poisoning, fouling, disintegration Unintended reactions elsewhere: explosion, heating, polymerization, corrosion
Material characteristics	Vapour density; liquid density, viscosity; melting point, boiling point; latent heat; phase change; critical point effects; solids physical state, particle size, water content
Impurities	Contaminants; corrosion products; air; water
Localized effects	Mixing effects, maldistribution; adhesion, separation, vapour lock, surging, siphoning, vortex generation, sedimentation, fouling, blockage, hot spots
Time aspects	Contact time, control lags, sequential order
Process disturbances	Operating point changes, changes in linked plants, start-up, shut-down, utilities failure, equipment failure, control disturbance, operator disturbance, blockage, leakage, climatic effect, fire
Constructional defects	Plant not complete, not aligned, not level, not supported, not clean, not leak-tight; materials of construction incorrect or defective
Loss of containment	Leakage, spillage

Temperature deviations in reactors can occur as a result of errors in the charging sequence, delays in initiating agitation, feed flow or temperature variations, maldistribution of reactants, development of catalyst hot spots, loss of cooling and fouling of heat transfer surfaces.

Effects of temperature deviations include overtemperature and undertemperature of equipment, changes of pressure and flow, and runaway reactions. The appropriate measures should be taken to reduce the deviations. In particular, attention should be paid to the heat input and output from the plant and to the control of reactors.

11.13.3 Flow deviations

Flow deviations may be too high, too low, zero, reverse or fluctuating. Changes in flow are generally the result of pressure changes and should be considered in conjunction with these.

Some causes of no flow are lack of feed material, lack of pressure difference, vapour effects and equipment failures. Vapour effects which can cause loss of flow include vapour locks and gassing up of pumps. Equipment failures include the stoppage of pumping equipment, the fracture of equipment resulting in leakage, and the blockage of equipment.

Blockage may occur in a number of ways. Items may be left in the plant after construction and maintenance work. Deposits may build up from liquid impurities, from solid particles, from corrosion or erosion products. The fluid may polymerize or solidify. Cessation of flow for other reasons can cause solidification or polymerization in a heat exchanger. Low ambient temperatures increase the risk of freezing, particularly of liquids which are solids under ambient conditions.

Equipment which is prone to blockage includes pipes, heat exchangers, packed beds and filters. Control valves may block or jam shut.

Reverse flow occurs if there is a reversal of the pressure differential. It should therefore be considered in conjunction with pressure changes. Failure of pumping equipment is a main cause of reverse flow.

Flow deviation can cause deviations of pressure, temperature and level. It can result in materials entering the wrong parts of the plant, can cause erosion, cavitation and hammer blow, and can result in pump overload and trip.

Complete stoppage of flow may cause disturbances to other parts of the plant. Restart after temporary interruption of flow can be hazardous also, as in the case of the extinction of a flame followed by a resumption of flow of unignited fuel.

The manipulation of fluid flows is the principal means by which control is exercised. There are many hazards which can arise if there is a loss of control. A particularly serious one occurs if it is no longer possible to effect necessary heat removal. Low flow may be as hazardous as zero flow, if the deviation is not sufficient to activate the protective devices.

Leakage flow may cause contamination between process streams or emission to the atmosphere. Contamination may result in blockages, corrosion, phase changes, chemical reaction and explosion. Water is the most common substance used in process plants and can give rise to all of these effects. It may enter other streams through pinholes or other tube failures, or through leaking shut-off valves.

The measures required to reduce flow deviations depend on the specific cause, but include attention to the reliability of pumping equipment, the provision of adequate storage and the elimination of blockages and of phenomena which have a similar effect.

Arrangements should be made for the easy removal of blockages at points where these are reasonably foreseeable. Provision should be made for cleaning pipes and heat exchangers by such methods as rodding out, chemical cleaning and burning of carbon deposits. Surfaces of packed beds may be protected from blinding by putting a filter layer such as ceramic packing on top. It may be necessary to install bypasses on equipments which are liable to blockage, but these may introduce their own hazards, which should be considered. Where fluids may freeze, it may be necessary to provide trace steam or electrical heating to prevent this.

11.13.4 Level deviations

Levels may be too high, too low, zero or fluctuating. Changes in level result from flow changes and should be considered in conjunction with these. Level deviations often occur as a result of changes in the flow in or out of a vessel. These may be controlled changes which result in overfilling or emptying of the vessel, or they may be caused by failure of equipment, such as the off-take pump, by vapour effects such as gassing up of that pump, or by blockages.

Changes in the pressure above the liquid, such as loss of vacuum, also affect the level. Some of the other causes of level deviations are surging, foaming and thermal expansion, siphoning and blown lutes. Excessive agitation or vibration of the vessel can also cause level deviations.

The measurement of liquid level is often difficult if there are solids, two liquid phases or foam, or if inerts, water or sediment accumulate. If the level is too high, liquid may overflow, the vessel may be overpressured or the weight of the system may become excessive. Where there is a gas flow through the vessel, a high level may cause liquid entrainment. If the level is zero, the outlet liquid flow is lost. Loss of liquid level can also result in breakthrough of high pressure gas to a part of the plant which is not designed for it. Measures to reduce level deviations depend on the specific case. In particular, attention should be given to the problems of level measurement.

It is not always the aim to eliminate level deviations completely. For some vessels, such as a chemical reactor, the level should normally be held constant, but other vessels are specifically used as surge vessels to smooth fluctuations of flow between units. Such vessels can fulfil their function only if the level in them does vary. They are usually provided with a low gain control loop which permits this.

In the case of level, control of the upper level limit may be achieved without resort to automatic controls by the simple and reliable device of an overflow pipe, and this should always be considered.

In addition to the levels in the main vessels, those in other equipments should be considered. These include levels in heat exchangers and on distillation trays.

11.13.5 Inhomogeneities and accumulations

There are many ways in which inhomogeneities of conditions and accumulations of material can arise. Poor mixing in reactors or other equipment can result in: side reactions and reaction runaway; hot spots, overheating and thermal degradation; and fouling. The accumulation of substances which are relatively innocuous at high dilution but which when concentrated in some way, such as by vaporization with an insufficient bleed-off or by recycling of material, may present a hazard. Material which is held up in the system in a dead leg or elsewhere, for an abnormally long time may undergo degradation and become hazardous.

11.13.6 Control disturbances

The control system, including the process operator, may be a cause of operating deviations. One cause of this is errors, faults or lags in measurement. A level measurement based on liquid head may be in error due to frothing. The reading of a flow measuring instrument may be plausible, but the instrument may nevertheless have failed. There may be appreciable lags in the measurement of temperature.

Deviations may also be caused by the action of the automatic control system. The unsteady-state characteristics of the process such as the nature of the disturbances and of the time lags, the presence of dead time and loop interactions, and a requirement to operate at different throughputs, may make control inherently difficult. As a result, controller settings are sometimes inadequate. Other deviations may be introduced by the actions of the process operator, either through the control system or in other ways.

It is important for the process design to provide sufficient potential correction for control. If a variable is to be controlled, then there must be other variables which can be manipulated in order to achieve that control. This may seem obvious, but it is often not appreciated in practice. If, for example, a cement kiln is operated at maximum air flow, it is not possible to have close control of the outlet gas oxygen content by means of the air flow, since this requires that it be possible both to increase and decrease that flow.

11.14 Impurities

In the foregoing section frequent reference has been made to impurities. These merit some attention in their own right. The problem has been considered by Grollier-Baron (1992a,b), who gives a number of examples of incidents due to impurities, involving mainly explosion or corrosion. The use of nitrogen from ammonia cracking to inert a storage tank containing ethylene oxide led to decomposition of the latter due to traces of ammonia in the nitrogen. The presence of traces of acetylene in air passing over bronze fittings resulted in the formation of cuprous acetylide which then exploded. In a storage facility, replacement of demineralized water used in a heat exchanger for cooling acrolein with water from another source combined with a small leak in the exchanger allowed mineral ions to enter the acrolein, which polymerized exothermically so that the tank exploded. In catalytic crackers and methane reformers, unsaturated hydrocarbons and NCX are produced and when cooled to low temperature can form compounds, some of which are explosive. Mercury present in some natural gas condenses in the aluminium heat exchangers of the liquefaction units and forms an amalgam which corrodes the exchangers. Explosions can occur due to the accumulation of nitrogen trichloride in chlorine vaporizers.

Grollier-Baron outlines a formal approach to dealing with the problem of impurities based essentially on the following measures: (1) identification of the species present in trace quantities, (2) review of the fate of these species, (3) review of the hazards posed by the species, (4) formulation of corrective measures and (5) review to ensure that these countermeasures do not themselves create new hazards.

Identification involves consideration of the trace species in the raw materials, those created in the process and those which could be introduced accidentally. It also requires a review of the sensitivity of the raw materials, intermediates and products to these species. It cannot be assumed that the composition of the raw materials will necessarily remain constant with respect to trace species. There are many factors which may give rise to a change in composition of a raw material, ranging from minor changes in natural or quarried products or in inputs or process at the supplier plant to a complete change of supplier or of process.

There are a number of ways in which impurities may be formed in the process, including by side reactions and by corrosion. Impurities may also be introduced accidentally. One significant source is leaks. Another is deposits left behind in equipment or following maintenance.

It is desirable to have a material balance on, and to know the fate of, any impurities which may be significant. The hazard caused by impurities is increased by accumulation. This accumulation occurs because the impurity has some property different from that of the fluid in which it is present. Hydrogen from corrosion processes is light and may collect at the top of a tank or in a vent system. Nitrogen trichloride is less volatile than chlorine and can build up in a chlorine vaporizer. A difference in relative volatility can cause a compound to build up to quite a high concentration on the tray of a distillation column. Accumulation may also occur due to special circumstances. Cold weather can cause trace quantities to freeze out and cause blockages or worse.

Further treatment of contaminants is given by Tagoe and Ramharry (1993).

11.15 CCPS *Engineering Design Guidelines*

11.15.1 Guidelines for Engineering Design for Process Safety

Process design is one of the principal topics covered in the *Guidelines for Engineering Design for Process Safety* (CCPS, 1993/13) (the CCPS *Engineering Design Guidelines*). The scope of the *Engineering Design Guidelines* is, however, much broader. Table 11.15 gives the principal topics covered together with the location in this book where they are treated.

As far as process design is concerned, the *Guidelines* deal in particular with: (1) inherently safer design, (2) process equipment, (3) utilities, (4) heat transfer fluids, (5) effluent disposal and (6) documentation. The treatment of inherently safer design is organized around the themes of: (1) intensification, (2) substitution, (3) attenuation, (4) limitation of effects and (5) simplification and error tolerance, and includes an inherent safety checklist. The general approach is broadly similar to that taken in Section 11.6.

The items of process equipment treated in the *Guidelines* are: (1) chemical reactors, (2) columns, (3) heat exchangers, (4) furnaces and boilers, (5) filters, (6) centrifuges, (7) process vessels, (8) gas/liquid separators, (9) driers, (10) solids handling equipment, (11) pumps and compressors, (12) vacuum equipment and (13) activated carbon adsorbers.

Table 11.15 *Some principal topics treated in the CCPS Engineering Design Guidelines and their treatment in this text*

Topics	*Chapter*[a]
1. Overview	
2. Inherently safer plant	11
3. Plant design	10, 11
4. Equipment design	11, 12, 22
5. Material selection	12
6. Piping systems	12
7. Heat transfer fluid systems	11
8. Thermal insulation	12
9. Process monitoring and control	13, 14
10. Documentation	6, 11
11. Sources of ignition	10, 16
12. Electrical system hazards	10, 11, 16, 25
13. Deflagration and detonation flame arresters	17
14. Pressure relief systems	12, 15, 17
15. Effluent disposal systems	10, 11, 17
16. Fire protection	10, 16
17. Explosion protection	17

[a] Chapter in this book in which this topic is principally addressed.

The *Guidelines* give a table showing the common causes of loss of containment for different types of process equipment. They also include checklists for safe operation of fired equipment and activated carbon adsorbers. The treatment covers all the main utilities, with particular attention to reliability of electrical power supplies, and includes a checklist of possible utility failures and equipment liable to be affected.

The account of heat transfer fluid systems describes the fluids available and their applications, discusses the relative merits of steam, liquid and vapour–liquid systems, outlines the system design considerations and describes the system components, and considers the safety issues.

With regard to effluent disposal, the systems considered are: (1) flares, (2) blowdown systems, (3) incineration systems and (4) vapour control systems. The treatment does not extend to disposal of materials discharged in reactor venting.

The section on documentation covers: (1) design documentation, (2) operations documentation, (3) maintenance documentation and (4) record keeping.

12

Pressure System Design

Contents

Process materials are normally contained within a pressure system. The main problem in loss prevention is the avoidance of loss of containment from this system. Thus, the First Report of the ACMH (Harvey, 1976) states: 'Containment is the very essence of the problem of control of dangerous materials, and therefore we regard the integrity of pressure systems as of the highest importance' (paragraph 64).

The report continues: 'Scrutiny of incidents suggests that the outright failure of properly designed, constructed, operated and maintained pressure vessels is rare, perhaps because of the lessons learned over many years from steam boiler practice. It is pipework, valves, pumps, etc., which are vulnerable and much more prone to failure' (paragraph 65).

Some of the principal features of pressure systems are briefly discussed in this chapter. It cannot be too strongly emphasized, however, that the discussion is limited to the background information necessary for the appreciation of the problems which occur in loss prevention and that many of the topics touched on, such as materials of construction, pressure vessels, piping, process machinery and overpressure protection, are complex matters which require specialist knowledge. The operation of pressure systems is at least as important as their design. This is considered in Chapter 6 on management systems and in Chapter 20 on plant operation. Selected references on pressure systems and components are given in Table 12.1 and on materials of construction for and corrosion in pressure systems in Table 12.2.

12.1 Pressure Systems

Any system in which the pressure departs at all significantly from atmospheric, and which is therefore of rigid construction, needs to be considered as a pressure system. In the United Kingdom, pressure systems are covered by the Pressure Systems and Transportable Gas Containers Regulations 1989 (the Pressure Systems Regulations). For fixed plant the associated code is COP 37 *Safety of Pressure Systems* (HSE, 1990).

The definition of a 'pressure system' under the Pressure Systems Regulations is given in Regulation 2 and is: '(a) a system comprising one or more pressure vessels of rigid construction, any associated pipework and protective devices; (b) the pipework with protective devices to which a transportable gas container is, or is intended to be, connected; or (c) a pipeline and its protective devices; which contains or is liable to contain a relevant fluid, but does not include a transportable gas container'.

Regulation 2 defines 'relevant fluid' as: '(a) steam; (b) any fluid or mixture of fluids which is at a greater pressure than

0.5 bar above atmospheric pressure, and which fluid or mixture of fluids is – (i) a gas, or (ii) a liquid which would have a vapour pressure greater than 0.5 bar above atmospheric pressure when in equilibrium with its vapour at either the actual temperature of the liquid or 17.5°C; or (c) a gas dissolved under pressure in a solvent contained in a porous substance at ambient temperature and which could be released from the solvent without application of heat'.

Regulation 4 deals with the design, construction, repair and modification of pressure systems. Regulations 5–13 cover essentially operation, inspection and maintenance. Regulation 7 requires there to be safe operating limits. Regulation 5 requires marking of equipment, Regulation 8 a written scheme of examination, Regulation 9 examination in accordance with this scheme and Regulation 13 the keeping of records. Regulation 11 covers operation and Regulation 12 maintenance, whilst Regulation 10 deals with action in the case of imminent danger.

Requirements for the provision of protective devices are contained in Regulation 4 and also in Regulations 14 and 15. This aspect is discussed in more detail in Section 12.12.

12.2 Pressure System Components

The main components of pressure systems have been described by Dickenson (1976). They are:

(1) pressure vessels (reactors, distillation columns, storage drums and vessels);
(2) piping system components (pipes, bends, tees, reducers, flanges, valves, nozzles, nipples);
(3) means of adding, controlling or removing heat (fired heaters, reboilers, vaporizers, condensers, coolers, heat exchangers generally);
(4) means of increasing, controlling or reducing pressure (pumps, compressors, fans, letdown turbines, control valves);
(5) means of adding or removing fluids or solids to or from the process system (pumps, compressors, dump valves);
(6) measurement and control devices and systems (instrumentation);
(7) utilities and services (electricity, steam, water, air).

Item (7) was considered in Chapter 11 and item (6) is described in Chapter 13. The other items are dealt with in the following sections.

12.3 Steels and Their Properties

The main material of construction used in pressure systems is steel and it is necessary to consider some of the properties of steel which are particularly important in relation to pressure systems and which are the basis of pressure systems standards and codes of practice.

Steels and other materials are discussed in *Selecting Materials for Chemical and Process Plant* (L. Evans, 1974), *Handbook of Materials Science* (C.T. Lynch, 1974–), *Materials Handbook* (Brady and Clauser, 1978), *Construction Materials* (Hornbostel, 1978), *Materials for Low Temperature Use* (Wigley, 1979), *Mechanics of Materials* (Beer and Johnstone, 1981), *Physical Properties of Materials for Engineers* (Pollock, 1981–) and *Selection and Use of Engineering Materials* (Crane and Charles, 1984).

Accounts of the general properties of steels in relation to their use in pressure vessels are given in *Theory and Design of Modern Pressure Vessels* (Harvey, 1974), *Pressure Component Construction* (Harvey, 1980) and *Pressure Vessel Systems* (Kohan, 1987). The main steels used in process plant and their relation to the standards and codes are described by L. Evans (1974).

12.3.1 Stress, strain and elasticity

If a specimen test bar of a material is subjected to a tensile load in a tensile testing machine, stress is induced in the material and strain occurs.

The stress is:

$$\sigma = \frac{f}{a_0} \qquad [12.3.1]$$

where a_0 is the original cross-sectional area, f is the force and σ is the stress. The strain, or fractional elongation, is:

$$e = \frac{\delta}{l_0} \qquad [12.3.2]$$

where e is the strain, l_0 is the original length and δ is the elongation.

The typical load–extension, or stress–strain, diagram obtained for many metals, including mild steel, is shown in Figure 12.1. At low loads the material is elastic, returning to its original dimensions when the stress is removed, and the strain is proportional to the stress:

$$\frac{e}{\sigma} = \frac{1}{E} \qquad [12.3.3]$$

where E is the elastic modulus. Equation 12.3.3 is Hooke's law and the constant E is Young's modulus.

As the load increases, there is a change in material behaviour indicated by points A and B in Figure 12.1. The proportionality limit at A is the stress beyond which the strain is no longer proportional to the stress. The elastic limit at B is the stress beyond which the material no longer returns to its original dimensions, but undergoes some permanent deformation. For mild steel and many other materials the proportionality and elastic limits coincide, but for some, such as rolled aluminium, they are separate.

12.3.2 Yield and tensile strengths

The yield point C, which is close to points A and B, is the stress at which there occurs a marked increase in strain without an increase in stress. For many engineering applications it is not acceptable that the material should yield. The yield point represents the limit of strength in such applications.

As the load increases further, there is continued extension until point D is reached at which fracture occurs. The stress at fracture is the ultimate tensile stress, or strength:

$$\tau_u = \frac{f_u}{a_0} \qquad [12.3.4]$$

where f_u is the force at ultimate tensile stress and τ_u is the ultimate tensile strength.

The ultimate tensile strength given in Equation 12.3.4 is the engineering value based on the original cross-sectional area of the specimen. In fact, there is a reduction of this area prior to rupture so that the true tensile strength is:

$$\tau_{u,t} = \frac{f}{a} \qquad [12.3.5]$$

where a is the actual cross-sectional area and $\tau_{u,t}$ is the true ultimate tensile strength. The ultimate tensile stress represents the limit of strength in applications where yielding is acceptable, but rupture is not.

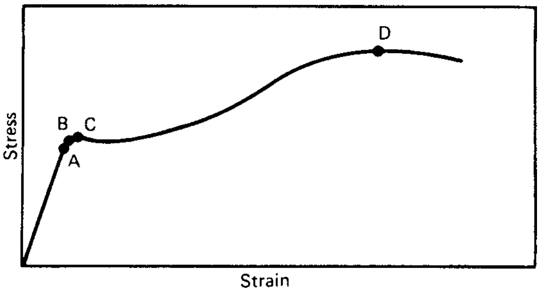

Figure 12.1 *Typical load–extension diagram for mild steel*

12.3.3 Ductility

Another important property of a material is its ductility, or its ability to undergo deformation. Ductility may be expressed as fractional elongation:

$$d_e = \frac{l_r - l_0}{l_0} \qquad [12.3.6]$$

or fractional reduction in area

$$d_a = \frac{a_0 - a_r}{a_0} \qquad [12.3.7]$$

where a_r is the cross-sectional area at rupture, d_a is the fractional reduction in area at rupture, d_e is the fractional elongation and l_r is the length at rupture.

Ductility is a very desirable property in a steel and is important for design and for fabrication. In pressure vessels, features such as joints, openings and nozzles create additional load stresses which may not be fully allowed for in the design. Ductility permits local yielding so that the stress is adjusted. Similarly, ductility allows material to undergo fabrication operations, such as rolling, forging, drawing and extruding, without fracturing.

12.3.4 Toughness and impact strength

A further property which is important in a material is its toughness, or ability to resist impact. Toughness is measured by the energy absorbed in stressing to fracture, which is the area under the stress–strain curve, and thus the modulus of toughness is given by the area:

$$T = \int_0^{e_r} \sigma \, de \qquad [12.3.8]$$

where e_r is the strain at rupture and T is the toughness. A material which has both high tensile strength and high ductility has high toughness. Toughness is another property which is very desirable in a steel, and loss of toughness, or embrittlement, is a serious defect.

12.3.5 Low temperature strength

At low temperatures, mild and other steels tend to suffer a loss of toughness as shown in Figure 12.2. For mild steel the ductile/brittle transition occurs at about 0°C; the precise transition temperature depends on the type and quality of the steel. An account of brittle fracture is given in *The Brittle Fracture of Steel* (Biggs, 1960). Since much process plant operates at low temperatures, such embrittlement is important. Low temperature embrittlement has been the cause of many failures, and is discussed further in Section 12.27.

12.3.6 High temperature strength

At high temperatures, the strength of many materials, including mild steel, tends to decrease, as illustrated in Figure 12.3. The yield point falls and becomes less pronounced, and the ultimate tensile strength also falls. Moreover, a further factor begins to limit strength at high temperature. This is creep.

12.3.7 Creep strength

Creep is an extension which occurs in metals, including mild steel, at high temperatures under constant load over

$$\sum_{i=1}^{n} \frac{t_i}{t_{ri}} = 1 \qquad [12.3.9]$$

where t_i, is the time at stress and temperature conditions i and t_{ri} is the creep life at stress and temperature conditions i. Similarly, for strain at different stresses and temperatures the condition is given by the 'strain fraction' rule:

$$\sum_{i=1}^{n} \frac{e_i}{e_{ri}} = 1 \qquad [12.3.10]$$

where e_i, is the strain at stress and temperature conditions i, and e_{ri} is the strain for rupture at stress and temperature conditions i.

Use is also made of the following equation which utilizes the geometric mean of these two approaches:

$$\sum_{i=1}^{n} \left(\frac{t_i}{t_{ri}} \frac{e_i}{e_{ri}} \right)^{1/2} = 1 \qquad [12.3.11]$$

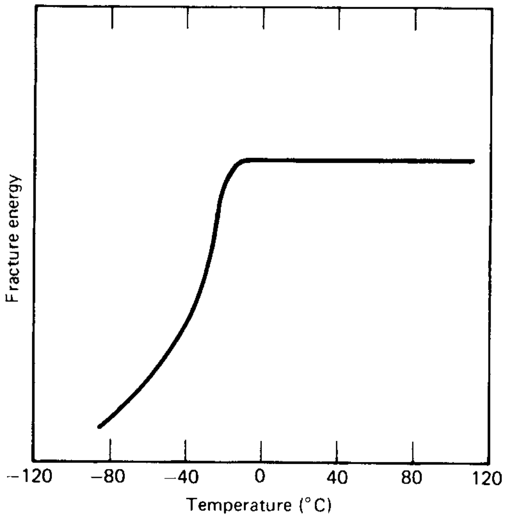

Figure 12.2 *Typical impact strength diagram for mild steel*

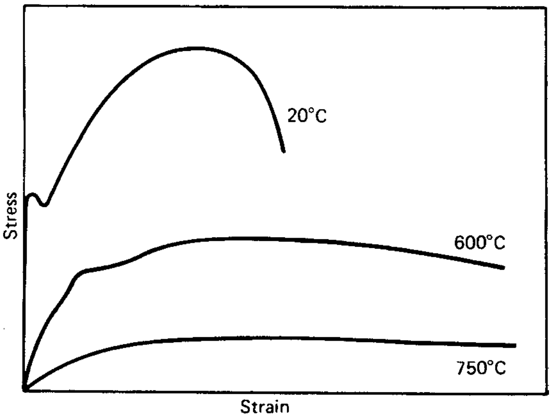

Figure 12.3 *Typical load–extension diagram at high temperatures for mild steel*

a period of time. Accounts of creep are given in *Perspectives in Creep Fracture* (Ashby and Brown, 1983) and *Mechanisms of Creep Fracture* (H.E. Evans, 1984).

The typical results of a creep test on mild steel carried out in a tensile testing machine at constant load and constant temperature are illustrated in Figure 12.4. There is a short primary phase (1) when the creep rate is fairly rapid, a long secondary phase (2) when it is approximately constant, and a short tertiary phase (3) when it accelerates to rupture.

The typical variation of creep rate with loading and temperature is illustrated by Figure 12.5. The creep strength of a material at a particular temperature is usually expressed either as the stress for 1% extension in 100,000 h or as the stress for rupture in 100,000 h. The former is normally taken as not less than two-thirds of the latter.

Frequently, a steel is subjected to a number of different temperatures and/or stresses. For such cases, it is common practice to calculate the fraction of creep life used up as follows. For time at different stresses and temperatures, the condition for exhaustion of the creep life is given by the 'life fraction' rule: it is emphasized that Equations 12.3.9–12.3.11 are approximate. The applicability of these equations is discussed in more detail by Harvey.

Since high temperatures are common in process plant, creep is very important. It is considered again in Section 12.27.

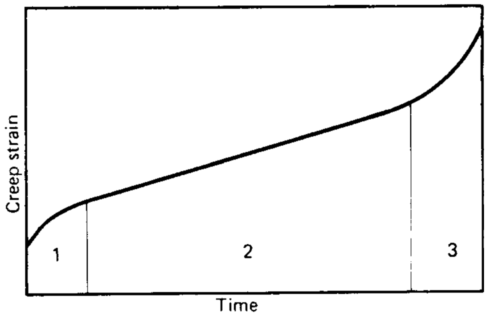

Figure 12.4 *Typical creep test at high temperatures for mild steel*

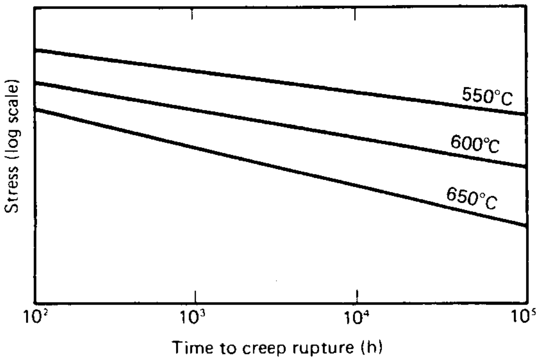

Figure 12.5 *Typical variation of creep rate with loading and temperature for mild steel*

12.3.8 Fatigue strength

Many ductile metals, including mild steel, can under certain conditions suffer fatigue failure at a stress well below the ultimate tensile strength if subjected to repeated cycles of stress. Accounts of fatigue are given in *Fatigue and Fracture of Metals* (Dryden, Rhode and Kuhn, 1952), *Fatigue of Metallic Materials* (Klesnil and Lukas, 1980), *The Mechanics of Fatigue and Fracture* (A.P. Parker, 1981), *Fatigue at High Temperatures* (Skelton, 1983) and *High Temperature Fatigue* (Skelton, 1987).

Whether fatigue failure occurs depends on the magnitude of the stress range which is applied and on the number of repetitions of the stress. The relationship between these two factors is shown in Figure 12.6, which illustrates the results of a typical fatigue test on mild steel. Fatigue testing is usually done using the reversed bending test, in which a load is applied at the end of a cantilever test specimen which is then rotated at constant speed, so that the full reverse bending stresses are created each revolution. The data from such tests may be plotted as maximum stress or as stress range. The stress range is the fundamental parameter, but the maximum stress is often plotted.

The curve given in Figure 12.6 has two distinct regimes. In the first region, to the left of the break point, failure occurs at decreasing stresses but increasing number of cycles, while in the second region to its right there is a stress level below which failure does not occur irrespective of the number of cycles. This stress level is the fatigue limit, or endurance limit, and is an important property. For most steels at room temperature a good estimate of the fatigue limit may be obtained from the ultimate tensile stress using the relation:

$$\sigma_E = d_a \sigma_u \qquad [12.3.12]$$

where σ_E is the fatigue limit and σ_u is the ultimate tensile stress. The fatigue limit for steels other than high strength steels is generally 40–55% of the ultimate tensile strength.

The number of cycles at which the fatigue limit occurs at room temperatures is of the order of 10^6–10^7. It is often convenient, therefore, to take the fracture stress at 10^8 cycles as the practical limit.

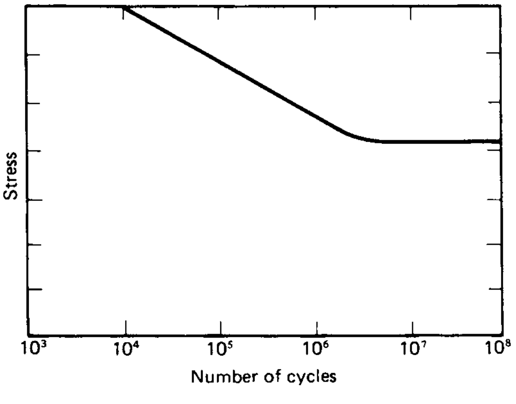

Figure 12.6 *Typical fatigue test for mild steel*

Although it is high cycle fatigue which has been most studied, low cycle fatigue is also important. This occurs at higher stresses and smaller number of cycles and corresponds to the first region in Figure 12.6. In this region, if the data are expressed as stress there is usually considerable scatter, but the scatter is reduced if the data are expressed as strain. A strain is often multiplied by one-half of the elastic modulus to give a pseudo-stress amplitude. Low cycle fatigue is generally considered to cover the region below 10^5 cycles.

It can be shown for many metals, including mild steel at room temperature, that the relation between the stress amplitude and the number of cycles N at fatigue failure can be described approximately by the equation:

$$\sigma = \frac{e}{4N^{1/2}} \ln\left(\frac{1}{1-d_a}\right) + \sigma_E \qquad [12.3.13]$$

This equation covers the range of both low cycle and high cycle fatigue. It may be used to calculate a fatigue life curve. A fatigue design curve may then be obtained using suitable factors of safety. Typical factors of safety are 2 on stress amplitude or 20 on the number of cycles, whichever is the more conservative.

A steel is generally subjected to a number of cycles at a number of different stresses. At each stress the fraction of life used up is given by the cycle ratio n/N. The condition for fatigue failure is given by the 'cycle ratio' rule:

$$\sum \frac{n}{N} = 1 \qquad [12.3.14]$$

where n is the actual number of cycles and N is the number of cycles at fatigue failure. It is emphasized that Equation 12.3.14 is approximate.

There are a number of other factors which also affect fatigue strength. They include (1) temperature, (2) corrosion and (3) surface condition. In the range from room temperature up to about 350°C many steels, including mild steel, show no loss of fatigue strength. In fact there is often a slight gain. But at higher temperatures fatigue strength begins to decrease. At higher temperatures still, creep becomes a significant factor. Reduction of fatigue strength by corrosion may be the result of surface roughening or of reduction of cross-sectional area. More serious is true corrosion fatigue, in which deterioration is due to the interaction of fatigue and corrosion.

The general effect of corrosion fatigue is to reduce the fatigue strength. With corrosion fatigue there is generally no definite fatigue limit. Corrosion fatigue tends to be worse if oxygen is present. Oxygen normally reduces the low cycle fatigue strength. Whether the fatigue limit is reduced depends on the surface condition. A reduction in fatigue strength due to oxygen tends to occur if very sharp cracks are present.

Fatigue strength is, in general, greatly reduced if there are cracks or similar surface defects. A high stress concentration occurs at the extremities of the crack and the crack grows a finite amount each cycle. The growth of fatigue cracks is the subject of fracture mechanics, which is considered in Section 12.28.

Another important factor in fatigue is the temperature changes which occur and which cause thermal stress fatigue. This is an effect quite separate from that of temperature on fatigue strength. Thermal changes are a source of cycling and tend to be difficult to predict, but are often appreciable. If the thermal stress is large, it may cause the metal to deform. This deformation results in a more favourable stress distribution, and to this extent thermal stress is self-correcting, but there may also be some cracking. Cracks arising during thermal stress may grow as a result of mechanical stress.

An index of susceptibility to thermal stress is given by the thermal shock parameter

$$\phi = \frac{E\alpha}{k} \qquad [12.3.15]$$

where k is the thermal conductivity, α is the coefficient of thermal expansion, and ϕ is the thermal shock parameter.

The higher the thermal shock parameter, the more susceptible the metal is to thermal stress. The thermal shock parameter of mild steel is less than that of austenitic stainless steel by a factor of about 3 at room temperature. The difference decreases with temperature, but there is still a factor of about 2 at 350°C.

Mechanical and thermal stresses arising from the operation of process machinery, from pressure changes and from temperature changes are normal in process plant. Fatigue due to these stresses is one of the most common causes of failure and is very important. A further discussion is given in Section 12.27.

12.3.9 Types of steel

The main types of steel which are used in process plant are: (1) carbon steel, including mild steel, (2) low alloy steel and (3) stainless steel, including ferritic and austenitic types. Of prime importance is the temperature at which the steel begins to undergo creep. At room temperature, the strength of the steel is limited by the yield and/or tensile strengths. As the operating temperature increases, however, the creep strength becomes the limiting factor. Thus, the operating temperatures may be divided into (1) temperatures below the creep range and (2) temperatures above the creep range. The basis of design is different for these two cases.

The approximate threshold temperatures at which onset of creep occurs are:

Mild steel	400°C
Low alloy steel	500°C
Austenitic stainless steel	600°C

The change with temperature in the limiting strengths of these three types of steel is shown in Figure 12.7. The shape of the curve is broadly similar for all three types.

12.3.10 Carbon steel

Carbon steels are generally defined as those containing iron, carbon and manganese. Most steels have a carbon content of 0.1–0.9% carbon and 0.5–2.0% manganese.

The most common type of carbon steel is low carbon, or mild, steel with a carbon content up to 0.25%. Mild steel is described in the following subsection. High carbon steels are those with a carbon content above this figure, up to about 0.9%.

Steels containing more than 0.3% carbon are difficult to weld. High carbon steel is produced mainly as bar and forgings for uses such as shafts, bolts, etc. These steels require heat treatment by way of quenching and tempering to give their optimum properties.

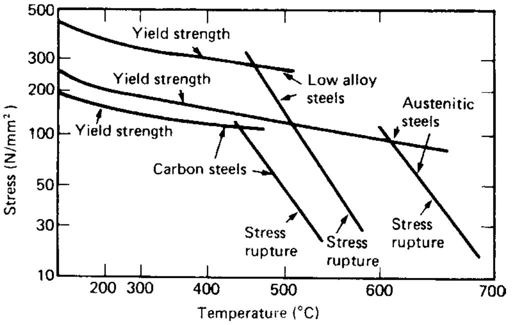

Figure 12.7 Typical yield stress and creep rupture stress curves for mild, low alloy and austenitic steels. (L. Evans, 1974) (Courtesy of Business Books)

12.3.11 Mild steel

Mild steel is low carbon steel with, as just stated, a carbon content less than 0.25%. It is the cheapest and commonest form of steel. The properties of mild steel may be illustrated by the room temperature properties given in BS 4360: 1990 for plate to grade 43EE:

Tensile strength	430/580 N/mm^2
Yield strength	265 N/mm^2
Elongation	20%

where the yield strength applies to thicknesses in the range 16–40 mm and the elongation applies over 200 mm. Mild steel is ductile and weldable, but it has certain limitations which are related to:

(1) corrosion resistance;
(2) strength at
  (a) room temperature,
  (b) high temperature,
  (c) low temperature.

There are many chemicals which corrode mild steel. Examples are dilute acids, such as sulfuric, nitric and hydrochloric acids, and chemicals containing water, such as wet chlorine.

For pressure vessels, it is often attractive to use a material which has a higher strength than mild steel and so to have a thinner walled vessel. Low alloy steel is generally used instead of mild steel in such applications.

At high temperatures, above about 400°C, mild steel suffers quite severe creep and it becomes necessary to use other steels. At low temperatures, below about 10°C, the ductility of mild steel falls off sharply, and brittle fracture can occur, as described above. Again, other steels have to be used.

Mild steel can be modified by the incorporation of small amounts of alloying elements. Addition of up to 0.1% niobium can increase yield strength and low temperature ductility. Addition of up to 1.5% manganese can give substantial increases in yield strength such as from 230 to 400 N/mm^2.

12.3.12 Low alloy steel

The low alloy steels which are important in process plant are mainly those which have a carbon content less than 0.2% and contain a total $<12\%$ alloying elements (Ni, Cr, Mo, V, B, W or Cu).

Many low alloy steels are given a heat treatment of normalizing and tempering by the manufacturer, but there is an increasing tendency to a quenching and tempering treatment. Low alloy steels are all weldable, but for some steels pre- or post-weld heat treatment is necessary in order to avoid weld zone cracking.

Some principal low alloy steels are:

0.5 Mo	12 CrMoVW
1.25 CrMo	0.25 Cr 0.25 Mo 1.5 Ni
2.25 CrMo	

Some significant advantages of low alloy steels over mild steel are:

(1) yield strength;
(2) high temperature properties
  (a) creep strength,
  (b) oxidation resistance,
  (c) hydrogen resistance;
(3) low temperature ductility.

The improvement in yield strength and in creep strength is illustrated in Figure 12.7. Yield strength is the main design parameter used in advanced codes for pressure vessels and the gain in yield strength is valuable. Low alloy steels make it possible to have thinner walled pressure vessels. Low alloy steels such as 0.5 Mo, 1.25 CrMo, 2.25 CrMo and 12 CrMoVW are used for their creep properties in applications such as steam boilers and refinery crackers and reformers. The upper temperature limit for low alloy steels is about 600°C.

Oxidation resistance is another important property of low alloy steels. The principal alloying element which imparts oxidation resistance is chromium. Low alloy steels also offer greater resistance to hydrogen attack in such operations as cracking and reforming. Mild steel ceases to be suitable above 250°C, 0.5 Mo steel can used up to about 350°C, while 2.25 CrMo steel can go up to about 550–600°C. Apart from resistance to oxidation and hydrogen attack, low alloy steels do not offer much greater resistance to corrosion than does mild steel.

An increase in low temperature ductility down to −50°C can be obtained by addition of 1.5 Ni to 0.25 Cr 0.25 Mo steel. This is a most valuable modification, since low temperature embrittlement is a serious problem. Nickel is the main alloying element used to give low temperature ductility.

12.3.13 Stainless steel

The main alloying elements in high alloy steels are chromium and nickel. A stainless steel is one which contains 11% or more of chromium. The chromium forms an oxide film giving a passive surface, rendering it generally more resistant to corrosion than that on the lower alloy or carbon steels.

Accounts of stainless steels are given in *Handbook of Stainless Steels* (Peckner and Bernstein, 1977), *Corrosion of Stainless Steels* (Sedriks, 1979), *Austenitic Stainless Steels* (P. Marshall, 1984) and *High Temperature Alloys* (Marriott *et al.*, 1988) and by Redmond and Miska (1982), J.R. Fletcher (1984), Henderson, King and Stone (1990), and Warde (1991).

The review by Redmond and Miska (1982) covers: the role of the alloying elements; the classes of stainless steel; their corrosion resistance; their physical and mechanical properties; and their fabrication. It also gives numerous tables listing the American Iron and Steel Institute (AISI) types and Unified Numbering System (UNS) numbers for the different classes of stainless steel.

The principal alloying elements in stainless steel are chromium, nickel and molybdenum. Each has a number of effects, and mention is made here of only a few. As already stated, chromium gives a passive oxide layer which increases the corrosion resistance. It also promotes the formation of the ferrite phase. Nickel, by contrast, promotes the formation of the austenite phase and enhances toughness, ductility and weldability. It also increases resistance to strong acids. A principal function of molybdenum is to enhance the resistance of the stainless steel to pitting and crevice corrosion.

Broadly, stainless steels have four main advantages: (1) higher corrosion resistance, (2) higher resistance to heat, (3) higher creep and stress rupture resistance and (4) higher strength at ambient and intermediate temperatures.

For a long time the development of stainless steels was hampered by the presence of carbon and nitrogen, which can have deleterious effects, but the use of techniques such as argon–oxygen decarburization (AOD), vacuum–oxygen decarburization (VOD) and vacuum induction melting (VIM), which allow the production of steels with very low carbon and nitrogen contents, has largely obviated these difficulties.

Redmond and Miska distinguish five classes of stainless steel: (1) austenitic, (2) ferritic, (3) duplex, (4) martensitic, and (5) precipitation hardening. The last two classes are considered later in this subsection and the first three in the next three subsections. Heat treatment is essentially confined to the martensitic and precipitation hardening classes of stainless steel.

The AISI has defined standard types of stainless steel and these steels are commonly described in terms of the AISI types. Also widely used is the UNS of the American Society for Testing and Materials (ASTM). Relevant British Standards are BS 1449: Part 2: 1983 for stainless steel plate and BS 3605: 1973 for austenitic stainless steel pipe.

The stainless steels are dominated by austenitic stainless steels in the AISI 300 series and ferritic steels in the 400 series. The latter series is not confined, however, to steels of the ferritic class, but also includes some in other classes such as martensitic and superduplexes.

Martensitic stainless steels generally contain 11–18% chromium but little or no nickel, and have a structure which can be transformed by suitable cooling from austenite at high temperature to martensite at room temperature. They include a low carbon subclass and a high carbon one, the division occurring at a carbon content of about 0.15%. Martensitic steels, given suitable heat treatment, can have very high strength and hardness. They have a ductile–brittle transition temperature which is usually close to room temperature. A general purpose low carbon martensitic steel is type 410. Martensitic steels are used for such items as bolts, shafts and bearings.

Precipitation-hardening (PH) stainless steels contain both chromium and nickel, and other alloying elements such as copper or aluminium, which impart the precipitation hardening property, allowing the steel to be hardened to high strength for use in such applications as gears.

12.3.14 Austenitic stainless steel

The basic austenitic stainless steel may be regarded as containing 18% chromium and 8% nickel, but there is a whole family of such steels with variations about these values. These steels are described in *Chromium Nickel Austenitic Steels* by Keating (1968) and Redmond and Miska (1982).

The workhorse austenitic steels include AISI types 304, 304L, 316, 316L, 321 and 347. The suffix L denotes low carbon. As already mentioned, austenitic steels are covered in BS 1449: Part 2: 1983 and BS 3605: 1973.

Type 304 is a 19/10 (19 Cr 10 Ni) steel. It contains the minimum amount of alloying elements to give a stable austenitic structure under all fabrication conditions. Type 304L has a lower carbon content than type 304 and is used for applications involving the welding of plate thicker than about 6.5 mm in order to avoid intergranular corrosion, or weld decay.

Type 316 is a 17/12 steel with 2.5 Mo addition to improve resistance to reducing conditions such as brine and dilute sulfuric acid. Type 316L has a lower carbon content than type 316 and is used in applications where the heat input during fabrication will exceed the incubation period of the 316 grade, such as the welding of plate thicker than about 10 mm.

Type 321 is an 18/10 steel with titanium addition to prevent intergranular corrosion. Type 347 is an 18/11 steel with niobium addition to improve welding properties.

Standard austenitic stainless steels are subject to chloride-induced stress corrosion cracking, although certain types exist such as 904L and, particularly 825, which are resistant.

More highly alloyed austenitic stainless steels include the HyResist 317LM and 94L steels, with enhanced corrosion resistance, and the HyProof 3126L and 317L steels with higher proof strength.

The absence of ferrite means that austenitic stainless steels do not have a ductile–brittle transition temperature.

12.3.15 Ferritic stainless steel

Ferritic stainless steels contain chromium but little or no nickel. The class may be subdivided into two main subclasses: those with 11% Cr and those with 17% Cr. Ferritic stainless steels can be rendered brittle by even quite low contents of carbon and nitrogen (say 0.1% C + N), and for a long time this inhibited their use, but in manufacture this problem has been largely obviated by the techniques of AOD, VOD and VIM mentioned above.

The workhorse ferritic stainless steels include AISI types 409, 430, 434 and 444. Type 409 has 11% Cr and type 430 17% Cr.

The welding of ferritic steels poses a problem in that carbon or nitrogen pick-up can have serious effects. In the 11% Cr steels an improvement in weldability, and also an extension of the size of section which can be produced, has been achieved with the use of the SCR 12 type, which is so balanced that some austenite forms above about 800°C, which is beneficial both in welding and rolling.

Ferritic, and also martensitic, stainless steels are immune to chloride-induced stress corrosion cracking but are susceptible to sulfide-induced stress corrosion cracking. Ferritic stainless steels have a ductile–brittle transition temperature. There are also superferritic stainless steels with a high alloy content, which imparts enhanced resistance to pitting corrosion and crevice corrosion.

12.3.16 Duplex stainless steel

Duplex stainless steels contain both ferrite and austenite, in approximately equal amounts. Their properties reflect the fact that they contain both phases. The presence of ferrite means that duplex stainless steels have a ductile–brittle transition temperature.

The duplexes differ from standard austenitic stainless steels in that they have higher resistance to stress corrosion cracking and higher yield strength. They differ from the ferritic stainless steels in having higher low temperature toughness and in being more weldable. Some types of duplex stainless steels are 'lean duplex', 22/5 and 25 Cr.

For some time the use of duplex stainless steels was inhibited by fabrication difficulties. The addition of nitrogen substantially eased these constraints and reduced the need for post-weld heat treatment to restore corrosion resistance.

Recent years have seen the introduction of a new breed of duplex, the superduplex stainless steels. Standard duplexes have limited resistance to pitting and crevice corrosion. The superduplexes include Ferralium 255, Zeron 100 and Uranus 52N+. They are not yet widely used but are starting to find application offshore. They are described by Warde (1991).

12.3.17 Low temperature steel

For low temperature applications use is made of alloy steels or aluminium alloys. Two principal applications are in storage tanks and in liquefied gas carriers. Some of the materials used are illustrated by the following list taken from the IMO *International Gas Carrier Code* (1983 IMO 782):

Minimum design temperature (°C)	*Chemical composition and heat treatment*	*Impact test temperature* (°C)
−60	1.5% nickel steel, normalized	−65
−65	2.25% nickel steel, normalized or normalized and tempered	−70
−90	3.5% nickel steel, normalized or normalized and tempered	−95
−105	5% nickel steel, normalized or normalized and tempered	−110
−165	9% nickel steel, double normalized and tempered or quenched and tempered	−196
−165	Austenitic steels such as types 304, 304L, 316, 316L, 321 and 347 solution treated	−196
−165	Aluminium alloys such as type 5083 annealed	Not required
−165	Austenitic Fe-Ni alloys (36% nickel), heat treatment as agreed	Not required

The qualifications on the use of these materials are given in the code.

12.3.18 Heat treatment of steel

There are a number of processes to which steel may be subjected in order to obtain a better microstructure and enhanced mechanical and corrosion properties. An account oriented to pressure vessels is given by Kohan (1987).

Critical temperature and transformation range

A basic concept in heat treatment of steel is that of the critical temperature at which a transformation occurs in the steel. Actually changes occur over a range of temperature (the transformation range). There are separate transformation ranges for heating and for cooling.

Quenching

Quenching is rapid cooling of the steel by immersion in a medium such as oil or water.

Hardening

Hardening is the heating and quenching of the steel to produce an increase in hardness.

Normalizing

Normalizing involves heating the steel to about 100°F (38°C) above its critical temperature and cooling in still air to room temperature.

Annealing

Annealing involves heating and controlled cooling of the steel in order to refine its structure, modify its properties and/or remove stresses. There is a variety of annealing processes. Full annealing involves heating above the critical temperature and then slow cooling.

Tempering

Tempering is an operation performed after hardening of the steel, and involves heating to a temperature below the critical value and then cooling.

Stress relief heat treatment

Stress relief heat treatment involves uniform heating of all or part of a component to a temperature sufficient to relieve the major part of the residual stresses and then uniform cooling.

Post-weld heat treatment

Post-weld heat treatment (PWHT) refers to any heat treatment carried out following welding.

12.3.19 Steel coding systems

There are a number of systems for the coding of types of steel. These include British, European and American systems.

BS 5500: 1991 for pressure vessels refers to BS 1501–1504 and BS 3059 and BS 3601–3605. These standards designate steels by type and grade, for example, 224 grade 490. Another relevant standard is BS 4360: 1990 *Weldable Structural Steels*. This refers to grades, for example, 50EE. The 1990 edition gives cross-referencing to nomenclature used in earlier editions of this standard. The standards also use the following classification of steels:

Grade	
M0	Carbon steels
M1	Carbon and carbon manganese steels
M2–M10	Low alloy steels
–	High alloy steels

Details are given in Appendix H of BS 5500.

Currently, in the United Kingdom, transition is taking place to the European system. This is described in BS EN 10027 *Designation Systems for Steel*; this and BS 10028 *Flat Products Made of Steels for Pressure Purposes* give cross-referencing.

For the United States, the ASTM has established a unified numbering system (UNS) and issues standards for steel, for example, ASTM A-515/A515M-90. ASME utilizes these standards adding the prefix S, for example, SA-515. Principal steels for process plant are given in the ASME *Boiler and Pressure Vessel Code*, Section II: 1990 *Materials Specifications*. Reference has already been made to the AISI system, particularly in relation to stainless steels. A further discussion of steel coding is given by Pilborough (1989).

12.4 Pressure Vessel Design

Pressure vessels are subject to a variety of loads and other conditions which stress them and, in certain cases, may cause serious failure.

Accounts of pressure vessel design are given in *Pressure Vessels* (Chuse, 1954–), *Pressure Vessel Design and Analysis* (Bickell and Ruiz, 1967), *The Stress Analysis of Pressure Vessels and Pressure Vessel Components* (Gill, 1970), *Theory and Design of Modern Pressure Vessels* (Harvey, 1974), *Pressure Component Construction* (Harvey, 1980), *Chemical and Process Equipment Design*: *Vessel Design and Selection* (Azbel and Cheremisinoff, 1981), *Pressure Vessels* (Chuse and Eber, 1984), *Pressure Vessel Design Handbook* (Bednar, 1986), *Mechanical Design of Process Systems* (Escoe, 1986), *Fundamentals of Pressure Vessel and Heat Exchanger Technology* (J.P. Gupta, 1986), *Pressure Vessel Systems* (Kohan, 1987), *Pressure Vessel Design Manual* (D.R. Moss, 1987), *Pressure Vessels* (Chuse and Carson, 1993) and *Pressure Vessel Design* (Spence and Tooth, 1994).

In general, structures are subject to two types of loading: (1) static loading and (2) dynamic loading. For pressure vessels this loading is normally due to pressure. The load caused by the pressure creates stresses in the vessel. There may also be other stresses, which include (1) residual stress, (2) local stress and (3) thermal stress.

12.4.1 Design basis

The basis of the design of pressure vessels is the use of appropriate formulae for vessel dimensions in conjunction with suitable values of design strength. In determining the strength of materials, a basic distinction is drawn between (1) temperatures below the creep range and (2) temperatures inside the creep range.

For temperatures below the creep range two important properties are (1) tensile strength, R; and (2) yield strength, E. Different design methods may use these properties as measured at room temperature (generally 20°C) or at the operating temperature (f°C). Use has been made, therefore, of all the four properties:

(1) tensile strength at room temperature, R_{20},
(2) tensile strength at operating temperature, R_t,
(3) yield strength at room temperature, E_{20},
(4) yield strength at operating temperature, E_t.

For temperatures inside the creep range, two further important properties are (1) stress for 1% extension in 100,000 h at the operating temperature, S_c and (2) stress for rupture in 100,000 h at the operating temperature, S_r. These material strengths are divided by a factor of safety to obtain the design strengths for use in the design.

12.4.2 Static pressure loading

Pressure vessels may often be treated as thin-walled cylinders or spheres. For a thin-walled cylinder, a simple force balance gives the longitudinal stress:

$$p\pi r^2 = \sigma_1 t 2\pi r \qquad [12.4.1]$$

$$\sigma_1 = \frac{pr}{2t} \qquad [12.4.2]$$

where p is the pressure, r is the radius of the vessel, t is the wall thickness, and σ_1 is the longitudinal stress. The circumferential, or hoop, stress is:

$$\sigma_2 = \frac{pr}{t} \qquad [12.4.3]$$

where σ_2 is the circumferential stress.

Similarly, for a sphere the longitudinal and circumferential stresses are:

$$\sigma_1 = \sigma_2 = \frac{pr}{2t} \qquad [12.4.4]$$

Other methods are required for thick-walled vessels.

12.4.3 Dilation

If the pressure vessel is subject to stress, it exhibits dilation, or radial growth. For an element which is subject to tensile stress in two perpendicular directions, the strain in one direction depends not only on the stress in this direction but also on that in the perpendicular direction and is a function of Poisson's ratio μ:

$$e_1 = \frac{\sigma_1}{E} - \frac{\mu\sigma_2}{E} \qquad [12.4.5]$$

$$e_2 = \frac{\sigma_2}{E} - \frac{\mu\sigma_1}{E} \qquad [12.4.6]$$

where e_1 is the longitudinal strain, e_2 the circumferential strain and E is the elastic modulus.

The dilation, or radial growth, of a cylindrical pressure vessel may be determined by integrating the hoop strain in the wall from an axis through the centre of rotation and parallel to a radius. If the coordinates of a point in the wall are r, ϕ, the dilation δ is:

$$\delta = \int_0^{\pi/2} e_2 r \cos\phi \, \mathrm{d}\phi \qquad [12.4.7a]$$

$$\delta = e_2 r \qquad [12.4.7b]$$

Then from Equation 12.4.6

$$\delta = r\left(\frac{\sigma_2}{E} - \frac{\mu\sigma_1}{E}\right) \qquad [12.4.8]$$

and from Equations 12.4.2 and 12.4.3

$$\delta = \frac{pr^2}{2tE}(2-\mu) \qquad [12.4.9]$$

Similarly, for a spherical vessel the dilation is

$$\delta = \frac{pr^2}{2tE}(1-\mu) \qquad [12.4.10]$$

12.4.4 Dynamic pressure loading

The behaviour of a material such as mild steel under dynamic loading differs considerably from its behaviour under static loading. The shape of the stress–strain diagram alters with the rate of loading. At very high strain rates (say $\mathrm{d}e/\mathrm{d}t = 300\ \mathrm{s}^{-1}$) the yield point more than doubles. There are also large increases in the ultimate tensile strength and elongation. In consequence of this characteristic, the loads which can be applied to the material without permanent deformation or rupture are considerably greater with dynamic loading than with static loading.

12.4.5 Residual stress

The basic design equations for pressure vessels assume that the stresses are caused only by external loads. They do not take into account residual stresses resulting from fabrication and construction processes such as heat treatment, weld shrinkage or casting cooling. These stresses are of great importance in brittle materials. They are usually rather less significant in ductile materials, which tend to yield and relieve the stress, but they can contribute to fatigue failure.

Moreover, in thick sections residual stresses can combine with load stresses to create a three-dimensional stress pattern which restricts the redistribution of the localized stresses by yielding. This is the reason why stress relieving is particularly important for thick vessels.

12.4.6 Local stress

Another assumption of the basic design equations is that there is continuity of stress. The localized stresses in a region where there is a discontinuity are therefore greater than those predicted. These localized stresses are more important in brittle than in ductile materials, but again they are significant for fatigue failure.

12.4.7 Thermal stress

Most materials undergo expansion if their temperature is raised and contraction if it is lowered. If an unrestrained body is subjected to non-uniform heating, the different parts experience different degrees of strain and these differential strains give rise to corresponding stresses. Such stresses do not develop if the body is heated up uniformly. If the body is restrained, however, stress is developed even though the heating is uniform. There are, therefore two basic causes of thermal stress, non-uniform temperature and restraint.

With a ductile material, thermal stresses do not on first application cause failure by rupture, because the material tends to yield and relieve the stress, but their repeated application can cause fatigue failure. In addition, the deflection or distortion due to normal stresses can render equipment unserviceable.

For a body which is restrained in one dimension only, the thermal stress σ is

$$\sigma = -E\alpha\Delta T \qquad [12.4.11]$$

where ΔT is the temperature difference and α is the coefficient of thermal expansion. The product $E\alpha$ is the thermal stress modulus. The minus sign indicates that the body is in compression. For a body restrained in two dimensions

$$\sigma = -\frac{E\alpha\Delta T}{(1-\mu)} \qquad [12.4.12]$$

and for one restrained in three dimensions

$$\sigma = -\frac{E\alpha\Delta T}{(1-2\mu)} \qquad [12.4.13]$$

Pressure vessel conditions mainly correspond to two-dimensional constraint.

Non-uniform temperature distribution may be either steady or unsteady state. The thermal stresses caused by thermal gradients in a long thin-walled cylinder or pipe may be shown to be as follows. For a steady state, linear temperature gradient through the pipe wall the stress on the inside of the pipe is:

$$\sigma = -\frac{E\alpha\Delta T}{2(1-\mu)} \qquad [12.4.14]$$

For a transient in which a hot fluid is suddenly contacted with the pipe wall, which previously was at a uniform temperature, the initial stress is:

$$\sigma = -\frac{E\alpha\Delta T}{(1-\mu)} \qquad [12.4.15]$$

12.4.8 Design construction features

There are numerous design features which tend to create local stresses. These include:

(1) discontinuities:
  (a) vessel ends,
  (b) changes of cross-section,
  (c) changes of thickness;
(2) joints:
  (a) bolted joints,
  (b) welded joints;
(3) bimetallic joints;
(4) holes and openings;
(5) flanges;
(6) nozzles and connections;
(7) bolt seating and tightening;
(8) supports and lugs.

The minimization of the local stresses caused by these stress raisers is a major aspect of pressure vessel design. Some of the principal methods of minimizing local stresses are as follows. Discontinuities are made as gradual as possible and sudden discontinuities are avoided. Weld defects such as overfill are kept to a minimum. Holes are spaced relative to each other so as not to cause serious weakening. The same applies to the spacing of nozzles and other connections. Flanges and nozzles are reinforced so as to minimize stress. The reinforcement relies on good design rather than on massive addition of metal. Self-adjusting nut seats are provided for bolts which have to be tightened on sloping surfaces. Thermal stresses at supports are reduced by measures to allow heat to flow between the vessel and the support, and so avoid large temperature gradients.

12.4.9 Vessels in composite materials

Pressure vessels may also be constructed in composite materials, notably glass-reinforced plastic (GRP), or fibre-reinforced plastic (FRP). The main use of GRP in the process industries is for atmospheric, or near-atmospheric, storage tanks, but vessels can be built to withstand higher pressures.

Accounts of the use of composite materials are given in *Glass Reinforced Plastic* (Parkyn, 1970), *Fibre Reinforced Materials Technology* (Parratt, 1972), *Fibre Reinforcement* (Catherall, 1977), *FRP Technology* (Weatherhead, 1980), *Materials and the Designer* (Cornish, 1987), *Composite Materials Handbook* (M. Schwartz, 1991) and by Puckett (1976), I.R. Miller (1979) and Britt (1993).

The use of GRP for storage tanks is discussed in Chapter 22.

12.5 Joining, Fastening and Welding

There are two main methods by which materials may be joined: (1) mechanical fastening and (2) physical bonding. For pressure systems the main fastening methods are riveting and bolts and nuts, while the methods of bonding are soldering and brazing and fusion welding. Although riveting was used as a method of joining in older pressure vessels, some of which are still in use, the modern method of joining is by fusion welding. Fastening by bolts and nuts, however, is a widely used method of joining, particularly on flanged joints. Flanged joints are used mainly in pipework and are considered in Section 12.7.

Soldering and brazing are methods of bonding in which the joint is made by introducing molten metal between the two parts to be joined without deliberate fusion of the parent metal. With fusion welding, by contrast, the parts of the parent metal adjacent to the joint are brought to molten temperature and caused to fuse together, generally with the addition of molten filler material. Fusion welding is the principal method of making permanent joints in pressure vessels and pipework.

An account of methods of joining, fastening and welding is given by Pilborough (1971, 1989).

12.5.1 Fusion welding

In fusion welding, the parts to be welded are heated so that they are molten along the line of the joint, and then generally a filler rod, also raised to molten temperature, is brought over the joint. This forms a pool of molten metal which is made to run along the joint and fuse the two parts together so that when they cool and solidify a homogeneous joint is made.

Some of the main methods of fusion welding described are:

(1) oxyacetylene welding;
(2) metallic arc welding;
(3) inert gas shielded welding:
  (a) argon arc welding,
  (b) CO_2 gas shielded welding,
  (c) pulsed arc welding;
(4) electrical resistance welding:
  (a) spot welding,
  (b) seam welding,
  (c) projection welding,
  (d) butt welding,
  (e) flash welding.

Oxyacetylene welding is cheap and is widely used. It is suitable where high quality welds are not required and where corrosion is not a serious problem. In oxyacetylene welding heat is generated by combustion of acetylene in oxygen using a blowtorch and the weld is made using a filler rod. The flame should be kept as nearly neutral as possible. Excess acetylene tends to cause carburization of the weld, leading to lower corrosion resistance and possibly embrittlement, while excess oxygen generally gives an oxidized and porous weld.

Metallic arc welding is perhaps the most commonly used method. It is suitable for welding a wide range of plate thicknesses, from thin plate up to plate many centimetres thick, and a wide range of materials including stainless steel. In metallic arc welding, an electrode of the same metal as the work is used and an arc is struck between the two. The heat of the arc melts both the tip of the electrode and the parent metal beneath it, and metal drops across the arc from this electrode to the parent metal. Both a.c. and d.c. are used, the former being cheaper, but the latter being more suitable for some high quality work and for stainless steel.

Inert gas shielded welding is widely used to obtain a high quality weld. In the United Kingdom, the inert gas used is generally argon and the method is also known as 'argon arc welding'. Helium is normally used in the United States. The two main methods used are tungsten inert gas (TIG) and metal inert gas (MIG) welding. In the TIG technique, an arc is struck between the tungsten electrode and the work in an inert atmosphere. Filler is added as necessary in the form of a bare wire. In the MIG process, the arc is struck and a bare wire filler and inert gas are fed in through a feeder gun or head.

An alternative gas used in inert gas shielded welding is CO_2, which is much cheaper than argon. CO_2 gas shielded welding tends to be used for high quality work on ferrous metals and argon shielded welding for high quality work on stainless steel and on other materials.

The quality of the weld in MIG welding is affected by the mode of transfer of the molten metal to the work. The most desirable mode is spray transfer, in which the metal passes from the wire to the weld pool as small drops, but there occur also dip transfer, in which metal is deposited when the wire is dipped in the pool and which causes irregularity, and globular transfer, in which large drops are released. Spray transfer is favoured by high current, but the latter tends to burn through on thin material and a compromise is necessary.

Pulsed arc welding overcomes this problem and gives spray transfer without burn-through by using a high pulsed current to effect transfer, while maintaining a relatively low mean welding current.

There are a number of electrical resistance welding processes in which an electric current is passed through the work to be joined; the material is heated and rendered molten by the electrical resistance at the joint and is thus welded together.

In spot welding, the points to be joined are clamped together between two shaped electrodes. A heavy surge of current is passed between these electrodes and welds the work together by a small spot.

In seam welding, a series of spot welds is produced by a pulsed current from a rotating disc electrode. This method does not give a completely continuous weld. There is some tendency, therefore, for seam welds to leak and to entrap materials and corrode.

In projection welding, projections are raised on the parts to be joined, the parts are pressed together between the electrodes and the projections are fused by the weld current.

In butt welding, special projections are not used. The parts are pressed together between the electrodes and the adjoining surfaces are fused by the welding current. The adjoining faces in butt welding should be flat and parallel. In flash, or flash-butt, welding the parts are again pressed together between electrodes, a current is passed which causes the slight roughnesses of finish to melt and flash-off, the parts are pressed closer and more flashing occurs and, at the right moment, further pressure is applied, the parts fuse together and the current is switched off. Butt welding is used to join smaller components and flash welding large ones.

The terminology used in arc welding in the United States is described in the account by J.E. Jones and Olson (1986). They classify arc welding processes by type of shielding and by whether or not the electrode is consumed; they distinguish the following principal types:

Method	*Shielding*	*Electrode type*	*Usual thickness* (in.)
1. Shielded-metal arc welding (SMAW)	Flux plus coating; some generated gas	Solid wire, coated with flux	0.25–4
2. Submerged arc welding (SAW)	Granulated flux	Solid wire, maybe copper flashed	0.1–2
3. Gas-metal arc welding (GMAW)	Inert gas or gas mixture	Solid wire, maybe copper flashed	0.05–2
4. Fluxed-core arc welding (FCAW)	Flux and/or gas; may be self-shielding	Hollow electrode with core of metal powder	0.05–1.5
5. Gas-tungsten arc welding (GTAW)	Inert gas or gas mixture	Solid tungsten wire, water or air cooled	0.05–0.4
6. Plasma arc welding (PAW)	Inert gas or gas mixture	Solid tungsten wire, water cooled	0.04–0.24

In the first four of these methods the electrode is consumed, whilst in the last two it is not. The authors give details of the materials for which the different methods are suitable and of typical applications.

The American Welding Society (AWS) issues standards for most of these methods, with individual standards covering the arc welding of different materials such as carbon steel, stainless steel, etc. Thus, for example, AWS B2.1.001–90, B2.1.002–90 and B2.1.008–90, and B2.1004–90 cover welding of carbon steel by the SMAW, GTAW and GMAW methods, whilst B2.1.0013-91 and B2.1.005-90 cover welding of austenitic stainless steel by the SMAW and GMAW methods, respectively.

The qualifications of welders, the inspection of welds and defects in welds are considered in Chapter 19.

12.6 Pressure Vessel Standards and Codes

The design, fabrication and construction of pressure vessels is a subject which is particularly well covered by standards and codes of practice. Pressure vessel codes fall into two main types. The first type is the conventional codes, the second the so-called 'advanced codes'. The differences between the two types of code are considered below.

In the United Kingdom, the main pressure vessel codes until 1976 were BS 1500: 1958 *Fusion Welded Pressure Vessels for General Purposes* and BS 1515: 1965 *Fusion Welded Pressure Vessels for Use in the Chemical, Petroleum and Allied Industries*. BS 1500 was a conventional code and BS 1515 was an advanced code. In 1976, both these codes were superseded by a new pressure vessel code BS 5500.

The current version of this code is BS 5500: 1991 *Specification for Unfired Fusion Welded Pressure Vessels*.

The corresponding US code is the ASME *Boiler and Pressure Vessel Code*: 1992; this is described in Subsection 12.6.5.

Another code is ISO R831: 1968 *Recommendations for Stationary Boilers*, which is applicable to pressure vessels also.

There is an EC Directive 77/767/EEC on pressure vessels.

12.6.1 Conventional and advanced codes

The maximum design stresses allowed in a code either are tabulated in the code or are calculated from materials properties using factors of safety given in the code. The difference between the conventional and the advanced codes lies mainly in the design stress considered. These differences may be illustrated by considering on the one hand BS 1500: 1958 and ASME Section VIII, Division 1, and on the other BS 1515: 1965 and ASME Division 2.

At temperatures below the creep range the conventional codes BS 1500: 1958 and ASME Division 1 use as the design stress the tensile strength divided by a factor of safety, which is 4 in both codes, whilst the advanced codes BS 1515: 1965 and ASME Division 2 use the yield stress at design temperature divided by a factor of safety, which in BS 1515: 1965 is 1.5. This different design criterion favours the use of steel with high yield strength such as low alloy steels. The use of low alloy steels makes possible the design of thinner walled pressure vessels.

At temperatures within the creep range the design stress used is the creep strength, again in conjunction with a suitable factor of safety. The difference between the two types of code may be seen in the comparisons of design strengths given in the earlier BS codes by L. Evans (1974) and in the ASME code by Pilborough (1989). For a particular material at a particular temperature, the maximum permissible design strength is the lowest strength obtained by dividing the specified properties by the specified factor of safety. For BS 1500 and BS 1515 Evans gives the design strengths in terms of the material tensile strengths R_{20}, and R_t, the yield strengths E_{20} and E_t and the creep strengths S_r and S_c (as defined in Section 12.4), and an appropriate factor of safety.

BS 1500: 1958	$\frac{R_{20}}{4}$	$\frac{R_t}{4}$			$\frac{S_c}{1}$
BS 1515: 1965	$\frac{R_{20}}{2.35}$		$\frac{E_t}{1.5}$	$\frac{S_r}{1.5}$	$\frac{S_c}{1}$

The comparison given by Pilborough (1989) for the two divisions of the ASME code and also for ISO R831 may be summarized as follows. For each code the design strength is the lowest of:

ASME Section VIII Division 1	$\frac{R_{20}}{4}$	$\frac{R_t}{4}$	$\frac{E_{20}}{1.6}$	$\frac{E_t}{1.6}$	$\frac{S_r}{1.25}$	$\frac{S_c}{1}$
ASME Section VIII Division 2		$\frac{R_t}{3}$	$\frac{E_t}{1.5}$			$\frac{S_c}{1.5}$
ISO R831		$\frac{R_t}{2.7}$		$\frac{E_t}{1.5}$	$\frac{S_r}{1.5}$	$\frac{S_c}{1}$

The design strengths laid down in BS 5500: 1991 and the ASME code are given below.

12.6.2 Pressure vessel classification

BS 5500: 1991 gives a classification of pressure vessels. An earlier classification was given in BS 1500: 1958. The latter classified pressure vessels as Class I, II or III. For a Class I vessel the requirements include full radiography of the main seam welds, while Classes II and III have less stringent requirements. A Class I vessel also requires PWHT for stress relief.

BS 5500: 1991 places pressure vessels in three construction categories. For a Category 1 vessel full non-destructive testing of the main seam welds is required, while for Categories 2 and 3 the requirements are limited to spot non-destructive testing and visual examination, respectively. The PWHT requirements are related to steel type and thickness rather than to vessel category.

12.6.3 BS 5500

The coverage of BS 5500: 1991 *Specification for Unfired Fusion Welded Pressure Vessels* is indicated by the list of contents given in Table 12.3. The standard applies to the design, construction, inspection, testing and certification of pressure vessels. It does not cover certain defined types

Table 12.3 *Principal contents of BS 5500: 1991*

1. General
    - 1.1 Scope
    - 1.2 Interpretation
    - 1.3 Definitions
    - 1.4 Responsibilities
    - 1.5 Information and requirements to be agreed and documented
2. Materials
    - 2.1 Selection of materials
    - 2.2 Materials for low temperature applications
    - 2.3 Carbon, carbon manganese and alloy steels
3. Design
    - 3.1 General
    - 3.2 Application
    - 3.3 Corrosion, erosion and protection
    - 3.4 Construction categories and design stresses
    - 3.5 Vessels under internal pressure
    - 3.6 Vessels under external pressure
    - 3.7 Supports, attachment and internal structures
    - 3.8 Bolted flanged connections
    - 3.9 Flat heat exchanger tubesheets
    - 3.10 Design of welds
    - 3.11 Jacket construction
    - 3.12 Manholes and inspection openings
    - 3.13 Protective devices for excessive pressure or vacuum
4. Manufacture and workmanship
    - 4.1 General aspects of construction
    - 4.2 Cutting, forming and tolerances
    - 4.3 Welded joints
    - 4.4 Heat treatment
    - 4.5 Surface finish
5. Inspection and testing
    - 5.1 General

    - 5.3 Welder and operator approval
    - 5.4 Production control test plates
    - 5.5 Destructive testing
    - 5.6 Non-destructive testing
    - 5.7 Acceptance criteria for weld defects revealed by visual examination and non-destructive testing
    - 5.8 Pressure tests

Also various appendices including:

B Recommendations for cylindrical, spherical and conical shells under combined loadings, including wind and earthquakes.
C Recommendations for the assessment of vessels subject to fatigue.
D Requirements for ferritic steels in bands M0–M*E* inclusive for vessels required to operate below 0°C
E Recommendations for welded connections of pressure Vessels.
G Recommendations for methods of calculation of stresses from local lads, thermal gradients, etc.
H Recommendations for post-weld heat treatment of dissimilar ferritic steel joints.
J Recommendations for pressure relief protective Devices.
K Requirements for the derivation of material nominal design strengths for construction Category 1 and 2 vessels.
U Guidance on use of fracture mechanics analysis.

of vessel, which may be summarized as atmospheric storage tanks, vessels for very high pressure (e.g. strip wound compound vessels), vessels in which the stresses are less than 10% of the permitted design stress, vessels for specific applications covered by other British Standards and pressure vessels used in transport.

Specific recognition is given in the standard to the Inspecting Authority, which acts on behalf of the purchaser, and the Regulating Authority, which enforces the laws and regulations in the country concerned.

With respect to materials of construction the standard allows the use either of materials specified in British Standards or of other materials, provided these meet specifications agreed between the manufacturer and the user for certain specified properties as tested by specified methods listed in the standard. The latter should cover as a minimum the manufacturing process, compositional limits for all constituents, deoxidation practice, heat treatment and appropriate mechanical properties.

BS 5500: 1991 lists in its table 2.3 and appendix K the other standards which it uses for the design strength of steels. These include BS 1501–1504, BS 3059 and BS 3601–3605. It gives in tables 2.3(a)–(j) extensive tabulations of design strengths from these standards.

The basis for the determination of design strengths in the standards just listed is described in appendix K of BS 5500. A distinction is made between (1) the time-independent design strength and (2) the time-dependent design strength, in the creep region. For the former, distinctions are made between materials with and without specified elevated temperature properties and between carbon, carbon manganese and low alloy steels and austenitic stainless steels. Thus, for the time-independent strength, relations are given for the following four cases:

(1) carbon, carbon manganese and low alloy steels
    (a) materials with specified elevated temperature properties,
    (b) materials without specified elevated temperature properties;
(2) austenitic stainless steels
    (a) materials with specified elevated temperature properties,
    (b) materials without specified elevated temperature properties.

The nominal design strength f is taken as the lesser of the nominal design strength f_e corresponding to the short-time tensile strength characteristics and the nominal design strength f_F corresponding to the creep characteristics. The material strengths used are as follows. R_m is the minimum tensile strength at room temperature. R_e is the minimum yield strength at room temperature. Where a standard specifies minimum strength values of R_{eL} or $R_{p,0.2}$, these values are taken as corresponding to R_e. $R_{e(T)}$ corresponds to R_{eL}, or $R_{p,0.2}$ a temperature T. S_{Rt} is the mean stress required to produce rupture at time t at temperature T. The relations given in appendix K of the standard for the determination of the nominal design strength f are shown in Table 12.4. The design strength for a typical steel, BS 1501 26B, in plate form up to a thickness of 32 mm, which has a minimum tensile strength of 402 N/mm^2, is given in Table 12.5.

The equations given in the standard for minimum shell thickness for pressure loading only are as follows:

Cylinder:

$$e = \frac{pD_i}{2f - p} \qquad [12.6.1a]$$

or

$$e = \frac{pD_o}{2f + p} \qquad [12.6.1b]$$

Sphere:

$$e = \frac{pD_i}{4f - 1.2p} \qquad [12.6.2]$$

or

$$e = \frac{pD_o}{4f + 0.8p} \qquad [12.6.3]$$

where D_i is the internal diameter of the shell, D_o is the external diameter of the shell, e is the minimum thickness of the shell, f is the nominal design stress, and p is the design pressure. The dimensions do not include corrosion allowances.

The standard gives guidance on the design pressures and temperatures to be used. For the maximum design pressure it states that the design pressure, or the pressure to be used in the equations for the purposes of calculation, should not be less than:

(a) the pressure which will exist in the vessel when the pressure relieving device starts to relieve, or the set pressure of the pressure relieving device, whichever is the higher (see Appendix J of standard);
(b) the maximum pressure which can be attained in service where this pressure is not limited by a relieving device.

The static head should be taken into account.

For the minimum design pressure, the standard recommends that vessels subject to vacuum should be designed to a full negative pressure of 1 bar.

The maximum design temperature should not be less the actual metal temperature expected in service, allowing adequate margin for uncertainties in predicting this temperature. An appropriate design lifetime should be agreed between purchaser and manufacturer. No vessel designed

Table 12.4 *Design strengths given in BS 5500: 1991*

Material	*Regime*	*Temperature range* (°C)	*Design strength lowest of*
Carbon, carbon manganese and low alloy steels	Time-independent[a]	≤50	$f_E = \frac{R_e}{1.5}$ or $\frac{R_m}{2.35}$
		>150[b]	$f_E = \frac{R_{e(T)}{}^{c}}{1.5}$ or $\frac{R_m}{2.35}$
Austenitic stainless steel	Time-independent	≤50	$f_E = \frac{R_e}{1.5}$ or $\frac{R_m}{2.35}$
		>150[b]	$f_E = \frac{R_{e(T)}{}^{d}}{1.5}$ or $\frac{R_m}{2.35}$
Both types of steel	Time-dependent		$f_F = \frac{S_{R_t}}{1.3}$

[a] Values given for time-independent nominal design strengths are for material with specified elevated temperature values.
[b] For temperatures between 50 and 150°C values are interpolated.
[c] For materials without specified elevated temperature values, value is $R_{e(T)}/1.6$.
[d] For materials without specified elevated temperature values, values is $R_{e(T)}/1.45$.
[e] See detailed notes in Appendix K of the standard.

Table 12.5 *Design strengths (f, N/mm^2) for steel 224, 490 M1 (A and B) for plates up to 40 mm thick, as given in BS 5500: 1991 (Courtesy of the British Standards Institution)*

R_m (N/mm^2)	R_e (N/mm^2)	*Thickness* (mm)	*Design temperatures* (°C) *not exceeding*						*Design lifetime* (h)
			50	*100*	*150*	*200*	...	*480*	
490	325	3–16	208	192	177	160	...	42	100,000
	315	40	208	190	173	158	...	38	150,000
	305	63	204	187	171	156	...	34	200,000
	281	100	187	176	164	153	...	34	250,000
	250	150	167	162	157	150			

on this basis should remain in service beyond the agreed lifetime without a review as specified in the standard.

The minimum design temperature, which is used to assess the suitability of the material to resist brittle fracture, should be the lowest metal temperature expected in service. In the case of components with external thermal insulation, this temperature is that of the contents of the vessel under the appropriate loading conditions, whilst in the uninsulated case the minimum temperature is a matter for agreement.

Some of the topics on which the standard gives guidance are (1) local stresses, (2) low temperature properties, (3) corrosion and (4) fatigue. The calculation of local stresses is covered rather comprehensively in the standard, which gives a large number of charts for particular cases.

The standard deals in appendix D with the suitability of steels in bands M0–M4 for low temperature service, below 0°C. A design reference temperature #R is defined such that

$$\theta_R \leq \theta_D + \theta_S + \theta_C + \theta_H \qquad [12.6.4]$$

where θ_D is the minimum design temperature (°C), and θ_R is the design reference temperature (°C), and θ_S, θ_C and θ_H are temperature adjustments. θ_C is an adjustment which depends on the construction category and has the values 0, −10 and −20°C for Category 1, 2 and 3 vessels, respectively. θ_H is an adjustment in applications where all plates incorporating subassemblies undergo PWHT before they are butt welded together, but the main seams do not subsequently undergo PWHT. In these applications θ_H is +15°C. θ_S is an adjustment depending on the calculated membrane stress which has the value 0°C when this stress is equal to or exceeds $2f/3$, +10°C when the stress is equal to or exceeds 50 N/mm^2 but does not exceed $2f/3$; and +50°C when the stress does not exceed 50 N/mm^2. In the latter case, the membrane stress should take into account internal and external pressure, static head and self-weight.

Where the calculated membrane stress can vary with the minimum design temperature, for example in autorefrigeration during depressurization, the standard requires that the coincident values of θ_D and θ_S be evaluated, where appropriate, allowing for the possibility of repressurization whilst still cold, and gives detailed guidance.

The standard gives graphs showing the permissible design reference temperature/reference thickness/material impact test temperature relationships for (1) as-welded and (2) PWMT components.

Guidance on corrosion given in the standard is fairly general. It is recommended that the possible forms of corrosion such as chemical attack, rusting, erosion and high temperature oxidation be reviewed, that particular attention be paid to impurities and to fluid velocities, and that where doubt exists corrosion tests be done. If corrosion is expected to be negligible, no corrosion allowance is required, but where this is not the case, the recommended minimum allowance is 1 mm.

The standard deals in Appendix C with fatigue, for which it lists the following causes: (1) periodic temperature transients, (2) restrictions of expansion or contraction during normal temperature variations, (3) applications or fluctuations of pressure, (4) forced vibrations and (5) variations in external loads. Attention is drawn to the influence on fatigue of corrosion and of creep.

The standard requires that the design stress be kept reasonably below the fatigue limit if the expected number of cycles during the service life of the vessel might otherwise lead to fatigue failure. A detailed fatigue analysis is not required, however, where the design is based on previous and satisfactory experience of strictly comparable service or where certain alternative conditions are satisfied. A generalized chart for a design fatigue curve is given in the standard. It also gives a recommended method of constructing a design fatigue curve from test data.

The standard gives requirements for protective devices and for inspection. These are described here in Section 12.12 and Chapter 19, respectively.

12.6.4 Standards committees

Support for BS 5500: 1991 is provided by the Pressure Vessels Technical Committee (PVTC) (PVE/1) of the British Standards Institute (BSI). There is also a Pressure Vessel Quality Assurance Board (PVQAB) set up under the sponsorship of the Institution of Mechanical Engineers (IMechE).

12.6.5 ASME Boiler and Pressure Vessel Code

Another principal code is the American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code*: 1992. The 11 sections of the code are shown in Table 12.6. Of particular relevance here are Sections II and VIII which deal, respectively, with materials specifications and with pressure vessels themselves. Section VIII has two parts: *Pressure Vessels, Division 1* and *Pressure Vessels, Division 2 – Alternative Rules*. Division 1 is a conventional code and Division 2 an advanced code.

Table 12.6 *Principal contents of the ASME Boiler and Pressure Vessel Code*

Section No.	
I	Power boilers
II	Material specification
III	Nuclear power plant components
IV	Heating boilers
V	Non-destructive examination
VI	Recommended rules for care and operation of boilers
VII	Recommended rules for care of power boilers
VIII	Pressure vessels: Division 1 Division 2 – Alternative rules
IX	Welding and brazing qualifications
X	Fibre-glass reinforced plastic pressure vessels
XI	Rules for in-service inspection of nuclear power plant components

12.6.6 Fibre-reinforced plastic vessels

There are also a number of standards and codes for the design of vessels and tanks in FRP. Relevant standards and codes are BS 4994: 1987 *Specification for Design and Construction of Vessels and Tanks in Reinforced Plastic;* the ASME *Boiler and Pressure Vessel Code*, Part X, *Fiber-Glass Reinforced Plastic Pressure Vessels* (1992); ASTM D 4021-86 *Standard Specification for Contact Moulded Glass-fiber-reinforced Thermosetting Resin Underground Petroleum Storage Tanks* and ASTM D 4097-88 *Standard Specification for Contact Moulded Glass-fiber-reinforced Thermosetting Resin Chemical Resistant Tanks*. HSE guidance is given in PM 75 *Glass Reinforced Plastic Vessels and Tanks: Advice to Users* (1991).

12.6.7 Limitations of standards

It is important to appreciate that standards and codes of practice have certain inevitable limitations. They are by their nature generalized and cannot readily cover all situations that may arise. They are prepared by committees and may represent the minimum standard on which agreement can be obtained. Their revision is a time-consuming task and they can become out of date. A fuller discussion of standards and codes is given in Appendix 27. These points have particular relevance to plants which have major hazards and/or novel technology. In these cases it should be appreciated that the standards represent a minimum requirement. Nevertheless, standards and codes of practice have an essential role to play in the design and operation of process plant.

12.7 Pipework and Valves

Loss of containment from a pressure system generally occurs not from pressure vessels but from pipework and associated fittings. At least as much attention should be paid to the pipework and fittings as to the vessels.

The cause of the Flixborough disaster was a modification to a 28 in. pipe connection between two reactors. The modification involved the installation of a temporary 20 in. pipe with bellows at each end. The design of the pipe system was defective in that it did not take into account the bending moments on the pipe due to the pressure in it. The bellows were not installed in accordance with the manufacturer's instructions. The pipework assembly was not adequately supported. The relevant British Standards, notably BS 3351 and 3974, were not followed. Further details are given in Appendix 2.

12.7.1 Pipework

The plant pipework and fittings include the piping itself, flanges and joints, and fittings, such as the many types of valves, bellows, etc., together with the pipe supports.

Accounts of pipework on process plants include those given in the *Handbook of Industrial Pipework Engineering* (Holmes, 1973), *Process Piping Design* (Weaver, 1973), *Handbook of Pipeline Engineering Computations* (Marks, 1979), *Piping Stress Handbook* (Helguero, 1986), *Piping and Pipe Support Systems* (P.R. Smith and van Laan, 1987) and the *Engineering Design Guidelines of the Center for Chemical Process Safety* (CCPS, 1993/13).

Pipework in process plant in the United Kingdom has been covered by BS 3351: 1971 *Piping Systems for Petroleum Refineries and Petrochemical Plants* and by BS 3974: 1966 *Pipe Supports*, together with numerous other British Standards for pipework and fittings, some of which are listed in Appendix 27.

BS 3351: 1971 is now withdrawn. The code now commonly used is the ASME B31 *Code for Pressure Piping*. Also relevant until its withdrawal was the American Petroleum Institute *Guide for Inspection of Refinery Equipment*, Chapter 11, *Pipes, Valves and Fittings* (API, 1974). ASME B31.3 is described below, but first there are some preliminary points to be made.

A large proportion of failures of containment in process plants occur on the pipework and fittings. Some suggestions for reducing pipework failures have been given by Kletz (1984k) as part of a survey of such failures, which is described in Section 12.30. The design of pipework should be done by a fully integrated design organization working in a structured manner. There should be a relatively small number of designers of high quality making full use of computer aids. Similar principles should apply to the fabrication and construction stages.

Kletz recommends detailed design of even small bore pipework, though he recognizes that some organizations consider this impractical. He states that efforts should be made to reduce the number of grades of steel required so as to reduce the chance of installation of the incorrect grade, and instances restriction of steam temperatures so as to avoid the need for creep resistant steel. His survey highlights the high proportion of failures which are attributable to the construction phase and he makes suggestions for improved inspection during and after construction. Kletz states that the incidents which he lists suggest that of all the measures proposed this would be the most effective.

The pipework should be designed for ease of maintenance. If a joint may have to be broken, there should be adequate access and sufficient 'spring' in the pipework. If the insertion of a slip plate into a joint is likely to be a frequent operation, consideration should be given to installing a slip ring or spectacle plate.

Work on safe piping systems has been the subject of a study by the Institution of Chemical Engineers (IChemE), as described by Hancock (1990a). The principal features considered were (1) layout, (2) quality control, (3) construction, (4) pipe supports, (5) dead ends and (6) vibration and the principal causes of failure (1) vibration, (2) external corrosion, (3) temporary supports, (4) blocked in liquids, (5) water hammer, (6) steam hammer, (7) cavitation and (8) pressure surge.

12.7.2 ASME B31.3

The ASME B31 *Code for Pressure Piping* includes, in particular, Sections B31.1: 1992 *Power Piping*, B31.3: 1990 *Chemical Plant and Petroleum Refinery Piping*, B31.4 *Liquid Transportation Systems for Hydrocarbons, Liquid Petroleum Gas, Anhydrous Ammonia, and Alcohol*, B31.5: 1987 *Refrigeration Piping*, B31.8 *Gas Transmission and Distribution Systems*, and B31.9: 1988 *Building Services Piping*. In this chapter it is B31.3, the ASME *Chemical Plant and Refinery Piping Code*, which is the most relevant. The principal contents of ASME B31.3 are shown in Table 12.7.

Table 12.7 *Principal contents of ASME B31.3*

B	Stress tables and allowable pressure tables for non-metals	
C	Physical properties of piping materials	
E	Reference standards	
F	Precautionary considerations	
G	Safeguarding	
K	Allowable stresses for high pressure piping	
M	Owner's guide to classifying fluid services	
X	Metallic bellows expansion joints	

[a] Chapters VII–IX have a structure broadly similar to, but in some cases more detailed than, that of Chapter II.

B31.3 defines the following categories of fluid service: (1) Category D, fluid service; (2) Category M, fluid service; (3) high pressure fluid service and (4) normal fluid service. Category D applies where: (1) the fluid handled is non-flammable, non-toxic and not damaging to human tissues; (2) the design pressure does not exceed 150 psig (10.3 barg) and (3) the design temperature is in the range −20 to 366°F (−29 to 186°C). The term 'damaging to human tissues' describes a fluid such that 'exposure to the fluid, caused by leakage under expected operating conditions, can harm skin, eyes, or exposed mucous membranes so that irreversible damage may result unless prompt restorative measures are taken'.

Category M, which is particularly relevant here, is 'a fluid service in which the potential for personnel exposure is judged to be significant and in which a single exposure to a very small quantity of a toxic fluid, caused by leakage, can produce irreversible harm to persons on breathing or bodily contact, even when prompt restorative measures are taken'.

High pressure fluid service is one for which the owner specifies the use of chapter DC of the code. Normal fluid service is fluid service not covered by the other three categories and not subject to severe cyclic conditions, and is the most commonly occurring service.

Appendix M of the code gives a guide to classification of fluid services (Figure M-1). The code utilizes a system of listed materials and components, which are those conforming to a specification given in appendices A, B or K or to certain listed standards (tables 326.1, A326.1 and K326.1).

It also utilizes certain prefixes. These include A for entries in chapter VII on non-metallic piping, M for those in chapter VIII on Category M fluid service piping, and K for those in chapter DC on high pressure piping.

Dealing first with the provisions for metallic pipework, the code gives guidance in chapter II on design pressures and temperatures. Essentially, the design pressure of a component should not be less than the pressure at the most severe condition to which the equipment may be subject, the most severe condition being that combination of pressure and temperature which requires the greatest component thickness and highest component rating.

For a straight pipe under internal pressure the code gives for the pipe thickness:

$$t_{\mathrm{m}} = t + c \qquad [12.7.1]$$

where c is the sum of mechanical, corrosion and erosion allowances, t is the pressure design thickness and t_{m} is the minimum required thickness. The pressure design thickness t is given by:

$$t = \frac{PD}{2(SE + PY)} \qquad [12.7.2]$$

It also allows three alternative equations, one of which is

$$t = \frac{PD}{2SE} \qquad [12.7.3]$$

where D is the outside diameter of the pipe, E is the quality factor, P is the internal design gauge pressure, S is the stress value for the material and Y is a coefficient. Values for the quality factor E are given in appendix A of the code and those for the coefficient Y are given in a table. These equations apply for $t < D/6$. For $t > D/6$ or $P/SE > 0.385$ the design is more complex and requires account to be taken of factors such as thermal stress and fatigue, and application of failure theory.

The design temperature of a component should be that at which, in combination with the relevant pressure, the greatest component thickness and highest component rating are required. In determining the design temperatures, factors to be considered include fluid temperatures, ambient temperatures, solar radiation, and heating and cooling medium temperatures.

The code gives guidance on the component temperatures to be assumed for uninsulated, externally insulated and internally insulated components. For the former, for fluid temperatures below 150°F (65°C) the component temperature is taken as that of the fluid, unless there are factors such as solar radiation which indicate that a higher value should be taken. For fluid temperatures above 150°F the component temperature is taken as a given fraction of the fluid temperature, as follows: (1) 95% of the fluid temperature for pipes, valves, lapped ends, welding fittings, and other components of wall thickness comparable to that of the pipe; (2) 90% for flanges, except lap joint flanges; (3) 85% for lap joint flanges and (4) 80% for bolting. For externally insulated pipework the component temperature should be taken as the fluid temperature unless some other temperature can be justified by calculation, test or experience.

The code deal with materials in chapter III, in appendices A–C and also in other parts. For severe cyclic conditions only certain types of pipe may be used, as listed in chapter II (paragraph 305.2.3). The code gives guidance on materials suitable for use at high temperatures and those suitable for low temperatures. It contains a table of requirements for low temperature toughness tests for metals (table 323.2.2). This table gives design minimum temperatures.

Flanges, valves and other fittings are dealt with in chapter II of the code and also in chapter IV and appendix F. Chapter IV gives for flanges, valves and other fittings, listed components, each with its appropriate standard (table 326.1), together with guidance on the use of unlisted components.

Appendix F of the code on precautionary considerations provides guidance on certain potential hazards and weak points in pipework. It highlights certain hazards such as expansion of trapped liquids and fluid transients including geysering and bowing during cooldown, but is mainly concerned with: (1) valves; (2) flanged joints, including flanges, gaskets and bolting and (3) materials.

The integrity of a flanged joint depends on the flanges, the gasket and the bolting. For the flanges themselves, the code gives guidance on flange rating, type, facing and facing finish. It also gives guidance on selection of gaskets.

Bolting covers bolts, bolt studs, studs, cap screws, nuts and washers. The codes gives listed bolting. It also gives guidance for conditions subject to high pressure, to high and low temperatures and temperature cycling and to vibration. For high, low and cycling temperatures and for vibration conditions consideration should be given to the use of controlled bolting procedures to reduce (1) joint leakage due to differential thermal expansion and (2) stress relaxation and loss of bolt tension.

With respect to valves, the use of extended bonnet valves is recommended where appropriate to establish a differential between the temperature of the valve stem packing and that of the fluid. This can be an effective way of avoiding problems of packing shrinkage, leakage and icing. Attention is also drawn to the potential for entrapment of liquids in valves such as double-seated valves, with its attendant liquid expansion problem.

Metallic bellows expansion joints are treated in the code in Appendix X, which delineates the relative responsibilities of the pipework designer and the expansion joint manufacturer, and gives guidance on: expansion joint design conditions; joint design, including fatigue analysis; joint support and restraint; and fabrication, examination and pressure and leak testing. Reference is made to the standards of the Expansion Joint Manufacturers Association (EJMA). The use of expanded joints is not allowed in Category M (fluid service) or high pressure piping.

Appendix G of the code on safeguarding deals with measures to protect pipework against accidental damage and to minimize the consequences of pipework failure. Normal safeguards listed include: (1) plant layout; (2) equipment, such as instrumentation, ventilation and fire protection; (3) systems of access and of work; (4) means for fluid containment, recovery or disposal and (5) operating procedures. Whilst in most cases additional engineered safeguards are not necessary, in some they may be. Engineered safeguards listed include: (1) temperature protection by instruments, thermal insulation or thermal shields; (2) mechanical protection by shields, barricades, etc.;

(3) vibration protection; and (4) measures to mitigate pipework failure.

The code addresses the question of the use of isolation valves, or stop valves, in pressure relief piping. Stop valves between the piping being protected and the protective device (s) and between the latter and the point of discharge are not allowed, except subject to conditions. Essentially these are: (1) the stop valves are so constructed and subject to such positive control that any closure made does not reduce the pressure relief capacity; (2) the stop valves are either full-area valves or are such that they will not affect either the operation or the capacity of the pressure relief device(s); and (3) the stop valves are so arranged that they can be locked or sealed in both the open and closed positions. The procedures to be followed if stop valves installed according to these principles are to be closed whilst the plant is operating are given in appendix F of the code. This requires the presence of an authorized person who has the means to observe the pressure in the equipment and to relieve it in the event of overpressure. Before leaving the scene, this person should lock or seal open the stop valves.

The requirements for examination of the pipework are given in chapter VI of the code. For piping for normal fluid service the minimum requirements are certain specified visual examinations, covering materials, fabrication, longitudinal welds, assemblies and erection and examination by radiographic or ultrasonic methods of a random sample of 5% of circumferential butt welds and mitre groove welds.

Chapter VI also contains the provisions for testing. For normal fluid service piping the essential requirement is for a hydrostatic test. The test is performed using water and the test pressure is 1.5 times the design pressure, but with an adjustment for the difference between the test and design temperatures and with a limitation to ensure that the yield strength is not exceeded. There are various alternative provisions such as those for the use of a pneumatic test and of hydraulic test fluids other than water.

High pressure pipework is dealt with in chapter IX of the code. The basic approach is similar, but the requirements are more stringent in respect of a number of features. There is a different formula for the thickness of straight pipe under internal pressure.

Piping for Category M fluid service is treated in chapter VIII. Again, the requirements for certain features are more stringent.

12.7.3 Pipe supports

Pipe supports are dealt with in BS 3974: 1974. This standard lists the following loads for which supports are required: (1) mass of the pipe, including operating or testing medium, insulation and associated equipment; (2) expansion and contraction; (3) reaction due to pumping effects and discharge to atmosphere and (4) wind, snow or ice loads.

Equations are given for the calculation of maximum bending stresses and deflections based on a single span simply supported or a continuous beam. Pipes are usually assumed to be simply supported or unrestrained rather than supported as beams with fixed ends. Concentrated loads, direction changes and pipe joints require special attention. Increase in pipe diameter is sometimes used to obtain a greater distance between supports.

Some devices used to support horizontal pipes include pipe hangers, slider supports and roller supports. Spring and turnbuckle hangers are used for suspending hot insulated pipes. For vertical pipes methods of support include trunnions supported on guide lugs, and sling rods supported by pipe hangers.

Pipe clips or hangers should be in direct contact with the pipe or insulation, but should not be too tight around them. Distance pieces are generally used to prevent this. The insulating material should be capable of bearing the compression load imposed. Pipe guides are used to restrain sideways movement of pipes. Anchors are used where it is necessary to provide fixed points for pipe bends and loops.

Pipework supports are also dealt with in ASME B31.3. This code gives separate treatments for pipe supports for piping for normal fluid service, Category M fluid service and high pressure service, and for non-metallic piping.

12.7.4 Gaskets

Flanged joints in process plant are sealed mainly by gaskets or ring seals. Gaskets are considered in this subsection and ring seals in the next.

Two commonly used types of gasket are compressed asbestos fibre (CAF) gaskets and metallic spiral wound gaskets. These are covered in BS 1832: 1972 *Specification for Oil Resistant Compressed Asbestos Fibre Jointing* and BS 3381: 1989 *Specification for Spiral Wound Gaskets for Steel Flanges* to BS 1560. There is a trend towards the use of metallic spiral wound gaskets instead of CAF gaskets for many of the more severe and hazardous duties. A metallic spiral wound gasket takes the form of a ring made out of metal windings, with a V-shaped cross-section, wrapped in a continuous spiral with soft filler between the metal plies, all encased in an outer wrap.

The features of metallic spiral wound gaskets are discussed by Granek and Heckenkamp (1981). Such spiral wound gaskets have many merits. They provide a relatively simple and low cost joint. They offer the elasticity and material flow required for good sealing. They are well suited to high pressures. They are resistant to high temperature and corrosive conditions. They are resilient to thermal shock and vibration. The method of construction and the permutations of metal and filler support a family of gaskets with shapes compliant to different flange configurations and with properties such as the stiffness matched to the application. On the other hand, they have certain disadvantages. They are not readily tightened up to stop leaks and they are not resusable. They are also relatively sensitive to the quality control on the gasket itself, the application in which it is used and the manner in which it is bolted up. These authors also discuss the extent of confinement of the gasket, favouring the practice of confining it so that it has no freedom to move and immobilizing it to prevent leak paths when pressurized. Metallic spiral wound gaskets are resistant to blowout, and this is often an important factor in their selection.

12.7.5 Ring seals

The other main kind of seal for flanged joints is the ring seal, also known as a lens or ring type joint (RTJ). This type of seal is used particularly for high pressure plant. A ring seal is a ring with an approximately ovoidal cross-section which fits into two grooves, one on each of the two flanges. The seal is made at the edges rather than at the bottom of the groove. The ring is capable of a degree of deformation to make a good seal. It is good practice to use a new ring seal when remaking a joint. Ring seals are another form of blowout-resistant sealing.

12.7.6 Bellows

Pipework needs to incorporate means of accommodating expansion and contraction. One method of doing this is by utilizing bellows. A bellows assembly may be used, for example, between two pipe sections, between two vessels or between a pipe and a vessel.

After the Flixborough disaster in 1974, referred to above, the use of bellows came under a cloud. It is now subject to much stricter control. Typically, proposals to use bellows in pipework with potential for hazardous release are reviewed individually during design, and in some cases there may be restrictions on their use. An account of one company's policy on bellows is given by Boyett (1979).

Following Flixborough, a British Standard on bellows was issued. This is BS 6129: 1981 *Code of Practice for the Selection and Application of Bellows Expansion Joints for Use in Pressure Systems*, which has a single part, Part 1: 1981 *Metallic Bellows Expansion Joints*. In the United States, standards for bellows are issued by the EJMA.

An account of the design and application of bellows as expansion joints is given by C. Taylor (1985). The bellows itself consists of a convolution. The convolution may be 'thick-walled' or 'thin-walled', the latter term covering multi-wall construction which may be thicker than a 'thick-walled' unit. Its stiffness is expressed as a spring rate.

The design of a bellows assembly has to take into account: the forces on, and stresses induced in, the bellows, and its movement; the forces and moments on equipment connected to it; the external forces such as wind loads on it; its stability; and its fatigue performance. The design requires also to cover the anchors and guides.

The EJMA method gives relations for determining the spring rate of the convolution. It treats the bellows as an elastic shell with stresses induced by pressure and deflection. It deals with the stability of the bellows and gives a fatigue curve.

Taylor describes three types of system used to compensate for expansion: (1) compression systems, (2) tension systems and (3) pressure balanced systems. The compression system is the simplest: the bellows is placed between the two pipe sections and, when expansion occurs, the bellows is compressed. The fixed pipe section is held by an anchor which resists the compressive forces and the moving section may be provided with a guide.

In a tension system, the pressure end load is taken up not by anchors but in some other way. The arrangement exploits angulation, or slight off-axis movement of the bellows. Three tensile systems are hinged assemblies, gimbal assemblies and tied double assemblies. Hinged units give movements in one plane by angulating the bellows; the pressure end load is contained by the hinge parts. Gimbal assemblies allow angular movements. Tied double assemblies permit large movements in a plane and, using two tie bars, angulation.

In a pressure balanced system, the force induced by the pressure in the bellows is balanced so that only the spring rate needs to be accommodated by external means. Two commonly used systems are the in-line assembly and the elbow-type assembly. Systems of this kind tend to be relatively bulky and expensive, but find application where movements are small and space is restricted, and also on high pipework where anchors are impractical. They are widely used on compressors and turbines.

Hydrostatic testing requirements can present a difficulty in bellows design. Whereas with most pipework fittings there is no fundamental problem in increasing the strength, a bellows is unique in that there is a tradeoff to be made between strength and deflection. An increase in thickness of the bellows gives an increase in strength, but a decrease in allowable deflection, the limiting factor being squirm. The point is discussed by D.J. Peterson (1991), who instances design of bellows for piping on a fluid catalytic cracker unit with gas at 45 psig and 1300°F. He argues that in practice the metal temperature of such bellows would be 1000°F. Design for a test pressure of 76 psig and the actual operating temperature of 1000°F yields a bellows thickness of 0.048 in. However, if the test pressure is taken as that for the nominal operating temperature of 1300°F and, furthermore, as that applicable to the material of construction of the pipework rather that of the bellows, this results in a test pressure of 343 psig and a corresponding bellows thickness of 0.150 in. The spring rate is increased by a factor of 28 and the cycle life is reduced by a factor of 317.

12.7.7 High integrity pipework

Where the consequences of pipework failure could be especially serious, the pipework should be of high integrity. Measures to improve pipework integrity are discussed by numerous authors. A convenient summary of many of these is given for highly toxic materials in the CCPS *HTHM Guidelines* (1988/3).

Measures should be taken to reduce the stresses to which the pipework is liable to be subjected and to give it robustness in the face of such stresses. Sources of vibration and of severe cycling should be minimized and, if necessary, countermeasures taken. A flexibility analysis of the pipework should be carried out.

Joints on pipework should be welded or flanged, and threaded joints should be avoided. Features which may prove to be weak points should be minimized; these include expansion bellows, hoses and sight glasses.

Gaskets should be suitable for the fluid handled and the temperatures, and should be resistant to blowout. Blowout resistant-gaskets include metal reinforced, spiral wound and ring joint types.

Fittings, particularly valves, are potential weak points and should receive attention both in respect of fugitive emissions and outright failure. Leakage can be reduced by the use of double packing boxes or bellows seals.

The design should seek to limit the size of any release which may occur. One measure is the avoidance on vessels of nozzles larger than is strictly necessary. Another is the use of flow restrictor orifices in pipes. The approach taken here is to make the pipe of larger diameter, and thicker walled, with a lower normal flow velocity.

The pipework should be protected against overtemperature, particularly from fire. Methods of protection include fire insulation and water sprays used as alternatives or in combination. The fire insulation should not only possess a suitable nominal fire resistance but also should remain in place under fire conditions, which include the use of water jets for fire fighting. With respect to fire insulation there is a balance to be struck between fire protection which it affords and the threat of external corrosion beneath it.

Where the pipework may be subjected to low temperature, whether this be the normal operating temperature or one resulting from a deviation such as sudden depressurization, the constructional materials should have sufficient impact resistance to prevent low temperature brittle fracture.

If the material in the pipe may freeze at the lowest temperatures expected, countermeasures such as trace heating are necessary. Freezing poses two distinct threats. One is expansion on freezing. The other is uneven thawing and expansion of the unfrozen liquid.

The pipework should be protected against overpressure, using a suitable combination of protective measures. These may include trips, expansion chambers and pressure relief devices.

With respect to physical abuse the CCPS *Guidelines* state that a properly supported NFS 1.5 in. steel pipe is generally accepted as being resistant to loads such as being stepped on or struck by a heavy pipe wrench. It is desirable that piping of other materials be similarly resistant, whether by materials selection, pipe thickness or protection.

Impurities may constitute a threat to pipework integrity, particularly where the materials handled are highly reactive, which includes those which are strong oxidizers. The system may therefore need to be cleaned after construction. This can be assisted by a design which avoids dead spaces and provides adequate vents and drains.

In supporting pipework carrying a corrosive fluid, the hangers which support the pipe from above by rods are liable to suffer corrosion of these rods, and the arrangement is generally to be avoided. An arrangement which supports the pipe from below is less liable to fail. In more critical duties, it may be necessary to consider protection of the pipe support themselves against very low or high temperatures, including those occurring in fire conditions.

The routing of pipes should take account of the threat from tanks and vessels, pumps and pipework holding flammables and, generally, of the threat from fire. Routes should pass through protected areas and away from roads. It may be appropriate to furnish protection against vehicle impact and against physical abuse. In some cases, piping is armoured and extra protection is provided for nozzles and small bore pipework.

The pipework should be designed with a view to maintenance of the valves, important aspects being access and ease of slip plating. Attention should also be paid to the avoidance of unbolting errors in the maintenance of valves, so the bolts necessary to containment of the pressure are not removed in the mistaken belief that they are associated only with, say, the actuator or with a spool piece.

Tanks and vessels should be provided where necessary with remotely operated emergency isolation valves, as described below. Open-ended external valves should be fitted with a blind flange or plug.

Another potential weak point is the pumps. These should be designed to withstand the highest pressures and most extreme temperatures to which they may be subject.

Construction of the pipework should also be to high standards. This aspect is dealt with in Chapter 19. Aspects mentioned in the CCPS *Guidelines* include: colour coding for identification; cleaning after construction, and design to facilitate this; procedures for controlled bolting; and access for inspection.

12.7.8 Fibre reinforced plastic pipework

There are also a number of standards and codes for the design of pipework in FRP. Relevant standards and codes are BS 6464: 1984 *Specification for Reinforced Plastics Pipe, Fittings and Joints for Process Plants*, BS 7159: 1989 *Code of Practice for Design and Construction of Glass-reinforced Plastic (GRP) Piping Systems for Individual Plants or Sites*, and ASTM D 3517-91 *Standard Specification for 'Fiberglass' (Glass-fiber-reinforced Thermosetting Resin) Plastic Pipe*. ASME B31.3, the *Chemical Plant and Refinery Piping Code*, deals with non-metallic piping.

12.7.9 Valves

Valves constitute another important class of component in pipework systems. There is a wide variety of valves in use, and only a few types, that is, those with an essentially protective function, are considered here. They are (1) non-return valves, (2) excess flow valves and (3) emergency isolation valves. Regular control valves are dealt with in Chapter 13. Another aspect of protection is the interlocking of valves to prevent their being operated in an incorrect sequence. This is discussed in Subsection 12.7.13.

12.7.10 Non-return valves

Non-return valves (NRVs), or check valves, are used to prevent undesired reverse flows. Reverse flow can have serious consequences and some form of protection is often necessary. Some situations in which reverse flow occurs have been described by Kletz (1976b). They include: (1) flow into plant from storage vessels or blowdown lines, (2) flow from plant into service lines, (3) reverse flow through a pump and (4) reverse flow from reactors. An NRV is a prime means of preventing reverse flow in many of these situations, although it is not always an adequate, or even the most appropriate, method in all cases.

Process materials can flow back into service lines with disastrous results if a pressure reversal occurs. AN NRV should be installed on service lines, but other measures are also necessary. If the service line is in continuous use, it may be necessary to have low service pressure and high process pressure alarms/trips. If the service line is used intermittently, it should be isolated when not in use by positive means such as hose disconnection or double block and bleed valves.

NRVs are widely used on the discharge of pumps to prevent reverse flow through the pump. If reverse flow occurs, it can disintegrate the impeller and damage the motor. Consideration should also be given to reverse rotation locks on pumps.

Reverse flow of one reactant from a reactor into the feed pipe of another reactant is likely in many cases to result in an explosion. NRVs may be appropriate on the feed pipes. Another precaution is the use of a small inventory feed tank. This limits the scale of any possible explosion, although it also lessens the degree of dilution of a contaminant and may thus increase the probability of a reaction.

NRVs are not a fully reliable means of eliminating reverse flow. Numerous instances have occurred in which materials have travelled back not just through one but several NRVs in series. According to Ellis and Mualla (1986), a survey of stoppages in Central Electricity Generating Board (CEGB) power stations showed that some 16% were connected with NRVs.

NRVs on critical duties are important pressure system components and should be included in the pressure system register and regularly tested and maintained.

Leakage from storage vessels or blowdown lines into the plant tends to occur when the latter is shut-down, and can have serious consequences. It is usually due to leaks through closed but defective valves. The remedy is more positive isolation by means such as blanking off.

Increasingly, environmental considerations lead to requirements for vents from storage tanks and other equipment to be routed to a disposal system. It is necessary to ensure that reverse flow does not occur in such a system. However, reverse flow protection for storage tank vents is not readily effected by the use of NRVs, because the storage tank pressures are low and the flows are often very low and intermittent. The problem is discussed by Englund, Mallory and Grinwis (1992), who describe instrument systems for this duty. These authors also describe reverse flow protection arrangements, including NRVs, for a number of other situations, such as pump and reactor systems.

In some cases, it is necessary to take quite elaborate precautions to prevent reverse flow. The importance of avoiding reverse flow in ethylene oxide plants was emphasized in Chapter 11. Figure 12.8 shows a reverse flow protection system for the ethylene oxide feed to a reactor. There is a kick-back line around the pump to prevent overheating and an NRV on the pump delivery. There are two trip initiators and two shut-down valves with both initiators and valves arranged as 1-out-of-2 systems, as described in Chapter 13. One of the valves is also used as a control valve. There are two further NRVs. Diversity of the types of NRV is used to reduce the probability of common cause failure.

Reverse flow of ammonia into an ethylene oxide feed tank on a reactor was responsible for the disaster in 1962 at Doe Run, Kentucky (Case History A31). Appendix 1 also describes various other incidents involving reverse flow and NRVs. Further case histories are given by Kletz (1976b).

12.7.11 Excess flow valves

Another type of valve with a protective function is the excess flow valve (EFV). Such a valve is used to shut off flow in a situation where the flow has suddenly risen far in excess of its normal value. The rise in flow which triggers the operation of an EFV is generally 50% or more above the normal value.

EFVs are used at loading facilities to give flow shut-off in the event of rupture of a filling line hose. The EFV on a filling line may be installed internally in the storage vessel.

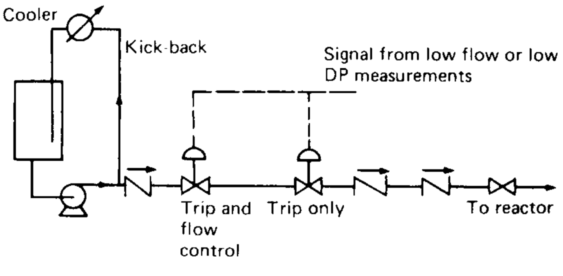

Figure 12.8 *Ethylene oxide feed system to a reactor (Kletz, 1976b) (Courtesy of Hydrocarbon Processing)*

Where the fluid is held as a superheated liquid under pressure and will flash when released to atmosphere, the flow will become two-phase. The sizing of the EFV thus involves a two-phase flow calculation. A calculation method for two-phase flow in this application has been described by R.A. Freeman and Shaw (1988). The method is presented as an alternative to testing of excess flow valves, which is a code recommendation for liquefied petroleum gas (LPG), but which the authors consider to be potentially hazardous.

12.7.12 Emergency isolation valves

Emergency isolation valves (EIVs) are used in process plant to prevent the loss from containment of large quantities of flammable or toxic substances. An account of EIVs has been given by Kletz (1975b). Kletz gives rules for deciding whether to install an EIV, and illustrations of the application of these rules in particular plants. Points where large escapes of material are liable to occur include (1) pumps, (2) drain points and (3) hose connections.

Large leakages can occur from pump glands and seals. Some cases of pump leakage are quoted by Kletz. In one instance there was a 3 ton escape of ethylene over a period of 20 min.

Drain points are also liable to large escapes. Again a number of examples are given by Kletz. The drainage of water from hydrocarbons can take some minutes, so that an operator tends to go and do something else. Then, if there is less water than he expected, or if he forgets to return, there may be a leak of hydrocarbons.

Another problem is the blockage of drain lines and drain valves by ice or hydrate formation. In some cases, a drain valve freezes open and the operator is unable to close it. In others, a blockage occurs and the operator clears it, but is then unable to approach to close the valve on account of the material escaping. The Feyzin disaster in 1966 (Case History A38) began with a blockage in the drain line from a propane storage sphere, due almost certainly to ice or hydrate.

EIVs may be installed between the inventory and the point of expected leakage, but it is unnecessary to install an emergency isolation valve between every inventory and every leakage point. In fact, it is undesirable to do so, since every such device itself introduces further chances of leakage. The decision as to whether an emergency isolation valve is required in a given case depends, therefore, on the expected scale and effects of a leakage and on its probability. Inventory is an important factor, but it is not the only one.

In many cases, a rough estimate of the probability of a leak may be sufficient to show that an EIV is or is not needed. In cases where the decision is not clear-cut, it may be helpful to do a hazard assessment as described in Chapter 9. Relevant to such assessment is the probability of pump fires. Some estimates given by Kletz (1971) are quoted in Table 16.55.

The condition of the material should also be taken into account in determining the need for an emergency isolation valve. A cold liquid that is well below its atmospheric boiling point is less hazardous than one which is superheated and will flash off when let down to atmospheric pressure. Other factors which may be taken into account include the possibility of isolating the inventory by other means, such as on the feed to the unit, or of pumping the inventory away.

Kletz (1975b) gives some examples of the need for emergency isolation valves, which illustrate the fact that inventory is not the only criterion. An emergency isolation valve is recommended for a 10 ton inventory on an ethylene side-stream pump which in the past has leaked and ignited, whereas one is not recommended for a 70 ton inventory on a naphtha feed pump which contains cold material and has not leaked.

An emergency isolation valve may be installed as a new valve or by motorization of an existing valve. Figure 12.9 illustrates the two methods for two pumps piped up in parallel. In this case the use of existing valves requires the motorization of two valves. But there are some advantages in this method in that the amount which can leak out after the valves are closed is much reduced and that the valves are more easily tested.

The valve may be arranged so that air, hydraulic or electrical power is required to keep it open or, alternatively, to close it. The normal arrangement is closure on power failure, unless this is undesirable for some reason. Valves which are very large and existing valves which have to be motorized, however, require power to move them either to open or close.

If the emergency isolation valve closes on loss of power, it is not generally necessary to provide fire protection on the air or electrical power lines to it. But if power is needed to close the valve, the power lines should be provided with 15-min protection and a latching device installed to keep the valve closed if the power lines are destroyed. The 15-min protection allows the operator time to decide whether to close the valve.

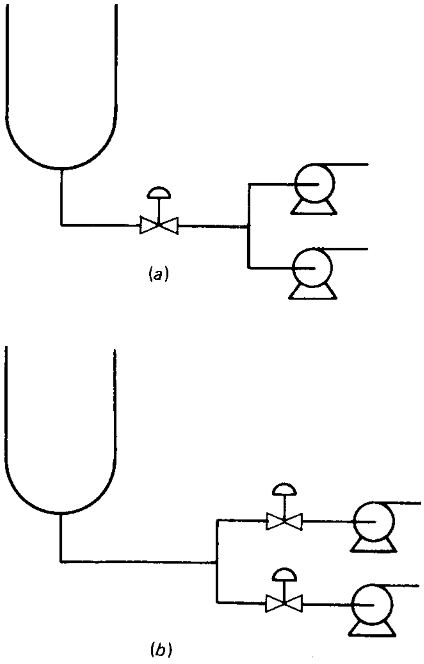

__Figure 12.9__ Emergency isolation valves between a vessel and pumps: (a) new isolation valve; (b) existing isolation valves motorized, (after Kletz, 1975b) (Courtesy of the American Institute of Chemical Engineers

There appears to be little evidence to suggest that either pneumatic or electrical operation is more reliable, but it is desirable to ensure that the valve actuator is sufficiently powerful, particularly on dirty fluids, slurries, and so on. An oversized actuator may well be worthwhile.

Operation of the emergency isolation valve should be sufficiently remote that the operator can close it readily in an emergency. He or she should not have to approach a gas cloud or a fire or to go up on higher level platforms or to stand on a ladder. The most suitable arrangement is often remote operation from the control room. Emergency isolation valves which are controlled remotely are also known as remotely operated valves (ROVs) and remotely operated block valves (RBVs).

For EIVs it is recommended by Kletz that two switches should be provided at a safe distance from potential leak points and separated by at least 30 ft. Where there is more than one device to be operated remotely, such as an emergency isolation valve and a pump shut-off, it will generally be desirable to group the switches for the different devices together.

In some older plants, the handles of emergency isolation valves are taken through a wall, which thus provides protection for the operator. This method is not recommended, however, since walls interfere with ventilation and hinder the dispersal of leaks. Remote operation is better.

Where an emergency isolation valve is fitted on the suction of a pump, operation of the valve should cause the pump motor to trip so that the pump does not overheat and ignite the leak.

The closure of an EIV is not instantaneous. An electrically operated valve typically takes about 1 min to close, a pneumatically operated ball valve somewhat less and a pneumatically operated gate valve somewhat more.

In some cases, an automatic control valve is used for emergency isolation. Such a valve is not an ideal isolation valve, because a characterized valve often does not give a tight shut-off, especially after a period of operation. But where a control valve is installed, it may be difficult to justify a separate emergency isolation valve. If a control valve is used for this purpose, there should be a separate manual control for isolation; the manual mode of the controller should not be used.

EIVs have not been widely used on compressors, but their installation on a new compressor plant has been described by Kletz. He makes the point that, since the valves are very large and are motorized, they are useful for plant operation as well as for emergencies, and this makes their installation easier to justify.

The Flixborough disaster involved the escape of large quantities of superheated flammable liquid from a train of high inventory reactors in series. It has been suggested that it would have been desirable to have an emergency isolation valve between each reactor. Conversely, it has also been argued that the probability of an escape from a pipe between two reactors in the original, as opposed to the modified, plant was remote and that the introduction of emergency isolation valves might have increased rather than decreased the hazard; the latter is probably the more widely held view.

EIVs may be used to prevent low temperature fluids getting into mild steel plant and causing low temperature embrittlement, but in general where this hazard exists it is better to use materials which can withstand the lower temperatures.

The most positive method of ensuring isolation of the bottom offtake from a storage vessel is to have a single offtake pipe with an EIV on it and with all other devices such as sample points or drain points downstream of this.

Self-closing valves using the dead-man's handle principle may be used for drains, but they are liable to be wired open by operators. Drain points which are required only for maintenance should be blanked off.

With regard to the type of valve used as an emergency isolation valve, relevant features are the torque required to operate it, the propensity to trap liquid and the leak tightness. Valves should be provided with power operated actuators, but should be capable of being operated manually. Valves which do not trap liquid include globe, ball and high pressure butterfly types. Leak-tightness cannot be assumed in an emergency isolation valve and the pipework arrangements should be such that positive isolation can be effected by methods such as double block and bleed systems or slip plates.

EIVs with potential exposure to flammables, and hence fire, should be fire resistant or should have fire protection in the form of fire shields and insulation or water deluge.

EIVs are also installed on pipelines as described in Chapter 23.

EIVs are important components of the pressure system. They should be included in the pressure system register and should be regularly tested and maintained.

12.7.13 Valve interlocks

In some cases, it is critical that operations in a pressure system take place in a specified sequence. This applies particularly to the opening and closing of valves. The control of such operations may be effected using interlocks. This topic is treated in Chapter 13, but it is convenient here to consider the more specialized matter of mechanical interlocks, particularly for valves.

Some principal forms of mechanical interlock are those used for (1) supply, (2) access and (3) exchange. In supply there is a choice between two mutually exclusive conditions. An example might be where two different fluids may be admitted to a system, but where only one is to be admitted at a time. One interlock system that can ensure this is to fit each of the two valves with a single lock and to provide a single key. The two states of the lock are (1) switch on with the key turned and trapped in the lock and (2) switch off with the key removable. When the key is turned and trapped the valve is closed and when it is removed the valve is open. Another example might be two power supplies that are configured in parallel but only one of which should be connected at a given time.

With regard to access, there is to be no access unless there is a safe condition. The safe condition generally depends on the isolation of a power supply or other source of energy or pressure. One interlock system that can ensure this is to fit both the access point and the power supply point each with a lock and to provide a single key. The basic principle is similar to that in the case of the two-valve system just described.

An alternative method, which is applicable to the systems just described but comes into its own particularly in more complex systems, is exchange. Some interlock systems based on key exchange may be illustrated by reference to the system shown in Figure 12.10 in which there are two lines, only one of which is operational at a given time.

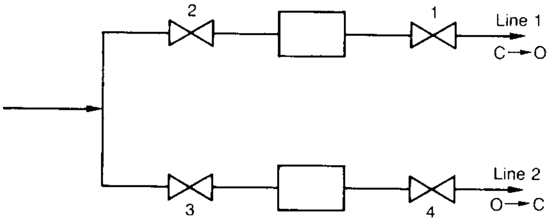

Figure 12.10 *Valve system controlled by key interlocks. C, closed; O, open*

The particular interlock system to be used for such a system will depend on whether it is critical that one line always be open or that one line always be closed. It is the first case which is considered here for illustrative purposes. One interlock system is: to fit each of the four valves with a single lock, valves 1 and 2 being fitted by key type A, and valves 3 and 4 by key type B such that when a key is turned and trapped the valve is locked and when the key is removed the valve is open; to provide two keys of each type, A and B; and to provide also a key exchange box with four locks which contains at any one time the pair of keys of one type such that the pair of keys in residence (say type B) are removable only when the pair of keys of the other type (A) are inserted, turned and trapped. For the case where the initial state is line 1 closed and line 2 open and the system is to be moved under interlock to the final state of line 1 open and line 2 closed, the procedure is to open valves 1 and 2, remove the two A keys, insert, turn and trap them in their locks in the key exchange, thus allowing the B keys to be removed from the exchange and inserted, turned and trapped in valves 3 and 4, thus closing it. The sequence is then as follows:

	Initial state		*Final state*	
	Key	*Valve*	*Key*	*Valve*
Key exchange	B, B	–	A, A	–
Valve 1	A	Closed	–	Open
Valve 2	A	Closed	–	Open
Valve 3	–	Open	B	Closed
Valve 4	–	Open	B	Closed

Another interlock system applicable to the same valve system is as follows. Each of the four valves is fitted with a double lock with two different keys such that when the first key is turned and trapped the valve is open and the second key is removable, and when the second key is turned and trapped the valve is closed and the first key is removable. Thus, for valve 1 the first key might be A and the second B. Five keys are used for the four valves. The keys overlap around the system so that for valve 2 the two keys are B and C, for valve 3 keys C and D, and for valve 4 keys D and E; key A would then be held in the key box. For the case where the initial state is line 1 closed and line 2 open with keys B and C turned and trapped to hold closed valves 1 and 2, respectively, with keys D and E turned and trapped to hold open valves 3 and 4, respectively, and with key A in the key box, and the system is to be moved under interlock to the final state of line 1 open and line 2 closed, the procedure is to insert, turn and trap key A in valve 1, thus opening it; this allows key B to be removed and inserted, turned and trapped in valve 2, thus opening it; this allows key C to be removed and inserted, turned and trapped in valve 3, thus closing it; this allows key D to be removed and inserted, turned and trapped in valve 4, thus closing it; and this allows key E to be removed and returned to the key box. The sequence is then as follows:

	Initial state		*Final state*	
	Key	*Valve*	*Key*	*Valve*
Key exchange	A	–	E	–
Valve 1	B	Closed	A	Open
Valve 2	C	Closed	B	Open
Valve 3	D	Open	C	Closed
Valve 4	E	Open	D	Closed

12.7.14 Fluid transients

There are a number of flow phenomena which can constitute a threat to the piping system. They include various forms of hammer, two-phase flow, and geysering. Some of these fluid transients are referred to in codes such as ASME B31.3: 1990 and API RP 521: 1990.

The best known of the hammer phenomena is water hammer, which occurs when the closure of a valve at the end of a pipe is too rapid. Steam hammer is another rather similar effect in high pressure steam mains. Steam flow may also accelerate condensate causing another hammer phenomenon which is referred to here as 'condensate hammer'.

The terminology used to describe these effects reflects the fact that, in many cases, the fluids concerned are water and/or steam, but similar effects can occur with other substances. Thus, for example, water hammer may more generally be termed 'hammerblow'. Another form of hammer which occurs when an NRV is slow to close, so that a return velocity builds up and the fluid movement is then arrested. It is referred to here as 'reverse flow hammer'.

12.7.15 Water hammer

If a valve on a liquid pipeline is closed quickly, a large change in momentum of the liquid column occurs in a short period of time and a large force is exerted on the valve. This is known as 'water hammer' and it can have a very destructive effect, resulting in the shattering of the valve and/or the line.

Accounts of water hammer are given in *Hydraulics* (Lewitt, 1952), *Hydraulic Transients* (Streeter and Wylie, 1967), *Analysis of Surge* (Pickford, 1969), *Hydraulic Analysis of Unsteady State Flow in Pipe Networks* (Q.A. Fox, 1977) and by Hayashi and Ransford (1960), Streeter (1964), Pearsall (1965–66), Ludwig and Ruiterman (1974), Ardron, Baum and Lee (1977), Kremers (1983) and D. Clarke (1988a,b).

Following Lewitt (1952), a simple treatment of hammer blow in a pipelines is as follows. Consider the pipeline system shown in Figure 12.11. If the valve at A is closed suddenly, there will be a rapid rise in pressure at this point due to the change in momentum of the column of liquid in the pipe. This sudden pressure rise at A causes a pressure wave to pass back down the pipe to B at the velocity of sound in the liquid. When this pressure wave reaches B, the liquid in the pipe surges back in the direction of B and causes the pressure at A to fall. The time for this to happen is

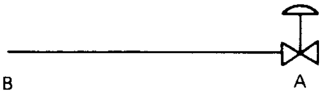

Figure 12.11 *Simple pipeline system*

$$t = \frac{l}{u_s} \qquad [12.7.4]$$

where l is the length of column of liquid, t is the time for the pressure wave to travel the length of the column of liquid, and u_s is the velocity of sound in the liquid. For any closure time less than this the pressure at A has its maximum value. Thereafter, the pressure at A oscillates as the pressure waves pass back and forth between A and B, the oscillation being damped by friction in the pipe.

For an inelastic pipe, the pressure on the valve may be obtained by equating the loss of kinetic energy of the liquid to the gain in the strain energy of the liquid. The latter is

$$W = \frac{1}{2}PV \qquad [12.7.5]$$

where P is the pressure of the liquid, V is the volume of the liquid, and W is the strain energy of the liquid.

The bulk modulus K of the liquid is defined as:

$$K = \frac{P}{(\mathrm{d}V/V)} \qquad [12.7.6]$$

Hence:

$$W = \frac{1}{2}\frac{P^2 V}{K} \qquad [12.7.7]$$

Then, equating the kinetic energy loss to the strain energy gain for a differential element:

$$\frac{\rho a\,\mathrm{d}l}{2}u^2 = \frac{1}{2}\frac{P^2}{K}a\,\mathrm{d}l \qquad [12.7.8]$$

$$P = u(K\rho)^{1/2} \qquad [12.7.9]$$

$$\frac{\rho a\,\mathrm{d}l}{2}u^2 = \frac{1}{2}\frac{P^2}{K}a\,\mathrm{d}l + \left(\frac{1}{2}\frac{\sigma_1^2}{E} + \frac{1}{2}\frac{\sigma_2^2}{E} - \frac{\mu\sigma_1\sigma_2}{E}\right)a\,\mathrm{d}l \qquad [12.7.10]$$

with

$$\sigma_1 = \frac{Pr}{2h} \qquad [12.7.11]$$

$$\sigma_2 = \frac{Pr}{h} \qquad [12.7.12]$$

where E is the elastic modulus of the pipe, h is the thickness of the pipe wall, r is the radius of the pipe, μ is Poisson's ratio of the pipe, σ_1 is the longitudinal stress in the pipe, and σ_2 is the circumferential stress in the pipe. Hence, assuming $\mu = 1/4$:

$$\frac{\rho u^2}{2} = \frac{1}{2}\frac{P^2}{K} + \frac{P^2 r}{Eh} \qquad [12.7.13]$$

$$P = u\left[\frac{\rho}{(1/K + 2r/Eh)}\right]^{1/2} \qquad [12.7.14]$$

Equation 12.7.14 reduces to Equation 12.7.9 as the elastic modulus E goes to infinity. A treatment of the case where the fluid flow is two-phase bubbly flow has been given by Karplus (1961).

A principal means of avoiding water hammer is the limitation of the rate of closure of the valve in question. There are available computer codes for the analysis of liquid flows in networks which can be used to analyse the system and determine the safe rate of closure of the valve.

12.7.16 Steam hammer

A treatment of transients in lines containing a steam–water mixture is given by Karplus (1961). An account of the occurrence in high pressure steam lines of a steam hammer effect on rapid closure of the stop valves to a steam turbine has been given by Crawford and Santos (1986). The closure time of the valves was very short, some 50–100 ms.

12.7.17 Condensate hammer

Another hammer effect can occur when steam is admitted, typically after a shut-down, into a line which contains condensate. The condensate can be propelled along the line with tremendous and destructive force.

This effect is treated in *Avoiding Water Hammer in Steam Systems* by Mortimer and Edwards (1988 HSE SIR 5). They distinguish three cases: (1) condensate driven by steam, (2) condensate drawn by vacuum and (3) flash steam effects. In the first case, condensate collects in a pipe or at fittings. When steam is admitted and flows past, at velocities which can be up to 40 m/s, waves are set up on the condensate surface and, in due course, slugs of condensate are formed. When a liquid slug encounters an obstruction, such as a sharp bend or valve, it strikes it with a 'hammer blow'. The second case is where the steam is admitted to a space where it is cooled in some way and condenses, drawing condensate at high speed towards the space. The third case occurs in a pipe containing superheated water which is let down in pressure so that some vaporizes as flash steam and drives the water away. The flash steam then condenses, creating a vacuum with the effects described in the second case. Frequently, the damage done is slight, but in some instances it is severe. It does not necessarily manifest itself at the point of hammer, but sometimes a metre or more away.

The principal measure taken to avoid condensate hammer is design to prevent the build-up of condensate. Provision of adequate fall in the pipe is one aspect, avoidance of fittings which collect condensate another and provision of means to remove condensate a third. Fittings such as globe valves and strainers are liable to collect condensate. With a globe valve, for example, the depth of water collecting behind the weir even when the valve is open can exceed half the pipe diameter. In this particular case, the problem can be avoided by mounting the valve with its spindle horizontal. Manual drain points may be appropriate at some locations, but automatic steam traps are the principal means of draining condensate.

There are also operational measures which can be taken. One is to drain condensate before starting up. Another is to exercise care in the admission of steam. It should be appreciated that condensate may form from leaks through closed steam valves, even several closed valves in series, while the pipe is shut-down.

12.7.18 Reverse flow hammer

Another form of hammer is that which occurs when an NRV does not close rapidly enough. This is referred to here as 'reverse flow hammer'. The effect is described by Ellis and Mualla (1986). If the closure of an NRV is not sufficiently rapid there is an appreciable 'reverse velocity', the arrest of which, when the valve does close, gives rise to a high pressure transient on one side of the valve and a low pressure one on the other. Incorrect selection of NRVs has for a long time been a source of troublesome pressure transients. In order to make the correct choice, it may be necessary to conduct tests and to model valve behaviour. The trend is to present the valve characteristics as a plot of reverse velocity on closure vs the rate of velocity reversal. The lack of a standard definition of the latter has caused some variability in treatments.

12.7.19 Two-phase flow effects

Two-phase flow can often give rise to pressure oscilllations and surges. Another phenomenon associated with such flow is 'bowing', which occurs when a refrigerated liquid is introduced at such a rate that two-phase stratified flow occurs, with attendant large temperature differences.

12.7.20 Geysering

Geysering is a phenomenon which occurs when a liquid near its boiling point is handled in a vertical, or sometimes in an inclined, pipe. It involves a rapid evolution of vapour, expelling liquid from the pipe and causing a destructive pressure surge.

12.8 Heat Exchangers

Heat exchangers are components of importance in pressure systems. They include (1) vaporizers, (2) reboilers, (3) condensers, and (4) waste heat boilers, as well as heat exchangers on general heat interchange duties. The design of heat exchangers is dealt with in *Process Heat Transfer* (D.Q. Kern, 1950) and in *Process Heat Transfer* (Hewitt *et al.* 1993).

Relevant standards are BS 3274: 1960 *Tubular Heat Exchangers for General Purposes*, API Std 660: 1973 *Heat Exchangers for General Refinery Services* and the Tubular Exchangers Manufacturers Association (TEMA) *Standards of the Tubular Heat Exchangers Manufacturers Association* (n.d.). Until its withdrawal, heat exchangers were dealt with in the API *Guide for Inspection of Refinery Equipment*, Chapter 7, *Heat Exchangers, Condensers and Cooler Boxes*.

Some problems that occur in heat exchangers and which may affect safe operation are (1) fouling, (2) polymerization and solidification, (3) leakage, (4) tube vibration and (5) tube rupture.

12.8.1 Fouling

If fouling occurs in a heat exchanger, it may affect (1) heat transfer and (2) pressure drop. Reduction of heat transfer capacity may be particularly serious if the heat exchanger is a cooler on a critical duty such as removal of heat from a reactor in which an exothermic reaction is carried out. Effects of increasing pressure drop which may be serious are reduction in the maximum flows which can be passed through the exchanger and reduction in the pressure drop across the control valve and hence deterioration in the tightness of control. In the extreme, fouling can result in complete blockage of the exchanger.

Fouling may be reduced by correct selection of tube and shell side fluids and by the use of appropriate fluid velocities. Thus, for example, D.Q. Kern (1950) gives separate tabulations of fouling factors for water velocities below and above 3 ft/s. An allowance may be made for fouling by the use of a fouling factor which is equivalent to a heat transfer coefficient. This may be a general value taken from the literature or a specific value determined on the plant.

Generally, the so-called 'fouling factor' measures all the deficiencies of the heat exchanger, not just fouling. Often these deficiencies are much more significant than fouling itself. Thus, for example, a symmetrical positioning of the inlet and outlet on a two-pass heat exchanger can cause bypassing of the tubes below and above the level of these connections and a consequent reduction in heat transfer. Or again, a vertical condenser tends to have an inferior performance if it is updraft rather than down-draft.

It is claimed, however, that it is possible by good design virtually to eliminate the features which tend to cause serious reductions in heat transfer. Detailed design aspects have been described by Gilmour (1965). He states that where heat transfer deficiencies do still occur, they are usually on the shell side.

The use of a large fouling factor is not necessarily conservative. It may give a degree of overdesign which results in higher than expected temperatures and greater corrosion or coke deposition in the equipment. An example is discussed by Small (1968).

The use of very compact equipment can give rise to fouling due to lack of turbulence. Gilmour quotes a case in which reboiler tubes were very tightly packed and tended to foul by polymerization with bridging of polymer between tubes. The original tubes were replaced by half the number of finned tubes so that turbulence was increased and satisfactory heat transfer restored. This point is clearly relevant to design for limitation of inventory.

Fouling can also occur due to operational factors such as stoppage of a pump, omission of a filter, transfer of debris from other equipment, and so on. If this can have a serious effect, it may be necessary to take appropriate precautions, but the incorporation of a fouling factor in the design is of little use in this situation.

12.8.2 Tube vibration

The use of high capacity, compact heat exchangers with long tubes and high fluid velocities has intensified the problem of tube vibration. Tube vibration can cause damage to the tubes themselves and possibly to the exchanger shell and its supports or to the pipework connected to it, can transmit destructive pressure fluctuations from the exchanger and can generate considerable noise. Vibration can be sufficiently severe to lead to shut-down with multiple tube failure within 1 or 2 days. Two such cases are quoted by Gainsboro (1968) and by Eilers and Small (1973).

A heat exchanger tube may be regarded as a beam clamped at both ends and with distributed load. For such a system the natural frequency f_n is:

$$f_n = k\frac{\pi}{l^2}\left(\frac{EI}{w}\right)^{1/2} \qquad [12.8.1]$$

with $k = 1.136$ and where E is the elastic modulus, I is the moment of inertia, l is the length of the beam, and w is the mass per unit length. In a more detailed treatment A.A. Thompson (1969) gives a value of the constant k for heat exchanger tubes in the range 0.781–1.125.

The tube may be excited to resonance by vortex shedding. The vortex shedding frequency f_v has been studied by Y.N. Chen (1968), who obtained for gases a correlation in terms of the Strouhal number S:

$$f_v = \frac{Su}{d} \qquad [12.8.2]$$

where d is the diameter of the tube and u is the fluid velocity (based on the minimum flow area between tubes of a row).

The Strouhal number was correlated by a relation of the following form:

$$S = f(x_l, x_t) \qquad [12.8.3]$$

where x_l is the longitudinal spacing ratio, and x_t is the transverse spacing ratio.

The problem of tube vibration in heat exchangers has been investigated by P.R. Owen (1965), Y.N. Chen (1968), Gainsboro (1968), A.A. Thompson (1969) and Eilers and Small (1973).

Also relevant is the acoustic frequency. The acoustic resonant frequency f_a in a cavity is

$$f_a = \frac{nc}{2z} \qquad [12.8.4]$$

where c is the velocity of sound, n is the wave mode (integer), and z is the characteristic dimension.

If the vortex shedding frequency approaches the acoustic resonant frequency, loud noise may be generated. Acoustic resonance in heat exchangers has been described by Barrington (1973). Resonance may be avoided by alteration of the parameters in Equations 12.8.1–12.8.4.

In one case quoted by Barrington, a heat exchanger with an operating weight of 125,000 lb suffered displacements of 1 mil (0.001 in.) at the anchor bolts with accelerations up to 175 ft/s. A force of 340 ton was applied to the foundations at a frequency of about 350 Hz. He found that few foundations can withstand such forces without damage. The monitoring of heat exchanger vibration is discussed in Chapter 19.

12.8.3 Tube rupture

In a heat exchanger with high pressure gas or vapour in the tubes and low pressure liquid in the shell, tube rupture can lead to overpressure of the shell. The need for protection of the heat exchanger shell is recognized in pressure vessel codes such as BS 5500 and the ASME *Boiler and Pressure Vessel Code*. The latter states: 'Heat exchangers and similar vessels shall be protected with a relieving device of sufficient capacity to avoid overpressure in the case of an internal failure'.

More specific guidelines are given in API RP 520: 1990. This recommends that it be assumed that the area available for flow of gas or vapour from the high pressure tube into the shell be taken as twice the cross-sectional area of the tube, which is the worst case for failure of a single tube.

The pressure rise in the shell caused by a tube rupture is not a simple matter, however. The problem has been investigated by Simpson (1972), who distinguished two effects: (1) local pressure rise at point of rupture and (2) overall peak pressure rise in shell. The time-scale of these two phenomena differs by an order of magnitude; the first occurs in about 1 ms, and the second in about 10 ms. But these times are very dependent on the precise conditions in the shell, particularly the amount of gas or vapour present initially. As little as 1% of inert gas in the shell can increase by a factor of 3 the time required to reach peak shell pressure.

Simpson presents a calculation of the bubble pressure created by the rupture in 1 ms of a tube at 10,000 psia. The peak bubble surface pressures reached at 1 tube diameter and 5 tube diameters from the rupture were about 900 and 550 psia, respectively. In other words, the peak bubble pressure was less than 10% of the tube pressure. The pressure experienced by the shell wall is the reflected pressure P_r:

$$P_r \approx 2P_i - P_0 \qquad [12.8.5]$$

where P_i is the incident pressure and P_0 is the initial liquid pressure. Here the effective incident pressure is that of the bubble surface. If the rupture time was halved, the peak bubble pressure was increased by about 50%.

Although the localized overpressure is less than the overall peak pressure rise in the shell which occurs later, the latter is normally catered for by a pressure relief device, while the former is not. The effect of local overpressure on the shell and its implications for the positioning of tubes relative to the shell should be considered as a separate matter. The pressure relief of heat exchangers is discussed in Section 12.12.

12.8.4 Waste heat boilers

Process heat recovery boilers, or waste heat boilers, are widely used, particularly on ethylene and ammonia plants and on sulfuric acid and nitric acid plants. This type of boiler has developed as a cross between a conventional shell-and-tube heat exchanger and a firetube boiler. Its original function was to cool high temperature process gas and, as a by-product, to generate low pressure steam. The steam generation aspect, however, has grown in importance and the operating conditions have become increasingly severe. Moreover, as with heat recovery schemes in general, the use of waste heat boilers increases the degree of interlinking of plant and its vulnerability to failure.

Waste heat boilers and their problems have been discussed by Streich and Feeley (1972). A comparison given by these authors of the typical process waste heat boiler with the traditional Scotch marine boiler is instructive:

Typical conditions	*Process waste heat boiler*	*Scotch boiler*
Heat load (BTU/ft^2 h)	11,000	15,000
Steam pressure (psig)	$\leq$2300	200–225

Waste heat boilers do not have a raw flame licking at the tube seats, but otherwise experience conditions at least as severe.

Firetube boilers tend to leak at the tube inlets and this problem occurs in waste heat boilers also. Tube size is a compromise between the conflicting requirements for low velocity at the high temperature inlet and high velocity at the low temperature outlet.

12.9 Fired Heaters and Furnaces

Fired heaters are another important component in pressure systems. They include pipe stills on crude oil units, furnaces on olefins plants, and heaters for reactors and for heat transfer media.

General treatments of fired heaters are given in *Safe Furnace Firing* by the American Oil Company (Amoco/3), *Handbook of Industrial Loss Prevention* by the Factory Mutual Engineering Corporation (FMEC, 1967), *Heaters for Chemical Reactors* by Lihou (IChemE 1975/61) and the *CCPS Engineering Design Guidelines* (1993/13).

Relevant codes include BS: 799: 1981– *Oil Burning Equipment* and 5410: 1976– *Code of Practice for Oil Firing*, and the British Gas (BG) *Code of Practice for Large Gas and Dual Fuel Burners* (the BG Burner Code) (1976/1). National Fire Protection Association (NFPA) codes include the NFPA 31, 85 and 86 series.

Selected references on furnaces, fired heaters and flare systems are given in Table 12.8.

Fired heaters are a prime source of hazards. These hazards are principally (1) explosion in firing space and (2) rupture of tubes. Explosion in the firing space occurs mainly either during lighting up or as the result of flame failure. Rupture of tubes is usually caused by loss of feed or by overheating. In addition, heaters are a source of ignition for escapes of flammable materials from other parts of the plant.

The elimination of hazards in fired heaters is a good illustration of the need for measures both in design and operation. The design aspects are considered here and the operating aspects in Chapter 20.

Many explosions in the firing space take place during start-up when an attempt is made to light a burner. The usual situation is that fuel leaks and forms a flammable atmosphere in the firing space while the plant is shut-down and an explosion occurs when an attempt is made to light a burner. There are a number of measures which should be taken to prevent this hazard. The most important is to eliminate the admission of unburnt fuel into the firing space. This is principally a matter of achieving a positive isolation on the main fuel feed pipe to the burner. The importance of this is strongly emphasized.

For isolation it is not sufficient to rely on a single valve. Use should be made either of double block and bleed valves or of slip plates. There are different views on which of these methods is preferable and in any case the choice is affected by the fuel. For gas, double block and bleed valves should be used and for oil either double block and bleed valves or slip plates.

Where oil is used, the configuration of the pipe between the shut-off valve and the burner should be such that oil does not flow from this section of pipe into the firing space after the valve has been shut. In addition, the entry of fuel from the main feed pipe during the few seconds while the burner is shutting down after flame failure or from the subsidiary feed pipe to the pilot burner should be avoided.

Explosions (*see* Table 17.1)

Before a burner is started up, the firing space should be purged with air. The atmosphere in the space should then be sampled to confirm that it is not flammable. The purging of the firing space is essential. It is emphasized, however, that it is in no way a substitute for elimination of leakage of fuel into this space.

Means for lighting a burner include a poker, a spark igniter, a permanent pilot burner and an interrupted pilot burner. An interrupted pilot burner is extinguished a few seconds after main flame ignition. The use of a poker is not a good method of ignition. An interrupted pilot burner may be more satisfactory than a permanent pilot burner, since the latter tends to go out.

The ignition period is a critical one. The approach adopted is illustrated by the procedures given in the BG *Burner Code*. The burner is started up on a start-gas flow which is less than the normal flow. The establishment of the start flame consists of two periods: an initial period of not more than 5 s in which ignition is checked and a second period of at least 5 s during which flame stability is checked.

It is essential that if the flame fails, the burner should be shut-down immediately. A flame failure detector is used to monitor the flame and to initiate the trip. Loss of combustion air also necessitates immediate shut-down. Methods of detecting this condition are measurement of static pressure or of air flow.

The sequence of operations for the start-up of a burner should be carefully specified. In particular, the following operations should be carried out in sequence and the start-up should not proceed unless this has been done: establishment of air flow; purging of firing space; testing of atmosphere in space; and establishment of flame. Some detailed start-up sequences are given in the BG *Burner Code* and by the FMEC (1967). It is necessary to ensure that any start-up sequence specified is rigidly adhered to. Generally, the reliability of execution of these sequences can be improved by the use of automatic operation or of interlocks.

Many cases of tube rupture in fired heaters occur because the flow of process fluid through the tubes either falls too low or ceases altogether. If this happens, it is essential for the flame to be extinguished immediately. It should be appreciated that in a furnace where at normal throughput the ratio of the heat required to vaporize liquid to that required to superheat vapour is high, a given reduction in feed flow can result in a disproportionate increase in outlet tube temperature. Overheating of the tubes is another cause of rupture. It is necessary, therefore, to have measurements of tube temperature.

Instrumentation should be provided to measure and control the main operating parameters and, if necessary, to trip the furnace. Measurements should normally include: fuel pressure and flow; combustion air flow and fuel/air ratio; combustion gas oxygen content; process fluid pressure, flow and outlet temperature; flame state; and tube temperatures. There should be appropriate alarms based on these measurements.

The fail-safe principle should be applied in the design of the control system. Thus there is frequently a control loop which manipulates the feed flow in order to control the temperature of the process fluid leaving the furnace. If the instrument measuring this outlet temperature fails, the control loop may increase the fuel flow, which is a hazardous condition. It is essential, therefore, that the measurement on which any alarm or trip is based be separate from that used for control.

There should be trip systems which shut off the fuel flow to the furnace and inject snuffing steam (1) if the electrical power fails, (2) if the fuel pressure and/or flow is low, (3) if the flame goes out, (4) if the combustion air pressure and/or flow is low, or (5) if the process fluid pressure and/or flow is low or its outlet temperature high.

The provision of automatic sequence controls or interlocks for burner start-up has already been mentioned. The safe operation of burners depends critically on the reliability of the instrumentation and it is essential for this to be high.

Difficulties are sometimes experienced with the flame failure device. One problem is instrument failure. Flame failure devices are available with some degree of self-checking. Another is sighting of a pilot burner flame instead of the main flame. If this situation might arise, the flame failure detector should be fitted in such a way that it cannot 'see' the pilot flame.

The foregoing indicates some of the general safety aspects of the design of fired heater systems, but it should be emphasized that this is a specialist matter.

12.10 Process Machinery

Process machines such as compressors and pumps are particularly important items in pressure systems. Not only are they themselves potential sources of loss of containment, but they also affect the rest of the plant by imposing pressure and/or flow fluctuations and by causing vibrations.

The size, complexity and severe operating conditions of many process machines create numerous problems. Much attention is devoted to critical machinery, however, as much for economic as for safety reasons. In consequence, the level of reliability attained is generally rather high. Nevertheless, a failure of a process machine can be serious.

An account of some of the problems associated with process machinery is given in *Safe Operation of Air, Ammonia and Ammonium Nitrate Plants* by the American Oil Company (Amoco/9). Selected references on process machinery are given in Table 12.9.

12.10.1 Process compressors

The process industries use both positive displacement and centrifugal compressors, some of which are very large machines with high throughputs and energy. An account of compressors is given in *Industrial Compressors* (O'Neffl, 1993).

The three principal types of compressor are centrifugal compressors, reciprocating compressors and screw compressors. Both the last two are positive displacement machines, but with reciprocating and rotary motions, respectively.

Reciprocating compressors have long been used for high pressure duties. There has been a trend, however, towards centrifugal compressors and, although these machines were originally used mainly for relatively low compressions, the pressures for which they are used have tended to increase. Some centrifugal compressors are now very big. A large ethylene plant may depend on single large compressors not only for main gas compression but also for refrigeration compression. Another trend is the increase in the application of screw compressors. The range of throughput and compression of these machines has extended so that they now constitute a significant third option.

Compressors are complex machines and their reliability is crucial. It is essential, therefore, to put much effort into the specification of the machine and to liaise with the manufacturer. It is equally necessary to maintain high standards in the operation of compressors. Some general features of compressors which are important are (1) lubrication, (2) protection, (3) isolation, (4) purging, (5) liquid slugs, (6) housekeeping and (7) observation.

The lubrication systems are an integral part of the compressor. It is essential for them to be well engineered and reliable if they are not to be a weak link.

Compressors are provided with protective devices such as pressure relief valves and pressure, temperature and vibration measuring instruments which activate alarms and trips. These are particularly important instruments and they should be reliable.

There need to be arrangements for the isolation of the compressor. Isolation may be by a single block valve and blind or by double block and bleed valves. It may also be appropriate to have an emergency isolation valve on the compressor suction.

Facilities should be provided to allow the compressor to be purged. A permanent purge connection is often considered undesirable because of the hazard of reverse flow from the compressor into the purge gas main. If a permanent connection is installed, it should be shut off when not in use by a blind.

A slug of liquid entering a compressor can be as destructive as a lump of metal. It is important, therefore, for the system to be designed so that this does not happen. It is also necessary before start-up to check that there is no liquid in the inlet or interstage piping, intercoolers, knock-out drums or pulsation bottles.

A high standard of housekeeping around compressors is very desirable. Leaks of oil or water should be eliminated and cleaned up promptly.

The process operators should, and usually do, learn to detect changes in external appearance, noise and vibration as well as in the pressure and temperature measurements. This monitoring by the operators often gives early detection of malfunction and allows corrective action to be taken in time. For large compressors, however, it is now usual to monitor condition and performance using instrumentation.

It is essential to have the highest standard of maintenance on compressors. The maintenance methods need to be thought out thoroughly and the maintenance personnel well trained in them. The conditions under which the maintenance is done should be suitable both with respect to weather and to cleanliness.

Prime movers for compressors include electric motors, turbines and gas engines.

12.10.2 Reciprocating compressors

Reciprocating compressors are utilized for high compressions. They have long been the machines used for compression to the high pressures required in ammonia plants and on offshore platforms. Accounts of reciprocating compressors are given by Whittaker (1975), Barnes (1976), Messer (1979) and Woollat (1993). Relevant standards are BS 7322: 1990 *Specification for the Design and Construction of Reciprocating Type Compressors for the Process Industry* and API Std 618: 1986 *Reciprocating Compressors for General Refinery Services*.

Reciprocating compressors can be provided with capacity control, or turndown, by the use of volume pockets and by drive speed control. Some principal malfunctions on reciprocating compressors are (1) valve leakage, (2) cylinder/piston scoring, (3) piston ring leakage, (4) gasket failure, (5) tail rod failure, and (6) vibration, as well as the general compressor failures such as those caused by liquid slugs or loss of lubricating oil or cooling water.

Leakage of the suction or discharge valves is one of the commonest failures. There are a number of symptoms of valve malfunction. The valve may become unusually hot, the cylinder capacity may fall, the discharge temperature may rise and the interstage pressures may be abnormal. The suction pressure may rise and the discharge pressure fall unless automatically controlled.

On some machines, there is nothing to prevent a suction valve being fitted on the discharge, or vice versa, by mistake. If this happens, it is possible to create very high pressures in the cylinder, particularly the high pressure cylinder, and so cause failure of the cylinder, the piston or the drive system. Preferably, this feature should be designed out. Where this is not the case, there should be procedures to minimize the probability of error.

The piston rod in high pressure cylinders is sometimes balanced by a tail rod on the other side of the piston. There have been some serious accidents in which the tail rod has broken off and flown out like a projectile. There should be a 'catcher' of sufficient strength to prevent escape of the tail rod if it does break. Tail rods are frequently surface hardened and it is important for them to be free of surface cracks. They should be regularly inspected. A tail rod failure allows the escape of high pressure gas.

The reciprocating movement of the piston inevitably causes some degree of vibration. This vibration may be transmitted to, and cause failures in, the process pipework. Small auxiliary piping on the machine tends to be particularly vulnerable to fracture from this vibration. It should be anchored to reduce vibration and inspected regularly.

Changes in the discharge temperature are often a sign of malfunction on a reciprocating compressor. High discharge temperature may be associated with valve failure, piston ring leakage, increased compression ratio, gas composition change or loss of cooling water.

On air compressors lubricated with oil, a high discharge temperature can result in an explosion. Such air compressor explosions, and the discharge temperature limits necessary to avoid them, are discussed in Chapter 17. Some compressors are required to produce compressed air which is free of oil. It is very desirable, for example, that instrument air be oil-free. Carbon ring compressors are often used for this purpose.

The reciprocating compressors were one of the potential sources of the gas leak investigated in the Piper Alpha Inquiry (Cullen, 1990). The questions of the tolerance of such machines to ingestion of liquid slugs and of the bolt tightening practices used were considered in evidence by Bett (1989).

12.10.3 Centrifugal compressors

Centrifugal compressors are the main workhorse machines in the process industries. They can be built for very high throughputs. Although the compression obtained has been lower than that given by reciprocating machines, the range of pressures attainable has gradually been extended. As mentioned, centrifugal compressors are used for the main duties on ethylene plants, both for process gas and for refrigeration.

Accounts of centrifugal compressors are given by Rehrig (1981), H. Davis (1983) and Sayyed (1985). A relevant standard is API Std 617: 1988 *Centrifugal Compressors for General Refinery Services*.

Centrifugal compressors have relatively limited turndown. On centrifugal compressors some of the main malfunctions are (1) rotor or shaft failure, (2) bearing failure, (3) vibration and (4) surge, as well as the general compressor failures mentioned earlier.

In some duties the rotor suffers relatively little attack, but rotors sometimes have flaws or suffer embrittlement or debris deposition. Rotors can become unbalanced or displaced axially. Shafts may contain flaws.

The various kinds of bearing failure are one of the commonest faults in centrifugal compressors. Shaft or casing misalignment and rotor imbalance are frequent causes of bearing failure.

Vibration can cause damage to parts of the compressor itself, such as the bearings. It may also be transmitted to and induce failure in the pipework.

Surging can cause serious damage on a centrifugal compressor. Surge is a condition which occurs when the machine is operating on too low a load, generally in the range 50–85% of normal capacity, which gives rise to violent rapid flow changes and vibration. It is usually prevented by automatic controls which detect the near-surge condition and bypass gas from the discharge to the suction of the compressor. A further discussion of surge control is given in Chapter 13.

12.10.4 Screw compressors

Screw compressors are positive displacement machines with rotary motion, and are also known as 'helical screw' or 'spiral lobe' compressors. They are relatively simple and low in capital cost. They have gradually extended their range of application to emerge as a third force in process industry compression. They are now in widespread use for lower compression and refrigeration duties.

Accounts of screw compressors are given by B.C. Price (1991) and Bloch and Noack (1992). A relevant standard is API Std 619: 1985 *Rotary Type Positive Displacement Compressors for General Refinery Services*.

The original screw compressors were oil-free, or dry, machines. They ran at high speed to minimize internal gas bypassing and were very noisy. In the 1950s, oil-injected machines came in and found application in natural gas compression and refrigeration.

Capacity control on screw compressors is effected by the use of a slide valve which moves axially along the housing. They have good turndown, being able to operate at loads as low as 10% of the normal throughput. Another feature of screw compressors is that they can tolerate relatively large changes in suction pressure, a characteristic useful in refrigeration duties.

Screw compressors have the advantage over reciprocating compressors that they require no suction or discharge valves. By comparison with centrifugal compressors, the spares problem with screw compressors tends to be less severe. Since screw compressors are designed for oil-injection, they have some tolerance to a liquid slug, although continuous liquid slugging can cause problems.

A large proportion of the heat of compression in a screw compressor is absorbed by the oil. This characteristic may be advantageous if it is desirable to avoid high gas compression temperatures, as in cases where the gas may polymerize or explode if overheated.

12.10.5 Gas engines

Gas engines are used to drive compressors. Some principal failures which occur are explosions of (1) starting air line, (2) fuel line and (3) crankcase. A number of explosions have occurred in the starting line to gas engines. Generally, these have been the result of leakage from the power cylinder through a defective NRV. Preventive measures include regular inspection and maintenance of the NRV on the starting line, elimination of oil from this line and venting of the header when the engine is in normal operation.

When the engine is shut-down, it is desirable that the fuel be shut off also. If this is not done, fuel may collect in the engine and the exhaust system, and may explode when the engine is restarted. There have been a number of explosions of combustible mixtures of oil or gas and air in crankcases during operation. Crankcase explosions may be minimized by ventilating the crankcase or purging it with inert gas and fitting an explosion relief device. A further discussion of crankcase explosions is given in Chapter 17.

12.10.6 Process pumps

Most process pumps are centrifugal machines, although reciprocating machines are used in some cases. Where the application is severe and/or critical, a degree of redundancy may be provided, using one or more standby pumps or using several pumps operating at less than full capacity. Thus, for example, the equipment to perform the duty of a single pump may be one pump operating at 100% throughput and a similar pump on stand-by or two pumps each rated for 100% capacity, but both operating at 50% throughput. Diversity of the power supply may also be provided using as drives steam turbines as well as electric motors, thus reducing dependence on electrical power.

If a stand-by pump is provided, it is necessary to ensure that it can be started up rapidly and dependably. The reliability of the pump set can be seriously degraded by pump changeover failure. The arrangements for pump shut-down also need to be reliable. This is particularly the case where there is a potential weak point in the discharge piping such as a flexible hose at a loading facility.

As described earlier, it will often be appropriate to install an emergency isolation valve between a pump and its feed vessel. It is good practice to group together controls for both items.

12.10.7 Centrifugal pumps

The principal malfunctions on centrifugal process pumps are:

(1) bearing failure;
(2) gland/seal failure;
(3) maloperation damage
    (a) cavitation,
    (b) deadheading,
    (c) dry running.

The most common pump faults are failures of bearings or of glands or seals. A common cause of failure is shaft misalignment. Also, a bearing failure can induce a gland or seal failure. If seal failure is particularly undesirable, a type of pump may be used which has a more reliable sealing arrangement. Such pumps include:

(1) pumps with mechanical seals
    (a) single mechanical seals,
    (b) double mechanical seals;
(2) seal-less pumps.

The pump sealing arrangements should both minimize fugitive emissions and have a low probability of catastrophic failure. Gland seals and single mechanical seals leak to some degree. Leaks may be minimized by the use of double mechanical seals or of seal-less pumps. As a precaution against catastrophic failure, use may be made of a double mechanical seal with monitoring of the atmosphere between the two seals. Another arrangement with the same purpose is a single mechanical seal with a packing gland backup.

Seal-less pumps are also referred to as ‘glandless pumps’ or ‘canned pumps’. In a canned pump, the impeller of the pump and the rotor of the motor are mounted on an integral shaft, the rotor and stator being encased, or canned, so that the process fluid can circulate in the space which is normally the air gap of the motor. The bearings are lubricated by the process fluid. Pumps with mechanical seals and seal-less pumps are less liable to leakage, but are also more expensive.

Pumps are particularly liable to be damaged by maloperation. Cavitation, deadheading and dry running can have destructive effects and failure can be catastrophic. Not infrequently, pumps are allowed to run whilst cavitating. Cavitation occurs if the liquid is close to its boiling point and involves incipient vaporization in the pump, the bubbles formed collapsing on the pump impeller due to the pressure induced condensation. This causes pitting and, eventually, more serious damage to the impeller, and can be very destructive. It is avoided by provision of adequate net positive suction head. In order to ensure this it is helpful to keep the suction lines to the pump short. Another measure which may be taken is the provision of a bypass.

Deadheading involves pumping against a closed outlet, or possibly a closed outlet with a closed inlet also. The pump may then generate enough heat and/or pressure to rupture. Cases have occurred of a runaway reaction in the pump or a reaction between the pump material and the fluid. Although avoidance of deadheading is principally an operations matter, there are countermeasures which can be taken in the design. One is a trip system, based on rise in temperature or pressure in the pump. Another is a bypass line free of valves from the pump delivery to the feed tank, or 'kickback' line.

The provision of bypasses on centrifugal pumps is discussed by I. Taylor (1987). Apart from boiler feed-water pumps, centrifugal pumps have traditionally not been equipped with a bypass. Over the last 20 years, however, this has changed. It remains true that most centrifugal pumps do not need a bypass. In order to decide whether one is needed, it is necessary to establish the expected frequency and extent of low flow operation, including shut-off of a downstream control valve, and the extent of any hazard if failure occurs. Centrifugal pumps can generally tolerate '1-min' periods of low flow immediately after start-up. The cases where bypasses are required tend to be those involving pumps which are of large size, high horsepower and high head, and are in continuous low flow operation. The author gives some 10 reasons for installing a bypass, the two principal ones being to prevent excessive temperature rise and to avoid unstable flow conditions. For pump thermal control a bypass flow of 10% is generally sufficient.

Taylor discusses the net positive suction head (NPSH) required to prevent Cavitation. In the 1960s and the early 1970s a spate of problems occurred on high head and high horsepower pumps, involving excessive vibration and pulsation at low flows. Work by Minami *et al.* (1960) and others showed that, whereas traditionally a 3% reduction of first stage head had been taken as an indication of impairment of pump performance by cavitation due to lack of NPSH, at low flows incipient cavitation can occur even at a much higher suction head. In fact, the NSPH required to suppress 'low flow' cavitation in such cases could be two to five times as much as the conventional figure. Subsequently, Fraser (1981) presented a method of estimating the minimum continuous flow based on the suction specific speed index number N_{ss}.

Incorrect design of a bypass, however, can itself be a cause of failure at pumps. Taylor recommends that, with certain exceptions, an automatic bypass should branch off on each pump upstream of the first valve, whether this be an isolation valve, NRVor control valve. Whilst it is true that in many cases involving two motor driven pumps, a common bypass has often been satisfactory, there are two dangers. One is that if one pump stops or trips out and the other, on stand-by, cannot be started up, the bypass opens and connects the high pressure of the delivery side to the suction side. The other danger is that if both pumps are running but with one at a higher speed, perhaps because one is driven by a motor and the other by a steam turbine, the difference in speed may be sufficient to hold closed the NRV valve of the lower speed pump, so that it overheats.

Pumps are sometimes allowed to run completely dry, often due to loss of head in a feed tank. Under these conditions the pump can be wrecked very quickly. Pumps which are not operating can suffer damage due to vibration of the plant, which causes 'brinelling' at one particular point. Such pumps may be turned over periodically to prevent this.

12.10.8 Positive displacement pumps

Positive displacement pumps are less common in process plant than are centrifugal pumps, and, apart from metering applications, are used mainly for high pressure work. In particular, reciprocating pumps are used to obtain high pressures. The discharge side of a positive displacement pump requires protection against overpressure. The usual arrangement is the provision of a pressure relief valve with its discharge returned to the suction side.

12.11 Insulation

Another element of the pressure system on process plants is the insulation. Insulation is employed to control heat transfer both in normal operation and in fire conditions. It has more implications for safety than might at first appear. Accounts of insulation are given in *Thermal Insulation* (Malloy, 1969), in the *CCPS Engineering Design Guidelines* (1993/13) and by Britton (1991), Britton and Clem (1991), Irwin (1991a,b), McMarlin and Gerrish (1992), Reddi (1992) and Gamboa (1993).

There are two basic types of insulation: thermal insulation and fire insulation. There is potential for confusion in that many types of thermal insulation have fire-resistant properties. Thermal insulation is used to (1) reduce heat loss from plant operating at temperatures above ambient, (2) reduce heat gain from plant at temperatures below ambient, (3) protect personnel from hot or cold surfaces on the plant and (4) attenuate sound from the plant. Two particular reasons for reducing heat loss are to prevent (1) freezing of liquid and (2) condensation of vapour.

12.11.1 Safety aspects of insulation

Some of the principal safety aspects of insulation are (1) corrosion beneath insulation, (2) self-heating in insulation, (3) insulation against fire and (4) effect on the process of inadequacies, defects or failures of insulation. Corrosion beneath insulation is considered in Section 21.11.4, self-heating in insulation in Section 12.11.6, fire insulation in Section 12.11.7 and fire properties of thermal insulation in Section 12.11.8. The effects on process or storage of defects in insulation depend on the particular case, but may include hazards from freezing, condensation, rollover, etc.

12.11.2 Materials for thermal insulation

The thermal conductivity is by no means the sole criterion in selecting an insulation. Materials with similar thermal conductivities may differ widely in their other relevant properties. Categories of non-combustible insulation material are (1) calcium silicate, (2) expanded perlite, (3) expanded vermiculite, (4) mineral fibre, and (5) cellular glass.

Some properties of thermal insulation which are important in the present context, in addition to its thermal conductivity, are its characteristics in respect of fire resistance, liquid absorption, fabrication, durability and damage resistance. The liquid absorptivity and fire resistance of insulation are considered in Sections 12.11.3 and 12.11.8, respectively.

The insulation should provide complete cover of the areas of the equipment which it is intended to insulate. Properties which bear on this are dimensional stability and shrinkage. Furthermore, it should be sufficiently easy to fabricate that gaps do not occur as a result of fabrication difficulties. Insulation is often subject to conditions which lead to its being crushed or torn, damage from feet being quite common. Vibration may lead to degradation of short-fibre insulation.

12.11.3 Absorption of liquids in insulation

An important property of an insulation is the extent to which it retains liquid that it already contains or that leaks into it. This property is relevant to the insulation in respect of its (1) thermal performance, (2) mechanical performance and (3) weight, and to (4) corrosion beneath the insulation and (5) self-heating in the insulation.

Water absorption is greatest for calcium silicate and least for cellular glass, whilst for the other types it is variable, depending in part on any added water repellent. Water may enter the insulation as rain or washing water or in other ways such as a steam leak from a trace heating system. Water present in insulation can cause a marked increase in the effective thermal conductivity of the latter, as spaces which should be filled with air become filled with water, with a thermal conductivity more than 20 times that of air. Water also has the potential to cause disruption of the insulation, a typical situation being that which occurs when water freezes to ice and then melts. Since some insulation materials can absorb twice their mass in liquid, water absorption can cause a significant increase in the weight of the insulated system.

Another effect of water is to cause external corrosion of the equipment beneath the insulation, as discussed in Section 12.11.4.

With some insulations the moisture can be driven out and thermal performance restored, but with others this is not so. Calcium silicate, which has a high propensity to absorb water, falls in this latter group.

Process liquids may enter from pipework as may heat transfer fluids. Possible sources of in-leak are flanges and drain and sample points. Some liquids react with the binder in the insulation and promote its disintegration. Flammable liquid entering insulation can give rise to self-heating, as described in Section 12.11.6.

12.11.4 External corrosion beneath insulation

Factors which determine the extent of external corrosion beneath insulation include (1) the insulation material, (2) the equipment material, (3) the equipment configuration, (4) the equipment coating, (5) the equipment stress, (6) the service temperature, (7) any temperature transients and (8) the climate and location.

One important factor governing external corrosion is the insulation material. An insulation which absorbs a large amount of water is likely to cause increased corrosion. One which contains chloride is liable to cause corrosion of stainless steel. The extent to which water is excluded by efficient cladding is another significant factor in external corrosion.

The material of construction of the equipment insulated is another factor. In particular, stainless steel is prone to corrosion by chloride in the insulation. A further factor is the equipment configuration. There are a number of equipment features where corrosion is especially likely to occur. On a vessel these might include nozzles, manholes, supports, brackets, lifting lugs and small bore and instrumentation piping. There are also features such as flanges and drain and sample points which may allow entry of liquids into the insulation. The extent of external corrosion under insulation also depends on the degree of protection afforded by any coating such as paint. External corrosion may be increased by residual stress in the equipment. This is a factor particularly in the stress corrosion cracking of stainless steel.

External corrosion under insulation occurs mainly on equipment operating in the range −5 to 105°C, and especially in the range 60–80°C. At lower temperatures the reaction rate is slower, whilst at higher temperatures water tends to be driven off. Much equipment is subject to temperature transients, which can increase external corrosion. These may be major changes occurring during the start-up and shut-down of high or low temperature plants, or they may take the form of temperature cycling. High plant temperatures can cause concentration of salts which then cause severe corrosion when rewetted.

Corrosion occurs on low temperature plant at thawing zones which tend to remain wet and corrosive.

External corrosion can be aggravated by the presence of salt, as at a coastal location, especially in combination with water precipitating, say, from cooling towers, or condensing, say, from low temperature plant. Pollack and Steely (1990) have described a case in which a large steel column had to be replaced due to corrosion underneath the insulation.

One of the proposals put to the Piper Alpha Inquiry (Cullen, 1990) was that gas risers on production platforms should be provided with passive fire protection in the form of lagging. However, the Inquiry heard evidence that there were also potential problems with this approach – a riser could be put at risk by corrosion beneath the lagging. It made no recommendation on the fire insulation of risers.

It is also convenient to mention at this point the tendency of some insulation to cause abrasive wear of equipment.

12.11.5 External corrosion beneath insulation: protective measures

Measures to prevent external corrosion under insulation relate broadly to (1) the insulation material, (2) the cladding, (3) the equipment coating and (4) the equipment design features. The insulation material should match the equipment to be insulated. For example, an insulation for stainless steel should contain minimal amounts of chloride. The insulation should be one with low water content and absorption capacity.

The insulation should be designed to exclude water. It should be provided with weatherproof cladding. This should permit water entering to be drained and water in the insulation to vaporize and exit when the insulation is heated. The equipment should be protected by coating with paint or other suitable covering.

The design should assist inspection for external corrosion. Inspection ports are available which are specifically designed for this purpose. With regard to abrasive wear of the equipment, there are available anti-abrasive coatings which can be used to reduce this.

12.11.6 Self-heating in insulation

Another insulation issue related to fire is self-heating in insulation soaked with a flammable liquid. Above a critical temperature, which depends on the liquid–substrate system and on the geometry, self-heating initiates and smouldering occurs, limited both by heat transfer from the combustion zone and mass transfer of oxygen into the zone. The explosive destruction of an ethylene oxide column at Antwerp in 1989 was found to be due to self-heating of a leak of the fluid into the insulation (Case History A122).

Accounts of self-heating in insulation are given by Gugan (1974a), Britton (1991) and Britton and Clem (1991). The latter authors discuss the spontaneous ignition temperature (SIT) of liquid in insulation. Values of the SIT range from above 180°C down to near ambient temperature.

Precautions against self-heating include (1) use of a non-porous insulation, (2) exclusion of flammable liquids, and (3) use of a geometry less favourable to its occurrence. One non-porous insulation is cellular glass. However, its fire resistance properties leave something to be desired. Measures for the exclusion of flammable liquids have been discussed in Section 12.11.3. Both self-heating in general and lagging fires in particular are discussed in more detail in Chapter 16.

12.11.7 Fire insulation

Fire insulation proper is provided on equipment which requires fire protection but not thermal insulation. For fire insulation use is made of material which is generally cementitious, such as vermiculite cement. A further discussion of fire insulation, including criteria and tests, is given in Chapter 16.

12.11.8 Fire performance of thermal insulation

On equipment which does require thermal insulation, fire protection may be provided by a fire resistant thermal insulation system. This phrasing is used advisedly, since the effectiveness of the protection is a function of the whole system rather than of the insulation alone.

From the fire protection viewpoint, the ideal thermal insulation is one which does not burn or melt and is non-absorbent. To the extent that it does undergo combustion, it should not give off toxic fumes. Some insulating materials such as polyisocyanurate foam are not suitable. The main categories of non-combustible insulation are listed in Section 12.11.2.

Standard tests of fire properties such as those for flame spread and smoke development are applicable to the insulation materials. There are also standard fire tests such as ASTM E-119 and other tests which seek to simulate more closely hydrocarbon fires. Tests for the insulation material itself and for the insulation system are discussed in the CCPS *Guidelines* and by Britton and Clem (1991). A review of insulation materials for fire protection has been given by Wright and Fryer (1982).

The insulation needs to be protected against the weather. Methods of weatherproofing include the use of caulking, of mastic or of metal jacketing. Metal jacketing is to be preferred. Stainless steel provides a quality jacket, with galvanized steel being a less expensive alternative. There is some experimental evidence of good fire performance of galvanized steel jackets, but it is uncertain how far this can be generalized. Aluminium jackets melt on exposure to fire, in some cases within minutes.

The jacket should have points through which any water entering can drain away and should allow for the egress of any water vaporized when the insulation is heated. In a fire the insulation system may be subject to quite severe conditions, including impingement by flame and/or water jets. These need to be borne in mind in the design.

Britton and Clem (1991) describe the measures used in Union Carbide for certain situations where fire insulation is regarded as particularly critical. One such case is fire insulation of equipment handling reactive chemicals. An example of such a chemical is acetylene. For such reactive chemicals a double layer of insulation is used with staggered joints. Stainless steel is specified for the metal jacketing.

12.11.9 Personnel protection by insulation

One function of thermal insulation is to prevent injury to personnel. Hazard exists not only on high temperature plants but also on those operating at low temperatures which can cause 'cold burns'. The usual method of protection is to make the insulation sufficiently thick to prevent injury. For high temperatures, a criterion commonly used is that the external surface of the insulation should not exceed 60°C. Britton and Clem (1991) discuss the effect on the outer surface temperature of the insulation of its emissivity and absorptivity. An alternative means of protecting personnel from hot or cold equipment is the use of guards to prevent access to the hazardous surface.

12.11.10 Design of insulation systems

As already emphasized, design must address the total insulation system rather than just the insulation itself. It needs to have regard to the several goals of thermal insulation, fire protection and personnel protection and to the avoidance of corrosion beneath the insulation, self-heating and hazardous effects on the process. It is likely to involve a number of trade-offs. Attention should be paid to any special situations. These include, as discussed above, the insulation of stainless steel equipment and of equipment handling reactive chemicals.

Some of the errors commonly made in insulation, not all in design, are rehearsed by Irwin (1991a,b). They include (1) using the wrong insulation material, (2) installing the wrong thickness, (3) struggling with difficult calculations, (4) specifying the wrong thickness for jacketing, (5) laying insulation over jacketing, (6) poor workmanship, (7) hiding damage and (8) no insulation at all.

12.12 Overpressure Protection

Pressure systems need to be provided with protection against failure, particularly from overpressure. Standards and codes which deal with overpressure include: BS 5500: 2003; the ASME *Boiler and Pressure Vessel Code* 2001; the ASME B31 *Code for Pressure Piping*, particularly B31.3: 2002 *Process Piping*; API RP 520: 2000 *Sizing, Selection, and Installation of Pressure-Relieving Devices in Refineries*; API RP 521: 1997 *Guide for Pressure-Relieving and Depressuring Systems*; and API Std 2000: 1998 *Venting Atmospheric and Low-Pressure Storage Tanks*.

Accounts of pressure relief include those given in *Relief Systems Handbook* (Parry, 1992) (the IChemE Relief Systems Guide), *Guidelines for Pressure Relief and Effluent Handling Systems*, (CCPS, 1998/nn) (the CCPS Guidelines for PRS), and by Isaacs (1971), Fitt (1974), Duxbury (1976), Crawley and Scott (1984), A. Moore (1984), Cunningham (1985), Tomfohrde (1985), Crooks (1989), Duckworth and McGregor (1989), and Parry (1989).

The overpressure protection considered here applies to situations in which the pressure rise is relatively gradual. Protection against explosion overpressure is treated in Chapter 17. A number of equations given in the standards and codes are quoted in the following sections. Particular symbols may have different meanings in different equations, but in all cases the symbols are fully defined with the equation and in the notation at the end of the chapter. Selected references on overpressure protection, pressure relief and blowdown are given in Table 12.10.

12.12.1 Requirements for protection

The statutory requirements for protection of pressure vessels and the legislative background to these were outlined in Chapter 3. As described in Section 12.1, the principal legislation in the United Kingdom covering pressure systems is the Pressure Systems and Transportable Gas Containers Regulations 1989 (the Pressure Systems Regulations), with, for fixed plant, the associated code COP 37 Safety of Pressure Systems (HSE, 1990).

The requirement for protection is given in Regulation 4(5) which states 'The pressure system and transportable gas container shall be provided with such protective devices as may be necessary for preventing danger; and any such device designed to release contents shall do so safely, so far as is practicable.' It is also required by Regulations 14 and 15 that a permanent outlet to the atmosphere, or to a space at atmospheric pressure, be kept open and free of obstruction at all times.

It has been a requirement of the Factories Act 1961 in Sections 32, 35 and 36 that steam boilers and receivers and air receivers have a safety valve to prevent overpressure. These sections of the act were revoked by the Pressure Systems Regulations 1989.

Relevant to disposal is the legislation dealing with pollution. The Control of Pollution Act 1974 requires the use of best practicable means for preventing emission of noxious or offensive substances and for rendering harmless and inoffensive any which may be emitted. There is also the general duty to provide safe equipment, which is reinforced by the Health and Safety at Work, etc. Act 1974.

The statutory controls are not the only external influence to which industry is subject. Provision of protection similar to the statutory requirements is normally a condition of obtaining insurance for other vessels.

It is necessary to define both the conditions against which protection is required and the nature of the system to be protected. PD 5500: 2003 requires that every pressure vessel be protected from excessive pressure or vacuum. If the source of pressure or temperature, however, is external to the vessel and is controlled so that overpressure of the vessel cannot occur, then the standard does not require the use of a protective device. Thus, overpressure protection is not required, for example, if the source of pressure is a pump which has a maximum delivery pressure less than the design pressure of the vessel.

For a vessel that is subdivided, each compartment should be treated as a separate vessel and suitably connected to a protective device. On the other hand, PD 5500 states: 'Vessels connected together in a system by piping of adequate capacity, free from potential blockages and which does not contain any valve that can isolate any vessel may be considered as a system of vessels for the application of pressure relief.' The protective device should have adequate capacity to prevent overpressure in the face of failure of any heating coil or other similar element in the vessel.

The protective devices envisaged in the standard are primarily safety valves and bursting discs complying with BS 6759: 1984 and BS 2915: 1990, respectively, but it also allows other devices provided they are suitable and reliable. It requires the maintenance of a register of all protective devices fitted to the vessel. The standard states 'Where the total capacity of the devices necessary to protect an installation from overpressure requires appropriate account to be taken of operating and fault conditions, the register should also include a record of the relevant calculations.'

12.12.2 API RP521

Guidance on protection of plant against overpressure is given in API RP 521: 1997. The contents are (1) general, (2) causes of overpressure, (3) determination of individual relieving rates, (4) selection of disposal systems, (5) disposal systems, and (6) bibliography. The appendices are: A, determination of fire relief requirements; B, special system design considerations; C, sample calculations for sizing a flare stack; and D, typical details and sketches. This is supplemented by the information on the relief devices themselves given in API RP 520, Part I: 2000, and Part II: 1994.

12.12.3 IChemE Relief Systems Guide

Further guidance is available in the *Relief Systems Handbook* by Parry (1992) (IChemE *Relief Systems Guide*). The contents are (1) introduction, (2) relief devices, (3) determining the set pressure and bursting pressure, (4) total relief systems, (5) vacuum relief, (6) thermal relief, (7) fire relief, (8) reliability of relief systems, (9) performance of relief systems, (10) installation of relief devices, (11) operation and maintenance, (12) current and future developments and (13) concluding remarks. The Guide contains some 19 appendices covering the legislation and (1) causes of relief situations, (2) relief rates, (3) minimum discharge velocity for dispersion, (4) Mach number, (5) atmospheric dispersion from a relief, (6) heat radiation at ground level from an elevated flare, (7) steam supply for smokeless flare operation, (8) flare purge gas velocity, (9) knockout drum droplet drag coefficient, (10) ground flares, (11) elevated flares, (12) thermal relief rate, (13) classification of liquids for thermal relief, (14) reliability data and (15) discharge reaction force. The Guide gives a brief summary of eighteen pressure relief case histories, classifying them as (1) safety valve failures, (2) bursting disc failures or (3) failures of containment systems.

12.12.4 Sources of overpressure

API RP 521 gives detailed guidance on causes of overpressure. The principal events may be summarized as follows: (1) connection to a high pressure source, (2) disconnection from a low pressure sink, (3) increased heat input, (4) decreased heat output, (5) vapour evolution, (6) absorbent failure, (7) heat exchanger tube failure, (8) expansion of blocked-in liquid, (9) reverse flow, (10) fluid transients and (11) plant fire.

Connection to a high-pressure source can occur if a valve is opened in error. Likewise, loss of connection to a low-pressure sink can occur if a valve is erroneously closed.

Increased heat input can occur due to malfunction of heating equipment or to chemical reaction. A heat exchanger such as a reboiler when just cleaned may temporarily have a high heat transfer capacity.

Decreased heat output, or loss of cooling, can occur in numerous ways. Malfunction of cooling equipment such as a heat exchanger is an obvious case. Distillation columns particularly can lose cooling in a number of ways. In a single column, loss of cooling can occur not only due to malfunction of the condenser but also due to loss of reflux or of subcooled feed. Where there is a set of columns in series, loss of heat input to one column can cause overpressure of the next column, due to carry forward of light ends in the bottoms from the first column which then overload the second column.

Overpressure can be caused by admission of water or light hydrocarbons to hot oil resulting in rapid evolution of vapour. Failure to remove sufficient gas due to loss of flow of absorbent can also cause overpressure. Failure of a tube in a heat exchanger so that the low-pressure shell is exposed to the high-pressure tube fluid can cause overpressure. This has been discussed in Section 12.8. Overpressure can be caused by expansion of liquid in a section of line between two closed block valves.

A particular case of increased heat input is a fire on the plant. In this case the potential heat input is so great that it is accorded special treatment, as described in Section 12.14. Failure of a pressure raiser and reverse flow from the high-pressure discharge to the low-pressure suction can cause overpressure of the latter. Fluid transients, such as those described in Section 12.7, can be another source of overpressure.

Some of these events may themselves be caused by failure of a utility such as electrical power to equipment or cooling water, or other coolant, or by failure of air or electrical power to instruments. The actions of control loops and those of the process operator are further causes. API RP 521 gives a table (table 1) of possible utility failures and the equipment affected.

12.12.5 Identification of relief requirements

An account of the identification of the nature and magnitude of the sources of overpressure has been given by Fitt (1974), with emphasis on practical interpretation. The first step in dealing with hazards is to ensure that they have been fully identified. The overview of sources of overpressure presented in API RP 521: 1997 and summarized above provides an excellent starting point and 'check list' for the task of identifying potential overpressure scenarios. Hazard identification, which has been described in Chapter 8, is an essential part of the design of protection for pressure systems. The technique of hazard and operability (hazop) studies can be helpful in ensuring that all potential overpressure scenarios have been considered.

Once the hazards have been identified, it is appropriate to consider whether measures other than overpressure protection are more suitable. Some alternatives are to make the plant inherently safer by means such as increasing vessel strength or limiting the delivery pressure of pumps. It must be emphasized that typical process and safety controls (such a pressure or level alarms or trips), while reducing the probability of an overpressure scenario, are not sufficiently reliable to remove the need for overpressure protection by a pressure relief valve, a bursting disc or a device with equivalent reliability.

Full consideration should be given to the action of the process operator. He or she is an integral part of the hazard situation. It is usually reasonable to place some reliance on operator action in averting a hazard, but the extent of such reliance depends on such factors as ease of recognition of the existence of the hazard, instructions and training for dealing with it, and difficulty of and time available for this task. The possibility that the operator would do something positively harmful has to be allowed for, although this is less probable than that he will fail to take some beneficial action. Problems associated with action by the process operator are discussed in Chapter 14.

Some hazards may have such a low probability that they can be disregarded. The cut-off level is commonly determined by the consequences of a failure, which in turn depend on factors such as the number of people exposed to the hazard. Overpressure protection should be considered at an early stage in the design so that unnecessarily severe demands can be identified and averted, but the main work has to be done at a relatively late stage.

Pressure relief becomes necessary when plant conditions are abnormal. Thus, flow sheet quantities provide only a partial guide to the required relief capacities and conditions. Some cases discussed by Fitt to illustrate the practical application of pressure relief are (1) shut-down pumps and compressors, (2) pressure let-down, (3) continuous distillation columns, (4) isolable equipment, (5) low pressure storage tanks, (6) control loop failures, (7) power turbines and let-down engines, (8) heat exchanger tube bursts, and (9) batch operations.

For a pump discharging into a receiver, the pressure relief valve should pass the volume of fluid that the pump could deliver if the feed valve is open and the receiver discharge is blocked. While it is common to assume normal operating (i.e. flow sheet) suction conditions, some designers assume more conservative conditions, such as a suction pressure at alarm or trip value.

Failure of pressure let-down devices can cause a large and sudden rise in downstream pressure, particularly where a liquid line is blown down by gas. Therefore, consideration should always be given to making the downstream section capable of withstanding the upstream pressure. An alternative policy is to size the downstream pressure relief device to handle the combination of let-down valve and bypass valve both fully open. Neither of these valves should be oversized and bypasses should be avoided or limited in capacity (e.g. by a reduced trim or installation in series with a restriction orifice) wherever practicable.

On a continuous distillation column, overpressure may be created by an increase in heat input. Some causes of increased heat input include increase in temperature difference in the reboiler, loss of cooling, loss of reflux and loss of subcooled feed. Loss of cooling is often, but not always, the worst case. In some columns, a subcooled feed provides as much cooling as the condenser.

The case of a column with a subcooled feed also provides an illustration of the need to consider the action of the process operator. If there is a loss of reflux on the column, he may well shut off the feed while he tries to re-establish normal conditions. This then represents a worse case for pressure relief than loss of either reflux or feed alone.

Pressure relief should be provided between isolations if the equipment is subject to pressure from a source of high pressure or of process heat and, generally, if the equipment can be isolated when the plant is operating and it is in a fire zone. Relief need not be provided, however, between isolations if there is no such high pressure or process heat source and if either there is no significant fire risk or the equipment cannot be isolated while the plant is on line, there is adequate provision of vents and drains between the isolations, and operating and maintenance procedures ensure that the segment is drained and vented upon isolation. This philosophy applies to all fluids, including steam and water. It is particularly applicable to valved spare heat exchanger sets.

Low-pressure storage tanks are capable of withstanding only a very low pressure. It is important, therefore, to avoid exposing them to high pressure. The problem is discussed in Chapter 20 on plant operation and in Chapter 22 on storage.

Failure in a control loop may occur in the measuring element, in the controller, in the control valve or its actuator, in the transmission lines or by operator action. The possible failures and combinations of failure should be reviewed and the worst case considered. In evaluating the relief load upon control failure, a credible set of simultaneous occurrences must be selected. Is the upstream pressure at the normal operating, high-pressure alarm, or high-pressure trip value? Should the bypass be assumed fully or partially opened when the control failure occurs? In the design of new facilities, it is usually assumed that both the control valve and the bypass may be fully open, if this constitutes a worst case. It need not be assumed that all control valves on equipment will fail to danger simultaneously, but neither should it be assumed that all control loop actions will be favourable. In considering control loops, it should be assumed that flow may not be fully controlled by the control valve, either because the bypass is open or because the controller is on manual setting.

The system downstream of a power turbine or let-down engine is liable to be subjected to the upstream pressure. Such machines often have a low resistance to flow when stopped. Flow may also occur through an open bypass. The pressure relief valve on the downstream system should be sized to handle the maximum flow from the combination of let-down engine and open bypass. Sentinel 'relief valves' function merely as mechanical high-pressure alarms; they are not intended as, nor are they capable of serving as, a means of pressure relief.

For the bursting of a high-pressure tube in a heat exchanger, the pressure relief valve on the low-pressure side should be sized to handle the flow from twice the cross-sectional area of the tube. If the high-pressure fluid is gas or vapour and the low-pressure side contains liquid, particular attention must be given to the potential for a water-hammer effect as the compressible fluid contacts the incompressible fluid as it flows through the rupture. Pressure increase rates in the liquid-filled low-pressure side can be very high; for many such scenarios designers prefer the high response rate of a bursting disc over the relatively slow-opening pressure relief valve (IP, 2000). The internal failure of a heat exchanger may also bring a hot fluid into direct contact with a highly volatile one. Consideration should be given to the potential for a greatly increased rate of vaporization upon such direct contact.

Batch operations require special consideration, because the conditions change throughout the cycle.

12.13 Overpressure Protection: Pressure Relief Devices

12.13.1 Pressure relief valves

Valves for the relief of pressure are referred to by a number of names and there is no universally agreed terminology. Two names commonly used as generic terms are 'pressure relief valve' and 'safety valve'.

A set of definitions is given in the successive editions of API 520. These are very similar to those given in ASME documents, primarily PTC 25-2001. These documents use 'pressure relief valve' as the generic term. API RP 520: 2000 defines it as a pressure relief device designed to open and relieve excess pressure and to reclose and prevent further flow of fluid after normal conditions have been restored. RP 520 proceeds to make the following distinctions. A 'relief valve' is a spring-loaded pressure relief valve actuated by the static pressure upstream of the valve. It opens normally in proportion to the increase in pressure over the opening pressure. It is used mainly for incompressible fluids. A 'safety valve' is a spring-loaded pressure relief valve actuated by the static pressure upstream of the valve and characterized by rapid opening or pop action. Normally it is used for compressible fluids. A 'safety relief valve' is a spring-loaded pressure relief valve that can be used as either a safety or a relief valve, depending on the application.

According to the IChemE *Relief Systems Guide*, the BSI has decided that the use of these definitions is impossible without ambiguity. The relevant standard, BS 6759: 1984, describes any mechanical valve designed for the automatic relief of pressure as a 'safety valve'. Similarly, BS 5500: 1990 refers to 'safety valve'. This term is also that adopted in the *Guide*. The generic term used here is 'pressure relief valve'.

BS 5500 requires that safety valves comply with BS 6759 *Safety Valves*. BS 6759 has three parts, the most relevant here being BS 6759: Part 3: 1984 *Specification for Safety Valves for Process Fluids*. Part 1: 1984 deals with steam and hot water and Part 2: 1984 with compressed air or inert gases. The installation is required to comply where appropriate with these standards and with BS 1123: 1961 *Safety Valves, Gauges and Other Safety Fittings for Air Receivers, and Compressed Air Installations*, which has one part, Part 1: 1987 *Code of Practice for Installation*.

There are a number of different types of pressure relief valve. Three broad categories of valve are (1) the conventional, direct-loaded valve, (2) the balanced valve, and (3) the pilot-operated, indirect-loaded valve.

A conventional pressure relief valve, the simplest type, is a spring-loaded valve. The pressure at which the valve relieves is affected by the back pressure.

The direct-loaded pressure relief valve has a number of variants. One is the assisted-opening valve, which has power-assisted opening. One use of this type of valve is to give depressurization down to a predetermined level. In a supplementary-loaded pressure relief valve, an external power source is used to impose an additional sealing force, which is released automatically when the set pressure is reached. This arrangement gives an improved degree of leak-tightness.

A third variant is the pilot-assisted valve, which is a different type from the pilot-operated valve. A pilot-assisted valve is a direct-loaded valve in which some three-quarters of the load is due to the spring and the rest to the pressure of the fluid from the pilot valve. When the set pressure is reached, the pilot opens and that part of the load contributed by it is removed.

A balanced pressure relief valve is one that incorporates means of minimizing the effect of back pressure on performance. With this type of valve the back pressure has little effect on the pressure at which the valve relieves. A balanced relief valve is used to accommodate the back pressure in a relief header.

The principal type of balanced pressure relief valve is the balanced bellows valve. The valve incorporates a bellows with an effective area equal to that of the valve seat so that it counteracts the effect of back pressure on the set pressure. The balanced pressure relief valve also comes in a number of variants. They include the balanced piston valve, in which the counteracting balance is effected by a piston, and the balanced bellows valve with auxiliary piston.

A pilot-operated, indirect-loaded pressure relief valve is one in which the main valve is combined with and controlled by an auxiliary direct-loaded pressure relief valve. The whole load on the main valve is provided by the fluid pressure from the pilot valve. When the set pressure is reached, the pilot valve opens and releases the loading pressure.

A pilot-operated pressure relief valve may be used where the margin between the operating and set pressures is narrow or where the set pressure is low. It is also used when discharging direct to atmosphere to ensure high discharge velocity and hence good jet mixing. The principal drawback of a pilot-operated pressure relief valve is that the small passages of the pilot valve are liable to become blocked if the process fluid is dirty, so that is suitable only for relatively clean duties.

Some pressure relief valves are illustrated in Figure 12.12. Figure 12.12(a) shows a conventional pressure relief valve and Figure 12.12(b) a pilot-operated pressure relief valve. Further accounts of pressure relief valves are given in API RP 520 and the IChemE *Guide*. Each of these documents includes diagrams of the various types.

12.13.2 Bursting discs

As for reclosing pressure relief devices, there is no universally agreed terminology for non-reclosing diaphragm-type devices. In API and ASME parlance, such devices are 'rupture disks'. According to the BSI, they are 'bursting discs', which is the term used here.

The conventional bursting disc is the simple disc illustrated in Figure 12.13(a). The disc has its dome with the direction of the bursting pressure. Conventional bursting discs tend to be very thin. Many are less than 0.05 mm in thickness.

A conventional bursting disc should be carefully installed. Manufacturers provide disc mountings that have a number of fool proofing features of which the following are typical. The ring holding the disc on the vent side is made thicker than the dome in order to protect the latter. The disc has an identification tag with full details stamped on. The tag neck serves to centre the disc in place and is notched on one side so that, if correctly installed, the disc does not seat properly and, if not readjusted, will vent at a low pressure. Discs with different pressures have pegs located at different points so that a disc for one pressure will not fit into a holder for a different pressure. Conventional bursting discs are normally made of metal, but graphite discs are also used.

Some other types of disc which are used in general applications include:

(1) composite slotted disc;
(2) reverse buckling disc.

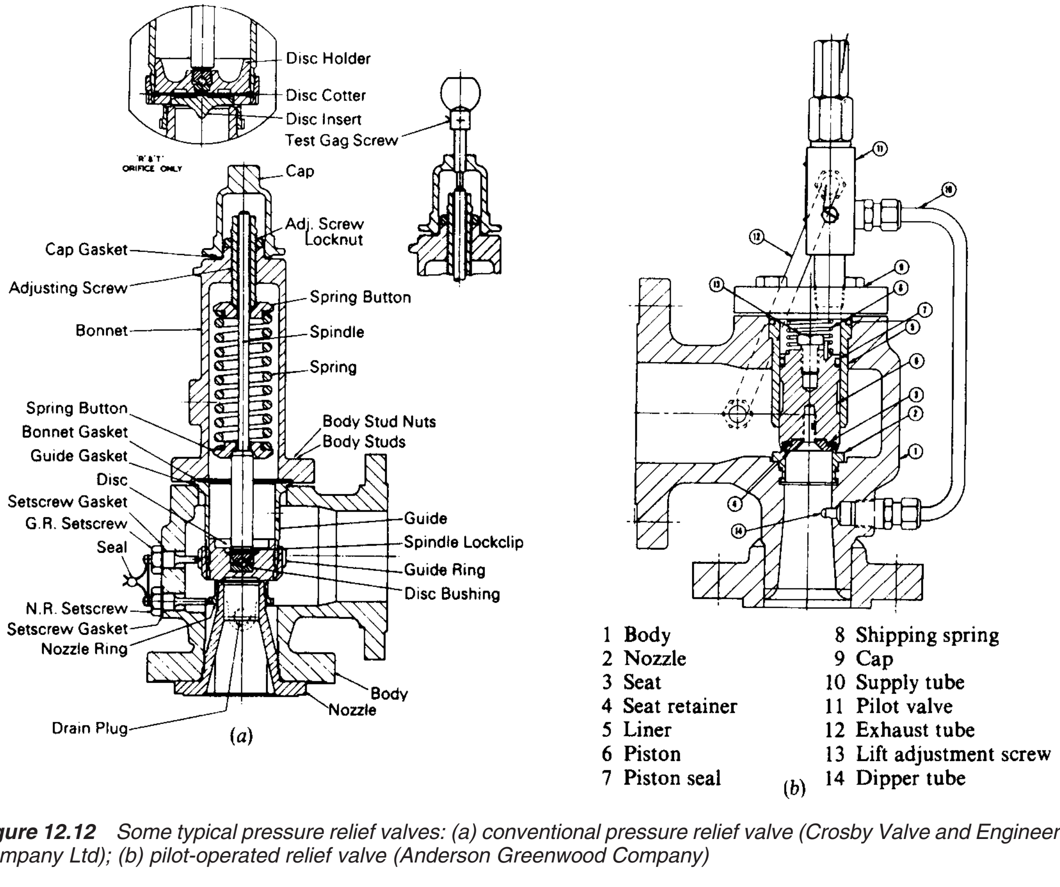

Figure 12.12 *Some typical pressure relief valves: (a) conventional pressure relief valve (Crosby Valve and Engineering Company Ltd); (b) pilot-operated relief valve (Anderson Greenwood Company)*

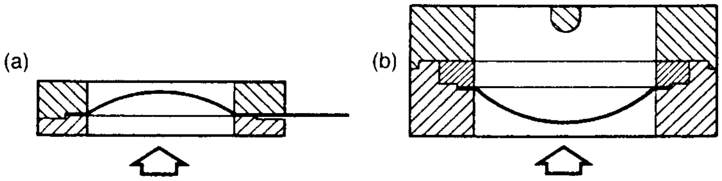

Figure 12.13 *Some typical bursting discs: (a) conventional bursting disc; and (b) reverse buckling bursting disc*

A composite slotted disc is a variation on the conventional disc. It consists of the main disc, which is slotted to burst at the rated pressure, and a protective membrane, in plastic or metal. The use of slotting allows the disc to be made of thicker material so that it is less liable to fatigue, while the use of the membrane gives protection against corrosion by the process fluid. There are also grooved discs, which are less deeply scored.

A reverse buckling disc has its dome against the direction of the bursting pressure, as shown in Figure 12.13(b). An account of reverse buckling discs is given by Watton and Brodie (1984), who list the following types:

(1) disc that, on reversal, bursts by being sheared either radially or circumferentially by serrated cutters mounted on the vent side;
(2) disc with preformed diametral grooves which, on reversal, opens at the grooves;
(3) disc that, on reversal, slips out of the holder;
(4) disc that, on reversal, shears around the dome.

The latter type is available in metal or graphite.

A reverse buckling disc is thicker than a conventional disc for the same duty. Watton and Brodie quote for 50 mm diameter discs rated for a burst pressure of 20 bar at 20°C thicknesses for stainless steel of 0.04 and 0.3 mm for conventional and reverse buckling discs, respectively. The latter is thus 7.5 times thicker than the former. The greater thickness of a reversed buckling disc makes it less liable to failure by fatigue, creep or corrosion.

The reversal time of a reverse buckling disc bursting as designed is very short. For 450 mm diameter discs, Watton and Brodie quote reversal times of 40 ms at 0.035 bar and 5 ms at 10 bar. In order for the disc to be cut by the knife there needs to be sufficient energy. The disc may fail to burst properly if the pressure rise is too slow. If the disc is damaged, even by a quite small dent, in the dome, it may 'roll through' and lie on the knife without being cut. The disc may then fail to burst at the design burst pressure. Furthermore, the knife blades generally must receive routine sharpening to maintain their cutting edge. For these reasons, designers have begun to prefer reverse-buckling discs equipped with preformed grooves.

A reverse-buckling disc should be carefully installed and securely mounted. The following fool proofing features are typically provided by the manufacturer. The disc is preassembled in the holder and pretorqued. The holder is provided with a pin to ensure that it is mounted the right way up. The screws in the holder are of a special type that can require the use of a special tool. Another device to prevent the holder being installed the wrong way up is the use of a J-bolt. Only when the bolt is in can the holder be centred and the flange bolts tightened. This arrangement is particularly useful where frequent cleaning of discs to remove blockages is necessary.

In addition to its use as the primary relief device a bursting disc may also be used mounted in series below a pressure relief valve to protect the latter from corrosion. This arrangement is suitable only if the bursting of the disc will not cause obstruction of the relief valve, and is effective only as long as there are no pinhole leaks in the disc. A pressure gauge is usually mounted on the space between the valve and the disc to detect any rise of pressure due to leakage. This 'tell-tale' gauge is one of several alternative installation details required by ASME Section VIII to ensure proper operation of a pressure relief valve/bursting disc series combination.

In a similar arrangement, a bursting disc is sometimes installed on the discharge side of a pressure relief valve to provide isolation between the valve and a collection system. In this arrangement, the burst pressure of the disc is typically a minimal value, as there is little to no static pressure at the discharge of the pressure relief valve.

There are also available disc assemblies based on the reverse buckling principle that give protection against both overpressure and underpressure, or vacuum. An arrangement described by Watton and Brodie consists of a reverse buckling metal disc perforated with a number of holes and sealed with a graphite membrane. If overpressure occurs, the metal disc and graphite membrane burst in the normal reverse buckling mode; in effect, the system has the characteristics of the metal disc. If underpressure occurs, the graphite membrane bursts, acting like a simple domed disc.

Bursting discs can be made in quite large diameters. Manufacturers are able to supply discs up to some 1.2 m. There are a number of other applications for which special bursting disc systems are available. They include (1) high temperature gas relief, (2) general liquid relief, (3) liquid relief, (4) pulsating liquid relief and (5) two-way relief.

12.13.3 Other relief devices

In addition to pressure relief valves and bursting discs, there are a number of other devices that may be used to relieve pressure. One such device is the buckling pin device (Taylor and Austin, 1992), which is classified by ASME Section VIII – along with the bursting disc – as a 'non-reclosing' pressure relief device. In such a device, sanctioned by the ASME under Code Cases 2091 and 2169, a pressure-containing member (e.g. a piston) is held closed against the system pressure by a thin, typically metal, pin. When installed, the pin is held in compression; it has been engineered (and tested) to fail when the force exerted upon it by the system pressure reaches a specified value. Following an overpressure event, such a device can be restored to its closed position by simply sliding the piston back against the process and inserting a new pin with the correct failure pressure. This convenience is touted relative to the bursting disc, which requires separation of flanges to restore the process to operability following an overpressure event.

A variety of devices is used to provide overpressure protection of low-pressure and atmospheric storage tanks. The simplest of these devices is the atmospheric vent, typically a short pipe. An atmospheric vent is used on atmospheric storage tanks where there is minimal hazard from the ingress of air or egress of vapour.

On an atmospheric storage tank where the liquid held is more volatile, use is generally made of pressure-vacuum valves, which allow the tank to 'breathe'. Another device that can be used to provide pressure relief on low-pressure tanks is the liquid seal. Fire relief for an atmospheric storage tank may be provided in the form of a weak roof-to-shell seam, or rupture seam. For a pressure vessel a device that can provide fire relief is the fusible plug, a non-reclosing device actuated by high temperature.

12.14 Overpressure Protection: Relief System Design

12.14.1 Location of relief devices

In some cases, the provision of a pressure relief device on a particular kind of equipment is a legal or code requirement. An example is the requirement in the Factories Act 1961 for a pressure relief device on a steam boiler, steam receiver or air receiver. ASME Section VIII states: 'All pressure vessels . . . shall be provided with pressure relief devices in accordance with the requirements' of the subsequent approximately fifteen pages of the code. It must be noted directly that those pages include the statement that vessels connected together by adequate piping not containing isolation valves may be considered as one unit in evaluating the pressure relief requirements. But furthermore, in appendix M, it is noted that an isolation valve would be permissible in such a collection of vessels if, when isolating one component vessel from its protective relief device, the valve also isolated the vessel from all source of overpressure.

The only logical method for determining the required location of pressure relief devices is by starting with the identification of potential sources of overpressure. This is best done for each equipment item in the process unit. When this task has been completed, relief devices are then 'located' on equipment or associated piping in such a way that they will be accessible to provide relief for each potential overpressure scenario identified. The relief devices should be installed not simply to protect the particular points at which they are located, but to provide protection for all vulnerable points. Generally, a process vessel is provided with a pressure relief device, but, as described below, there are exceptions, as noted above for section VIII, and discussed further below for API RP 521.

Conditions for the protection of several components in a pressure system by a single pressure relief device are given in API RP 521: 1997 in appendix B. Four criteria are given. The first is that there should not exist any means for blocking in any of the components so protected. The other three criteria, given in detail in the code, have to do with the set pressure, the accumulation pressure and the operating pressure. RP 521 gives an example of a hydrotreater–reactor–recycle gas loop system that has a compressor and six process vessels/units but is protected by a single pressure relief device on the last vessel in the train, and lists the conditions for the acceptability of such protection in this case.

12.14.2 Selection of relief devices and systems

Guidance on the selection of the pressure relief devices to be used for a particular duty is given in the IChemE *Relief Systems Guide*. The first decision is whether to make use of a bursting disc, either alone or in combination with a pressure relief valve. It advises the use of a bursting disc if there is a completely free choice and if this is the more economic option or if either (1) the pressure rise is too rapid for a pressure relief valve or (2) the process fluid properties make a pressure relief valve unsuitable (toxicity, corrosiveness, blockage-forming components, aggressiveness).

If a system based on pressure relief valves alone is indicated, this may be a single valve or a set of multiple valves in parallel, depending on whether a single valve can provide the necessary capacity. The principal types of pressure relief valve are (1) conventional valves, (2) balanced valves, and (3) pilot-operated valves. The characteristics and applications of these different valves are described in Section 12.13.

One fundamental factor that affects the choice of relief valve type is the sink to which the valve will discharge. If this is a relief header and therefore exerts a back pressure, a balanced valve may be indicated. On the other hand, if discharge is to atmosphere, a pilot-operated valve may be selected for its high discharge velocity. Other factors that affect the choice are (1) the margin between operating and the set pressure, (2) the required speed of opening and (3) the required valve tightness. The first and third cases favour a pilot-operated valve.

If the discharge is into a header where the built-up back pressure is expected to exceed 10% of the gauge set pressure, a balanced pressure relief valve is needed, the workhorse valve being of the balanced bellows type. In this case, consideration should be given to the effects of bellows failure in altering the set pressure or leaking process fluid into the valve bonnet.

If the system is to incorporate a bursting disc, it is necessary to consider whether, following operation of the relief, (1) the loss of the plant contents is acceptable and (2) the plant can be shut-down to replace the disc. If neither is acceptable, a system incorporating a bursting disc in series with a pressure relief valve is indicated. If only the first is acceptable, use may be made of two bursting disc systems in parallel. If both are acceptable, a bursting disc system alone suffices. For a bursting disc system, use may be made of a single bursting disc or, if the process conditions are aggressive, two bursting discs in series. The latter case would require installation details as shown in Figure 12.14 and as described above in Section 12.13.2 for the series combination of a bursting disc and a pressure relief valve.

For a bursting disc/pressure relief valve system, the valve may have a bursting disc (1) upstream, (2) downstream, or (3) on both sides, depending on whether it is the process-side fluid, the discharge-side fluid or both fluids that are aggressive.

The principal types of bursting disc are (1) conventional domed disc, (2) reverse domed disc and (3) composite slotted disc; these are discussed in further detail in Section 12.13.2. Use of the conventional type is suitable provided that there is a wide margin, say 30%, between the operating and design pressures and that the pressure does not pulsate. If these conditions are not met, if a long life is required or if the disc is to be used in series with a safety valve, consideration should be given to the other two types.

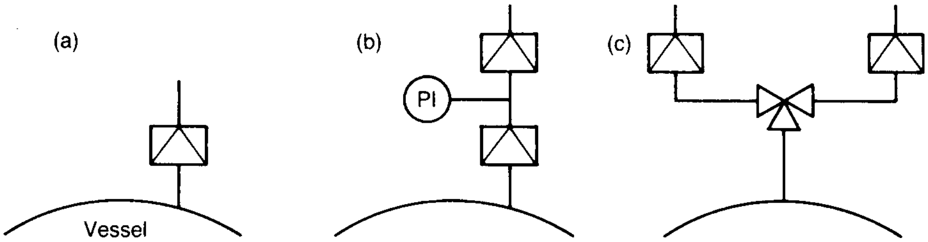

Figure 12.14 *Some typical bursting disc arrangements: (a) single bursting disc; (b) two bursting discs in series with pressure indicator (PI) on intermediate space; (c) two bursting discs in parallel with three-way valve to allow replacement without plant shut-down*

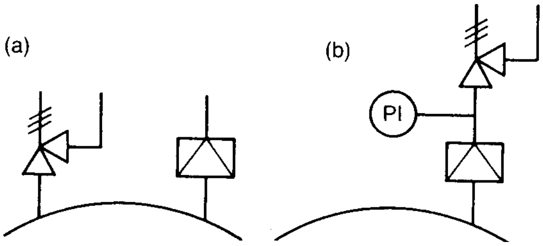

Figure 12.15 *Some typical pressure relief valve + burst-bursting disc arrangements: (a) pressure relief valve and bursting disc in parallel; and (b) pressure relief valve in series with bursting disc upstream and with pressure indicator on intermediate space*

12.14.3 Relief device configurations

Figure 12.14 illustrates some relief configurations based on bursting discs only. Figure 12.14(a) shows a single bursting disc. Figure 12.14(b) shows two bursting discs in series with a pressure indicator on the space between to detect pinholes leaks. Figure 12.14(c) shows two bursting disc in parallel with a three-way valve.

Figure 12.15 illustrates some pressure relief valve + bursting disc configurations. Figure 12.15(a) shows a pressure relief valve and bursting disc in parallel and Figure 12.15(b) a pressure relief valve with an upstream bursting disc to protect against aggressive process conditions. Other arrangements (not shown) are a pressure relief valve with a downstream bursting disc to protect against aggressive discharge conditions, and one with both upstream and downstream bursting discs to protect against aggressive conditions on both sides.

12.14.4 Setting of relief devices

Once the location of the relief system and the type of system to be used have been decided, it is possible to determine the setting and capacity of the device. Guidance on the set pressure for pressure relief valves and for bursting discs is given in the codes. Discussion of this aspect is deferred to Sections 12.19 and 12.20, respectively.

12.14.5 Sizing of relief devices

Guidance on the sizing of individual pressure relief valves in given in API RP 521, which considers in detail the assumptions to be made in relation to each of the sources of overpressure listed in Section 12.12. The situations treated are similar to those discussed in Section 12.12. The approach taken is to describe the scenario and to define a basis for the determination of the relief capacity, indicating whether credits can be taken for particular mitigating factors and discussing features to be taken into account. The account given in Section 12.15 of the treatment of external fire illustrates the general approach. An essentially similar philosophy is applicable to the sizing of bursting discs.

12.15 Overpressure Protection: Fire Relief

The pressure relief requirements just discussed are those for relief of conditions that may arise during operation. In addition to such operational relief, there is a requirement for fire relief. 'Fire relief' refers to an overpressure scenario in which flames external to an equipment item heat the contained fluid, producing a pressure increase either via vaporization of liquid or thermal expansion of gas or vapour. Except in storage areas, operational upsets are more likely to give rise to a requirement for pressure relief than are fires. But fires tend to require a larger pressure relief capacity. In cases where fire can affect a number of vessels, the requirement for fire relief is very much greater than that for operational relief.

Equipment for which fire relief may be required includes atmospheric storage tanks, pressure storage vessels and process systems. For pressure vessels there are two distinct cases: vessels containing gas, vapor, or supercritical fluids only and vessels containing liquids. Guidance on fire relief for pressure storage vessels has been given in the successive editions of API RP 520 and RP 521. In the most recent editions of these documents (RP 521: 1997 and RP 520: 2000), the fire relief guidance appears only in RP 521. There are also a number of other codes which give recommendations on fire relief. A critique of these codes and summary of the current situation is given in the IChemE *Relief Systems Guide*, as described below.

The account of fire relief given here is supplemented by the further discussion in Chapter 22 of fire relief for storage.

12.15.1 Scenarios for fire relief

The first step in design for fire relief is to define the scenarios for which such relief is to be provided. A discussion of this aspect is given by Fitt (1974). The amount of fire relief required depends on the surfaces which may be exposed to fire. The requirement is greatest for groups of process vessels and of storage vessels. If the scenario indicates that the fire would develop slowly and would cause overpressure only after a long period, say several hours, it is sometimes assumed that the fire would be brought under control by fire fighting before overpressure occurs.

12.15.2 Fire protection measures

Some methods of protection against fire in addition to pressure relief are (1) inventory reduction, (2) fire insulation, and (3) water sprays. These alternative protection methods have been the subject of recent experimentation and recommendations (IP 2002, Salater, Overaa and Kjensjord 2002, Bjorn Hekkelstrand and Skulstad 2002; Roberts, Medonos and Shirvill 2000). Inventory reduction is discussed in the following section. Fire insulation and water sprays are discussed in Chapter 16 and fire insulation and water sprays for storage vessels in Chapter 22.

12.15.3 Inventory reduction in fire

Consideration also needs to be given to measures for limitation of developed pressure and for reduction of inventory in fire conditions. One method of limiting the overpressure which can develop is vapour depressurization, or blowdown. Vapour is blown down to a suitable disposal system through a depressurization valve which is separate from any pressure relief device and which is normally operated before the pressure reaches the set pressure of the relief device. This reduces the stress on the vessel walls, reducing the likelihood of their failure as the fire increases their temperature. It also reduces the potential consequences if failure should occur. The depressurization valve needs to be capable of remote operation. Depressurization systems are discussed further in Section 12.23.

Provision may also be made for the removal of the liquid inventory. One reason for doing this is to limit the amount of vapour which has to be handled. Another is to limit the release of material which could then feed the fire if the vessel should fail. The preferred means of removal is the normal liquid withdrawal system, but a separate liquid pulldown system may be used. However, removal of the liquid inventory is not necessarily the best policy. Liquid remaining in the vessel provides effective cooling for the portion of the walls which it wets. Each case needs to be considered on its merits.

12.15.4 Fire relief of pressure vessels containing liquid: API RP 521

A method for determining of the requirement for fire relief of a pressure vessel is given in section 3.15 and appendix A of API RP 521: 1997.

API RP 521 gives one treatment for a vessel containing liquid and another for a vessel containing only gas, vapor, or supercritical fluid when exposed to fire. For the former, it is the wetted surface which is effective in generating vapour. The code states that the portion of the vessel to be considered is that which is wetted by the liquid and which is at a height equal to or less than 25 ft (7.6 m) above the source of the flame, usually, but not necessarily, the ground surface. For the heat absorbed, two cases are considered. For the case where there is drainage of flammable liquid away from the vessel and fire fighting is prompt, the relation given is:

$$Q = 21000\ FA^{0.82} \qquad [12.15.1]$$

where A is the total wetted surface (ft^2), F is the environment factor and Q is the total heat absorption to the wetted surface (BTU/h). For the case where these conditions are not met:

$$Q = 34500\ FA^{0.82} \qquad [12.15.2]$$

The heat absorbed per unit area q is therefore proportional to $A^{-0.18}$, which is termed the 'area exposure factor'; it accounts for the fact that a large vessel is less likely than a small one to be completely exposed.

From Equation 12.15.1 or 12.15.2, the flow of vapour generated may be obtained and hence the capacity required of the pressure relief valve determined. The two important parameters of this model, therefore, are the wetted area A and the environment factor F.

For the wetted area, the standard gives guidance (table 4) on the degree of fill to be assumed for various vessels, including storage vessels, process vessels, distillation columns, etc.

The environment factor F is, in principle, a function of a number of variables related to fire protection: (1) insulation, (2) water application, and (3) depressurizing and emptying facilities. The factor F has a value of unity for bare metal and 0.3, 0.15, 0.075 and 0.03 for insulations with conductances of 4, 2, 1 and 0.4 BTU/(ft^2 h °F), respectively. A full set of values is given in the code (table 5). No credit is given by way of reduction of this factor (i.e. F is unity) for depressurizing and emptying facilities or for water sprays on a bare vessel. The reason given is that neither of these mitigation steps is sufficiently reliable to reduce the relief requirement.

As described below, differences between API RP 521 and other codes in respect of fire relief are in large part associated with differences in the credit given for fire protection by way of the environment factor F.

12.15.5 Fire relief of pressure vessels containing no liquid: API RP 521

For a vessel containing only gas, vapour, or fluid above the critical pressure and exposed to fire, API RP 521 gives the following simplified method, which in this case gives directly the required discharge area of the pressure relief valve:

$$A = F'A'/P_1^{1/2} \qquad [12.15.3]$$

with

$$F' = \frac{0.1406}{CK_{\mathrm{d}}}\left[\frac{(T_{\mathrm{w}} - T_1)^{1.25}}{T_1^{0.6506}}\right] \qquad [12.15.4]$$

$$T_1 = T_\eta(P_1/P_\eta) \qquad [12.15.5]$$

where A is the effective discharge area of the valve (in.^{2}), A' is the entire exposed surface area of the vessel (ft^2), C is a coefficient, F' is a parameter, K_{d} is the coefficient of discharge, P_1 is the upstream relieving pressure (psia), P_η is the normal operating pressure (psia), T_1 is the upstream relieving temperature (°R), T_{w} is the vessel wall temperature (°R) and T_η is the heated fluid's normal operating temperature (°R). RP 521 states that the recommended minimum value of F' is 0.01 and when the minimum value is unknown, a value of 0.045 should be used. Then, from

Equations 12.15.3 and 12.15.4 together with Equation 12.19.15 given below the relief load is:

$$W = 0.1406\left(\frac{MP_1}{Z}\right)^{1/2}\left[A'\frac{(T_w - T_1)^{1.25}}{T_1^{1.1506}}\right] \qquad [12.15.6]$$

where M and Z are, respectively, the molecular weight and compressibility of the fluid at relief conditions and W is the required mass flow (lb/h).

This simple method is based on the assumption that the gas behaves as an ideal gas, that the vessel is uninsulated and has negligible mass, that the gas temperature does not change and that the vessel wall temperature does not reach its rupture value. The document states that these assumptions should be reviewed and, if necessary, use made of a more rigorous method, on which it gives some further guidance.

It must be emphasized that the heat flux modelling used in the fire relief methods described in API RP 521: 1997 are based on empirical observations of heat flux to pressure vessels from fires of pools of flammable liquids. Therefore, the heat flux correlations above are not appropriate for fire scenarios involving jet fires. In jet fire cases, particularly those in which the fire may impinge upon a vessel, the intense, localized heating of the vessel wall may cause vessel failure before the relief pressure is reached. In such cases, depressurization and fireproofing may present the only feasible means of protection.

12.15.6 Fire relief of pressure vessels: other codes

There are several other codes which give guidance on fire relief. A critical review is given in the IChemE *Guide*. The other major code discussed in the Guide is NFPA 30: 1981, together with the Occupational Safety and Health Administration code (OSHA) 1910.106: 1981, which is essentially similar. It states that for storage equipment with wetted areas below 2000 ft^2, NFPA 30 appears to give heat fluxes twice those of API RP 521, but that this difference gradually reduces for wetted areas between 2000 and 2800 ft^2 so that for wetted areas above the latter value the two coincide.

It is also necessary, however, to consider the environmental factor. For good drainage, NFPA 30 gives credit in the form of a value of 0.5 for this factor. As stated above, API RP 521 gives no explicit credit for good drainage, the existence of good drainage being a condition of the use of Equation 12.15.1. Thus for wetted areas of less than 2000 ft^2 the heat fluxes given by the method of API RP 521 and that of NFPA 30 are the same. The *Guide* concludes that the method of API RP 521 is to be preferred. A further discussion of heat fluxes to pressure vessels is given in Chapter 16.

The *Guide* also considers the Compressed Gas Association code CGA S-1.3: 1980 for gas cylinders, together with the Chlorine Institute code CI 5.3.3: 1977, which is essentially similar. CGA S-1.3 utilizes for gas cylinders the more conservative Equation 12.15.2. The *Guide* argues that cylinders may well be exposed to higher heat fluxes so that a case can be made for this approach.

12.15.7 Fire relief of atmospheric storage tanks: API Standard 2000

Guidance on fire relief for atmospheric and low pressure storage tanks is given in API Std 2000: 1998. This standard distinguishes between tanks with a weak roof-to-shell attachment, or rupture seam, and those without. For tanks with a rupture seam, the standard does not require any further emergency venting for fire relief. For tanks without a rupture seam, the standard provides a table of relieving requirements given as a function of the wetted area of the tank. It should be noted that recent reports indicate that the rupture of seams on tanks with diameters less than 50 ft cannot be sufficiently relied upon to remove the need for separate relief devices. (Ferry, 2002).

For a vertical tank, the wetted area is taken as the total cylindrical surface area of the shell up to height of 30 ft above grade. For a horizontal tank, it is the greater of 75% of the total surface area or the surface area to a height of 30 ft (9.14 m) above grade. For a sphere or spheroid it is the greater of 55% of the total surface area or the surface area to a height of 30 ft above grade.

The value of the wetted area used in API Std 2000 reflects the fact that such an atmospheric storage tank normally stands in a bund in which there could be a liquid fire. This contrasts with the values of the wetted area in API RP 521, which reflect the fact that the ground under a pressure storage vessel is normally sloped to drain any liquid away. Fire relief for atmospheric storage is discussed further in Chapter 22.

12.15.8 Effect of fire on relief devices

It is also necessary to consider the effect of fire on pressure relief devices. On a pressure relief valve there are two main effects of fire. One is to cause thermal expansion of the spring, which reduces the force on the valve and is a deviation in the safe direction. The other is to cause thermal expansion of the valve spindle which can lead to jamming. However, if the valve is immersed in the fire so that the temperatures in it are equalized, this effect may be minimal. On a bursting disc the effect of fire is to reduce the bursting pressure or to cause rupture, both of which are effects in the safe direction.

12.15.9 Heating of unwetted surfaces

Provision of fire relief does not give full protection against fire. Unwetted surfaces which are exposed to fire may experience overtemperature and may rupture, even though overpressure of the vessel has not occurred. API RP 521 gives a graph for the time taken by steel plate of different thicknesses to reach particular temperatures when exposed to an open gasoline fire on one side, and another graph for the time to rupture at different rupture stresses and temperatures. These two graphs are shown in Figure 12.16(a) and (b), respectively. RP 521 quotes the example of an unwetted steel vessel of plate thickness 1 in. and with a stress of 15,000 psi in an open fire. The time for the vessel wall to heat up to 1300°F is 17 min and the time for rupture to occur at that temperature is 2.5 min.

The failure of LPG pressure storage vessels in 1966 at Feyzin (Case History A38) was due to the effect of fire on the unwetted walls, even though the pressure relief valves operated.

12.16 Overpressure Protection: Vacuum and Thermal Relief

12.16.1 Vacuum relief

Vacuum collapse of equipment is destructive and hazardous, despite the fact that in some instances the pressure differential may appear relatively small. There is a wide variety of situations that can lead to at least a partial

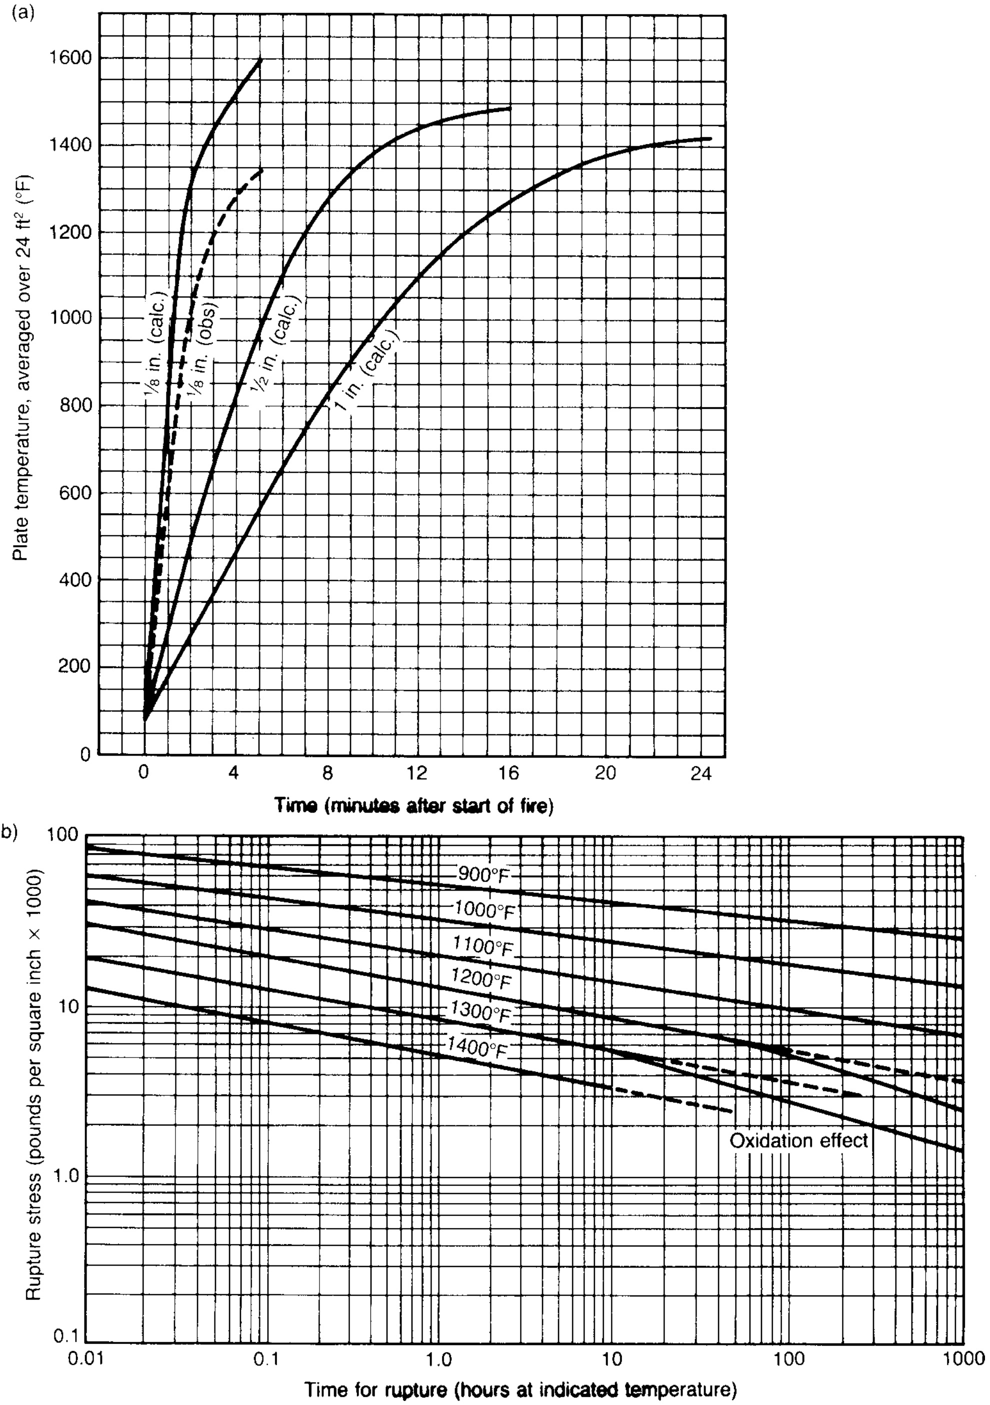

Figure 12.16 *Effect of fire engulfment on steel plate (American Petroleum Institute, 1997 API RP 521): (a) average rate of heating of steel plates of different thickness exposed to an open gasoline fire on one side; and (b) time to rupture of steel plate (ASTM A515 grade) as a function of temperature and stress (Courtesy of the American Petroleum Institute)*

vacuum. They include (1) pumping out with inadequate vent opening, (2) condensation of a vapour, (3) absorption of a vapour, (4) cooling of a volatile liquid, (5) connection to a source of vacuum or suction, (6) depletion of oxygen in air by rusting, and (7) sudden arrest of a moving column of liquid. Some scenarios of storage tank collapse due to such situations are illustrated in Chapter 22.

Some equipment is capable, as designed, of withstanding full vacuum. This is often the case with steel pressure vessels. Other equipment such as plastic storage tanks or large diameter pipework may not have full vacuum strength.

The IChemE *Guide* states that a cylindrical pressure vessel with a length/diameter ratio not exceeding about three and a design pressure of 3.5 barg can generally withstand full vacuum, but that it is prudent to make the check. An increase in the vacuum strength of a vessel can often be obtained by a quite small increment in wall thickness or addition of a stiffening ring.

Vacuum relief devices include vacuum valves and bursting discs. A vacuum valve is a direct-loaded valve which opens to admit air. An alternative is a vacuum bursting disc, which may be preferred where the fluid is corrosive or liable to create blockage, or where it is sufficiently toxic that even a small leak is unacceptable. Bursting disc arrangements are also available which provide both overpressure and vacuum protection, as described in Section 12.13.

On atmospheric storage tanks widespread use is made of pressure/vacuum valves which allow flow in either direction. These are discussed in more detail in Chapter 22. In some cases, vacuum protection may be provided by way of a liquid seal. Where it is not acceptable for air to be admitted to the equipment, inert gas may be used. A typical inert gas arrangement on a storage tank is illustrated in Figure 12.17.

In such an installation, the tank pressure is maintained within acceptable limits primarily by inflow or venting of the inert 'blanket' gas. Installation of pressure and vacuum vents is still required, however, as these provide the ultimate means of protection in the event of failure of the blanketing system. Inflow of air or venting of tank vapours is generally to be preferred over tank rupture or implosion.

12.16.2 Thermal relief

Another form of pressure relief which may be required is thermal hydraulic relief. This is the relief of pressure due to expansion of a liquid that is blocked in and then heated. The pressure generated by a blocked-in and heated liquid is independent of the volume, but the latter does affect the consequences of any escape.

A treatment of thermal relief is given in the IChemE *Relief Systems Guide*. The factors governing the decision as to whether to provide thermal relief are (1) the nature of the liquid, (2) the heat source, (3) the volume of the plant section or system, (4) the tightness of the closure, (5) the probability of blocking in, (6) the location of the system, and (7) the availability of other means of relief.

The *Guide* divides liquids into the following categories: (1) cryogenic, (2) low boiling point, (3) volatile, (4) flammable, (5) toxic, (6) other liquids, and (7) water.

Sources of heat are classified as (1) process heat, (2) heat tracing, (3) solar radiation, and (4) ambient temperature. Subject to the volume exemption described below, the first of these cases should be provided with relief, as should the second, unless the controls are such as to make it unnecessary, whilst the third and fourth cases require the exercise of judgement. For liquids in categories 1–5 relief should generally be provided except for insignificant volumes, that is, volumes $<0.1\,\mathrm{m}^3$ (perhaps less for toxic compounds). The location of the system may strengthen the case for relief, which is indicated if the system is located in an unmanned offsite area (where corrective action is unlikely) or on public property.

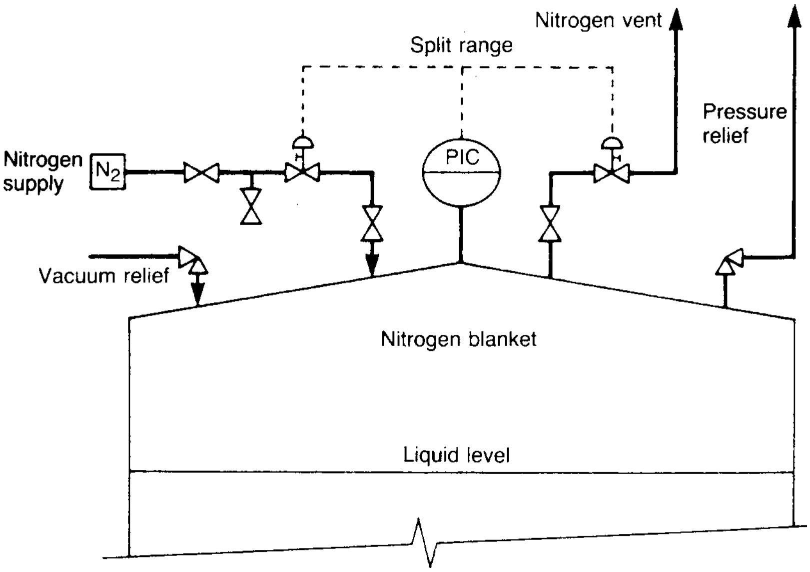

Figure 12.17 *Storage tank system showing inert gas blanketing and arrangements for pressure and vacuum relief (Parry, 1992). PIC, pressure indicator controller (Courtesy of the Institution of Chemical Engineers)*

Turning to category 6 liquids, these require judgement. Account may be taken of the frequency with which the system may be blocked in and the degree of control. If the frequency is judged sufficiently low, it may be possible to dispense with relief.

The *Guide* advises that in borderline cases account may be taken of the volume of the system. The volume which may be regarded as insignificant is related to the tightness of closure. The following tightness categories are given:

Construction	*Valves*		
	Bubble	*Soft*	*Metal*
All welded	A	A	B
Class 300 flanges or higher	A	B	C
Class 150 flanges	B	C	D

It also gives the following relationships between tightness category and limiting volume requiring thermal relief:

Tightness category	*Limiting volume* (m^3)
A	0.1
B	1.0
C	5.0
D	10.0

Separate thermal relief may not be needed if other means of relief exist. These may include a small hole in the valve or a small bore bypass around it, bellows, or relief provided for other purposes.

The following equation is given in the IChemE *Relief Systems Guide* for the thermal relief requirement:

$$W = Q\beta / S \qquad [12.16.1]$$

where Q is the heat input rate (W), S is the specific heat of the fluid (J/kg°C), W is the required relief rate (kg/s) and β is the coefficient of volumetric expansion ($°C^{-1}$).

12.17 Overpressure Protection: Special Situations

There are a number of special situations in pressure relief which require separate consideration. They include (1) extreme operating conditions, (2) aggressive fluids, (3) multiphase fluids, and (4) uncontrolled chemical reaction.

12.17.1 Extreme operating conditions

Extreme operating conditions that can affect pressure relief include (1) high pressure, (2) high temperature, and (3) low temperature.

With high pressure relief valves factors to be considered are valve tightness and precision of lift. Increased tightness may be obtained by the use of a supplementary-loaded valve. In high pressure processes, it is usual to operate close to the design pressure and precision of lift becomes important. A pilot-operated valve may meet the case for clean fluids. Advice on selection of valves for dirty fluids is given in the IChemE *Guide*. There are also available bursting discs for high pressure duties. A feature of relief flows at high pressure is that the gas behaviour may not be ideal.

For a high temperature pressure relief valve relevant factors are materials of construction, spring relaxation, the hot set pressure and the difference between the operating temperature and the relieving temperature. A valve spring subject to high temperature may suffer relaxation. The problem, and work on it, have been described by Aird (1982, 1983). A method of minimizing the effect by the hot set procedure has been described by Weighell (1980). The hot set procedure is specified by the valve manufacturer and should be followed.

If the process fluid has to travel any significant distance before reaching the valve, there may be a difference between the operating temperature and the relieving temperature. It is the latter which is to be used in performing the sizing calculations.

For a pressure relief valve on low temperature duty, factors to consider are materials of construction, the low temperature set pressure, the difference between the operating temperature and the relieving temperature and icing. The low temperature set pressure may be obtained by using a correction on the ambient set pressure but it is also practice to adjust a valve in place at the operating temperature. Icing is countered in various ways. Use may be made of insulation or trace heating. If the plant is in a cold box, the valve may be mounted outside it so that it is at a temperature close to ambient.

For a bursting disc on high or low temperature duty the important feature is the material of construction.

12.17.2 Aggressive fluids

Where a fluid is corrosive, it may be possible to use a pressure relief valve on its own if suitable materials of construction are available. Otherwise, options are the use of a bursting disc upstream of the valve, a bursting disc on its own, or, if the fluid is especially corrosive, two bursting discs in series.

Where the fluid is liable to cause blockage, a pressure relief valve alone may not be suitable. One option is to install a bursting disc upstream of the valve. Another is to use a bursting disc on its own.

If the fouling could be severe, further steps may need to be taken to keep the disc clear. Methods include the use of a coating or anti-fouling compound on the disc, or even water sprays to wash the disc clean.

12.17.3 Multiphase fluids

In some applications, the fluid flowing through the pressure relief valve will be a two-phase vapour–liquid mixture, either because the fluid is two-phase at the valve inlet or because it becomes so in passing through the valve. Two-phase flow through a pressure relief valve is a specialist topic of active current research. It is discussed further in Chapter 15.

Another type of two-phase system is a liquid containing solid particles. There are two potential effects of such solid matter. One is blockage, which has just been discussed. The other is any effect on the flow properties of the fluid.

12.17.4 Runaway reactions

Chemical reaction has long been recognized as a potential source of overpressure in equipment and piping elements. It is unavoidably a specialized domain within the field of overpressure protection, because the rate at which pressure builds – and must be relieved – is inextricably connected to the kinetics of each particular reactive system. Furthermore, reactions that may lead to overpressure include not only reactions intentionally carried out but control of which is lost, but also unintended reactions that occur due to feeding incorrect compounds, impurities, or failing to maintain process parameters within specified limits. An ongoing thrust of the DIERS User's Group – with worldwide participation – is to share, compare and validate experimental and theoretical studies of reactive systems of wide industrial relevance. A series of international symposia has featured reports of data for 'runaway reactions' (Runaway Reactions 1–3).

12.18 Overpressure Protection: Disposal

12.18.1 Disposal and disposal systems

Pressure relief necessarily involves the provision of arrangements for the disposal of the material vented. The selection of the method of relief disposal and the design of any relief disposal system are integral to the overall design.

With all credible overpressure scenarios as a starting point, the nature, temperature, phase and flow rate of the each relief stream are defined. Fluids may be flammable, toxic and/or corrosive. Some may be at high or low temperature. Some flows may be two-phase or liable to condense on release.

For each relief location there will be a flow profile with time. There may also be contributions to the total flow from other devices such as depressuring valves. If the overall profile shows too high a peak, measures may be taken to shave the peaks by means such as the staggering of pressure relief valve settings.

Discharge of gas or vapour to atmosphere is relatively simple and dependable, but its use may be constrained by regulatory and other requirements. API RP 521 recognizes this method for use where it is acceptable. The code also deals with some of the problems which can arise with atmospheric discharge, including formation of flammable plumes, ignition of such plumes, toxic or corrosive plumes, noise and pollution. Its guidance on avoidance of flammable plumes is discussed in the next subsection.

Another option for gas or vapour, which is applicable in some cases, is disposal to a lower pressure system. Minimum requirements in this case are that the unit have the capacity to receive the relief safely and that it be available to do so, bearing in mind that the lower-pressure system may be affected by the same conditions that created the need for relief in the first place.

If these methods of disposal are not appropriate, other methods available include: scrubbing, followed by discharge of the scrubbed gas; discharge from a vent stack; or burning from a flare stack. In these cases, the necessary pipework has to be provided in the form of a relief header, or headers. Here a basic distinction is between single- and multiple-valve disposal systems. In the design of the latter there are a number of features which need to be taken into account.

It is common practice to use a common header both for normal vents and for emergency relief. In this case the normal vent flows should be added to the emergency relief flows in designing the header. Alternatively, separate headers may be provided for normal vents, for gas/vapour relief and for liquid blowdown. Separate headers for gas/vapour and for liquid permit separate disposal arrangements such as a flare stack and blowdown drums, respectively. It may be necessary to consider segregation of streams which are in some way incompatible. Such incompatibility may have to do with fluids that react together, with a low-temperature fluid that requires a more expensive material of construction, or with a fluid that is susceptible to freezing by another, colder fluid.

As far as liquids are concerned, some may be suitable for disposal to the drains. Others may need to be routed to a liquid blowdown receiver or disposed of in an earth burning pit.

12.18.2 Load on disposal system

If the relief flows are discharged to a closed system rather than to atmosphere, it becomes necessary to define the load the system is required to handle. The determination of the flow for which the relief header should be designed is not a simple matter. Its capacity must lie somewhere between the largest single relief flow and the sum of all relief flows. Except for very small plants the latter solution is too conservative and uneconomic.

Before the total design load of the disposal system can be determined, credible 'global scenarios' must be defined. These are scenarios in which multiple relief devices can credibly be expected to discharge simultaneously into the disposal system as a result of a single initiating event. All sources tied to the disposal system – which typically include relief devices, blowdown valves, and process control valves (e.g. pressure bleeds to flare) – must be considered in this evaluation.

Guidance on the identification of global scenarios and determination of the associated loads on the disposal system is given in API RP 521. The essential principle is to design for the set of individual contingencies, rather than for coincident occurrence of multiple independent contingencies. However, each contingency should be carefully examined, because the consequences of certain events can be very widespread.

The code gives guidance particularly on loss of utilities. For failure of electrical power to equipment, the design is commonly based on failure of one bus, or possibly of the distribution centre or the incoming line. Sudden total or partial loss of instrument air or instrument electrical power is also typically considered. The presence of large reservoirs of instrument air may provide for the failure of an air compressor, but cannot protect against the rupture of an air manifold.

Definition of the load resulting from fire requires a specific study taking into account the plant layout, including location of potential sources of release, natural barriers and drainage, etc. The fire on a plant handling only gas can generally be assumed to be more localized than on one handling liquids. RP 521 states that in the absence of special factors the ground area of fire is often taken as being limited to 2500–5000 ft^2 (230–460 m^2).

Fitt (1974) describes an approach to this problem based on certain 'standard hazards'. These are (1) fire, (2) electrical power failure, (3) instrument air failure and (4) cooling water failure.

Fire may affect a group of vessels. It should be assumed, therefore, that there would be simultaneous relief on these vessels. It is usually not necessary to assume a process upset at the same time.

Failures of electrical power, instrument air or cooling water are all obvious causes of simultaneous relief. Total power failure can cause failures on a large number of equipments and all electronic instrumentation. Partial power failure can be even more hazardous. Thus, for example, reboiler fuel pumps might continue to operate after reflux pumps have stopped.

Total instrument air failure disables all pneumatic instrumentation. It is normal practice, however, to design instrument systems so that the control valves 'fail safe' on air failure. Thus again, it may be more hazardous if the air failure is partial. In this case the movement of valves may be in the directions opposite to those on total air failure. In addition, a control valve with an open bypass will not shut off flow completely even if it does close.

Failure of cooling water is usually a consequence of power failure and should be assumed unless the supply can be maintained by pumps with prime movers which have an independent power supply. Note that RP 521 recommends against taking credit for independent-driver pumps not normally operating, stating that their start-up upon power failure has proven not sufficiently reliable.

According to Fitt (1974), once the credible standard hazards have been identified, the flows expected to occur over three different time periods (1) less than 10 min, (2) 10–30 min, and (3) up to 1 h (4 h for fire), are determined.

12.18.3 Disposal to atmosphere

Disposal of gas or vapour by direct discharge to atmosphere possesses the virtue of being relatively simple and dependable, and may be used where it is acceptable. A method for the design of atmospheric discharge arrangements is given in API RP 521. The case considered is that of a safety relief valve discharging a flammable vapour upwards through a vertical tail pipe. The vapour is discharged at a velocity sufficiently high that it is rapidly diluted below the lower flammability limit (LFL).

The criterion for the vapour to be diluted below the LFL whilst the mixing is still dominated by the momentum of the jet is that the Reynolds' number, Re, exceed following value:

$$Re > 1.54 \times 10^4 \rho_j/\rho_\infty \qquad [12.18.1]$$

where ρ_j is the density of the vapour at the vent outlet and ρ_∞ is the density of the air.

The code quotes the work of Taylor, Grimmett and Comings (1951) and gives for the dilution of the discharged vapour the relation:

$$\frac{W}{W_0} = 0.264\frac{y}{D} \qquad [12.18.2]$$

where D is the diameter of the nozzle (ft), W is the mass flow of vapour–air mixture at distance y from the tail pipe (lb/h), W_0 is the mass flow of vapour from the safety relief valve (lb/h), and y is the distance from the end of the tail pipe (ft).

On this basis it is calculated that, provided that the velocity of the discharged material leaving the tail pipe is more than 500 ft/s (150 m/s) so that sufficient energy is supplied for mixing to occur, a hydrocarbon discharging from a safety relief valve into the atmosphere will entrain enough air to become diluted below its LFL at a distance of approximately 120 diameters from the end of the tail pipe.

The code recognizes that, whilst this is fine as long as the valve discharges at this high rate, it cannot be assumed that the flow through a safety relief valve is the full capacity flow. Once a spring-loaded valve has opened, the force exerted on it by the flowing fluid is sufficient to prevent reclosure until the flow has fallen to about 25% of capacity. However, the code quotes a study by Hoehne, Luce and Miga (1970) which has shown that even at flows of 25% of capacity the vapour is safely dispersed.

API RP 521 also refers to studies on venting of oil tankers (ICS, 1978) which indicate that dilution is effective at release velocities exceeding 100 ft/s (30 m/s). It gives a set of graphs for the estimation, for petroleum gases, of the maximum vertical and downwind horizontal distances from the jet exit to the LFL and of the axial distances to the upper flammability limit (UFL) and LFL. For the vertical distance the correlation is:

$$\frac{y}{d_\mathrm{j}(\rho_\mathrm{j}/\rho_\infty)^{1/2}} \quad \text{vs} \quad U_\infty/U_\mathrm{j} \qquad [12.18.3]$$

where d_j is the inside diameter of the tip, or jet exit diameter, U_j is the jet exit velocity, U_∞ is the wind speed and y is the vertical distance to the LFL. The correlations for horizontal distance x and axial distance S are of similar form, with y replaced by x and S, respectively.

The code comments that the studies demonstrate the adequacy of the industry practice of locating the discharge of a safety relief valve at a horizontal distance of at least 50 ft (15 m) from any equipment or structure above the discharge level.

API RP 521 also gives consideration to the case in which the vapour discharged condenses to form a mist. In principle, condensation can occur if the ambient temperature is below the dewpoint of the vapour. However, there are two factors that may mitigate this situation. One is that condensation does not necessarily occur and the other is that, even if it does, the droplets may coalesce and fall out.

Vapour let down in pressure through a safety relief valve becomes superheated and this may prevent condensation. Furthermore, the vapour may be diluted so rapidly that condensation is avoided. A method of determining whether condensation occurs has been given by Loudon (1963). It shows that condensation does not occur with most hydrocarbons, though it may with some of high molecular weight, a finding which is in accord with industrial experience.

RP 521 states that, whilst conclusive data are lacking, condensation at a hydrocarbon partial pressure of 5 psi (0.34 bar) or less should be assumed to result in a fine mist, the dispersion and flammability of which are similar to those of a vapour. A further discussion of discharge to atmosphere and from vents is given in Chapter 15.

12.18.4 Design of a relief header

The use of a closed system involves the design of the relief discharge pipework. In certain cases, use may be made of individual discharge lines, but commonly there is a relief header taking discharges from a number of points.

A discussion of relief headers is given by Fitt (1974) in the study mentioned. As stated above, he considers for a given standard hazard the flows occurring over the three time periods (1) less than 10 min, (2) 10–30 min, and (3) up to 1 h (4 h for fire). The relief header is designed to handle the sum of the flows of the largest of these groups. The header may be required to handle both gas/vapour and liquid flows.

If conventional relief valves are used, relief headers should be so sized that the back pressure developed is limited to 10% of the set pressure. This requirement can be relaxed, however, if balanced relief valves are used. The latter thus permit a more economical design of the relief header.

The pressure drop in the header is sometimes high and the changes in gas density and velocity are correspondingly large. Not infrequently, sonic flow conditions occur. The design of relief headers is therefore relatively complex.

The gas flow in the header may be treated either as isothermal or as adiabatic. For an ideal gas the flow is greater under adiabatic than under isothermal conditions, but for a ratio of specific heats $\gamma < 1.8$ this difference does not exceed 23%. Frequently, calculations are done on the basis of isothermal flow.

API RP 521 gives in Section 5.4.1 guidance on the design basis for a relief header. Essentially, the flows are determined for each credible global scenario and the design is based on the most severe flow condition. This is the condition which gives the highest pressure drop, which is not necessarily that with the highest mass flow; the volumetric flow is relevant, and hence so are molecular weight and temperature.

Once the design loadings are determined, then for each global scenario the maximum allowable back pressure on each pressure relief valve should be calculated. The code gives detailed guidance on these back pressures.

In addition to the flows from the pressure relief valves, there may be flows from depressuring valves. Normally, a depressuring valve is treated as fully open or fully closed and the maximum flow from it taken as the flow capacity of the valve at the maximum pressure of the equipment that it protects, which may be the maximum accumulated pressure. However, the code advises that where the same equipment is protected by both a pressure relief valve and a depressuring valve, only the larger of the two flows is to be considered.

API RP 521 gives a method for the design of the relief header, which is based on the method of Lapple (1943) for isothermal flow of gas through pipes at high pressure drop. The design of relief headers is a specialist matter. It is also an economically important one, since relief headers can be expensive items, particularly if it is necessary to use special materials of construction. Some of the specialist topics in the sizing of relief headers, including non-ideal gas flow and pipe section changes, are discussed by Duxbury (1976).

12.18.5 Disposal to a flare stack

Guidance on the design of a flare for the disposal of gas or vapour is given in API RP 521. The code gives methods for the determination of the diameter and height of the flare stack, the fuel gas supply to the flare, and the steam requirement for a smokeless flare.

The selection of flare stack diameter and height is treated in appendix C of the code. As described there, the diameter is chosen to give a particular Mach number at the flare tip and the height is chosen to limit thermal radiation at ground level. Appendix D of the code gives typical sketches and details of a complete flare system, and of seal drums and knockout drums.

The code also deals with thermal radiation and pollution from the flare. Appendix C gives two models for the flame on the flare, a simple model and the model of Brzustowski and Sommer. These API flare models are described in Chapter 16.

API RP 521 gives information on the exposure times necessary to reach the threshold of pain (table 7) and recommended design radiation levels (table 8). RP 521: 1997 differs from previous editions in that table 8 specifies recommended design values of total radiation; in previous editions the corresponding table explicitly excluded solar radiation from the design values. These and other thermal radiation limits are discussed in Chapter 16.

With regard to the estimation of ground level concentrations of combustion products from the flare, the code refers to the method of Gifford (1960a).

Methods for dispersion from elevated stacks are considered in Chapter 15.

12.18.6 Disposal to a vent stack

API RP 521 also contains guidance on the design of a vent stack for the disposal of gas or vapour. It gives methods for the determination of the diameter and height of the stack.

The diameter is chosen to give a high exit velocity. As discussed above, the code states that excellent dispersion is obtained with a velocity of 500 ft/s (150 m/s). However, sonic velocity should be avoided, or else allowance made for the effect on the pressure drop of the pressure discontinuity at the discharge. The choice of the height of the stack is governed by the need to ensure acceptable concentrations at the points of interest. The code gives guidance on the level of noise from such a stack.

An equation for the maximum ground concentration of a gas downwind of a vent stack is:

$$C_{\max} = \frac{W}{VH^2M} \qquad [12.18.4]$$

where $C_{\max}$ is the maximum ground concentration (% v/v), H is the height of the stack (ft), M is the molecular weight, V is the wind velocity (mile/h) and W is the mass flow rate of gas (lb/h).

There are a number of restrictions on the use of Equation 12.18.4. It assumes that the air velocity increases with height above the ground and that the gas–air mixture is not much heavier than air itself. It is not applicable if the wind velocity is zero or very low, or if the discharge velocity is much below 500 ft/s.

12.18.7 Selection of disposal system

Guidance on the selection of a disposal system is given in the IChemE *Relief Systems Guide*. The disposal systems considered in the guide are to (1) atmosphere, (2) quench vessel, (3) process, (4) storage, (5) dump tank, (6) sewer, (7) elevated flare, (8) ground flare, (9) incinerator, or (10) scrubber.

The selection scheme passes through four broad stages. If the fluid to be disposed of is mainly vapour and if it is lighter than air or can be discharged at high velocity, disposal to atmosphere is a technical option. If the fluid contains both vapour and liquid and needs to be cooled, disposal to a quench vessel is indicated. Otherwise, if a sink for the fluid is available in process or in storage, it may be disposed of to that sink. If the fluid is mainly liquid and it is suitable for discharge to a plant sewer, it may be so disposed of. Otherwise it should be discharged to a dump tank.

If the fluid is both vapour and liquid and cannot be disposed of as described above, other options must be considered. Flammable vapours with some liquid may be sent to a flare. If the fluid contains toxic and/or particulate matter which can be scrubbed out, treatment in a scrubber is suitable. Otherwise the fluid should be sent to an incinerator.

Guidance on selection and design of systems for dipsosal of relief streams is also provided in the CCPS *Relief*

Guidelines (CCPS/NN). This work considers a wide variety of collection, treatment, and containment equipment. It also makes brief mention of several treatment and disposal alternatives that may be applied in special circumstances, noting that the highly variable flow rates associated with relief systems limit the general applicability of these alternatives.

12.19 Overpressure Protection: Pressure Relief Valves

The basics of pressure relief valves have been outlined in Section 12.13. In this section, consideration is given to valve set pressure, sizing and failure.

12.19.1 Valve set pressure

A pressure vessel has a design pressure. The definition of design pressure given in PD 5500: 2003 was quoted in Section 12.6. The set pressure of a safety valve is defined in codes by reference to a specific terminology. The pressure relationships used in PD 5500: 2003 for a safety valve on a vessel are indicated in Figure 12.18(a), which shows the case of a safety valve on gas or vapour service with a 10% overpressure. The pressures on the left-hand side refer to the vessel, whilst those on the right-hand side refer to the safety valve. For the vessel, the normal operating pressure lies between 90 and 95% of its design pressure. The maximum permitted regulated pressure is 110% of the design pressure, the difference between the two being the accumulation. For the safety valve, the set pressure is equal to the design pressure. The relieving pressure is 110% of the set pressure, the difference between the two being the overpressure. Where the set pressure of the valve is the design pressure of the vessel, the overpressure equals the accumulation.

PD 5500: 2003 states that a safety valve should normally be set to operate at a nominal pressure not exceeding the design pressure of the vessel at the operating temperature. However, if the capacity is provided by more than one safety valve, it is permissible for only one of the valves to be set to operate in this way and for the additional valve (s) to be set to operate at a pressure not more than 5% high. The pressure relationships given in BS 5500: 1991 for a safety valve for liquid service with a 25% overpressure are shown in Figure 12.18(b).

Figure 12.18(c) gives the pressure relations for pressure relief valves on a vessel used in API RP 520: 2000. Again, pressures pertaining to the vessel are shown on the left of the figure, whilst those on the right refer to the relief device. For the vessel, the maximum expected operating pressure is 90% of the maximum allowable working pressure (MAWP), which is not less than the design pressure at a coincident design temperature. The figure shows several values of the maximum allowable accumulation, for the following three cases: (1) non-fire exposure with a single valve, (2) non-fire exposure with multiple valves, and (3) fire exposure. The accumulation values are 110, 116 and 121%, respectively. For the pressure relief valve, a similar set of distinctions apply. The maximum set pressure and maximum relieving pressure are equal, respectively, to 100 and 110% of the design pressure for case 1; 105 and 116% for case 2; and 110 and 121% for case 3. Note that in all cases, at least one pressure relief valve must be set no higher than the vessel MAWP. Where the set pressure of the valve is the design pressure of the vessel, the overpressure equals the accumulation. RP 520 states that Figure 12.18(c) conforms to the ASME *Boiler and Pressure Vessel Code*, Section VIII.

Note that all applicable codes would require that where a single relief device or set of devices is designed to protect multiple equipment items, the set pressure of at least one relief device be no higher than the equipment with the lowest design pressure.

For further details of, and qualifications and variations on, the above pressure relief requirements, such as the use of multiple pressure relief valves, reference should be made to the appropriate codes, including the codes just mentioned, and other codes such as API RP 521 and Std 2000.

12.19.2 Valve sizing: BS 5500

Equations for pressure relief valve sizing were given in BS 5500: 1976. PD 5500: 2003 simply refers to the standards for pressure relief valves BS 6759. The equations given in PD 5500: 2003 are widely quoted and are given here for reference.

For a gas or vapour under critical flow conditions:

$$W = \frac{KAp}{C}\left(\frac{M}{T}\right)^{1/2} \qquad [12.19.1]$$

where A is the actual discharge area (m^2), K is the coefficient of discharge for gas flow, M is the molecular weight, p is the absolute accumulation pressure (N/m^2), T is the inlet temperature (K), W is the rated capacity (kg/s) and C is a constant.

For saturated steam:

$$W_s = \frac{KAp}{686} \qquad [12.19.2]$$

and for air at 20°C

$$W_a = \frac{KAp}{423} \qquad [12.19.3]$$

where W_a is the rated capacity for air at 20°C (kg/s) and W_s is the rated capacity for saturated steam (kg/s).

The coefficient of discharge, K, may vary. The standard quotes a value of 0.25 for a parallel inlet guided wing type valve of high lift and 0.97 for a nozzle inlet type valve with flat disc. The value of the coefficient should be provided by the manufacturer. The value of C is 133 for a ratio of specific heats of 1.4.

For liquid flow:

$$W = KA(2\Delta pG)^{1/2} \qquad [12.19.4]$$

where G is the density (kg/m^3) at the inlet temperature, K is the coefficient of discharge for liquid flow and Δp is the pressure drop (N/m^2).

12.19.3 Valve sizing: BS 6759: 1984

The relations given for pressure relief valve sizing in BS 6759: Part 3: 1984 are as follows. For air or any gas at critical flow conditions:

$$q_{mg} = pC\left(\frac{M}{ZT}\right)^{1/2} \qquad [12.19.5]$$

$$= 0.2883\, C\left(\frac{p}{v}\right)^{1/2} \qquad [12.19.6]$$

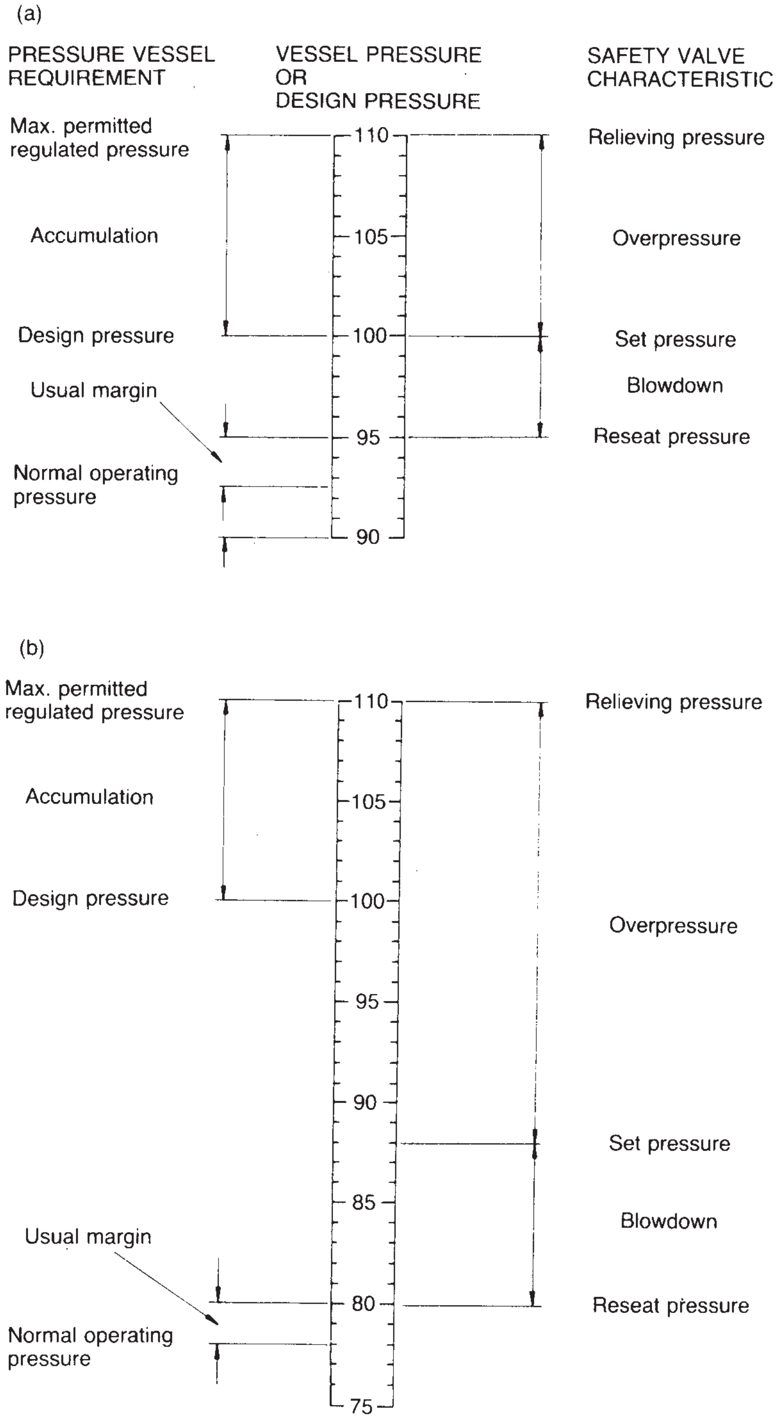

Figure 12.18 *continued*

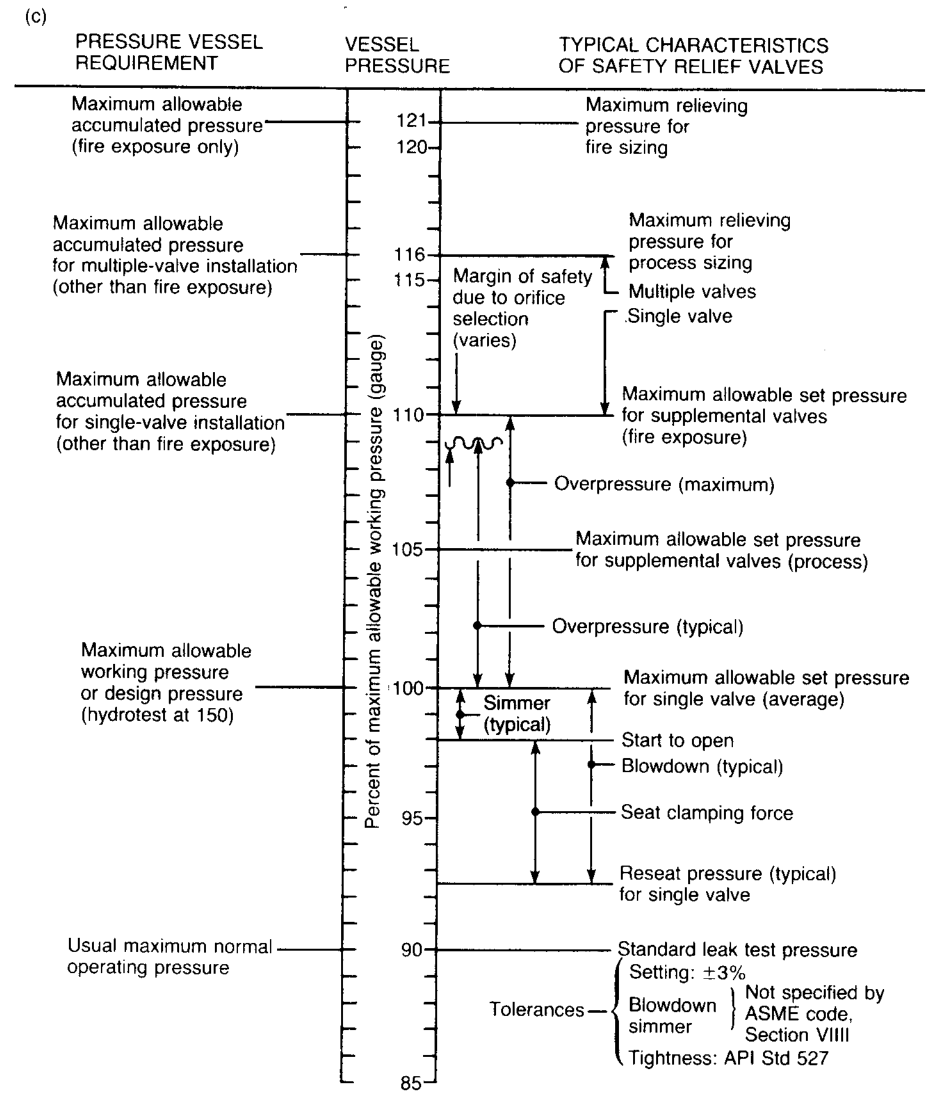

Notes:

1. The operating pressure may be any lower pressure required.
2. The set pressure and all other values related to it may be moved downward if the operating pressure permits.
3. This figure conforms with the requirements of Section VIII, Division 1, of the ASME Code.
4. The pressure conditions shown are for safety relief valves installed on a pressure vessel (vapor phase).

***Figure 12.18** Settings for pressure relief valves: (a) safety valve with 10% overpressure for gas or vapour service (BS 5500: 1991) (Courtesy of the British Standards Institution); (b) safety valve with chosen 25% overpressure for liquid service (BS 5500: 1991) (Courtesy of the British Standards Institution); and (c) pressure relief valve for vapour or liquid service (API RP 520: 2000) (Courtesy of the American Petroleum Institute)*

with

$$C = 3.984\left[k\left(\frac{2}{k+1}\right)^{(k+1)/(k-1)}\right]^{1/2} \qquad [12.19.7]$$

where q_{mg} is the theoretical flowing capacity (kg/h/mm^2 of flow area), M is the molecular mass of gas (kg/kmol), p is the actual relieving pressure (bara), T is the actual relieving temperature (K), v is the specific volume at the actual relieving pressure and temperature (m^3/kg), Z is the compressibility factor, k is the isentropic expansion coefficient at the relieving inlet conditions and C is a parameter which is a function of that coefficient.

For air or any gas at subcritical conditions:

$$q_{\mathrm{mg}} = pCK_{\mathrm{b}}\left(\frac{M}{ZT}\right)^{1/2} \qquad [12.19.8]$$

$$= 0.2883\ CK_{\mathrm{b}}\left(\frac{p}{v}\right)^{1/2} \qquad [12.19.9]$$

with

$$K_{\mathrm{b}} = \left\{\frac{(2k)/(k-1)[(p_{\mathrm{b}}p)^{2/k} - (p_{\mathrm{b}}/p)^{(k+1)/k}]}{(k(2/(k+1)))^{(k+1)/(k-1)}}\right\}^{1/2} \qquad [12.19.10]$$

where K_{b}, is the capacity correction factor for back pressure and p_{b} is the back pressure (bara).

For liquids:

$$q_{\mathrm{ml}} = 1.61(\rho\Delta p)^{1/2} \qquad [12.19.11]$$

with

$$\Delta p = p - p_{\mathrm{b}} \qquad [12.19.12]$$

where Δp is the pressure difference (bar), q_{ml} is the theoretical flowing capacity (kg/h/mm^2 of flow area) and ρ is the mass density (kg/m^3).

For dry saturated steam with a minimum dryness fraction of 0.98 or a maximum superheat of 10°C:

$$q_{\mathrm{ms}} = 0.525p \quad p \leq 110 \qquad [12.19.13]$$

where q_{ms} is the theoretical flowing capacity of dry saturated steam (kg/h/mm^2 of flow area).

The coefficient of discharge K_{d} is the ratio of the actual to the theoretical flow capacity. A derated coefficient of discharge K_{dr} is also defined as $0.9K_{\mathrm{d}}$.

12.19.4 Valve sizing: API RP 520

The relations given in API RP 520: 2000 for sizing of pressure relief valves are as follows. The critical flow pressure ratio is estimated as:

$$\frac{P_{\mathrm{CF}}}{P_1} = \left(\frac{2}{k+1}\right)^{k/(k-1)} \qquad [12.19.14]$$

where k is the ideal gas ratio of specific heats, p_{CF} is the absolute critical flow throat pressure (lb$_{\mathrm{f}}$/in.^{2}) and P_1 is the absolute upstream relieving pressure (lb$_{\mathrm{f}}$/in.^{2}). The code gives values of the ratio of specific heats k for a number of gases.

For critical flow conditions:

$$W = CK_{\mathrm{d}}AK_{\mathrm{b}}P_1\left(\frac{M}{ZT}\right)^{1/2} \qquad [12.19.15]$$

or, in the form actually given

$$A = \frac{W}{CK_{\mathrm{d}}P_1K_{\mathrm{b}}}\left(\frac{ZT}{M}\right)^{1/2} \qquad [12.19.16]$$

with

$$C = 520\left[k\left(\frac{2}{k+1}\right)^{(k+1)/(k-1)}\right]^{1/2} \qquad [12.19.17]$$

where A is the effective discharge area (in.^{2}), K_{b} is the capacity correction factor due to back pressure, K_{d} is the effective coefficient of discharge, M is the molecular weight of the gas, T is the relieving temperature (°R), W is the required flow rate through the valve (lb/h), Z is the compressibility factor and C is a coefficient. The effective coefficient of discharge K_{d} has the value 0.975. Two further equations are also given for volumetric flows, one for air and one for gas.

The capacity correction factor due to back pressure is obtained from manufacturer's literature or from a graph given in the code; the graph is for balanced bellows pressure relief valves. The correction factor is not a means of extending Equation 12.19.15 to subcritical flow, for which separate equations are given.

For subcritical flow:

$$W = 735\,F_2K_{\mathrm{d}}A\left[\frac{MP_1(P_1-P_2)}{ZT}\right]^{1/2} \qquad [12.19.18]$$

or, in the form given

$$A = \frac{W}{735F_2K_d}\left[\frac{ZT}{MP_1(P_1-P_2)}\right]^{1/2} \qquad [12.19.19]$$

with

$$F_2 = \left[\left(\frac{k}{k-1}\right)r^{2/k}\left(\frac{1-r^{(k-1)/k}}{1-r}\right)\right]^{1/2} \qquad [12.19.20]$$

$$r = P_2/P_1 \qquad [12.19.21]$$

where F_2 is the coefficient of subcritical flow, P_2 is the absolute back pressure (lb$_{\mathrm{f}}$/in.^{2}) and r is the ratio of back pressure to upstream pressure.

For liquid flow:

$$A = \frac{Q}{38K_{\mathrm{d}}K_{\mathrm{w}}K_{\mathrm{v}}}\left(\frac{G}{P_1-P_2}\right)^{1/2} \qquad [12.19.22]$$

where G is the specific gravity of the liquid at the flowing temperature relative to water at 70°F, K_{d} is the effective coefficient of discharge, K_{v} is the viscosity correction factor, K_{w} is the back pressure correction factor and Q is the required flow (USgal/min). For the effective coefficient of discharge, the value should be obtained from the manufacturer; for preliminary estimates a figure of 0.65 can be used. For the viscosity correction factor, K_{v}, the code gives a graph. For the correction factor due to back pressure, K_{w}, the approach is as follows. If the back pressure is atmospheric $K_{\mathrm{w}} = 1$. If a balanced bellows valve is used, the correction factor may be obtained from a graph given in the code. If a conventional valve is used, no correction is necessary.

12.19.5 Valve sizing: two-phase flow

With the publication of its seventh edition, API RP 520: 2000 includes for the first time two-phase flow sizing methods designed to include the effects of vapour generation as the fluid flows through the relief valve. The equations presented in appendix D of the code are based on the omega method of Leung (1995), which explicitly assumes both thermal and mechanical equilibrium are maintained as the fluid passes through the safety valve. RP 520 notes that these assumptions are equivalent to those made in the development of the homogeneous equilibrium model (HEM). The code makes note of the fact that the methods presented have not been validated experimentally, principally because there is no recognized procedure for certifying the flow capacity of relief devices in two-phase service.

RP 520 distinguishes among four potential types of two-phase flow scenarios, depending on the character of the fluid entering the relief valve. These are: (1) vapour and liquid at equilibrium, containing no non-condensable gas, (2) highly subcooled liquid with either non-condensable gas or condensable vapour or both, (3) subcooled liquid with no gases or vapours, and (4) subcooled or saturated liquid, with either non-condensable gas or condensable vapour or both. Mixtures (1), (3) and (4) are expected to flash as they flow through the relief valve, but mixture (2) will not flash, due to its high degree of subcooling. Having classified his fluid into one of these categories, the designer is directed to one of three procedures for evaluating the mass flux through the relief valve. Appendix D includes examples of the application of each of these three calculation procedures.

Additional discussion of two-phase flow, and of methods for calculating relevant flow rates, including the cases of relief flow and of reactor venting, appears in Chapter 15.

12.19.6 Valve sizing: safety factors

A discussion of safety factors applicable to pressure relief valves and relief systems is given in Appendix 13.

12.19.7 Valve failure

Pressure relief valves are relatively reliable equipment and the incidence of overpressure due to failure of a relief valve appears low. Accounts of pressure relief valve failure are given by Aird (1982), Maher *et al.* (1988), Crombie and Green (1994), D.W. Thompson (1994), A.B. Smith (1995) and Parr (1998). Modes of failure of pressure relief valves include:

(1) failure to open on demand
  (a) total failure to open,
  (b) opening at a pressure higher than set pressure (lifting ‘heavy’);
(2) opening in the absence of demand
  (a) opening at a pressure lower than set pressure (lifting ‘light’),
  (b) chattering,
  (c) failure to reseat after a correct opening on demand,
  (d) leakage;
(3) disabling of valve inlet or outlet.

Failure to open is a functional failure and opening in the absence of demand an operational, or spurious, failure.

Information on the failure rates of pressure relief valves is given in Appendix 14.

API RP 576: 2000, *Inspection of Pressure Relieving Devices*, provides a detailed discussion of failure modes of both pressure relief valves and bursting discs, and provides guidance on frequency and methods of inspection and maintenance of these devices.

12.20 Overpressure Protection: Bursting Discs

An alternative pressure relief device is a bursting disc. The circumstances under which a bursting disc may be applicable are given in PD 5500: 2003 as those where the pressure rise may be so rapid that the inertia of a relief valve may be a disadvantage, where even minute leakage cannot be tolerated, or where blockage may render a valve inoperative.

The relevant standard is BS 2915: 1990 *Specification for Bursting Discs and Bursting Disc Devices*. The basics of bursting discs have been outlined in Section 12.13. In this section, consideration is given to disc set pressure, sizing and failure.

12.20.1 Bursting disc sizing: BS 2915

For a bursting disc it is usual to specify a range of pressures within which the disc will burst. Therefore, a disc has minimum, mean and maximum bursting pressures.

Equations for the sizing of bursting discs are given in BS 2915: 1990. Earlier editions of this standard contained the following treatment, given here for reference. For gas or vapour:

$$W = CKAP\left(\frac{M}{T}\right)^{1/2} \qquad [12.20.1]$$

where A is the actual orifice area (mm^2), K is the coefficient of discharge, M is the molecular weight of the gas, P is the absolute vessel pressure (bara), T is the inlet temperature (K), W is the rated capacity (kg/h) and C is a constant. For saturated steam

$$W_s = 0.535KAP \qquad [12.20.2]$$

and for air at 20°C

$$W_a = 0.85KAP \qquad [12.20.3]$$

where W_a is the rated capacity for air at 20°C (kg/h) and W_s is the rated capacity for saturated steam (kg/h). The coefficient of discharge is usually taken as 0.6 and the value of C is 2.7 for a ratio of specific heats of 1.4.

These equations have similarities with Equations 12.19.1–12.19.3.

BS 2915: 1990 gives the following relations for bursting disc sizing.

For compressible fluids:

$$Q_{mg} = A_0 p F \alpha (M/ZT)^{1/2} \qquad [12.20.4]$$

where A_0 is the required minimum cross-sectional area (mm^2), M is the molecular mass (kg/kmol), p is the relieving pressure (bara), Q_{mg} is the required flow of gas (kg/h), T is the relieving temperature (K), Z is the compressibility factor, α is the coefficient of discharge of the branch/nozzle type and bursting disc combined and F is a correction factor (described below).

For steam

$$Q_{\mathrm{mw}} = 0.2883 A_0 (F/x) \alpha (p/v)^{1/2} \quad 0.9 \le x < 1.0 \qquad [12.20.5]$$

and for saturated or superheated steam ($x = 1$)

$$Q_{\mathrm{ms}} = 0.2883 A_0 F \alpha (p/v)^{1/2} \qquad [12.20.6]$$

where Q_{mw} is the required flow of wet steam (kg/h), Q_{ms} is the required flow of saturated or superheated steam (kg/h), x is the dryness fraction and v is the specific volume at the relieving pressure and temperature (m^3/kg).

The standard gives a graph for the coefficient of discharge α. The correction factor F is:

$$F = 3.984 \left\{ \frac{2k}{k-1} \left[(p_b/p)^{2/k} - (p_b/p)^{(k+1)/k} \right] \right\}^{1/2} \qquad [12.20.7]$$

where k is the isentropic expansion exponent and p_{b} is the back pressure (bara). For steam, the standard gives a graph for the isentropic exponent k.

For incompressible fluids:

$$Q_{\mathrm{ml}} = 1.610 A_0 f_\mu \alpha (\Delta p \cdot \rho)^{1/2} \qquad [12.20.8]$$

where f_μ is the correction factor for liquid viscosity, Q_{ml} is the required flow of liquid (kg/h), Δp is the pressure difference (bar) and ρ is the mass density ($\mathrm{kg/m^3}$). The pressure difference term should take account of any static head. The standard gives a graph for the correction factor for liquid viscosity f_μ. The coefficient of discharge has the value of 0.5 or 0.62, depending on the type of branch/nozzle; details are given in the standard.

12.20.2 Bursting disc sizing: API RP 520

API RP 520: 2000 presents two methods for sizing bursting discs used as independent relief devices. The first method is essentially identical to that used for pressure relief valves (as embodied in Equations 12.19.16, 12.19.19 and 12.19.22). The sole distinction is that for bursting disc sizing, a value of 0.62 is to be used for the coefficient of discharge K_{d}. Consistent with the requirements of ASME Section VIII: 2001, this method is applicable only for bursting disc installations in which:

(a) piping from the protected vessel to the bursting disc and from the disc to the atmospheric discharge location has a nominal diameter at least as large as the disc, and
(b) the bursting disc is installed within 8 pipe diameters of the protected vessel, and
(c) the length of the discharge pipe is less than 5 pipe diameters.

The second sizing method described by RP 520: 2000, is applicable to all installations in which a bursting disc is used as the sole pressure relief device. In this method, the flow capacity of the entire piping system, of which the bursting disc is one component, is calculated using accepted engineering practices. The calculation is to take into consideration the flow resistance of the bursting disc device, piping and piping components (tees, elbows, reducers, valves, etc.), and entrance and exit losses. Per ASME Section VIII, the calculated flow capacity is to be multiplied by 0.9 to determine the relief capacity of the bursting disc system. Finally, the flow resistance coefficient, K_{R}, of the bursting disc device is typically to be supplied by the manufacturer (who will have measured it per the certification requirements of ASME VIII). If manufacturer's data are not available, a value of 2.4 is to be used for K_{R}.

12.20.3 Bursting disc sizing: two-phase flow

The standards and codes described refer to, but do not give calculation methods for, two-phase flow in bursting discs. Methods for two-phase flow, including the case of reactor venting, are considered in Chapter 15.

12.20.4 Bursting disc sizing: safety factors

A discussion of safety factors applicable to bursting discs and relief systems is given in Appendix 13.

12.20.5 Bursting disc failure

Like a relief valve, a bursting disc may suffer functional or operational failures. In other words, it may fail to burst at the set burst pressure and thus fail to danger, or it may burst below that pressure and thus fail prematurely but, generally, be safe.

Some of the principal modes of failure of a conventional bursting disc are fatigue, creep and corrosion. Pulsation of the fluid pressure induces fatigue, while high temperature causes creep and contributes to fatigue.

Another type of failure is caused by blockage. Blockage may occur on the process side and may be caused by corrosion, crystallization or polymerization. It can also occur on the vent side.

Malinstallation constitutes a third type of failure. The disc may be installed upside down. Another example of malinstallation is putting more than one disc in the holder. Discs are sometimes supplied in stacks and in this case duplication may be a simple error. In other cases, the use of more than one disc is done deliberately to avoid frequent bursting, particularly during commissioning.

Reverse buckling discs are thicker and less prone to fatigue, creep and corrosion, but they have their own characteristic failures. One of these is 'roll through'. The dome of the disc becomes dented and it rolls through onto the knife but with insufficient energy to cause bursting.

In a reverse buckling disc equipped with knife blades, the condition of the knife is critical. It may suffer corrosion, cracking or blunting so that it is no longer capable of cutting. Failure of a reverse buckling disc may also occur if there is insufficient energy to cause cutting of the disc. This is particularly liable to occur on liquid systems.

Malinstallation is another type of failure with a reverse buckling disc. Again the disc may be put in upside down. This may occur where the fitter is accustomed to installing conventional discs and is insufficiently alert to the difference between the two.

Information on the failure rate bursting discs is given in Appendix 14.

12.21 Overpressure Protection: Installation of Relief Devices

In addition to the factors already considered, it is necessary in the design of a relief system to pay close attention to the installation of the relief devices. The installation of relief devices is treated in API RP 520 Pt II, the CCPS *Engineering Design Guidelines* (CCPS/13), the IChemE *Relief Systems Guide*, and the CCPS *Relief Systems Guidelines* (CCPS/NN).

12.21.1 API RP520: Part II

A prime source of guidance on the installation of relief devices is API RP 520 Pt II: 1994 *Sizing, Selection and Installation of Pressure-relieving Devices in Refineries*, Part II, *Installation*. This deals with the following topics: (1) general, (2) inlet piping, (3) discharge piping, (4) isolation valves, (5) bonnet or pilot vent piping, (6) drain piping, (7) valve location and position, (8) bolting and gasketing, (9) multiple pressure-relieving devices with staggered settings, and (10) pre-installation handling and inspection.

12.21.2 Inlet piping to pressure relief valves

A pressure relief valve should be mounted directly on the vessel which it protects at a dedicated nozzle unless there is good reason to do otherwise. Similar considerations apply to bursting discs.

Cases where a pressure relief valve may be positioned at some short separation from the vessel include those where this improves access, allows the valve to be put outside the insulation, reduces the valve temperature, minimizes the vibration to which the valve is subject, or permits improved drainage of the discharge pipework.

Where a pressure relief valve is connected to the vessel by piping, the desirable features of this piping are that it should be short, full bore, vertical and self-draining with low pressure drop and exerting minimum stress on the equipment.

12.21.3 Reaction force from pressure relief valve discharge

The reaction forces due to discharge from a pressure relief valve can be appreciable and need to be allowed for in the design. Accounts of reaction forces are given in API RP 521 Pt II: 1994 and the IChemE *Relief Systems Guide* and by Moody (1969, 1973), Stikvoort (1986), Huff (1990, 1991), Hansen (1991), and Leung (1992, 1998).

API RP 520 Pt II gives a relationship for the reaction force for the case where the pressure relief valve is mounted vertically with its discharge entering a pipe which runs a short distance horizontally, then through a 90° elbow, and vertically upwards. The equation is:

$$F = \frac{W}{366}\left(\frac{kT}{(k+1)M}\right)^{1/2} + A_0P_2 \qquad [12.21.1]$$

where A_0 is the area of the outlet at the point of discharge (in.^{2}), F is the reaction force (lb$_f$), k is the ratio of specific heats of the gas, M is the molecular weight of the gas, P_2 is the static pressure at the point of discharge (lb$_f$/in.^{2}), T is the absolute temperature (°R) and W is the mass flow of gas (lb/h). The reaction force is exerted downwards on the horizontal section. The code shows a support between this section and the vessel.

12.21.4 Isolation of relief devices

There are certain circumstances in which it would be convenient to be able to isolate a relief device on an operating vessel. This is particularly the case where the device needs to be removed for maintenance. Any such isolation is restricted by regulatory requirements and by good practice.

In British legislation, as described in Section 12.12, steam boilers and air receivers have long been subject to specific requirements. It has not been permitted even to install an isolation valve between a steam boiler and its safety valve. For air receivers, BS 1123: Part 1: 1987 permits the installation of an isolation valve between the vessel and its safety valve, provided (1) that the source of supply is also isolated by the same valve and (2) the receiver is fitted with a fusible plug. For process vessels, the installation of an isolation valve between the vessel and its relief valve without further precaution is regarded as bad practice.

BS 5500: 1991 does, however, provide in appendix J for installation of isolation valves subject to the following conditions: 'Intervening stop valves or cocks may be installed provided that they are so constructed and controlled by mechanical interlocks that a limited number only can be closed at any one time and that those stop valves or cocks which remain open are adequately sized to permit the unaffected pressure relieving devices to discharge at the required capacity for the vessel'. Thus, there must be at least duplicate pressure relief valve systems and there must be a mechanical interlock between the two systems.

ASME Section VIII specifies that there shall be no intervening stop valves between a vessel and its relief device except when (1) the stop valves are constructed or positively controlled such that closing the maximum number of stop valves at one time will not reduce the available relief capacity below the required value, or (2) the stop valve is installed for inspection or repair purposes only, is installed such that it can be locked or sealed open, and shall be closed only by an authorized person who shall remain stationed at the stop valve during the period of the vessels operation while the valve remains closed and who shall relock or reseal the valve open before leaving that station.

The fitting of an isolation valve on a single relief device is permitted in some companies, provided that there are strict administrative controls. A case in point might be the fitting of an isolation between a liquid relief device and the space protected. It may be a condition of such exemption that it be shown by hazard assessment that the probability of a demand during the period of valve isolation is acceptably low.

The requirements of the Pressure Systems Regulations 1989 given in Regulation 4(5) have been quoted in Section 12.12. Guidance is given in COP 37: 1990. This states: 'every plant item in which the pressure can exceed the safe operating limit for pressure should be protected, whenever operational, by at least one pressure relieving or pressure limiting device.'

12.21.5 Overpressure protection: design basis documentation

The design basis of a process unit's pressure relief system is widely recognized as a key element of the unit's process safety information (see Chapter 6, and CCPS nn/YYYY, OSHA 29 CFR 1910.119, EPA 40 CFR 68). The US EPA, in guidance materials for its Risk Management Program (EPA, 'General Guidance for Risk Management Programs' (40 CFR Part 68)), has defined the relief systems design basis in the following manner:

> Design basis means documenting how the loads and sizes of the relief system, as well as inlet and outlet sizes, were determined. This includes a description of overpressure scenarios considered, the scenario that creates

> the largest load to be relieved, the assumptions used, and if the device meets a certain code. . . . Industry codes (e.g. API RP 520) also provide guidance on scenarios that should be considered and on equations for sizing of devices.

In documenting pressure relief systems, Berwanger and Kreder, (Kreder and Berwanger, 1995; Berwanger and Kreder, 1998) have argued that an equipment-based rather than a relief-device-based approach is necessary, giving two central reasons. First, the purpose of the relief system is to ensure that the entire process unit – that is, every pressure-containing component – is protected against potential overpressure. Accordingly, the rationale for each equipment item's need for – or lack of need for – overpressure protection must be documented. Second, having the relief device, with its specification and purchase, be central to the documentation of the relief system design has traditionally placed exclusive emphasis on documentation of the 'worst-case' overpressure scenario. Subsidiary cases that may have been considered in the original system design are documented insufficiently, or not at all (particularly when the relief device specification sheet is the only piece of documentation that is maintained). When process changes are considered years after original commissioning, these subsidiary cases may become governing. Because of their poor or missing documentation, these cases are then overlooked by plant engineers – rarely experts in relief system design – contemplating the consequences of the process change under consideration.

As evidence of the need for an equipment-based approach, Berwanger and Kreder cite statistical analysis of their findings in detailed revalidations of the pressure relief systems in over 400 process units in the chemicals, refining, and oil production sectors of the process industries during the period 1994 through 2002 (Berwanger *et al.,* 2000; Berwanger, 2002). These studies reviewed the overpressure protection of some 42,000 equipment items, provided by approximately 25,000 relief devices. Evaluating these relief systems against design standards specified by the owner/operators of the process units, these studies found that 12% of the equipment items analysed were left unprotected against one or more credible overpressure scenario. These results are in substantial agreement with those of Parr (1998), who reports one study in which 25% of the relief systems evaluated were found to be inadequately documented (i.e. the basic purpose of the design was unclear), and another study in which UK HSE personnel over a 10-year period found that nearly 40% of reportable pressure systems incidents were associated with equipment not fitted with a relief valve. Berwanger *et al.* (2000) note that nearly all of the process units in their studies found to have unprotected equipment had recently undergone Process Hazard Analysis (PHA) studies, and conclude that this finding is attributable to the 'traditional' approach of documenting the adequacy of each relief device. The authors reiterate the need for a paradigm shift to documenting the adequacy of the protection of each plant equipment item.

The core purpose of the relief system design basis documentation is two-fold: (1) to ensure that the entirety of the process unit is adequately protected against all credible sources of overpressure, and (2) to ensure that this design basis information is available to all interested parties throughout the operating life of the unit. These goals may be satisfied if the documentation captures the analysis process of the original designers of the unit's pressure relief system. The key steps in this design process given by Kreder and Berwanger (1995) are:

(a) for each equipment item, identify all potential scenarios that can credibly lead to overpressure; for these, and for commonly occurring scenarios that may have been deemed not credible, document the rationale for the identification of the scenario as potentially causing overpressure (or not)
(b) for each overpressure scenario identified as credible in (a), calculate the required relief flow rate
(c) for each flow rate calculated in (b), specify a relief device with the set pressure, flow capacity, and installation location required to protect the associated equipment item(s) against overpressure.
(d) for each credible overpressure scenario and combination of scenarios, ensure that the relief devices are equipped with effluent handling systems to dispose safely of the relief streams while not compromising the performance of the relief devices.

The Process Safety Management committee of the DIERS Users Group has recommended a list of information to be included in all pressure relief system documentation (Lee, 1996). In addition to data concerning the individual relief device, the equipment it protects, and the inlet and outlet piping associated with the device, the list includes 'summary of all relief cases considered, including the worst credible design case', and a description of 'containment, handling, and treatment of relief device effluents'.

12.22 Flare and Vent Systems

A principal method of disposal of gases and vapours discharged from the process is flaring. The function of a flare system is generally to handle materials vented during (1) normal operations, particularly start-up and (2) emergency conditions.

Guidance on flare system design is given in API RP 521: 1990, on which much of the other literature draws heavily. Accounts of flare systems are given in *Flare Gas Systems Pocket Handbook* (Bannerjee, Cheremisinoff and Cheremisinoff, 1985), the CCPS *Engineering Design Guidelines* and the IChemE *Relief Systems Handbook* and by Bluhm (1961, 1964b), Husa (1964), G.R. Kent (1964, 1968, 1972), P. Peterson (1967), Tan (1967a,b), Kilby (1968), Seebold (1984), Straitz (1987), Swander and Potts (1989) and Tite, Greening and Sutton (1989).

12.22.1 Types of flare system

There are three main types of flare system: (1) elevated flare, (2) ground flare, and (3) low pressure flare. The last two are described first.

12.22.2 Ground flares

A ground flare generally consists of a battery of tubular burners contained in a short refractory-lined stack, which serves as combustion chamber and windshield. The bottom of the stack is above grade so that the combustion air can enter. Typically, this air inlet is provided with a louvred shield to maintain flame stability and masks the glare from the flame; the stack is circular or square in cross-section and it is set inside an octagonal windshield. The elements of a ground flare system are knockout drum, seal drum, burner system, ignition system, stack and windshield.

In one design of ground flare systems, the height H of the stack is about $0.3D$, where D is the diameter of the combustion chamber, and the bottom of the stack wall is also about $0.3D$ from grade. Other designs of ground flare are described by Swander and Potts (1989), who give illustrations of designs ranging from a completely open flare to one with a quite high stack. There are also variations in the number of burners, some low volume ground flares having just a single burner. Details of ground flare systems are given in the IChemE *Guide*.

A ground flare may be favoured where there is a limitation on the height of the flare which can be installed. Insofar as the products of combustion are discharged relatively close to ground level, a ground flare is not suitable if these gases are noxious or pollutant. Flare glow and noise may also be limiting factors.

12.22.3 Low pressure flares

There are in process plants various low pressure units which may produce an off-gas stream. These include storage tanks, and oil–water separator and wastewater treatment units. These off-gases may be routed to a low pressure flare. The tightening of controls on the emission of volatile organic compounds increases the number of situations where a low pressure flare may be needed. There are available a number of designs of low pressure flare such as small ‘stick’ flares.

The principal problems and hazards of a low pressure flare arise from the fact that the pressure in the discharging unit may be barely sufficient to maintain the flow. The pressure drop in the low pressure header should be calculated with care and the header adequately sized. Not all computer programs used for header design are suitable for this case, and it may be necessary to resort to hand calculation.

Where the discharge source pressure is insufficient, use may be made of a blower installed in the off-gas line. The use of an off-gas blower, however, is not an ideal arrangement in that it introduces rotating equipment which may fail and which may have the potential to act as a source of ignition. Designs based on off-gas blowers are discussed in the CCPS *Guidelines*.

12.22.4 Elevated flares

Elevated flares are used to handle both normal and emergency loads and are generally the system of choice except where environmental considerations prevent their use. An elevated flare is a normal feature of a refinery or a petrochemical plant.

A flare system consists of a flare stack and of gathering pipes which collect the gases to be vented. Other features include the flare tip, which typically has steam nozzles to assist entrainment of air into the flare, seals installed on the stack to prevent flashback of the flame and a knockout drum at the base of the stack to remove the liquid from the gases passing to the flare.

A typical elevated flare system is illustrated in the widely quoted diagram from API RP 521 shown in Figure 12.19. The elements of this system are gas collection pipework, knockout drum, seal drum, flare stack, flare tip, molecular seal, ignition system, steam injection system and purge system.

12.22.5 Flaring policy

The type of flare system required and the associated hazards depend very much on the venting and flaring policies adopted. Thus, for example, the decision to vent certain cold columns of an ethylene plant direct to the atmosphere can greatly reduce the size of the system and avoid the need to use the special steels required to handle cold gases.

The emergency load on the flare is highly dependent on factors such as the extent to which trip systems are used to reduce the frequency of discharges from pressure relief valves and on the staggering of such discharges.

Descriptions of practice in flaring include those given in the CCPS *Guidelines*, and the IChemE *Guide*, and by Barker, Kletz and Knight (1977), Bonham (1977), R. Schwartz and Keller (1977) and Straitz *et al.* (1977).

12.22.6 Flare system hazards

There are a number of hazards associated with a flare system. These include (1) failure of the collection system pipework due to low temperature embrittlement or corrosion, (2) obstruction in the flare system, (3) explosion in the flare system, (4) heat radiation from the flare, (5) liquid carryover from the flare, and (6) emission of toxic materials from the flare.

Even if these features are not such as to present a hazard, the latter three may be environmentally objectionable. Other features which cause environmental problems are (1) smoke in the flare, (2) glare from the flare, and (3) noise from the flare.

12.22.7 Flare collection system

The collection system which gathers the gas and vapour to be flared may comprise a single system or a set of systems in which different types of stream are segregated. Brittle fracture of the pipework in the gathering system is a hazard if the temperature of the steel is taken below its transition value. It may be necessary to use stainless steel in parts of the pipework where this condition may occur. Stainless steel may also be required for highly corrosive gases. The use of such steel is expensive, however, and the amount used is kept to a minimum. The extent to which stainless steel is required depends on the discharge and segregation policies adopted.

The CCPS *Guidelines* distinguish the following cases: (1) cold gas, (2) intermediate gas, (3) hot gas and (4) sour gas. Typical cold gas is ethane and lighter hydrocarbons flashing at or below −45°C. The material of construction used for the header is commonly austenitic stainless steel. Most gaseous effluents are hot wet gases above 0°C which are generally collected in a header made of carbon steel. Liquid droplets are separated in the knockout drum. A third class of gaseous effluent is cold dirty gases at a temperature intermediate between 0 and −45°C. For these use is frequently made of a header constructed in killed carbon steel.

Certain processes give rise to sour gas streams containing appreciable concentrations of hydrogen supplied which are toxic and corrosive. A sour gas stream is often provided with its own header, made of stainless steel. This segregation avoids the use of an expensive steel for the whole gas collection system. Frequently a separate flare is also used, which gives better control of the flaring.

Separate collection systems may also be provided for low and high pressure gas streams. The size of the system is generally governed by the low pressure streams, but if the system is to take all the discharges, it must be designed for

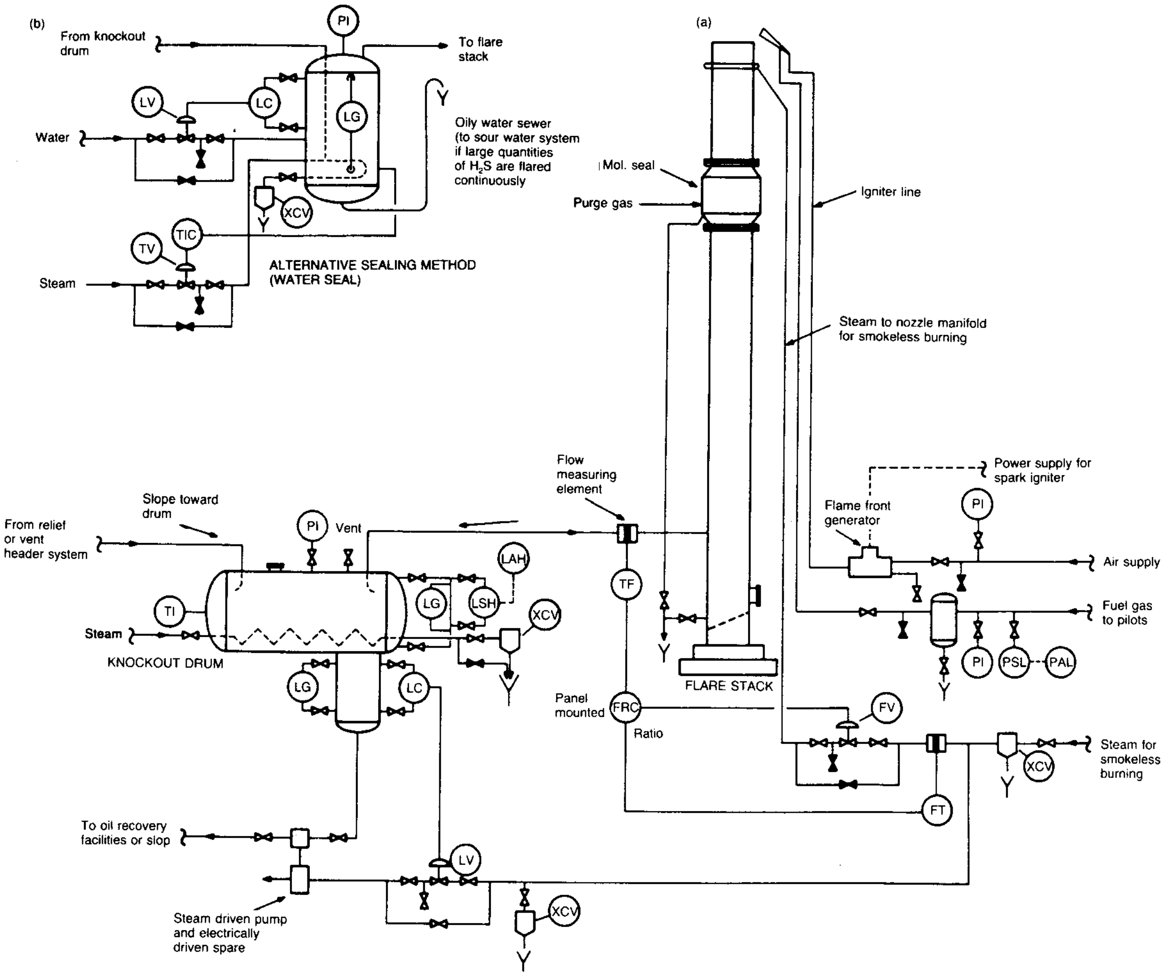

Figure 12.19 *Typical flare system (American Petroleum Institute, 1990 API RP 521): (a) flare system; and (b) alternative sealing system. Note: this figure represents an operable system arrangement and its components. The arrangement of the system will vary with the performance required. Correspondingly, the selection of types and quantities of components, as well as their applications, should match the needs of the particular plant and its specifications. FRC, flow recorder controller; FT, flow transmitter; FV, flow valve; LAH, level alarm (high); LC, level controller; LG, level gauge; LSH, level switch (high); LV, level valve; PAL, pressure alarm (low); PI, pressure indicator; PSL, pressure switch (low); TIC, temperature indicator controller; TV, temperature valve; XCV, steam trap*

the highest pressure which it could experience. It can be more economic to use a separate high pressure collection system with smaller piping.

Elements of the collection system are the various relief headers, the piping from the individual valves discharging into these headers and the flare header connecting these relief headers to the flare itself.

12.22.8 Flare system

The flare system consists of the collection system, the liquid knockout and seal drum system, the flare assembly and the ancillary equipment. The collection system is described in the next section. The flare assembly comprises the flare stack itself and the associated components, notably (1) the flare tip, (2) the pilot burners, (3) the pilot igniters, and (4) the steam injection system. Between the collection system and the flare stack comes the knockout and seal drum system. This typically includes a knockout drum and a seal drum, and may also have a quench drum.

12.22.9 Flare stack

The flare stack itself is tyically self-supporting or supported by guy wires. Associated components are (1) the flare tip, (2) the pilot burners, (3) the pilot igniters, (4) the steam injection system, and (5) the flame monitoring instrumentation.

The process design of the flare stack is essentially the determination of the stack height and diameter. API RP 521 gives one design method. The stack height is basically governed by the heat radiation from the flare, which is described below.

The stack diameter is set by the gas velocity. API RP 521 suggests that the design aim for a flare tip Mach number of 0.2 at normal gas flows and 0.5 for short, infrequent peak flows. It also states that a smokeless flare should be sized for the conditions under which it will operate smokelessly.

Flare stack conditions are discussed further in Chapter 16. Discussion of the other elements in the flare system is deferred until the flare stack obstruction and explosion hazards have been considered.

12.22.10 Flare system obstruction

Obstruction of the flare system is a hazard which can occur in a number of ways. One is the blockage of devices such as flame arresters and molecular seals. Another is the freezing of water seals in cold weather.

In some flare systems steam is injected at the base of the stack. The combination of contact with a cold gas such as ethylene and of cold weather may cause the water injected to freeze. There may also be other fluids in the flare system which are liable to freeze in cold weather. Freezing points of two common hydrocarbons are: benzene 5°C and cyclohexane 6.5°C.

The solidification of heavy oils can create blockage. Blockage can also be caused by refractory debris at the base of the flare stack, unless this is catered for in the design.

12.22.11 Flare system explosion

In a flare system there is a hazard that air will enter and form a flammable mixture. The hazard is particularly serious, because a source of ignition is always present in the form of the flame on the flare tip. Air may enter the flare system due to factors such as open valves or corrosion, or by diffusion down from the flare tip when the flame is not operating.

There are three specific conditions which are conducive to entry of air into the flare stack. One is when flaring has just ceased and cooling and shrinkage of the gas column in the stack draws air in. Another is when the gas being flared is light, especially if it is hydrogen, so that the pressure at the bottom of the stack is lower than atmospheric and air may enter through any apertures. The third is when the flare stack creates a natural draught and air leaks in at the bottom.

The precautions taken against the hazard of an explosion in a flare system divide into those aimed at avoiding a flammable mixture, such as (1) use of purge gas, (2) elimination of leaks, (3) monitoring the oxygen concentration, and those directed to mitigating the results of any ignition which may occur, such as (4) the use of flame arresters. Associated measures include the use of (5) molecular seals and (6) seal drums.

The discharge of waste gas to the flare system is inevitably somewhat erratic. If the gas flow falls too low and if there are air leaks into the system, a flammable mixture may form. Also if the gas flow is too low, the flame may go out, flash back down the stack or start pulsating. It is common practice, therefore, to maintain the gas flow in the flare system. This purge is usually a fuel gas. A method of calculating the purge gas rate is given by Husa (1964).

The best approach to the prevention of explosions in flare systems, however, is to prevent air from getting into the system in the first place and to monitor the oxygen content to check that this has been achieved. The elimination of air inleak into the pipework should be a specific objective. The prevention of air inleak through open valves is particularly important.

Air may also enter the system by diffusion down the stack when the flare is not operating. A molecular seal is often installed to prevent this. The use of molecular seals (described below) effects a large reduction in the purge gas flow required to prevent air diffusion down the stack.

The oxygen concentration in the flare system should be monitored. This is necessary in order to ensure that a large air inleak does not develop undetected.

The elimination of air inleak by the measures just described is preferable to the use of large purge gas flows to dilute such inleak. Devices which are used to guard against flashback of the flame down the stack are flame arresters and water seals.

12.22.12 Seal drums

A device widely used to prevent ingress of air from the flare stack into the gas collection system is a seal drum in which the gas passes through a water seal. API RP 521 gives one design for a seal drum together with the method of sizing. The IChemE *Guide* gives further design details.

A seal drum is generally designed for an internal pressure of at least 50 psig in order to withstand an internal explosion. Two problems with water seals are the creation of an uninterrupted gas passage through the water at high gas flows, which can render the seal ineffective, and the tendency to surge, which can affect operation of the flare. Proprietary water seals are available which are designed to overcome both these difficulties.

Another difficulty with water seals is the loss of the water from the seals. A further disadvantage of water seals is that they tend to freeze in cold weather. This problem is sufficiently serious that some operators prefer not to use them at all.

12.22.13 Molecular seals

A molecular seal is a device designed to limit the rate at which air can flow back into the flare stack. The principle of operation is to make the air flow through a set of concentric tubes in which it suffers reversals of direction so that its flow is reduced. A molecular seal is best located close to the top of the stack.

The benefit of a molecular seal is economy of purge gas. Molecular seals have the disadvantage that they tend to block up. One cause of blockage is corrosion products from the stack. Another is blockage by water or ice. In cold climates, prevention of ice formation requires the use of heating.

12.22.14 Flashback arresters

One common device for preventing passage of a flame along a pipe or stack is the flame, or flashback, arrester. A disadvantage of flame arresters is the tendency for the small passages to become obstructed. This problem is sufficiently serious that some companies do not use them.

12.22.15 Flare combustion and smoke control

Brzustowski and co-workers (Brzustowski, 1973, 1977; Brzustowski and Sommer, 1973; Brzustowski *et al.*, 1975) have studied the fundamentals of combustion in flare systems. Efficient combustion in the flame depends on achieving good mixing between the fuel gas and the air, and avoidance of a pure diffusion flame. Failure to achieve efficient combustion results in a smoky flame.

There are various methods which are used to promote efficient combustion. One of the principal methods is steam injection. The main function of the steam is to increase the entrainment and mixing of the air. The steam also takes part in the water gas shift reaction

$$C + H_2O = CO + H_2$$

and the steam reforming reaction

$$C_xH_y + H_2O = xCO + zH_2$$

Alternatively, low pressure air may be used to assist the entrainment and mixing of the atmospheric air.

There are available a number of proprietary flare tips for steam injection. One which is widely used is the Zink S type, which has a ring of small jets around the tip of the flare.

The equation given in API RP 521 for the amount of steam injection required to give a smokeless flare is that of Tan (1967):

$$W_{st} = W_{HC}\left(0.68 - \frac{10.8}{M}\right) \quad M > 16 \qquad [12.22.1]$$

where M is the molecular weight of the gas, W_{HC} is the mass flow of hydrocarbons (kg/s) and W_{st} is the mass flow of steam (kg/s). This is based on maintaining a steam/CO_2 mass ratio of about 0.7.

The control of the state of the flame by the manipulation of the steam supply has traditionally been done by the process operator relying on visual observation. Automatic control is difficult, because it is not easy to obtain a good measure of the state of the flame. One automatic system now in use is based on the measurement of the heat radiation at the root of the flame, where the difference in the heat radiated by a smoky and by a non-smoky flame is particularly pronounced.

There are a number of problems involved in achieving positive ignition and in retaining a flame on the flare tip as well as in preventing flashback. These problems are particularly difficult where the turndown ratio is high, which is often the case.

12.22.16 Flare heat radiation

The flare stack radiates intense heat which constitutes a potential hazard. The flame on a flare stack is often several hundred feet long and has a heat release of the order of 10^7 BTU/h. There is intense heat radiation from a flare. It is generally necessary, therefore, to have an area around the flare in which people do not normally work. A large flare can thus sterilize a sizeable area of land. It may be acceptable in some cases, however, to locate certain types of equipment within the flare compound, provided that the time which personnel have to spend in the compound is strictly limited.

Methods of caculating the heat radiated from a flare are given in API RP 521: 1990. This code gives the following equation based on the work of Hajek and Ludwig (1960):

$$D = \left(\frac{\tau F Q}{4\pi K}\right)^{1/2} \qquad [12.22.2]$$

where D is the distance from the centre of the flame, F is the fraction of heat released which is radiated, K is the allowable intensity of heat radiation, Q is the net heat release rate and τ is the atmospheric transmissivity.

Combustion in the flare is a complex process. In Equation 12.22.2 this complexity is subsumed in the factor F. This factor has traditionally been taken as a property of the fuel only. Some typical values of F are:

Gas	*F*	*Reference*
Methane	0.16	Brzustowski and Sommer (1973)
Propane	0.33	G.R. Kent (1964)
Butane	0.30	Brzustowski and Sommer (1973)
Ethylene	0.38	Brzustowski and Sommer (1973)

It has been shown, however, that the F factor depends also on other features of the flame such as the Reynolds number. The F factor is discussed by Brzustowski (1977) and Straitz *et al.* (1977).

Models of the flame on a flare are considered in Chapter 16.

Guidance on the permissible level of heat radiation from a flare in different situations is given in API RP 521 and BS 5908: 1990. Further discussions of acceptable levels of heat radiation are given by G.R. Kent (1964), R. Schwartz and Keller (1977) and Straitz *et al.* (1977). This aspect is considered in Chapter 16.

12.22.17 Liquid carryover in flares

Liquid carryover from the flare stack may result in a more smoky flame, in dispersion of burning drops of flammable material or dispersion of drops of toxic material. Liquid drops as small as 15 μm can negate the devices used for smokeless operation and give a smoky flame. The principal means used to prevent liquid drops reaching the flame is the use of a knockout drum at the base of the stack. It is sometimes difficult, however, to eliminate completely spray and condensation.

12.22.18 Toxics in flares

In some flares, gases containing materials such as chlorine and sulfur are burned, giving compounds such as HCl and SO_2. In such cases the flare stack should be sufficiently high to prevent unacceptable ground level concentrations of these toxic gases.

12.22.19 Flare environmental problems

Smoke, glare and noise from a flare are environmentally objectionable. The elimination of smoke has already been discussed. There is relatively little which can be done to eliminate light from the flame. If this is a serious problem, it may be necessary to use a low level enclosed burning system instead of a flare. Flare noise is discussed in Appendix 12.

12.22.20 Combined flare systems

In some installations, the flaring arrangements consist of an elevated flare combined with a ground flare. Normal operating and start-up loads are handled by the ground flare, while both flares are used to handle the relatively infrequent high volume emergency loads. In this way the environmental impact of the flaring is kept to a minimum.

12.23 Blowdown and Depressuring Systems

The response to a plant emergency may require the disposal of hazardous inventories. This is effected by the emergency blowdown and depressuring systems.

12.23.1 Blowdown systems

Disposal of liquid streams in an emergency is through the blowdown system. An emergency blowdown system has two basic features: treatment and disposal. An account of blowdown systems is given in the CCPS Engineering Design Guidelines.

Fluids which may require disposal are, in general, streams containing volatile organics or mixtures of volatile organics and water. More specific cases are reaction fluids vented from a reactor and cooling water contaminated with organics following a tube burst in a heat exchanger where the process fluid is at the higher pressure. The streams to be disposed of may contain flammable, toxic, corrosive or pollutant substances.

Blowdown streams may be unsuitable for immediate disposal, and may therefore require treatment. Principal types of treatment are disengagement of gases and vapours from liquid, and quenching to cool and partially condense hot vapours.

Disengagement is effected in a disengagement drum. The CCPS *Guidelines* refer to the API RP 521 knockout drum design. In a typical disengagement operation, involving a mixture of organics and water, the vapour is sent to a flare and the organic and water phases are separated by gravity in the drum.

Quenching is carried out in a quench nozzle, a quench drum or a blowdown drum. In a quench nozzle, water is injected to effect at least partial condensation of the blowdown fluid. In a quench drum, condensation of the blowdown fluid is effected by spraying water or other liquid onto it. The CCPS *Guidelines* refer to the API RP 521 quench drum design (figure D-2).

A blowdown tank is charged with an inventory of solvent through which the blowdown fluid is sparged, effecting condensation. The design of blowdown tanks for high rate releases of short duration has been discussed by Fauske and Grolmes (1992).

The sinks to which the liquid effluent part of a blowdown stream may be sent include a clean water sewer, an oily water sewer, a closed drain header and a tank for further treatment. The CCPS *Guidelines* give a detailed discussion.

12.23.2 Depressuring systems

Disposal of vapours from equipment at pressures below those of the pressure relief devices is by means of the emergency depressuring system. Depressuring is used to reduce hazard by removing vapour or gas from an equipment. This may be necessary where the equipment may fail at a pressure below the set pressure of the pressure relief valve, as in fire engulfment of a vessel which is filled with gas or one which contains some liquid but in which part of the walls is unwetted. Another situation where depressuring may be appropriate is where there may be benefit in anticipating the operation of the relief, as in the depressuring of a reaction runaway. A third case is where the equipment pressure is very high (say, 1000 psig) where depressuring reduces both the inventory and the stress in the equipment.

12.24 Pressure Containment

An alternative to pressure relief is pressure containment. This may be effected by ensuring that the system is sufficiently strong that any pressure generated is contained. This approach is currently applied only to a relatively limited extent. A discussion of the potential for wider application is given by Wilday (1991).

12.24.1 Problems of pressure relief

Protection against overpressure by the provision of pressure relief has a number of disadvantages. In general, pressure relief involves the use of an active system which is subject to failure and has to be inspected and maintained, and which may operate spuriously.

Pressure relief creates the problem of relief disposal. Environmental pressures make this an increasingly onerous matter. The basis for the design of the disposal train is often not well defined. The demands on the disposal train will be rare and its reliability in responding to them uncertain.

In some cases pressure relief is not a practical option. This is the case, for example, where the vent area on a reactor is simply too large to fit on the vessel.

12.24.2 Inherently safer design

The containment approach to overpressure protection requires that all the potential sources of overpressure be identified. Generic sources include (1) flow in, (2) momentum effects, (3) heat input, and (4) chemical reaction.

Likewise, in principle, it is necessary to identify all the potential sources of underpressure. Generic causes of underpressure include (1) flow out, (2) heat removal, and (3) chemical reaction. However, vacuum-causing events, such as vapour condensation, are often difficult to quantify. Thus in the case of underpressure the practical approach is often to design for full underpressure. The pressure deviation scenarios, including combinations, should then be considered and a credible worst case determined as the basis of design.

Design for full overpressure is assisted if sources of overpressure can be designed out. Wilday (1991) gives as examples (1) heat exchanger tube failure, (2) process heating, and (3) runaway reactions. A heat exchanger with high pressure gas in the tubes and liquid in the shell can present a difficult case for pressure relief. If the design is to be based on the common assumption of full bore rupture of a single tube, a large two-phase flow may be generated and the pressure relief requirement is severe. One solution may be to eliminate the pressure differential by raising the liquid pressure.

Other aspects of heat exchanger tube failure considered by Wilday include the use of a non-reactive cooling medium to eliminate reaction between the material cooled and cooling water and the merits of using air-cooled heat exchangers.

In the heating of a liquid, the total pressure due to the vapour pressure of the liquid and the partial pressure of non-condensable gases can be high. Methods of dealing with this problem include the use of a lower vapour pressure liquid, the provision of adequate gas space, the limitation of the heat input, the prevention of isolation of the equipment, and the use of a sufficiently high design pressure.

The measures suggested for avoidance of high pressure in reactors include laboratory screening to identify reaction exotherms and decompositions, use of a low vapour pressure solvent, avoidance of accumulation of reactants, use of a semi-batch configuration with one component fed continuously, and provision of a trip to cut off the feed.

12.24.3 Safety instrumented systems

One approach to the elimination of sources of overpressure is the use of safety instrumented systems. The use of such systems as an alternative to pressure relief is relatively limited and generally subject to strict conditions. Several international standards for the criteria and methods for the design and application of these systems have recently been promulgated by the ASME (Code Case 2211, 1996), the ISA (S84.01, 1996), and the IEC (IEC 61511, 2003). Guidance is provided by CCPS (2001/MM), Karcher *et al.* (1996).

The use of an instrumented protective system requires that all the sources of high pressure be identified and protected against. Another problem is that such a system is an active one, with the disadvantages already mentioned. Nevertheless, where the pressure relief option also poses severe difficulties, as in some reactor relief situations, there has been considerable interest in the use of instrumented protective systems. Work on the options for overpressure protection of reactors is described in Chapter 11.

Examples of the use of instrumented protection given by Wilday are (1) the protection of plant downstream of a pressure letdown valve by a trip which shuts a trip valve and (2) the protection of a reactor by a trip which shuts off the feed.

IEC 61511, *Functional Safety – Safety Instrumented Systems for the Process Industry Sector* is published in three parts. Part 1 provides the overview and core of the standard; it is entitled *Framework, Definitions, System, Hardware and Software Requirements*. It is divided into 19 sections, which deal with issues such as safety life cycle requirements, process hazard and risk analysis, allocation of safety functions to protective layers, SIS safety requirements specification, SIS design and engineering, factory acceptance testing, and SIS installation and commissioning, safety validation, operation and maintenance, modification, and decommissioning. This overview document describes the framework of the standard and the relationship between IEC 61511 and IEC 61508.

Part 2, referred to as 61511-2, is titled *Guidelines for the Application of 61511-1*. It has an organizational structure that is clause-by-clause identical to that of 61511-1, so as to provide clear, concise guidance on the application of that Part 1.

Part 3, 61511-3, is called *Guidance for the Determination of the Required Safety Integrity Levels*, and is divided into only three sections – scope, terms and definitions, and risk and safety integrity – general guidance. It also contains six informative annexes.

12.24.4 Problems of, and scope for, containment

Containment also has its problems. One general problem is protection against external fire. If a vessel is engulfed in a fire it is liable to fail due to overtemperature of the metal, even though the normal failure pressure has not been attained. There may also be additional hazards such as a liability of the material held to decompose.

There are certain measures which may be taken in some cases to limit the degree of potential fire exposure such as elimination or reduction of flammable materials near the vessel, provision of fire insulation and, possibly, location of the vessel above the level at which flame impingement could occur, but the overall conclusion is that it is very difficult to protect against external fire by containment.

There are certain types of equipment, such as atmospheric storage tanks, to which overpressure protection by containment is not applicable. The same applies to certain reactors. Wilday suggests that a plant protected solely by containment would be likely to be designed for a relatively high pressure and for full vacuum and would require to be engineered so as effectively to eliminate the external fire hazard or the need for fire relief. However, even if a policy of full containment is not adopted, the principles described may be used to limit the extent of pressure relief needed.

12.25 Containment of Toxic Materials

Some plants handle substances which rank as high toxic hazard materials (HTHMs) and the pressure system must ensure their containment. Guidance is given in the CCPS *Guidelines for Safe Storage and Handling of High Toxic Hazard Materials* (1988/3) (the CCPS *HTHM Guidelines*), which covers a wide range of topics. These guidelines are considered in Chapter 22. Many aspects are dealt with in other parts of the present text. Table 22.10 gives an indication of the chapter or section where relevant material is to be found.

Containments for HTHMs should be designed and constructed to standards which are higher than average. This applies to, among other things, the vessel wall thickness and connections, the materials of construction, the welds and the quality control.

12.25.1 Storage tanks and vessels

US standards and codes applicable to the storage of HTHMs include API Std 620: 1990, API Std 650: 1988 and the ASME *Boiler and Pressure Vessel Code* 1992. Also relevant is the ASME B31.3: 1990 *Chemical Plant and Petroleum Refinery Piping Code*.

API Std 650 is the standard for large oil storage tanks and has limited relevance to HTHMs. The safety factors and welding standards are less stringent and the tank relief is to atmosphere. The more relevant standard is API Std 620. For storage of larger quantities of HTHMs the preferred method will often be the use of refrigerated storage. This is dealt with in the standard in appendices R and Q which treat, respectively, tanks for refrigerated liquids stored in the temperature range 40 to −60°F and those stored at temperatures in the range down to −270°F.

Tank designs for refrigerated storage given in API Std 620 include both single and double wall metal tanks, but in the latter the outer wall is not intended to withstand major failure of the inner tank, either in respect of the hydrostatic head or of the temperature of the liquid stored. A more suitable design is one incorporating a high bund close to the metal tank. The CCPS *Guidelines* refer to that given the CIA *Refrigerated Ammonia Storage Code*, which is considered in Chapter 22. Materials of construction for refrigerated storage of HTHMs need to possess both the necessary impact toughness and corrosion resistance.

In design of storage tanks for HTHMs, particular attention should be given to features such as the foundations, the weld radiography and the pressure testing. API Std 620 contains stress relief requirements which are given in appendices H and I.

With a storage tank designed to API Std 620 the pressure relief is generally designed for normal 'breathing'; and for operational variations. These arrangements are less suitable for HTHMs, for which there are more severe restrictions on release to atmosphere. It may be necessary to use a closed relief and vent system. If direct relief to atmosphere is permissible, a rupture disc should not be used alone, as it does not reclose after opening.

API Std 620 contains provisions by which fire relief may be provided by a rupture seam. The CCPS Guidelines state that a rupture seam is not normally acceptable for HTHMs. The implication of this is that there need to be specific alternative arrangements for fire relief. Whatever arrangements are adopted, it is essential to ensure that the tank does not rupture at the wall–floor seam, which would allow discharge of its entire contents.

For storage vessels, the ASME Boiler and Pressure Vessel Code recognizes lethal service. It states that 'by lethal substances are meant poisonous gases or liquids of such a nature that a very small amount of gas or of the vapour of the liquid, mixed or unmixed with air, is dangerous to life when inhaled . . . this class includes substances of this nature which are stored under pressure or which may generate a pressure if stored in a closed vessel.'

The minimum wall thicknesses given in pressure vessel codes may yield for small vessels at low pressure relatively thin walls, and it may be prudent for certain HTHMs to use a thicker walled container. A suggestion made in the CCPS Guidelines is the use of compatible DOT cylinders.

The nozzles are frequently the weak points on a vessel and for containment of HTHMs they need to be of high integrity. Measures to ensure this include high nozzle specifications, use of sufficient thickness and of suitable welds and avoidance of small nozzles and of excessive projection. The CCPS Guidelines recommend that: nozzles should preferably be to Class 300 flanged welding necks; all nozzle-to-shell welds be full penetration welds; nozzles of less than 1–1.5 in. nominal bore (NB) be avoided, or at least protected; and nozzles less than 2 in. NB do not project more than 6 in., or be provided with additional strength or protection.

Since for HTHMs avoidance of catastrophic failure is of particular importance, use should be made of fracture mechanics so that, where practical, the vessel operates in the lower risk 'leak-before-break' regime. This is discussed in Section 12.28.

12.25.2 Pipework

As for tanks and vessels, so for piping – design and construction for HTHM service should be to high standards. Some features of high integrity pipework have been discussed in Section 12.7. Only those aspects are considered here where the toxicity of the material is of particular relevance.

ASME B31.3 recognizes a Category M Fluid Service in which the potential for personnel exposure is judged to be significant, and in which a single exposure to a very small quantity of a toxic fluid, caused by leakage, can produce serious irreversible harm to persons upon breathing or bodily contact, even when prompt restorative measures are taken. Chapter VIII of the code deals with Category M Fluid Service.

It is preferable that filling and discharge lines enter a storage tank through the top, thus avoiding piping penetration below the liquid level. However, for discharge this requires the use of submerged pumps, which may constitute a maintenance problem.

The pipework should have an adequate degree of fire protection. Whereas, in general, the emphasis in fire protection is avoidance of further releases which could feed the fire, in the case of HTHMs it shifts rather to the avoidance of serious toxic release. It follows that for HTHMs it may be necessary to provide pipework with protection which would otherwise be considered unnecessary. The CCPS Guidelines recommend a fire resistance of at least 30 min at 1100°F.

12.25.3 Limitation of release

There are a number of devices which may be used to shut off or reduce releases of HTHMs. These include EIVs, NRVs, excess flow valves, restrictor orifices and pump trips.

Storage tanks and vessels for HTHMs should be provided with emergency isolation valves or control valves with separate shut-off facilities. Other situations which may merit an emergency isolation valve are a large vapour line on a pressurized storage vessel and a long pipeline.

NRVs, or check valves, can be used with the purpose of preventing back flow out of a tank in the event of rupture of a liquid line on it, but are notoriously unreliable and are not suitable as the sole device in a critical duty. The flow from a line may be reduced by the use of an excess flow valve or a restrictor orifice. Another measure is remote shut-off of pumps providing the pressure behind the release.

12.25.4 Secondary containment

There are a number of arrangements which can be used to contain a release and prevent its escape to atmosphere. Such secondary containments include double-walled equipment, enclosures and bunds. Pressure relief and vent systems are also sometimes so classified. Common to all these arrangements is the need to provide in addition some form of disposal system.

Double-walled equipment is used particularly for storage tanks. In particular, the principle is exploited in the design of large refrigerated ammonia storage tanks. This is described in Chapter 22.

The double-wall principle is also used to a limited extent for pipework. One system involves the enclosure of the pipe carrying the HTHM in a second, concentric pipe. The annular space between the two pipes is filled with inert gas either at a pressure higher than that in the inner pipe or at a lower pressure with monitoring to detect leakage of the toxic fluid. An alternative system involves the use of double seals on flanges and of bellows seals on valves, both purged with monitored inert gas.

The use of an enclosure building provides another form of secondary containment but allows accumulation of small leaks. It therefore requires the provision of toxic detectors and alarms and of ventilation and disposal systems. Where toxic liquids are handled, it is also necessary to provide for their retention, collection and disposal. The sump should be of small cross-sectional area but deep, in order to minimize vaporization. If there is a possibility of an internal overpressure sufficient to cause structural damage, consideration should be given to this.

Material from the pressure relief and depressuring, or blowdown, devices should be collected in a closed relief or vent header system. This is usually a common header, though in some instances this approach may need to be modified in order to avoid a problem arising from the interconnection of systems. The header typically passes to a knockout drum or catchpot and then to the disposal system, usually a flare or scrubber. Disposal systems are considered in Chapters 11 and 22.

12.26 Pressure Systems for Chlorine

As just described, the design of pressure systems for hazardous materials requires special consideration. This is illustrated by the requirements for chlorine, which is highly toxic and, if wet, very corrosive, and which is produced in large tonnages.

The handling of chlorine is treated in the publications of the Chlorine Institute, including the *Chlorine Manual* (1986 Pamphlet 1). The generally used code has been the Chemical Industries Association (CIA) *Code of Practice for Chemicals with Major Hazards: Chlorine* (BCISC, 1975/1) (the CIA Chlorine Code). Another CIA publication has been *Guidelines for Bulk Handling of Chlorine at Customer Installations* (1980/9). These are both now superseded by HS(G) 28 *Safety Advice for Bulk Chlorine Installations* published by the Health and Safety Executive (HSE, 1986) in cooperation with the CIA; it is this document which now appears in the CIA publication list.

An account of chlorine as a chemical is given in Chapter 11. The storage of chlorine is considered in Chapter 22 and its transport, including pipeline transport, is discussed in Chapter 23. The principles of chlorine handling are, in large part, applicable to the handling of many other chemicals which are toxic, irritant and non-flammable, and are made on a large scale.

12.26.1 Chlorine and chlorine plants

Typically, chlorine is produced in integrated systems in which part of the production is liquefied and transported away and part is consumed as gas in user plants within the works. Such a system is illustrated in Figure 18.11.

The quantity of chlorine handled in a producer plant, or cell room, is generally much greater than in a user plant. In a producer plant the important thing is to be able in an emergency to stop the production of the gas quickly and so avoid a large release to atmosphere. This requires that means be provided to detect this need, to communicate it and to shut-down rapidly and safely. There should be facilities for emergency venting of the chlorine to gas absorption plant.

In a user plant, the size of potential chlorine release is usually less, but the operating conditions tend to be more arduous. In such a works chlorine is handled both as gas and as liquid (see Chapter 11). Particularly important in chlorine handling are the facts that wet chlorine attacks mild steel and that chlorine forms the unstable explosive compound nitrogen trichloride.

12.26.2 Materials of construction

The usual material of construction for dry chlorine is mild steel. If the chlorine is wet, however, it attacks mild steel severely. It is essential, therefore, for water to be excluded if mild steel is to be used for handling chlorine. Corrosion is particularly severe with liquid chlorine if there is a separate water phase. The corrosiveness of wet chlorine also depends on the temperature.

The *Chlorine Code* states that the normal dissolved water content of chlorine is 20–60 ppm and that this is satisfactory for the common materials of construction. In conformity with BS 3947, commercial chlorine should have a maximum water content of 100 ppm.

Mild steel equipment for use with dry chlorine itself needs to be dried out before commissioning. HS(G) 28 recommends purging with air or inert gas down to a dewpoint of −40°C.

Corrosion of mild steel by chlorine is also affected by temperature. The *Chlorine Code* states that attack is significant at about 200°C and rapid at about 230°C and that it is normal practice to impose a limit of 120°C. This is the normal limit advised by HS(G) 28, for example, for steel tubes in chlorine vaporizers.

Materials widely used for handling wet or dry chlorine gas include ebonite-lined mild steel or reinforced polyester resin. Glass and stoneware may also be used in appropriate applications. With certain exceptions, plastic materials are unsatisfactory for liquid chlorine. Another material which can be used for chlorine gas or liquid up to about 100°C is titanium, but only provided that the fluid is wet; titanium is attacked by dry chlorine. If this material is used for wet chlorine, therefore, there must be assurance that it will not be contacted with dry chlorine, even under fault conditions, otherwise some alternative material should be selected. There are available carbon steels which are suitable for the low temperatures found in the normal handling of chlorine.

12.26.3 Vessels, pipework and equipment

Pressure systems for handling chlorine should be of a particularly high standard, with appropriate attention paid to control of impurities, isolation arrangements, protective devices, pressure relief arrangements and protection against external damage.

Chlorine vessels are designed to normal pressure vessel codes but with the additional requirements stated in

HS(G) 28. Storage tanks and vessels for chlorine are discussed in Chapter 22. For chlorine process vessels, particular consideration should be given to possible impurities in the chlorine, which are a more severe problem in process than in storage.

Chlorine pipework may carry chlorine gas in which the presence of liquid is excluded, chlorine gas which may contain some liquid, or liquid chlorine. Pipelines are designed for dry gas, wet gas and dry liquid. HS(G) 28 gives guidance on pipework for liquid chlorine. The pipework should be designed, fabricated, inspected and tested to a recognized code. The design pressure should be in accordance with the code, but in any case not less than 12 barg which corresponds to a design temperature of 45°C.

Seamless steel tubing is preferred, but resistance seam welded tubing that has been welded and stress relieved automatically during manufacture is acceptable. The number of flanged joints should be kept to a minimum. All butt welds should be fully radiographed or ultrasonically examined.

Gaskets used for liquid chlorine are of compressed asbestos fibre and should be to BS 2815 Grade A. The use of an incorrect gasket for chlorine can be hazardous and gaskets should be tabbed if there is any possibility of misidentification.

Pipelines should be sited so as to be as safe as possible from impact, fire or other threats. They should be protected from external corrosion, but accessible for inspection and maintenance.

HS(G) 28 gives less guidance on lines for chlorine gas. The following guidance is given in the *Chlorine Code*, but it should be borne in mind that it is somewhat dated. Gas pipelines in which it is known with confidence that there will be no liquid chlorine are usually designed so that they are sufficiently strong to withstand the highest pressure which can be applied or so that relief is inherent in the design, and do not normally require relief devices. Pipelines for gas which may contain liquid are operated at rather higher pressures than the previous ones, but are not necessarily designed for the full pressure which could arise from the vaporization of trapped liquid chlorine. Usually some relief capacity is necessary to cater for any liquid present and this should be considered in relation to the gas absorption facilities. Often such pipelines contain vaporized chlorine. It may be appropriate to provide trace heating. This is necessary if the lowest winter temperature to which the pipeline is exposed could cause formation of the liquid. The gaskets used for dry gas are compressed asbestos fibre, whilst those for wet gas are a special rubber. Although the latter is suitable for low pressure dry gas, it is quite unsuitable for liquid or high pressure gas. It is essential, therefore, that means such as tabbing be provided to ensure that the correct gasket is used.

Liquid pipelines may be subject to overpressure caused by hammer blow resulting from rapid closure of valves and by thermal expansion of the liquid. Slow-acting valves and surge vessels may be used to protect against hammer blow from liquid chlorine. Good communication between operators is also helpful in reducing this problem.

Liquid chlorine has a high coefficient of thermal expansion and the possible effects of liquid thermal expansion should always be considered in liquid chlorine pipework systems. The trapping of liquid between two valves should be minimized by a combination of design and operations measures. Liquid trapping is particularly likely to occur if there is a proliferation of valves which can close automatically. This may be avoided by the judicious use of a proportion of valves which are manually operated.

Traditionally, for small lines the industry has placed some reliance on liquid thermal relief by the springing of flanged joints. Thus, the *Chlorine Code* states that on smaller systems the release may be relatively small and harmless, and indicates that in order to provide such relief flanged joints should not be eliminated completely.

HS(G) 28 states that if the capacity of the system is such that a release could have serious consequences, automatic means of relief should be provided and that reliance on the springing of flanged joints for thermal relief is not acceptable. It refers to two means of relief: (1) a bursting disc discharging to a suitable disposal system and (2) an expansion tank designed to accommodate the gas phase.

The *Chlorine Code* states that an expansion bottle or other relief device is normally used if:

(1) the system is fully welded and includes no flanged joints;
(2) there is a substantial length of pipework involved such that the volume of chlorine released in easing a potential pressure would be significant;
(3) the two valves, the closure of which traps the liquid chlorine, are under the control of different operators and there is a reasonable chance of this occurring without either being aware of it;
(4) overpressure due to external causes can be foreseen.

However, it also states that an expansion bottle is effective only provided it contains non-condensable inert gas and does not fill up with liquid. HS(G) 28 states that, in view of the difficulty in determining whether the gas space contains chlorine or inert gas, the use of such a device is not recommended for new installations.

Arrangements for pressure relief of chlorine pipelines using these two systems are given in HS(G) 28. In both cases the relief volume needs to be at least 20% of the line volume. Figure 12.20 shows the two systems. Figure 12.20(a) gives the bursting disc system. The disc relieves into a pressure vessel fitted with a pressure alarm and vents from there to the disposal system. Figure 12.20(b) gives the expansion vessel system. There is a heating system to maintain the temperature at around 60°C. There are a number of further design requirements, which are given in the guide. In each case the vessel used should be a pressure vessel and entered as such in the pressure vessel register.

The possibility of low temperature embrittlement should be considered carefully for pipelines carrying liquid chlorine. The line may be subjected to temperatures down to the normal boiling point of chlorine (−34°C) or even lower. Pipelines carrying liquid chlorine are liable to ice up on the outside and to corrode under the ice, and require to be protected by suitable wrapping or painting.

Valves for chlorine pipelines should be carefully chosen, particularly in respect of corrosion resistance, strength against possible overpressures, leak-tightness of the gland and ease of removal and maintenance. Some requirements for valves in liquid chlorine systems are given in HS(G) 28. Such valves should preferably be in forged steel, and in any event not in cast iron. If the valve is of a type in which liquid chlorine may become trapped, measures need to be taken to prevent the development of excessive pressure due to temperature rise. The types of valve referred to in HS(G) 28 as

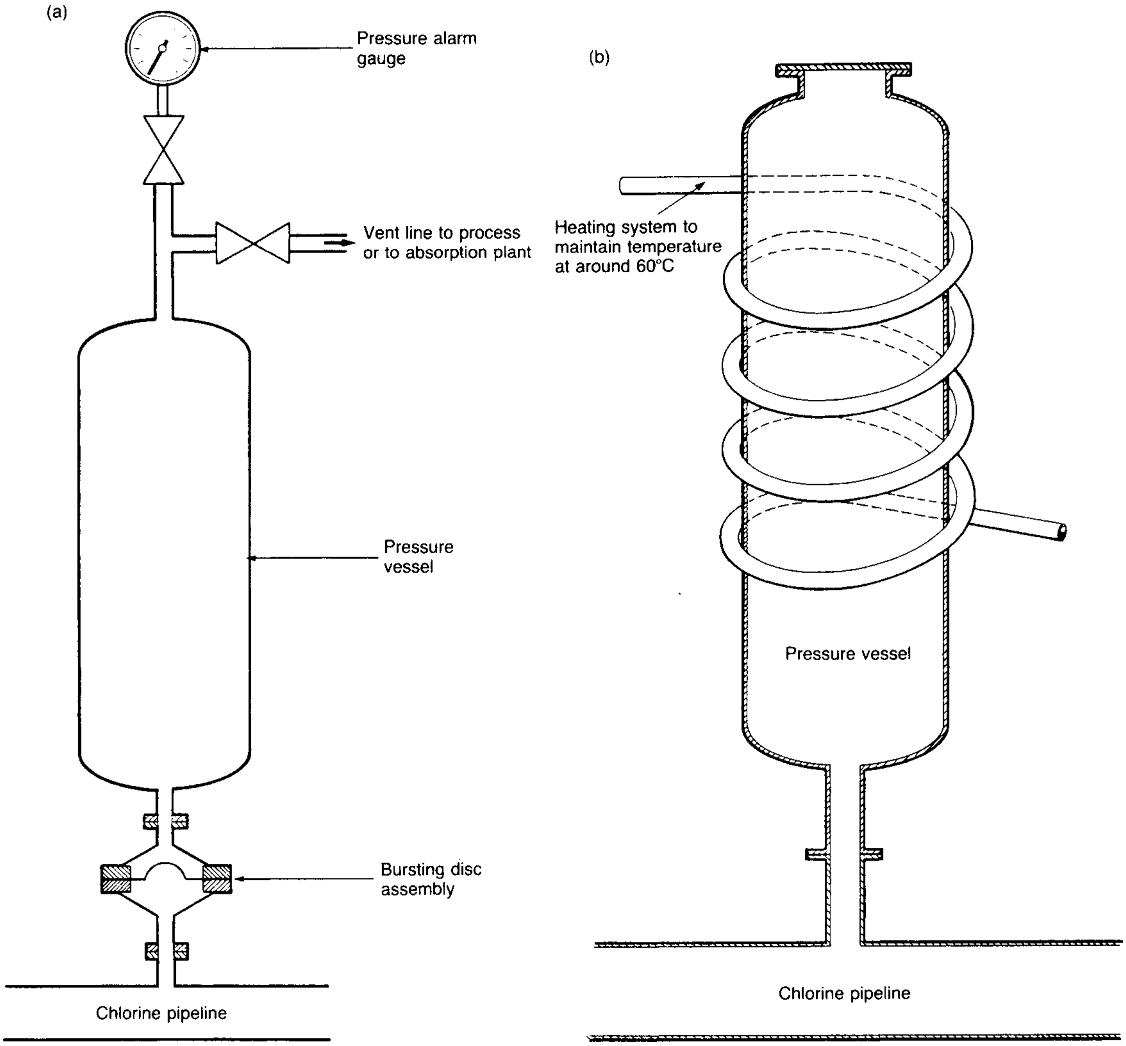

Figure 12.20 *Overpressure protection arrangements for chlorine pipelines (Health and Safety Executive, 1986 HS(G) 28): (a) bursting disc system; and (b) expansion vessel system (Courtesy of HM Stationery Office. Copyright. All rights reserved)*

suitable for liquid chlorine or dry chlorine gas are (1) vertical globe valves, (2) conical plug valves and (3) ball valves. Detailed guidance is given on each type.

Isolation arrangements are particularly important in chlorine systems. A single valve should not be relied on to give complete isolation. More positive isolation is required using means such as the provision of spool pieces which can be removed and replaced by blanks and the use of slip plates. Where the latter are to be utilized, the layout and piping should provide for this. Large low-pressure chlorine gas mains are particularly difficult to isolate effectively due to the size of the line and the dirtiness of the gas. Ease of removal of valves and of insertion of slip plates is especially important in such systems.

Every item of equipment which contains, and could release, a significant quantity of chlorine should have a means of isolation and a means of venting to a gas absorption unit. Stop valves at inlet and outlet are the normal means provided for effecting immediate isolation, but the arrangements should facilitate the insertion of slip plates.

Chlorine liquefiers are subject to the general requirements for chlorine vessels, but involve some special considerations. The operating temperatures are low and require suitable materials of construction. The chlorine gas, even after drying, is not completely clean and tends to cause blockage and corrosion, so that ease of cleaning is important. The refrigerant used should not react with the chlorine if there is a leak.

Likewise, there are some particular considerations in chlorine vaporizers. There is a potential for creating overpressure. The higher temperatures are conducive to increased corrosion. The impurities, particularly nitrogen trichloride, may concentrate and explode. There is a possibility of failure of the heating surfaces. Materials of construction for chlorine vaporizers should withstand both the temperatures and impurities. There should be effective control on pressure, temperature and level. Pressure relief should be provided and should take account of the possibility of heating surface failure. There should be specific arrangements to prevent concentration of nitrogen trichloride. The effects of heating surface failure should be thoroughly reviewed and means provided for its prompt detection. Chlorine vaporizers are utilized by users of chlorine which are not necessarily large chemical works. A robust design is therefore important. A further discussion of chlorine vaporizers is given in Chapter 22.

12.26.4 Compressors, pumps and padding

Compressors are used to re-compress chlorine vapour and need to be suitable for intermittent operation. Dry carbon ring and diaphragm types are used, the latter having double stainless steel diaphragms with inert fluid in between. The shaft of a carbon ring compressor needs to be sealed so as to prevent escape of chlorine and ingress of moist air. The shaft glands should be pressurized during operation with dry inert gas. After use the compressor should be purged with dry air to prevent leakage of residual chlorine.

The temperature rise in the compressor may need to be controlled. The cooling arrangements should take account of the possibility of water leaks. Direct water cooling should be avoided. It is preferable to use air cooling. The compressor should have a bypass allowing the chlorine to be recycled so that its temperature is high enough to avoid liquefaction in the delivery lines. There should, however, be an alarm which will activate if the temperature exceeds 90°C.

In general, transfer of liquid chlorine may be effected by the use of (1) chlorine vapour at the vapour pressure of the liquid, (2) dry compressed chlorine vapour, (3) dry compressed padding gas, and (4) pumping. The choice of method for different applications such as transfer from storage to consuming units and unloading from tankers to storage is discussed in HS(G) 28. For the former, all four methods are listed, but with the first two preferred, whilst for the latter the third method is the preferred one, with the second as a possible alternative.

In many cases, transfer of liquid chlorine from storage may be effected under the vapour pressure of the liquid. If this method is used, factors to be taken into account are the effect on the vapour pressure of low external temperatures and the need to maintain in the vessel a positive pressure, which should be specified. Alternatively, liquid chlorine may be transferred by pressure of gas, such as dry air or nitrogen, or of chlorine vapour from a vaporizer or compressor. HS(G) 28 gives the following guidance.

Gas used for transfer of liquid should be a dedicated supply. Nitrogen at pressure may be obtained from a liquid nitrogen vaporizer. Compressed air can be provided by an air compressor. It is highly desirable that this be an oil-free machine; if oil lubrication is used, the machine should have an oil filter which is regularly maintained. Measures should be taken to ensure that the air is dried to a dewpoint of −40°C. The padding gas, nitrogen or air, should have its own pressure control and pressure relief arrangements. It should be held in a gas receiver with a relief valve set to operate at the safe working pressure of the chlorine plant or 150 psig, whichever is the lesser. Further detailed requirements are given in the guide.

Chlorine vapour for padding may be obtained by recompression of vapour from a storage vessel or by vaporization of liquid chlorine. The storage vessel from which transfer is made should have a design pressure and pressure relief arrangements which protect against pressures which the padding gas or vapour can develop. It should also have a relief to the gas absorption facilities.

It may be necessary to pump liquid chlorine if it has to be delivered at a higher pressure (say, 100 psig) or if the use of dry padding gas is for some reason inappropriate. Some of the problems in pumping chlorine are discussed in the *Chlorine Code*. Pump cavitation can be a problem in pumping chlorine, which tends to vaporize. It is essential to provide sufficient liquid head on the suction side to avoid liquid flashing. Severe cavitation can damage the pump or even cause the casing to fail. Another problem in pumping chlorine is seal leakage. This virtually rules out the use of rotating shaft seals. Liquid chlorine pumps are generally canned, diaphragm or submersible types. The code recommends that centrifugal pumps should be provided with a bypass to a pumping tank to prevent liquid boiling and that a positive displacement pump should have a pressure relief valve on the outlet bypassing to the suction.

HS(G) 28 describes the use of an arrangement in which liquid chlorine is transferred from a storage vessel using a canned pump. There should be sufficient NPSH and a remotely operated emergency isolation valve installed either inside the vessel or between it and the pump. The guide also discusses the use of submersible pumps.

12.26.5 Pressure relief and gas absorption

The philosophy of pressure relief for chlorine has traditionally been somewhat different from that for most other materials. It is stated in the Chlorine Code thus:

(1) Any relief system shall be regarded as a safeguard of last resort; its existence shall not be regarded as an alternative to providing protective systems and operating instructions such that process conditions cannot, in the absence of human or equipment failure, lead to the relief conditions arising.
(2) Relief to atmosphere shall be sanctioned only as a last resort when the consequences of not doing so would be worse.
(3) A relief device shall not be isolated unless approved alternative arrangements to protect the vessel have been made.

Likewise, the philosophy in HS(G) 28 for chlorine systems lays emphasis on prevention of overpressure with pressure relief as a last resort. These measures include (1) prevention of overfilling of storage tanks by use of weighing systems or of ullage pipes giving warning of entry of liquid into vent lines, combined in both cases with alarms and (2) prevention of overpressure by pressure control and relief on the padding gas system and storage vessel high-pressure alarms.

As a last line of defence, a chlorine storage vessel should be provided with pressure relief. This pressure relief should be provided by a bursting disc rather than a relief valve, because chlorine tends to corrode the latter. The relief should normally pass to an expansion vessel. For a simple system consisting of a single storage tank and expansion tank, a single bursting disc system may suffice, installed directly on the storage vessel without isolation valves. A system commonly found on much existing plant is two bursting discs in series with a pressure alarm on the intervening space and with isolation valves upstream and downstream of this assembly, with both valves locked open. The preferred arrangement is two such assemblies of bursting discs and isolation valves in parallel. In this case one arrangement is that the valves are interlocked and another that the upstream valves and at least one downstream valve are locked open.

Where there are several storage vessels, they may each be provided with an expansion vessel or there may be a common expansion vessel. An expansion vessel should have a capacity at least 10% of the largest storage vessel. It should be capable of being vented manually to an absorption system. It should be fitted with a high pressure alarm to indicate build-up of chlorine. Any necessary measures should be taken to ensure that the expansion vessel is not itself overpressurized.

Arrangements should be made to ensure that facilities exist for absorption of chlorine gas vented by the pressure relief system. In some installations, there are chlorine-consuming plants to which the relief gas can be routed, and a separate gas absorption facility may be deemed unnecessary. In this case, it is essential to ensure that the absorption capability is available whenever it may be required. Usually it is necessary to provide a separate gas absorption facility. This should be a high reliability plant with adequate redundancy and comprehensive instrumentation. HS(G) 28 gives detailed recommendations.

The pressure relief arrangements should cater for fire relief as well as operational relief. In some cases it may be necessary to provide protection against the risk of explosion of chlorine with other gases, particularly hydrogen. The design of such explosion relief is a specialist matter. The Chlorine Code refers to the possible need for explosion relief to atmosphere in unavoidable cases, and states that this a matter for expert advice. HS(G) 28 does not consider this eventuality.

12.27 Failure in Pressure Systems

Maintenance of the integrity of the pressure system and avoidance of loss of containment is the essence of the loss prevention problem. It is necessary, therefore, to consider the failures which occur in pressure systems. Of particular importance are catastrophic failures in service.

Catastrophic failure of a properly designed, constructed and operated pressure vessel is comparatively rare. The most common cause of such failure is inadequate operational procedures. Most failures in pressure systems occur, however, not in pressure vessels but in the rest of the system, which includes pipework, valves and fittings and equipment such as heat exchangers and pumps.

The problem of failure in pressure systems is treated here by first describing some principal causes of failure, particularly sudden failures, and then giving some historical data on failure. In the present context it is service failures which are of prime importance. Service failures of pressure systems are generally caused by exposure to operating conditions more severe than those for which the system was designed.

It is usual to classify service failures as (1) mechanical failure, through stress and fatigue and (2) corrosion failure, although many failures have an element of both of these. Accounts of causes of failure in pressure systems are given in *Defects and Failures in Pressure Vessels and Piping* (Thielsch, 1965) and *Inspection of Chemical Plant* (Pilborough, 1971, 1989).

12.27.1 Materials identification errors

Mistakes in identifying materials of construction which result in the construction of plant using the wrong materials are a significant problem. Such errors are particularly likely to occur where the materials have a somewhat similar appearance, for example low alloy steel and mild steel, or stainless steel and aluminium-painted mild steel. It is necessary, therefore, to exercise careful control of materials. Methods of reducing errors involve marking, segregation and instrument spot checks. For critical applications, is may be necessary to carry out a full 100% *in situ* check on materials using an instrument such as a Metascope.

Misidentification of materials and some accidents caused by it have been described by W.D. Clark and Sutton (1974). In 1984, a leak due to erosion failure on a hydrocarbon liquid line at Fort McMurray, Alberta, resulted in a major fire (Case History A109). The investigation found that inadvertently an 18 in. long section of carbon steel had been inserted into an alloy steel line.

12.27.2 Mechanical failure

Some common causes of mechanical failure in process plant are:

(1) excessive stress;
(2) external loading;
(3) overpressure;
(4) overheating;
(5) mechanical fatigue and shock;
(6) thermal fatigue and shock;
(7) brittle fracture;
(8) creep;
(9) hydrogen attack.

Excessive stress in equipment may be caused by factors such as stress raisers or by malpractices such as uneven tightening of flanges.

Equipment may be externally loaded by loads carried on additions such as lugs, supports, brackets and hangers. Common sources of external loads are platforms, stairs and ladders. Movement of foundations may cause external loads, as may restraint on thermal expansion of pipework passing through concrete walls. Wind and occasionally ice may contribute a significant external load.

Overpressure may occur due to failure of a pressure relief valve to fulfil its function. Such failures may be due to poor design or incorrect operation, or to relief valve failure. Freezing of liquid, particularly in pipework, is another cause of overpressure.

Gross overheating may cause rapid failure due to operation well outside the temperature range of the material. In particular, direct flame impingement can give rise to sudden failure. Less severe overheating can cause creep as discussed below.

The other causes of mechanical failure are now considered.

12.27.3 Mechanical fatigue and shock

Conditions which give rise to mechanical fatigue include (1) pressure variations, (2) flow variations, (3) expansion effects, and (4) imposed vibrations. Stress cycling can be caused by normal changes of pressure in the process. Normal flow fluctuations or effects such as hammer blow or cavitation also give rise to stress cycles. So do differential expansions and contractions of the process plant. Other stress cycling is imposed by vibrations from such equipment as compressors, pumps or valves.

Although there is often some degree of vibration in pressure vessels and pipework, it is usually at a sufficiently low level as not to cause fatigue failure. In some cases, however, fatigue can progress very rapidly. Thielsch quotes the case of the fatigue failure of a carbon monoxide generator which was subjected in a period of only 17 days to several hundred million stress cycles.

Mechanical shock differs from mechanical fatigue in that the load is greater and causes failure within only one or a few cycles. Shock is often caused by hammer blow or liquid slugs. In 1975 at Antwerp, Belgium, a leak of ethylene at high pressure due to fatigue failure of a vent connection on the suction of a compressor led to an explosion and fire at a low-density polyethylene plant (Case History A74). Six persons were killed and extensive damage was done.

12.27.4 Thermal fatigue and shock

Similarly, the distinction between thermal fatigue and thermal shock is that in the latter the applied temperature difference and the rate of change of temperature are greater and cause failure in one, or a few, cycles. A given temperature cycle may give rise to thermal fatigue or shock, depending on the material. It may constitute thermal fatigue for a ductile material, but shock for a brittle one. Thermal cycling is caused by (1) intermittent operation and (2) particular equipment conditions.

There are many types of intermittent operation ranging from batch processes to throughput changes and including forced shut-downs. These all create thermal stress cycles. This source of thermal fatigue is much reduced if the plant is operated continuously, even though the operating temperatures may be relatively high.

Thermal fatigue is also caused by the conditions in particular types of equipment. Steam desuperheaters using direct water spray cooling may suffer thermal fatigue failures. Thermal fatigue occurs in reducing valves due to repeated flow changes. Slugs of condensate can cause thermal fatigue in steam lines.

12.27.5 Brittle fracture

The materials used in plant handling low temperature fluids should have a ductile–brittle transition temperature below not only the normal operating temperature but also the minimum temperature which may be expected to occur under abnormal conditions. If this requirement is not observed and cold fluid contacts metal below the transition temperature, brittle fracture may occur. Brittle fracture is catastrophic, since the fracture can propagate at a velocity close to that of sound.

In 1973 at Potchefstroom, South Africa, an ammonia tank suffered brittle fracture, which resulted in the release of some 30 ton of ammonia (Case History A65). The fracture occurred in a dished end which was fabricated in carbon steel and which had not been stress relieved after manufacture. The minimum transition temperatures obtained by subsequent testing were 20°C for the fragment and 115°C for the remaining part of the dished end. Thus, the metal was below its transition temperature under normal operating conditions.

The possibility of accidental entry of cold fluids into parts of the plant where they are not normally present and the resultant hazard of brittle fracture present a difficult problem. In general, the best practice is to use suitable materials in any part of the plant where it is realistic to expect that low temperature fluids could enter under abnormal conditions. But alternative means of protection such as trip systems may be used in some cases. An example of the application of hazard analysis to this problem was discussed in Chapter 9.

Where a liquefied gas is held under pressure, sudden depressurization to atmospheric pressure will cause the temperature of the gas to fall to its normal boiling point. This could be below the transition temperature of the metal unless this has been taken into account in the design.

It is not only the vessels and pipework which may suffer low temperature embrittlement, but also features such as vessel supports and flange bolts. It is essential, therefore, for these latter also to be made of the appropriate material.

12.27.6 Creep

The problem of creep at high temperatures has already been discussed in Section 12.3. Since design for high temperatures is based on creep strength, failure due to creep is usually unlikely under normal operating conditions and is generally caused by abnormal conditions such as maloperation or fire. It is appropriate to emphasize here the very rapid increase in creep rate with temperature. For mild steel in the creep range, a temperature increase of about 10–15°C is sufficient to double the creep rate. A stress which gives an 11-year life at 500°C can result in rupture in 1 h at 700°C.

Creep involves plastic deformation and, eventually, rupture. However, some metals have a very low ductility in the normal creep range, although they are more ductile at low and at very high temperatures. Low ductility fractures with an elongation of less than 1% are frequently associated with the formation of cavities at the grain boundaries. The development of cavities can occur at low stress over long time periods. The application of higher temperatures and higher strain rates, as in a fire, can accelerate cavitation and cause low ductility failure.

Creep cavitation of stainless steel occurred on the plant at Flixborough, as described in Appendix 2. The 8 in. pipe, which was made of 316L stainless steel, had a 50 in. rupture which was initiated by creep cavitation. It was estimated that for failure in 20 min, a temperature of 900–950°C would have been needed.

If there has been overheating, there may be creep effects such as deformation and distortion which can be detected by visual examination and by measurement. Often there are also oxidation and scaling. But, since creep can occur with very little deformation, it may not be readily detectable. Expert advice should be sought if this is a possibility.

Fire on a process plant may result in local overheating and hence creep. Equipment should be protected against overheating by fixed protection such as fire insulation and by fire fighting. If equipment has been exposed to fire so that creep may have occurred, expert advice should be sought before it is put back into service.

The process should be operated at the temperatures specified. If an alteration is proposed, its effect on creep should be checked. This includes such alterations as change in lagging thickness, since this affects equipment temperature.

Further information on creep is given in TDN 53/3 *Creep of Metals at Elevated Temperatures* (HSE, 1977).

12.27.7 Hydrogen attack

Mild steel is subject to the following types of hydrogen attack: (1) hydrogen blistering and (2) hydrogen embrittlement and damage.

Hydrogen blistering can occur when atomic hydrogen diffuses into steel. Normally the atomic hydrogen diffuses right through, but if it encounters voids it forms molecular hydrogen, which can generate pressures of several hundred bar. Internal splitting of the steel occurs and gives surface blisters. Steels which are dirty and contain numerous voids, laminations and inclusions are especially prone to hydrogen blistering. Hydrogen blistering has been a quite common problem in catalytic reformers and has occurred at temperatures as low as low as 315°C. It has also been reported in butane storage tanks with butane run down from a gas separation treatment plant at 21°C. The butane was sometimes contaminated with small amounts of water with traces of hydrogen sulphide. When corrosion occurs, the latter favours the evolution of atomic rather than molecular hydrogen.

At high temperatures and high hydrogen partial pressures, steels can suffer hydrogen embrittlement and damage. The steel suffers decarburization by the hydrogen, which causes a loss of ductility, and development of microfissures at the grain boundaries, which leads to loss of strength. The decarburization reaction is reversible, but the formation of cracks is not. These two effects are sometimes distinguished as hydrogen embrittlement and hydrogen damage, but often one of these terms is used to describe both phenomena. Both effects are referred to here as 'hydrogen attack'.

Hydrogen attack has been a relatively common problem in equipment handling hydrogen at high temperatures such as refinery boilers and catalytic reformers. Failures usually occur in the temperature range 300–550°C. The resistance of steel to hydrogen attack can be greatly increased by the addition of suitable alloying elements, and CrMo steels are widely used for hydrogen service. Operating limits for steels in hydrogen service have been given by a number of workers, notably G.A. Nelson (1966). The Nelson curves are published with periodic amendments in *Steels for Hydrogen Service at Elevated Temperatures and Pressure in Petroleum Refineries and Petrochemical Plants* (API, 1991 Publ. 941). Typical Nelson limit curves are illustrated in Figure 12.21. These are used to select a suitable material. The basis of design for equipment in which hydrogen attack may occur is therefore selection of a suitable material and use of a design stress less than the lower critical stress.

In 1984 at Romeoville, Illinois, an absorption column came apart at the weld and rocketed up, initiating a vapour cloud explosion and a series of fires and boiling liquid expanding vapour explosions (BLEVEs), in which 17 people were killed (Case History A111). The vessel had a history of hydrogen attack problems.

12.27.8 Corrosion failure

A large proportion of failures in process plant are due to corrosion Accounts of corrosion include *Deterioration of Materials* (Greathouse and Wellel, 1954), *Seawater Corrosion Handbook* (Schumacher, 1979), *Basic Corrosion and Oxidation* (Q.M. West, 1980), *Corrosion Inhibitors* (Rozenfeld, 1981), *Corrosion Processes* (R.N. Parkins, 1982), *Intergranular Corrosion of Steels and Alloys* (Cihal, 1984), *Corrosion Control in the Chemical Process Industries* (Dillon, 1986), *Corrosion Engineering* (Fontana, 1986), *DECHEMA Corrosion Handbook* (DECHEMA, 1987–), *The Chemical Engineering Guide to Corrosion Control in the Process Industries* (R.W. Green, 1987), *High Temperature Corrosion* (Kofstad, 1988) and *Corrosion and Corrosion Protection Handbook* (Schweitzer, 1989).

Corrosion occurs as (1) general corrosion, (2) local corrosion and (3) erosion. In general corrosion, there is a fairly uniform deterioration of the overall surface. In contrast, localized corrosion involves little generalized corrosion but severe local attack, often at points of surface defects or stress. Erosion is also localized at points of high velocity or impact.

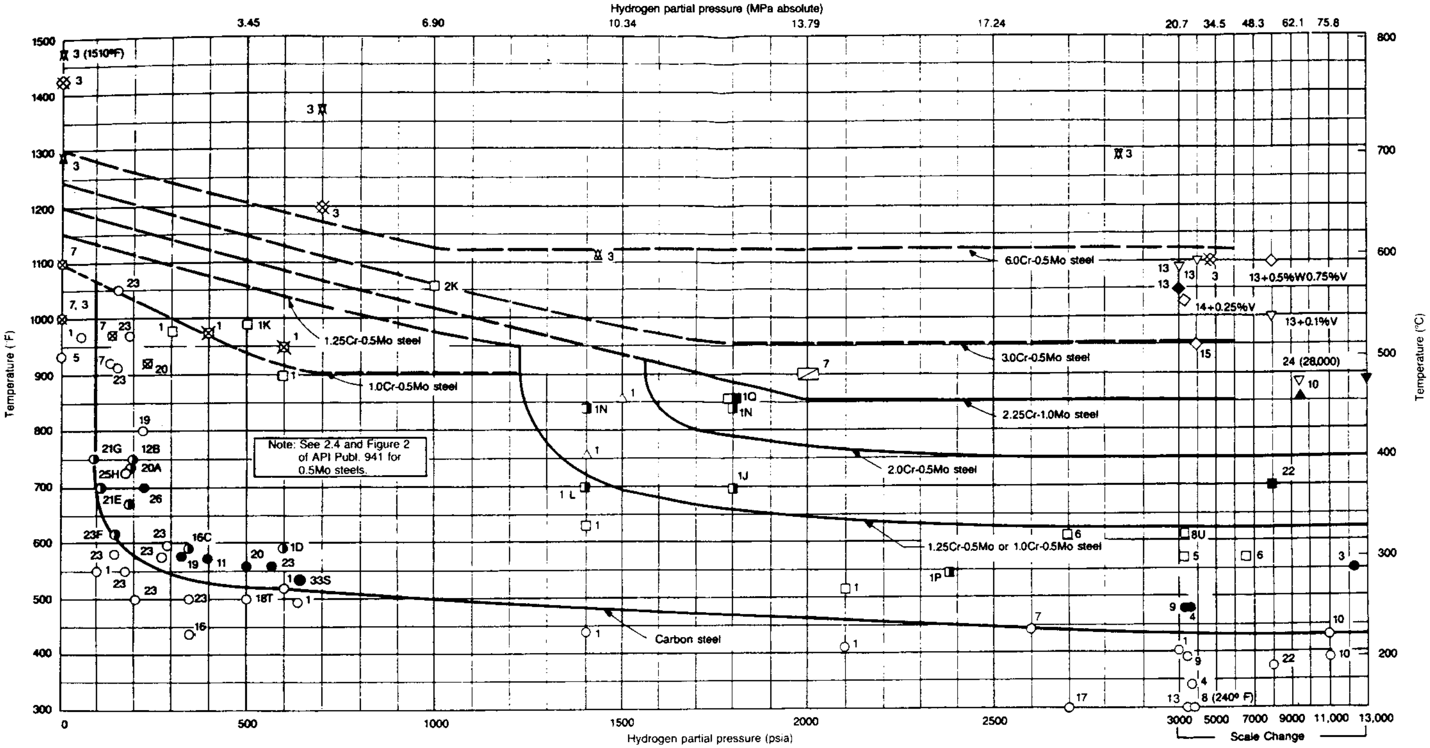
Some common types of corrosion in process plant, following Thielsch (1965), are

(1) general corrosion;
(2) scaling;
(3) exfoliation;
(4) galvanic corrosion;
(5) crevice corrosion;
(6) corrosion pitting;
(7) stress-related corrosion
    (a) stress corrosion cracking,
    (b) corrosion fatigue,
    (c) stress-enhanced corrosion;
(8) intergranular corrosion;
(9) knife-line corrosion;
(10) erosion;
(11) external corrosion.

It should be emphasized, however, that many corrosion failures are not easily classified and may involve more than one type of corrosion. Corrosion frequently occurs at welds rather than in the parent metal and corrosion at welds ranks as a topic in its own right. Accounts of the practical treatment of corrosion problems in process plants have been given by M. Turner (1987, 1988, 1989a,b, 1990a,b).

General corrosion often results from attack by a corrosive chemical or impurity over the whole exposed surface. Scaling corrosion is the result of oxidation in a gaseous atmosphere caused by exposure to high temperatures. It occurs particularly in steam boilers. Exfoliation is another type of scaling corrosion caused again by oxidation, but in a steam atmosphere. Steam-heated boiler feedwater heaters exhibit exfoliation.

There are several kinds of corrosion which are associated with concentration cells. In the salt concentration cell, which involves a dissolved salt containing ions of the metal, there is a difference of salt concentration at two parts of the exposed surface. The metal in contact with the lower salt concentration becomes the anode and corrodes preferentially. In the differential aeration cell, two parts of the exposed surface are subject to a difference of oxygen concentration. The metal in contact with the lower oxygen concentration becomes anodic and corrodes. Such corrosion takes two forms: pitting corrosion of an exposed surface, and crevice corrosion in a crevice. The detailed mechanisms are described further in relation to crevice



Notes:
1. The limits described by these curves are based on service experience originally collected by G. A. Nelson and on additional information gathered by or made available to API.
2. Austenitic stainless steels are generally not decarburized in hydrogen at any temperature or hydrogen pressure.
3. The limits described by these curves are based on experience with cast steel as well as annealed and normalized steels at stress levels defined by Section VIII, Division I, of the ASME Code. See 2.7 and 2.8 in text for additional information.

corrosion. Both types of concentration cell corrosion occur in water containing chloride ions. Galvanic corrosion is considered in Section 12.27.9; crevice corrosion in Section 12.27.10; corrosion pitting in Section 12.27.11; stress-related corrosion, including stress corrosion cracking, corrosion fatigue and stress-enhanced corrosion, in Section 12.27.12; particular forms of stress corrosion in Sections 12.27.13 and 12.27.14; and inter-granular corrosion, or weld decay, in Section 12.27.18.

Knife-line corrosion takes place between the parent and weld metals. It occurs mainly in austenitic stainless steels. Erosion and external corrosion are discussed in Sections 12.27.16 and 12.27.17.

In 1970 in Brooklyn, New York, a road tanker carrying liquid oxygen ruptured violently causing a number of fires, with two deaths (Case History A48). The investigation found, amongst other things, that there had been a appreciable loss of metal from the aluminium tank shell, even though the tank had been in service for only a month.

In 1988 at Norco, Louisiana, an explosion occurred on a catalytic cracker (Case History A121). The cause was a release due to internal corrosion of an elbow in the depropanizer overhead piping. Some 9 te of hydrocarbons was released and there was a vapour cloud explosion. Seven people were killed and damage was extensive.

Some of the types of corrosion mentioned are now considered in more detail.

12.27.9 Galvanic corrosion

Galvanic corrosion is caused by current flowing between two dissimilar metals which form a galvanic cell, or bimetallic couple. A discussion of galvanic corrosion in process plants is given by M. Turner (1990c).

A typical pair of dissimilar metals which exhibits galvanic corrosion is copper and iron, typically in steel. In this case it is the steel which corrodes. The electromotive series gives the ranking of metals in descending order of their electrode potential relative to that of the hydrogen electrode, the metals higher in the series being the more noble. If a galvanic cell is set up, it is the less noble metal which suffers the corrosion. The noble metal forms the cathode and the less noble one the anode.

The electromotive series is an imperfect indicator of what happens in practice. For this a more relevant guide is the galvanic series which ranks metals according to their nobility in seawater. Some materials in this series, in descending order of nobility, are 316 stainless steel > ferritic stainless steel > copper > low alloy steel > carbon steel > aluminium > zinc. However, while the galvanic series is applicable to an aqueous medium of wide interest, the ranking in other solutions is not necessarily the same.

In galvanic corrosion, the corrosion rate is a function of the potential difference between the two surfaces and the slope of the cathodic and anodic polarization curves, which may be analysed using the Evans diagram. In neutral solutions, particularly with dissolved oxygen, the cathodic polarization is crucial. The relative sizes of the cathode and anode are also important in this situation. Features which reduce cathodic polarizations, and can therefore greatly increase the corrosion rate, include agitation and air sparging. A large surface area of the cathode favours an increased corrosion rate.

Galvanic corrosion may occur in equipment incorporating two dissimilar metals. It can also occur when two such metals are joined together at a weld. It may also result from the utilization of a second metal as a plated surface. But such corrosion can also occur with minor dissimilarities in composition such as different metallurgical phases.

Measures which can be taken against galvanic corrosion include the selection of compatible materials and the insertion in the circuit of an ohmic resistance, either in the metal path or in the ionic path. Examples of the insertion of a resistance for these two paths are the use of an insulated gasket in pipework and the coating of one of the metal surfaces, respectively.

The purpose of such coating is to protect the less noble metal, but it does not follow that it is this metal which should be coated. The coating is liable to contain holes, or ‘holidays’. A couple of coats of paint may still leave gaps of perhaps 1% of the area. If the coating is put on the less noble metal and gaps exist amounting to 1% of the area, the corrosion at these gaps will simply be enhanced by a factor of about 100.

12.27.10 Crevice corrosion

Crevice corrosion of steel occurs in crevices sufficiently narrow for an oxygen deficiency to occur which leads in due course to a build-up of acidity. Its occurrence in process plant is described by M. Turner (1989a).

It is exemplified by the corrosion of carbon steel in salt water. In general corrosion of an exposed surface, part of the surface acts an anode and part as a cathode. The corrosion can be represented as:

$$\mathrm{Fe} \rightarrow \mathrm{Fe}^{2+} + 2\mathrm{e}^- \qquad \text{Anodic reaction}$$

$$\mathrm{O}_2 + 2\mathrm{H}_2\mathrm{O} + 4\mathrm{e}^- \rightarrow 4\mathrm{OH}^- \qquad \text{Cathodic reaction}$$

The location of the anodes and cathodes shifts with time.

Where the metal surface is within a crevice the situation is quite different. The cathodic reaction consumes oxygen and the concentration falls, since the rate of diffusion into the crevice is slow. A differential aeration cell is set up. The metal surface in the crevice becomes anodic relative to the exposed surface. The anodic reaction creates ferrous ions, which combine with chloride ions to give ferrous chloride; this oxidizes to ferric chloride, which combines with hydroxyl ions from the cathodic reaction to form ferric hydroxide. This insoluble hydroxide in turn forms ferric oxide, or rust, and hydrochloric acid. The chloride ions are attracted to the anode. The water in the crevice can become so acidic that corrosion then occurs simply by acid attack.

From this point on, the rate of corrosion is determined by the acidity, which depends on the particular solution. In the example just given the solution contained chloride. There is a rank order of aggressiveness, headed by chlorides, then sulfates, phosphates, etc. With crevice corrosion, the corrosion rate can be orders of magnitude greater than with general corrosion.

Crevice corrosion can occur where the two surfaces forming the crevice are of the same metal, where they are of different metals or where one is non-metallic. In the second case there may be bimetallic corrosion as well.

Many of the situations where crevice corrosion occurs involve single-sided fillet welds. It occurs, for example, on lap joints with such a weld. On process plants, use is often made of a support ring welded around the inside of a vessel. The use of a full penetration weld instead of a single-sided fillet weld can minimize such corrosion. Another support detail in plants is a pad seal welded to the inside of a thin walled vessel to support a heavy internal member. In this case, crevice corrosion may be reduced by making the seal weld a continuous one. In some cases, a 'sentinel hole' is drilled from the outside through the vessel wall to leak test the weld; it also serves to provide warning of any leak during service. Crevice corrosion occurs at the tube–tube plate joints of heat exchangers. It is fairly common in threaded joints.

12.27.11 Corrosion pitting

Corrosion pitting also involves concentration cell corrosion by a differential aeration cell, but in this case without crevice effects. The anode and cathode move over the surface of the exposed metal, with the oxygen-lean area acting as the anode and suffering preferential corrosion. Pitting is favoured by no-flow conditions and by surface defects. It occurs in boiler feedwater heaters during shut-down if the oxygen content of the feedwater is high. This type of corrosion may be prevented by chemical treatment.

The resistance of steels to pitting and crevice corrosion can be characterized by the pitting index (Henderson, King and Stone, 1990)

$$\mathrm{PRE_N} = \%\mathrm{Cr} + 3.3(\%\mathrm{Mo}) + 16(\%\mathrm{N}) \qquad [12.27.1]$$

Broadly, alloy steels with an index value below 32 are susceptible to pitting and crevice corrosion in salt water, whilst those with a value of 36 are resistant. A minimum value of 40 is quoted for resistance to hot seawater.

12.27.12 Stress-related corrosion

Often failure results from a combination of corrosion and stress. Stress corrosion cracking (SCC) is non-ductile failure caused by the combination of corrosion and static tensile stresses. Corrosion fatigue is caused by corrosion and stress cycling. An account of stress corrosion is given in *The Stress Corrosion of Metals* (Logan, 1966).

Many types of steel are liable to SCC, including mild steel and austenitic stainless steel. The stresses necessary to cause SCC may be internal or due to externally applied loads. Generally, normal operating pressures are not alone sufficient to cause such cracking and appreciable internal stress must be present. SCC can occur in the parent metal of vessels and pipes, in welds and on nozzle connections and support attachments. In welds the cracks may be transverse or longitudinal.

Chlorides are a common cause of SCC. They are a very widespread impurity and are rather difficult to eliminate. SCC due to chlorides is discussed in Section 12.27.13. There is also a form of SCC due to nitrates, which is considered in Section 12.27.14.

SCC caused by an alkaline solution is known as 'caustic embrittlement', which has been a frequent cause of failure in boilers. It is normal to treat boiler feedwater to reduce the risk of caustic embrittlement. SCC, particularly by chlorides, can occur externally as well as internally. A common cause is the leaching of chlorides from lagging. Some failures caused by SCC have been described by Ashbaugh (1970) and M. Turner (1989b).

Corrosion fatigue involves a mutual interaction between corrosion and fatigue. Corrosion occurs in the fatigue cracks. Alternation of stress prevents the build-up of films which protect against corrosion. Thus, corrosion reduces the fatigue limit and fatigue speeds up the corrosion. In consequence, corrosion tends to occur with a wider range of chemicals and concentrations than is the case in the absence of fatigue.

Stress-enhanced corrosion describes corrosion at features where there are high residual stresses, such as welds, nozzles and attachments. Measures to counter stress-related corrosion depend on the particular case, but include selection of suitable materials, operation in a suitable temperature range, elimination of corrodants, reduction of residual stresses, reduction of vibrations, and close control of operations.

12.27.13 Chloride stress corrosion cracking

Chloride SCC occurs in austenitic stainless steels. A discussion of this form of SCC is given by M. Turner (1989b). When a dislocation propagates and a slip plane forms, there is a rupture of the protective oxide layer. Although the passive film usually reforms on the surface thus exposed, in an aqueous solution of chloride ions the repair is imperfect and the film contains chloride ions, so that the renewed surface has a different composition. The repaired surface constitutes an anode and, since it is small relative to the rest of the surface which becomes the cathode, rapid corrosion occurs. This in turn creates a crack, which propagates along the slip plane. The corrosion is further promoted by the build-up of acidity at the anodic crack and now becomes well established.

There are four main factors which influence SCC: (1) the temperature, (2) the chloride ion concentration, (3) the stress, and (4) the grade of steel. SCC rarely occurs at temperatures below 60°C, but above 200°C it can progress rapidly, the relevant temperature being that of the metal rather than of the liquid. The rate at which SCC occurs is a function of the chloride ion concentration, the relevant concentration being that in the liquid film at the metal surface. The stress causing SCC may sometimes be the tensile stress in the metal surface at the operating pressure, but a more common cause is residual stresses. Stainless steels such as the commonly used 304, 321 and 347 types are susceptible, and the 316 and 317 types are only marginally less so.

Where SCC is detected, specialist advice is required. If the cracks are sufficiently deep, immediate shut-down is necessary. If they are more shallow, the advice may be that it is possible to continue in operation with appropriate monitoring and perhaps that the cracks may be dealt with in due course by grinding out.

Prevention of SCC by elimination of stress is generally difficult. Stress relief may be practised, although the temperatures required are high and can cause distortions. On the other hand, operation with a metal temperature below 60°C eliminates the problem. Control of chloride ion concentration is more problematic, particularly if chlorides can concentrate by evaporation. Selection of an appropriate stainless steel is an effective measure. The steels which show resistance to SCC are those with higher nickel contents: the 904L grade is resistant and the 825 grade highly so.

Other measures of protection include exclusion of oxygen, use of inhibitors and cathodic protection. A critique is given by M. Turner (1989b), who rehearses some drawbacks of these methods. The quantity of oxygen required to initiate SCC is very small. Inhibitors have not proved universally effective. Cathodic protection requires very precise control. Failures due to SCC are mostly not catastrophic, though hey can be. They tend to exhibit leak-before-break behaviour.

12.27.14 Nitrate stress corrosion cracking

A particular type of SCC is the nitrate SCC of mild steel. It was nitrate stress corrosion which caused the crack in No. 5 Reactor at Flixborough and led to the removal of the reactor and the installation of the 20 in. pipe. The cracking occurred because cooling water treated with nitrite had been played on the reactor to dilute small leakages of cyclohexane.

The conditions for nitrate cracking of mild steel to occur are a high concentration of nitrate, a low pH, a temperature above 80°C and high stress. This combination of features is not often present and nitrate cracking is not common outside plants handling nitric acid and nitrates. Most water contains some nitrates. In particular, water treatment of industrial cooling water results in an appreciable nitrate concentration. But such cooling water does not normally cause nitrate cracking. It is concentration of nitrates which presents the main hazard of nitrate cracking. Concentration may occur on a nitric acid plant or a plant producing nitrates, inside a crack which has been created by some other mechanism such as fatigue, or due to evaporation.

Contamination with nitrates should be avoided as far as practicable. In particular, it is not good practice to let water penetrate thermal insulation. This creates a risk of various kinds of corrosion apart from nitrate cracking. If heavy contamination may occur, equipment should be stress relieved. This is not a full answer for all fittings, since some items such as bolts have a high working stress. These need to be checked by regular inspection.

Where it is not possible to rely on either avoidance of contamination or stress relief, some protection may be obtained by the use of certain paint coatings. On plants handling nitric acid and nitrates, nitrate cracking is a well-known problem and special procedures have been evolved.

Further information on nitrate cracking is given in TON 53/2 *Nitrate Stress Corrosion of Mild Steel* (HSE, 1976).

12.27.15 Zinc embrittlement

At high stresses and temperatures, traces of other metals such as copper or zinc can cause rapid and severe embrittlement of some types of steel. The effects of zinc embrittlement of austenitic stainless steel were illustrated at Flixborough. Many of the stainless pipes found on the site had suffered zinc embrittlement.

For zinc embrittlement of stainless steel to occur it is necessary for the material to be under high stress and at a high temperature, but given these conditions the quantity of molten zinc required to cause embrittlement is very small and failure can occur in seconds. The features which determine zinc embrittlement of stainless steel are (1) temperature, (2) applied stress, (3) wetting, (4) type of steel, and (5) time.

Austenitic stainless steel is not used in process plant above 750°C except in certain specialized applications. Zinc embrittlement is not likely to occur below this temperature. Zinc has a melting point of 419°C and molten zinc penetrates stainless steel above 450°C, but embrittlement is improbable below 750°C. Investigations by Cottrell and Swann (1976), after Flixborough, showed that the most favourable metal temperature for rapid attack is 800−900°C. Thus zinc embrittlement is unlikely to occur under normal operating conditions, but requires temperatures such as usually occur only in a fire.

High stress is also a condition for zinc embrittlement to occur. In Cottrell and Swann's work zinc embrittlement did not occur at low stress, even though the temperature was 1050°C and the specimen was coated on all sides by a pool of zinc.

Wetting of the steel by the molten zinc is the condition most favourable to zinc embrittlement. Surface layers such as metal oxides can prevent penetration, but if the layer is broken in some way, such as by abrasion or a reducing atmosphere, wetting can occur. There is some evidence that embrittlement can be caused by contamination from zinc vapour, but this is unlikely to occur, unless the molten zinc is at a distance of no more than an inch or so.

The type of stainless steel affects its susceptibility to zinc embrittlement. The latter is believed to be the result of interaction between zinc and nickel in the steel. It is the austenitic chromium nickel steels which are particularly affected.

Given conditions favourable to zinc embrittlement failure can be rapid. Cottrell and Swann obtained failures in a matter of seconds.

There are a number of possible sources of zinc on process plants. Zinc is used in galvanized, sprayed and painted coatings. Typical zinc-coated items are galvanized fittings, walkways, wire and finned tubes. Paints which contain zinc compounds but not metallic zinc are not a serious risk in this respect.

The principal hazard posed by zinc embrittlement is rapid and catastrophic failure as a result of a fierce local fire on the plant. Zinc embrittlement also creates the problem that, after a general plant fire, stainless steel equipment which has a nearby source of zinc is suspect. The problem of zinc embrittlement, however, should be kept in perspective. It is significant mainly as a secondary effect which can increase the severity of a local fire.

On stainless steel plant where zinc embrittlement could have serious consequences in the event of fire, zinc should be eliminated as far as possible. In particular, zinc-coated items should not be placed in direct contact with stainless steel or in positions where they could drip molten zinc onto it. Thus, for example, galvanized wire netting used in insulation should not be in direct contact with stainless steel pipe. Similar considerations apply to stainless steel plant which has a normal operating temperature above 400°C. Care should also be taken to prevent zinc contamination of stainless steel in welding and other fabrication or maintenance activities.

If plant made of stainless steel is subjected to fire, it should be examined by experts to check that it has not suffered zinc embrittlement. Deterioration is difficult to determine by normal inspection methods and requires metallurgical examination. Further information on zinc embrittlement is given in TDN 53/1 *Zinc Embrittlement of Austenitic Stainless Steel* (HSE, 1976).

12.27.16 Erosion

Erosion is a common form of corrosion and takes many forms. It occurs particularly at sites where there is a flow restriction or change of direction. These included nozzlesand valves, elbows, tees and baffles, and points opposite to inlet nozzles. It is enhanced by the presence of solid particles in gas or liquid, by drops in vapours or by bubbles in liquids and by two-phase flow. Conditions which can cause severe erosion include pneumatic conveying, wet steam flow, flashing flow and pump cavitation.

12.27.17 External corrosion

External corrosion can be caused by components in insulation and in fireproofing. The leaching of chloride salts from insulation by dripping water corrodes pipework. An account of corrosion beneath lagging has been given in Section 12.11. External corrosion is also considered in relation to maintenance in Chapter 21.

Underground pipework can be corroded by the soil. This form of corrosion is often electrochemical, and cathodic protection is used to combat it.

12.27.18 Corrosion at welds

In much process equipment, the welds constitute both a potential fault line and a line of common cause failure, in that if there is corrosion at one point in the weld it is quite likely to be occurring along much of it. It is this combination, with its potential for catastrophic failure, which makes corrosion at welds so serious. An account of corrosion at welds is given by M. Turner (1990a), who distinguishes three basic causes of such corrosion: (1) hydrodynamics, (2) differences in composition and (3) differences in metallurgical structure.

Corrosion due to hydrodynamic effects is seen in butt welds on pipes. One cause is lack of root fusion, such that there is a small hollow at the root of the weld on the inner surface of the pipe, which then becomes the site of turbulence and impingement corrosion. Another cause is protrusion of a weld bead, which gives rise to impingement pitting in the pipe surface beyond the protrusion. In both cases, attack can be rapid and can accelerate. If the defect extends sufficiently far round the pipe, it may result in pipe rupture. In addition to control of welding to eliminate such defects, countermeasures may include the use of a backing ring; for a small bore connection, the use of an undersized connection which is then drilled out to size; and the limitation of fluid velocity.

A weld has the structure of cast metal and, if made of the same material as the parent metal, will generally be weaker. In order to compensate for this, use is commonly made of a weld metal of different composition. However, this difference in composition can be another cause of weld attack, by galvanic cell, or bimetallic couple, corrosion. The corrosion effects are governed by the ionic conductivity of the liquid which determines the extent of the pipe which participates as an electrode. If the weld metal is more noble, it is cathodic towards the parent metal, and it is principally the latter which will corrode, but even if the corrosion zone is relatively narrow, the rate of corrosion will tend to be limited by the small area of the cathode. If the weld metal is less noble and is therefore anodic, corrosion will occur mainly at the weld, with the rate of corrosion being dependent on the area of the pipe acting as the cathode. If the ratio of this area to that of the weld is high, corrosion can be rapid.

During welding a zone of the parent metal is affected by the heat. This heat affected zone (HAZ) can be some 20 mm wide and usually it is more susceptible to corrosion. Early stainless steels suffered serious problems of grain boundary corrosion, or weld decay, which led to brittle failure. The cause was depletion of chromium at the grain boundaries, due to the fact that under these conditions the carbon in solid solution migrates to the boundaries and forms chromium carbide, which precipitates, whilst chromium migrates more slowly and thus the chromium deficiency is not made good. The solution was the production of stainless steels with low carbon contents.

In steels, generally, the high temperatures involved in welding cause a number of metallurgical changes in the HAZ, many of which make it more susceptible to corrosion. One mechanism of corrosion is a bimetallic couple. Control of the welding, including the heat input and interpass temperatures, can minimize, but generally not totally eliminate, the corrosion susceptibility. This susceptibility is, however, little affected by post-weld heat treatment, which is a form of tempering aimed at partial stress relief of the weld to reduce its brittleness, and is conducted at temperatures below those required to reverse changes in the metallurgical structure of the heat affected zone.

In 1984, an oil line fracture at Las Piedras, Venezuela, sprayed hot oil across a roadway onto hydrogen units, causing a major fire (Case History A110). The pipe failure was a circumferential fracture in the parent metal in the heat affected zone about 1.5 in. from the weld.

12.27.19 Corrosion testing

Corrosion is generally a function of a number of variables and can be very sensitive to the particular process conditions. It is not always easy to predict, and in some cases corrosion testing is necessary. As described by M. Turner (1988), there are essentially two distinctly different types of corrosion test. The first type is standard tests, which are characterized by the fact that they apply essentially to a set of relatively straightforward conditions and are precise, reproducible, rapid and cheap, and require neither skilled supervision and interpretation nor input from the client. Plant simulation tests, on the other hand, which simulate actual plant conditions, are not very precise or reproducible, can be prolonged and expensive, and require close supervision, skilled interpretation and client input.

Since in a candidate design corrosion is likely to proceed relatively slowly, testing can take a long time. It is therefore not uncommon to use some form of accelerated test. As with any form of accelerated testing, this can be misleading. An alternative is the use of corrosion rate monitoring for which instrumentation now exists. This allows information to be obtained in tests which simulate the plant conditions. However, since the corrosion rate can vary with time, if this method is used it is necessary to ensure that the steady-state rate has been reached. It is desirable that the design of corrosion tests be a joint exercise between the chemical engineer and the corrosion specialist.

12.27.20 Corrosion policy

In establishing a policy on corrosion, there is a need to strike a balance between neglect and excessive caution. Process plants live with corrosion. The important thing is to identify, and act on, those cases where corrosion can be especially hazardous or costly. Some of the factors to be considered are discussed, with illustrations, by M. Turner (1987, 1990b). Most experienced corrosion engineers will themselves admit to cases where they have been surprised by the rapid corrosion which has occurred and others where they anticipated corrosion which never materialized.

The *Report of the Committee on Corrosion and Protection* (Hoar, 1971) (the *Hoar Report*) reviewed national policy on corrosion. It made the point that there were substantial gains to be made simply by applying existing knowledge; in other words, there is a need for 'corrosion awareness' on the part of engineers. However, there has to be an economic balance. Corrosion technologists for their part need a keen appreciation of the practicalities of the economics of process plants. For example, in many applications the choice of carbon steel will be the right one, even though it will corrode faster than an alternative, more expensive material.

As an instance of living with corrosion, M. Turner (1987) cites the case of the steam reforming process for hydrogen. Theoretically, this should have been severely inhibited by the problem of creep rupture of the catalyst tubes, which, since creep is a probabilistic process, was liable to cause disruption due to premature failures. The solution was the use of 'pigtails' which could be nipped closed, allowing the furnace to continue in operation.

Corrosion is another area in which it is important that engineers know enough to recognize those situations in which specialist advice is necessary.

12.28 Fracture Mechanics

A very powerful tool for the avoidance of catastrophic failure in pressure equipment is fracture mechanics. In this section an account is given of deterministic fracture mechanics, which deals essentially with the propagation of cracks, whilst the following section treats probabilistic fracture mechanics, which deals with the probabilistic aspects of equipment failure due to cracks such as the probabilities of prior existence of defects, of failure to detect them, and so on.

Accounts of fracture mechanics are given in *Fracture of Structural Materials* (Tetelman and McElivy, 1967), *Elements of Elasticity* (Dugdale, 1968), *Fracture – An Advanced Treatise* (Liebowitz, 1968), *Fundamentals of Fracture Mechanics* (Knott, 1973), *Elementary Engineering Fracture Mechanics* (Broek, 1974), *Fracture and Fatigue Control in Structures* (Rolfe and Barsom, 1977, 1987), *The Mechanics of Fracture and Fatigue* (A.P. Parker, 1981) and *Engineering Safety Assessment* (Thomson, 1987). Background treatments of elasticity and plasticity include those by Godfrey (1959), W. Johnson and Meller (1962), Spencer (1968), Timoshenko and Goodier (1970) and Benham and Warnock (1973).

Fracture mechanics deals with the initiation and growth of cracks to a critical size and with failure due to cracks. It identifies different regimes of crack growth, and the effect of material properties, plate thickness, and so on. It provides the basis for strategies for the avoidance, control and mitigation of crack propagation.

As such it provides a tool not only for the avoidance of catastrophic failure, but also for discrimination between those defects which require prompt action and those which do not. The failure mechanism mainly treated in fracture mechanics is fatigue, but it is applicable to other mechanisms also.

12.28.1 Loading regimes

The account of fracture mechanics given here is concerned essentially with steel plate such as is used in pressure vessels. An applied load gives rise in a body to stress σ and strain ϵ. The general problem of determining the stresses and strains within a loaded body is a complex one. A considerable simplification can be obtained if for a body of coordinates x, y, z it can be assumed that there is no change in the distribution of stress in the z direction. Then for deformation in the x, y plane two cases may be distinguished: plane stress and plane strain.

Plane stress is applicable to the case of a plate sufficiently thin that it can be assumed incapable of supporting stress σ_z through the thickness (the z direction) so that $\sigma_z = 0$. Plane strain applies in the case of a plate sufficiently thick that it prevents strain t_z through the thickness so that $\epsilon_z = 0$.

In most engineering applications, the combination of the dimensions of the structure and the steels used is such that at normal service temperatures the thickness of the steel is not sufficient to ensure plane strain under slow loading conditions. The material exhibits a behaviour which is not purely elastic but is to some degree elastic–plastic. Another distinction is in the mode of crack surface displacement. Three such modes are commonly treated. The modes involve opening (Mode I), shearing (Mode II) and tearing (Mode III). It is the first mode which is of interest here.

12.28.2 Modelling of crack behaviour

In describing the modelling of the stresses and strains caused by an applied load, and of the effect on cracks, it is usual to start by considering purely elastic behaviour. Models of loading are based on equations of equilibrium and compatibility. There are a number of stress functions which can be shown to satisfy the equilibrium conditions. One of these is the Airy stress Function F. There are also a number of complex stress functions which satisfy both the equilibrium and compatibility conditions. It can be shown that both sets of conditions are satisfied by the solution

$$F + iB = \bar{z}\phi(z) + \int \psi(z)\,dz \qquad [12.28.1]$$

where F is the Airy function, B is some other function, ϕ and ψ are analytic functions, and $z = x + iy$ and $\bar{z} = x - iy$.

12.28.3 Stored energy

When a body is loaded the movement caused by the applied load does work which is stored as strain energy. For uniaxial tension this work is:

$$U = \sigma^2/2E \qquad [12.28.2]$$

where E is the modulus of elasticity, or Young's modulus and U is the energy stored per unit volume of material.

12.28.4 Griffith crack model

Early work on fracture faced the apparent paradox that a sharp notch is capable of producing very high stress concentration, yet an infinitely sharp one does not necessarily lead to failure. This problem was addressed by Griffith (1920–21), who for the case of a single crack of length $2a$ in a brittle material considered the energy changes associated with an incremental extension of that crack and showed that

$$U = \frac{\sigma^2}{2E}\pi a^2 \qquad \text{plane stress} \qquad [12.28.3]$$

$$U = \frac{\sigma^2}{2E}\pi a^2(1 - v^2) \qquad \text{plane strain} \qquad [12.28.4]$$

since for plain strain

$$\epsilon = (1 - v^2)\sigma/E \qquad [12.28.5]$$

where a is the crack half-length and v is Poisson's ratio. The energy release rate for crack extension G is defined as

$$G = \partial U/\partial a \qquad [12.28.6]$$

Hence from Equations 12.28.3, 12.28.4 and 12.28.6

$$G = \frac{\pi\sigma^2 a}{E} \qquad \text{plane stress} \qquad [12.28.7]$$

$$G = \frac{\pi\sigma^2 a}{E}(1 - v^2) \qquad \text{plane strain} \qquad [12.28.8]$$

The energy absorption rate for crack extension

$$R = \partial W/\partial a \qquad [12.28.9]$$

where W is the energy absorbed in producing crack extension.

At the threshold condition for unstable crack growth $\mathrm{d}U/\mathrm{d}a = \mathrm{d}W/\mathrm{d}a$ and hence $G = R$. But since R is a constant, there is a critical value G_{cr} at which such growth will occur and this value is a constant. Then from Equations 12.28.7 and 12.28.8

$$G_{cr} = G_c = \frac{\pi\sigma_c^2 a}{E} \qquad \text{plane stress} \qquad [12.28.10]$$

$$G_{cr} = G_{IC} = \frac{\pi\sigma_c^2 a}{E}(1 - v^2) \qquad \text{plane strain} \qquad [12.28.11]$$

where G_c and G_{IC} are the critical values of G for plane stress and plane strain, respectively, and U_c is the critical value of the stress. Equations 12.28.10 and 12.28.11 give

$$\sigma_c^2 = \frac{EG_c}{\pi a} \qquad \text{plane stress} \qquad [12.28.12]$$

and

$$\sigma_c^2 = \frac{EG_{IC}}{\pi a(1 - v^2)} \qquad \text{plane strain} \qquad [12.28.13]$$

Equation 12.28.12 is sometimes written as

$$\sigma_c = \left(\frac{2\gamma E}{\pi a}\right)^{1/2} \qquad [12.28.14]$$

with

$$G_c = 2\gamma \qquad [12.28.15]$$

where γ is the surface energy per unit area.

12.28.5 Stress intensity factor

For a body containing a crack the magnitude of the stress field at the crack tip may be characterized by the stress intensity factor K. For the first mode of crack surface displacement, Mode I, which is that of interest here, the stress intensity factor is K_I.

This stress intensity factor K_I has a critical value K_c at which unstable crack propagation occurs. As the plate thickness is increased, the value of K_c decreases asymptotically to a minimum value K_{IC}. In other words, under plain strain conditions K_c has a minimum value K_{IC} the plane strain fracture toughness or, simply the fracture toughness.

For biaxial loading an expression for the stress intensity factor is

$$K_I = \sigma(\pi a)^{1/2} \qquad [12.28.16]$$

Then from Equations 12.28.7, 12.28.8 and 12.28.16

$$K_I = (GE)^{1/2} \qquad \text{plane stress} \qquad [12.28.17]$$

$$K_I = \left(\frac{GE}{1 - v^2}\right)^{1/2} \qquad \text{plane strain} \qquad [12.28.18]$$

Compilations of stress intensity factors are given by Sih (1973a), Rooke and Cartwright (1976) and Hudson and Seward (1978).

The fracture toughness is a property of the material, and plays a crucial role in fracture mechanics. It is discussed further below.

12.28.6 Westergaard stress function

Mention has already been made of the Airy function. Another stress function, or rather family of functions, which has proved fruitful is the Westergaard stress function Z_I, where the subscript I refers to the x axis of symmetry. The stress intensity factor k_I may be expressed in terms of a Westergaard function:

$$K_I = (2\pi)^{1/2} \lim_{z \to a} (z - a)^{1/2} Z_I(z) \qquad [12.28.19]$$

It can be shown that using the appropriate Westergaard function the stress intensity factor for a biaxially loaded crack in a plate is given by

$$K_I = \sigma(\pi a)^{1/2} \qquad [12.28.20]$$

as already given.

Another situation of interest is that of an array of cracks aligned in the same direction. Then, using the Westergaard function appropriate to this case, it can be shown that

$$K_I = \sigma(\pi a)^{1/2}\left[\frac{2b}{\pi a}\tan\left(\frac{\pi a}{2b}\right)\right]^{1/2} \qquad [12.28.21]$$

where the distance between the centres of the cracks is $2b$. Equation 12.28.21 reduces to Equation 12.28.20 as $b/a \to \infty$.

12.28.7 Geometric factor

Equation 12.28.20 may be generalized to cover other cases such as that given in Equation 12.28.21 by the introduction of a configuration correction factor, or geometric factor Q, so that

$$K_I = Q\sigma(\pi a)^{1/2} \qquad [12.28.22]$$

Then, for example, for the case of an array of cracks given by Equation 12.28.21

$$Q = \left[\frac{2b}{\pi a}\tan\left(\frac{\pi a}{2b}\right)\right]^{1/2} \qquad [12.28.23]$$

The geometric factor Q has the value unity for a central through crack in a thick plate. Values for other configurations are given by Harvey (1974).

12.28.8 Fracture toughness

The fracture toughness K_{IC} is a property of the material and there are standard tests for it. They include BS 5447: 1977 and ASTM Test Method E-399: 1990. There are also relations between fracture toughness and other parameters such as the Charpy V-notch (CVN) toughness and the crack opening displacement (COD). Both tests and relationships are described by Rolfe and Barsom (1987).

As described earlier, below the transition temperature there is a marked fall in the toughness of a ferritic steel. Typically the fracture toughness is reduced by a factor of about four. Hydrogen embrittlement and impurities can also cause a pronounced reduction in fracture toughness.

12.28.9 Modelling of crack behaviour: plastic deformation

In the account given so far the assumption has been made that the behaviour of the material is elastic. In practice, most materials exhibit at some critical combination of stresses a degree of plastic deformation, or yielding.

There are two principal criteria for the onset of yielding. These are the Tresca criterion

$$|\sigma_1 - \sigma_3| = \sigma_{ys} \qquad [12.28.24]$$

and the von Mises criterion

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_{ys}^2 \qquad [12.28.25]$$

where σ_{ys} is the yield stress and $\sigma_1 > \sigma_2 > \sigma_3$.

Some principal models of crack tip plastic behaviour are those given by Irwin (1958) and Dugdale (1960).

12.28.10 Irwin model

A model of crack tip plastic behaviour has been given by Irwin (1958). If the plastic zone is treated as a circle of radius λ, the model gives

$$\lambda = \frac{1}{2\pi}\left(\frac{K_I}{\sigma_{ys}}\right)^2 \qquad [12.28.26]$$

The crack may be envisaged as having a notional length $(a + \lambda)$. Then, following Equation 12.28.22, an alternative stress intensity factor K^* may be defined as

$$K^* = Q\sigma[\pi(\alpha + \lambda)]^{1/2} \qquad [12.28.27]$$

12.28.11 Dugdale model

Another model for crack tip plasticity is that of Dugdale (1960). In this model the notional length of the crack is taken as $(a + \rho)$, where ρ is the length of the plastic zone. The model yields the relation:

$$\rho = \frac{\pi}{8}\left(\frac{K_I}{\sigma_{ys}}\right)^2 \qquad [12.28.28]$$

which may be compared with Equation 12.28.26 in the Irwin model.

12.28.12 Modelling of critical crack length

There are a number of models for the critical length of crack for fracture. They include the following: the linear elastic fracture mechanics (LEFM) model, the stress concentration theory (SCT) model, the Bilby, Cottrell and Swinden (BCS) model, and the J integral model.

An early model for failure at the crack tip was that of Neuber (1937). In this model failure is considered to occur when, over some characteristic distance b from the crack tip, the average stress, or stress integrated over the distance from a to $(a + b)$, reaches a critical value.

The characteristic distance b has a critical value b_{cr}, such that at shorter distances the stress concentration at the crack becomes critical. Following the treatment of Thomson (1987), itself based on that of Irvine (1977 SRD R48), when the average stress over the characteristic distance reaches a critical value

$$\frac{\sigma_u}{\sigma_c} = \left(\frac{2a}{b_{cr}} + 1\right)^{1/2} \qquad [12.28.29]$$

where b is a 'spreading length', b_{cr} its critical value and σ_u is the ultimate tensile stress.

Use is also made of another parameter S, effectively an alternative critical spreading length, where

$$b_{cr} = \frac{2}{3}S \qquad [12.28.30]$$

An account is now given of the first three models mentioned earlier. The fourth is the J integral model of Rice (1968a,b).

12.28.13 LEFM model

The linear elastic fracture mechanics (LEFM) model follows directly from Equation 12.28.29. If the spreading length is much less than the crack size ($b_{cr} \ll a$), then from that equation:

$$\frac{\sigma_u}{\sigma_c} = \left(\frac{2a}{b_{cr}}\right)^{1/2} \qquad [12.28.31]$$

and from Equations 12.28.30 and 12.28.31

$$\frac{a}{S} = \frac{1}{3}\left(\frac{\sigma_u}{\sigma}\right)^2 \qquad [12.28.32]$$

12.28.14 SCT model

The stress concentration theory (SCT) model is a modification of the LEFM model. It may be expressed in the form of Equation 12.28.29 or, using equation 12.28.30, as:

$$\frac{a}{S} = \frac{1}{3}\left[\left(\frac{\sigma_u}{\sigma}\right)^2 - 1\right] \qquad [12.28.33]$$

12.28.15 BCS model

The third model, that of Bilby, Cottrell and Swinden (1963), or the BCS model, may be stated as:

$$\frac{a}{S} = \frac{\pi}{8}\left[\ln \sec\left(\frac{\pi\sigma}{2\sigma_u}\right)\right]^{-1} \qquad [12.28.34]$$

12.28.16 Crack opening displacement

In the extension of the modelling of fracture into the region of elasto-plastic behaviour, an important concept is the crack opening displacement (COD), or crack tip opening displacement (CTOD), proposed by Wells (1961). In this region, if a crack is envisaged as a triangular wedge extending some distance λ into a circular plastic zone, such that the effective half-length is $(a + \lambda)$, then at the distance a from its centre, where it enters the plastic zone, it must have a certain width. This width is the COD.

The COD is a property of the material, is the subject of standard tests and may be related to other properties such as the fracture toughness. Standard tests include BS 5762: 1979 and ASTM Test Method E1290: 1990 and relations exist between the COD and other parameters; the tests and relationships are discussed by Rolfe and Barsom (1987).

Expressions for the COD δ may be obtained from the models of crack tip plastic behaviour. For the model of Dugdale (1960):

$$\delta = \frac{8}{\pi}\frac{\sigma_{ys}}{E} a \ln\left(\frac{a+\rho}{a}\right) \quad [12.28.35]$$

and also

$$\delta = \frac{8}{\pi}\frac{\sigma_{ys}}{E} a \ln\left[\sec\left(\frac{\pi a}{2\sigma_{ys}}\right)\right] \quad [12.28.36]$$

This last equation may be

$$\delta \approx \frac{\pi\sigma^2 a}{E\sigma_{ys}} \qquad \sigma < 0.7\sigma_{ys} \quad [12.28.37]$$

Then from Equations 12.28.16 and 12.28.37

$$\delta = K_I^2/E\sigma_{vs} \quad [12.28.38]$$

The crack opening displacement δ has a critical value δ_C corresponding to the critical stress σ_c.

In line with the foregoing, a general relation for the critical crack opening displacement has been given by J.N. Robinson and Tetelman (1974)

$$\delta_c = \frac{K_{IC}^2}{\lambda' E\sigma_{ys}} \qquad \text{plane stress} \quad [12.28.39]$$

$$\delta_c = \frac{K_{IC}^2(1-v^2)}{\lambda' E\sigma_{ys}} \qquad \text{plane strain} \quad [12.28.40]$$

where λ' is a constraint factor.

12.28.17 Fatigue crack growth

A principal mechanism of crack propagation is fatigue. If a crack is subjected to a cyclic stress of amplitude $\Delta\sigma$ this induces a corresponding range of the stress intensity factor ΔK. Then from Equation 12.28.22

$$\Delta K = Q\Delta\sigma(\pi a)^{1/2} \quad [12.28.41]$$

If the rate of increase $\mathrm{d}a/\mathrm{d}N$ of the crack length is plotted against the stress intensity factor range ΔK on a log–log plot, then as shown in Figure 12.22, the curve has three regions. In the first region (1) there is rapid crack growth; in the second region (2) the crack growth is slower and more predictable; and in the third region (3) the crack growth accelerates again to failure. Over the second region the curve is given by the Paris equation:

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C(\Delta K)^m \quad [12.28.42]$$

where N is the number of loading cycles, C is a constant, and m is an index. For most ferrous and non-ferrous metals $m \approx 4$.

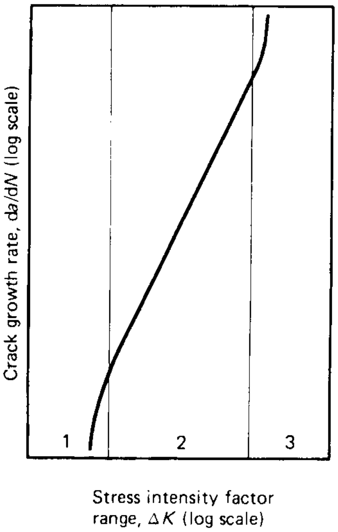

Figure 12.22 *Typical crack growth rate for mild steel*

Equation 12.28.42 may be integrated as follows:

$$N = \int_{a_i}^{a_f} \frac{1}{C(\Delta K)^m}\,\mathrm{d}a \quad [12.28.43]$$

where subscripts f and i indicate final and initial, respectively. Fatigue is not, however, the only mechanism of crack propagation. At high temperatures, crack growth can occur by creep. In this case the rate of growth is expressed not in terms of the number N of cycles but of time t, hence as $\mathrm{d}a/\mathrm{d}t$. Treatments have been given by Tomkins (1983) and by Ainsworth and Goodall (1983).

12.28.18 Failure assessment diagram

A method for the assessment of the regime in which a particular equipment is operating has been developed at the CEGB, and is described by R.P. Harrison and Milne (1981).

Linear elastic failure and fully plastic failure represent two limiting cases. Two parameters are defined as follows. For linear elastic failure

$$K_r = K_I(a)/K_{IC} \quad [12.28.44]$$

and for fully plastic failure

$$S_r = \sigma/\sigma_1(a) \quad [12.28.45]$$

where K_r is a measure of the proximity to linear elastic failure, S_r is a measure of the proximity to fully plastic failure and $\sigma_1(a)$ is the plastic collapse stress. As indicated, both K, and σ_1 are functions of the crack half-length.

Figure 12.23 illustrates the failure assessment diagram (FAD) given by the authors and based on these two parameters. The failure assessment line in the diagram is constructed using an elastic-plastic model from the work of Dugdale (1960), Bilby, Cottrell and Swinden (1963) and Heald, Spink and Worthington (1972) to interpolate

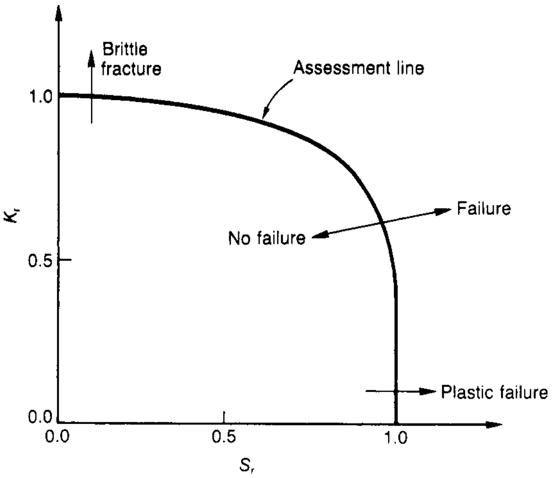

Figure 12.23 *Failure assessment diagram (after R.P. Harrison and Milne, 1981) (Courtesy of The Royal Society)*

between the two limiting behaviours. It has been shown by Chell (1978) that this approach is a reasonable approximation to the failure curve for any structural geometry. It is supported by tests on laboratory specimens and on structures as described by R.P. Harrison, Loosemore and Milne (1979). Failure is conceded if the assessment point lies outside (to the right) or on the curve. If lower bound data areused, the curve may be regarded as a failure avoidance line.

The method has been developed to support a comprehensive system of fracture mechanics used in the CEGB and elsewhere. This system is referred to as the 'R6 Procedure'. Its third revision is given in a CEGB report by Milne *et al.* (1986) and in the open literature by Milne *et al.* (1988b).

12.28.19 Fracture analysis diagram

Another widely used diagram is the fracture analysis diagram (also FAD). This was developed by Pellini (1971) as a means of providing guidance on steels which exhibit a transition temperature. The diagram is a plot of stress vs temperature and has four reference points: the null ductility transition (NDT), fracture transition elastic (FTE) and fracture transition plastic (FTP) points and midrange point between NDT and FTE. As described by the author, restricting the service temperature to just above the NDT provides fracture initiation protection for most common failures; restricting it to the mid-range between NDT and FTE provides fracture arrest protection for $\sigma \leq 0.5\sigma_{ys}$; restricting it to above the FTE provides fracture arrest protection for $\sigma \leq \sigma_{ys}$; and restricting it above the FTP ensures that the fracture is fully ductile.

12.28.20 Through-thickness yielding

It is of interest to be able to establish in a given case whether through-thickness yielding will occur before fracture. Such yielding is a function of plate thickness. As already described, the two limiting conditions are those of plane stress in thin plates and plane strain in thick plates. Practical situations to lie between these two extremes.

Through-thickness yielding is generally treated in terms of the dimensionless parameter β

$$\beta = \frac{1}{B}\left(\frac{K_{IC}}{\sigma_{ys}}\right)^2 \qquad [12.28.46]$$

where B is the plate thickness.

A discussion of the values given by various workers for the parameter β and their interpretation is given by Rolfe and Barsom (1987). They quote ASTM Committee 24 on Fracture Testing as advising that to ensure plain strain behaviour it is necessary to have $\beta \geq 0.4$. Hahn and Rosenfield (1968) found a significant increase in the rate at which through-thickness deformation occurs for $\beta \geq 1$. Irwin (1962) used a value of $\beta = 1.4$ in his leak-before-break model, described below.

12.28.21 Leak-before-break behaviour

If a crack grows to the point where it will cause failure, it is obviously desirable that it give warning of impending failure by leaking. It is possible using fracture mechanics to assess whether or not in a given situation the crack will exhibit such leak-before-break (LBB) behaviour. This behaviour is also sometimes called leak-before-fracture (LBF) and its obverse as fracture-before-leak (FBL).

The LBB criterion was proposed by Irwin *et al.* (1967) with the aim of predicting the toughness required in a pressure vessel so that before fracture occurs a surface crack will grow through the wall and give a leak. Another way of putting this is that the critical crack size is greater than the wall thickness.

An account of the LBB criterion is given by Rolfe and Barsom (1977). It is assumed that a surface crack might grow through a wall of thickness B into a through-thickness crack of length $2B$. Hence the LBB criterion is $2a \approx 2B$. The authors use for the stress intensity factor K_I, the relation

$$K_I^2 = \frac{\sigma^2 \pi a}{1 - 0.5(\sigma/\sigma_{ys})^2} \qquad [12.28.47]$$

or, for low stress

$$K_I = \sigma(\pi a)^{1/2} \qquad [12.28.48]$$

as given earlier. Then for the critical stress $K_I = K_c$. The critical stress intensity factor K_c is obtained using the following relation:

$$K_c^2 = K_{IC}^2(1 + 1.4\beta_{IC}^2) \qquad [12.28.49]$$

with

$$\beta_{IC} = \frac{1}{B}\left(\frac{K_{IC}}{\sigma_{ys}}\right)^2 \qquad [12.28.50]$$

where B is the wall thickness and β_{IC} a dimensionless parameter.

Another treatment of LBB is given by Harvey (1974), who deals with practical aspects such as allowance for residual stress.

One use of the LBB method is in the design of a vessel to ensure that it operates in the LBB region. Another is to calculate the allowable stress in a vessel where a crack has been observed. Another is to check that the size of crack which requires a reduction in operating stress is detectable by the inspection methods used.

12.28.22 Some design features

The fracture characteristics just described have a number of implications for the design of pressure systems. They include: the effects of plate thickness and through-thickness yielding; the effect of the use of advanced design codes; and the LBB principle.

If a plate is sufficiently thin, fracture is ductile; if it is sufficiently thick, fracture is brittle. Much equipment in pressure systems will lie somewhere in between. The relations for through-thickness yielding provide a means of quantifying this behaviour.

Advanced design codes such as BS 5500 and ASME *Boiler and Pressure Vessel Code*, Section VIII, Division 2, permit the use of a stress which constitutes a higher proportion of the ultimate tensile stress; in other words the ratio σ_u/σ is lower, so that instead of being 4 it lies in the range 2–3. Whilst this gives economies in equipment design, it means that the length of the critical crack is appreciably reduced, thus making it more difficult to ensure detection of such a crack.

For critical equipment, such as a vessel containing a large inventory of a hazardous material, it is possible to identify the region in which a fracture will exhibit LBB behaviour, with a view to designing to ensure that the equipment operates always in that region.

There are also implications for inspection. Fracture mechanics can indicate the size of crack which needs to be detected by the inspection procedures and the inspection interval necessary to ensure that no crack grows to its critical value before the next inspection.

12.29 Probabilistic Fracture Mechanics

A comprehensive approach to equipment failure from crack propagation requires that the deterministic treatment just described be complemented by probabilistic methods. Probabilistic fracture mechanics addresses such questions as the probability that a crack will be present, that it is not detected on a given inspection and that it grows to a critical size before the next inspection, causing failure. Accounts of probabilistic fracture mechanics include those by O'Neil (1980), Temple (1983, 1985), Haines (1983), Lidiard (1984) and Thomson (1987).

The probability that a pressure vessel, or similar equipment, will fail due to crack propagation may be expressed as follows:

$$P_f = P_{x0}(x) P_{nf} P_{gc} \qquad [12.29.1]$$

where P_f is the probability that the vessel fails, P_{gc} is the probability that the defect grows to critical size before the next inspection, P_{nf} is the probability that the defect is not detected by non-destructive examination (NDE) at a given inspection, $P_{x0}(x)$ is the probability that the vessel has an initial defect of depth $> x$, and x is the crack depth (mm).

Work in this area has focused particularly on pressure vessels for nuclear pressurized water reactors (PWRs). In a study of this problem, Lidiard (1984) obtained the relation

$$P_{x0}(x) = \frac{A}{\Theta}\exp(-\Theta x) \qquad [12.29.2]$$

where A and Θ are constants (both mm^{-1}). He obtained for such vessels values of A and Θ of 0.59 and 0.16, respectively. These values imply, for example, that the probability of such a vessel having a crack of depth exceeding 25 mm is 0.067 and the probability of one exceeding 50 mm is 1.24×10^{-3}.

The reliability of detection by NDE was the subject of a study by the European Community Plate Inspection Steering Committee (PISC). Information obtained on defect detection probability (DDP) is described by O'Neil (1980) and an analysis is given by Haines (1983).

The data on the probability of detection, or DDP, may be fitted to an appropriate distribution. That used by W. Marshall (1982) is the exponential distribution. Thomson (1987) proposes, for a simplified analysis, that the probability of detection by NDE, P_n may be fitted to a log–normal distribution, as given by Equation 7.7.20. He gives for the parameters of the distribution m^* and σ the values 3.135 and 0.667 mm, respectively. The probability P_{nf} of failure to detect is the complement of P_n.

The probability that a crack will grow to critical size may be obtained deterministically by the method described in the previous section. Alternatively, it too may be treated probabilistically. This approach has been described by Temple (1985). The probability P_{gc} that the crack grows to critical size given that it has an initial depth x_0 and stress intensity factor range ΔK and is subject to N loading cycles may be written as $P_{gc}(x/x_0, \Delta K, N)$. Then, taking for this probability a log-normal distribution, Temple obtains for PWR vessels:

$$m^* = x_0 + 6.56 \times 10^{-5} \Delta K \cdot N \text{ mm}$$

$$\sigma = 2.93 \times 10^{-5} \Delta K \text{ mm}$$

where ΔK is the stress intensity factor range (MPa/m$^{1/2}$). The application of the relations just described to obtain the probability of vessel failure is discussed, with illustrative examples, by Thomson. He casts Equation 12.29.1 in the form

$$P_f = \int_0^{x_c} P_{x0}(x) P_n(x) p_{gc}(x)\, dx \qquad [12.29.3]$$

where p_{gc} is the probability density function corresponding to the probability distribution P_{gc} and x_c is the critical crack length.

H.M. Thomas (1981) describes an approach to the determination of the probability ρ_c of catastrophic failure and ρ_L of leak which starts with generic estimates but involves a learning process using data from the actual plant to obtain more refined estimates.

12.30 Failure of Vessels, Equipment and Machinery

There is a certain amount of statistical information available on the failure of pressure system components.

12.30.1 Failure of pressure vessels

Work on the failure rates and modes of pressure vessels has been driven initially by the needs of the nuclear industry.

Information on pressure vessel failure is given in *A Survey of Defects in Pressure Vessels Built to High Standards of Construction and its Relevance to Nuclear Primary Circuit Envelopes* by Phillips and Warwick (1968 UKAEA AHSB(S) R162). The survey deals with pressure vessels built to Class 1 requirements of BS 1500, BS 1515 and comparable standards. It classifies failures as catastrophic or potentially dangerous. The former are disruptions of the vessel which require major repair or scrapping; the latter are defects which might deteriorate under the working conditions and which require remedial action. The following information is given on failures prior to service and in service:

	Sample size	*Failure rate* (failures/year)	
		Potentially dangerous failures	*Catastrophic failures*
Failure in construction	12,700 vessels	5.5×10^{-4}	2.3×10^{-4}
Failure in service	100,300 vessel-years	1.25×10^{-3}	0.7×10^{-4}

For all the service failures the causes were classified. The results are shown in Table 12.11. The vast majority of failures, some 89.3%, were due to cracks. The causes of cracks were therefore analysed separately as shown in the table. The table also gives the methods by which the failures were detected.

In addition, Phillips and Warwick analysed the effects of other variables such as materials of construction, design conditions, fluid handled, component state and age. The results are given in Table 12.12. As indicated in Table 12.12, there were seven catastrophic failures. The causes of these failures were: maloperation (four cases), fatigue (two cases), and pre-existing from manufacture (one case). The authors comment: 'Most of these catastrophic failures are due to inadequate operational procedures and highlight the need for more consideration of control techniques.'

The authors then analyse the data to assess the failure frequency of the pressure vessels used in nuclear reactor primary circuit envelopes. They conclude that many of the failures given in the survey would not apply in such vessels, for example, cracks in boiler furnaces, and reduce the total number of applicable service failures from 132 to 62 and the number of applicable catastrophic failures from 7 to 2. Then the failure frequencies become:

	Failure rate (failures/year)	
	Potentially dangerous failures	*Catastrophic failures*
Failure in service	6×10^{-4}	2×10^{-5}

These results agree reasonably well with the catastrophic failure frequencies estimated for nuclear vessels by Kellerman and Seipel (1967). This study provides a good illustration of the determination of failure data and of the derivation from crude data of failure data applicable to the

Table 12.11 *Causes and methods of detection of service failure in pressure vessels (after Phillips and Warwick, 1968 UKAEA AHSB(S) R162) (Courtesy of the UK Atomic Energy Authority)*

	No. of cases	*Percentage of total cases*
Causes of failures:		
Cracks	118	89.3
Maloperation	8	6.1
Pre-existing from manufacture	3	2.3
Corrosion	2	1.5
Creep	1	0.8
	132	100.0
Causes of cracks:		
Fatigue	47	35.6
Corrosion	24	18.2
Pre-existing from manufacture	10	7.6
Miscellaneous	2	1.5
Not ascertained	35	26.5
	118	89.4
Method of detection:		
Visual examination	75	56.9
Leakage	38	28.8
Non-destructive testing	10	7.5
Hydraulic tests	2	1.5
Catastrophic failure	7	5.3
	132	100.0

Table 12.12 *Other variables relevant to service failure in pressure vessels (after Phillips and Warwick, 1968 UKAEA AHSB(S) R162) (Courtesy of the UK Atomic Energy Authority)*

Variables	*Failures*			
	Potentially dangerous failures[a]		*Catastrophic failures*[a]	
	No.	(%)	*No.*	(%)
Materials of construction:				
Mild steel	105	79.5	5	3.9
Alloy steel	20	15.1	2	1.5
Design pressure:				
<500 lb/in.^{2}	41	31.1	4	3.1
≥ 500 lb/in.^{2}	84	63.5	3	2.3
Design temperature:				
<600°F	15	11.4	1	0.7
≥600°F	69	52.5	1	0.7
Not stated	41	31.1	5	3.9
Age:				
<10 years	59	45.0	6	5.0
≥10 years	64	48.5	1	0.7
Not stated	2	1.5		
Component state:

Unfired	96	72.6	3	2.3
Fluid handled:				
Gas (including steam)	69	52.2	4	3.1
Liquid	14	10.6		
Mixture	42	31.8	3	2.3

[a] These columns give alternative breakdowns of the 125 potentially dangerous and seven catastrophic failures.

case which is of interest. The survey just described has been updated by a further survey by Smith and Warwick (1974 SRD R30). Again this survey dealt only with pressure vessels built to Class 1 requirements. The period covered by the survey was from the latter half of 1967 to the end of 1972. The information shown in the table below was obtained on failures prior to service and in service:

Sample size		*Failure rate* (failures/year)	
		Potentially dangerous failures	*Catastrophic failures*
Failure in construction	8,823 vessels	2.1×10^{-3}	–
Failure in service	105,402 vessel-years	1.1×10^{-3}	1.5×10^{-4}

In this latter survey, therefore, there were no catastrophic failures in construction, but the failure rates of potentially dangerous failures in construction and catastrophic failures in service are appreciably greater than in the earlier survey. The failure rate of potentially dangerous failures in service is similar. The survey includes further tables giving the classifications of service failures and the variables relevant to service failures similar to Tables 12.11 and 12.12.

A further analysis of pressure vessel failure statistics made by the Atomic Energy Commission (AEC) Advisory Committee on Reactor Safety (ACRS) has been described by Engel (1974). This work refers to further large collections of pressure vessel failure data by the Edison Electric Institute-Tennessee Valley Authority (EEI-TVA), by the American Boiler Manufacturers Association (ABMA) and by the Institut fur Reactorsicherheit der Technischen Uberwachungs-Verein (TUV). The EEI-TVA data are effectively a subset of the ABMA data. Studies based on the TUV2 data have been published by Kellerman (1966), Kellerman and Seipel (1967) and Slopianka and Mieze (1968).

The most severe category of failure used by Engel is a disruptive failure, which is breaching of the vessel accompanied by the release of a large volume of contained fluid. He treats this as a more restrictive category other than of catastrophic failure used by Phillips and Warwick. Engel considers failures of non-nuclear vessels applicable to nuclear reactor vessels. The largest data collections are as tabulated below:

Data source	*Sample size* (vessel-years)	*Disruptive failures* (failures/year)	
		No. of failures	*Upper bound of failure rate at 99% confidence*
Phillips and Warwick (1968)	100,300	0	4.6×10^{-5}
ABMA (Marx, 1973)	723,000	0	0.64×10^{-5}
Kellerman and Seipel (1967)	1,700,000	0–49	0.27×10^{-5}–4.0×10^{-5}

The work by Kellerman and Seipel does not indicate how many of the 49 failures reported might be classified as disruptive and therefore the number of failures and the upper bound on this failure rate are shown in the table as ranges. The upper bound of the failure rate in the table is determined by the statistical methods described in Chapter 7 and for zero disruptive failures is equal at the 99% confidence level to 4.6 (9.2/2) divided by the number of vessel-years.

Engel concludes that the ABMA data are the most useful and significant. These data are for pressure vessels designed to the ASME *Boiler and Pressure Vessel Code*, Section I or Section VIII, version 1956 or later, for pressures and temperatures equal to or exceeding those in light water reactors (LWRs) and with wall thicknesses exceeding 1.5 in. He states that the data support the conclusion that for failure of pressure vessels applicable to nuclear reactors the disruptive failure rate is less than 1×10^{-5} failures/year.

In a further survey, Smith and Warwick (1981 SRD R203) obtained for the period 1962–78 the following failure rates for pressure vessel failures in service. For some 20,000 vessels they obtained the results given below. Of the 229 failures, 206 were cracks.

Sample size (vessel-years)	*No. of failures*		*Failure rate* (failures/year)	
	Potentially dangerous failures	*Catastrophic failures*	*Potentially dangerous failures*	*Catastrophic failures*
310,000	216	13	6.9×10^{-4}	4.2×10^{-5}

A survey of pressure vessel failures in process plants has been reported by Arulanantham and Lees (1981). The work covered process pressure vessels, pressure storage vessels, non-pressure storage vessels, heat exchangers and fired heaters. The plants studied were four olefins plants and one plant handling a toxic and corrosive material, in a single works. Two of the olefins plants were commissioned in the 1950s and closed down in the 1960s, one was commissioned in the 1960s and closed in the 1970s and one was commissioned in the 1960s and was still operating. The toxics plant was also commissioned in the 1960s and was still operating. The olefins plants operated at about 3.5 and 35 barg at the hot and cold ends, respectively, except that at the hot end there was steam generation at about 85 barg. The temperatures ranged from –100° to 800°C. The toxics plant operated at relatively low pressures and mild temperatures. Excluded from the survey were failures in steam boilers and steam and air receivers and in pipework and also heat exchanger tube failures. The authors define failure as a condition in which a crack, leak or other defect has developed in the equipment so that repair or replacement is required, a definition which they treat as including some of the potentially dangerous as well as all the catastrophic failures in that of Phillips and Warwick. They report failure rates classified by type of vessel, operating conditions and causes of failure.

For pressure vessels other than fired heaters, that is, process pressure vessels, pressure storage vessels and heat exchangers they obtain:

Sample size		*No. of failures*	*Failure rate* (failures/year)
Vessels	Vessel-years		
1216	16,417	70	4.3×10^{-3}

Other failure data given are as follows. For the olefins plants:

Vessel	*Sample size*		*No. of failures*	*Failure rate* (failures/year)
	Vessels	Vessel-years		
Process pressure vessel	415	5535	15	2.7×10^{-3}
Pressure storage vessel	129	2220	4	1.8×10^{-3}
Heat exchanger	446	5950	10	1.7×10^{-3}
Fired heaters	36	447	181	405×10^{-3}
High temperature vessel, except fired heater	58	809	6	7.4×10^{-3}
Low temperature vessel	147	1941	3	1.5×10^{-3}

Here the pressure storage vessel data are for the whole works and the fired heater data are for the toxics plant also. For the toxics plant:

Vessel	*Sample size*		*No. of failures*	*Failure rate* (failures/year)
	Vessels	Vessel-years		
Process pressure vessel	131	1572	15	26×10^{-3}
High temperature vessel, except fired heater	16	192	7	36×10^{-3}
Vessel in corrosive duty	45	540	21	39×10^{-3}
Vessel subject to stress corrosion	49	588	12	20×10^{3}

Davenport (1991) has reported a survey involving some 360,000 vessels and 1.8×10^6 vessel-years over the period 1983–88, which is a much larger sample than that obtained by Smith and Warwick. The survey was not confined to Class 1 vessels, but took in a much larger range, and in fact is dominated by relatively thin-walled air receivers, so that the two surveys are not comparable. In the survey by Davenport there were 92 failures, of which 60 were cracks.

The distribution of pressure vessel disruptive failure rates from a number of sources has been analysed by Hurst, Davies *et al.* (1994). In this work the authors give various sets of failure rate data as plots of $\log_{10}\lambda$ vs normal quantiles, where λ is the failure rate of the exponential distribution, in order to check whether the failure rates are log-normally distributed. Their plot for pressure vessels is shown in Figure 12.24(a), the straight line confirming that the distribution of the failure rates is log–normal. The mean pressure vessel disruptive failure rate obtained from this plot is $\lambda \approx 10^{-5}$/year. The failure rates vary, however, by some five orders of magnitude at the 95% confidence level.

With regard to pressure vessel failure rates used in hazard assessments, the First *Convey Report* gives for spontaneous failure of a pressure vessel a failure rate of some 10^{-5}–10^{-4} failures/year. A failure rate of 10^{-5} failures/year is used in the study, but the sensitivity of the results to the higher failure rate is also given. The treatment of pressure vessel failure rates in the report is described in Appendix 7.

The *Rijnmond Report* gives for catastrophic failure and for serious leakage of a pressure vessel failure rates of 10^{-6} and 10^{-5} failures/year, respectively.

The estimated failure rate of a pressure vessel is given by Batstone and Tomi (1980) as 10^{-6} failures/year.

12.30.2 Failure of pipework

There is a considerable amount of data available on pipework failures, but the range of values quoted is wide and tends to be confusing. There are several important distinctions to be made. One concerns the type of failure. Complete pipe breaks, or guillotine fractures, constitute only a small proportion of failures. Another relates to the pipe size. The failure rate tends to be higher for small than for large diameter pipes. A further difference in the figures arises from the basis on which figures are quoted, which may be per unit length of pipe run, per pipework section or per plant.

Even so, the quoted failure rates of pipework show considerable variation. Table 12.13 shows some estimates of the failure rate of pipework on nuclear plants quoted in the Rosmussen Report. Similarly, Figure 12.25 has been given by Hawksley (1984) to illustrate the variability of pipework failure rates.

As with pressure vessels, so with piping, early work on failure rates and modes was directed to nuclear industry needs. Data on pipework failure have been given by a number of authors, particularly those concerned with nuclear systems, such as Smith and Warwick (1974 SRD R30) and Bush (1977).

Smith and Warwick (1974 SRD R30), applying definitions of catastrophic and potentially dangerous failures, similar to those which they used for pressure vessels as described in the previous section, obtained for reactor systems the data contained in the table below.

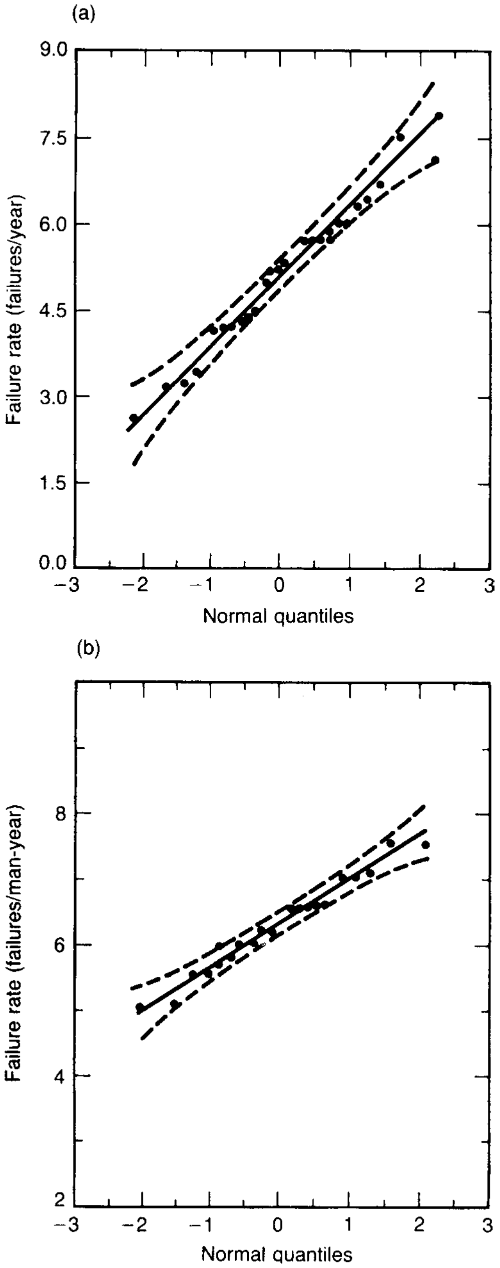

Figure 12.24 *Distribution of disruptive failure rates of pressure vessels and pipework (Hurst Davies et al., 1994): (a) pressure vessel disruptive failure rates (failures/year); and (b) pipework guillotine fracture failure rates (failures/m-year). In these graphs the variable of interest is the logarithm of the exponential failure rate, which is shown plotted against the quantiles of the normal distribution. A straight line through the points indicates that this variable is log-normally distributed. The value corresponding to the zero value of the normal quantile is the mean of the failure rate values.*

Sample size (reactor system-years)	*No. of failures*		*Failure rate* (failures/year)	
	Potentially dangerous failures	*Catastrophic failures*	*Potentially dangerous failures*	*Catastrophic failures*
2397	35	6	1.5×10^{-2}	2.5×10^{-3}

The reactor system included reactors and other equipment such as heat exchangers as well as pipework, but the failures were predominantly in the latter.

The failure rate of pipework in nuclear plants is given by Bush (1977) as 4.3×10^{-5} failures/man-year derived from eight failures, which are individually described and of which four were due to water hammer.

A survey of pipework failure in nuclear plants to provide information more up-to-date than that given in *Rosmussen Report* has been described by R.E. Wright, Steverson and Zuroff (1987). They distinguish between pipework for which a failure would result in a loss-of-coolant accident (LOCA), which they term 'LOCA-sensitive', and other pipework. Their summary of the pipework failure rates used in the *Rosmussen Report* is shown in Table 12.14.

The authors obtained data for US nuclear reactors with a total operating time of nearly 800 reactor-years, covering both PWRs and boiling water reactors (BWRs). They consider three pipe ranges: 0.5–2 in. > 2–6 in. and > 6 in. For LOCA-sensitive systems they defined a failure as a leak flow ≥ 50 US gal/min for PWRs and ≥ 500 US gal/min for BWRs. For non-LOCA-sensitive systems all pipe break failures were collected which had a leak flow ≥ 1 US gal/min for pipes ≥ 2 in. diameter or which had a leak flow of ≥ 50 US gal/min for all pipe sizes.

For PWRs with a total period of operation of 485 years and BWRs with a period 313 years, there were no failures of LOCA-sensitive pipework. There were, therefore, 798 years of operation of the two types of (LWR) free of failure. The point estimates of the failure rate based on this information were 0.0005, 0.0007 and 0.0003 failures/reactor-year for PWRs, BWRs and LWRs, respectively. The value for LWRs is evidently not the average of the values for the two types of LWR, but a value determined in its own right and based on the total of 798 years accumulated by both reactor types.

For the non-LOCA-sensitive pipework there were nine failures in PWRs and 10 in BWRs, making a total of 19 failures for LWRs. Pipe length and weld population data were available for 18 plants. The authors used these data to give the pipe length and weld populations of a nuclear plant. The mean pipe lengths and weld numbers obtained are given in Table 12.15, Sections A and B. Breakdowns of the failures by plant type and pipe size, by leak flow and by operational mode are given in Sections C, D and E of Table 12.15, respectively. The causes of failure were mainly vibration (10 cases) and water hammer (3 cases). The other cases were attributed one each to pump seizure, corrosion, fatigue, impact, operator error and unknown cause.

In the survey of failure rates of pressure equipment in process plants described in the previous section, Arulanantham and Lees (1981) also report data on major failures of pipework in one of the olefins plants. Over a 9.5-year period there were seven failures, giving a failure rate of 0.74 failures/plant. The failures are described

Table 12.13 *Estimates of failure rates of pipework in nuclear plants given in the Rasmussen Report (after Atomic Energy Commission, 1975)*

	Failure rate
'Probability of large scale rupture of primary coolant system' (A.E. Green and Bourne) (1968)	$3 \times 10^{-6} - 2 \times 10^{-3}$/plant-year
'Catastrophic rupture of primary system pipes' (Salvatory) (1970)	1×10^{-4}/plant-year
'Pipe rupture' (Erdmann) (1973):	1.5×10^{-6}/section-year
which corresponds roughly to	1×10^{-4}–1×10^{-2}/plant-year
'Pessimistic probability for catastrophic failure of primary system of PWR' (Otway)	1.7×10^{-7}/plant-year
'Total probability of severence anywhere in primary system piping' (General Electric Report) (1970):	
Without ultrasonic testing	1×10^{-3} /plant-year
With ultrasonic testing	1×10^{-4}/plant-year
'Failure rate for rupture of primary coolant system piping' (Wells-Knecht) (1965)	1×10^{-7}/plant-year

Note: The references given in this table refer to those in the *Rasmussen Report*, not this book.

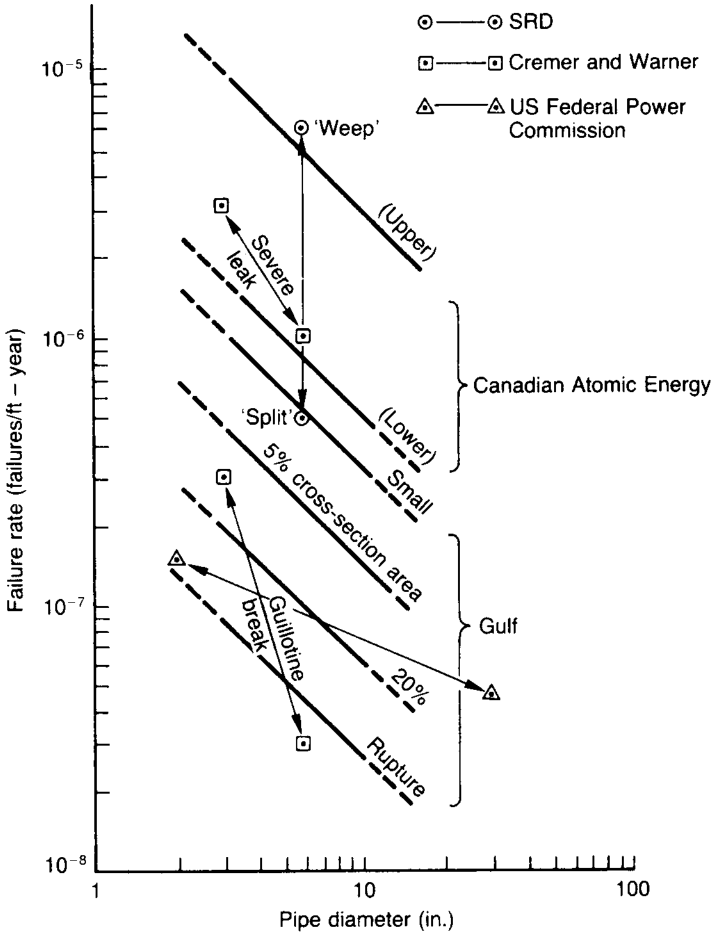

Figure 12.25 *Some data on pipework failure rates (Hawksley, 1984)*

Table 12.14 *Failure rates for LOCA-initiating ruptures used in the Rasmussen Report (after R.E. Wright, Steverson and Zuroff, 1987)*

Pipe repture size (in.)	*LOCA-initiating rupture rates* (failures/plant-year)	
	Median	*Range*
$\frac{1}{2}-2$	1×10^{-3}	1×10^{-4}–1×10^{-2}
2–6	3×10^{-4}	3×10^{-5}–3×10^{-3}
>6	1×10^{-4}	1×10^{-5}–1×10^{-3}

individually: two were due to water hammer, two to vibration-induced fatigue, one to brittle fracture resulting from admission of freezing hydrocarbon and one to overpressure of a pump suction line.

A survey of pipework failure in plants in the nuclear, chemical and other industries had been described by Blything and Parry (1988 SRD R411). The data sources were as follows. For chemical plants use was made of data from a medium-sized plant and of incident data from four separate sources; for refineries data were obtained from the plants of an oil company and from incidents; for nuclear plants data sources were a study by Riso National Laboratory and a presentation by the Nuclear Installations Inspectorate (NII); for steam plants the data were taken from T.A. Smith and Warwick (1974) and Gibbons and Hackney (1964).

The data were analysed by 'failure cause' and 'root cause'. Essentially, failure causes are the mechanical causes, such as corrosion, fatigue and water hammer, and root causes are activities such as error in design, operation and maintenance. Their results are summarized in Table 12.16, which gives the failure causes vs root causes for chemical plants and refineries (Section A) and for nuclear plants and steam plants (Section B).

The severity of failure expressed as leak flow is shown in Table 12.17 for the medium-sized chemical plant in Section A and for the GEC steam plant survey in Section B. The mechanical failures for the five chemical plant sources were as follows:

	No.	*Proportion* (%)
Weld failure	45	33.1
Stress rupture	30	22.1
Bending stress	2	1.5
Fatigue	3	2.2
External load	4	2.9
Bellows failure	3	2.2
Valve failure	27	19.9
Seal failure	15	11.0
Miscellaneous	7	5.1
Total	136	100.0

Kletz (1984k) has given information on some 50 major pipe failures in process plants as shown in Table 12.18. Section A of the table gives general failures, Section B gives failures in dead ends, and Section C gives bellows failures. The suggestions which Kletz makes for prevention of each failure are given in Table 12.19. He also makes proposals for reduction of pipework failures by improved design and describes some points to look for in inspection of pipework. These aspects are described in Section 12.7 and Chapter 19, respectively.

A study of pipework failures in process plants has been described by Bellamy and co-workers (Bellamy, Geyer and Astley 1989; Geyer *et al.*, 1990; Geyer and Bellamy, 1991; Hurst *et al.*, 1991). This work was concerned particularly with human factors as a cause of failure. This study reviewed 921 incidents from incident data bases such as the HSE MARCODE, the Safety and Reliability Directorate (SRD) MHIDAS and (the Toegepast-Natuurwetenschappelijk Onderzoek (TNO) FACTS data bases. Some analysis was undertaken on all 921 incidents, and some 500 of these incidents were selected as suitable for further analysis. Pipelines and flexible hoses were excluded.

The data were biased towards failures in larger pipes, as the following breakdown of pipework failures shows:

Pipe size (mm)	*Frequency of failure*
>150	70
51–149.9	31
26–50.9	19
13.1–25.9	22
≤13	3
Total	145

This reflects the fact that the study was based on incidents held in data bases.

Incidents were classified under the three headings: (1) direct cause, (2) origin of failure or underlying cause, and (3) recovery from failure or preventive mechanism. Detailed accounts of these definitions are given by Bellamy and Geyer (1989) and by Hurst *et al.* (1991).

Table 12.20 gives the direct causes of failure and Table 12.21 the underlying causes vs the recovery failure.

Table 12.22 gives a breakdown of the failures of pipes, valves and other equipment, for those incidents where the information was available. Table 12.23 shows the state of the equipment, again for those cases where there was information. The survey also yielded information on various aspects of the releases, some of which is described in other chapters.

In the work already described, Hurst Davies *et al.* (1994) also plotted the distribution of pipework guillotine failure rates from a number of sources, in order to check whether the failure rates are log-normally distributed. Their plot for pipework guillotine failure rates is shown in Figure 12.24(b), the straight line confirming that the distribution of the failure rates is log–normal. The mean pipework guillotine failure rate obtained from this plot is $\lambda\approx4.6\times10^{-7}$/m-year. The failure rates vary, however, by some 2.5 orders of magnitude at the 95 % confidence level.

Further values for pipework failure are quoted in work on hazard assessment. Estimated failure rates of pipework quoted by Batstone and Tomi (1980) are given in Table 12.24.

Pape and Nussey (1985) in a hazard assessment of a chlorine installation have used for 25 mm diameter pipe the following values:

Frequency of guillotine fracture
$= 3\times10^{-7}$ failures/m-year

Table 12.15 *Failure rates for rupture in non-LOCA-sensitive pipework in US nuclear plants (after R.E. Wright, Steverson and Zuroff, 1987)*

A Pipe length populations (ft)[a]

	Pipe size (in.)^2				
	2	*>2–6*	*>6*	*No. of plants*	*Total length* (in.)
PWRs:					
LOCA-sensitive	212	338	209	6	1,834
Non-LOCA-sensitive[b]	6,312	11,883	15,021	2–8 (av. 4.7)	33,239
BWRs:					
LOCA-sensitive	2,603	3,024	4,427	1–2 (av. 1.7)	5,803
Non-LOCA-sensitive[b]	–	5,906	6,577	0–2 (av. 1.0)	3,045

B Pipe weld populations (no. of welds)[a]

	Pipe size (in.)^2				
	2	*> 2–6*	*> 6*	*No. of plants*	*Total*
PWRs:					
LOCA-sensitive	123	161	100	8	579
Non-LOCA-sensitive[b]	2,914	3,862	3,800	3–10 (av. 5.2)	12,289
BWRs:					
LOCA-sensitive	870	448	622	2	1,078
Non-LOCA-sensitive[b]	–	1,915	2,114	1–2 (av. 1.7)	861

C Failures by plant type and pipe size

Pipe size (in.)	*No. of failures*	*No. of reactor-years*	*Failure rate* (failures/reactor-year)
PWRs:			
$\frac{1}{2}$–2	2	484	0.0041
≥2–6	4	484	0.0083
≥6	3	484	0.0062
Total			0.0186
BRWs:			
$\frac{1}{2}$–2	3	313	0.0096
≥2–6	2	313	0.0064
≥6	5	313	0.0160
Total			0.0320
LWRs:			
Total	19	798	0.0238

D Failures by leak flow

Leak flow (US gal/min)	*No. of failures*	*No. of reactor-years*	*Leak frequency* (leaks/reactor-year)
PWRs:			
>1–<15	5	484	0.0103
>15	4	484	0.0083
BWRs:			
>1–<15	1	313	0.0032
>15	9	313	0.0287

E Failures by operational mode

Plant type	*No. of failures*			*Total*
	Starting up	*Normal operation*	*Whilst shut-down*	
PWR	2	5	2	9
BWR	0	8	2	10

[a] The figures in Sections A and B of the table are for background information only. They give an indication of the population of pipe lengths and welds on which data were available. They were not used as such in determining failure rates, which are given as failures/ reactor-year. The total in the final columns is not necessarily the sum of those in the earlier columns. A full explanation of these data is given by the authors.

[b] For PWRs this is primary circuit pipework, for BWRs it is recirculation, main steam and main feed (interpreted as feedwater) pipework.

***Table 12.16** Failure of pipework in chemical, refinery, nuclear and steam plants: failure cause vs root cause (after Blything and Parry, 1986 3 RD R 441) (Courtesy of the UKAEA Safety and Reliability Directorate)*

A Failures in chemical plants and refineries – 'failure cause' vs 'root cause'

	Design	*Installation*	*Design/ installation*	*Operation*	*Maintenance*	*Manufacture*	*Unknown*	*Unspecified*	*Total*
Corrosion:									
External	18	8	–	2	4	–	–	1	33

Water hammer	2	1	1	4	–	–	–	–	8
Work systems	6	4	36	47	49	–	–	2	144
Unknown	–	–	–	–	–	–	29	1	30
Unspecified	1	1	13	3	3	–	–	33	54
Total	158	38	75	73	74	22	31	85	556

B Failures in steam plan is – 'failure cause' vs 'root cause'

	Design	*Installation*	*Design/ installation*	*Operation*	*Maintenance*	*Manufacture*	*Unknown*	*Unspecified*	*Total*
Corrosion:									
External	–	–	–	–	–	–	–	–	–
Internal	16	–	–	14	–	1	–	–	31
Stress	5	–	–	–	–	1	–	–	6
Erosion	13	–	–	53	–	1	–	–	67
Restraint	2	–	2	–	–	–	–	–	4
Vibration	7	1	–	–	–	–	–	–	8
Mechanical	11	6	–	4	1	22	1	–	45
Material	3	–	–	–	–	14	–	–	17
Freezing	1	–	–	–	–	–	–	–	1
Thermal fatigue	7	–	–	–	–	3	–	–	10
Water hammer	–	–	–	2	–	–	–	–	2
Work systems	–	2	1	–	–	–	–	–	3
Unknown	–	–	–	–	–	–	4	–	4
Unspecified	–	–	–	–	–	4	–	–	4
Total	65	9	3	73	1	46	5	–	202

Frequency of lesser failure
$= 3 \times 10^{-6}$ failures/m-year

Frequency of gasket failure
Gaskets 0.6 mm thick $= 3 \times 10^{-6}$ failures/year
Gaskets 3 mm thick $= 5 \times 10^{-6}$ failures/year

The authors state that these data include valve leaks.

The failure rates given by Hawksley (1984) in Figure 12.25 yield the values given in Table 12.25. Comparison of the frequency of a guillotine rupture for pipe diameters > Sin. quoted by some of these sources gives:

	Failure frequency (failures/year)
Gulf	3×10^{-7}
Pape and Nussey	3×10^{-7}
Cremer and Warner	$\approx 1 \times 10^{-6}$
Batstone and Tomi	3×10^{-6}

In converting the data of Batstone and Tomi, it has been assumed that a connection is a pipe section 10 m long.

From these data it might be estimated that for regular pipework the frequency of guillotine rupture for a pipe > 3 in. diameter is 1×10^{-6} failures/m-year and that for more critical pipework it is some three times less.

12.30.3 Failure of process equipment

A survey of the causes of service failure in process equipment generally has been given by Collins and Monack and this has been further analysed by Lancaster (1975). Some 685 failures were recorded. The results of the survey are shown in Table 12.26. Causes of general service failure which are emphasized by this work are general corrosion, stress corrosion cracking and mechanical failure. The number of failures caused by brittle fracture is small.

12.30.4 Failure of process machinery

The results of a survey of causes of service failure in process machinery are shown in Table 12.27. The importance of misalignment as a cause of failure is brought out strongly.

Table 12.17 Failure of pipework in chemical, refinery, nuclear and steam plants: leak flows (after Blything and Parry, 1986 SRD 441) (Courtesy of the UKAEA Safety and Reliability Directorate)

A Failures in a chemical plant

Pipe	*No. of leaks*	*No. of ruptures*
$d < 6$	29	2
$10 < d < 15$	12	–
Total	41	2

B Failures of steam plant (GEC study)

Pipe size (in.)	*No. of leaks*	*No. of ruptures*
$d \leq 6$	115	9
$10 < d \leq 15$	26	7
$d > 15$	6	1
Unspecified	18	2
Total	165	19

Table 12.18 Some pipework failures in process plants: individual cases (after Kletz, 1984k) (Courtesy of the American Institute of Chemical Engineers)

A General failures

1. A pipe was secured too rigidly by welding to supports; vibration caused a section to be torn out
2. Thermal expansion of a pipe caused a $^{3}/_{4}$-in. branch to press against a girder on which the pipe rested; the branch was torn off
3. A batch of pipe-hangers were too hard and many cracked
4. A crane was used to move a live line slightly so that a joint could be remade
5. An old pipe was reused after being on corrosive/erosive service; it failed
6. A pipe was laid on the ground and corroded badly. Construction team may have used a pipe which was already corroded
7. Water injection caused excessive corrosion/ erosion because the mixing arrangements were poor
8. Water injection caused excessive corrosion/ erosion because the mixing arrangements were poor
9. A temporary support was left in position
10. The exit pipe from a converter was made of carbon steel instead of $^{1}/_{2}$% Mo; the pipe fragmented and the reaction force caused the converter to fall over
11. A crane hit an overhead pipeline
12. Vibration caused fatigue failure of a 2-in. long pipe
13. The wrong valve was opened and liquid nitrogen entered a mild-steel line causing it to disintegrate
14. Vibration caused fatigue failure of a 1-in. long pipe
15. An underground pipeline corroded and leaked
16. Vibration caused a fatigue failure at a badly designed joint
17. A construction worker cut a hole in a pipeline in the wrong place and, discovering his error, patched the pipe. The repair was substandard, corroded, and leaked badly
18. A heat transfer oil line failed by fatigue as the result of repeated expansion and contraction. There should have been more expansion bends in the line
19. Water froze in an LPG drain line. A screwed joint fractured. Screwed joints should not be used for LPG
20. A section of steam tracing was isolated, causing a blockage. Expansion of the liquid in the rest of the pipe caused it to burst
21. A level controller fractured at a weld, the result of poor workmanship. According to the report, the failure 'emphasizes the need for clear instructions on all drawings and adequate inspection during manufacture'
22. A 1-in. screwed nipple blew out of a hot oil line. It was installed 20 years before, during construction, for pressure testing and was not shown on any drawing
23. Water injection caused corrosion/erosion because a properly designed mix nozzle was installed pointing in the wrong direction (see (7))
24. A Be/Cu circlip was used in an articulated arm carrying ammonia instead of a stainless steel one. The joint blew wide open
25. Decomposition of the contents caused a pipeline to fail
26. An LPG line corroded because it passed through a pit full of water contaminated with acid
27. The tail pipe from a relief valve came down to the ground and dipped into a pool of water which froze
28. Underground propane and oxygen lines leaked causing an underground explosion, the report states, 'During execution of the pipework, doubts were expressed by the works management as to the quality of the workmanship and the qualifications of those employed'
29. A little-used line was left full of water. Frost split it
30. A portable hand-held compressed air grinder being used on a new pipeline was left resting between two live lines. When the air compressor was started the grinder, which had been left switched on, started to turn and ground away part of a live line
31. A new line had the wrong slope so the contractors cut and welded some hangers. They failed. Other hangers failed due to incorrect assembly and absence of lubrication
32. The space between a reinforcement pad and the pipe was not vented. Water in the space vaporized causing collapse of a pipe
33. An old pipe was reused after use on duty which used up most of its creep life (see (5))
34. Two pipe-ends which were to be welded together did not fit exactly and were welded with a step between them
35. An ice/hydrate plug blocked a blowdown line. It was cleared by external steaming. When the choke cleared the pressure above it caused it to move with such force that the line fractured at a T
36. A carbon steel line was installed instead of $1^{1}/_{4}$ Cr $^{1}/_{2}$ Mo and ruptured after 16 years by H_2 attack (see (10))

B Failures in dead ends

1. Water collected in a dead end branch 10 ft long and caused corrosion. Five men were killed when the branch failed and the escaping gas ignited
2. Water collected in a dead end branch and froze, breaking the branch

3. Water collected in the dead end branch leading to a flowmeter which had been removed. It froze and damaged a valve
4. Corrosion products collected in the branch leading to a spare pump which was never used; the branch failed
5. A stainless steel line operating at 360°C was fitted with a branch leading to a relief valve. The branch was made of stainless steel for 1 m and then mild steel. The temperature of the mild steel exceeded the 100°C estimate and the line failed by hydrogen attack
6. Corrosive by-products collected in a blanked branch; the branch failed
7. Water collected in a branch on the feed line to a furnace; the branch was permanently connected to a steam supply. The water froze and fractured the line
8. Water collected in an open-ended branch which was welded onto a pipeline as an instrument support. After 4 years the process line had corroded right through

C Bellows failures

1. A bellows was damaged before delivery
2. A Fluon bellows failed because the pipe was free to move sideways
3. Two pins in a hinged bellows failed by fatigue and the bellows became distorted
4. A bellows was designed for normal operating conditions but distorted under abnormal, but foreseeable, conditions
5. A bellows blew apart a few hours after installation. The split rings around the convolutions which support them and equalize expansion were slack
6. Flixborough – two 28-in. bellows failed completely

Table 12.19 *Some pipework failures in process plants: preventive measures (after Kletz, 1984k) (Courtesy of the American Institute of Chemical Engineers)*

A Points to look for during construction

1. Equipment is made of the grade of steel specified and has received the right heat treatment
2. Old pipe is not being reused without checking that it is suitable
3. Pipes are not laid underground
4. Workmanship is of the quality specified and tests are carried out as specified
5. Purchased equipment is undamaged

B Points to look for after construction

1. Pipes are not secured too rigidly (by welding or clamping) so that they are not free to expand
2. Pipes will not foul supports or other fixtures when they expand
3. Pipes are not in contact with the ground
4. Temporary supports have been removed
5. Pipes are free to expand
6. Screwed joints have not been used
7. Steam tracing cannot be isolated on different sections of the same process line
8. Temporary branches, nipples, and plugs have been removed and replaced by properly designed welded plugs
9. Equipment has not been assembled wrongly (First identify equipment which can be assembled wrongly)
10. Pipes do not pass through pits or depressions which will fill with water
11. Relief-valve tail pipes are not so close to the ground that they may be blocked by ice or dirt
12. Lines which may contain water can be drained
13. The slope of lines is correct (for example blowdown line should slope towards the blowdown drum)
14. There is no 'bodging'
15. Reinforcement pads are vented
16. There are no dead ends in which water or corrosive materials can collect (Note: dead ends include little used branches as well as blanked lines)
17. There are no water traps formed by brackets, etc., fixed to equipment
18. Bellows are not bent because the two pipe ends are not in line
19. The support rings on bellows are not loose

C Points to look for after start-up

1. Pipes are not vibrating

Table 12.20 *Failures of pipework in incidents: direct causes (after Bellamy, Geyer and Astley, 1989) (Courtesy of the Health and Safety Executive)*

	No. of incidents	*Contribution*

Control System Design

Contents

The operation of the plant according to specified conditions is an important aspect of loss prevention. This is very largely a matter of keeping the system under control and preventing deviations. The control system, which includes both the process instrumentation and the process operator, therefore has a crucial role to play. Selected references on process control are given in Table 13.1.

Traditionally, control systems have tended to grow by a process of accretion as further functions are added. One of the thrusts of current work is to move towards a more systematic design approach in which there is a more formal statement of the control objectives, hierarchy, systems and subsystems.

Once the objectives have been defined, the functions of the systems and subsystems can be specified. Typical subsystems are those concerned with measurement, alarm detection, loop control, trip action, etc. The next step is the allocation of function between man and machine – in this case the instrumentation and the operator. This allocation of function and the human factors aspects of process control are discussed in Chapter 14.

It is convenient to distinguish several broad categories of function that the control system has to perform: these are (1) information collection, (2) normal control and (3) fault administration. A control system is usually also an information collection system. In addition to that required for immediate control of the process, other information is collected and transmitted. Much of this is used in the longer term control of the process. Another category which is somewhat distinct from normal control is the administration of fault conditions which represent disturbances more severe than the control loops can handle.

13.1 Process Characteristics

The control system required depends very much on the process characteristics (E. Edwards and Lees, 1973). Important characteristics include those relating to the disturbances and the feedback and sequential features. A review of the process characteristics under these headings assists in understanding the nature of the control problem on a particular process and of the control system required to handle it.

Processes are subject to disturbances due to unavoidable fluctuations and to management decisions. The disturbances include:

(1) raw materials quality and availability;
(2) services quality and availability;
(3) product quality and throughput;
(4) plant equipment availability;
(5) environmental conditions;

and due to

(6) links with other plants;
(7) drifting and decaying factors;

(8) process materials behaviour;
(9) plant equipment malfunction;
(10) control system malfunction.

Quality may relate to any relevant parameter such as the composition or particle size of the material, the voltage level of a power supply or the specification of a product. Plant equipment may be taken off or brought back into service. Links with other plant may require changes in the operation of the process. Typical drifting and decaying factors are fouling of a heat exchanger and decay of catalyst. Process materials introduce disturbances through such behaviour as the clogging of solids on weighbelts or the blocking of pipes. Plant equipment failures constitute disturbances, as do those of the control system such as instrument faults, measurement noise, control loop instability or operator error.

Certain trends in modern plants tend to intensify the process disturbances. They include use of continuous, high throughput processes, existence of recycles, elimination of storage and interlinking of plants.

Some process characteristics which tend to make feedback control more difficult include:

(1) measurement problems;
(2) dead time;
(3) very short time constants;
(4) very long time constants;
(5) recycle;
(6) non-linearity;
(7) inherent instability;
(8) limit cycles;
(9) strong interactions;
(10) high sensitivity;
(11) high penalties;
(12) parameter changes;
(13) constraint changes.

Measurement has always been one of the principal problems in process control. A measurement may be difficult to make; it may be inaccurate, noisy, or unreliable; or it may be available in sampled form only. Even if the measurement itself is satisfactory, it may not be the quantity of prime interest. An ‘indirect’ or ‘inferred’ measurement may have to be computed or otherwise obtained from the actual plant measurement(s). Feedback control is totally dependent on measurement.

Dead time or time delay arises in various ways in processes. It may be introduced by the distance–velocity lag in pipework, the nature of distributed parameter systems or the time to obtain a sample or laboratory analysis. Dead time makes feedback control more difficult, owing to the delay before any error is measured and corrective action is initiated.

Processes with very short time constants are obviously difficult to control, because the speed of response required for control decisions and actions is rapid. But so also are processes with very long time constants, where the problems have to do with the increased chance of disturbances and other control interactions upsetting the control action taken and with the difficulty of remembering all the relevant factors.

Recycle takes a number of forms, including recycle of a process stream to an earlier point in the process and internal recycle within a vessel.

If a process is very non-linear, its behaviour tends to vary with throughput, its responses to disturbances and corrective actions differ, and it becomes difficult to find satisfactory controller settings.

Some processes, notably certain chemical reactors, are inherently unstable over a certain range of operation. If the process enters the unstable region, variables such as temperature and pressure may increase exponentially, leading to an explosion. In other cases, the process enters a limit cycle and oscillates between definite limits.

The relationships between the input and output variables of a process are often complex and there may be strong interactions. One input may change several outputs and one output may be changed by several inputs. Where the output variables are controlled by single loops, severe interactions may occur between these loops.

Some processes are very sensitive and this clearly intensifies the difficulty of control. So also does the existence of very high penalties for excursions outside the control limits.

Process parameter changes tend to reduce the effectiveness of controller settings and may make the process inherently more difficult to control. Constraint changes alter the envelope within which the process is to be controlled.

The sequential control characteristics of a process include:

(1) plant start-up;
(2) plant shut-down;
(3) batch operation;
(4) equipment changeover;
(5) product quality changes;
(6) product throughput changes;
(7) equipment availability changes;
(8) mechanical handling operations.

The sequential element in the start-up and shut-down of continuous processes and in batch processes is obvious, but there are other operations with sequential features. Continuous processes often contain semi-continuous equipment, particularly where regeneration is necessary. Deliberate changes in product quality or throughput or in equipment status involves sequential operation. In general, a sequence consists of a series of stages, of which some are initiated by events occurring in the process and others are initiated after the lapse of a specified time.

Some other process characteristics which may be significant include requirements for:

(1) monitoring;
(2) feedforward control;
(3) optimization;
(4) scheduling;
(5) process investigation;
(6) plant commissioning.

Monitoring is usually a very important function in the control system. The monitoring requirements posed by a process vary, but in cases such as multiple identical units or batch operations, they can be very large.

Feedforward control may be appropriate if there are difficulties in feedback control due to measurement problems or process lags. It is applicable where the disturbances can be measured but not eliminated, and where a model exists which makes possible the prediction of the effect on the controlled variable of both the disturbing and correcting variables.

If the plant has a time-varying operating point, continuous optimization may be appropriate. Although optimization is carried out normally for economic reasons, it is characterized by adherence to a set of constraints. Operation within the envelope of constraints contributes to process safety.

Some processes pose a scheduling requirement, particularly where batch operations are concerned. There is normally some element of novelty in the process or plant equipment, and this may give rise to a requirement for process investigation and collection of information which is not otherwise needed for control.

The investigative element is particularly important during plant commissioning. So also is the need for facilities which assist in bypassing problems on plant equipment or control instrumentation, while solutions are sought or equipment ordered.

13.2 Control System Characteristics

The characteristics of process control systems have passed through three broad phases: (1) manual control, (2) analogue control and (3) computer control (covering all forms of programmable electronic system). However, such a classification can be misleading because it does not bring out the importance of measuring instrumentation and displays, because neither analogue nor computer control is a homogeneous stage and because it says very little about the quality of control engineering and reliability engineering and the human factors involved.

The sophistication of the measuring instrumentation greatly affects the nature of the control system even at the manual control stage. This covers instruments for measuring the whole range of chemical and physical properties. The displays provided can also vary widely. These are discussed in more detail in the next chapter.

The stage of analogue control implies the use of simple analogue controllers, but may also involve the use of other special purpose equipment. Most of this equipment serves to facilitate one of the following functions: (1) measurement, (2) information reduction and (3) sequential control.

The first two functions, therefore, improve the information available to the operator and assist him to digest it, but leave the control to him. The equipment typically includes data loggers and alarm scanners. The third function does relieve the operator of a control function. Batch sequential controllers exemplify this sort of equipment.

Another crucial distinction is in the provision of protective or trip systems. In some cases, the safety shut-down function is assigned primarily to automatic systems; in others it is left to the operator. Similarly, computer control is not a homogeneous stage of development. In some early systems, the function of the computer was limited to the execution of direct digital control (DDC). The real control of the plant was then carried out by the operator with the computer as a rather powerful tool at his disposal. In other systems the computer had a complex supervisory program which took most of the control decisions and altered the control loop set points, leaving the operator a largely monitoring function. The two types of system are very different.

The quality of the theoretical control engineering is another factor which distinguishes a system and largely determines its effectiveness in coping with problems such as throughput changes, dead time and loop interactions.

Equally important is the reliability engineering. Unless good reliability is achieved nominally automated functions will be degraded so that they have to be done manually or not at all. Control loops on manual setting are the typical result.

The extent to which human factors has been applied is another distinguishing feature. This aspect is considered further in Chapter 14. The general trend in control systems is an increase in the degree of automation and a change in the operator's role from control to monitoring.

Computer control itself has progressed from control by a single computer, or possibly several such computers, to distributed control by programmable electronic systems (PESs). These are described further in Section 13.4.

13.3 Instrument System Design

The design of process instrument systems, like most kinds of design, is largely based on previous practice. The control panel instrumentation and the control systems on particular operations tend to become fairly standardized. Selected references on process instrumentation are given in Table 13.2.

13.3.1 Some design principles

There are some basic principles which are important for control and instrument systems on hazardous processes. The following account has been given by Lees (1976b):

(1) There should be a clear design philosophy and proper performance and reliability specifications for the control and instrumentation. The design philosophy should deal among other things with the characteristics of the process and of the disturbances to which it is subject, the constraints within which the plant must operate, the definition of the functions which the control system has to perform, the allocation of the function of these between the automatic equipment and the process operator, the requirements of the operator and the administration of fault conditions. The philosophy and specification should cover: measurements, displays, alarms and control loops; protective systems; interlocks; special valves (e.g. pressure relief, non-return, emergency isolation); the special purpose equipment; and the process computer(s).

(2) The process should be subjected to a critical examination such as a hazop study to discover potential hazards and operating difficulties.

(3) If a process contains serious hazards and requires an elaborate instrument system, it should be re-examined to determine whether the hazards can be reduced at source.

(4) If the process continues to contain serious hazards, these should be assessed and protective systems provided as appropriate. If necessary, these should be high integrity protective systems (HIPS).

(5) For pressure systems it is necessary to provide protection not just against overpressure, but also against other conditions such as underpressure, overtemperature, undertemperature, overfilling, etc.

(6) The measurements should be as far as possible on the variable of direct interest. If this variable has to be inferred from some other measurement, this fact should be made clear. It is also important that the measurement should be at the right location.

(7) If the variable is critical for process safety, the same measurement should not be used for control and for an alarm or trip.

(8) If the variable is critical for operator comprehension, it may be desirable to provide additional integrity.

(9) The alarm system should have a properly thought out philosophy, which relates the variables alarmed, the number, types and degrees of alarm, and the alarm displays and priorities to factors such as instrument failure and operator confidence, the information load on the operator, the distinction between alarms and statuses, and the action which the operator has to take.

(10) The control loops should have fail-safe action as far as possible, particularly on loss of instrument air or electrical power to the control valves. The action for other equipment should also be fail-safe where applicable.

(11) Those control loops which can add material or energy to the process are particularly critical and it may be desirable to provide additional integrity.

(12) The control system as a whole and the individual instruments should have the 'rangeability' necessary to maintain good measurement and control at low throughputs.

(13) The control system should be designed for off-normal as well as normal conditions, for example, start-up and shut-down.

(14) Restart situations, such as restarting after a trip or restarting an agitator, tend to be particularly hazardous.

(15) Manual stations should be provided which allow the operator to manipulate control valves in situations such as the failure of the automatic controls.

(16) The fact of instrument failure should be fully taken into account. The reliability of critical instrumentation should be assessed quantitatively where possible.

(17) The ways in which dependent failures can occur and the ways in which the instrument designer's intentions may be frustrated should be carefully considered.

(18) Instrumentation which is intended to deal with a fault should not be disabled by the fault itself. And if the process operator has to manipulate the instrumentation during the fault, he should not be prevented from doing so by the condition arising from the fault.

(19) The services (instrument air, electrical power, inert gas) on which instruments depend should have an appropriate degree of integrity.

(20) The instrument system should be checked regularly and faults repaired promptly. It should not be allowed to deteriorate, even though the process operator compensates for this. The process operator should be trained not to accept instrumentation unrepaired over long periods.

(21) Ease of detection of instrument faults should be an objective in the design of the instrument system. The process operator should be trained to regard detection of malfunction in instruments as an integral part of his job.

(22) Instruments which are required to operate only under fault conditions, and which may therefore have an unrevealed fault, require special consideration.

(23) Important instruments should be checked regularly. The proof test interval should, where possible, be determined from a reliability assessment. The checks should not be limited to protective systems and pressure relief valves, but should include non-return valves, emergency isolation valves, etc., and often also measurements, alarms, control loops, etc.

(24) Tests should correspond as nearly as possible to the expected plant conditions. It should be borne in mind that an instrument may pass a workshop test, but still not perform satisfactorily on the plant.

(25) Valves, whether control or isolation valves, are liable to pass fluid even when closed. Characterized control valves in particular tend not to give a tight shut-off. More positive isolation may require measures such as the use of double block and bleed valves or of slip plates.

(26) Valves, particularly control valves, also tend to stick. This can give rise to conditions which do not always emerge from a simple application of fail-safe philosophy. Jamming in the open position is often particularly dangerous.

(27) Practices which process operators tend to develop in their use of the instrumentation should be borne in mind, so that these practices do not invalidate the assumptions made in the reliability assessments.

(28) The fact of human error should be fully taken into account. To the extent that is practical, human factors principles should be applied to reduce human error, and the reliability of the process operator should be assessed quantitatively.

It is also necessary to pay careful attention to the details of the individual instruments used. Some features which are important are as follows:

(1) Instruments are a potential source of failure, either through a functional fault on the instrument or through loss of containment at the instrument.

(2) Use of inappropriate materials of construction can lead to both kinds of failure. Materials should be checked carefully in relation to the application, bearing in mind the possible impurities as well as the bulk chemicals. It should be remembered that the instrument supplier usually has only a very general idea of the application.

(3) Instruments containing glass, such as sight glasses or rotameters, can break and give rise to serious leaks and should be avoided if such leaks could be hazardous.

(4) Instruments may need protection against the process fluid due to its corrosiveness. Examples of protection are the use of inert liquids in the impulse lines on pressure transmitters or of chemical diaphragm seals on pressure gauges.

(5) Sampling and impulse lines should be given careful attention. Purge systems are often used to overcome blockages in impulse lines. Freezing is another common problem, which can be overcome by the use of steam or electrical trace heating.

(6) Temperature measuring elements should not normally be installed bare, but should be protected by a thermowell. A thermowell is frequently exposed to quite severe conditions such as erosion/corrosion or vibration and should be carefully designed.

(7) Pulsating flow is a problem in flowmeters such as orifice plate devices and can give rise to serious inaccuracies. This is a good example of a situation where replication of identical instruments is no help.

(8) Pressure transmitters and regulators are easily damaged by overpressure and this needs to be borne in mind.

(9) Complex instruments such as analysers, speed controllers, vibration monitors and solids weighers are generally less reliable than other instruments. This requires not only that such instruments should receive special attention but also that the consequences of failure should be analysed with particular care.

(10) Different types of pressure regulators are often confused, with perhaps a pressure reducing valve being used instead of a non-return valve, or vice versa. It is specially necessary with these devices to check that the right one has been used. Also, bypasses should not be installed across pressure regulators.

(11) Selection of control valves is very important. A control valve should have not only the right nominal capacity but also appropriate rangeability and control characteristics. It should have any fail-safe features required, which may include not only action on loss of power but also a suitable limit to flow when fully open. It should have any necessary temperature protection, for example cooling fins. Bellows seals may need to be provided to prevent leaks. The valve should have a proper mechanical balance for the application, so that it is capable of shutting off against the process pressure. It should be borne in mind that any valve, but particularly a characterized valve, may not give completely tight shut-off, and also that a badly adjusted valve positioner can prevent shut-off.

(12) Instruments should not be potential sources of ignition and should conform with the hazardous area classification requirements.

Further discussions of the safety and loss prevention(SLP) aspects of instrument systems are given by Mix (1972) and the Center for Chemical Process Safety (CCPS, 1993/14).

13.3.2 Instrument distribution

A feel for the distribution of types of instrument on a process plant may be obtained from the following figures given by Tayler (1987a):

	Overall (%)	*Monitoring* (%)	*Control* (%)
Pressure	40	26	21
Temperature	32	56	15
Flow	20	8	47
Level	8	4	8
Analysis		3	4
Miscellaneous		3	5

The first column evidently refers only to the four main types. It can be seen that, whereas temperature is dominant for monitoring, it is flow which predominates in control.

13.3.3 Instrument accuracy

Most process plant instrumentation are quite accurate provided they are working properly. Information on the expected error limits of commercially available instrumentation has been given by Andrew and Williams (1980), who list limits for over 100 generic types of instrument. Some ranges of total error quoted by these authors are:

Pressure:

Bellows transmitter ±0.5%

Temperature:

Thermocouple ±0.25–5%
Resistance thermometer ±0.2–0.5

Flow:

Orifice meter ±0.5–1%

Level:

Differential pressure ±0.5–2%

Analysis:

Gas chromatograph ±0.5–1%

13.3.4 Instrument signal transmission

Pneumatic instrument signals are transmitted by tubing, but several means are available for the transmission of electrical signals: wire, fibre optics and radio waves. The signals from measuring instruments can become corrupted in transmission. Pneumatic signals may be affected by poor quality instrument air, while electrical signals are liable to be subject to electromagnetic interference.

Both pneumatic and electrical instrument signals utilize live zero, standard ranges being 3–15 psig for pneumatic instruments and 4–20 mA for electronic ones. This avoids the situation where a zero signal is ambiguous, meaning either that the measured variable actually has a zero value or that the instrument signal has simply gone dead.

13.3.5 Instrument utilities

Instrument systems require high quality and high reliability utilities. A general account of instrument utilities has been given in Chapter 11. As far as quality is concerned, pneumatic systems require instrument air which is free of dirt and oil. Many electronic instrument systems can operate from an electrical feed which does not constitute an uninterruptible power supply (UPS). But computers and PESs are intolerant of even millisecond interruptions, unless they have their own in-built means of eliminating them. A further treatment of instrument utilities is given by the CCPS (1993/14).

13.3.6 Valve leak-tightness

In many situations on process plants, the leak-tightness of a valve is of some importance. The leak-tightness of valves is discussed by Hutchison (1976) in the *ISA Handbook of Control Valves*.

Terms used to describe leak-tightness of a valve trim are (1) drop tight, (2) bubble tight or (3) zero leakage. Drop tightness should be specified in terms of the maximum number of drops of liquid of defined size per unit time and bubble tightness in terms of the maximum number of bubbles of gas of defined size per minute.

Zero leakage is defined as a helium leak rate not exceeding about 0.3 cm^3/year. A specification of zero leakage is confined to special applications. It is practical only for smaller sizes of valves and may last for only a few cycles of opening and closing. Liquid leak-tightness is strongly affected by surface tension.

Specifications for leak-tightness of a stop, or isolation, valve are given in SP-61 by the US Valve Manufacturers Standardization Society, and are quoted in the *ISA Handbook*. In respect of control valves, the *Handbook* states:

> Properly designed control valves can achieve stop valve tightness and maintain it throughout a long service life before trim replacement; particularly with cage guided, balanced trim having elastomer plug-to-cage seals. The control valve, however, is expected to throttle and often shuts off much more frequently than stop valves. For example, some dump valves may have from 4000 to 7000 opening and closing cycles per day, handling high pressure and erosive fluids at 1000 to 4000 psi pressure drop. Few stop valves could match this performance and remain tight.

It is normal to assume a slight degree of leakage for control valves. It is possible to specify a tight shut-off control valve, but this tends to be an expensive option. A specification for leak-tightness should cover the test fluid, temperature, pressure, pressure drop, seating force and test duration. For a single-seated globe valve with extra tight shut-off, the *Handbook* states that the maximum leakage rate may be specified as 0.0005 cm^3 of water per minute per inch of valve seat orifice diameter (not the pipe size of the valve end) per pound per square inch pressure drop. Thus, a valve with a 4 in. seat orifice tested at 2000 psi differential pressure would have a maximum water leakage rate of 4 cm^3/min.

13.3.7 Hazardous area compatibility

The instrument system, including the links to the control computers, should be compatible with the hazardous area classification. Hazardous area classification involves first zoning the plant and then installing in each zone instrumentation with a degree of safeguarding appropriate to that zone. Since much instrumentation is of low power, an approach based on inherent safety is often practical. These various aspects of hazardous area classification are dealt with in Chapter 16.

13.3.8 Multi-functional vs dedicated systems

An aspect of basic design philosophy which occurs repeatedly in different guises is the choice which has to be made between a multi-functional and a dedicated system. Some basic functions which are typically required are (1) monitoring, (2) control, (3) trips and interlocks, (4) fire and gas detection, (5) ESD and (6) communication. The trip system may well be separate from the monitoring and control system and the ESD system trips separate from the other trips.

The situation which develops is illustrated in Figure 13.1(a) which shows a traditional design for an offshore production platform system (A. Morris, 1986). The alternative design which he proposes for consideration is shown in Figure 13.1(b). To the objection that this latter design puts all its eggs in one basket, the author puts two arguments. First, the overall reliability has been improved to such an extent that the frequency of a complete system failure will be very low. Second, in the majority of cases, the process should be able to survive such failure because it can be brought to a safe state by simple measures, notably by shutting off the heat input and depressurizing.

A particular but common example of the multi-functional vs dedicated system problem is the choice between a computer-based and a hardwired trip system. This aspect is discussed further in Sections 13.9, 13.12 and 13.15.

13.4 Process Computer Control

The use of computers in control systems began in the late 1950s and is now a mature technology. Process control computer systems and applications are described in *Computer Control of Industrial Processes* (Savas, 1965), *Computer Control of Industrial Processes* (Lowe and Hidden, 1971), *Handbook of Industrial Control Computers* (Harrison, 1972), *Understanding Distributed Process Control* (Moore and Herb, 1983), *Computer Systems for Process Control* (Giith, 1986) and *Industrial Digital Control Systems* (Warwick and Rees, 1986), while a description of computer control and its relation to operator control has been given in *Man and Computer in Process Control* (E. Edwards and Lees, 1973). Selected references on process computer control are given in Table 13.3.

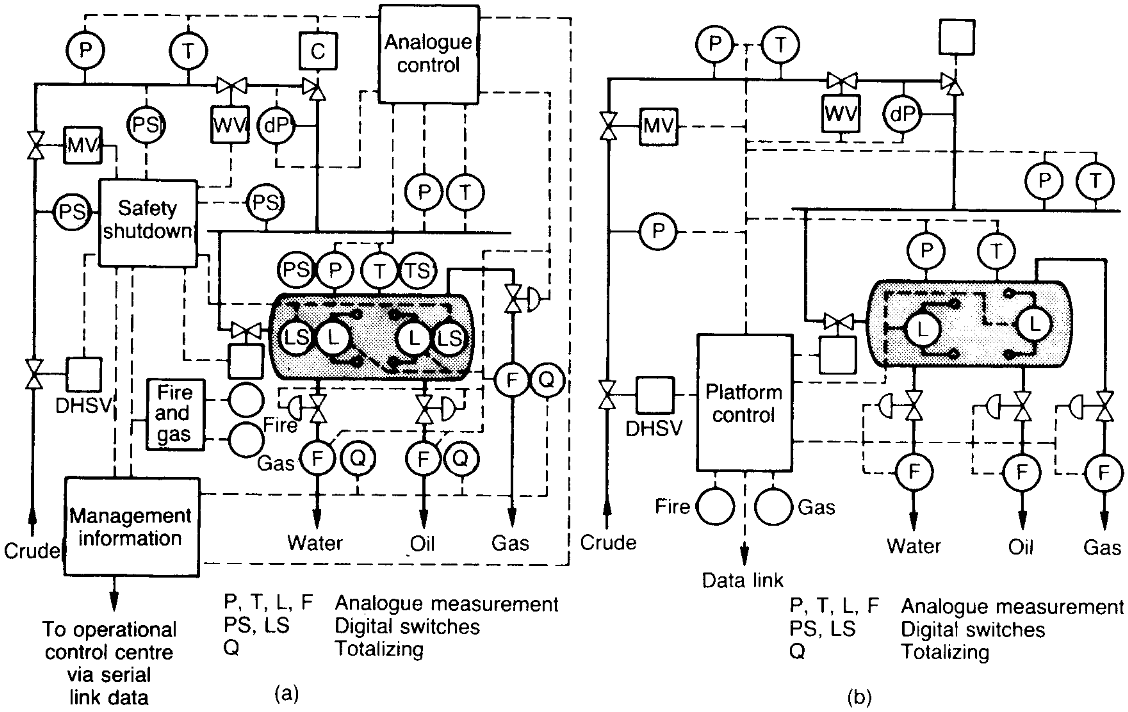

Figure 13.1 *Instrumentation for a system on an offshore production platform (A. Morris, 1986): (a) conventional system and (b) alternative system (Courtesy of Process Engineering)*

The inclusion of a process control computer greatly extends the capabilities, but also affects the reliability, of the control system. These two aspects are now considered.

13.4.1 Computer configurations and reliability

There are several ways in which a computer may be incorporated in a process control system. The approaches originally used are illustrated in Figure 13.2. If there is no computer, then the loops are controlled by analogue controllers as shown in Figure 13.2(a).

The configuration given in Figure 13.2(b) is set-point control. The computer takes in signals from measuring instruments and sends signals to the set points of analogue controllers. If there is a computer failure, control is still maintained by the analogue controllers. Figure 13.2(c) shows DDC. The computer again takes in signals from measuring instruments, but now sends signals direct to the control valves; there are no analogue controllers. If there is a computer failure, control is lost on all loops, unless standby arrangements have been made. Although set-point control developed first, it was followed quickly by DDC, and both methods came into use.

The first large DDC installation on a chemical plant was on the ammonia soda plant of Imperial Chemical Industries (ICI) at Fleetwood (Burkitt, 1965; A. Thompson, 1965). The computer carried out DDC on 98 loops and achieved an availability of about 99.8%. Further accounts of DDC systems have been given by Barton *et al.* (1970) and by Higson *et al.* (1971).

Although the initial intention was for DDC to save the cost of analogue controllers, it soon became apparent that many other factors were involved in the choice between set-point control and DDC. Since, with DDC, computer failure leads to loss of control, it may be necessary to achieve a much higher reliability than with set-point control. The effort required to implement a DDC installation tends, therefore, to be much greater. It is necessary to pay very careful attention to details of the computer, the power supply and the environment, the input–output equipment and the programming. Usually DDC does not reduce the cost of adding computer control to the control system much below that for set-point control. Savings in costs per loop tend to be slight, because the equipment needed to get measurements into the computer and to position the control valves from it is quite expensive. It is necessary to provide stand-by analogue controllers for critical control loops and change-over equipment to transfer between computer and analogue control. The extra general effort required to assure integrity in DDC is also significant.

On the other hand, DDC does offer some advantages, not only over conventional control but also over set-point control. The advantages derive from the fact that the computer takes in signals from the measuring instruments and can process them in all sorts of ways before sending out the results as signals to the control valves. It makes it possible to: carry out operations on the measurements, such as

calculation of indirect measurements and filtering of measurement signals; ensure that the control algorithm is truly proportional, integral and derivative without the inaccuracies and interactions which tend to occur in analogue controllers; use different control algorithms such as nonlinear or asymmetrical algorithms or algorithms with some logic in them; eliminate features such as integral saturation and derivative kick; position valves more accurately; alter the control configuration; and so on.

There are several ways in which the reliability of DDC systems can be improved. One of these, as mentioned earlier, is the use of standby controllers on critical loops. But this is by no means a complete answer to the problem. The system may still be upset by intermittent faults, there may be difficulties in keeping the standby instrumentation maintained and avoiding degradation, and the operator is faced with a different interface to use on loss of computer control. Another approach is the use of duplication. In this case it is necessary not only to use dual computers, but also to duplicate other parts of the system such as power supplies and input–output equipment. Various configurations are possible and in normal operation the work may be divided either on a parallel or a hierarchical basis, but in all cases the essential principle is that the surviving computer takes over the critical control functions. The reliability of dual computer systems is undoubtedly higher, but it can still be affected by factors such as intermittent failures, data link troubles, hardware faults in common, such as earthing, and software faults in common, such as programming errors. With regard to reliability, for the type of system just described, the most reliable systems achieved a mean time between failures (MTBF) and an availability of not less than 2000 h and 99.9%, respectively.

Advances in process control systems, and particularly the trend towards distributed PESs, have largely resolved

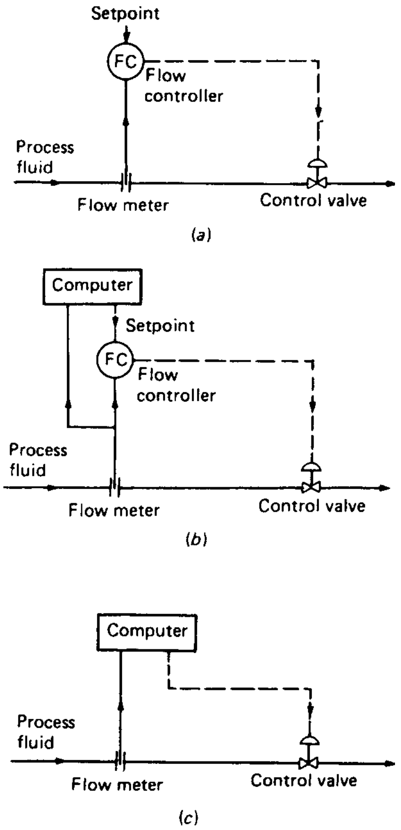

Figure 13.2 *Process computer control systems: set-point and direct digital control: (a) analogue control; (b) set-point control by computer; (c) direct digital control by computer*

the dilemmas described and have gone far towards solving the reliability problems. Figure 13.3 shows schematically a system configuration typical of these developments. The backbone of the system is a data highway to which various devices are connected. The individual PES controllers are capable of operating as DDC controllers in the stand-alone or set-point control modes. The VDU display can also operate independently of the computer. Thus, the system allows the full facilities of DDC if the computer is working, but on computer failure, the controllers maintain control and the VDU display continues to provide the operator with the usual interface.

Various configurations may be used to obtain back-up control of critical loops. Where a loop is backed up, it is desirable to ensure 'bumpless' transfer when the standby equipment assumes control. This involves a process of initialization before control is transferred.

Accounts of computer-based and PES-based process control systems based on these principles include those by E. Johnson (1983), Tatham, Jennings and Klahn (1986), Cobb and Monier-Williams (1988) and the CCPS (1993/14). PESs for process control are considered further in Section 13.12. Data on the reliability of computer systems are given in Appendix 14.

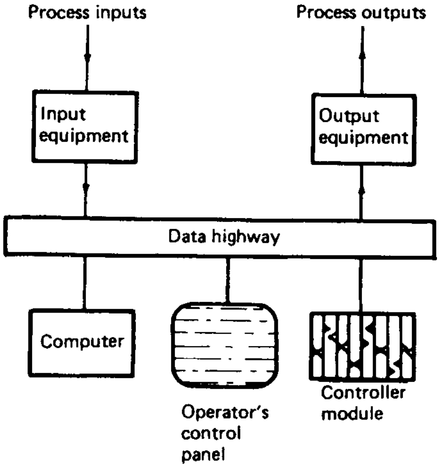

Figure 13.3 *Process computer control systems: distributed control system*

13.4.2 Computer functions

If the computer carries out DDC, then this is its most important function. The facilities and flexibility which DDC offers have already been described. However, as just described, modern process control systems are generally based on distributed PESs.

The other main functions which a process control computer or PES performs are:

(1) measurement;
(2) data processing and handling;
(3) monitoring;
(4) other control;
(5) sequential and logical control;
(6) optimization;
(7) scheduling;
(8) communication.

Several of these functions are important in relation to SLP.

The measurements on which control depends are critical. The computer is often used to carry out certain checks on the measurements as described in Chapter 30. It can also upgrade them in various ways such as by extraction of nonlinearities, zero or range correction, or filtering.

The computer's ability to calculate 'indirect' or 'inferred' measurements is widely used. These are calculated from one or more process measurements and possibly other data inserted into the computer, for example, laboratory analyses. Thus, the mass flow of a particular component may be calculated from a total mass flow and a concentration measurement. It is often such indirect measurements which are of principal interest and their use represents a real advance in control. An indirect measurement can be subjected to all the operations which are carried out on direct measurements: it can be displayed, logged, monitored, controlled and used in modelling and optimization.

The computer usually logs data and provides summaries for the process operator and management. These logs often contain important information on equipment faults, operator interventions, etc. Arrangements are also sometimes made for a post-mortem log in the event of a serious incident on the process. This usually involves holding a continuously updated set of data on process instrument readings so that it can be replayed if necessary.

The computer almost invariably carries out monitoring of the process measurements and statuses to detect abnormal conditions. This constant scanning of the operating conditions is invaluable in maintaining control of the process. Computer alarm scanning is considered, together with other aspects of the alarm system with which the operator interacts, in more detail in Chapter 14.

Frequently, there are one or two process variables, equipments or operations which are particularly difficult to control, and for these, more advanced control methods may be appropriate. These methods are usually difficult to implement without a computer. The following appear to be especially useful: (1) indirect variable control, (2) automatic loop tuning, (3) control of dead time processes and (4) non-interacting control.

The execution by the computer of sequential operations in a reliable manner is another common function which is invaluable in maintaining trouble-free operation of the process. Such sequential control involves much more than simply sending out control signals. It is essential for checks to be made to ensure that the process is ready to proceed to the next stage, that the equipment has obeyed the control signals, and so on. There is, therefore, a liberal sprinkling of checks throughout the sequence. Thus, sequential control involves continuous checking of the state of the process and the operation of equipment.

Using a computer, it is possible to carry out more complex sequences with greater reproducibility. This is particularly useful in operations where it is necessary to follow a rather precise schedule in order to avoid damage to the equipment.

On some processes where there is a time-varying optimum, the computer carries out continuous optimization. Optimization is usually performed with a set of constraints. Computer optimization therefore provides as by-product, a more formal definition of, and adherence to, process constraints.

There are several other computer functions which are particularly relevant to SLP. These include computer alarm analysis, valve sequencing and malfunction detection. These are dealt with in Chapter 30.

For many years there was very little use of computers to carry out the protective function of tripping plant when a hazardous condition occurs. The protective system has almost invariably been a system separate from the control system, whether or not the latter contains a computer, and engineered for a greater degree of integrity. There is now movement towards the use of PESs for the trip functions also, but only where it can be demonstrated that the system has a reliability at least equal to that of a conventional hardwired system.

13.4.3 Computer displays and alarms

Process computers, as just indicated, are powerful tools for the support of information display and alarm systems. The design of such systems is intimately bound up with the needs of the process operator, and discussion is therefore deferred to Chapter 14.

13.4.4 Fault-tolerant computer systems

To the extent practical, process computer systems should be fault tolerant. A fault-tolerant system is one which continues to perform its function in the face of one or more faults. Accounts of fault-tolerant design of computer systems, including process computer systems, are given by Shrivastava (1991), the CCPS (1993/14) and Johnston (1993).

The creation of a fault-tolerant system involves a combination of approaches. A necessary preliminary effort is to obtain high reliability and thus to eliminate faults. The methods of reliability engineering may be used to model the system and to identify weak points. The use of redundancy and diversity is a common strategy. Dependent failures and methods of combating them should receive particular attention.

Prompt detection and repair of faults is an important part of a strategy for a fault-tolerant system. A fault-tolerant system should degrade gracefully, and safely. One important aspect is the fail-safe action of the system.

13.4.5 Computer power supplies

Process computers and PESs require a high reliability and high quality power supply. A general account of power supplies is given in Chapter 11. The operation of such equipments can be upset by millisecond interruptions, unless they have in-built means of dealing with them. They therefore generally require a UPS. Devices used to provide a UPS include motor generators, DC/AC inverters and batteries.

The power supply also needs to be uninterruptible in the sense that it has high reliability. One option is the use of batteries, another is some form of redundancy or diversity of supply.

A treatment of power supplies for PESs is given by the CCPS (1993/14). A relevant code for UPSs is IEEE 446.

13.4.6 Computer system protection

Process computers and PESs require suitable protection against fire and other hazards.

For fire protection, the relevant codes are BS 6266: 1992 Code of Practice for Fire Protection of Electronic Data Processing Installations, NFPA 75: 1992 Protection of Electronic Computer/Data Processing Equipment and NFPA 232: 1991 Protection of Records.

Lightning protection is covered in NFPA 78: 1989 Lightning Protection Code.

Codes for earthing are BS 1013: 1965 Earthing and IEEE 142: 1982 Grounding of Industrial and Commercial Power Systems (the IEEE Green Book).

These hazards and protection against them are treated by the CCPS (1993/14).

13.5 Control of Batch Processes

The control of batch processes involves a considerable technology over and above that required for the control of continuous processes. Accounts of batch process control are given in *Batch Process Automation* (Rosenof and Ghosh, 1987), *Batch Control Systems* (T.G. Fisher, 1990) and *Computer-Controlled Batch Processing* (Sawyer, 1993a) and by Love (1987a–c, 1988).

Batch processes constitute a large proportion of those in the process industries. Sawyer (1993a) gives the following figures:

Many batch plants are multi-purpose and can make multiple products. Their outstanding characteristic is their flexibility. They differ from continuous plants in that: the operations are sequential rather than continuous; the environment in which they operate is often subject to major variability; and the intervention of the operator is to a much greater extent part of their normal operation rather than a response to abnormal conditions. A typical batch plant is shown in Figure 13.4.

13.5.1 Models of batch processing

There are a number of models which have been developed to represent batch processing. Three described by T.G. Fisher (1990) are (1) the recipe model, (2) the procedure model and (3) the unit model.

The recipe model centres on the recipe required to make a particular product. Its elements are the procedures, the formula, the equipment requirements and the 'header'. The procedure is the generic method of processing required to make a class of product. The formula is the raw materials and operating conditions for the particular product. The equipment requirements cover the equipment required to execute the formula, including materials of construction. The header is the identification of the batch in terms of product, version, recipe and so on.

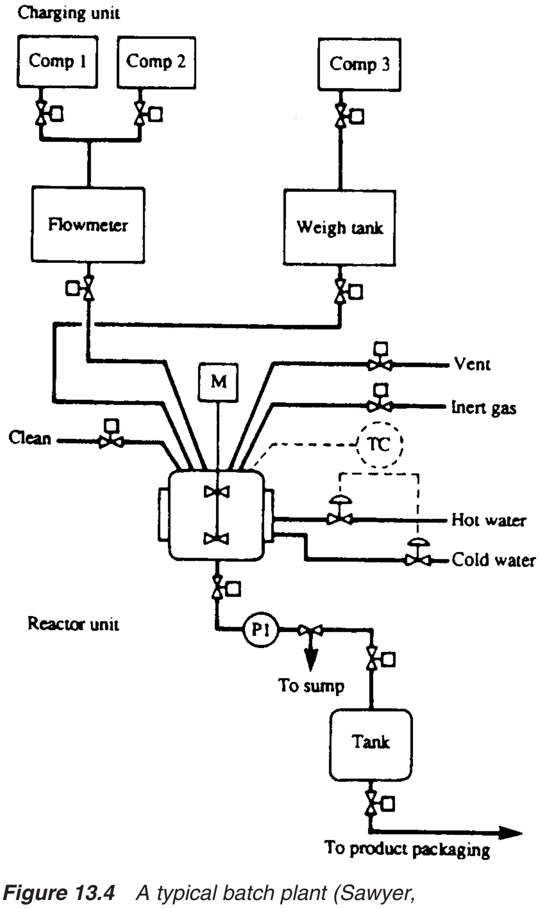

Figure 13.4 *A typical batch plant (Sawyer, 1993) (Courtesy of the Institution of Chemical Engineers)*

The procedure model has the form:

Procedure → Operation → Phase → Control step

The overall procedure consists of a number of operations, akin to the unit operations of continuous processes, except that they may be carried out by the same equipment. The phase is a grouping of actions within an operation. The control step is the lowest level of action, typically involving the movement of a small number of final control elements.

The concept of phase is a crucial one in batch processing. A phase is a set of actions which is logical to group together and which ends at a point where it is logical and safe for further intervention to take place. It is closely connected, therefore, with the concept of 'hold' states at which it is safe for the process to be held. The possibility that other facilities on which the progress of the batch depends may not be immediately available makes such hold states essential.

The unit model is equipment-oriented and has the form:

Unit → Equipment module → Device/loop → Element

The unit is broken down into functional equipment modules such as vessels and columns. These in turn are decomposed into devices and loops which are groupings of elements such as sensors and control valves.

13.5.2 Representation of sequential operations

The control of a batch process is a form of sequential control. A typical sequential control procedure, expressed in terms of the procedure model, is shown in Table 13.4. Various methods are available for the specification of sequences. They include (1) flowcharts, (2) sequential function charts and (3) structured plain language.

The flowchart is a common method of representing sequences, but its successful use requires that: a consistent style be adopted; that the method cater to the procedure hierarchy by the use of a hierarchy of charts for operations, phases and control steps; it also allows for parallel activities and for actions prompted by alarms and failures; and is supplemented by information on recipes, units, etc., and by other representations such as structured language. Computer-based drafting aids are invaluable in creating flowcharts.

The sequential flowchart has been developed expressly to describe sequential control and has three basic features: (1) steps, (2) transitions and (3) directed links. A step is an action and ends with a conditional transition. If the condition is satisfied, control passes to the next step. This latter step then becomes active and the previous step inactive. A directed link creates a sequence from steps and transitions. Figure 13.5 shows a sequential flowchart together with the standard symbols used in the creation of such charts.

With regard to the use of structured language, Rosenof and Ghosh advise that: (1) simple statements should be used; (2) the required function should be clearly defined in a statement; (3) the plant hardware addressed should, where possible, be identified; (4) text should be indented where necessary; (5) negative logic should be avoided and (6) excessive nested logic should be avoided.

13.5.3 Structure of batch processing

The overall structure of batch processing is commonly represented as a hierarchy. The following structure and

Table 13.4 *Typical sequential control procedure (Sawyer, 1993a) (Courtesy of the Institution of Chemical Engineers)*

Operations	*Phases*	*Controls steps*
Initialize	Initialize	Start jacket circulation pump. Put reactor temperature controller in SECONDARY AUTO mode with set-point of 120°C
Weigh	Weigh Component 3	Initialize (tare-off weigh tank). Open outlet valve from head tank. When weight of component 3 equals preset, close outlet valve from head tank
Charge	Add Component 3	Open outlet valve from weigh tank. When enough of component 3 has been added, start the agitator. When weigh tank is empty, close outlet valve
	Add Component 1	Initialize (reset flow totalizer to zero). Open outlet valves from head tank to flowmeter and from flowmeter to reactor. When volume of Component 1 charged equals preset, close outlet valves
React	Heat	Initialize (put reactor temperature controller in CASCADE mode with set-point of 120°C)
	Hold	Initialize (reset timer). Start timer
	Sample	
Discharge	Cool	Initialize (set reactor temperature set-point to 35°C)
	Transfer	Initialize (set reactor outlet valves to correct destination, i.e. storage tank). Start discharge pump. Set reactor temperature controller to MANUAL mode with output at zero (full cooling). Before agitator blades are uncovered, stop agitator. When reactor is empty, close reactor outlet valves, stop discharge pump, stop jacket circulation pump

terminology by Rosenof and Ghosh (1987) is widely used:

Production planning → Production scheduling
→ Recipe management → Batch management
→ Sequential control → Discrete/regulatory control
→ Process interlocks → Safety interlocks

A treatment of batch processing as a form of computer integrated manufacturing (CIM) is given in Section 13.7.

13.5.4 Batch control systems

Batch processing may be controlled by the process operator, by a system of single controllers or by a programmable logic control (PLC) system, a distributed control logic system (DCL) or a centralized control system (CCS). The selection of the system architecture and hardware is discussed by Sawyer (1993).

Recommendations for batch control have been made in Europe by the NAMUR committee (1985), which addresses particularly the need for standard terminology and for a hierarchical structure of the control system which reflects that of batch processing itself.

In the United States, guidance is available in the form of ISA SP88: 1988 Batch Control Systems.

13.6 Control of Particular Units

The safe operation of process units is critically dependent on their control systems. Two particularly important features of control in process plant are (1) compressor control and (2) chemical reactor control. These are now considered in turn.

13.6.1 Compressor control

Centrifugal and axial compressors are subject to the phenomenon of surging. Surging occurs when flow through the compressor falls to a critical value so that a momentary reversal of flow occurs. This reversal of flow tends to lower the discharge pressure and normal flow resumes. The surge cycle is then repeated. Severe surging causes violent mechanical shock and noise, and can result in complete destruction of parts of the compressor such as the rotor blades.

A typical centrifugal compressor characteristic showing the surge limit is illustrated in Figure 13.6(a). A centrifugal compressor is usually fitted with antisurge controls which detect any approach to the surge conditions and open the bypass from the delivery to the suction of the machine, thus increasing the flow through the machine and moving it away from the surge conditions.

The compressor delivery and suction pressures P_d and P_s are related to the gas flow Q as follows:

$$P_d - P_s \propto Q^2 \qquad [13.6.1]$$

The shape of the surge curve is therefore parabolic as shown in Figure 13.6(a). An expression of this form is generally inconvenient in instrumentation, for which linear relations are preferred. A linear relation can be obtained by making use of the relation for pressure drop ΔP across the orifice flowmeter on the compressor suction:

$$Q^2 \propto \Delta P \qquad [13.6.2]$$

Hence from relations 13.6.1 and 13.6.2,

$$P_d - P_s \propto \Delta P \qquad [13.6.3]$$

Figure 13.6(b) shows the compressor characteristics redrawn in terms of this pressure drop. The surge condition is now given by a straight line. The antisurge control system is set to operate on a line somewhat in advance of the

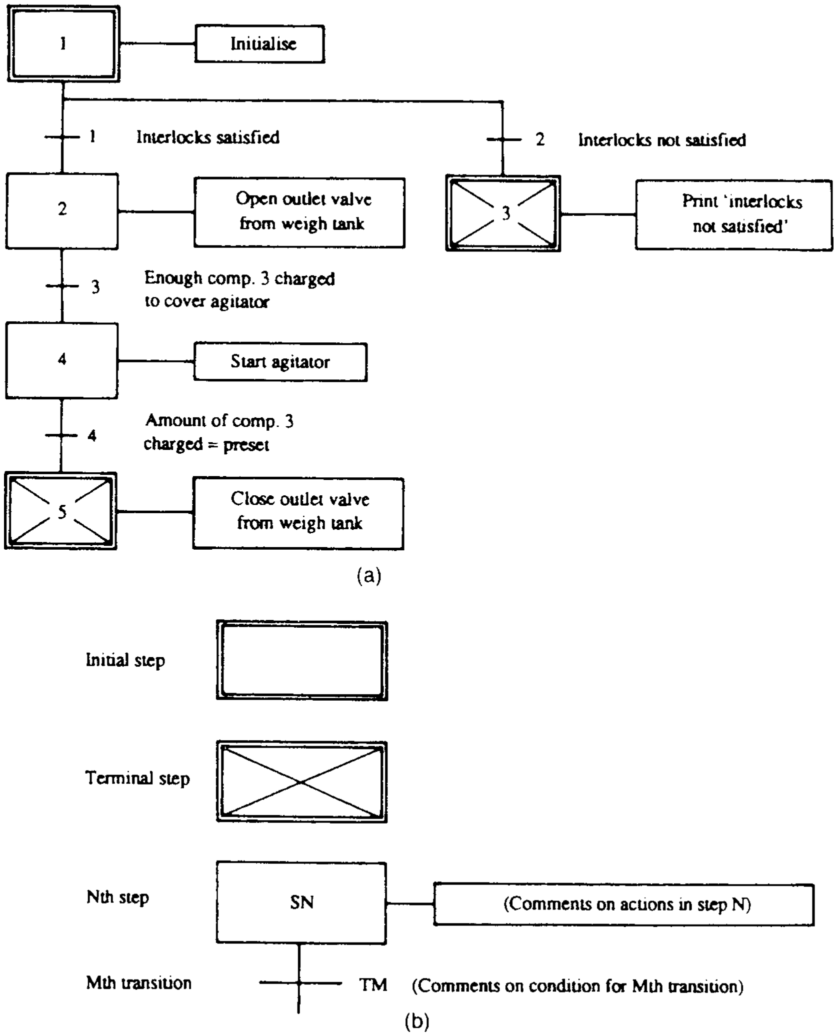

Figure 13.5 *Sequential function chart (Sawyer, 1993): (a) chart for control steps ADD COMPONENT; and (b) basic symbols (Courtesy of the Institution of Chemical Engineers)*

surge limit, as shown in Figure 13.6(b). The antisurge controller is usually a P+I controller and, since it operates only intermittently, it needs to have arrangements to counteract integral saturation.

Accounts of centrifugal and axial compressor control are given by Claude (1959), R.N. Brown (1964), Daze (1965), Hatton (1967) and Magliozzi (1967), and accounts of reciprocating compressor control are given by Hagler (1960) and Labrow (1968). Multi-stage compressor control is discussed by D.F. Baker (1982), Maceyka (1983) and Rana (1985), and control of compressors in parallel by Nisenfeld and Cho (1978) and B. Fisher (1984).

13.6.2 Chemical reactor control

The basic characteristics of chemical reactors have already been described in Chapter 11, in which, in particular, an account was given of the stability and control of a continuous stirred tank reactor. It is appropriate here to consider some additional aspects of reactor control.

A continuous stirred tank reactor is generally stable under open-loop conditions, but in some cases, a reactor may be unstable under open-loop but stable under closed-loop conditions. Some polymerization reactors and some fluidized bed reactors may be open-loop unstable under certain conditions.

The reactor should be designed so that it is open-loop stable unless there is good reason to the contrary. One method of achieving this is to use jacket cooling with a large heat transfer area. Another is to cool by vaporization of the liquid in the reactor. This latter method gives a virtually isothermal reactor.

If the reactor is or may be open-loop unstable, the control system should be very carefully designed. The responses of the controls should be fast. One method of achieving this

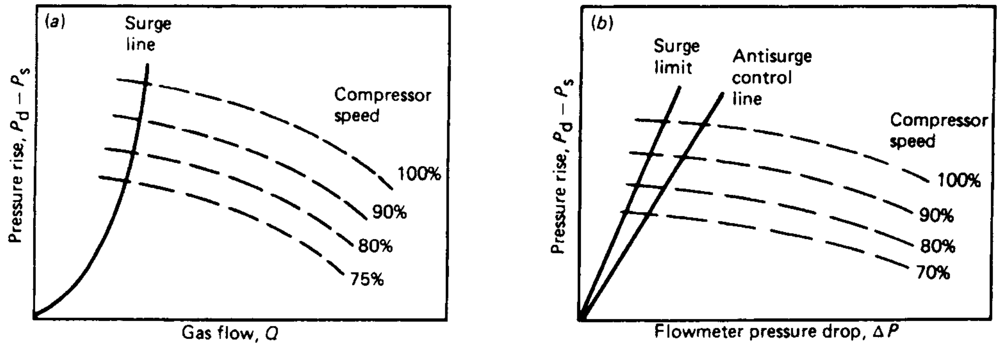

***Figure 13.6** Centrifugal compressor characteristics illustrating surge and antisurge control: (a) conventional characteristic; (b) characteristic for antisurge control*

is the use of cascade control for the reactor temperature to the coolant temperature. The dead time should be minimized. A high coolant flow assists in reducing dead time.

Continuous stirred tank reactors and batch reactors have their own characteristic control problems. Some of the control problems of continuous stirred tank reactors are as follows. A reaction in a continuous reactor is often carried out in a single phase in one pass. This requires accurate control of the feed flows to the reactor. Failure to achieve such control may have effects such as unconverted reactant leaving the reactor, undesirable side reactions or rapid corrosion.

It is often possible for impurities to build up in a continuous reactor. Where this is the case, arrangements should be made to purge the impurities. If the reactants to a continuous reactor need to be preheated, this should be done before they are mixed, unless the reaction requires a catalyst. A continuous reactor is sometimes provided with regenerative preheating. It should be borne in mind that such preheating constitutes a form of positive feedback.

As described in Chapter 11, batch reactors are of two broad types. In the first, the 'all-up' batch reactor, the main reactants are all charged at the start. In the semi-batch reactor, one reactant is not charged initially but is fed continuously.

The reaction mass in a batch reactor cannot necessarily be assumed to be completely mixed. It is not uncommon for there to be inhomogeneities, hot spots and so on. This has obvious implications for reactor control.

Some of the control problems of batch reactors are as follows. In a typical all-up batch cycle, the reactants and catalyst are charged, the charge is heated to reaction temperature, and the reaction mass is then cooled and discharged. In some cases the reaction stage is followed by a curing stage which may be at a temperature below or above the reaction temperature.

In the initial heating up period, the temperature of the charge should be brought up to the operating point rapidly, but it should not overshoot. If the reactor temperature is controlled by an ordinary three-term controller, integral saturation in the controller will cause overshoot. It is necessary, therefore, to employ a controller which is modified to avoid this. Alternatively, the heating up may be controlled in some other way which avoids overshoot. Once the reaction is under way in a batch reactor, the initial heat release is large. The cooling system should be adequate for this peak heat release.

Semi-batch reactors have different problems. The addition of the continuously fed reactant before the batch is up to temperature should be avoided, otherwise it is liable to accumulate and then react rapidly when the operating temperature is reached.

If agitation is interrupted and then resumed, there may be a sudden and violent reaction of reactants which have accumulated. There should be suitable alarms, trips and interlocks to signal loss of agitation, to cut off feed of reactant, and to ensure an appropriate restart sequence.

In both types of reactors, there should be arrangements to prevent material from the reactor passing back into reactant storage tanks where this could constitute a hazard. The control of flows in the reactant feed pipes is important. It is necessary to ensure tight shut-off of the reactants and to prevent flow from the reactor into the reactant feed system.

The reactor should be provided with suitable display and alarm instrumentation, so that the process operator has full information on the state of the reactor. Important variables are typically the flows of the reactants and of the coolant, the pressure in the reactor and the temperature of the reactor and of the coolant. Important statuses are the state of the agitator, of the pumps and of the valves.

The reactor should have a control system which is fully effective in preventing a reaction runaway. The main reactor control is usually based either on reactor temperature or on reactor pressure. The dynamic response of the loop is especially important. There should be adequate potential correction on the control loops. In other words, the steady-state gain between the manipulated variable and the controlled variable should be high enough to ensure that control of the latter is physically possible.

The instrumentation should possess both capability and reliability for the duty. Important aspects of capability are accuracy and dynamic response. The effects of instrument failure should be fully considered. In particular, failure in the measurement and control of the main variable, which is usually temperature, should be assessed. The ease of detection of instrument malfunction by the process operator should be considered. Factors which assist in malfunction detection include the use of measuring instruments with a continuous range rather than a binary output and the provision of recorders and of indications of valve position.

Trip systems should be provided to deal with potentially hazardous conditions. These typically include loss of feed, loss of coolant, loss of agitation and rise in reactor temperature. ESD arrangements for reactors are discussed in Chapter 11.

Use should be made of interlocks to ensure that critical sequences which have to be carried out on the reactor are executed safely and to prevent actions which are not permissible. Many of these control functions are facilitated by the use of a process control computer. A fuller discussion of instrumentation is given in Section 13.8.

13.7 Computer Integrated Manufacturing

There is now a strong trend in the process industries to integrate the business and plant control functions in a total system of CIM. Accounts of CIM are given by T.J. Williams (1989), Canfield and Nair (1992), Conley and Clerico (1992), Mehta (1992), Nair and Canfleld (1992), Bernstein *et al.* (1993) and Koppel (1993).

The aim of CIM is essentially to obtain a flexible and optimal response to changes in market demand, on the one hand, and to plant capabilities on the other. It has been common practice for many years for production plans to be formulated and production schedules to be produced by computer and for these schedules to be passed down to the plant. In refineries, use of large scheduling programmes is widespread. In addition to flexibility, other benefits claimed are improved product quality, higher throughputs, lower costs and greater safety.

A characteristic feature of CIM is that information also flows the other way, that is, up from the plant to the planning function. This provides the latter with a continuous flow of up-to-date information on the capability of the plant so that the schedule can be modified to produce the optimal solution. A CIM system may therefore carry out not only the process control and quality control but also scheduling, inventory control, customer order processing and accounting functions.

The architecture of a CIM system is generally hierarchical and distributed. Treatments of such architecture are given in Controlling Automated Manufacturing Systems (O'Grady, 1986) and by Dempster *et al.* (1981).

For such a system to be effective, it is necessary that the data passing up from the plant be of high quality. The system needs to have a full model of the plant, including the mass and energy balances and the states and capabilities of the equipment. This involves various forms of model-based control, which is of such prominence in CIM that the two are sometimes treated as if they are equivalent.

Plant data are corrupted by noise and errors of various kinds, and in order to obtain a consistent data set, it is necessary to perform data reconciliation. Methods based on estimation theory and other techniques are used to achieve this. Complete and rigorous model-based reconciliation (CRMR) is therefore a feature of CIM. Data reconciliation is discussed further in Chapter 30. One implication of CIM is that the plant is run under much tighter control, which should be beneficial to safety.

13.7.1 Batch plants

Batch processing involves not only sequential operations but also a high degree of variability of equipment states and is particularly suited to CIM. Accounts of integrated batch processing include those by Rosenof (1982b), Armstrong and Coe (1983), Rippin (1983), Severns and Hedrick (1983), Bristol (1985), Krigman (1985), Egli and Rippin (1986), Kondili, Panteides and Sargent (1988), Cott and Macchietto (1989) and Crooks, Kuriyna and Macchietto (1992).

In the system described by Cott and Macchietto (1989), use is made of three levels of control, which are, in descending order: plant level control, batch level control and resource level control, operating respectively on typical time-scales of days, minutes and seconds. A comprehensive approach to batch processing requires the integration of tools for plant design, automation and operating procedures.

13.8 Instrument Failure

Process plants are dependent on complex control systems and instrument failures may have serious effects. It is helpful to consider first the ways in which instruments are used. These may be summarized as follows:

Instrument	*System application*
Measuring instrument	Input to: Display system-measurement/status/alarm Control loop Trip system Computer model
Control element	Output from: Control loop Trip system

Measuring instruments are taken to include digital as well as analogue outputs. Control elements are normally control valves, but can include power cylinders, motors, etc.

The important point is that some of these applications constitute a more severe test of the instrumentation than others. The accuracy of a flowmeter may be sufficient for flow control, but it may not be good enough for an input to a mass balance model in a computer. The dynamic response of a thermocouple may be adequate for a panel display, but it may be quite unacceptable in a trip system.

This leads directly, of course, to the question of the definition of failure. In the following sections, various kinds of failure are considered. It is sufficient here to emphasize that the reliability of an instrument depends on the definition of failure, and may vary depending on the application.

13.8.1 Overall failure rates

There are more data on the failure rates of instrumentation than on most other types of plant equipment. It is now usually possible to obtain sufficient data for assessment purposes, though there are inevitably some gaps. There are two types of failure data on instruments. The first relates to performance in standard instrument tests and the second to performance on process plant. It is the latter which is of primary interest here.

Many of the data on the failure rates of instruments on process plants derive from the work of the UK Atomic Energy Authority (UKAEA). Table 13.5 gives data quoted in early investigations by UKAEA workers. Table 13.6 shows data in another early survey by Anyakora, Engel and Lees

Table 13.5 *Some data on instrument failure rates published by the UKAEA*

Instrument	*Failure rate* (faults/year)		*Reference*[a]
	Observed	*Assumed/predicted*	
Control valve[b]	0.25		1–4
		0.26	5, 6
Solenoid valve		0.26	5, 6
Pressure relief valve		0.022	5, 6
Hand valve		0.13	5, 6

(1971) in three works in the chemical industry. The first (works A) was a large works producing a wide range of heavy organic chemicals. The second (works B) made heavy inorganic chemicals. The third (works C) was two sites in a glass works. The failures were defined as and derived from job requests from the process operators. The failure rates were calculated on the assumption of a constant failure rate. The environment factor quoted in Table 13.6 is explained below.

The failure rates given in Table 13.6 are in broad agreement with other work published about the same time, such as that of Skala (1974). It should be emphasized that, of the failures given in the tables, only a very small proportion resulted in a serious plant condition. In most cases the failures were detected by the process operator, who then called in the instrument maintenance personnel.

The failure rates quoted are those for normal commercial instruments in the process industries. In certain other applications where higher instrument costs are acceptable, the failure rates are lower. Thus, instruments used in some defence applications are of an order of magnitude more expensive, but have a much higher reliability. Further data on instrument failure rates are given in Appendix 14.

13.8.2 Factors affecting failure

Some of the factors which affect instrument failure are listed below.

(1) System context:
   (a) application (display, control, etc.);
   (b) specification (accuracy, response, etc.);
   (c) definition of failure.
(2) Installation practices.
(3) Environmental factors – process materials:
   (a) degree of contact (control room, plant);
   (b) material phase (gas, liquid, solid);
   (c) cleanliness;
   (d) temperature;
   (e) pressure;
   (f) corrosion;
   (g) erosion.
(4) Environmental factors – ambient and plant conditions:
   (a) temperature;
   (b) humidity;
   (c) dust;
   (d) frost exposure;
   (e) vibration;
   (f) impact exposure.
(5) Operating factors:
   (a) movement, cycling.
(6) Maintenance practices.

There is little information available on which to assess the effect of these factors. In the survey by Anyakora, Engel and Lees, an attempt was made to assess the effect of environment, defining this rather loosely in terms of both ambient conditions and process materials. Two approaches were tried. One was to compare the effect of being or not being in contact with process fluids. Table 13.7 shows this effect for two groups of instruments, one consisting of those which are in contact and one consisting of those which are not. The instruments which are not in contact with process fluids show a much lower failure rate,

***Table 13.6** Some instrument failure rate data from three chemical works (Anyakora, Engel and Lees, 1971) (Courtesy of the Institution of Chemical Engineers)*

Instrument	*No. at risk*	*Instrument years*	*Environment factor*	*No. of faults*	*Failure* (faults/year)

although control valves and temperature measurements are exceptions.

The other approach, which was applied to instruments which are in contact with process fluids, was to distinguish between ‘clean’ and ‘dirty’ fluids. A fluid was regarded as dirty if it contained ‘gunk’, polymerized, corroded, etc. Table 13.8 gives data for instruments in these two cases.

From this work it was concluded, as a first approximation and for the instruments considered, that the severity of the environment of an instrument depends on the aggressiveness of any process materials with which it is in contact and that other factors are generally of secondary importance.

If the failure rate is taken to be a product of a base failure rate and of an environment factor, then Tables 13.7 and 13.8 suggest that a maximum value of about 4 is appropriate. Environment factors are given in Table 13.6; the failure rates given in the table are the original data and should be

Table 13.7 *Effect of environment on instrument reliability: instruments in contact with and not in contact with process fluids (Anyakora, Engel and Lees, 1971) (Courtesy of the Institution of Chemical Engineers)*

Instrument	*No. at risk*	*No. of faults*	*Failure rate* (faults/year)
Instruments in contact with process fluids:	2285	1252	1.15

Temperature measurement	2391	326	0.29

Table 13.8 *Effect of environment on instrument reliability: instruments in contact with clean and dirty fluids (Anyakora, Engel and Lees, 1971) (Courtesy of the Institution of Chemical Engineers)*

Instrument	*No. at risk*	*No. of faults*	*Failure rate* (faults/year)
Control valve:			
Clean fluids	214	17	0.17
Dirty fluids	167	71	0.89
Differential pressure transmitter:			
Clean fluids	27	5	0.39
Dirty fluids	90	82	1.91

divided by the environment factor to give the base failure rate. It should also be noted that the sampling/impulse line failure rates given in Table 13.6 should be added to the failure rates of the instruments themselves to obtain the failure rates of installations.

13.8.3 Failure modes

The overall failure rate of an instrument gives only limited information. It is often necessary to know its failure modes. Failure modes can be classified in several ways. Some important categories are (1) condition, (2) performance, (3) safety and (4) detection.

In a failure classification based on conditions, a failure mode is exemplified by a faulty bellows on a flowmeter or a broken diaphragm in a control valve. In a classification by performance, illustrations of failure are a zero error in a flowmeter or the passing of fluid when shut by a control valve. A performance classification emphasizes effects and a condition classification emphasizes causes, but the distinction is not rigid: a blockage in a control valve could reasonably be classed either way. The safety classification divides faults into fail-safe and fail-dangerous. The detection classification distinguishes between revealed and unrevealed faults: a revealed fault signals its presence and is at once detectable, an unrevealed fault is not immediately detectable, but is usually detected by a proof check.

Condition and performance may be regarded as the primary types of failure. Safety and detection modes may be obtained from these and from the system context of the instrument.

Table 13.9 *Failure modes of some instruments (Lees, 1973b) (Courtesy of the Institution of Chemical Engineers)*

Instrument failure mode	*No. of faults*
Control valve:	
Leakage	54
Failure to move freely:	
Sticking (but moving)	28
Seized up	7
Not opening	5
Not seating	3
Blockage	27
Failure to shut off flow	14
Glands repacked/tightened	12
Diaphragm fault	6
Valve greased	5
General faults	27
Thermocouple:	
Thermocouple element faults	24
Pocket faults	11
General faults	20

Table 13.9 shows some data obtained by Lees (1973b) in the survey already described on failure modes in thermocouples and control valves. These failure modes are essentially classified by condition, although the condition is often revealed by a performance failure. Similar data for other instruments are given in the original paper. Some

data used in reliability studies described in the literature on failure modes of instruments and control loops are shown in Table 13.10.

If information is available on overall but not on mode failure rates, it is sometimes assumed that about one third of the faults are in the fail-dangerous mode. The safety and detection failure modes of the temperature trip amplifier shown in Figure 13.7 have been analysed by Eames (UKAEA 1973 SRS/GR/12) as shown in Table 13.11. The fault is described by a four-letter code. The first indicates that it is fail-safe (S), fail-dangerous (D) or a calibration shift in the dangerous direction (C). The second is the number of the equipment adversely affected by the fault. The number 1–5 refers to, respectively, the main trip, the excess margin alarm the low margin alarm and the indicating meter shown in the figure and the indicating lamp (not shown). The third letter indicates that the fault is revealed (r) or unrevealed (u). The fourth is the number of the equipment which reveals the fault; the numbering code is as before. The various failure rates of the equipment are as follows:

Faults	*Failure rate*	
	(faults/10^6 h)	(faults/year)
Fail-dangerous (D1)	9.85	0.086
Fail-dangerous, unrevealed (D1u)	4.6	0.040
Total	145.5	1.27

Thus, the total fail-dangerous and fail-dangerous unrevealed faults are, respectively, 6.8% and 3.2% of the total faults, which is one measure of the success of the fail-safe design of the equipment.

Control valve fails shut or misdirected shut	0.5	

FRC, flow recorder controller.

13.8.4 Prediction of failure rates

It is sometimes necessary to know the failure rate of an instrument for which field data are not available. To meet this situation, methods have been developed for estimating the failure rate of an instrument from those of its constituent parts. Table 13.12 shows part of a prediction by Hensley (UKAEA 1969 AHSB(s) R178) of the failure rate of a pressure switch.

A comparison of some observed and predicted failure rates is given in Table 13.13. It can be seen that the agreement is quite good. A more quantitative measure of the effectiveness of the technique is Figure 13.8, which is given by A.E. Green and Bourne (1972) and shows the ratio of observed and predicted failure rates for a number of equipments. The median value of this ratio is 0.76 and the probabilities of the ratio being within factors of 2 and 4 of this value are 70% and 96%, respectively.

13.8.5 Loop failure rates

Data on failure rates of complete control loops have been the given by Skala (1974) and are shown in Table 13.14. Loop failure rates can be calculated from the failure rates of the constituent instruments. The failure rates of a loop with a pneumatic flow indicator controller, as calculated from the

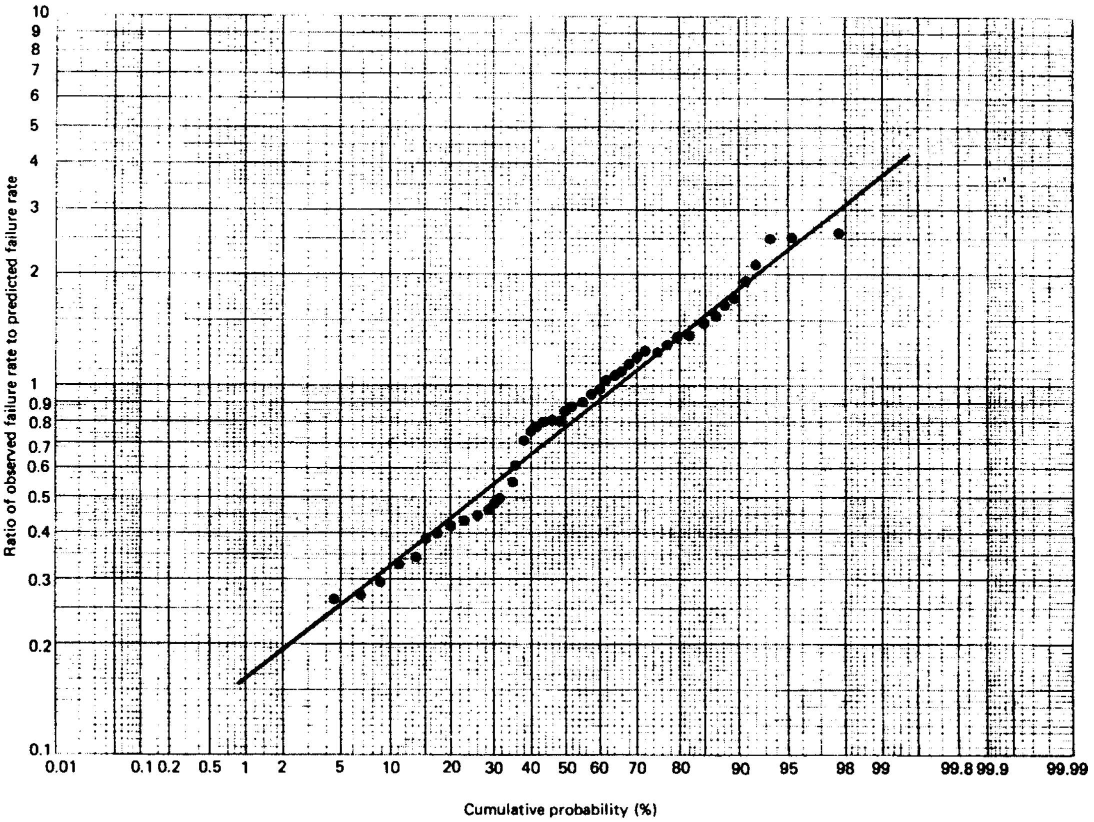

Figure 13.8 *Ratio of observed to predicted equipment failure rates (A.E. Green and Boume, 1972) (Reproduced with permission from Reliability Technology by A.E. Green and J.R. Boume, Copyright ©, 1972, John Wiley & Sons Inc.)*

data in Table 13.5 (UKAEA), as calculated from the data in Table 13.6 (Anyakora, Engel and Lees), and as given by Skala, are shown in Table 13.15.

Again it should be emphasized that, of the failure rates for loops given in these tables, only a very small proportion results in a serious plant upset or trip. In one study of the control loop failures on a large chemical plant quoted by M.R. Gibson (1978), it is found that there had been three control loop failures which resulted in plant trips and that the frequency of such failures was one failure every 20 years per loop.

13.8.6 Detection of failure

If instrument failure occurs, it is important for it to be detected. The ease of detection of an instrument failure depends very much on whether the fault is revealed or unrevealed. Unrevealed faults are generally detectable only by proof testing.

An instrument fault which is revealed is usually detected by the process operator either from the behaviour of the instrument itself or from the effect of the failure on the control system. There are, however, developments in the use of the process computer to detect instrument faults. Fault detection by the operator and by the computer is discussed in Chapters 14 and 30, respectively.

The detection of failure in instruments which have a binary output such as pressure or level switches is particularly difficult, because the fault if generally unrevealed, but is particularly important, because such instruments are frequently part of an alarm or trip system. One approach to the problem is to use an instrument with a continuous range output rather than a binary output. Thus, a level measuring instrument may be used instead of a level switch. In this way, many of the faults on the instrument which would otherwise be unrevealed become revealed.

13.8.7 Self-checking instruments

Developments are also made in instruments which have a self-checking capability. Principles on which such instruments are designed include (1) multiple binary outputs and (2) electrical sensor check.

A self-checking level measuring instrument which uses multiple binary outputs has been described by Hasler and Martin (1971). The instrument has a series of binary output points, which measure the liquid level at different heights. These points provide a mutual check. Thus, for example, if there are 10 points and the liquid level is up to point 5, so that this point gives a positive output, the absence of a positive output from point 4 indicates a failure on that point

A self-checking level switch in which electronic signals are used to check the state of the sensor has been described by J.O. Green (1978).

Increasingly, instruments are also being provided with the enhanced capabilities available from the incorporation of microprocessors. Self-checking is one such capability.

A general account of such instruments is given in Intelligent Instrumentation (Barney, 1985). A further discussion of intelligent, or smart, instruments is given by the CCPS (1993/14).

13.8.8 Fault-tolerant instrumentation

Instrument systems should have a degree of fault tolerance. The need for fault-tolerant systems has already been mentioned in relation to computer systems, where certain basic principles were outlined. These principles are equally applicable to the design of fault-tolerant instrument systems. Two main features of such instrumentation are redundancy and/or diversity and fail-safe operation. Fault-tolerant design of instrument systems is discussed by Bryant (1976), Ida (1983), Frederickson and Beckman (1990) and the CCPS (1993/14).

13.8.9 Instrument testing

Information is also available on the performance of instruments when subjected to a battery of standard tests. The evaluation of instruments is carried out both by special testing organizations and by major users. In the United Kingdom, the main organization concerned with instrument evaluation is the SIRA. Some of the tests carried out by SIRA have been described by Cornish (1978a). The instruments tested are normal production models.

Results of instrument evaluations by SIRA for the period 1971–76 have been given by Cornish (1978b) and are shown in Table 13.16. The reference conditions are the manufacturer's specification or, where no specification is quoted, an assumed specification based on current practice. The influence conditions refer to variations in electrical power or instrument air supply, high and low temperature, and humidity. These failure rates under test are high, but similar results are apparently obtained in other industrial countries.

13.9 Trip Systems

It is increasingly the practice in situations where a hazardous condition may arise on the plant to provide some form of automatic protective system. One of the principal types of protective system is the trip system, which shuts down the plant, or part of it, if a hazardous condition is detected. Another important type of protective system is the interlock system, which prevents the operator or the automatic control system from following a hazardous sequence of control actions. Interlock systems are discussed in Section 13.10.

Accounts of trip systems are given in *Reliability Technology* (A.E. Green and Bourne, 1972) and by Hensley (1968), R.M. Stewart (1971), Kletz (1972a), de Heer (1974), Lawley and Kletz (1975), Wells (1980), Barclay (1988), Rushton (1991a,b) and Englund and Grinwis (1992).

The existence of a hazard which may require a protective system is usually revealed either during the design process, which includes, as routine, consideration of protective features, or by hazard identification techniques such as hazop studies.

The decision as to whether a trip system is necessary in a given case depends on the design philosophy. There are quite wide variations in practice on the use of trip systems. There is no doubt, however, about the general trend, which is towards the provision of a more comprehensive coverage by trip systems. The problems are considered further in Chapter 14. The decision as to whether to install a trip system can be put on a less subjective basis by making a quantitative assessment of the hazard and of the reliability of the operator in preventing it.

13.9.1 Single-channel trip system

A typical, single-channel trip system is shown in Figure 13.9. It consists of a sensor, a trip switch and a trip valve. The configuration of a trip loop is therefore not dissimilar to that of a control loop. The difference is that, whereas the action of a control loop is continuous, that of a trip loop is discrete.

The trip switch may be of a general type, being capable of taking an electronic or pneumatic signal from any type of sensor. Thus, in a pneumatic system, a pressure switch would serve as the trip switch. Alternatively, the trip switch and the sensor may be combined to give a switch dedicated to a particular variable. Thus, common types of trip switch include flow, pressure, temperature, level and limit switches.

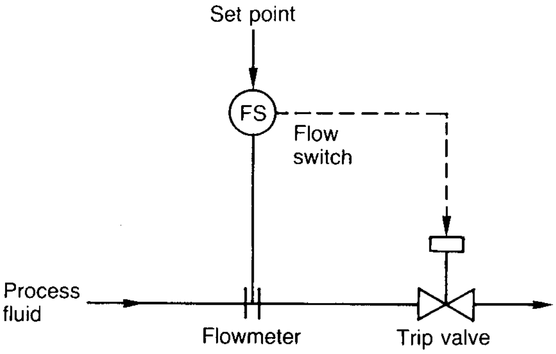

Figure 13.9 *A trip system*

13.9.2 Dependability of trip systems

Since a trip system is used to protect against a hazardous condition, it is essential for the system itself to be dependable. The dependability of a trip system depends on (1) capability and (2) reliability. Thus, it is necessary both for the system to have the capability of carrying out its function in terms of features such as accuracy, dynamic response, etc., and for it to be reliable in doing so. The reliability of the trip system may be improved by the use of (1) redundancy and (2) diversity. Thus, one approach is to use multiple redundant instruments, which generally give a reliability greater than that of a single instrument. But redundancy is not always the full answer, because there are some dependent failures which may disable the whole set of redundant instruments. This difficulty can be overcome by the use of diversity, which is exemplified by the use of different measurements to detect the same hazard and by the use of different instruments to measure the same variable.

Most trip systems consist of a single channel comprising a sensor, a switch and a shut-off valve, but where the integrity required is higher than that which can be obtained from a single channel, redundancy is generally used.

A trip system should be reliable against functional failure, that is, failure which prevents the system shutting the plant down when a hazardous condition occurs. Such a condition is not normally present and its rate of occurrence, which is the demand rate on the trip system, is usually very low. Thus, functional failures of the system are generally unrevealed failures. The trip system should also be reliable against operational failure, that is, failure which causes the system to shut the plant down when no hazardous condition exists. Thus operational failures of the system are always revealed failures.

It is the object of trip system design and operation to avoid both loss of protection against the hazardous condition due to functional failure and plant shut-down due to operational failure, or spurious trip. Since functional failure of the system is generally unrevealed, it is necessary to carry out periodic proof testing to detect such failure.

The simpler theoretical treatments of trip systems usually assume that the functional failures are unrevealed and the operational failures revealed and that the failure rates are constant; this approach is followed here. The treatment draws particularly on the work of A.E. Green and Bourne (1966 UKAEA AHSB(S) R117), some of which was later published by the same authors in *Reliability Technology* (1972).

13.9.3 Fractional dead time

The fractional dead time (FDT) of an equipment or system gives the probability that it is in a failed state. If the failure of an equipment is revealed with a revealed failure rate λ, the FDT ϕ depends on the failure rate and the repair time τ_r:

$$\phi = \lambda\tau_r \qquad \tau_r \ll 1 \qquad [13.9.1]$$

For a series system with revealed failure, the FDT ϕ of the system is related to the FDT ϕ_i of the constituent equipments as follows:

$$\phi = \sum_{i=1}^{n} \phi_i \qquad \lambda_i\tau_{ri} \ll 1 \qquad [13.9.2]$$

For a parallel system with revealed failure, the FDT ϕ of the system is related to the FDT ϕ_i of the equipments as follows:

$$\phi = \prod_{i=1}^{n} \phi_i \qquad \lambda_i \tau_{ri} \ll 1 \tag{13.9.3}$$

For a parallel redundant, or 1/n (1-out-of-n), system with revealed failure, the FDT $\phi_{1/n}$ of the system is related to the FDT $\phi_{1/1}$ of a single equipment as follows:

$$\phi_{1/n} = \phi_{1/1}^{n} \tag{13.9.4}$$

If, however, the failure of an equipment is unrevealed with an unrevealed failure rate λ, the FDT depends on this failure rate and on the proof test interval τ_p. The probability q of failure within time period t is:

$$q = 1 - \exp(-\lambda t) \tag{13.9.5}$$

or, for small values of λt

$$q = \lambda t \qquad \lambda t \ll 1 \tag{13.9.6}$$

Then the FDT is:

$$\phi = \frac{1}{\tau_p} \int_0^{\tau_p} q \mathrm{d}t \tag{13.9.7}$$

For a $1/n$ system with unrevealed failure, the FDT $\phi_{1/n}$ of the system is obtained from the probability $q_{1/n}$ of failure of the system within the time period t:

$$\phi_{1/n} = \frac{1}{\tau_p} \int_0^{\tau_p} q_{1/n} \mathrm{d}t \tag{13.9.8}$$

A detailed account of FDTs is given by A.E. Green and Bourne (UKAEA 1966 AHSB(S) R117).

13.9.4 Functional reliability of trip systems

Functional failure of a trip system here is assumed to be unrevealed. The failure rate λ used in the equations in this section is that applicable to these unrevealed fail-dangerous faults.

For a simple trip system consisting of a single channel 1/1 (1-out-of-1) system with a failure rate λ, the probability q of failure within proof test interval τ_p is:

$$q = 1 - \exp(-\lambda \tau_p) \tag{13.9.9}$$

For small values of $\lambda \tau_p$:

$$q = \lambda \tau_p \qquad \lambda \tau_p < 1 \tag{13.9.10}$$

The trip system is required to operate only if a hazardous plant condition occurs. The probability p_δ that such a plant demand, which has a demand rate S, will occur during the dead time τ_0 after the failure is:

$$P_\delta = 1 - \exp(-\delta \tau_0) \tag{13.9.11}$$

But, on average, the dead time I$_o$ is half the proof test interval τ_p:

$$\tau_0 = \frac{\tau_p}{2} \tag{13.9.12}$$

Hence:

$$P_\delta = 1 - \exp(-\delta \tau_p / 2) \tag{13.9.13}$$

For small values of $\delta \tau_0$:

$$p_\delta = \frac{\delta \tau_p}{2} \qquad \delta \tau_\rho \ll 1 \tag{13.9.14}$$

The probability p, that a plant hazard will be realized can be written in terms of the plant hazard rate η:

$$P_\eta = 1 - \exp(-\eta \tau_p) \tag{13.9.15}$$

For small values of $\eta \tau_p$:

$$P_\eta = \eta \tau_p \qquad \eta \tau_p \ll 1 \tag{13.9.16}$$

Frequently, some or all of the approximations of Equations 13.9.10, 13.9.14 and 13.9.16 apply. If all do, then taking

$$P_\eta = q p_\delta \tag{13.9.17}$$

gives

$$\eta = \frac{\delta \lambda \tau_p}{2} \qquad \lambda \tau_p \ll 1; \quad \delta \tau_p \ll 1; \quad \eta \tau_p \ll 1 \tag{13.9.18}$$

If the assumptions underlying Equation 13.9.18 are not valid, an expression which has been commonly used is:

$$\eta = \lambda p_\delta \tag{13.9.19}$$

Alternatively, the plant hazard rate can be expressed in terms of the FDT ϕ of the system:

$$\eta = \delta \phi \tag{13.9.20}$$

As given earlier, the probability q of failure of the simple trip system within the time period t is:

$$q = 1 - \exp(-\lambda t) \tag{13.9.21}$$

For small values of λt:

$$q = \lambda t \qquad \lambda \mathrm{t} \ll 1 \tag{13.9.22}$$

Then the FDT ϕ of the simple trip system is:

$$\phi = \frac{1}{\tau_p} \int_0^{\tau_p} q \mathrm{d}t \tag{13.9.23}$$

Hence:

$$\phi = \frac{\lambda \tau_p}{2} \tag{13.9.24}$$

and

$$\eta = \frac{\delta \lambda \tau_{\mathrm{p}}}{2} \qquad [13.9.25]$$

as before.

For a parallel redundant, or $1/n$ (1-out-of-n), system, or for an m/n (m-out-of-n) system, which may be a majority voting system, the following treatment applies. If there are n equipments of which m must survive for the system to survive and r must fail for the system to fail*:

$$r = n - m + 1 \qquad [13.9.26]$$

The probability $q_{m/n}$ of failure of this system within the proof test interval is:

$$q_{m/n} = \sum_{k=r}^{n} \binom{n}{k} q^k (1-q)^{n-k} \qquad [13.9.27]$$

For small values of q:

$$q_{m/n} = \binom{n}{r} q^r \qquad q \ll 1 \qquad [13.9.28]$$

The FDT $\phi_{m/n}$ of the system is:

$$\phi_{m/n} = \frac{1}{\tau_{\mathrm{p}}} \int_0^{\tau_{\mathrm{p}}} q_{m/n} \mathrm{d}t \qquad [13.9.29]$$

Then, from Equations 13.9.22, 13.9.28 and 13.9.29, the FDT $\phi_{m/n}$ of the system is:

$$\phi_{m/n} = \binom{n}{r} \frac{(\lambda \tau_{\mathrm{p}})^r}{r+1} \qquad [13.9.30]$$

Thus, for a 2/3 majority voting system:

$$\phi_{2/3} = (\lambda \tau_{\mathrm{p}})^2 \qquad [13.9.31]$$

For the special case of a parallel redundant, or $1/n$ (1-out-of-n), system, Equation 13.9.30 reduces to give the FDT $\phi_{1/n}$:

$$\phi_{1/n} = \frac{(\lambda \tau_{\mathrm{p}})^n}{n+1} \qquad [13.9.32]$$

Thus, for a 1/2 parallel system:

$$\phi_{1/2} = \frac{(\lambda \tau_{\mathrm{p}})^2}{3} \qquad [13.9.33]$$

and for a 1/3 system

$$\phi_{1/3} = \frac{(\lambda \tau_{\mathrm{p}})^3}{4} \qquad [13.9.34]$$

FDTs calculated from Equation 13.9.30 are shown in Table 13.17, both as functions of $\lambda \tau_{\mathrm{p}}$ and of the FDT $\phi_{1/1}$ for a single channel. Table 13.17 assumes that the instruments are tested simultaneously at the end of the proof test interval. Some improvement can be obtained by staggered testing, as shown by the data in Table 13.18, which are taken from A.E. Green and Bourne (1972).

13.9.5 Operational reliability of trip systems

It is also necessary to consider operational failure of trip systems. Operational failure here is assumed to be revealed. The failure rate λ used in the equations in this section is that applicable to these revealed fail-safe, or fail-spurious, faults.

For a simple trip system consisting of a single channel 1/1 system with a failure rate λ the operational failure, or spurious trip, rate γ is:

$$\gamma = \lambda \qquad [13.9.35]$$

For a parallel redundant, or $1/n$, system the operational failure rate $\gamma_{1/n}$ is:

$$\gamma_{1/n} = n\lambda \qquad [13.9.36]$$

For an m/n system, which may be a majority voting system, the following treatment applies. The rate at which the first operational failure of a single channel occurs is $n\lambda$.

Table 13.17 *Fractional dead times for trip systems with simultaneous proof testing*

System	n	m	r	ϕ	
1/1	1	1	1	$\frac{\lambda \tau_{\mathrm{p}}}{2}$	$\phi_{1/1}$
1/2	2	1	2	$\frac{(\lambda \tau_{\mathrm{p}})^2}{3}$	$\frac{4}{3}\phi_{1/1}^2$
1/3	3	1	3	$\frac{(\lambda \tau_{\mathrm{p}})^3}{4}$	$2\phi_{1/1}^3$
2/2	2	2	1	$\lambda \tau_{\mathrm{p}}$	$2\phi_{1/1}$
2/3	3	2	2	$(\lambda \tau_{\mathrm{p}})^2$	$4\phi_{1/1}^2$

System	ϕ^*	ϕ/ϕ^*
1/1	$\frac{\lambda \tau_{\mathrm{p}}}{2}$	1
1/2	$\frac{5}{24}(\lambda \tau_{\mathrm{p}})^2$	1.6
1/3	$\frac{1}{12}(\lambda \tau_{\mathrm{p}})^3$	3.0
2/2	$\lambda \tau_{\mathrm{p}}$	1
2/3	$\frac{2}{3}(\lambda \tau_{\mathrm{p}})^2$	1.5

ϕ, Fractional dead time for simultaneous testing; ϕ^*, fractional dead time for staggered testing.

---

* In this trip chapter, the number of equipments which must fail for the system to fail is r. This notation differs from that used in Chapter 7 for r-out-of-n parallel systems, in which r was used for the number of equipments which must survive for the system to survive. These two notations are used in order to preserve correspondence with established usage in texts on general reliability (e.g. Shooman, 1968) and on trip systems (e.g. A.E. Green and Bourne, 1972).

This first failure only results in a system trip if further operational failure of single channels sufficient to trip the system occurs within the repair time τ_r. The probability q_γ that this will occur is:

$$q_\gamma = \binom{n-1}{m-1}(\lambda\tau_r)^{m-1} \qquad \lambda\tau_r \ll 1 \qquad [13.9.37]$$

Then the operational failure rate $\gamma_{m/n}$ of the system is:

$$\gamma m/n = n\lambda q_\gamma \qquad [13.9.38]$$

$$\gamma_{m/n} = n\lambda\binom{n-1}{m-1}(\lambda\tau_r)^{m-1} \qquad [13.9.39]$$

Thus, for a 2/3 majority voting system:

$$\gamma_{2/3} = (3\lambda)\cdot(2\lambda\tau_r) \qquad [13.9.40]$$

$$\gamma_{2/3} = 6\lambda^2\tau_r \qquad [13.9.41]$$

Operational failure, or spurious trip, rates calculated from Equations 13.9.36 and 13.9.39 are shown in Table 13.19. It is emphasized again that the foregoing treatment is a simplified one. The expressions derived here appear, however, to be those in general use (e.g. Hensley, 1968; Kletz, 1972a; de Heer, 1974; Lawley and Kletz, 1975). Full theoretical treatments of trip systems have been given by A.E. Green and Bourne (1966 UKAEA AHSB(S) R117) and Wheatley and Hunns (1981). The latter gives expressions for a wide variety of trip systems.

13.9.6 Proof testing of trip systems

The treatment of the functional reliability of trip systems which has just been given demonstrates clearly the importance of the proof test interval. The expressions derived show that the condition for high functional reliability is

$$\lambda\tau_p < 1 \qquad [13.9.42]$$

As an illustration of the effect of the proof test interval, consider a simple trip system which has a failure rate of 0.67 faults/year on a duty where the demand rate is 1 demand/year:

$\delta = 1$ demand/year

$\lambda = 0.67$ faults/year

If the proof test interval is 1 week:

$\tau_p = 0.0192$ year

Table 13.19 *Spurious trip rates for trip systems*

System	γ
1/1	λ
1/2	2λ
1/3	3λ
2/2	$2^2\tau_r$
2/3	$6\lambda^2\tau_r$

Then the FDT is:

$$\phi = \frac{\lambda\tau_p}{2}$$
$$= 0.0064$$

and the plant hazard rate is

$\eta = \delta\phi = 0.0064$ hazards/year

The plant hazard rate for a range of proof test intervals is:

τ_p	η (hazards/year)
1 week	0.0064
1 month	0.027
1 year	0.26

For the longer proof test intervals, the approximate Equation 13.9.18 is not valid and Equation 13.9.19 was used.

Some additional factors which affect the choice of proof test interval are the facts that, while it is being tested, a trip is disarmed and that each test is an opportunity for an error which disables the trip, such as leaving it isolated after testing.

Thus, for a simple trip system with a trip disarmed period τ_d and an isolation dead time ϕ_{is}, the FDT becomes:

$$\phi = \frac{\lambda\tau_p}{2} + \frac{\lambda_d}{\tau_p} + \phi_{is} \qquad [13.9.43]$$

This expression has a minimum at:

$$(\tau_p)_{min} = \left(\frac{2\tau_d}{\lambda}\right)^{1/2} \qquad [13.9.44]$$

The effect of these factors can be illustrated by considering the trip system described in the previous example. If the trip disarmed period is 1 h and the isolation dead time is 0.001:

$\tau_d = 1.14 \times 10^{-4}$ year

$\phi_{is} = 0.001$

$(\tau_p)_{min} = 0.0184$ year = 0.96 weeks

Assume that a proof test interval of 1 week is chosen:

$\tau_p = 0.0192$ year

Then the FDT is

$\phi = 0.013$

and the plant hazard rate is

$\eta = 0.013$ hazards/year

In some instances it is not possible to test all parts of the trip system every time a proof test is carried out. For example, it is often not permissible to close the shut-off valve completely. In such cases a partial test is done, checking out the system to demonstrate valve movement but not valve shut-off.

If for a simple trip system the functional failure rate and proof test interval of the first part of the system are λ_A and τ_{pA} respectively, and those of the second part are λ_B and τ_{pB}, respectively, then:

$$q_A = 1 - \exp(-\lambda_A t) \qquad [13.9.45]$$

$$q_A = \lambda_A t \qquad \lambda_A t \ll 1 \qquad [13.9.46]$$

Similarly

$$q_B = \lambda_B t \qquad \lambda_B t \ll 1 \qquad [13.9.47]$$

Then the FDT is:

$$\phi = \frac{1}{\tau_{pA}} \int_0^{\tau_{pA}} q_A \mathrm{d}t + \frac{1}{\tau_{pB}} \int_0^{\tau_{pB}} q_B \mathrm{d}t \qquad [13.9.48]$$

$$\phi = \frac{1}{2}(\lambda_A \tau_{pA} + \lambda_B \tau_{pB}) \qquad [13.9.49]$$

There appears to be some variability in industrial practice with respect to the proof test interval. Generally a particular firm tends to have one longer interval, which is the standard one, and a shorter interval which is used for more critical cases. One such pair of intervals is 3 months and 1 month. Another is 1 month and 1 week. Thus, 1 month and 1 week proof test intervals are mentioned in many of the trip system applications described by Lawley and Kletz. In some cases the policy is adopted that if analysis shows that the proof test interval for a single trip is short, a redundant trip system is used.

13.9.7 Some other trip system characteristics

There are certain general characteristics which are desirable in any instrument system, but which are particularly important in a trip system. A trip system should possess not only reliability but also capability. In other words, when functional, it should be capable of carrying out its function. If it is not, then no amount of redundancy will help. The measuring instrument of the trip system should be accurate. This is particularly important where the safety margin is relatively fine.

The trip system should have a good dynamic response. What matters here is the ability of the trip to give rapid detection of the sensed variable and to effect rapid correction of that variable or rapid plant shut-down. This response therefore depends on the trip system itself, but also on the dynamic response of the plant. This aspect is considered further in Section 13.9.16.

The trip system should have sufficient rangeability to maintain accuracy at different plant throughputs. Another important property of a trip system is the ease and completeness with which it can be checked. It is obviously desirable to be able to check all the elements in a trip system, but this is not always easy to arrange.

13.9.8 Trip system applications

Some illustrations of the specification and design of protective systems have been given by Kletz (1972a, 1974a) and by Lawley and Kletz (1975). As already mentioned in Chapter 12, the use of trip systems instead of pressure relief valves is sometimes an attractive proposition, particularly where the relief valve solution involves large flare or toxic scrubbing systems. This is considered by Kletz (1974a) and by Lawley and Kletz (1975), who suggest that if a trip system is used instead of a relief valve, it should be designed for a reliability 10 times that of the latter. The reason for this is the uncertainty in the figures and the difference in the modes of failure; a relief valve which fails to operate at the set pressure may nevertheless operate at a higher pressure, whereas a trip is more likely to fail completely.

The fail-dangerous failure rates of a pressure relief valve and of a simple 1/1 trip system are quoted by these workers as 0.01 and 0.67 faults/year, respectively (Kletz, 1974a). Then, using these failure rates and assuming a demand rate of 1 demand/year, the plant hazard rates shown in Table 13.20 are obtained. For the longer proof test interval, $\delta\tau_p \ll 1$ and $\lambda\tau_p \ll 1$ do not apply, and for this case, the data in the table are obtained not from the approximate Equation 13.9.18, but from Equation 13.9.19. Thus, to meet the design criterion suggested for functional reliability, a 1/2 trip system with weekly testing is required. The spurious trip rate for this system, however, might be unacceptable, leading to a requirement for a 2/3 system.

Another example of the use of trip systems is the hydrocarbon sweetening plant shown in Figure 13.10 (Kletz, 1972a). The hydrocarbon is sweetened with small quantities of air which normally remain completely dissolved, but conditions can arise in which an explosive mixture may be formed. Initially it was assumed that the principal problem lay in a change in the air/hydrocarbon ratio but a hazop study revealed that a hazard could arise in a number of ways. One is for an air pocket to be formed, which can occur as follows:

(1) the temperature can be so high that the amount of air normally used will not dissolve;
(2) an air pocket can be left behind when a filter is recommissioned;
(3) the pressure can fall, allowing air to come out of solution;
(4) a fault in the mixer can prevent the air being mixed with hydrocarbon, so that the pockets of air can be carried forward;
(5) a fault in the air/hydrocarbon ratio controller can result in the admission of excess air.

Table 13.20 *Plant hazard rates for pressure relief valves and for trip systems (after Kletz 1974a) (Courtesy of Chemical Processing)*

System	*Plants hazard rate,* η (hazards/year)	(years/hazard)
No relief valve or trip	1	say, 1
Relief valve:		
Annual testing	0.004	250
Single 1/1 trip:		
Annual testing	0.264	4
Monthly testing	0.027	36
Weekly testing	0.0064	180
Duplicate 1/2 trip:		
Weekly testing	5.5×10^{-5}	18,000

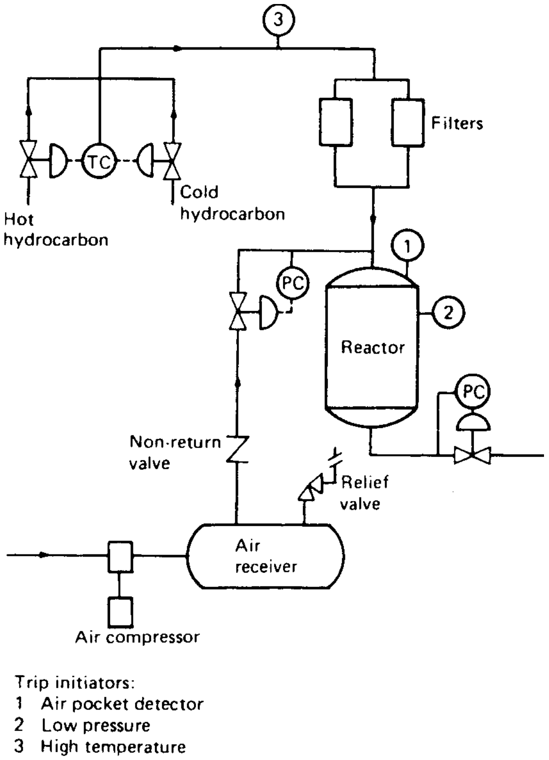

Figure 13.10 *Hydrocarbon sweetening plant (Kletz, 1972a) (Courtesy of the American Institute of Chemical Engineers)*

In this case it is also necessary for the feed to be above its flashpoint, which can occur in a number of ways: (1) the temperature can be above the normal flashpoint and (2) the feed can contain low flashpoint material. Alternatively, if there is both a loss of pressure in the receiver and a failure of the non-return valve, hydrocarbon may find its way into the air receiver.

The fault tree for the hazard is shown in Figure 13.11. The probabilities of the various fault paths were evaluated from this and the trip requirements were identified. The trip initiators considered, shown by the circles in Figures 13.10 and 13.11, were

(1) a device for detecting a pocket of air in the reactor;
(2) a pressure switch for detecting a low pressure in the receiver;
(3) a temperature measurement device for detecting a high temperature in the feed;
(4) laboratory analysis for detecting a low flashpoint feed;
(5) a device for detecting a high air/hydrocarbon ratio.

As the latter condition is detected by the trip initiator 1 anyway, trip initiator 5 was not used. The shut-down arrangement was that any of the trip initiators 1–3 shuts a valve in the air line and shuts down the compressor. The use of the laboratory analysis of feed flashpoint was restricted to ensuring that low flashpoint feeds were only present a for sufficiently small fraction of the time to meet the system specification.

A third example is the distillation column heating system shown in Figure 13.12 (Lawley and Kletz, 1975). Heat was supplied to the distillation column from an existing steam-heated reboiler and a hot-water-heated feed vaporizer. The plant was to be uprated by the addition of another reboiler and vaporizer.

The existing pressure relief valve was a 2/2 system and was adequate to handle overpressure from the existing reboiler and vaporizer. The problem was to cope with the overpressure which the new reboiler and vaporizer might give rise to. Both re-sizing of the existing relief valves and the addition of a third were unattractive in the particular situation. There was therefore a requirement for a trip system which would shut-down both the steam to the new reboiler and the hot water pump on the new vaporizer.

Both 1/1 and 1/2 trip systems were considered. The 1/1 system consisted of a pressure switch for detecting a high pressure on the overhead vapour line, a relay and a contact on the power supply to the hot water pumps and a relay and contact on that to the solenoid-operated shut-off valve on the reboiler steam supply. The 1/2 system consisted of a duplication of the 1/1 system. The summary of the failure rates of a simple trip system for this case is shown in Table 13.21.

The functional reliability of the existing 2/2 relief valve system was calculated as follows:

$$\lambda = 0.005 \text{ faults/year}$$

$$\tau_p = 2 \text{ years}$$

$$\phi = \lambda\tau_p = 0.01$$

The target FDT for the new trip system was taken as a factor of 10 less than this, namely 0.001, for the reasons already explained. The functional reliability of a 1/1 trip system was calculated as follows:

$$\lambda = 0.42 \text{ faults/year (from Table 13.21)}$$

$$\begin{aligned}\phi &= \frac{\lambda\tau_p}{2}\\ &= 0.21\tau_p\end{aligned}$$

Then, taking into account also the disarmed time and the isolation dead time:

$$\begin{aligned}\tau_d &= 1 \text{ h/test}\\ &\approx 0.0001 \text{ years/test}\end{aligned}$$

$$\phi_{is} = 0.001$$

$$\phi = 0.21\tau_p + \frac{0.0001}{\tau_p + 0.001}$$

The minimum FDT is at a proof test interval of

$$\begin{aligned}(\tau_p)_{min} &= (2\tau_p/\lambda)^{1/2}\\ &= 0.022 \text{ years}\\ &= 8 \text{ days}\end{aligned}$$

Assuming a proof test interval of 1 week, the FDT is

$$\phi = 0.01$$

This does not meet the target.

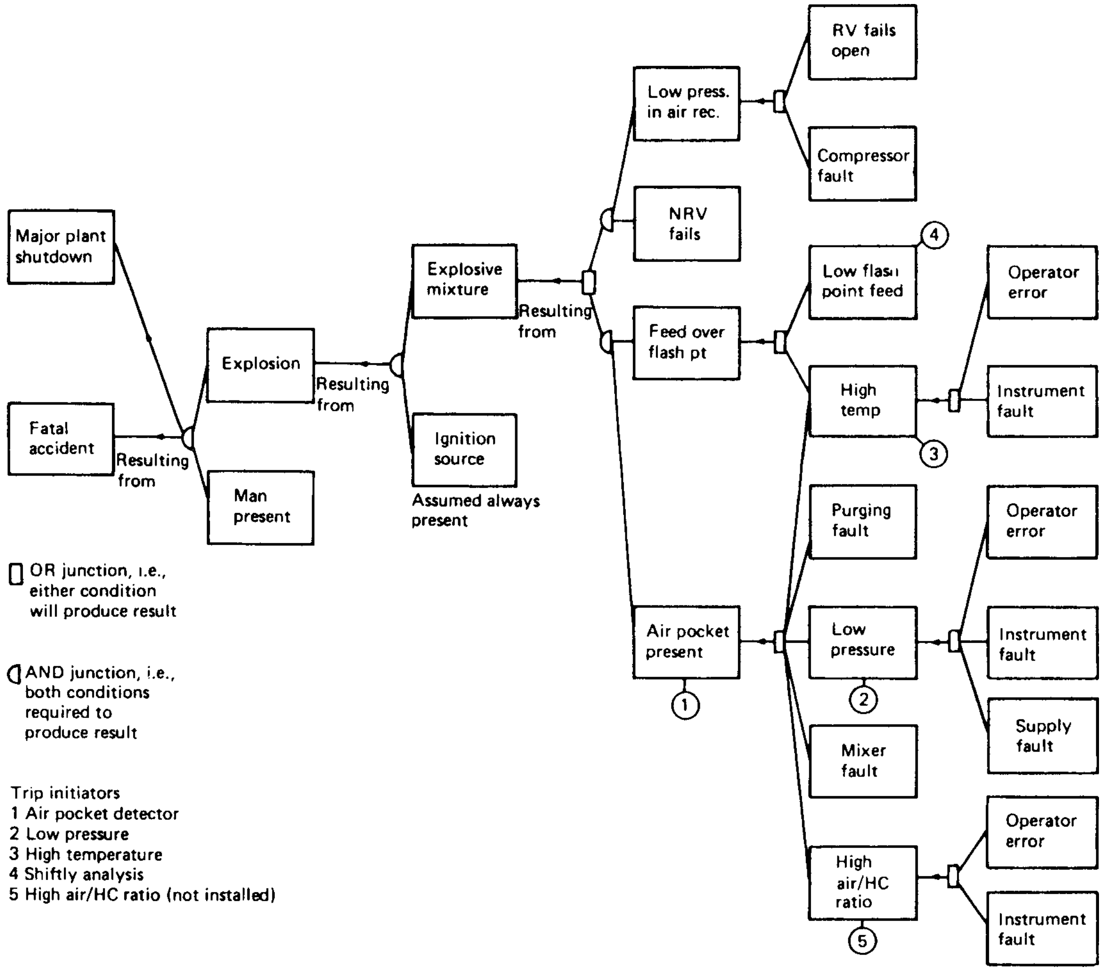

Figure 13.11 *Fault tree for explosion on a hydrocarbon sweetening plant (after Kletz, 1972a) (Courtesy of the American Institute of Chemical Engineers)*

The authors therefore consider a 1/2 trip system. The analysis for this system is more complex and takes into account the fact that the complete shut-off of the valves can be checked only on a proportion of the tests. It is concluded that a 1/2 system does just meet the target set.

13.9.9 High integrity trip systems

The trip system applications described so far have been 1/1 or 1/2 systems. The more complex system with 2/3 majority voting is now considered.

A major system of this kind, which appears to be the then most sophisticated on a chemical plant and which has been influential in the general development of protective systems in the industry, is that on the ethylene oxide process of ICI described by Stewart and co-workers (R.M. Stewart, 1971, 1974a; R.M. Stewart and Hensley, 1971). The ethylene oxide process is potentially extraordinarily hazardous: it operates with a reaction mixture very close to the explosive limit, there is a fire/explosion hazard and a toxic release hazard.

The design of the protective system followed the methods already outlined. The risk criterion was set at a probability of one fatality of 3×10^{-5} per year. The hazards were assessed by means of a fault tree, part of which is shown in Figure 13.13.

The system devised is a HIPS, consisting of the high integrity trip initiators (HITIs), the high integrity voting equipment (HIVE) and the high integrity shut-down system (HISS). A schematic system diagram, which omits replicated signal connections, is shown in Figure 13.14.

Redundancy is fully exploited throughout the system. Against each logic path to fire/explosion in the fault tree at least one parameter was selected initially to be a trip initiator. The integrity specified in fact required the use of at least two parameters. The choice of the trip initiating parameters is important but difficult. Some are obvious such as high oxygen concentration, high reactor temperature, low recycle gas flow. Others are far less obvious, but are needed to guard against combinations of faults or to substitute for other parameters. The latter occurs, for example, where the measurement response is too slow, for example oxygen concentration, or where the trip could result in a hazardous condition, for example recycle compressor trip.

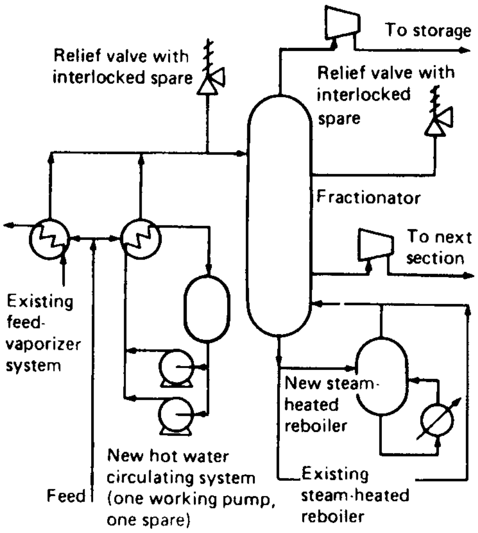

Figure 13.12 Distillation column heating system (Lawley and Kletz, 1975) (Courtesy of Chemical Engineering)

The measuring instruments used are carefully selected and, if necessary, modified to ensure high reliability. Each parameter is measured by triplicate instruments. The cables from each trip initiator on a parameter go by different routes so that there is less chance of all three being disabled by an incident such as a flash fire; the equipments have separate power supplies; and so on. The arrangement of the shut-down valves in the oxygen line illustrates further the use of redundancy. There are two lines each with three valves. A single line represents a 1/3 shut-down system. Duplication is provided to permit complete testing without disarming.

The advantages of the system are that the failure of one trip initiator in the fail-safe mode does not cause the plant to be tripped spuriously, the failure of one trip initiator in the fail-dangerous mode does not prevent the plant from being tripped, and the proof testing can be done without disarming the system.

The design of the system was subjected to an independent assessment by assessors within the company who were advised by the UKAEA. The assessors checked all feasible faults which could lead to hazardous conditions: the capability of the HIPS to carry out the protective action against the hazardous conditions arising from such faults and the occurrence rate of other hazardous conditions which the HIPS would not prevent, in relation to the design target Table 13.22 shows an extract from the table produced during this assessment.

The assessment showed that at this stage the plant hazard rate was 4.79×10^{-5}/year, which was higher than the target of 3×10^{-5}/year. An extra HITI was used to reduce the contribution of fault 3 from 2.72×10^{-5} to

Table 13.21 Failure rates of trip systems for a distillation column heating systems (Lawley and Kletz, 1975) (Courtesy of Chemical Engineering)

Components	*Failure rate* (faults/year)		
	Fail-to-danger	*Fail-safe*	*Total*
Trip initiator:			
Impulse lines – blocked	0.03	–	0.03
– leaking	0.06	–	0.06
Pressure switch (contacts open to give trip signal on rising pressure)	0.10	0.03	0.13
Cable fractured or severed	–	0.03	0.03
Loss of electrical supply	–	0.05	0.05
Total	0.19	0.11	0.30
Steam shut-off system:			
Relay coil (de-energize to trip)	–	0.05	0.05
Relay contact	0.01	0.01	0.02
Relay terminals and wire	–	0.01	0.01
Solenoid valve (de-energize to trip)	0.10	0.20	0.30
Loss of electrical supply (to solenoid valve)	–	0.05	0.05
Trip valve (clothes on air failure)	0.10	0.15	0.25
Air supply line – blocked or crushed	0.01	–	0.01
– fractured or holed	–	0.01	0.01
Loss of air supply	–	0.05	0.05
Total	0.22	0.53	0.75
Pump shut-off system:			
Relay coil, contact, terminals and wire (as above)	0.01	0.07	0.08
	0.01	0.07	0.08

0.8×10^{-5}/year, which brought the system within specification.

The assessors also examined the HIPS as installed to ensure that there were no significant deviations from design and reviewed the maintenance, calibration and testing procedures. The quality of the maintenance and testing is crucial to the integrity of a protective system and much attention was paid to this aspect.

It was estimated that an alternative system with $70^{1}/_{1}$ single trip initiators would result in some 30 spurious trips a year and that the system used reduced this by a factor of over 12. Since the cost of a trip was estimated as £2000, the saving due to avoidance of spurious trips was about £55,000 per annum. The cost of £140,000 for the installation was therefore considered justified on these grounds alone.

A coda to this account has been given by A. Taylor (1981), who describes the operation of the trip system over the period 1971–80. The information on the performance of the trip system is of two kinds: operations of and tests on the system. Events were classified as spurious, genuine and deliberate, the last being initiations by the operators.

Analysis of these events revealed that in a few cases the demand frequency was greater than that originally estimated by orders of magnitude. The author gives a table listing seven fault conditions, with the event numbering rising to 53, which exemplify the worst discrepancies. The two fault conditions which show the greatest discrepancies are the opening of a certain relief valve and loss of reaction:

Fault description		*Fault condition*		
		Predicted frequency (events/year)	*Actual frequency* (events/year)	*Ratio of actual/predicted frequency*
15	A certain relief valve opens	0.001	1.68	1680
48b	Loss of reaction	0.01	1.16	116

The relief valve fault was due to 'feathering', which had not been anticipated. The loss of reaction fault is not explicitly explained, but references by the author to the effect of modifications in reaction conditions may bear on this. It is noteworthy that of the seven fault conditions, it is those for which the original frequency estimates were lowest which are most in error.

With regard to instrument failure rates, in the case of magnetic float switches, three different failure mechanisms, and three different failure rates, were observed. Switches operating submerged in clean lubricating oil recorded no failures; those operating in recycled gas with occasional slugs of dirty water choked up; and a new type of switch was found to suffer from corrosion.

The author quotes three examples of dependent failure. One of these relates to the choked level switches just mentioned, which were all on one vessel. On four occasions, testing of the switches revealed that all were choked. The test procedure was altered to require that if one switch was found to be choked, the others should be tested.

There were also mistakes made in the installation of the instruments. In one case, pneumatic pressure switches, of a flameproof type which is not waterproof, were located downwind of a low pressure steam vent pipe, and suffered water ingress and corrosion.

13.9.10 PES-based trip systems

A trip system needs to be highly reliable. For this reason, it has been the practice to design trip systems as separate, hardwired systems. The acceptability of using a PES to implement the trip functions has long been a matter of debate. There has been a marked reluctance to abandon dedicated, hardwired systems.

The most constructive approach to the problem is to try to define the conditions which must be met by a PES-based trip system. As described in Section 13.12, the Health and Safety Executive (HSE, 1987b) has issued guidance based on this approach. Further guidance is given in the CCPS *Safe Automation Guidelines* described in Section 13.15, which are largely concerned with this topic.

An account of a computer-based trip system on an ammonia plant has been given by Cobb and Monier-Williams (1988). The reason given for moving to such a system is the avoidance of spurious trips. Design options were considered based on PLC and computer systems. The latter was selected largely because it offered a better interface with the operator. The system uses two computers operating in parallel. Some features of the system are: the ability to use inferred measurements; improved reliability of the trips; decreased defeating, or disarming, of the trips; and better control of any disarming which does occur.

13.9.11 Disarming of trip systems

It may sometimes be necessary to disarm a trip. This need arises particularly where a transition is being made between one state and another such as during start-up. The disarming of a trip should be assessed to ensure that it does not negate the design intent, whether this check is made at the time of the original design or subsequently. Such disarming should be the subject of a formal authorization procedure. This may be supplemented by hardware measures such as a key interlock.

If a trip proves troublesome, it is liable to be disarmed without such authorization. This is particularly likely to occur if there are frequent spurious trips, due to sensor failure or other causes. In order to disarm a trip, it may not be necessary to interfere with the hardware. It is often sufficient simply to alter to set-point.

13.9.12 Restart after a trip

Once a trip has operated, it is necessary to reset the system so that a safer restart can be made. Therefore, the trip action which has driven the plant to a safe state should not simply be cancelled, but instead a planned sequence of

Table 13.22 *Assessment of reliability of a high integrity trip system (after R.M. Stewart, 1971) (Courtesy of the Institution of Chemical Engineers)*

Description	*Fault condition*				*Relevant trip initiator No.*	*Fractional deed time*				*Hazard rate* ($\times 10^5$) (hazards/year)

6 etc.										etc.

PCV, pressure control valve.

actions taken to effect the restart. One situation which has frequently led to incidents is the restart of agitation in a batch reactor following an interruption of agitation.

A case history caused by restart after a trip has been described by Kletz (1979a). A cumene oxidation reactor was fitted with a high temperature trip for which the trip action was to shut off the air and dump the contents of the reactor into a water tank. A spurious trip occurred, the air valve closed and the dump valve opened. The trip condition cleared itself, the dump valve remained open, but the air valve reopened. Air passed into the reactor, creating a flammable mixture.

13.9.13 Restart after a depressurization

A particular case of restart after a trip is the repressurization of a vessel following emergency depressurization (EDP). The effect of rapid reduction of pressure in a vessel containing a material such as liquefied gas may be to chill the vessel below the transition temperature, thus creating the hazard of brittle fracture. Too prompt a repressurization, before the vessel has warmed up sufficiently, can result in realization of this hazard.

Cases where this has occurred are mentioned by Valk and Sylvester-Evans (1985). Treatment of the problem using a model of blowdown has been described by S.M. Richardson and Saville (1992).

13.9.14 Hazard rate of a single-channel trip system

In the relations for the functional reliability of a single-channel trip given in Section 13.9.3:

$$\eta = \frac{\delta \lambda \tau_{\mathrm{p}}}{2} \qquad [13.9.50]$$

The assumptions made are that $\lambda\tau_{\mathrm{p}} \ll 1$; $\delta\tau_{\mathrm{p}} \ll \eta\tau_{\mathrm{p}} \ll 1$, as stated.

If Equation 13.9.50 is used outside its range of validity, the results obtained can be not only incorrect but also nonsensical. Consider the case where the failure rate is $\lambda = 0.01$ failures/year, the demand rate is $\delta = 3$ demands/year and the proof test interval is $\tau_{\rho} = 1$ year. Then, Equation 13.9.50 gives for the hazard rate η a value of 0.015 hazards/year, which is actually greater than the failure rate λ.

A treatment is now given for the more general case, based on the work of Lees (1982a) as extended by de Oliveira and Do Amaral Netto (1987). For a single-channel trip, one formulation of the possible states is: (1) trip operational; (2) trip failed but failure undetected and (3) trip failed, failure detected and trip under repair. The corresponding Markov model is:

$$\dot{P}_1(t) = -\lambda P_1(t) + \mu P_3(t) \qquad [13.9.51a]$$

$$\dot{P}_2(t) = \lambda P_1(t) - \delta P_2(t) \qquad [13.9.51b]$$

$$\dot{P}_3(t) = \delta P_2(i) - \mu P_3(t) \qquad [13.9.51c]$$

where P_n is the probability that the trip is in state n.

With the initial condition that the trip is operational, the solution of Equation 13.9.51 is as follows:

$$\begin{aligned} P_1(t) = {} & \frac{\mu\delta}{r_1 r_2} \\ & + \frac{(r_1 + \mu + \delta) + \mu\delta}{r_1(r_1 - r_2)} \exp(r_1 t) \\ & - \frac{r_2(r_2 + \mu + \delta) + \mu\delta}{r_2(r_1 - r_2)} \exp(r_2 t) \end{aligned} \qquad [13.9.52a]$$

$$\begin{aligned} P_2(t) = {} & \frac{\lambda\mu}{r_1 r_2} + \frac{\lambda(r_1 + \mu)}{r_1(r_1 - r_2)} \exp(r_1 t) \\ & - \frac{\lambda(r_2 + \mu)}{r_2(r_1 - r_2)} \exp(r_2 t) \end{aligned} \qquad [13.9.52b]$$

$$\begin{aligned} P_3(t) = {} & \frac{\lambda\delta}{r_1 r_2} + \frac{\lambda\delta}{r_1(r_1 - r_2)} \exp(r_1 t) \\ & - \frac{\lambda\delta}{r_2(r_1 - r_2)} \exp(r_2 t) \end{aligned} \qquad [13.9.52c]$$

with

$$\gamma_1 = \frac{-(\mu + \lambda + \delta) - [(\lambda + \delta - \mu)^2 - 4\lambda\delta]^{1/2}}{2} \qquad [13.9.53a]$$

$$r_2 = \frac{-(\mu + \lambda + \delta) - [(\lambda + \delta - \mu)^2 - 4\lambda\delta]^{1/2}}{2} \qquad [13.9.53b]$$

Then the FDT and hazard rate obtained from Equations 13.9.52b and 13.9.52c are instantaneous values, and are:

$$\varphi(t) = P_2(t) + P_3(t) \qquad [13.9.54]$$

$$\eta(t) = \delta[P_2(t) + P_3(t)] \qquad [13.9.55]$$

The FDT and the hazard rate given in Equations 13.9.54 and 13.9.55 are functions of time. The average value of the hazard rate over the proof test interval is:

$$\eta = \frac{1}{\tau_{\mathrm{p}}} \int_0^{\tau_{\mathrm{p}}} \eta(t)\,\mathrm{d}t \qquad [13.9.56]$$

Then, substituting Equation 13.9.55 in Equation 13.9.56 and integrating gives the average hazard rate:

$$\begin{aligned} \eta = {} & \frac{\lambda\delta(\mu + \delta)}{r_1 r_2} + \frac{\lambda\delta(r_1 + \mu + \delta)}{r_1^2 \tau_{\mathrm{p}}(r_1 - r_2)} [\exp(r_1 \tau_{\mathrm{p}}) - 1] \\ & - \frac{\lambda\delta(r_2 + \mu + \delta)}{r_2^2 \tau_{\mathrm{p}}(r_1 - r_2)} [\exp(r_2 \tau_{\mathrm{p}}) - 1] \end{aligned} \qquad [13.9.57]$$

The foregoing treatment is based on the assumptions that the trip is always operational after a proof test is performed and that the test duration is negligible compared with the proof test interval.

Although this model has a high degree of generality, it is based on the assumption that, following detection of a trip failure, the plant continues to operate while the trip is repaired. If in fact the policy is that the plant operation does not continue while the trip is being repaired, different expressions apply. If the state $P_3(t)$ is dropped from the instantaneous hazard rate $\eta(t)$ in Equation 13.9.55 and if the repair rate $\mu = 0$, Equation 13.9.57 for the average hazard rate, then becomes:

$$\eta = \frac{1}{\tau_p}\left\{1 - \frac{1}{\lambda - \delta}[\lambda \exp(-\delta\tau_p) - \delta \exp(-\lambda\tau_p)]\right\} \qquad \lambda \neq \delta \tag{13.9.58a}$$

$$\eta = \frac{1}{\tau_p}[1 - (1 + \lambda\tau_p)\exp(-\lambda\tau_p)] \qquad \lambda = \delta \tag{13.9.58b}$$

This case is essentially that considered by Lees (1982a), who used the joint density function method. Two of the relations which he gives, for the failure density function f_η, and the probability ρ_η of realization of the hazard, are also of interest and are

$$f_\eta = \frac{\lambda\delta}{\lambda - \delta}[\exp(-\delta\tau_p) - \exp(-\lambda\tau_p) \qquad \lambda \neq \delta \tag{13.9.59a}$$

$$f_\eta = \lambda^2\tau_p \exp(-\lambda\tau) \qquad \lambda = \delta \tag{13.9.59b}$$

and

$$\rho_\eta = 1 - \frac{1}{\lambda - \delta}[\lambda \exp(-\delta\lambda_p) - \delta \exp(-\lambda\tau_p)] \quad \lambda \neq \delta \tag{13.9.60a}$$

$$\rho_\eta = 1 - (1 + \lambda\tau_p)\exp(1 + \lambda\tau_p) \qquad \lambda = \delta \tag{13.9.60b}$$

A number of other relations have been given in the literature for situations where Equation 13.9.50 is not valid. An expression given by Kletz and Lawley (Kletz, 1972a; Lawley and Kletz, 1975; Lawley, 1976) is

$$\eta = \lambda[1 - \exp(-\delta\tau_p/2)] \tag{13.9.61}$$

This is in effect Equation 13.9.19. It may be derived from Equation 13.9.17 together with Equations 13.9.10, 13.9.13 and 13.9.16. It is applicable for small $\lambda\tau_p$ and $\eta\tau_p$, but higher $\delta\tau_p$.

Lawley (1981) has subsequently given the more accurate Equation 13.9.58. The assumptions underlying this equation have just been described.

Wells (1980) has given an expression

$$\eta = \frac{\delta\lambda}{\delta + \lambda} \tag{13.9.62}$$

as an upper bound on the hazard rate for higher values of $\delta\tau_p$ (>2). This expression is equivalent to taking the FDT as $\varphi = \lambda/(\lambda + \delta)$. De Oliveira and Do Amaral Netto give the relation:

$$\eta = \delta\left\{1 - \frac{1}{\lambda\tau_p}[1 - \exp(-\lambda\tau_p)]\right\} \tag{13.9.63}$$

for low values of δ but higher values of $\lambda\tau_p$.

Numerical results for some of these expressions have been given by Lees and by de Oliveira and Do Amaral Netto. Table 13.23 shows some comparative results obtained, mainly by the latter workers.

13.9.15 Frequency of events in a trip system

A method of determining for a trip system the frequency of the events of principal interest has been described by Kumamoto, Inoue and Henley (1981). These events are the demand, the functional failure and the operational failure of the trip. The method is implemented in the program PROTECT.

The procedure is to designate each of these events in turn as the top event of a fault tree, to create the fault tree and to determine its cut sets. These cut sets together with the proof test interval for the trip are the inputs used by the model to provide estimates of the frequency of the events mentioned.

The application of this program to determine the expected frequency of these events for an ammonia–air mixing plant as a function of the proof test interval has been described by Kumar, Chidambaram and Gopalan (1989).

13.9.16 Time response of a trip system

The point has already been made that the dependability of a trip system is a function not only of its reliability but also of its capability. An important aspect of capability is the dynamic response. The effect of the dynamic response of the instrument is illustrated in Figure 13.15. It is assumed in the figure that, when a fault occurs, the variable increases linearly from its normal level to the danger level. The nominal trip point is set part way up the ramp, but the trip will not usually occur at the point in time corresponding to this level of the variable. There will normally be delays due to sampling and the dynamic response of the measuring instrument and there may be an instrument error. After the measuring instrument has responded, there will be delays in the safety circuitry and the shut-down valve. There will be a further delay in the process itself, before the effect of the shut-off is felt on the variable measured. All these factors, delays and errors, erode the nominal safety margin and should be considered carefully. The original assumptions concerning the maximum rate of rise of the variable are clearly critical also.

Further reduction of the nominal trip point may be appropriate, but the setting should not be put so low that noise on the variable at its normal level activates the trip. A spurious trip can arise from too low a level of the trip setting as well as from instrument unreliability.

The dynamic response of the complete situation against which the trip system is designed to protect may be modelled using standard methods. An account of unsteady-state modelling of plant is given in *Mathematical Modeling in Chemical Engineering* (Franks, 1967) and the modelling of instrumentation is treated in texts on process control such as those by Harriott (1964) and Coughanowr and Koppel (1965).

[a] In equations where μ is used, $\mu = 365$/year.

The following treatment is confined to the dynamic response of the measuring instrument, or sensor. The inputs to a sensor are generally characterized by a set of idealized forcing functions, of which the main types relevant here are (1) the step function, (2) the ramp function and (3) the impulse function. The unit step function changes suddenly at time zero from a value of zero to one of unity. The unit ramp function increases linearly with time and has a slope t. The unit impulse is a function which is infinitely large at time zero and zero elsewhere, but which also has an area which is unity. These three forcing functions are shown in Figure 13.16(a)–(c).

The instrument itself is typically modelled as either a first- or second-order system. Thus, a temperature sensor might be modelled as a first-order system:

$$Mc_p \frac{dT}{dt} = UA(T_i - T) \qquad [13.9.64]$$

where A is the area for heat transfer to the sensor, c_p is the specific heat of the sensor, M is the mass of the sensor, t is time, T is the temperature of the sensor, U is the overall heat transfer coefficient, and the subscript i indicates input, or forcing. Thus, T_i is the temperature of the surrounding fluid.

Equation 13.9.64 may be written in the more general form for a first-order system as:

$$\tau \frac{dT}{dt} = T_i - T \qquad [13.9.65]$$

where

$$\tau = Mc_p/UA \qquad [13.9.66]$$

and τ is a time constant. A lag of the form given by Equation 13.9.65 is known as a 'transfer lag'.

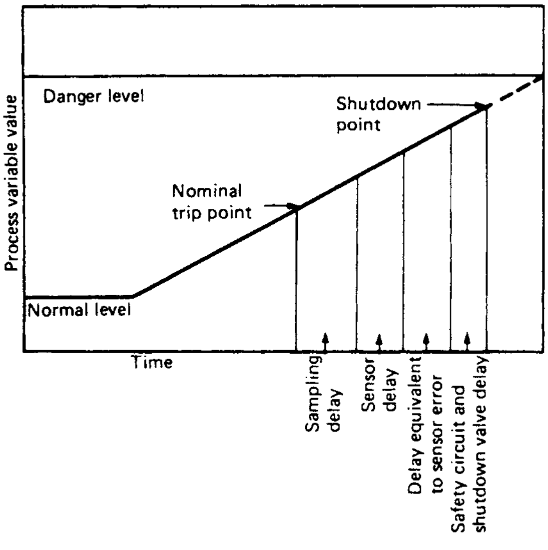

Figure 13.15 *Effect of instrument error and dynamic response on the safety margin in a trip system (after Hensley, 1988) (Courtesy of the Institute of Measurement and Control)*

In this case, the model obtained is a linear one. If the model obtained is non-linear, it needs first to be linearized. A non-linear model is obtained, for example, if the mode of heat transfer to the sensor is radiation rather than conduction.

The normal approach is then to express each term in the linear model as the sum of the steady-state value and of

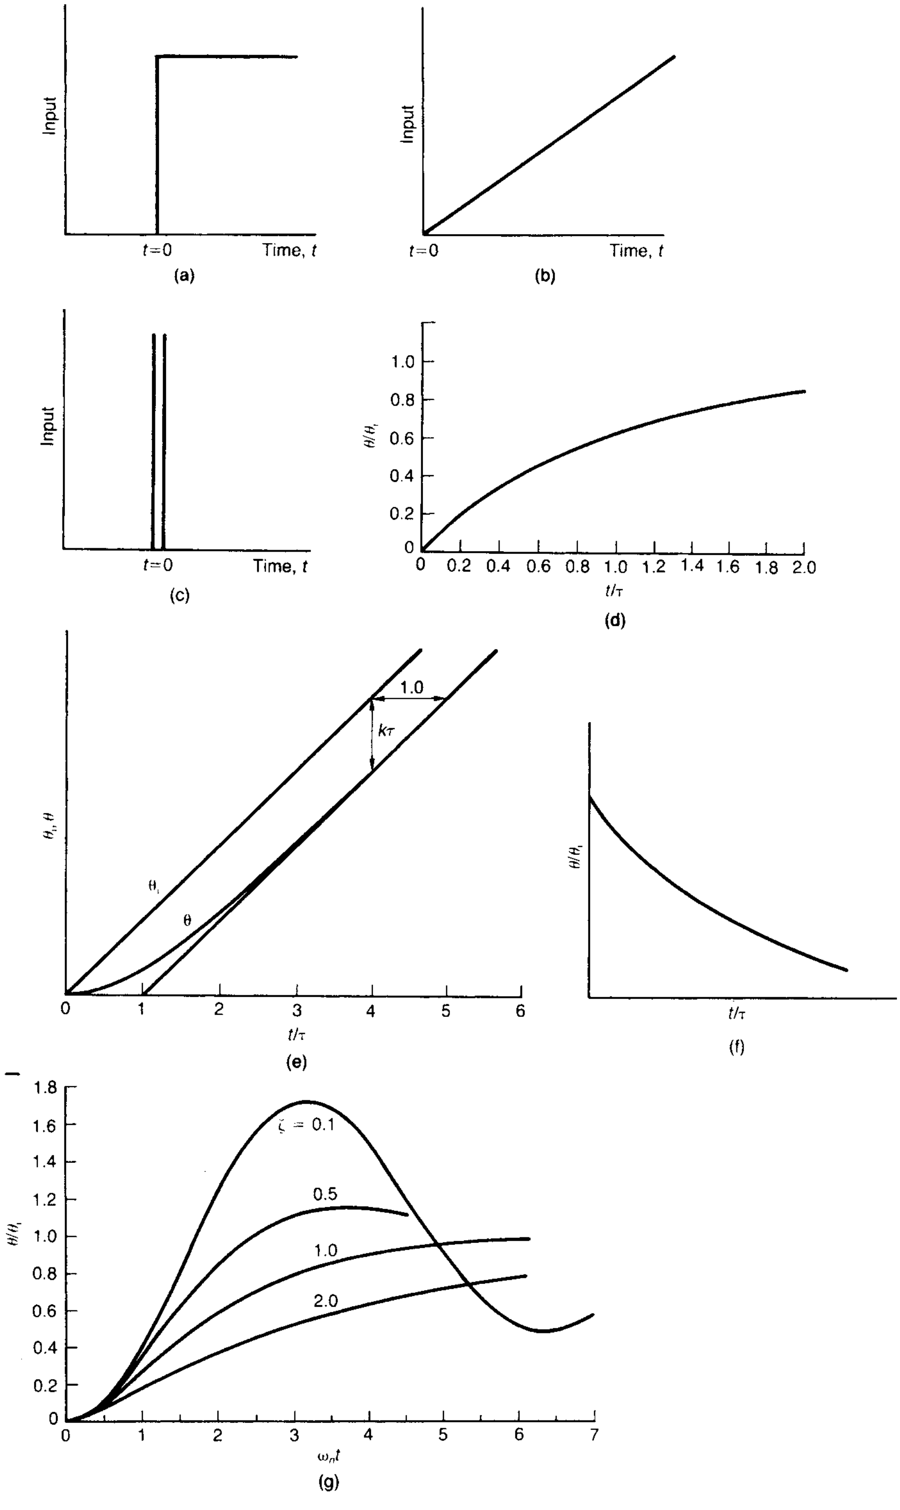

Figure 13.16 *Dynamic response of sensor systems: (a) step forcing function; (b) ramp forcing function; (c) impulse forcing function; (d) response of first-order system to step forcing function; (e) response to first-order system to ramp forcing function; (f) response to first-order system to impulse forcing function; (g) response of second-order system to step forcing function. For second order system:* ω_n *natural frequency:* ζ*, damping factor*

a transient component. Equation 13.9.65 then becomes:

$$\tau\frac{\mathrm{d}(T_{\mathrm{ss}}+\theta)}{\mathrm{d}t}=(T_{\mathrm{i,ss}}+\theta_{\mathrm{i}})+(T_{\mathrm{ss}}+\theta) \qquad [13.9.67]$$

The corresponding steady-state equation is:

$$0=\mathrm{T}_{\mathrm{i,ss}}-\mathrm{T}_{\mathrm{ss}} \qquad [13.9.68]$$

Subtracting Equation 13.9.68 from Equation 13.9.67 gives:

$$\tau\frac{\mathrm{d}\theta}{\mathrm{d}t}=\theta_{\mathrm{i}}-\theta \qquad [13.9.69]$$

where θ is the transient component of temperature and the subscript ss indicates steady state.

Equation 13.9.69 is then transformed into the Laplace, or s, domain by taking the Laplace transform:

$$s\bar{\theta}-\theta(0)=\bar{\theta}_{\mathrm{i}}-\bar{\theta} \qquad [13.9.70]$$

Taking the initial condition as the steady state with zero deviation gives $\theta(0)=0$, and hence the ratio of the output to the input, or the transfer function, is:

$$\frac{\bar{\theta}}{\theta_{\mathrm{i}}}=\frac{1}{1+\tau s} \qquad [13.9.71]$$

The response of the first-order system to the three forcing functions is then as follows. For the step response:

$$\theta_{\mathrm{i}}=k \qquad [13.9.72]$$

where k is a constant. Taking the Laplace transform of Equation 13.9.72 gives

$$\bar{\theta}_{\mathrm{i}}=\frac{k}{s} \qquad [13.9.73]$$

Substituting Equation 13.9.73 in Equation 13.9.71 gives:

$$\bar{\theta}=\frac{k}{(1+\tau s)s} \qquad [13.9.74]$$

Inverting the Laplace transformed expression 13.9.74 back into the time domain:

$$\theta=k[1-\exp(-t/\tau)] \qquad [13.9.75]$$

Equation 13.9.75 is sometimes written as:

$$\frac{\theta}{\theta_{\mathrm{i}}}=1-\exp(-t/\tau) \qquad [13.9.76]$$

Where this is done, it should be noted that θ_{i} is a constant, defined by Equation 13.9.72, whereas in Equation 13.9.69, it was a variable. For the ramp response, proceeding in the same way:

$$\theta_{\mathrm{i}}=kt,\ \text{say} \qquad [13.9.77]$$

$$\bar{\theta}_{\mathrm{i}}=\frac{k}{s^2} \qquad [13.9.78]$$

$$\bar{\theta}=\frac{k}{(1+\tau s)s^2} \qquad [13.9.79]$$

$$\frac{\theta}{\theta_{\mathrm{i}}}=\tau\left\{\frac{t}{\tau}-[1-\exp(-t/\tau)]\right\} \qquad [13.9.80]$$

The ramp response has the important property that

$$\frac{\theta}{\theta_{\mathrm{i}}}=t-\tau \qquad t\to\infty \qquad [13.9.81]$$

In other words, after an initial transient, the measured value lags the actual value by a time equal to the time constant τ. For the impulse response:

$$\theta_{\mathrm{i}}=k\delta(t),\ \text{say} \qquad [13.9.82]$$

$$\bar{\theta}_{\mathrm{i}}=k \qquad [13.9.83]$$

$$\bar{\theta}=\frac{k}{1+\tau s} \qquad [13.9.84]$$

$$\frac{\theta}{\theta_{\mathrm{i}}}=\frac{1}{\tau}\exp(-t/\tau) \qquad [13.9.85]$$

where $S(t)$ is the impulse function. The step, ramp and impulse responses of a first-order system are shown in Figure 13.16(d)–(f).

An overdamped second-order system is equivalent to two transfer lags in series. The basic model is therefore

$$\tau_1\frac{\mathrm{d}T_1}{\mathrm{d}t}=T_{\mathrm{i}}-T_1 \qquad [13.9.86]$$

$$\tau_2\frac{\mathrm{d}T_2}{\mathrm{d}t}=T_1-T_2 \qquad [13.9.87]$$

where subscripts 1 and 2 indicate the first and second stages, respectively. The transfer function of the second-order system is:

$$\frac{\bar{\theta}_2}{\theta_{\mathrm{i}}}=\frac{1}{(1+\tau_1 s)(q+\tau_2 s)} \qquad [13.9.88]$$

The step response is:

$$\frac{\theta_2}{\theta_{\mathrm{i}}}=1-\frac{1}{\tau_1-\tau_2}[\tau_1\exp(-t/\tau_1)-\tau_2\exp(-t/\tau_2)] \qquad [13.9.89]$$

The impulse response is:

$$\frac{\theta_2}{\theta_{\mathrm{i}}}=\frac{1}{\tau_1-\tau_2}[\exp(-t/\tau_1)-\exp(-t/\tau_2)] \qquad [13.9.90]$$

The step response of a second-order system is shown in Figure 13.16(g).

It is sometimes required to provide an unsteady-state model of the sensor for incorporation into an unsteady-state model of the total system. In this case, an equation such as Equation 13.9.65 may be used for a first-order system and a pair of equations such as Equations 13.9.86 and 13.9.87 for a second-order system.

The three forcing functions may be illustrated by the example of a flammable gas cloud at a gas detector. The gas cloud may present to the sensor as any one of these forcing functions. The gas concentration may rise suddenly from zero to a value which then remains constant (step function), it may rise linearly (ramp function) or it may rise momentarily from zero to a high value and then subside as rapidly (approximated by an impulse function).

An account of the time lags which occur in practical trip systems has been given by R. Hill and Kohan (1986), who characterize the dynamic response of a trip by a ramp function similar to that shown in Figure 13.15 and consider in turn the individual time lags. If the total interval from the time when the process starts to deviate to the time when it reaches the danger point exceeds 2 min, there is normally no problem in designing a trip system, but if the interval is less than this, there is a potential problem, and, if it is of the order of seconds, a trip solution may well not be practical.

The signal transmission lags to and from the logic system, and the logic system delay itself is normally negligible, even for pneumatic systems. Exceptions may occur where there are very long pneumatic transmission lines or where the logic is executed on a time-shared device. The more significant lags are likely to be in the sampling and the sensor, in the final control element, and in the process itself. Sampling lags may amount to a dead time of 10–30 s. Transfer lags in sensors vary, with temperature measurement lags often being large due to the thermal inertia of the measuring pocket. The lag at the control valve can vary from a fraction of a second up to several minutes, depending on the valve size. The lag in the process is also highly variable.

13.9.17 Configuration of trip systems

Inspection of Tables 13.17 and 13.19 indicates that the use of parallel redundant, or $1/n$, systems gives an increase in functional reliability, but a decrease in operational reliability compared with a 1/1 system. Better overall reliability characteristics can be obtained by the use of a majority voting system, of which the 2/3 system is the simplest. A comparison of a 2/3 system with a 1/1 system shows that the 2/3 system has a high functional and operational reliability, while a comparison with a 1/2 system shows that the 2/3 system has a slightly lower functional reliability, but a much higher operational one. The 2/2 system is little used for trip systems but has some interesting characteristics. It is effectively a series system which has a rather lower functional reliability than a 1/1 system, but its operational reliability exceeds not only that of the 1/1 but also that of the 2/3 system.

The configuration of trip systems has been discussed by Rushton (1991a,b), who describes a formal approach. According to Rushton, for typical systems, the ranking of trip systems with respect to their functional and operational reliability is invariant and is as shown in Table 13.24. The trip systems most commonly used are the 1/1, 1/2 and 2/3 systems. The requirement for functional reliability is rarely such as to justify a $^1/_3$ system and that for operational reliability rarely such as to justify a 2/2 or 3/3 system.

Table 13.24 *Ranking of trip system configurations with respect to functional and operational failure (Rushton, 1991b) (Courtesy of the Institution of Chemical Engineers)*

Functional ranking		*Operational ranking*	
$\phi_{m/n}$	*System*	$\gamma_{m/n}$	*System*
Low	1/3	Low	3/3
↓	1/2	↓	2/2
	2/3		2/3
	1/1		1/1
	2/2		1/2
High	3/3	High	1/3

The criterion given by Rushton for selection of the trip system configuration is an economic one and is:

$$V = nC + \delta\phi_s H + \gamma_s S + \delta(1-\phi_s)G \qquad [13.9.91]$$

where C is the annualized cost of a single channel trip, G is the cost of a genuine trip, H is the cost of realization of a hazard, S is the cost of a spurious trip, V is the overall annual cost, and the subscript s indicates the trip system (as opposed to a single channel). The most economic solution is that which minimizes V.

For a genuine trip, there is an element of loss related to the process failure which causes the demand. If, for purposes of comparison, this element (which will occur in all cases) is neglected, the cost of a genuine trip is approximately the same as that of a spurious one ($G = S$), so that Equation 13.9.91 becomes:

$$V = nC + \delta\phi_s H + [\gamma_s + \delta(1-\phi_s)]S \qquad [13.9.92]$$

If the basic parameters of a particular application are known, namely the demand rate δ, the fail-to-danger and spurious failure rates λ_s and γ_S, the proof test interval τ_p, the repair time τ_r and the costs of hazard realization H and spurious trip S, then a plot of H/C vs S/C gives a map showing the regions where a particular configuration is optimal. The boundaries of the regions are curves of constant V/C.

As an illustration, consider the case given by Rushton where the application is characterized by $\delta = 0.01$ demands/year, $\lambda = 0.2$ failures/year, $\gamma = 0.5$ failures/year, $\tau_p = 1/12$ and $\tau_r = 1/52$. The map giving the optimal configurations for this case is shown in Figure 13.17(a). If δ is increased to 1.0 demands/year, the map becomes that shown in Figure 13.17(b).

Rushton also treats the case where there is an element of common cause failure (CCF) and uses for this the beta method described in Chapter 9. He considers the simplest trip configuration to which such failure applies, the 1/2 system. For such a system:

$$\phi_{1/2} = \frac{[\lambda(1-\beta_1)\tau_p]^2}{3} + \frac{\beta_1\lambda\tau_p}{2} \qquad [13.9.93]$$

$$\gamma_{1/2} = 2 \times (1-\beta_2)\gamma + \beta_2\gamma \qquad [13.9.94a]$$

$$= (2-\beta_2)\gamma \qquad [13.9.94b]$$

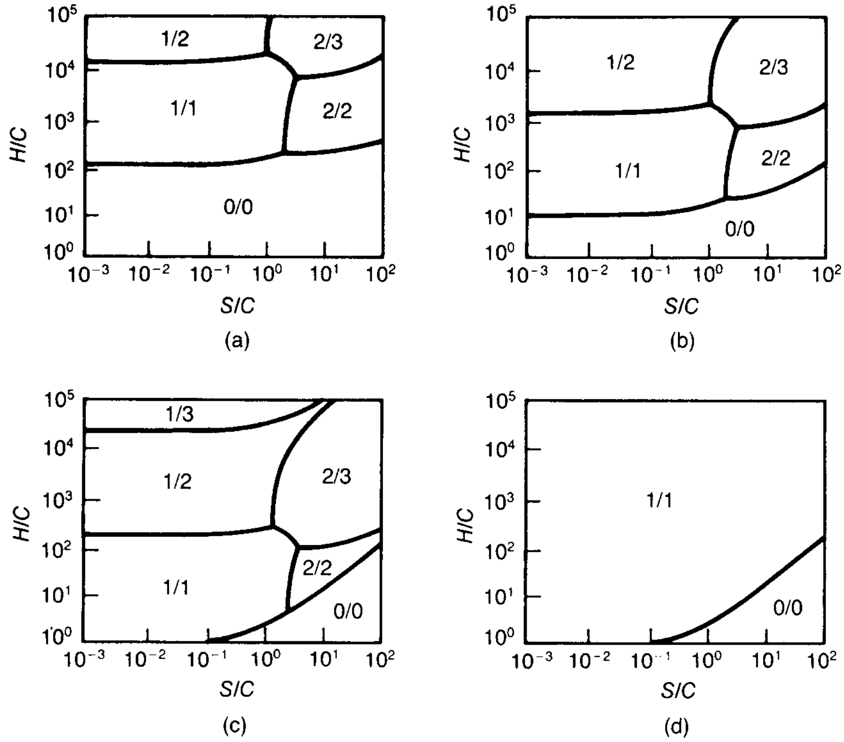

Figure 13.17 Configuration selection map for trip systems: illustrative examples (Rushton, 1991b): (a) case with $\delta = 0.01$, $\beta = 0$; (b) case with $\delta = 0.1$, $\beta = 0$; (c) case with $\delta = 1$, $\beta = 0.3$ and (d) case with $\delta = 1$, $\beta = 1$. See text for further details (Courtesy of the Institution of Chemical Engineers)

where β_1 is the fraction of the functional failure rate which is common cause, or the beta value for that failure rate, and β_2 is the operational beta value.

The effect of CCF may be illustrated by considering the extension given by Rushton of his example to the case of a 1/2 trip system where $\delta = 1$ demand/year, $\lambda = 0.2$ failures/year, $\gamma = 0.5$ failures/year, $\tau_p = 1/12$, $\tau_r = 1/52$ and where $\beta_1 = \beta_2 = \beta_3$. Maps of the configuration space for this case are shown in Figure 13.17(c) and (d) for different values of β. Table 13.25 gives expressions for the FDT and spurious trip rate for different trip configurations.

This cost-based approach allows the different trip system configurations to be put on a common basis for purposes of comparison. Where the hazard includes one to human life, there will be a certain level of functional reliability which must be achieved and this should be a factor in the choice of configuration. The approach described may still be applicable with adaptation in judging which configurations are reasonably practicable.

13.9.18 Integration of trip systems

As already described, a trip system is normally dormant and comes to life only when a demand occurs. An element of the trip system such as a sensor or a valve may experience failure and such a failure will lie unrevealed unless detected by proof testing or some other means. By contrast, equivalent elements in a control system are exercised continuously, and failure in such an element is liable to cause an operational excursion of some kind. The failure in this case is a revealed one. Yet the actual physical fault in the two cases may well be identical. A sensor may fail giving a low/zero or high reading, or a valve may jam open or shut. The concept of trip integration, which has been described by Rushton (1992), is based on this contrast between a fault which lies unrevealed in a trip system but is revealed in a measurement and control system. The principle applies to any system which has a protective function. The system is regarded as integrated provided it is regularly exercised, which generally means that it is in use during the normal operation of the plant. As an illustration, Rushton describes a refrigerated storage tank for a toxic liquid, equipped with a cooling system and a pressure relief valve. Both are protective systems, but the cooling system is in more or less continuous use and is thus integrated, whereas the relief valve is not.

In this case the integration is benign, but it can also be malignant. As an example of the latter, the author cites the case of a sensor which is common to both a level control loop and a high level alarm. Failure of the sensor results in failure not only of the control loop but also of the alarm.

It should be an aim of trip system design to convert unrevealed failures into revealed failures, and hence to enhance reliability, by the judicious exploitation of benign integration.

Table 13.25 *Fractional dead times and spurious trip rates for trip systems with simultaneous proof testing and common cause failures accounted for by the beta method (Rushton, 1991b) (Courtesy of the Institution of Chemical Engineers)*

System	$\phi_{m/n}$	$\gamma_{m/n}$
1/1	$\frac{\lambda\tau_p}{2}$	γ
1/2	$\frac{[\lambda\tau_p(1-\beta_1)]^2}{3}+\frac{\beta_1\lambda\tau_p}{2}$	$(2-\beta_2)\gamma$
2/2	$\lambda\tau_p(1-\beta_1/2)$	$2\gamma^2(1-\beta_2)^2\tau_r+\beta_2\gamma$
1/3	$\frac{(\lambda\tau_p)^3}{4}(1-\beta_1)^3+\frac{\beta_1\lambda\tau_p}{2}$	$(3-2\beta_2)\gamma$
2/3	$(\lambda\tau_p)^2(1-\beta_1)^2+\frac{\beta_1\lambda\tau_p}{2}$	$6\gamma^2(1-\beta_2)^2\tau_r+\beta_2\gamma$
3/3	$\frac{\lambda\tau_p}{2}(3-2\beta_1)$	$3\gamma^3(1-\beta_2)^3\tau_r^2+\beta_2\gamma$
m/n	$\binom{n}{r}\frac{[\lambda\tau_p(1-\beta_1)]^r}{r+1}+\frac{\beta_1\lambda\tau_p}{2}$	$n\gamma(1-\beta_2)\binom{n-1}{m-1}[\gamma(1-\beta_2)\tau_r]^{m-1}+\beta_2\gamma$

13.9.19 Maintenance of trip systems

The foregoing account of trip systems has brought out the importance of proof testing. This testing and, more generally, the maintenance of trips needs to be of a high standard if the design reliabilities are to be achieved. Accounts of the testing and maintenance of trip systems have been given by R.M. Stewart (1971), A. Taylor (1981) and Barclay (1988).

The system described by Barclay is broadly as follows. The trips on a plant are covered by a testing schedule which specifies a test interval for each trip system. A common test interval is 12 months, but the interval is established for each trip individually. A change to the test interval, or complete removal of the trip, are governed by formal procedures which involve consultation with the interested parties.

There is a written procedure for the test which details the actions to be taken. This is necessary because the procedure can be quite complex, because the individual performing the test may not be familiar with the particular trip and because in many cases the test is one of the last tasks done prior to a start-up when there may be considerable pressure. This procedure can be changed only after formal consultations.

The test should cover the whole trip from initial to final element. From the point of view of testing, the preferred method is an actual test in which the procedure is to take the process to the trip point and verify the trip action. The alternative is a simulated test which is performed by simulating process conditions using test equipment.

In many cases it is impractical to carry out an actual test. In the case of a hazardous process, the reasons are obvious. But even for a less hazardous process, the number of trips may be such that repeated shut-down and start-up is not practical. On a plant with 30 or 40 trips the equipment may be worn out just by testing.

It can be misleading to rely on a single-point trip as a sufficient test. And particularly where there is complex logic, it is necessary to exercise all the steps in the chain; omission of intermediate steps can be misleading.

Instruments which are part of a trip system are provided with identification, both on circuit diagrams and in the field by a tag. This helps avoid shut-downs caused by work on such instruments.

The trip system is maintained in good condition by preventive maintenance. Equipment is inspected for deterioration. Critical equipment is classified as such and subject to periodic overhaul. It is required that following maintenance work a function check be carried out on the equipment. A trip which is out of service or fails to operate is not tolerated. It is classed as a hazard and action is taken.

At the site described by Barclay, there are some 35,000–40,000 instruments with more than 5000 trips and interlocks. Trip maintenance is handled by a computerized system. The responsibility for testing in this works lies with the operations rather than the mechanical function. Essentially similar considerations apply to the maintenance of interlocks.

13.10 Interlock Systems

Interlocks are another important type of protective device. They are used to control operations which must take place in a specified sequence and equipments which must have specified relations between their states. This definition of an interlock differs from that often used in the American literature, where the term 'interlock' tends to be applied to both trip and interlock systems (as defined here).

Accounts of interlock systems are given in *Applied Symbolic Logic* (E.P. Lynch, 1980) and *Logical Design of Automation Systems* (V.B. Friedman, 1990) and by D. Richmond (1965), E.G.Williams (1965), Becker (1979), Becker and Hill (1979), Kohan (1984) and the CCPS (1993/14).

There are various kinds of interlock The original type is a mechanical device such as a padlock and chain on a hand valve. Another common type is the key interlock. Increasing use is made of software interlocks based on process computers.

Some typical applications of interlocks are in such areas as:

(1) electrical switchgear;
(2) test cubicles;
(3) machinery guards;
(4) vehicle loading;
(5) conveyor systems;
(6) machine start-up and shut-down;
(7) valve systems;
(8) instrument systems;
(9) fire protection systems;
(10) plant maintenance.

An interlock is often used to prevent access as long as an equipment is operating. Thus, electrical switchgear may be installed in a room where an interlock prevents the door opening until there is electrical isolation. Similarly, an interlock prevents access to a test cubicle for operations involving high pressure or explosive materials until safe conditions pertain. An interlock may be used to stop access to a machine or entry into a vessel unless the associated machinery cannot move. In vehicle loading, interlocks are used to prevent a tanker moving away while it is still connected to the discharge point.

Where synchronized operation of equipment is necessary, as in a conveyor system, interlocks are used to ensure this. Interlocks are used for the start-up of machinery to ensure that all the prestart conditions are met, that the correct sequence is followed and that conditions for transition from stage to stage are met. For large rotating machinery, key factors are process conditions and oil pressures.

Pressure relief valves have interlocks to prevent all the valves being shut off simultaneously. There may be interlocks on other critical valve systems. Interlocks are also a part of instrument systems. An interlock may be used to prevent the disarming of a trip system unless certain conditions are met. Fire protection systems are provided with interlocks as a safeguard against leaving the system disabled, particularly after testing or maintenance. Plant maintenance operations make much use of interlocks to prevent valves being opened or machinery started up while work is in progress.

Some features of a good hardware interlock are that it (1) controls operations positively, (2) is incapable of defeat, (3) is simple, robust and inexpensive, (4) is readily and securely attachable to engineering devices and (5) is regularly tested and maintained.

Some interlocks are quite simple, but some interlock systems are quite complex. Such systems are often not confined to interlocks, but incorporate other logic functions. Interlock systems therefore shade over into general logic control systems. In particular, there are some very large interlock systems on boilers and gas turbines.

An especially important type of logic control is the control of sequential operations. Sequential control systems usually have numerous checks which must be satisfied before the next stage is initiated and checks that equipment has obeyed the control signals. These checks constitute a form of interlock.

Since an interlock can bring the process to a halt, it is important to provide adequate status and alarm signals to indicate which feature is responsible for the stoppage. It will be apparent that some interlocks are effectively trips. The distinction between the two is often blurred.

The interlocks described so far are simple rather than high integrity systems, but the latter can, of course, be used, if the situation warrants it. The general approach is similar to that described for trip systems.

13.10.1 Interlock diagrams

As with protective systems so with interlock systems, the design may involve a number of parties and a common language is needed. Unfortunately, this is an area of some difficulty, for three reasons. The description of interlock systems involves the use of several different types of diagram; there appears to be considerable variability in the types of diagram employed and in the nomenclature used to describe them. The symbols for use in these diagrams are given in standards; however, not only are these standards subject to continuous revision, but also the symbols given are often not those in common use. Interlock systems are not well served with textbooks. In particular, there is in electrical engineering a large literature on switching systems, but very little of this addresses process interlock systems as such.

Three types of diagrams commonly used in the design of interlock systems in the process industries are (1) the process flowchart, (2) the logic diagram and (3) the ladder diagram. The last two are sometimes referred to as the 'attached logic diagram' and the 'detached logic diagram', respectively.

The starting point for design of an interlock system is a description of a sequence of operations. A diagram showing this is a process chart. Process chart symbols have been given in *Work Study* (Curie, 1960) and are shown in Table 13.26, Section A.

The logic required to implement this sequence may be shown in a logic diagram. This utilizes standard symbols for functions such as OR, AND and NOT, similar to those used in fault tree work, as described in Chapter 9. Standard symbols for fault trees are given in BS 5760 *Reliability of Systems, Equipment and Components*, Part 7: 1991 *Guide to Fault Tree Analysis*. For some functions, two sets of symbols are given, the preferred and the alternative. It is the latter which is commonly used in the process industries and which is used here. The logic symbols used here are the alternative symbols given in BS 5760 and are shown in Table 13.26, Section B.

The logic diagram may then be converted to a ladder diagram. Standard symbols for protective logic systems are given in BS 3939: 1985 *Graphical Symbols for Electrical Power, Telecommunications and Electronic Diagrams*. The relevant IEC standard is IEC 617 Graphical Symbols for Diagrams. BS 3939: Part 7: 1985 *Switchgear, Controlgear and Protective Devices*, which is identical to IEC 617-7, gives relevant symbols. Other sets of symbols include those given by E.G. Williams (1965) and those of E.P. Lynch (1980). An account of the evolution of logic symbols is given in *An Introduction to the New Logic Symbols* (Kampel, 1986). Table 13.26, Section C, shows a selection of symbols, including those used here, from those given by Lynch.

13.10.2 Some basic systems

Some of the basic building blocks of interlock systems are illustrated in Figure 13.18. Figure 13.18(a) shows a simple starting circuit. Activation of the circuit occurs if there is a signal due to depression of the start pushbutton AND a signal due to non-depression of the stop pushbutton. Since the signal from the start pushbutton will disappear when it

Table 13.26 *Interlock logic symbols*

A Work study symbols[a]

Symbol	*Activity*	*Predominant result*
	Operation	Produces accomplishes changes further the process

	Storage	Holds, retains or stores

B Logic symbols[b]

	AND
	OR
	NOT
	Delay

C Ladder diagram, symbols[c]

	Pushbutton start
	Pushbutton stop
	Position, or limit, switch
	Relay or solenoid contracts, normally open, closed when relay or solenoid is energized
	Relay or solenoid contacts normally closed, opened when relay or solenoid is energized
	Motor *n*
	Relay *n*
	Solenoid *n*

[a] These symbols are given by Currie (1960), who attributes them without reference to the American Society of Mechanical Engineers.
[b] These symbols are given in BS 5670: Part 7: 1991. The alternative symbols for NOT is a common alternative and is that used by E.P. Lynch (1980).
[c] These symbols are those used by E.P. Lynch (1980).

is no longer being depressed by the operator, it is necessary to provide the feedback signal shown, which ensures that there continues to be an output signal. If the stop pushbutton is depressed, the output signal is extinguished.

Figure 13.18(b) shows a time delayed holding circuit. If following activation by the start pushbutton, the signal X does not appear within the time interval specified, the output signal disappears. A typical application of this circuit is start-up of a motor-driven pump which is supplied with lubricating oil by a lube oil pump driven from the same motor. If the lubricating oil pressure signal is still absent after the time interval specified, the pump is shut-down.

Figure 13.18(c) shows a self-extinguishing circuit. Activation of the pushbutton gives an output signal which continues until the time interval specified has elapsed, when the output signal is extinguished. This circuit might typically be used to have a motor-driven equipment run for a period and then shut-down.

13.10.3 Illustrative example: conveyor system

As an illustration of an interlock system, consider the conveyor system described by Lynch. A screw conveyor A feeds material from a car vibrator to an elevator, which discharges to screw conveyor B above two storage bins A and B. There is a slide gate on the pipe between conveyor B and each bin, with a limit switch on each gate. Material is fed from a bin by a star feeder into screw conveyor C. The loading equipment can fill the bins at several times the rate at which it can be withdrawn.

Figure 13.19(a) shows a logic diagram for the interlocks for manual operation of this system. Conveyor B can be started only if either A or B slide gate is open. The elevator can be started only if conveyor B is running. Conveyor A can be started only if the elevator is running. The diagram also shows the simple non-interlocked starting circuit for the car vibrator.

The corresponding ladder diagram is shown in Figure 13.19(b). The diagram shows six circuits A–F. Certain relays occur in more than one circuit, for example, relay Rl in circuits A and D, and it is this which imparts the interlocking feature. Circuit A is the starting circuit for conveyor B. This circuit can be activated only if either relay R2 or R3, the relays for the slide gates limit switches (LS), is closed. If this condition is met, depression of the start pushbutton (PB) energizes relays R1 and Ml and causes R1 to close and Ml to operate a relay in the power circuit. When the stop pushbutton is pressed, the circuit is de-energized and Rl opens.

In circuit B, closure of the slide valve limit switch LSI energizes relay R2 and causes it to close, and opening of the switch causes R2 to open. Circuit C implements a similar relationship between limit switch LS2 and relay R3. Circuit D is the starting circuit for the elevator. The circuit can be activated only if relay R1 is closed. If this condition is met, depression of the start button energizes relays R4 and M2 and causes R4 to close and M2 to operate. Circuit E is the starting circuit for conveyor A, and is similar to circuit D. The circuit can be activated only if relay R4 is closed. Circuit F is a simple starting circuit and is not interlocked.

13.10.4 Illustrative example: reactor system

Another example of a simple interlock system is illustrated in Figures 13.20 and 13.21. Figure 13.20 shows a plant consisting of a water-cooled reactor in which a batch reaction is carried out. The reactor is charged with chemical A and chemical B is then fed in gradually from a weigh tank as the reaction proceeds. The interlock system is required to cut off the supply of B from the weigh tank if any of the following conditions apply: (1) the shut-off valve V3 on reactor 2 is open; (2) the agitator is not operating; (3) the agitator paddle has fallen off or (4) the reactor temperature has risen above a fixed limit. The loss of the agitator paddle is detected by a current-sensitive relay on the motor.

An interlock system for carrying out these functions is shown in Figure 13.21. The start input opens valve 1, unless valve 3 is open or the agitator is stopped, which conditions inhibit start-up. If these conditions occur later or if the reactor temperature rises or the agitator paddle falls off, valve 1 is closed. The interlock causing the closure is signalled by a status or alarm display. There is a 10 s delay on the reactor high temperature interlock to

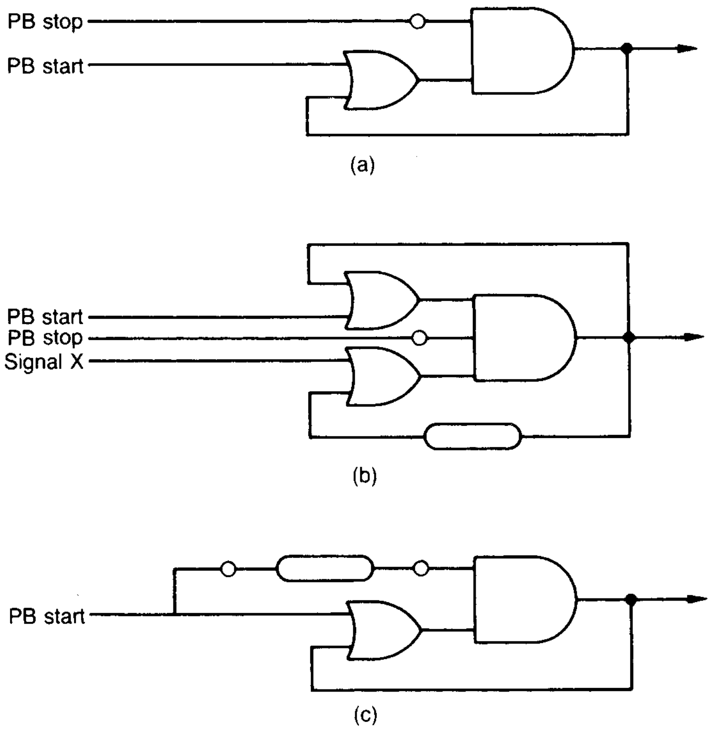

Figure 13.18 *Some basic interlock system logic diagrams: (a) simple starting circuit; (b) time delayed holding circuit and (c) self-extinguishing circuit. PB, pushbutton*

(b)

Figure 13.19 *Conveyor interlock system diagrams: (a) logic diagram; and (b) ladder diagram (E.P. Lynch, 1980) (Reproduced with permission from Applied Symbolic Logic by E.P. Lynch, Copyright ©, 1980, John Wiley & Sons Inc.)*

allow for noise on that signal. If operation is inhibited by the reactor high temperature or agitator stoppage interlocks, these inhibitions are removed 5 and 10 min, respectively, after the inhibiting condition has disappeared. An account of the reliability of interlock systems is given by R.A. Freeman (1994).

13.11 Programmable Logic Systems

As already indicated, increasing use is made in process control systems of PLCs. An account of the application of PLCs to functions such as pump change over, fire and gas detection and ESD has been given by Margetts (1986a,b). He describes the planning of an operation such as pump

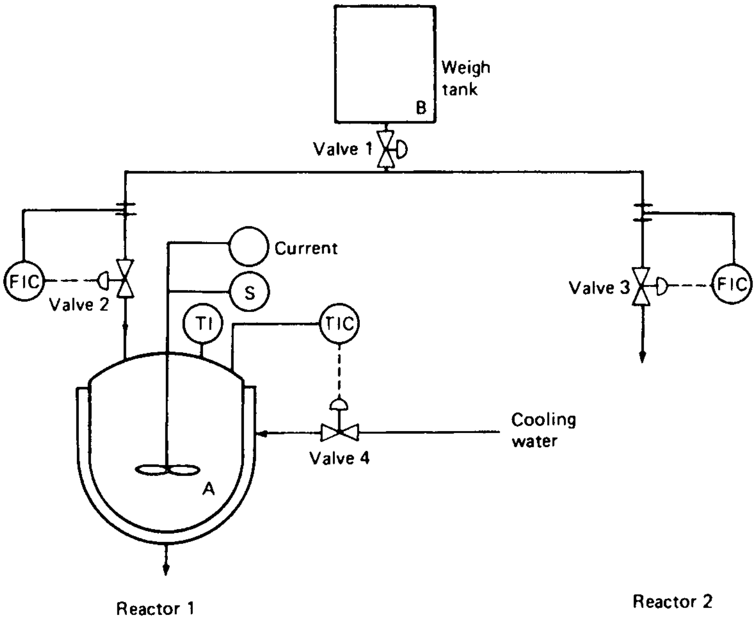

Figure 13.20 *Batch reactor system. FIC, flow indicator controller; S, speed measurement; TI, temperature indicator; TIC, temperature indicator controller*

change over using hierarchical task analysis, in which the change over task is successively redescribed until it has been broken down into executable elements, and the application of the hazard and operability (hazop) method to assess the adequacy of the resultant design.

He also deals with the reliability of the PLC system. For the system which he considers, the MTBFs of the input device, the control logic and the output device are 100,000, 10,000 and 50,000 h, respectively, giving an overall system MTBF of 7690 h. Use of as many as four control logic units in parallel would raise the system MTBF to 14,480 h, but this is not the complete answer. The method described by the author for the further enhancement of reliability is the exploitation of the ability of the PLC to test the input and output devices and also itself.

13.12 Programmable Electronic Systems

Increasingly, the concept of computer control has become subsumed in the broader one of the PES. The account given here is confined to the safety aspects of PESs and is based on the *HSE PES Guide*. The treatment in the *CCPS Safe Automation Guidelines* is discussed in Section 13.15.

13.12.1 HSE PES Guide

An account of PESs and their safety implications is given in *Programmable Electronic Systems in Safety Related Applications* (HSE, 1987b) (the *HSE PES Guide*), of which Part 1 is an *Introductory Guide* (PES 1) and Part 2 the *General Technical Guidelines* (PES 2). The general configuration of a PES is shown in Figure 13.22.

Whereas in a safety-related system the use of conventional hardwired equipment is routine, the use of a PES in such an application has been relatively unknown territory. The approach taken, therefore, has been to assess the level of integrity required in the PES by reference to that obtained with a conventional system based on good practice. This level of integrity is referred to as 'conventional safety integrity'.

PES 2 gives three system elements which should be taken into account in the design and analysis of safety-related systems:

(1) configuration;
(2) reliability;
(3) overall quality.

Safety integrity criteria for the system should be specified which cover all three of these system elements.

13.12.2 Configuration

The configuration of the system should be such as to protect against failures, both random and systematic. The former are associated particularly with hardware and the latter with software. PES 2 lays down three principles which should govern the configuration:

(1) the combined number of PES and non-PES safety-related systems which are capable, independently, of maintaining the plant in a safe condition, or bringing it to a safe state, should not be less than the number of conventional systems which have provided conventional safety integrity;
(2) no failure of a single channel of programmable electronic (PE) hardware should cause a dangerous mode of failure of the total configuration of safety-related systems;
(3) faults within the software associated with a single channel of PE should not cause a dangerous mode of failure of the total configuration of safety-related systems.

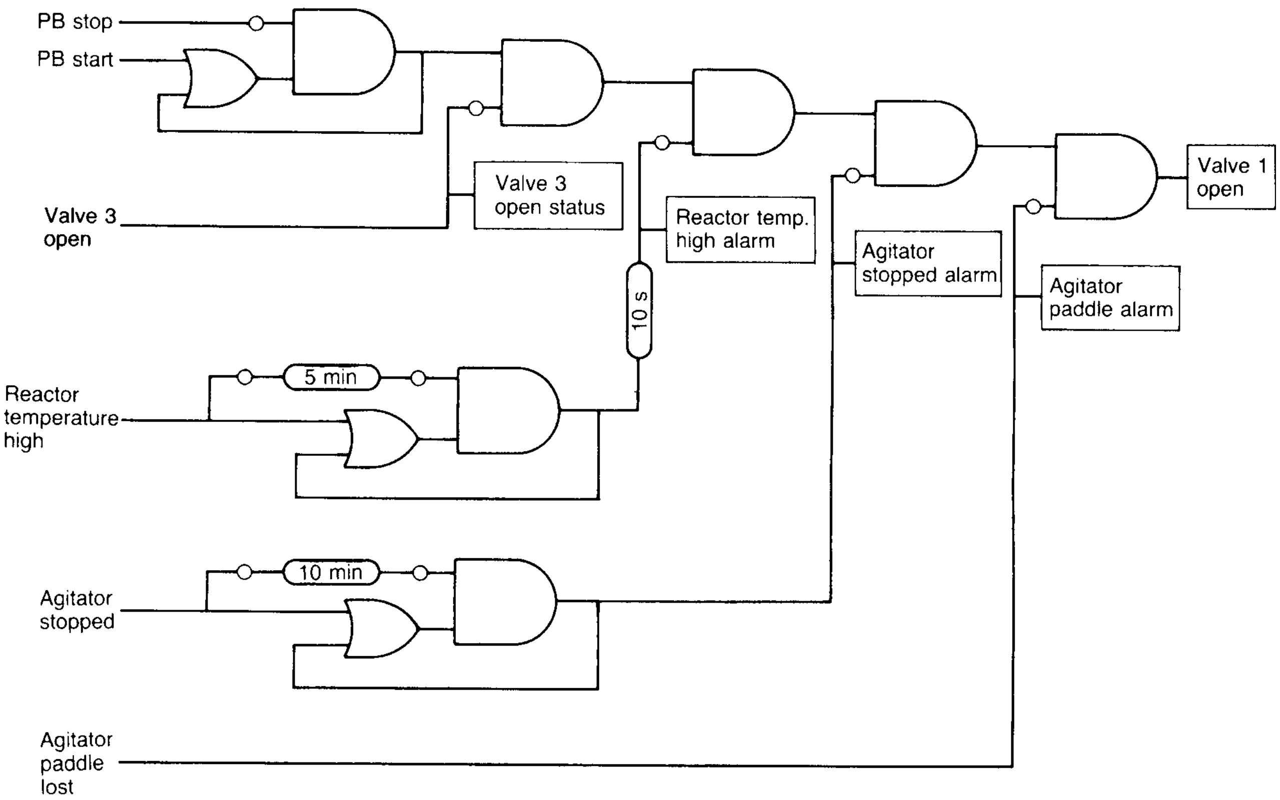

Figure 13.21 *Batch reader interlock system logic diagram*

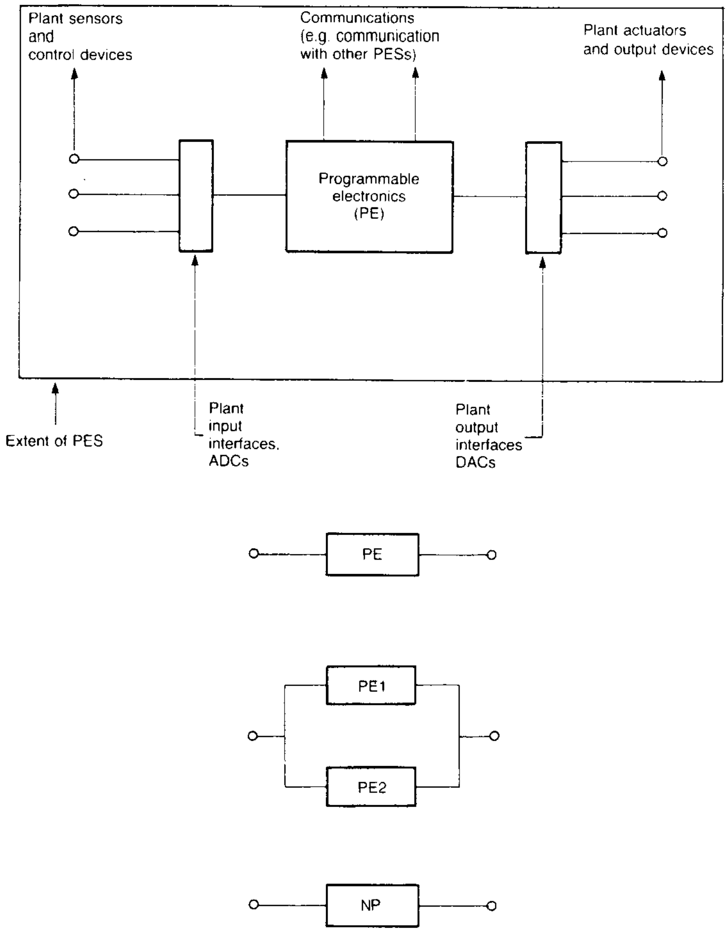

Figure 13.22 *A programmable electronic system (HSE, 1987b). ADC, analogue-to-digital converter; DAC, digital-to-analogue converter; NP, non-programmable hardware; PE, programmable electronics (Courtesy of HM Stationery Office)*

Observance of the second principle may require that, in addition to the single channel of PE hardware, there should be at least one additional means of achieving the required level of safety integrity. Three such means might be:

(1) additional non-programmable hardware;
(2) additional programmable hardware of diverse design;
(3) additional PE hardware of same design.

The latter is applicable only where the design is well established and there is a record of reliable operation in an environment similar to that under consideration.

Observance of the third principle may require that where a single design of software is used, there should be an additional means of achieving safety integrity. Such means may be:

(1) additional software of diverse design;
(2) additional non-programmable hardware.

Diversity of software is required only where:

(1) PES safety-related systems are the sole means of achieving the required level of safety integrity;
(2) faults in the software of a single channel of PE might cause a dangerous mode of failure of the total configuration of safety-related systems.

This strategy is intended to protect against systematic failures and, in particular (a) software errors in the embedded or applications software; (b) differences in the detailed operation of microprocessor and other large-scale integrated circuits from that specified; (c) incompatibility between original and replacement hardware modules and (d) incompatibility of updated or replacement embedded software with original software or hardware.

The extent to which it is necessary to have diversity of software depends on the application. As a minimum, the safety-related function should use diverse applications software. For higher reliability it may be necessary to consider also diverse embedded software. The safety requirements specification is necessarily a common feature of the diverse software implementations. It is therefore important that it be correct.

PES 2 recognizes that there may exist other ways of providing against failure. In some applications it may be possible to achieve the required level of safety integrity by adopting a formal approach to the software design and testing. Furthermore, for situations where a relatively low level of reliability is acceptable, the use of a single PE channel may be acceptable provided there is extensive self-monitoring of the hardware and automatic safety action on detection of failure.

13.12.3 Reliability

The governing principle for reliability of the hardware is that the overall failure rate in a dangerous mode of failure, or, for a protection system, the probability of failure to operate on demand, should meet the standard of conventional safety integrity. PES 2 specifies three means of meeting this criterion:

(1) a qualitative appraisal of the safety-related systems, using engineering judgement;
(2) a quantified assessment of the safety-related systems;
(3) a quantified assessment of the safety of the plant.

Essentially, the level of reliability should be governed by the conventional safety integrity principle. Where the acceptable level of reliability is relatively low, the first method may suffice, but where a higher reliability is required, the second and third methods will be appropriate.

13.12.4 Overall quality

Whilst the foregoing measures concerning configuration and reliability are a necessary framework, they are not in themselves sufficient. In particular, systematic errors creep in due to deficiencies in features such as the safety requirements specification and software faults. They need, therefore, to be supplemented by the third system element, overall quality. Overall quality is concerned essentially with high quality procedures and engineering. These should cover the quality of the specification, design, construction, testing, commissioning, operation, maintenance and modification of the hardware and software.

In determining the level of overall quality to be aimed for, regard should be paid to the level which would be appropriate for conventional safety integrity and to the level determined for the system elements of configuration and reliability. As a minimum, attention should be paid to (1) the quality of manufacture and (2) the quality of implementation. For overall quality to match a higher level of reliability (3) each procedural and engineering aspect should be reviewed.

Qualitative assessment checklists in support of such a review are included in PES 2 in Appendix 7. Three sets of checklists are given for (1) a control computer, (2) PLC and (3) CCF. The headings of these checklists are (1) safety requirements specification, (2) hardware specification, (3) hardware design, (4) hardware manufacture, (5) hardware test, (6) installation, (7) system test, (8) operations, (9) hardware maintenance and modification, (10) software specification, (11) software design, (12) software coding, (13) software test, (14) embedded software, (15) application programming and (16) software maintenance and modification. The applicable headings are: for a control computer, all except (14)–(15); for a PLC, all except (10)–(13); and for CCF, all.

13.12.5 Design considerations

PES 2 describes a number of design considerations which are particularly relevant to the safety integrity of PESs. The replacement of a control chain in which the sensor sends a signal directly to the actuator by one which involves analogue-to-digital (A/D) converters and PEs may reduce the safety integrity. Unless there is a positive contribution to safety by doing otherwise, the direct route between sensor and actuator should normally be retained. An additional signal may be taken from the sensor with suitable isolation to the PEs.

For the execution of safety functions, it may be necessary to have a shorter sampling interval than is required for normal measurement and control functions.

There should be hardware or software to ensure that on switch-on or on restart after a power failure, the resetting of the system is complete and the point in the program at which entry occurs is a safe one. Interruptions of the power supply should be catered for and should not lead to unidentified or unsafe conditions.

As far as practicable, safety critical functions should be automatically monitored or should be self-checking. The emergency ESD systems should be proof checked at appropriate intervals to discover unrevealed failures.

PES 2 also gives detailed guidance on the environmental aspects of PESs, particularly in respect of electrical interference and of electrostatic sensitive devices.

13.12.6 Software considerations

The software for use in safety-related applications needs to be of high quality and PES 2 gives an account of some of the measures which may be taken to achieve this. These include:

(1) safety requirement specification;
(2) software specification;
(3) software design, coding and test;
(4) system test.

They also include:

(5) software modification procedures.

For all these aspects, there should be

(6) Formal documentation.

PES 2 puts considerable emphasis on the safety requirements specification, as already described. It also devotes a good deal of space to the control of software changes.

A further account of software reliability is given in Section 13.13.

13.12.7 Illustrative example

PES 2 gives as an illustrative example part of the safety integrity assessment of a plant for the manufacture of the explosive pentaerythritol tetranitrate (PETN). Figure 13.23 shows a schematic diagram of one of the nitrators.

A particularly critical parameter is high temperature in the nitrator, the limit being 35°C. For this, protection is provided in the form of a dump valve, which opens to dump the reactor contents to a drowning tank. The conventional control and protection system for such a plant is a control system incorporating some protection features and a single dedicated protection system.

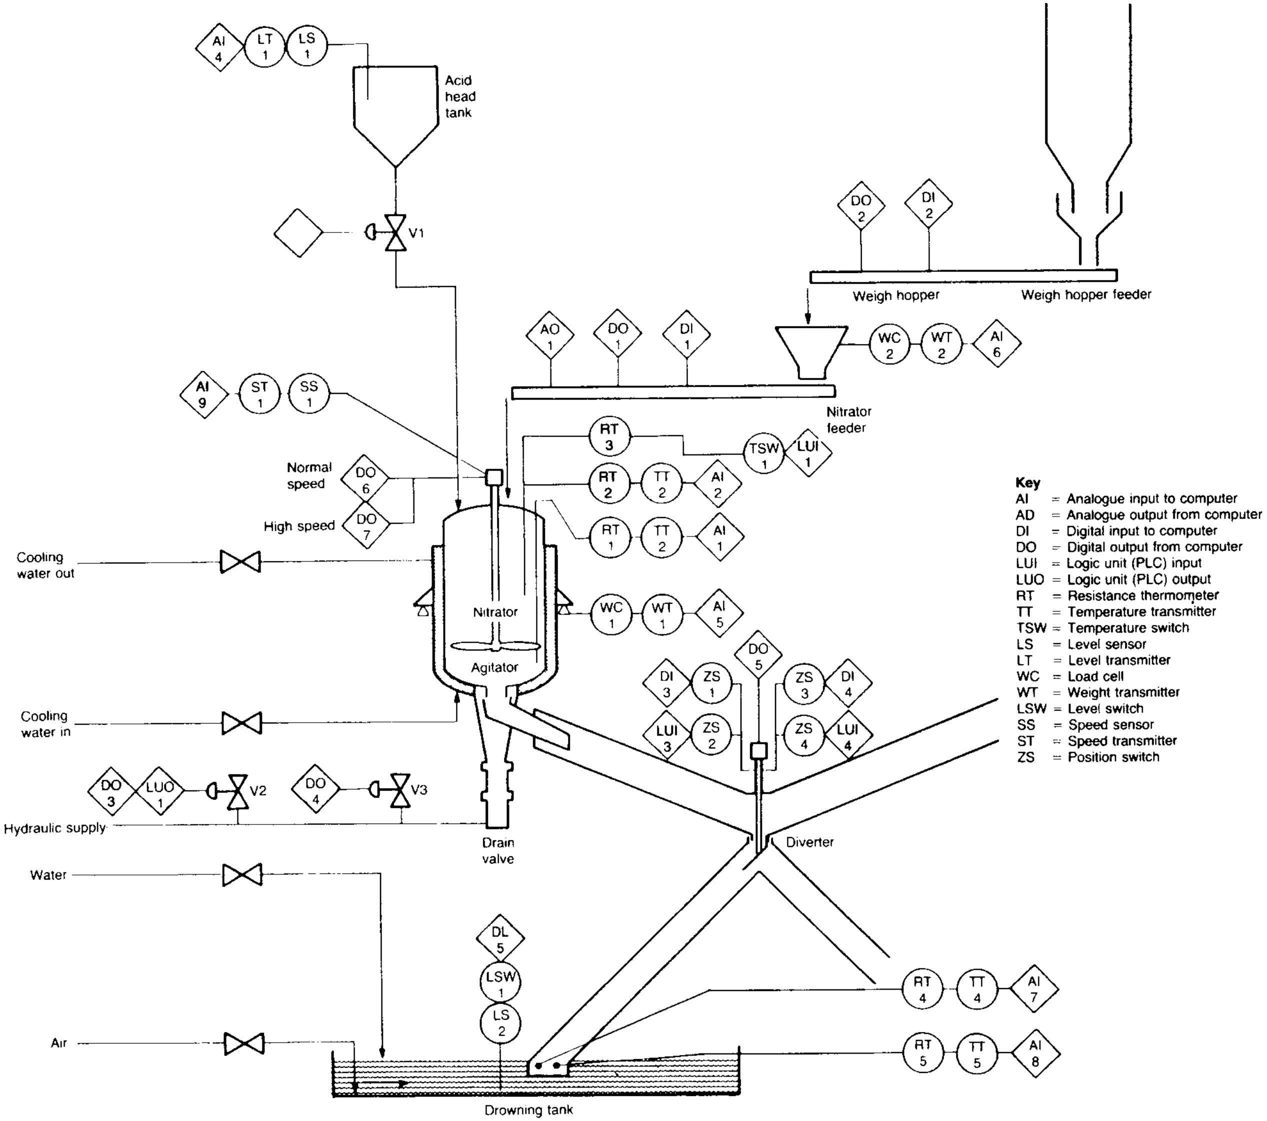

Figure 13.23 *A nitrator unit under control of a PSE (HSE, 1987b) (Courtesy of HM Stationery Office)*

In the design considered, the plant is controlled by a control computer which performs the basic control of the operating sequence. At each stage of the sequence the computer performs checks to ensure that the previous stage is complete and that the plant is in the correct state and ready to proceed to the next stage.

On each of the critical parameters there are duplicate sensors. The signal from one sensor goes to the computer and that from the other to a PLC. The computer and the PLC operate their own relays in the appropriate interlock system. An attempt by the computer to take an action is inhibited if: (1) the PLC relay contact is not closed in agreement with the computer; or (2) the combination of permissives being sent to the computer is correct but indicates that the action is to be inhibited; or (3) the combination of permissives being sent to the computer is incompatible with the inputs to the PLC. The latter occurrence is assessed by the computer. Thus, the control of critical parameters and sequences is by the computer monitored by the PLC, which is in turn monitored by the computer.

For the critical parameter of high temperature in the nitrator, the computer and PLC act in effect as a 1/2 protective system. If either detects a high temperature, it acts to open the dump valve on the reactor.

A hazard analysis of the nitrator system was performed and a fault tree developed for the top event 'Decomposition', as shown in Figure 13.24(a). This event occurs if there is a demand in the form of high temperature and a failure of the top level of protection ('protection fails'). The guide includes the further fault trees for the events C1–C4 and B4–B8.

Figure 13.24(b) shows one of these constituent fault trees, subtree B5 for the event 'no dump signal'. This has several interesting features. The top event in the subtree will occur if both the computer and the PLC fail to send a trip signal. Among the causes for the computer failing to send this trip signal are various combinations of instrument failure, including CCF of all the instruments in one group, for example, resistance thermometers RT1 and RT2. In the tree the failures of RT1 and RT2 are regular random failures, whilst the failure 'CCF of RTs' is the CCF for this group. The separation of the CCF in this way both highlights it as a specific event and assists in assigning to it a numerical value.

Other CCFs occur higher up the subtree just beneath the top event. These are the CCFs of: (1) all three resistance thermometers, RT1 and RT2 on the computer and RTS on the PLC; (2) the hydraulic valves and (3) both the computer and the PLC.

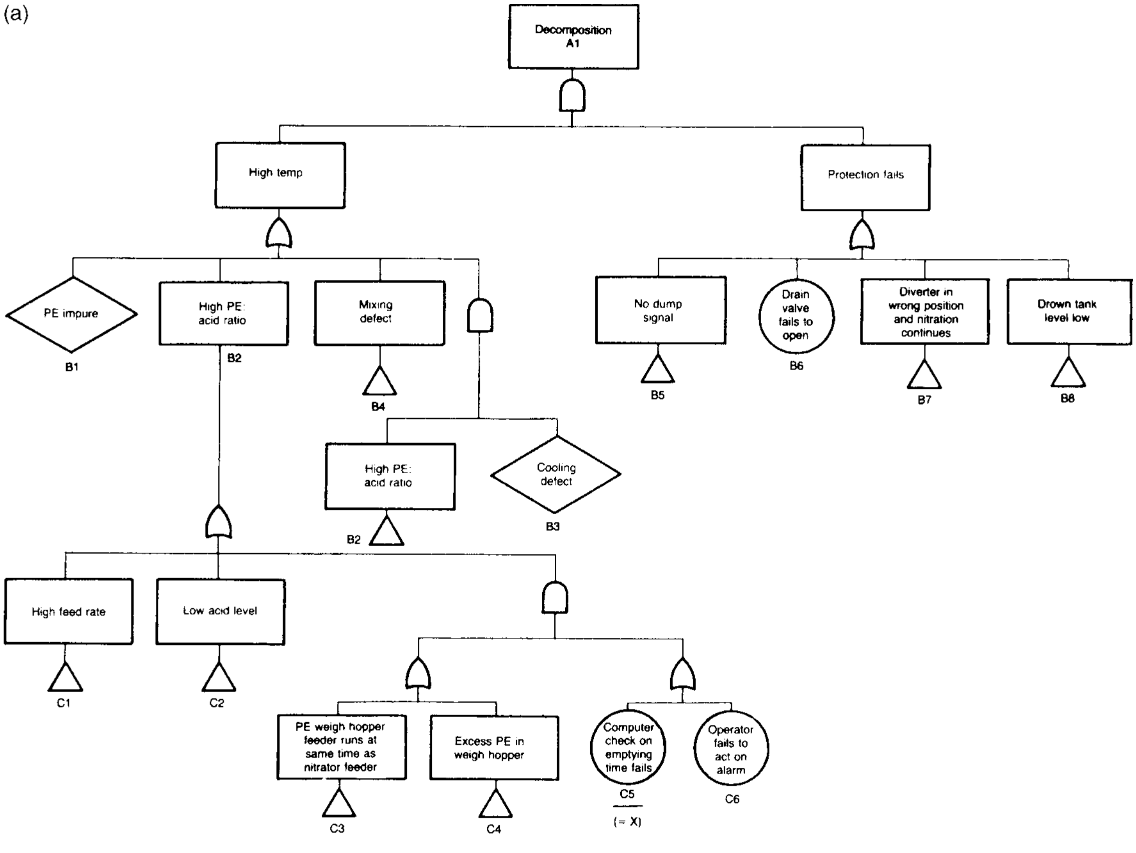

Figure 13.24 *continued*

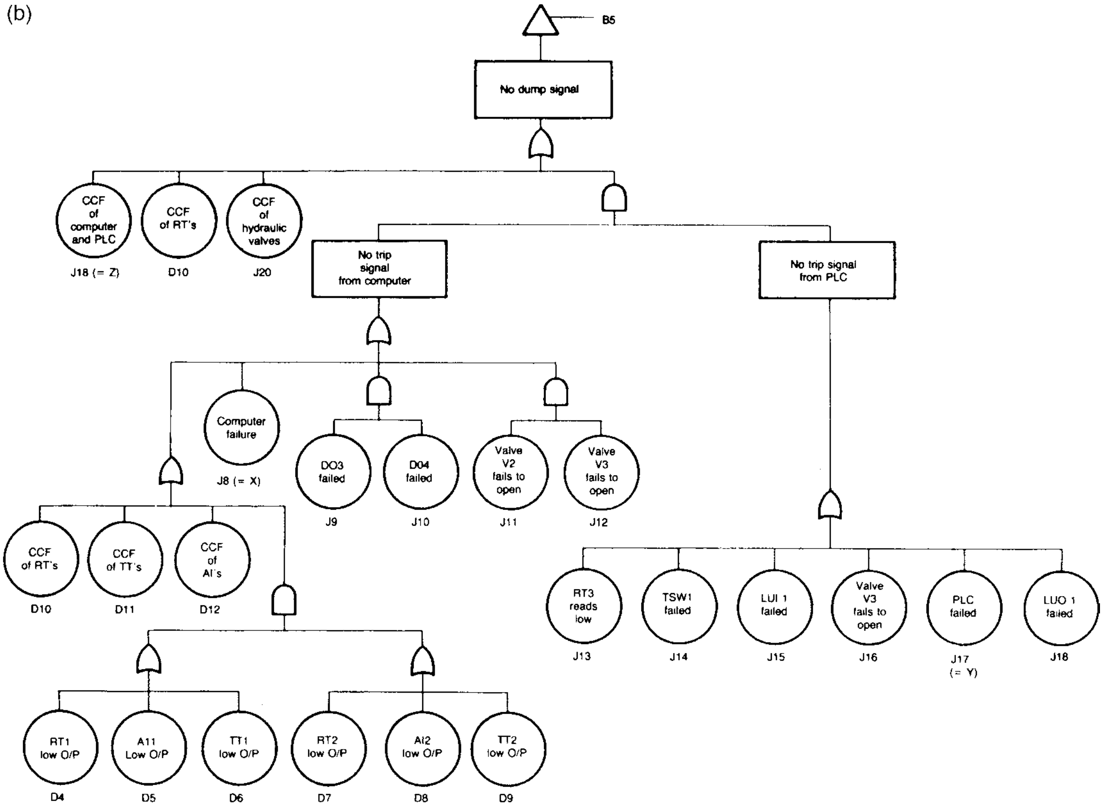

Figure 13.24 *Sections of fault tree for the top event 'Decomposition' for the nitrator unit shown in Figure 13.23 (HSE, 1987b): (a) top section of fault tree; and (b) subtree for event B5 (Courtesy of HM Stationary Office)*

A safety integrity analysis of the system is given in which each of the three system elements (configuration, reliability and overall quality) are examined. For configuration, a check is made against each of the three principles given in Section 13.12.2. In respect of criterion 1, the combined number of PES and non-PES systems is two, as in the conventional system, so this criterion is met. For criterion 2, failure of no single channel, computer or PLC, will cause loss of protection, so criterion 2 is met. For criterion 3, failure of no single set of software, on the computer or on the PLC, will cause loss of protection, so criterion 3 is met.

For reliability, the fault tree is analysed to produce the cutsets and it is shown that the Boolean relation for the top event A1 is:

$$\begin{aligned}\mathrm{A1} = {} & \mathrm{D10} + \mathrm{Z} + \mathrm{X}(\mathrm{B6} + \mathrm{J13} + \mathrm{J14} + \mathrm{J15} + \mathrm{J16} + \mathrm{J18} + \mathrm{J20} \\ & + \mathrm{L1} + \mathrm{L2} + \mathrm{Y}) + \mathrm{Y}(\mathrm{D11} + \mathrm{D12}) + (\mathrm{B1} + \mathrm{D1} + \mathrm{D2} \\ & + \mathrm{D11} + \mathrm{D12} + \mathrm{HI} + \mathrm{H2})(\mathrm{J20} + \mathrm{B6})\end{aligned} \qquad [13.21.1]$$

The frequency of the top event A1 was then estimated by applying data on the frequency of failures and, for protective features, by utilizing Equation 13.9.18 with data on proof test intervals. Table 13.27 shows the numerical values obtained for the events given in Equation 13.12.1. The frequency of the top event was found to be 8.8×10^{-4}/year. This was based on a number of pessimistic assumptions and on this basis was deemed an acceptable frequency.

For overall quality, it was considered necessary to examine not only the quality of manufacture and implementation, but also the procedures and engineering. For this the checklists given in appendix 7 of PES 2 were used and the results obtained for each item in this example are shown in that appendix. This check led to consideration of the following modifications: (1) addition of software limits on programmable alarm and trip levels; and (2) provision of test signal injection and monitoring points, particularly on the resistance thermometers measuring high temperature in the nitrator.

13.13 Software Engineering

The use of various types of computer aid in process plant design and operation is now routine. The dependability of these aids is determined by the quality of the computer programs. The dependability of this software is therefore important and may be critical. This is especially the case in real-time, on-line computer-based systems.

The dependability of software, particularly in SCS, is a major topic in software engineering and is beyond the scope of this book. However, it cannot be neglected, and

Table 13.27 *Some results obtained in the estimation of the hazard rate of the nitrator shown in Figure 13.23 (HSE, 1987b) (Courtesy of HM Stationery Office)*

Event reference	*Event description*	*Failure rate* (failures/10^6 h)	*Test interval*	*Probability of failure on demand*
D10	Common cause failure of resistance thermometers RT1, RT2 and RT3 giving low output	0.06

B1	PE impure	Not quantified		
D1	Feeder fails at high speed	2.6		
D2	Control computer analogue output A01 fails to high O/P	1.0		
D11	Common cause failure of temperature transmitters TT1, TT2	0.06		
D12	Common cause failure of control computer analogue inputs A11, A12	0.03		
H1	Hydraulic failure of agitator causing high speed	Negligible		
H2	Stirrer breaks from shaft	Negligible		
Σ_3		3.7		
J20	Common cause failure of hydraulic valves V2 and V3	2.3×10^{-6}		
B6	Drain valve fails to open	3.8×10^{-4}		
Σ_4		3.8×10^{-4}		
$\Sigma_3 \cdot \Sigma_4$		1.4×10^{-3}		
Total	$(D10 + Z + X\Sigma_1 + Y\Sigma_2 + \Sigma_3\Sigma_4)$	0.1		

therefore a brief description is given of some of the principal issues of which engineers in the process industries should be aware.

Accounts of software engineering and software reliability are given in *Software Engineering* (Bauer, 1975a), *Software Reliability, Principles and Practice* (Meyers, 1976), *Quality Assurance for Computer Software* (Dunn and Ullman, 1982), *Program Verification Using ADA* (McGettrick, 1982), *Software Engineering* (Shooman, 1983), *Software Defect Removal* (Dunn, 1984), *Program Construction and Verification* (Backhouse, 1986), *Systematic Software Development Using VDM* (C.B. Jones, 1986), *The Spine of Software: Designing Probably Correct Software – Theory and Practice* (Baber, 1987), *Achieving Safety and Reliability with Computer Systems* (Daniels, 1987), *The Craft of Software Engineering* (Macro and Buxton, 1987), *Software Reliability* (Littlewood, 1987b), *Software Reliability* (Musa *et al.*, 1987), *Handbook of Software Quality Assurance* (Schulmeyer and MacManus, 1987), *Software Diversity in Computerised Control Systems* (Voges, 1987), *Managing the Software Process* (Humphrey, 1989), *High Integrity Software* (Sennett, 1989), *Software Engineering* (Somerville, 1989), *Case Studies in Systematic Software Development* (C.B. Jones and Shaw, 1990), *Deriving Programs from Specifications* (C. Morgan, 1990), *Software Quality and Reliability* (Ince, 1991a), *Software Engineers Reference Book* (McDermid, 1991), *Developing Safety Systems: A Guide Using ADA* (Pyle, 1991), *Reliability in Instrumentation and Control* (Cluley, 1993) and *Safety Aspects of Computer Control* (P. Bennett, 1993).

13.13.1 Software dependability

The software provided should be dependable in serving the purposes of the system. The dependability of the software has two aspects: (1) specification and (2) reliability. The requirements of the system need to be defined and then converted into a specification. Both the formulation of the requirements and the conversion into a specification are critical features. It is then necessary to ensure that the software conforms with the specification to a high degree of reliability. One of the recurring themes in discussions of software dependability is that reliability alone is not enough. If the specification is defective, the software will be so too, however high its reliability.

13.13.2 Some software problems

There are some persistent problems associated with software. A review of these problems by Bauer (1975b) gives the following tendencies: (1) software is produced in a relatively amateurish and undisciplined way, (2) it is developed in the research environment by tinkering or in industry by a human wave approach, (3) it is unreliable and needs permanent maintenance, (4) it is messy, opaque and difficult to modify or extend and (5) it arrives later, costs more and performs less well than expected.

13.13.3 Software error rates

There are a number of rules-of-thumb used in the software industry for the error rates which occur in programming. An account is given by Cluley (1993). For software, an important distinction is that made between a fault and failure. A fault is an error in the program. A failure occurs when the program is run and produces an incorrect result for software reasons. It is a common occurrence that a program which contains a fault may be run many times before a failure occurs.

A rule-of-thumb widely used in the industry is that a program typically contains 1 fault per 1000 instructions. This is supported by data given by Musa *et al.* (1987) to the effect shown that for programs of some 100,000 lines of source code, when, first operational, the incidence of faults varies between 1.4 and 3.9 faults per 1000 lines. For programs when first written, the number of faults is much higher.

Faults may be corrected, but correction is not always straightforward and the potential exists to introduce other faults. The data of Musa *et al.* indicate that between 1 and 6 new faults are introduced for every 100 faults corrected.

Musa *et al.* also quote data for the number of failures per fault for a single run of a program. The average value of this ratio is 4.2×10^{-7} failures/fault. In other words, this implies that in order to detect a fault by triggering a failure, it is necessary on average to run a program 2.4×10^{-6} times.

In real-time applications of SCS, another metric of concern is the failure intensity, or frequency of failure per unit time, or per mission. For passenger aircraft, an error rate used has been 10^{-9} per mission, where the mission is a flight of 1–10 h.

The progress of a debugging task may be monitored by 'seeding' the program with deliberate errors which are not known to the team engaged in the work. Thus, if 35 faults have been introduced deliberately and 25 genuine and 7 deliberate faults are found, the estimated number of original faults is 125 ($= 25 \times 35/7$).

There exist reliability growth models for software which may be used by management to estimate the time necessary to debug a program. One such model is described by Cluley.

13.13.4 Software management

Management commitment is crucial in achieving dependability in software, as in other fields. Management needs to create a culture which gives priority to, and so ensures, dependability of the software. The management of a software project includes the following aspects:

(1) project management;
(2) software quality assurance (QA);
(3) software standards;
(4) system requirements and software specifications;
(5) software development;
(6) software documentation;
(7) software verification;
(8) software modification control;
(9) software validation and testing;
(10) software maintenance.

Accounts of project management are given by Tsichritzis (1975a) and P.A.V. Hall (1991). The other aspects are considered below.

13.13.5 Software quality assurance

There should by a system of QA for the software. The extent of this system will depend on the scale of the operation, and in some cases will be governed by standards and/or user requirements, but as a minimum, there should be a formal system and an independent QA function. Some of the methods of assuring quality are described below.

13.13.6 Software standards

Use has long been made in software development of the traditional quality standards such as BS 5750 and ISO 9000, but there are an increasing number of standards specific to software. Accounts of developments in these standards are given by P. Bennett (1991a), the CCPS (1993/14) and Rata (1993). In the United Kingdom, standards and guidance include: BS 5887: 1980 *Code of Practice for Testing of Computer-Based Systems*, BS 6238: 1982 *Code of Practice for Performance Monitoring of Computer-based Systems*, BS 5515: 1984 *Code of Practice for Documentation of Computer-based Systems and* BS 6719: 1986 *Guide to Specifying User Requirements for a Computer-based Systems; Programmable Electronic Systems in Safety Related Applications* (HSE, 1987b) (the HSE *PES Guide*); the Ministry of Defence (MoD) Interim Defence Standards 0055: 1989 *Requirements for the Procurement of Safety Critical Software in Defence Equipment* (MoD, 1989c) and 0056: 1989 *Requirements for the Analysis of Safety Critical Hazards* (MoD, 1989b).

Relevant US standards are IEEE 1058-1987 *Software Project Management Plans*, IEEE 1012-1987 *Software Verification and Validation Plans*, IEEE 1028-1988 *Software Reviews and Audits*, IEEE 730-1989 *Software Quality Assurance Plans* and IEEE 1063-1989 *Software User Documentation*, as well as the guides IEEE 830-1984 *Guide to Software Requirement Specifications* and IEEE 1042-1987 *Guide to Software Configuration Management*. An international standard is IEC SC65A WG9: 1991 *Software for Computers in the Application of Industrial Safety-related Systems*.

The *PES Guide* has been described in Section 13.12.

MOD 0055 is in three main sections. The first deals with the project management, the parties involved and the documentation; the second with the software engineering; and the third relates the requirements of these two sections to the life cycle of the project.

MOD 0056 gives requirements for the hazard analysis of SCS.

There are also two IEC working groups, WG9 and WG1O, which deal with software for safety-related applications and with generic safety aspects, respectively. WG9 is responsible for IEC SG65A.

13.13.7 Software development

The process of software development is generally described broadly in the following terms:

(1) requirements specification;
(2) system specification;
(3) program specification;
(4) program design;
(5) program production;
(6) program verification;
(7) program validation and testing;
(8) system integration and testing.

In software development, two terms that are widely used are 'Verification' and 'Validation' (V&V). Verification is the process of determining whether the product of a given phase of development meets the requirements established in the previous phase. Validation is the process of evaluating software at the end of the software development process to ensure compliance with software requirements.

It is good practice to verify the software produced in each phase of the project before proceeding to the next phase. Another aspect of good practice is the production of good documentation.

One method of software development which is found useful in many cases is prototyping. There is more than one kind of prototype. An account of prototyping is given by Ince (1991b).

13.13.8 Software specification

The conversion of the user's requirements into an unambiguous specification for the system and then for the software is one of the most important, but difficult, tasks in software development. There is a high degree of formality in the approach taken to the specification of the software and a number of formal methods have been developed. An account is given by Webb (1991). Use is made of mathematically based languages such as VDM, Z and OBT and of mathematically based methodologies such as JSD, EPOS and Yourdan Structural Development. For many SCS, such formal methods are a requirement

13.13.9 Software design, production and verification

There are a number of basic principles governing software design. They include (1) modularity and (2) hierarchy.

The computer program required for even a moderately sized project may be large. A large program needs to be subdivided into manageable parts, or modules. Whilst subdivision into modules is necessary, problems arise if the interfaces between modules are poorly defined. The specification of the interfaces between modules requires careful attention. In some applications, it may be possible to exploit the use of verified modules and of a module library.

The program will generally have a hierarchical structure, with the higher level modules controlling the lower level ones. Structured programming involves the use of a hierarchy of conceptual layers and provides a formal approach to the creation of hierarchical software.

As already mentioned, verification of the programs produced at each phase should not be relegated until the end but should be performed before proceeding to the next phase.

13.13.10 Software modification control

A major software project will generally be subject to modifications. Demands to make modifications may occur at any level, starting with the system requirements. There should be a system for the control of such modifications. The ease with which such a system can be created and operated depends very much on the quality of the software design and documentation.

13.13.11 Software reliability

The point has already been made that 'software reliability' is not the same as 'software dependability'. It is nevertheless an essential feature. Accounts of software reliability are given in the quoted texts and by Tsichritzis (1975b). Some aspects of software reliability are:

(1) programming language;
(2) programming practice;
(3) software design;
(4) measurement of reliability;
(5) assessment of reliability.

The programming language used can influence the reliability of the software produced. A number of examples of differences between languages in this respect are given by Tsichritzis.

Likewise, the programming style can affect reliability. One aspect is the naming of items. It is usually recommended that semantic naming be practised in which the name is a meaningful one. Another aspect is the length of sections of the program. Here the recommendation is to keep the verification length short. A practice which tends to increase the verification length is the use of GO TO statements.

One aspect of good design practice which contributes to software reliability is a strong structure. Another is transparency of the programs. A third is well-defined interfaces between modules.

In principle, improvement of reliability depends on the ability to measure it. Traditionally, metrics have been concerned primarily with aspects of performance such as execution time rather than with reliability. Measures for reliability are discussed by Tsichritzis. Software protection contributes to reliability by providing barriers to the transmission of errors between different features of the system.

13.13.12 Software testing and debugging

The traditional way of dealing with errors in a program is testing and debugging. An account of this aspect is given by Poole (1975). Debugging and testing are greatly facilitated if they are planned for in the design phase. Another feature which can make a major contribution is documentation written with this requirement in mind.

Debugging tends to be a difficult task and various aids are available. One is the system dump, activated by a call in, or by catastrophic failure of, the program. Another is the snapshot, similar to a dump, but occurring during execution. The trace mode of program execution causes an output to be made for each statement in the section traced. The traceback facility shows how control reached the point in the program where the error has occurred.

It is helpful to debugging if key quantities in the program are made parameters which the user can alter. This permits a fuller exploration of the program characteristics. Debugging is also assisted by the incorporation of debugging code in the program. The use of such code is discussed by Poole.

Testing is assisted by subdivision of the program into modules. It is not, however, a straightforward matter to devise test beds and test strategies for modules.

13.13.13 Software protection

Software protection may be regarded as an aspect of software reliability. The aim of software protection is to guard against error and malice. There are a variety of items, such as files and programs, which need to be protected and a corresponding variety of means of achieving protection.

Protection establishes barriers to the transmission of an error between one part of the system and another. It therefore contributes to reliability by limiting the effect of an error. Protection contributes to reliability in another way. The occurrence of an error usually results in an attempt to violate a protection barrier. This can be used as a means of error detection.

Closely related to software protection is software security. The aim of software security is to guard against unauthorized use.

13.13.14 Software assessment

There are a number of methods available for the assessment of the software reliability. Accounts of these techniques are given in the texts mentioned and by Tsichritzis (1975b), Fergus *et al.* (1991), Webb (1991) and M.R. Woodward (1991). Three main approaches are:

(1) auditing;
(2) static analysis;
(3) dynamic analysis.

Auditing particularly addresses aspects such as the QA and standards, the comprehensibility and readability of the program, and the documentation.

Static analysis involves analysing the program without running it. Some methods which may be used include:

(1) semantic checking;
(2) control flow analysis;
(3) data use analysis;
(4) information flow analysis;
(5) semantic analysis;
(6) compliance analysis.

The program compiler is generally utilized to perform checks on statements in the program, or semantic checks. The power of this facility depends on the programming language used.

The control flow of the program may be analysed to reveal its structure and to detect undesirable features such as multiple starts, multiple ends, unreachable code, etc. One method of doing this is to represent the program as a graph of nodes joined by arcs, where initially each node represents a statement. A process of reduction is then applied whereby nodes are successively eliminated to reveal the underlying structure.

The data use of the program may be analysed to identify incorrect uses of data such as attempts to read data which are not available or failure to utilize data which have been generated.

The information flow in the program may be analysed to identify the dependence of output variables on input variables.

Semantic analysis determines the mathematical relationship between the input and output variables for each semantically feasible path. It can be used to determine the outputs for the whole input space, including unexpected inputs.

Compliance analysis compares the program with the specification and reveals discrepancies. The specification is expressed as a statement in the predicate calculus of the pre-conditions and post-conditions to be satisfied by the program. For a complex program, assertions may be provided about the functionality of the program for intermediate stages.

Use may also be made of diagrams showing the logic of the program, such as fault trees, event trees, Petri nets, and state transition diagrams, as described by P. Bennett (1991a). The application of fault tree analysis to programs has been developed by Leveson and co-workers (Leveson and Harvey, 1983; Leveson and Stolzy, 1983). Figure 13.25 shows the analysis of an IF . . . THEN . . . ELSE statement by fault tree, Petri net and event tree methods.

Fault trees and event trees are described in Chapter 9, but the Petri net representation requires brief explanation. A Peiri net consists of the quintuple C:

$$C = (P, T, I, O, u) \qquad [13.13.1]$$

where P is a place, T a transition, I an input, O an output and u an initial condition. Initialization of a Petri net is called 'marking' it. A transition is said to 'fire'. Assigning a value is referred to as 'passing' a 'token' to a place.

Software tools have been developed to assist in the static analysis of software. Some of the tools available are described by Fergus *et al.* (1991). They include MALPAS, SPADE and the LDRA testbed. An account of MALPAS, which includes control flow, data use, information flow, semantic and compliance analysers, is given by Webb (1991).

Dynamic analysis, or testing, involves running the program and analysing the results. The basic technique is to force situations where errors are revealed. There are two main approaches. One is 'black box' testing and the other 'white box' testing. The distinction is that the latter relies on knowledge of the structure of the program, whilst the former has no such knowledge but tests the performance against the requirements and relies essentially on knowledge of the application domain. Dynamic testing may be control flow or data flow driven. A discussion is given by M.R. Woodward (1991).

One aim of testing is to remove whole classes of error. A technique for doing this is mutation testing. An account is given by Woodward. The basic concept is to make a small change to the program in the expectation that this will make an observable difference in its performance.

It should be appreciated that good results from a validation test do not necessarily indicate high reliability.

This is so only if the exercise of the control path in the validation test corresponds to that which will occur in practice.

The level of assessment should be matched to the application. This aspect is discussed by P. Bennett (1991a). He lists five classes of assessment:

0 System overview.
1 System structure analysis.
2 System hazard analysis.
3 Rigorous analysis.
4 Formal mathematical methods.

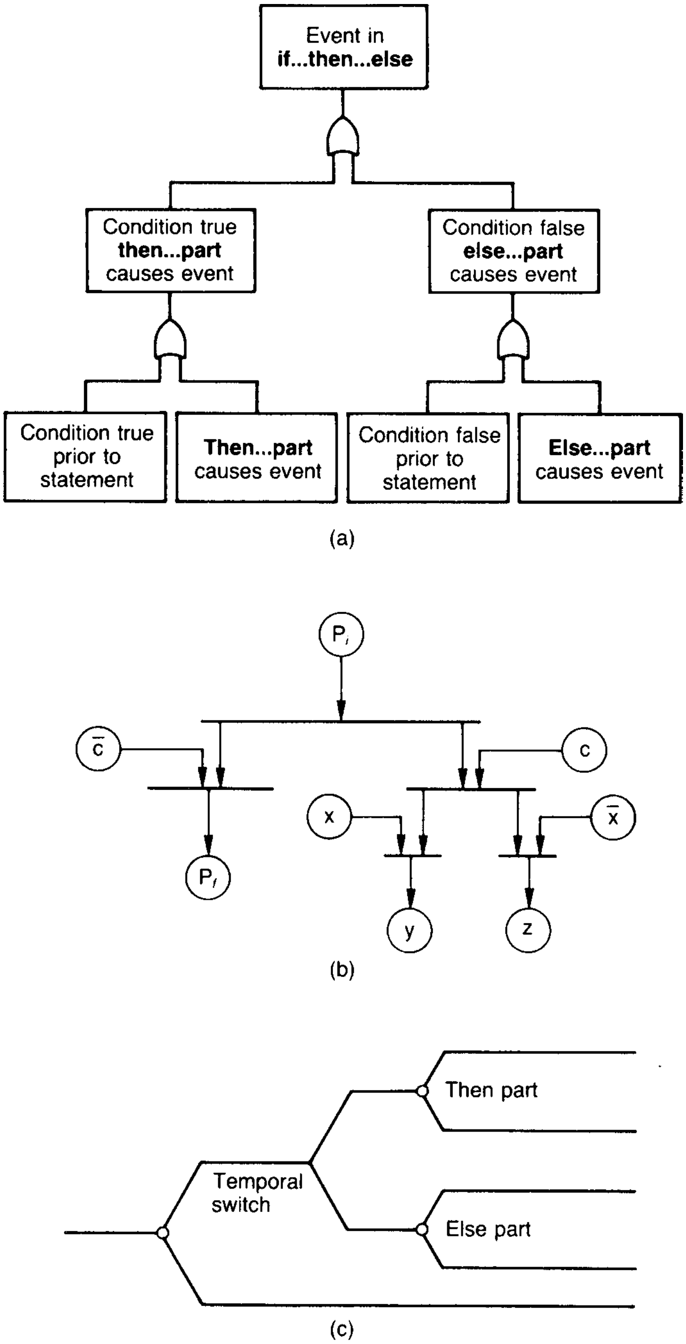

Figure 13.25 *Some representations used in error analysis of an IF… THEN… ELSE statement in a computer program (after P. Bennett, 1991a): (a) fault tree; (b) Petri net and (c) event tree (Courtesy of Butterworth-Heinemann)*

13.13.15 Software correctness

The use of formal methods to prove the correctness of the program has already been mentioned. This is a major area of research. There are differing views as to the feasibility of such proof.

The methods used to prove correctness may be informal or formal. The informal method derives from the work of Naur (1966), Floyd (1967) and London (1968), following von Neumann. Points are selected on all the control paths at which assertions can be made about the variables. Then if

A is an assertion at one point in a control path and B an assertion at the following point, the approach taken is to prove that the code is such that if A is true, B is true. If this verification is performed for all adjacent pairs of assertions and for all control paths, the partial correctness of the program is proved. Proof of complete correctness requires a separate proof of halting. It tends to be a substantial task, however, to develop the assertions and to perform the proofs.

The formal method of proving correctness is based on the demonstration by Floyd (1967) that proof of partial correctness is equivalent to proving corresponding theorems in the first order-predicate calculus. Manna and Pnueli (1969) extended such proof to include halting. The approach taken is to formulate the problem so that it is possible to apply automatic theorem-proving techniques.

13.13.16 Software maintenance

Software generally requires a good deal of maintenance. This is particularly true of safety-related software, especially real-time software. The project management should make suitable provisions for software maintenance. The quality of the software, and the associated documentation, largely determines the ease of maintenance.

13.13.17 Software for real-time systems

Real-time, on-line systems controlling process plants place even more stringent demands on software. An account of the software aspects is given by Fergus *et al.* (1991).

The characteristics of real-time systems have been described by Quirk (1985). In such systems the demands are driven in timing and sequencing by the real world, they may occur in parallel and they may be unexpected and even conflicting. The software must satisfy time constraints and it must continue to operate. Moreover, the software is part of a total system and is difficult to validate in isolation.

Work on the methods of describing the behaviour of real-time systems typically deals with issues such as concurrency and synchronization, resource scheduling, and liveness and deadlock.

The dynamic testing of a real-time program may be carried out using an off-line host machine. Such testing is described by Fergus *et al.*

13.13.18 Safety critical systems

If the consequences of failure of a real-time computer system are sufficiently serious, the system is a SCS. SCSs are of particular concern in the military, aerospace and nuclear fields, but are of growing importance in the process industries.

SCSs are treated in *Safety Aspects of Computer Control* (P. Bennett, 1993). Other accounts are given in the texts cited at the start of this section and by P. Bennett (1991a,b), Bologna (1993), Ehrenberger (1993), Malcolm (1993), McDermid (1993) and Pyle (1993). Standards are particularly important for SCSs. Some relevant standards and guidance are detailed in Section 13.13.6. Practical guidance is available in the *HSE PES Guidelines* and the *CCPS Safe Automation Guidelines*, described in Sections 13.12 and 13.15, respectively.

There are a number of real-time languages and environments which have special safety-related features. One such is ADA. Accounts are given in *Program Verification Using ADA* (McGettrick 1982), *ADA for Specification and Design* (Goldsack, 1985), *ADA in Industry* (Heilbrunner, 1988) *and Developing Safety Systems: A Guide Using ADA* (Pyle, 1991). Pyle (1993) discusses the guidance given in the *HES PSE Guide* in the context of ADA.

Where the process is dependent on a computer or PES, methods are required to identify the associated hazards. The application of hazop to process computers (chazop) is described in Chapter 8.

13.14 Safety-related Instrument Systems

It will be apparent from the foregoing that it is necessary to adopt a systematic approach to the whole system of instrumentation, control and protection.

13.14.1 EEMUA Safety-related Instrument System Guide

A scheme for this is described in *Safety-related Instrument Systems for the Process Industries* by the EEMUA (1989 Publ. 160) (the *EEMUA Safety-related Instrument System Guide*). This document complements the *HSE PES Guide* by proving additional guidance specific to the process industries. The background to, and an account of, the scheme is given by W.S. Black (1989).

The starting point is the practice in conventional systems of separating the protective functions from the control functions. Whereas in such systems control functions may be performed by a PES, it has been almost universal practice to use hardwired systems for protective functions.

13.14.2 Categories of system

Four categories of system are defined:

0 Self-acting devices.
1 Non-self-acting devices.
2 System which protects against damage to environment.
3 System which ensures reliable production and keeps plant operation with operational limits.

These categories are amplified in Table 13.28

13.14.3 Categorization process

Assignment of systems to these categories should be made on the basis of a review, involving consideration of the plant line by line. A schedule should be prepared of all the failures which result in excursions outside normal process operating limits. The process conditions after failure should be determined. Cases where the process conditions are unacceptable with respect to safety should be identified. The option of making a modification to eliminate the unacceptable condition should be considered. If it is decided to rely on the instrument system to prevent the unacceptable condition, the system should be listed together with the potential hazard.

The review may be part of a hazop study or it may be separate. A separate review has the advantage that any rethinking can be done outside the hazop. If a separate review is undertaken, the results should be considered in the hazop.

13.14.4 Selection of systems

In selecting a system for a Category 1, 2 or 3 duty, consideration should be given as to whether the system should be programmable or non-programmable. The IEE classification of programmable systems recognizes three types:

(1) fixed program system;
(2) limited variability system;
(3) full variability system.

Table 13.28 *Categories of control and protective system given in the EEMUA Guide (after EEMUA, 1989) (Courtesy of the Engineering Equipment Manufacturers and Users Association)*

Category	*Type of system*	*Purpose*	*Consequence of failure*	*Requirements*
0[a]	Self-acting device such as PRV, BD, or containment	Safety	Hazard to persons	Relevant BSs
1[b]	Instrument safety system	Safety	Hazards to persons	PES Guide: *EEMUA Guide*
2[c]	Protective system	Economic or environmental	Loss of production or harm to environment	Reliability comparable to conventional analogue systems so that demands on protective devices are limited
3[c]	Control system	Operational	Loss of production and possible demand on category 0, 1, of 2 system	

[a] Where Category 0 devices are installed and their capability and integrity alone are adequate to ensure safety, Category 1 systems will be unnecessary.

[b] Where mechanical devices cannot be used or are not adequate alone to ensure safety, category 1 systems will be necessary.

[c] If programmable systems are used for Category 2 or 3 systems, a full assessment of the system according to the *PES Guide* or the *EEMUA Guide* will be unnecessary.

Table 13.29 *Selection scheme for control and protective systems given in EEMUA Guide (EEMUA, 1989) (Courtesy of the Engineering Equipment Manufacturers and Users Association)*

System	*Self-acting*	*Non-programmable*	*Fixed program*	*Limited variability*	*Full variability*
Ultimate safety, Category 0	Preferred	–	–	–	–
Ultimate safety, Category 1	–	Preferred	Acceptable	Acceptable	Avoid
Protection, Category 2	–	Preferred	Preferred	Acceptable	Avoid
Regulatory, Category 3	–	Acceptable	Acceptable	Preferred	Avoid
Supervisory control	–	–	Avoid	Preferred	Acceptable
Information	–	–	–	Acceptable	Preferred

Examples of these three types are a three-term controller which emulates its analogue equivalent, a PLC and a minicomputer. Table 13.29 gives the selection scheme presented in the *EEMUA Guide*.

13.14.5 Review of systems

Once the systems have been selected, the arrangements should be subjected to a review by a team including process engineers, control engineers and operations managers. It should be established that the requirements given in the *PES Guide* for configuration, reliability and quality are met The *EEMUA Guide* refers to the checklists in the *PES Guide* and gives its own checklists.

13.14.6 Implementation of systems

A Category 0 or 1 system should have the capability and reliability to deal with the foreseeable failure modes and failure frequency of the plant itself and of the Category 2 and 3 systems.

Where a Category 1 system is used, the system should be engineered in accordance with the *PES Guide* and the *EEMUA Guide*. The requirements in these documents relating to hardware, quality and reliability are applicable both to programmable and non-programmable systems. For the latter, however, the requirements relating to software are not applicable.

Failure of a Category 2 or 3 system may put a demand on a Category 0 or 1 system. Where a Category 0 or 1 system is used which is based on a PES, the failure rate should not exceed that of the equivalent conventional system.

13.14.7 Failures in systems

The *EEMUA Guide* gives an account of, and guidance on, the failures which occur in conventional and programmable systems. In conventional systems, a single output failure is usually to the zero or low states. This is the mode of failure on loss of air or power. Systems are designed so that the plant goes to a safe state on this failure mode. In such systems the usual assumption is that multiple failures are in the zero or low mode. This is commonly the basis on which relief capacity is sized.

In programmable systems, a single output failure will be due to failure in an input or output channel. The failure rate to the high state is unlikely to exceed that in a conventional system. There is potential, however, in a programmable system for multiple failures to the high state due to random hardware failure or systematic software failure. An assessment should be made of the system to ensure that the probability of multiple failure to the high state due to random hardware failure is low.

Failures of software may be failures of system software or of applications software. It is rare for system software to be fault free, although a mature system can be expected to contain fewer faults than a new one. The system software for any control system to be used in a safety-related application should be evaluated. The alternative means given are formal evaluation and user experience.

Failure in the applications software should be minimized by good software engineering. The *EEMUA Guide* gives guidance on software development and testing.

13.14.8 Loop allocation strategies

There are two basic strategies for loop allocation: (1) outputs distributed and (2) outputs grouped. The principles are that, in the first case, the outputs from a single PES unit are distributed around a number of process units, whereas in the second they are concentrated at a single process unit or at least at a minimum number of units.

If the outputs are distributed, loops which may fail simultaneously are not concentrated on the same process unit. The resultant problem at any given unit will therefore be less severe. In particular, this policy allows the pressure relief system to be designed for a single failure on each unit. On the other hand, there may then be a quite large number of process units with some degree of problem. Alternatively, the outputs may be grouped. The problem of multiple failures of loops is then concentrated on one process unit.

The choice between these strategies depends on the characteristics of the process and the probability of multiple failure. A distributed strategy may be suitable for a simple, slow-responding process, but a grouped strategy for a fast-acting process. With a well-designed instrument system, particularly with redundancy, the probability of multiple failure may be small compared with failures of the process unit for other causes.

13.15 CCPS Safe Automation Guidelines

13.15.1 Guidelines for Safe Automation of Chemical Processes

The safety aspects of process control systems are the subject of *Guidelines for Safe Automation of Chemical Processes* (CCPS, 1993/14) (*the CCPS Safe Automation Guidelines*). The *Safe Automation Guidelines* cover the safety aspects of the whole process control system, including the basic process control system (BPCS), the safety interlock system (SIS) and the human operator. Two types of interlock are distinguished: (1) failure interlocks and (2) permissive interlocks. The distinction corresponds to that used here between trips and interlocks proper.

The headings of the *Guidelines* are: (1) overview; (2) the place of automation in chemical plant safety – a design philosophy; (3) techniques for evaluating integrity of process control systems; (4) safety considerations in the selection and design of BPCSs; (5) safety considerations in the selection and design of SISs; (6) administrative controls to ensure control system integrity; (7) an example involving a batch polymerization reactor and (8) the path forward. Appendices deal with SIS technologies, separation of the BPCS and SIS, watchdog timer circuits, communications, sensor fail-safe considerations, SIS equipment selection, PES failure modes and factory acceptance test guidelines.

The *Guidelines* are concerned particularly with PES-based SISs. As described earlier, at least until recently, the normal approach has been to use for the safety interlock (SI) a hardwired system separate from the rest of the control system, whether or not this be computer based. The *Guidelines* describe a design philosophy in which the system of choice for an SIS is a PES-based system. In large part the guidance is concerned with ensuring that a PES-based system has the availability and reliability required for this duty.

This section gives an outline of the *Guidelines*. The latter contain a wealth of practical guidance on the various topics which are touched on here.

13.15.2 Basic design method

The design requirements for the SIS arise out of the process hazard analysis (PHA). The *Guidelines* require that the SIS should be designed by a formal method, but are flexible with respect to the method used. They give a basic design method, which includes what they term a 'qualitative approach to specification' of the SIs required but which allows for the use of alternative quantitative approaches.

The basic design method given in the *Guidelines* is based on the following features:

(1) independent protection layers;
(2) process risk ranking;
(3) SI integrity level specification;
(4) SI integrity level implementation.

This philosophy is outlined in Table 13.30 Section A of the table lists the features which are treated as layers of protection and Section B gives the criteria for a layer or combination of layers to constitute an independent layer of protection (IPL). An IPL protects against a particular type of hazardous event. The event severity and event likelihood are obtained from the process hazard analysis as shown in Section C. The scheme given in Section D indicates the integrity level (IL) required for any SI. There are three integrity levels: Levels 1, 2 and 3 (IL1, IL2 and IL3). As stated in the footnotes, the number of IPLs to be used in the table is the total number of IPLs, including the SI being classified. The implementation of a SIS of specified integrity level is indicated in Section E and an example of the determination of the integrity level of a SI is given in Section F.

13.15.3 Evaluation of control system integrity

The *Guidelines* review the various safety and integrity evaluation techniques applicable to process control systems, including under the qualitative techniques operating experience, standards and codes, design guidelines, checklists, What-If analysis, failure modes and effects analysis (FMEA) and hazop and under the quantitative techniques trip capability analysis, fault tree analysis, event tree analysis, reliability block diagrams, Markov models, Monte Carlo simulation, non-destructive fault insertion testing and QRA.

The BPCS and SIS should both be certified, either by self-certification or third party certification. For PES devices, three maturity levels are recognized: user-approved

***Table 13.30** Basic design philosophy of the safety interlock system in the CCPS safe Automation Guidelines (CCPS, 1993/14) (courtesy of the American Institute of Chemical Engineers)*

A Layers of protection

1. Process design
2. Basic controls, process alarms, operator supervision
3. Critical alarms, opearator supervision and manual intervention
4. Automatic SIS
5. Physical protection (relief devices)
6. Physical protection (containment dikes)
7. Plant emergency response
8. Community emergency response

B Criteria for independent layers of protection

The criteria for a protection layer or a combination of protection layers to qualify as an independent protection layer (IPL) are:

1. The protection provided reduces the indentified risk by large amount that is, at least by a 100-fold reduction
2. The protective function is provided with a high degree of availability – 0.99 or greater
3. The protection has the following characteristics:
   - *Specificity.* An IPL is designed solely to prevent or to mitigate the consequences of one potentially hazardous event (e.g. a runaway reaction, release of toxic material, a loss of containment, or a fire). Multiple causes may lead to the same hazardous event and therefore multiple event scenarios may initiate action of one IPL
   - *Independence*. An IPL is indepentent of the other protection layers associated with the identified danger
   - *Dependability.* It can be counted on to do what it was designed to do. Both random and systematic failure modes are addressed in the design
   - *Auditability.* It is designed to facilitate regular validation of the protective functions. Functional testing and maitenance of the safety system is necessary

C Process risk ranking

An event is assigned a severity and a likelihood:

Event severity	
Minor incident	Impact initially limited to local area of the event with potential for broader consequences if corrective action is not taken.
Serious incident	One that could cause: – any serious injury or fatality on-site or off-site – property damage of $1 million off-site or $5 million on-site
Extensive incident	One that is five more times worse than a serious incident
Event likelihood	
Low	A failure or series of failures with a very low probability of occurrence within the expected lifetime of the plant ($<10^{-4}$failures/year). Exambles: (1) three or more simultaneous instrument, valve or human failures; (2) spontaneous failure of single tanks or process vessels
Moderate	A failure or series of failures with a very low probability of occurrence within the expected lifetime of the plant (10^{-4} to 10^{-2} failures/year). Examples: (1) dual instrument failures; (2) combination of instrument failures and operator errors; (3) single failures of small process lines or fittings
High	A failure can reasonably be expected to occur within the expected lifetime of the plant ($>10^{-2}$ failures/year). Examples: (1) process leaks; (2) single instrument or valve failures; (3) human errors that could result in material releases

The event is designated low risk for any of the following combinations: (1) severity low, likelihood low; (2) severity serious, likelihood low; (3) severity low, likelihood moderate. It is designated high risk for any of the following combinations (1) severity extensive, likelihood high; (2) severity serious, likelihood high; (3) severity extensive.Likelihood moderate. It is designated moderate risk for the other three combinations.

D Safety interlock integrity level specification[a]

	Event severity								
	Minor			*Serious*			*Extensive*		
Event likelihood	Low	Moderate	High	Low	Moderate	High	Low	Moderate	High
No. of IPLs[b] 3	(5)	(5)	(5)	(5)	(5)	(5)	(5)	1	1
2	(5)	(5)	1	(5)	1	2	1	2	3 (2)
1	1	1	3	1	2	3 (2)	3 (2)	3 (2)	3 (1)

[a] The values in the table without brackets refer to the integrity level (IL) required; the values in brackets refer to the number of the note given below.

[b] Total number of IPLs, including the safety interlock being classified.

Table 13.30 *(continued)*

Notes:
1. One Level 3 safety interlock does not provide sufficient risk reduction at this risk level. Additional PHA modifications are required.
2. One Level 3 safety interlock may not provide sufficient risk reduction at this risk level. Additional PHA review is required.
3. Event likelihood – likelihood that the hazardous event occurs without any of the IPLs in service (i.e. the frequency of demand).
4. Event likelihood and total number of IPLs are defined as part of the PHA team work.
5. SIS IPL is probably not needed.

Integrity level availability

	Availability (%)
Level 1	about 99
Level 2	99–99.9
Level 3	up to 99.9–99.99

E Safety interlock integrity level implementation

Integrity level (IL)	*Minimum interlock design structure*
1	Non-redundant: best single path design
2	Partially redundant: redundant independent paths for elements with lower availability
3	Totally redundant: redundant, independent paths for total interlock system. Diversity should be considered and used where appropriate. A single fault of an SIS component is highly unlikely to result in a loss of process protection

F Illustrative example

Event severity	Extensive
Event likelihood without benefit of either IPL	Moderate
Total number of IPLs (non-SIS IPL + SIS interlock)	2
Required SIS interlock integrity level	2

(for BPCS), user-approved safety (UAS) (for SIS) and user-obsolete. The *Guidelines* give criteria for user approvals.

13.15.4 Basic process control system

The BPCS is not usually an IPL. It is, nevertheless, the next line of defence after the process design and has an important part to play. The *Guidelines* therefore deal with the safety considerations in the selection and design of the BPCS. The account given covers (1) the technology selection, (2) the signals, (3) the field measurements, (4) the final control elements, (5) the process controllers, (6) the operator/control interfaces, (7) communication considerations, (8) electrical power distribution systems, (9) control system grounding, (10) batch control, (11) software design and data structures and (12) advanced computer control strategies, and contain much practical material on these features.

The *Guidelines* advise that use of a supervisory computer should be subject to a discipline which restricts it to manipulation of loop set points. It should not normally be able to change the operational mode of the loops except for transfer to the back-up mode on computer failure or to computer mode on initialization. It should not compromise the integrity of the back-up controls.

The design philosophy of the *Guidelines* requires that the BPCS and the SIS should be separate systems. The BPCS should not be relied on to protect against unsafe process conditions. The integrity of the SIS should not be compromised by the BPCS. Appendix B of the *Guidelines* gives detailed guidance on separation.

13.15.5 Safety interlock system

As far as safety considerations in the selection and design of the SIS are concerned, the *Guidelines* cover (1) the design issues, (2) the requirements analysis, (3) the technology selection, (4) the architecture selection, (5) the equipment selection and (6) the system design. The necessary preliminaries are to determine the need for SIs and to establish their integrity levels.

Design issues

Design issues are of two main kinds: function and integrity. Issues concerning function include the parameters to be monitored, the trip actions to be taken, the testing facilities and policy. Among those bearing on integrity are the number of integrity levels required, which affects the choice of technology.

Some specific design issues addressed in the *Guidelines* are (1) the fail-safe characteristics, (2) logic structures, (3) fault prevention and mitigation, (4) separation of the BPCS and SIS, (5) diversity, (6) software considerations, (7) diagnostics, (8) the human/machine interface and (9) communications.

The fail-safe issue involves the choices de-energize-to-trip vs energize-to-trip. There is also the question of the failures modes of PES-based devices. Even at the chip level, probable states are equally likely to be on or off. The problem is even more severe at the level of a PES-based device. Effectively, the *Guidelines* suggest alternative approaches based on the use of equipment of proven reliability, capable of self-diagnosis and of proof-testing, with judicious use of redundancy.

There should be a separation between the SIS and BPCS such as to ensure the integrity of the former. Conventional SISs have long utilized separate sensors and power supplies. The *Guidelines* also bring into consideration the input/output system, the software and the human/machine interface.

Diagnostics may be used to detect fail-to-danger failures in the SI equipment including the sensor, the logic solvers, the final control elements and the energy sources. The *Guidelines* distinguish between passive and active diagnostics. In passive diagnostics, the failure is revealed only when a demand is imposed, either by the system or by a user test. In active diagnostics, the device is subjected continuously to testing by input of out-of-range conditions and its response monitored, but over a time interval short enough not to upset the SI loop. The example quoted is the perturbation of a solenoid valve on a control valve with sufficient rapidity that the control valve is not affected.

Requirements analysis

The requirements analysis determines the targets for availability and reliability (or functional and operational reliability).

Technology selection

The SIS technologies given in the *Guidelines* include: (1) fluid logic (pneumatic, hydraulic); (2) electrical logic, including direct-wired systems, electromechanical devices (relays, timers), solid state relays, solid state logic and motor-drive timers; (3) PES technology, involving PLCs and distributed control systems (DCSs) and (4) hybrid systems. The technologies are detailed in appendix A of the *Guidelines*.

The hardware of a typical SIS as envisaged in the *Guidelines* might consist of a logic solver with input modules receiving sensor signals, output modules sending out signals to final control elements, a BPCS interface, a human/machine interface and an engineer's interface.

Architecture selection

Under architecture selection, the *Guidelines* discuss the various ways of achieving an integrity appropriate for the integrity level determined. Thus, for IL1, redundancy is usually not necessary, though it may be appropriate for a lower reliability element. For IL3, on the other hand, there should be full redundancy. Other features mentioned for IL3 are use of analogue sensors so that active diagnostics can be practised, monitoring of the logic solver outputs by the BPCS and consideration of the use of diversity in the sensors. For both high availability and high reliability, use may be made of a triple modular redundant (TMR) system, or $\frac{2}{3}$ voting system.

Equipment selection

The equipment selected for a PES-based SIS should be of user-approved safety.

System design

The basic design method for the SIS has already been described, but the design involves more than this. The design should allow for the special features of PES-based systems. One of these, the difficulty of determining fail-safe states, has already been mentioned. Another feature is false 'turn-ons' of inputs or outputs.

Another problem in PES-based systems is that the life of a given version of the software is relatively short so that the version initially used is liable to become out of date and, after a time, no longer supported by the vendor. The problem then arises that insertion of an updated version constitutes a software modification, with all that that entails. There are various approaches to the problem, none entirely satisfactory.

The design should take into account the potential impacts of the SIS on the other components of the process control system, including the alarm system, the communications system and the human/machine interfaces.

Most process control systems involve some sequential control even if it is largely limited to start-up and shut-down. The sequential logic should operate in such a way as not to cause any safety problems. Its operation should be tested against the SI logic to ensure that normal operation of the sequential control does not trigger interlock action.

The documentation for the SIS specified in the *Guidelines* includes (1) the operational description, (2) the schematic diagrams, (3) the binary logic diagrams and (4) the single line diagrams. Examples are given of these different types of diagrams.

13.15.6 Administrative actions

In order to ensure the control system integrity, the design process just described needs to be supported by administrative actions The *Guidelines* outline minimum procedural requirements, the scope of which includes (1) operating procedures, (2) maintenance facilities, (3) testing of the BPCS, (4) testing of the SIS and alarms, (5) test frequency requirements, (6) testing facilities, (7) operations training, (8) documentation and (9) auditing of maintenance and documentation.

The test frequency indicated in the *Guidelines* for SIS functional testing is, for minimal risk systems, testing once every 2 years or at major turnarounds, whichever is more frequent, and for high risk systems, testing at least once a year or on major maintenance, whichever is more frequent.

13.16 Emergency Shut-down Systems

In quite a large proportion of cases, the plant is provided not just with individual trips but with a complete automatic emergency shut-down (BSD) system. There is relatively little written about BSD systems. One of the principal accounts is that given in *Offshore Installations: Guidance on Design and Construction, Guidance Notes to the Offshore Installations (Construction and Use) Regulations 1974* issued by the Department of Energy (1984) followed now by *Offshore Installations: Guidance on Design, Construction and Certification* (HSE, 1990b) (the HSE *Design, Construction and Certification Guidance Notes*).

13.16.1 Conceptual design of ESD

The function of an ESD system is to detect a condition or event sufficiently hazardous or undesirable as to require shut-down and then to effect transition to a safe state. The potential hazards are determined by a method of hazard identification such as hazop. Estimates are then made of the frequency and consequences of these hazards. The hazards against which the ESD system is to protect are then defined.

This protection is effected by identifying the operating parameters which must be kept within limits if realization of the hazards is to be avoided and selecting shut-down actions which will achieve this. A shut-down sequence is determined and the shut-down logic formulated. It is not always necessary to shut-down the whole plant and there are different levels of ESD which fall short of this, such as shut-down of an individual unit or of a section of plant.

13.16.2 Initiation of ESD

The arrangements for initiation of the ESD are critical. If these are defective, so that the system is not activated when it should be, all the rest of the design goes for nothing. There is a balance to be struck between the functional and operational reliability of the ESD system. It should act when a hazard arises, but should not cause unnecessary shut-downs or other hazards.

One factor which affects this balance is the fact that usually the plant is safest in the normal operating mode and that transitions such as shut-down and start-up tend to be rather more prone to hazards and are to be avoided unless really necessary. Another, related factor is that shut-down of one plant may impose shut-down on other, linked plants.

Initiation may be manual, automatic or, more usually, both. The usual arrangement is a manual initiation point, or shut-down button, in the control centre, other manual initiation points located strategically throughout the plant and initiation by instrumentation. Such automatic initiation may be effected by the fire and gas system and/or by process instruments. Measures should be taken to avoid inadvertent activation, including activation during maintenance and testing.

13.16.3 Action on ESD

There are a variety of actions which an ESD system may take. Three principal types are:

(1) flow shut-off;
(2) energy reduction;
(3) material transfer.

Flow shut-off includes shut-off of feed and other flows. It often involves shut-down of machinery and may include isolation of units. Energy reduction covers shut-off of heat input and initiation of additional cooling. Material transfer refers to pressure reduction, venting and blow-down.

A fundamental principle in ESD is failure to a safe state. The overall aim is failure to a safe state for the system as a whole. This is normally effected by applying the principle to individual units, but there may be exceptions, and cases should be considered individually. Each required action of the ESD system should be effected by positive means. Reliance should not be placed on the cascading effect of other trip actions.

13.16.4 Detail design of ESD system

It is a fundamental principle that protective systems be independent of the rest of the instrument and control system, and this applies equally to an ESD system. The design of the ESD system should follow the principles which apply to trip systems generally, as described in Section 13.9. There should be a balance between functional and operational reliability. Dependent failures should be considered. The reliability may be assessed using fault tree and other methods. The techniques of diversity and redundancy should be used as appropriate. Use may be made of majority voting systems.

The emergency shut-down valves (ESVs) should have a high degree of integrity. Such valves are frequently provided with pneumatic or hydraulic power supplies in addition to electrical power supply. An ESV should be located so that it is unlikely to be disabled by the type of incident against which it is intended to protect.

The ESD system should be provided with power supplies which have a high degree of integrity. The normal approach is to provide a UPS. This supply should be designed and located so that it is unlikely to be disabled by the incident itself. The cables from the power supply to the final shut-down elements should be routed and protected to avoid damage by the incident.

13.16.5 Operation of ESD system

The status of the ESD system should be clear at all times. There should be a separate display showing this status in the control centre. This display should give the status of any part of the EDS system which is under test or maintenance and of any part which is disarmed. Initiation of ESD should activate audible and visual alarms in the control centre. There should be an indication of the source of the initiation, whether manual or instrument. BSD should also be signalled by an alarm which is part of the general alarm system.

It may be necessary in certain situations such as start-up, changeover or maintenance to disarm at least part of the BSD system, but such disarming should be governed by formal arrangements. The principles are essentially similar to those which apply to trip systems generally, as described in Section 13.9.

13.16.6 Testing and maintenance of ESD system

The ESD system should be subject to periodic proof testing and such testing should be governed by a formal system. The principles of proof testing were discussed in Section 13.9. As far as is practical, the test should cover the complete system from initiation to shut-down condition.

The need for proof testing and, more generally, for the detection of unrevealed failure should be taken into account in the design. The equipment should be designed for ease of testing. It should be segregated and clearly identified. Techniques for detection of instrument malfunction should be exploited. In voting systems, the failure of a single channel should be signalled.

13.16.7 Documentation of an ESD system

The ESD system should be fully documented. *The HSE Design, Construction and Certification Guidance Notes* give details of recommended documentation.

13.16.8 ESD of a gas terminal

The design of systems for ESD and EDP of a gas terminal has been described by Valk and Sylvester-Evans (1985). The design philosophy described is that the ESD system should operate only in an extreme emergency, that the ESD and EDP systems are separate from the control, trip and relief systems, and that the systems should be simple and reliable.

The preliminary design of the ESD and EDP systems was reviewed by means of a hazop study. Potential operational failures were studied using general reliability engineering methods and functional failures were studied using, in particular, fault tree analysis. A further hazop was conducted on the final design for the ESD and EDP system.

Design studies showed that a totally fail-safe concept would result in a relief and flare system of exceptional size. Alternatives considered were to allow an increase in the depressurization time for certain critical equipment beyond that recommended in the codes and to control the peak depressurization flow in the relief and flare system. In the design adopted, the plant was divided into sections such that the depressurization of each section could be done independently and the operation of the sections was interlocked. The depressurization time of certain items was extended to 30 min as opposed to the 15 min recommended in API 521, but the design compensated for this extension by provision of additional fireproofing and water cooling arrangements.

The authors highlight the differences of philosophy between companies on whether the ESD and EDP systems should be used for normal shut-down and depressurization or reserved as systems dedicated for emergency use. This project reaffirmed the need to consider the ESD and EDP systems at an early stage and to avoid treating them as an 'add-on' feature to be dealt with late in the design.

13.16.9 ESD on Piper Alpha

The ESD system on Piper Alpha illustrates a number of the points just made. Overall, the system was largely effective in achieving shut-down and venting and blow-down, but there were a number of features which are of interest.

The main button for the initiation of the ESD caused closure of the ESV on the main oil pipeline but not on the three gas pipelines. One reason for this was that closure of these latter ESVs would impose a forced shut-down on the linked platforms. There were three separate shut-down buttons, one for each of these valves, and shut-down depended on manual action by the control room operator – he was thrown across the control room by the explosion.

The ESVs on the risers of the gas pipelines were so located that they were vulnerable to the fires that developed. This defect was widespread throughout the North Sea and regulations were introduced without delay to require such valves to be relocated. There was also evidence that some of the ESVs did not achieve tight shut-off. The explosion damaged power supplies, and in some cases closure of ESVs occurred, not due to survival of the intended power supply, but fortuitously. Further details are given in Appendix 19.

13.17 Level of Automation

The allocation of function between man and machine is a principal theme in human factors and is discussed in the next chapter. Of particular interest here is the allocation of control and protective functions to the process operator or the instrument system. This was touched on above and is now considered in more detail by means of a industrial example.

13.17.1 Illustrative example: steam boiler protective system

A case study of the optimum level of automation has been described by Hunns (1981). The system investigated was the protective system of a large steam plant. The plant consisted of a 100 MW boiler operating at 1500–2000 psi and producing 500 ton/h of steam, the boiler being dual fired with oil and gas. The principal relevant features of the three candidate control and protective systems are shown in Table 13.31.

Each system was assessed for its reliability in the start-up and operational phases of the plant. A variety of start-up sequences were considered, each related to the event which had caused the previous shut-down. Some 200 logic diagrams were produced.

The criterion used to determine the optimum system was a function of the expected shut-downs. These were classified as low penalty and high penalty. Low penalty shut-downs were unwanted shut-downs due to spurious trips and correct shut-downs in response to a demand, whilst high penalty, or catastrophic, shut-downs were those caused by a demand to which the protective system did not respond.

One such case is an excessive release of unignited fuel into the combustion chamber. Figure 13.26 shows a section of the logic, which the authors term 'matrix logic'. Events envisaged by the analyst are shown in the left-hand column. A particular event sequence is shown by a vertical column of the matrix containing one or more dots. The circle enclosing the '&' symbol at the head of the column indicates that the events are ANDed together. The set of event sequences is collected under the OR symbol, which indicates that these event sequences are related to the top event, the unignited release, by OR logic.

The equipment failure data were taken from the Safety and Reliability Directorate SYREL data bank, whilst the human error estimates were obtained by expert judgement. There were some 180 elements in the latter list. Estimates of the values in the list were made by two experienced analysts. Use was made of performance shaping factors such as 'time to react', 'prior expectancy', 'conspicuity of task' and 'perception of consequence'. Good agreement was obtained between the two. Those estimates which were particularly critical or where a divergence had emerged were mediated by a third, independent, analyst.

The results of the study were expressed in terms of the number of low and high penalty shut-downs per year and the corresponding mean outage time. The mean outage of

Table 13.31 *Elements of three candidate protective systems for a large steam boiler plant (after Hunns, 1981) (Courtesy of Elsevier Science Publishers)*

Control and protective features	*Protective system design*[a]		
	Manual	*Medium automated*	*Higly automated*
Trip parameters[b]	A	A	A
Boiler purge sequence	M	A	A
Burner flame failure detection	M	A	A
Gas valves leak test	M	M	A
Ignition burner control	M	M	A
Burner fuel valves operation	M	A	A

[a] A, automated; M, manual.

[b] Low boiler drum level; low combustion air flow; low instrument air pressure; low level fuel oil pressure; low atomizing steam pressure; low fuel gas pressurel; high fuel gas pressure; high knockout drum level; and loss of 110 DC supplies.

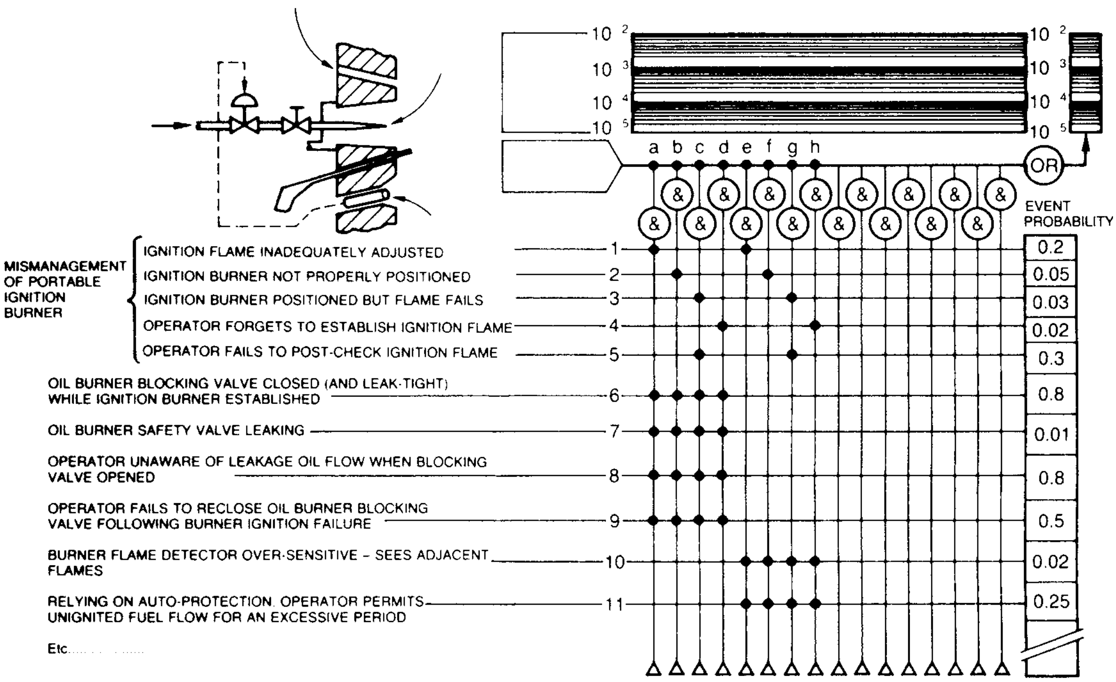

Figure 13.26 Matrix logic diagram for a steam boiler protective system: event 'excessive unignited fuel release' (Hunns, 1981) (Courtesy of Elsevier Science Publishers)

low penalty events was taken as 1/3 days/event and that of high penalty events as 60 days/event. The manual system gave appreciably more high penalty shut-downs but fewer low penalty ones and overall a higher outage than the other two systems. The medium automated system gave slightly more high penalty shut-downs and fewer low penalty ones than the highly automated one, but the same outage time. On a life cycle cost basis, for which the highly automated system had higher capital and maintenance costs, the medium automated system was superior. The total life cycle costs of the three systems – manual, medium automated and highly automated – were £0.122, 0.095 and 0.099 million/year, respectively.

13.18 Toxic Storage Instrumentation

On plants handling high toxic hazard materials (HTHMs), the instrumentation and control system assumes particular importance. Some relevant considerations are outlined in *Guidelines for Safe Storage and Handling of High Toxic Hazard Materials* by the CCPS (1988/2) (the CCPS HTHM Guide).

Depending on the degree of hazard, the instrumentation and control system should be a high integrity one. This requires adherence to the various principles already described for high integrity design, including the application of principles such as fail-safe and second chance design and the use, as appropriate, of high reliability instrumentation, instrument diversity and redundancy, and high quality maintenance. It also involves the application of the techniques of hazard identification and assessment to the design.

In respect of measurement, principal considerations are that the potential for release from the instrument, or its fittings, should be minimized, that the instrument be reliable and that the measurement be accurate. For flow measurement this favours the use of non-invasive sensors such as magnetic flowmeters and avoidance of glass in instruments such as rotameters. Orifice flowmeters also have the disadvantage of an extra flange and associated piping. For pressure measurement, diaphragm pressure sensors are preferred to direct-connected gauges of the Bourdon tube type. Precautions to be taken where the latter have to be used include protection by inert liquid filling in corrosive service and installation of shut-off valves and, possibly, flow limiters in the form of restriction orifices. For level measurement, weighing methods have advantages, but use of sightglasses should be avoided. For temperature measurement, particular care should be taken in the design of the thermowell, which can be a weak point.

The arrangements for control and protection should address the hazards of particular importance for the storage of tonics. These include (1) overpressure, (2) overfilling, (3) overtemperature and (4) high release flow. For overpressure, the main requirements are the provision of overpressure protection and of means of disposal for the relief flows. For overfilling, a significant role is likely to be played by trip systems. For temperature deviations, which may indicate reaction runaway or thermal stratification with its attendant risk of rollover, the need is for warning. Some methods of dealing with overtemperature are described below. High releases flow following a failure of containment may be mitigated by the use of suitable control valve trims and of restrictor orifices or excess flow valves.

Storage of a reactive chemical requires close control in respect both of temperature and of contamination. Methods of temperature control include the use of cooling coils, a reflux condenser, a quench system and short stop arrangement. All these methods of temperature control require for their effective functioning good mixing in the tank.

A toxic gas detection system should be provided, on the lines described in Chapter 18. Toxic gas detectors should also be installed on vents on which breakthrough of a toxic gas may occur. The sensors should have a range adequate for this duty. Instrumentation may also be required to ensure that the pilot burner remains lit on any flare which has the function of destroying by combustion any toxic gas routed to it.

13.19 Notation

Section 13.6

P_d	delivery pressure
P_s	suction pressure
ΔP	pressure drop
Q	gas flow

Section 13.9

f_η	density function for a plant hazard occurring
m	number of equipments which must survive for trip system to survive
n	number of identical equipments
P_η	probability of a plant hazard occurring
r	number of equipments which must fail for trip system to fail
t	time
γ	spurious trip rate
δ	plant demand rate
η	plant hazard rate
λ	equipment failure rate
τ_p	proof test interval
τ_r	repair time
ϕ	fractional dead time (with simultaneous testing)

Subsections 13.9.1–13.9.13

p_δ	probability of a plant demand occurring
q	probability of a single channel failing
q_γ	probability defined by Equation 13.9.37
τ_d	disarmed time
τ_0	dead time
ϕ^*	fractional dead time (with staggered testing)
ϕ_{is}	isolation dead time

Subscripts

m/n	for an m/n (m-out-of-n) system
min	minimum

Subsection 13.9.14

P_n	probability that system is in state n
r_1, r_z	terms defined by Equation 13.9.53

Subsection 13.9.16

A	heat transfer area of sensor
c_p	specific heat of sensor
k	constant
M	mass of sensor
s	Laplace operator
t	time
T	temperature
T_i	input temperature
U	overall heat transfer coefficient of sensor
$\delta(t)$	delta function
ζ	damping factor
ϕ	temperature division
ϕ_i	input temperature deviation
I	time constant of sensor
ω_n	natural frequency

Subscripts

i	input
ss	steady-state
1,2	first, second stage

Superscripts

–	Laplace transform

Subsection 13.9.17

C	annualized cost of a single channel trip
G	cost of genuine trip
H	cost of realization of hazard
S	cost of spurious trip
V	overall annual cost
β_1	functional beta value
β_2	operational beta value

Subscripts

s	trip system
1/2	1/2 system

14 Human Factors and Human Error

Contents

It is appropriate at this point to deal with the topic of human factors, and one important aspect of that, human error. Human factors considerations are relevant to all aspects of the design and operation of process plants. The topic is, however, a vast one and the account given here is necessarily limited. The approach taken is to consider in particular the process operator and then to touch on certain other aspects such as communications, maintenance and construction.

Overviews of human factors are given in *Biotechnology* (Fogel, 1963), *Human Factors Engineering* (McCormick, 1957b), *Human Engineering Guide to Equipment Design* (C.T. Morgan *et al.*, 1963), *Human Engineering Guide for Equipment Designers* (Woodson and Conover, 1964), *Human Factors Evaluation in System Development* (Meister and Rabideau, 1965), *Ergonomics* (Murrell, 1965a), *Human Performance in Industry* (Murrell, 1965b), *Human Factors* (Meister, 1971), *Handbook of Human Factors* (Salvendy, 1987), *Applied Ergonomics Handbook* (Burke, 1992 ACGIH/76) and *Human Factors in Design and Engineering* (Sanders, 1993). Accounts of human factors with specific reference to safety are given in *Ergonomics Guides* (AIHA, 1970−/1), *Human Aspects of Safety* (Singleton, 1976b) and *Human Factors in Process Operations* (Mill, 1992). HSE guidance is given in HS(G) 48 *Human Factors in Industrial Safety* (HSE, 1989).

Selected references on human factors are given in Table 14.1 and references on the process operator are given in Table 14.2.

14.1 Human Factors in Process Control

In the previous chapter the importance of plant operation was emphasized and the automatic control system was described. Consideration is now given to the other element in the overall control system – the process operator.

Although modern control systems achieve a high degree of automation, the process operator still has the overall immediate responsibility for safe and economic operation of the process. There are different philosophies on the extent to which the function of safety shut-down should be removed from the operator and assigned to automatic trip system. In general, the greater the hazards, the stronger the argument for protective instrumentation. This question is considered in more detail later. But, whatever approach is adopted, the operator still has the vital function of running the plant so that shut-down conditions are avoided.

The job of the process operator is therefore a crucial one, but it is also rather elusive in that it presents the engineer with a type of problem with which he is not normally required to deal. The study of industrial jobs and work situations is the province of ergonomics or, its American near-equivalent, human factors. It is appropriate, therefore, to consider the contribution which this discipline can make to the problems associated with the work of the process operator.

It should be said, however, that the chemical industry in general appears to make little use of human factors in this area. There is considerable willingness to do so among engineers, but perhaps also some lack of appreciation of the scope of human factors as a discipline.

14.2 Human Factors in System Design

The pace of technological change and the scale of systems have now become so great that it is often not possible to rely on evolutionary trial and error to achieve the proper adaptation of human tasks. Instead, it is necessary to try to foresee the problems and to design to overcome them. The discipline that is concerned with this on the human side of systems is human factors.

The development of human factors has been strongly influenced by the problems of large, complex man–machine systems that occur in the fields of defence, aerospace and computers. Much of the fundamental research and design experience are in these areas.

An important area of study in the early work on human factors was the compatibility of man and machine, with its emphasis on ‘knobs and dials’. More recent work has laid a greater stress on system design. In consequence, the ergonomist has concerned himself increasingly with all stages of the design process, particularly the early stages where the crucial decisions are made.

Human factors is now established, therefore, as an aspect of systems engineering. An outline of the human factors activities in system design is shown in Figure 14.1. Two main points may be noted: (1) human factors play a role at all stages of the design; and (2) the decisions taken early on, such as those on allocation of function, are especially important and the design process is a highly interactive and iterative one. Only one iteration loop is shown, but in fact iteration occurs at all stages of the design process. Important emphases in human factors, therefore, are the system criteria and the system design process.

The engineer unfortunately frequently misunderstands human factors. The view of the subject as being concerned with knobs and dials is entrenched. The application of human factors is too often ineffective because it is called upon too late in the day to fulfill a rescue or cosmetic function. Its greatest contribution should in fact come earlier, particularly at the allocation of function stage.

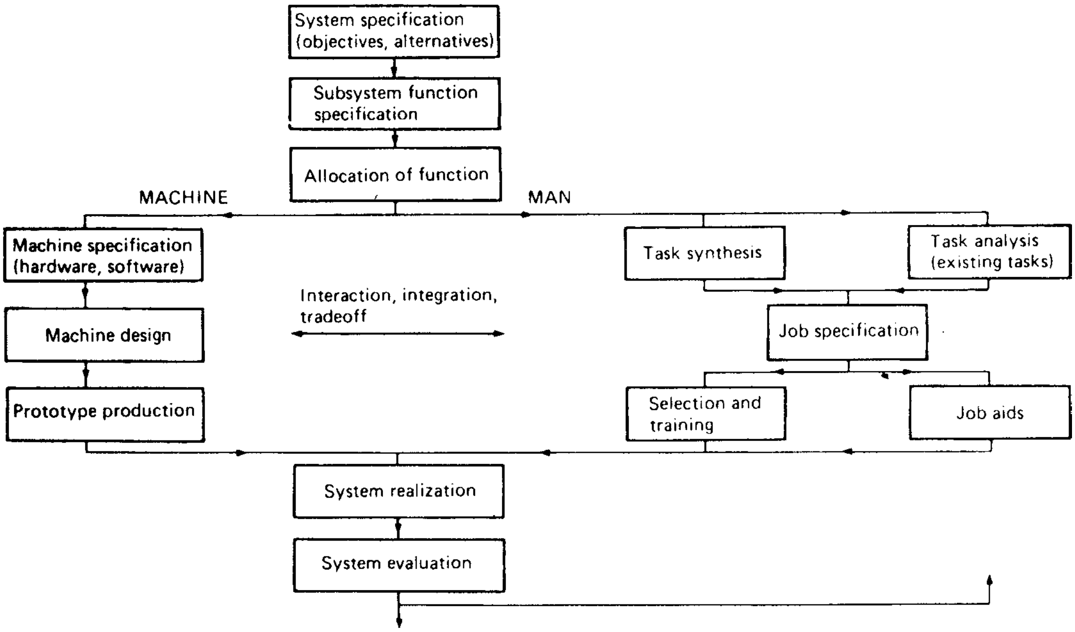

Figure 14.1 Human factors activities in system design (Lees, 1974c) (Courtesy of Taylor & Francis Ltd)

Like the engineer, the ergonomist is concerned with solving problems, particularly those arising in design. He draws on the work of psychologists and others, much as the engineer draws on that of physicists.

14.3 Themes in Human Factors

It is appropriate at this point to give a very brief account of some of the themes in human factors work which have obvious relevance to process control. Some of these are shown in Table 14.3. This is an abstract from a fuller table, which gives detailed references, in an account of the development of human factors in this context by Lees (1974c).

Much of the early work on human factors was concerned with physical tasks, but in more recent years, the emphasis has been increasingly on mental tasks. This is certainly more relevant as far as the process operator is concerned, since his job is essentially decision-making.

The question of the sampling and processing of information by the human operator is therefore of great importance. Work in this area largely evolved from study of the skills involved in physical tasks to investigation of those required for perceptual and decision-making tasks (Crossman, 1956). The model of man as an information processor has proved fruitful, although the application of information theory to the problem has not been entirely successful. Work in the area has emphasized: the ability of man to accept information coming through many sensory channels and coded in many different ways, and his ability to compensate for errors in the information; the differences in the amounts of information which can be handled by the various channels; the sampling of information and the updating of his mental model of the environment; the effect of information overload, resulting in selective omission of parts of the task; and the characteristics of memory, particularly short-term memory such as is exercised in remembering a telephone number to make a phone call.

Table 14.3 Selected topics in human factors

Information sampling and processing
Learning
Skill

Man–computer systems
Displays
Vigilance, signal detection
Inspection tasks
Controls
Control–display relations
Control panels, computer consoles
Personnel selection
Training
Organizational factors, job enrichment
Repetitive work, boredom, rest pauses, shift work

The ergonomist's approach to a particular job tends to be to enquire into the skill involved, including the nature of the skill, its acquisition through the learning process and its disintegration under stress. Skills differ greatly in their amenability to study; some skills, such as that of the process operator, are particularly inaccessible. Nevertheless, skilled performance does exhibit certain common characteristics. Skill seems to lie largely in the timing and co-ordination of activities to give a smooth and effortless performance. It is highly learned and barely accessible to consciousness, as indicated by the fact that the attempt to describe it, as in instructing a novice, often leads to actual degradation in performance.

The effects on skill of various forms of stress such as fatigue, workload and anxiety, have been investigated both on account of the importance of these effects in themselves and of the light which they throw on the nature of skill as it degrades under stress. An important finding is that skilled performance tends to improve with moderate stress, but that beyond a certain threshold, which varies greatly with the individual, it deteriorates rapidly.

The characteristics of human as opposed to mathematically optimal decision-making have been studied (W. Edwards, 1965). Interesting results are man's tendency to make decisions that are based on rather small samples, that is to jump to conclusions, and to make decisions that are biased towards optimism, that is to gamble on beating the odds.

A type of decision-making that is rather important is diagnosis (Dale, 1958, 1964; Tilley, 1967). Studies of this indicate that man does not so much follow through the decision tree irrespective of the probabilities of the various paths, but rather moves about the tree, testing first the high probability paths, and only goes to the low probability ones when the former have been exhausted.

Human performance in manual control tasks has been much studied. Early work evolved a transfer function model of the operator:

$$H(s) = K\frac{\exp(-\tau_d s)(1+\tau_L s)}{(1+\tau_N s)(1+\tau_I s)} \qquad [14.3.1]$$

where $H(s)$ is the transfer function; K the gain; s the Laplace operator; τ_d the reaction time (usually 0.1–0.3 s); τ_L the lead time constant (0.2–2.5 s); τ_N the neuromuscular lag time constant (0.1–0.2 s); and τ_I the compensatory lag time constant (5–20 s). Of these parameters, the gain is particularly significant, alteration of gain being a favoured response of the human operator to a changing situation. This approach has been developed by later workers to take account of nonlinearities, sampled data features, etc.

Work in this area shows clearly the increased difficulty which the human operator has in controlling processes with an increasing number of transfer lags or integrations or with dead time. Certain systems are virtually uncontrollable by the operator, unless he is provided with specially processed information. In particular, systems with more than three integrations in series tend to be beyond the limits of manual control. For systems such as submarines, which have this feature, the technique of quickening has been developed, in which the signal displayed to the operator is a weighted sum of signals from various points in the series of integrations. Another feature of man as a controller is his ability to carry out predictive and feedforward control functions. This is a rather characteristic feature of operator control.

Much work has been done on displays, in terms both of detailed design of dials, etc., and of the display layout, and it is perhaps this aspect which the engineer most readily identifies as human factors. Particularly relevant here is the classification of the uses of displays (Murrell, 1965a). These are:

(1) Indicating, that is the operator perceives one of two binary states.
(2) Quantitative reading, that is the operator requires a precise numerical value.
(3) Check reading, that is the operator requires confirmation that value lies within an acceptable range.
(4) Setting, that is the operator manipulates his machine controls in order to achieve a predetermined display state.
(5) Tracking, that is the operator carries out an on-going control task in order to achieve certain display conditions which may vary as a function of time.

These are very different uses and a display which is optimal for one is not necessarily so for another. There is some work which suggests that some 75% of industrial applications is accounted for either by check reading alone or by check reading and setting combined (Murrell, 1952b).

The acquisition of information from large display layouts is another important problem. Work in this area tends to emphasize the value to the operator of being familiar with the position of dials which give particular readings. Such spatial coding is lost, for example if the same instrument is used to display different variables at different times. The operator then has to devote more effort to finding out which variable is on a particular display and he is less able to recognize patterns.

Control–display relations can be important. In a given culture, there tend to be expectations of particular relations between control movements and display readings. A typical stereotype of a control–display relation is shown in Figure 14.2. Although an operator can be trained to use equipment that embodies faulty control–display relations in its design, he may tend under stress to revert to the expected relation. Violation of the stereotype can result in severe penalties.

Monitoring, signal detection and vigilance is another related and important area on which a large amount of work has been done. Some of this has been concerned with the fall-off in attention over the watch-keeping period, that is the vigilance effect. The application of this to process control is doubtful, but perhaps more relevant is the well-established relation between the frequency of a signal and

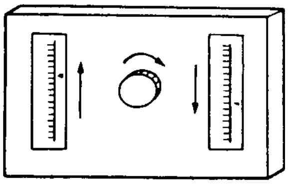

Figure 14.2 Expected relationships between control and display movements (E. Edwards and Lees, 1973) (Courtesy of the Institution of Chemical Engineers)

the probability of its detection. The probability of detection of a rare signal is rather low. This has been studied both in dial monitoring and in inspection tasks.

The problems of man–computer systems have been studied quite extensively. These include allocation of function between man and machine, man–computer interaction and man–computer problem-solving. For many functions the emphasis has moved away from early attempts at complete automation towards computer-assisted operator decision-making.

This rather brief survey is intended to show that the problems with which human factors deals are very relevant to process control by the human operator. These and other topics such as learning and training, organizational and social factors, and human error are now considered more specifically in relation to process control.

14.3.1 Human factors in process control

The task of process control is of interest to workers in human factors as an example of a task involving cognitive rather than manipulative skills and was the subject of a series of early classic studies by Crossman. Since then there have been numerous investigations of the process control task. This work is described below.

A review of the control of processes by operators and computers is given in *Man and Computer in Process Control* and some of the classic papers on the process operator are collected in *The Human Operator in Process Control,* both by E. Edwards and Lees (1973, 1974).

14.4 Process Operator Functions

The job of the process operator has developed over the years from one based largely on manual work to one consisting primarily of decision-making. The physical work content is now frequently vestigial.

The process operator is part of the control system. The primary functions of the control system and, therefore, of the operator, depend on the nature of the process. In a chlorine cellroom, it may be the monitoring of alarm conditions, and in a batch reactor plant the conduct of sequential operations.

The nature of the control system provided also influences strongly the operator's functions. The stages of development of control systems have already been described in Chapter 13. The job of the operator is generally different in systems based on analogue and on computer control. The job of the process operator, at least in the control room, is essentially decision-making in a rather artificial situation, involving the manipulation of symbolic displays.

If the process control task as a whole is considered, a number of distinct operator functions may be identified (E. Edwards and Lees, 1973; Lees, 1974c):

(1) goal formulation;
(2) measurement;
(3) data processing and handling;
(4) monitoring;
(5) single variable control;
(6) sequential control;
(7) other control;
(8) optimization;
(9) communication;
(10) scheduling;
(11) manual operations.

These functions have been discussed in detail by E. Edwards and Lees (1973). Although most process control tasks have elements of all these functions, the relative importance varies widely.

The state of the process also affects the operator's task. If process conditions are abnormal, he has the crucial function of fault administration. In simple terms, this may be regarded as having three stages: (1) fault detection, (2) fault diagnosis and (3) fault correction. But this can be an oversimplification, in that following fault detection the priority is often to move to a safe condition rather than to diagnose the fault. As control systems achieve increasing automation, the function of fault administration tends to grow in importance. It is a crucial one in relation to loss prevention.

14.5 Process Operator Studies

In a review in 1974 of studies of the process operator, Lees (1974c) listed some 140 items. This list was limited to work directly concerned with the process operator and did not include work on more general but related problems such as vigilance or manual control. There exists, therefore, a quite substantial body of work on the process operator and his problems, although it is not well known among engineers. Selected studies of the process operator are given in Table 14.4. Some of the salient points from these studies are now considered.

It may be mentioned at this point that the compilation of this list appears to have coincided with the end of that phase in the development of human factors in which studies were conducted of the process operator *per se*. Subsequent research has been directed rather to specific tasks, particularly fault diagnosis, to methodologies such as task analysis and to training.

Much of the pioneering work on the process operator was initiated by Crossman and his co-workers. His interest in process control was that it is a good example of an industrial skill that is predominantly cognitive rather than physical. Crossman (1960) did an investigation of a number of process control tasks and concluded that it is particularly difficult to control the following processes:

(1) where several display and control variables depend on one another;
(2) where the process has a long time constant;
(3) where important variables have to be estimated by the operator rather than measured by an instrument;
(4) where the readings of instruments at widely separated points have to be collated, and the operator has to remember one while going to another ('short-term memory');
(5) where the operator gets imperfect knowledge of the results of his performance, or where the knowledge arrives late;
(6) where the basic process is either difficult to visualize, for example chemical reactions, or contradicts 'common-sense' assumptions, or is too complicated to be held in mind at one time.

One aspect of process control skill, which was investigated by Crossman and his colleagues is information sampling (Crossman, Cooke and Beishon, 1964). The information sampling behaviour of the operator was studied in the laboratory task of controlling the temperature of a water bath

and the industrial one of controlling the basis weight on a paper machine. It was found that the Shannon–Wiener sampling theorem did give a basic minimum sampling rate, provided a system bandwidth modified for error tolerance was used. But many other factors were identified which tend to increase the sampling rate. Sampling behaviour depends on the operator's uncertainty and its growth over time and on the cost of sampling, and it cannot be separated from the control problem, which raises questions of the control accuracy required, the penalty for error, the operator's understanding of the system, the nature and predictability of the disturbances and the lags in the process. Five factors were identified as governing the sampling rate: (1) bandwidth, (2) noise, (3) tolerance, (4) predictability and (5) control calibration.

Bandwidth is a function of the maximum possible rate of change of the signal. Noise on the signal causes excursions of the signal near the tolerance limit. Tolerance limits depend on the importance of the variable, its possible rate of change and the signal noise. Predictability of the signal allows extrapolation and reduces the need for sampling. Control calibration, which gives the relation between the change of the manipulated variable and that of the controlled variable, assists predictability.

In the light of this work the authors criticized the use of displays which show only a deviation between the set point and a measured value. Such displays greatly reduce the operator's ability to learn the signal characteristics such as noise, predictability and control calibration. This problem has also been considered by de Jong and Köster (1971) in terms of the sampling of information from chart recorders.

Crossman and his colleagues also studied manual control of the laboratory water bath and the paper machine (Crossman and Cooke, 1962; Beishon, 1967). The control action required in both cases was to bring the system to a new operating point. The work showed that a good subject often begins with a closed-loop strategy that tends to produce the oscillatory response shown in Figure 14.3, but soon learns to use an open-loop approach, limiting the use of feedback to fine tuning as in Figure 14.3(b).

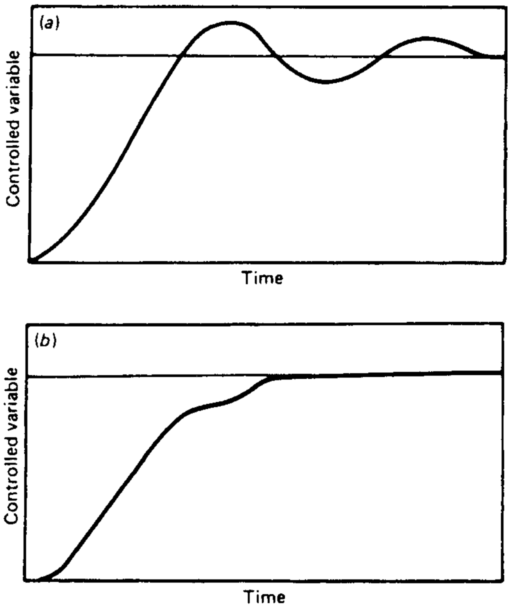

Figure 14.3 Change of operating point in a manually controlled system: (a) closed-loop behaviour; (b) open-loop behaviour

Similar work has been done by Attwood (1970), also on a laboratory water bath and a paper machine, by Kragt and Landeweerd (1974) on a laboratory heater and by B. West and Clark (1974) on a distillation column in a computer-controlled pilot plant. This work further confirms the importance of the open-loop strategy.

Crossman also raised the question of the operator's mental model of the process and investigated the difference in performance between subjects who were given an account of the physics of the plant and those who were simply told to control calibration settings. The performance of the former was much less effective. He concluded that the results cast some doubt on the practice of instructing operators in the physics and chemistry of the process. Similar results were obtained by Attwood and by Kragt and Landeweerd.

Brigham and Laios (1975) have studied manual control of level in a laboratory rig consisting of three tanks in series, with interaction between the levels. The tanks were glass, so that the operator also had feedback of information from intermediate points in the process. Cross-correlation of his control manipulations with level error showed little correlation between the two, indicating that the control was based on predictive rather than feedback strategy.

The effect of the number and types of lag in the process has also been studied. Crossman and Cooke added further lags to their laboratory apparatus by putting additional sheaths round the thermometer and found that control became more difficult and response was more oscillatory. Attwood introduced dead time into his water bath and found a similar effect. Control behaviour on paper machines observed by Crossman, Cooke and Beishon and by Attwood shows similar oscillatory responses.

Manual control of a liquid washing plant has been studied by Spencer (1962). This work highlighted the difficulties of control in the absence of feedback of information on the results of control actions and the wide differences between operators in terms of the control gain which they employ.

The mental load on the operator has been studied by Kitchin and Graham (1961) in an investigation covering some 50 plants. The decision-taking load was analysed under the following five headings: (1) number of factors in the situation; (2) complexity of comprehension of each factor; (3) memory; (4) interdependence of factors and (5) delay characteristics of situation. This is somewhat similar to Crossman's description of the factors which make process control difficult, as described earlier.

Another study which involved sampling of the operator's activities and assessment of the mental workload imposed by the work is that done by Daniel, Puffier and Strizenec (1971) on four chemical plants. The Monte Carlo simulation of the workload on the operator has been described by Munro, Martin and Roberts (1968).

There have been a number of studies by ergonomists of industrial control rooms. Examples are those of a hot strip mill by Sell, Crossman and Box (1962), of an Linz-Donau (LD) converter waste heat boiler control room by Sinclair *et al.* (1966) and of nuclear power station control rooms by the Central Electricity Generating Board (1966) and by Whitfield (1969).

Decision-making by the operator has been investigated by Bainbridge *et al.* (1968) in a simulation study of electric arc furnace scheduling. A running commentary, or verbal protocol, was given by the subjects as they performed the task and has since been analysed in detail by Bainbridge (1971, 1972, 1974). This analysis identifies subroutines which the operator uses and attempts to describe the executive programme which organizes these.

An important aspect of this work is the light which it throws on the way in which the operator keeps track of the state of the process and so updates his mental model of it. In general, he tends to predict the future of the process state and then subsequently samples only enough readings to confirm that his prediction was correct. This is in line with other work such as that of Crossman, Cooke and Beishon (1964) referred to earlier. This work has significant implications for displays. Good display facilities allow the operator to survey the state of the process as a whole with minimum effort.

The advent of the process computer has brought profound changes in the work of the operator. A number of investigations have been done (e.g. Vander Schraaf and Strauss, 1964; Bernard and Wujkowski, 1965) on the reaction of process operators to computers. Another such study is that by Dallimonti (1972, 1973), which was particularly concerned with the design of computer facilities.

The problem of system objectives and allocation of function in computer control of a basic oxygen furnace has been discussed by Crawley (1968). He gives as an example of a function that is more appropriately allocated to man the interpretation of the noise signal given by a bomb thermocouple. The point is also made, however, that the optimal allocation of function changes continuously as technology progresses.

The difficulty of automating certain functions is further illustrated by the work of Ketteringham, O'Brien and Cole (Ketteringham, O'Brien and Cole, 1970; Ketteringham and O'Brien, 1974) on the scheduling of soaking pits using a man–computer interactive system. Problems of providing all the necessary information to the computer and of complexity in the decision-making make it difficult to automate this function, but it is possible to provide computer facilities, which by storage of large amounts of information, the use of predictive models and the provision of appropriate displays, greatly assist the operator to make decisions. The work involved simulation using a realistic interface and actual steel works schedulers. The problem is very similar to that of air traffic control, which has been extensively investigated in human factors.

The importance of organizational and social factors is shown by the work of Engelstad (1970), who investigated these in a paper mill. The work revealed that individuals tended to operate too much in isolation and to have goals that were not necessarily optimal as far as the system was concerned. It sought to encourage communication by treating the control room as an information and control centre, which all concerned should use, and by designing jobs to give greater variety, responsibility, learning opportunity and wholeness. Other workers too have commented on the losses that can occur in continuous flow processes, if there are poor relationships between the men controlling the process at different points.

Other studies have been concerned with task analysis, fault administration, displays, selection and training and human error. These topics are considered below.

14.6 Allocation of Function

As already emphasized, human factors has at least as important a role to play in matters of system design, such as allocation of function as in those of detailed design. The classic approach to allocation of function is to list the functions which machines perform well and those which men perform well and to use this as a guide. One of the original lists was compiled by Fitts (1962) and such a list is often referred to as a 'Fitts' list'. However, this approach needs some qualification. As Fitts pointed out later, the functions which should be allocated to man are not so much those which he is good at as those which it is best from the system point of view that he perform, which is slightly different. The question of motivation is also important. De Jong and Köster (1971) have given a similar type of list showing the functions which man is motivated to perform. Further accounts of allocation of function is given by H.E. Price (1985) and Kantowitz and Sorkin (1987). Particularly important in relation to loss prevention are functions concerned with fault administration, fault diagnosis, plant shut-down and malfunction detection.

14.7 Information Display

Once the task has been defined, it is possible to consider the design of displays. Information display is an important problem, which is intensified by the increasing density of information in modern control rooms. The traditional display is the conventional control panel. Computer graphics now present the engineer with a more versatile display facility, offering scope for all kinds of display for the operator, but it is probably fair to say that he is somewhat uncertain what to do with it.

The first thing that should be emphasized is that a display is only a means to an end, the end being improved performance by the operator in executing some control function. The proper design of this function in its human factors aspects is more important than the details of the display itself. Some types of display that may be provided are listed in Table 14.5.

The provision of displays that the operator deliberately samples with a specific object in view is only part of the problem. It is important also for the display system to cater both for his characteristic of acquiring information 'at a glance' and for his requirement for information redundancy. There is a need, therefore, for the development of displays that allow the operator to make a quick and effortless survey of the state of the system. As already described, the operator updates his knowledge of system state by predicting forward, using a mental model of the process and sampling key readings to check that he is on the right lines. He needs a survey display to enable him to do this.

This need still exists even where other facilities are provided. Facilities, such as alarm systems are based on a 'management by exception' approach, which is essential if the large amounts of information are to be handled. But when the exceptional condition has been detected, the operator must deal with it and for this he needs knowledge of the state of the process, which a survey display provides. A display of system state also allows the operator to use his ability to recognize patterns. This aspect is considered below.

Table 14.5 *Some displays for the process operator*

- Displays of flow and mimic diagrams
- Displays of current measurements, other variables, statuses (other variables include indirect measurements, valve positions, etc.)
- Displays of trends of measurements, other variables, statuses
- Displays of control loop parameters
- Displays of alarms
- Displays of reduced data (e.g. histograms, quality control charts, statistical parameters)
- Displays of system state (e.g. mimic diagrams, 'status *array*', 'surface' and polar plots)
- Displays for manual control (e.g. predictive displays)
- Displays for alarm analysis
- Displays for sequential control
- Displays for scheduling and game-playing
- Displays for valve sequencing
- Displays for protective system checking
- Displays of maloperation
- Displays for malfunction detection
- Command displays

14.7.1 Regular instrumentation

It will be apparent from the foregoing that the conventional control panel has certain virtues. The panel shown in Figure 14.4 is typical of a modern control panel. The conventional panel does constitute a survey display, in which the instruments have spatial coding, from which the operator can obtain information at a glance and on which he can recognize patterns. These are solid advantages not to be discarded lightly. This is only true, however, if the density of information in the panel is not allowed to become too great. The advantages are very largely lost if it becomes necessary to use dense blocks of instruments which are difficult to distinguish individually.

An important individual display is the chart recorder. A trend record has many advantages over an instantaneous display. As the work of Crossman, Cooke and Beishon (1964) shows, it assists the operator to learn the signal characteristics and facilitates his information sampling. Both Attwood (1970) and B. West and Clark (1974) found that recorders are useful to the operator in making coarse adjustments of operating point, while the latter authors also noted the operator's use of recorders in handling fault conditions. Anyakora and Lees (1972a) have pointed out the value of recorders in enabling the operator to learn the signal characteristics and so recognize instrument malfunctions.

14.7.2 Computer consoles

The computer console presents a marked contrast to conventional instrumentation. This is illustrated with particular starkness in Figure 14.5(a), which shows the console of the original ICI direct digital control (DDC) computer. Some of the features of ergonomic importance in this panel are: (1) specific action is required to obtain a display; (2) there is no spatial coding and the coding of the information required has to be remembered or looked up; (3) only one variable is displayed at a time; (4) only the instantaneous value of the variable is displayed and (5) the presentation is digital rather than analogue.

This is a revolutionary change in the operator's interface. While there is, among engineers, a general awareness that the change is significant, its detailed human factors implications are not so well appreciated. The subsequent refinement of process computer consoles and the introduction of computer graphics have somewhat mitigated these features. A more modern computer console is shown in Figure 14.5(b). Moreover, the facilities that the computer offers in functions such as alarm monitoring or sequential control are powerful new aids to the operator.

It remains true, however, that the transition from the conventional panel to the computer console involves some

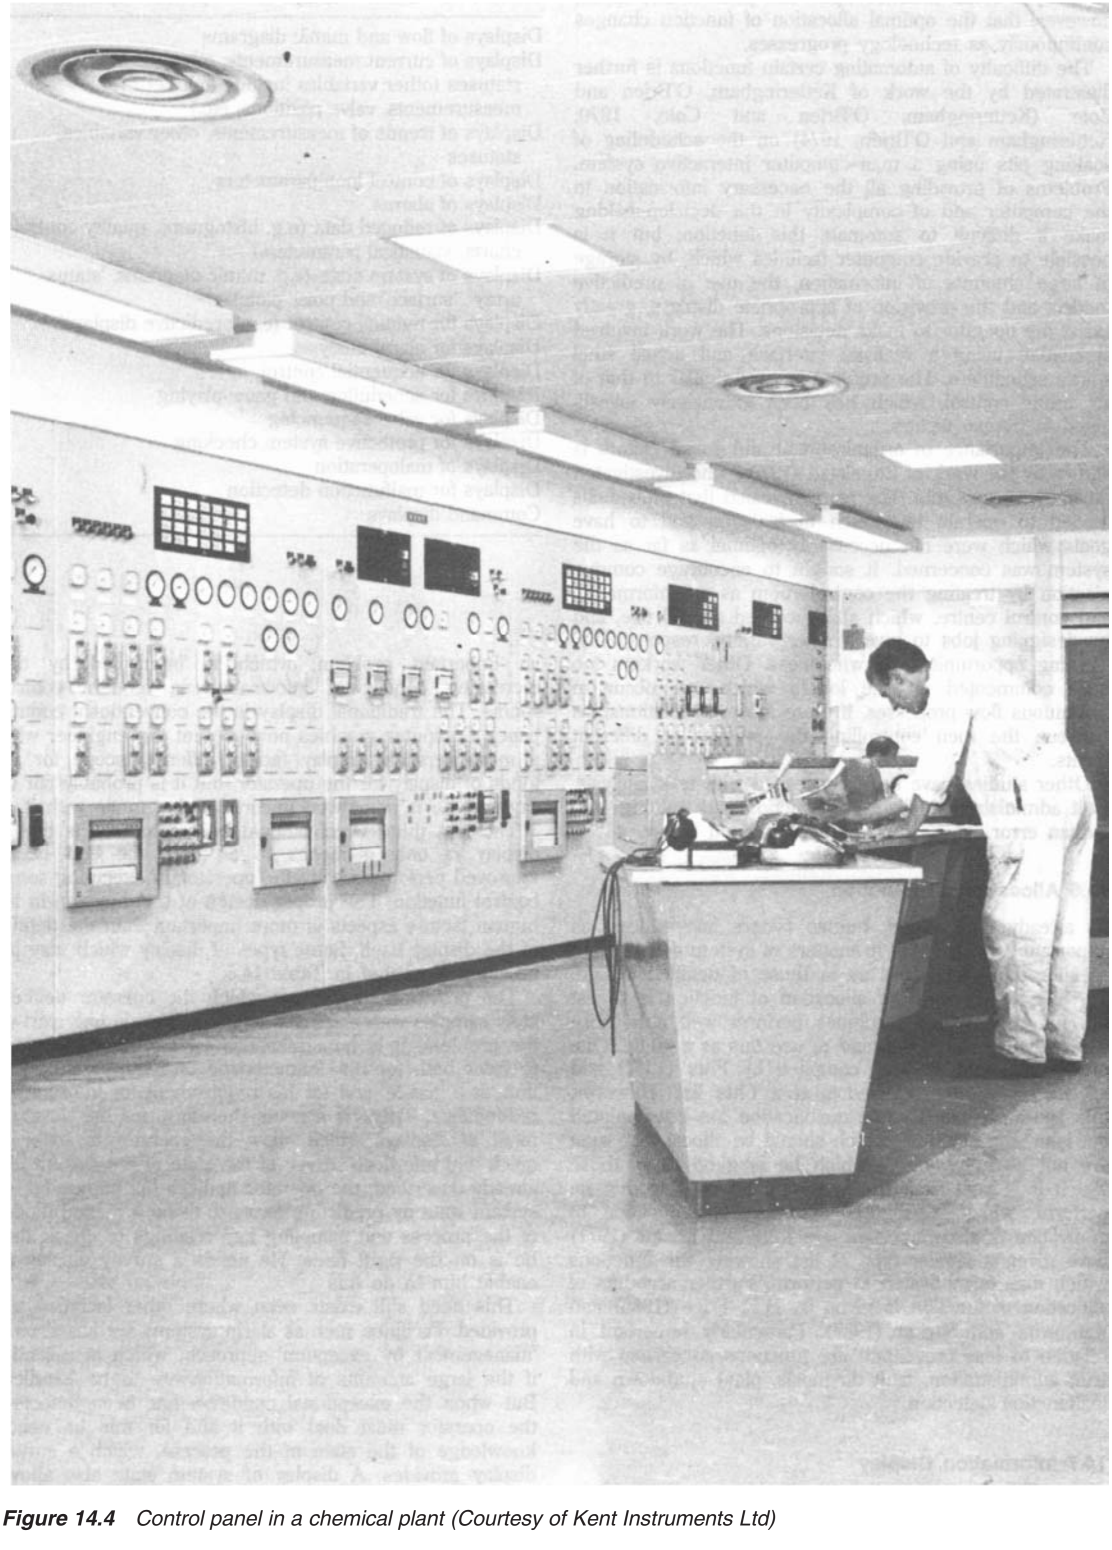

Figure 14.4 Control panel in a chemical plant (Courtesy of Kent Instruments Ltd)

serious human factors losses, particularly in information display. This does not necessarily mean that the change should not be made. Conventional panels are expensive and lose much of their advantage if the information density becomes too high. Computers offer some very worthwhile additional facilities. But the change should at least be made in the full awareness of its implications and with every effort to restore in the new system the characteristic advantages of the old.

14.8 Alarm Systems

As stated in the previous chapter, the progress made in the automation of processes under normal conditions has focused attention on the monitoring and handling of abnormal or fault conditions. It is the function of the control system to prevent, if possible, the development of conditions which will lead to plant shut-down, but to carry out the shut-down if necessary. The responsibility for averting shut-down conditions falls largely to the operator. The principal automatic aid provided to assist him is the alarm system. Alarm systems are an extremely important but curiously neglected and often unsatisfactory aspect of process control.

An alarm system is a normal feature of conventional control systems. If a process variable exceeds specified limits or if an equipment is not in a specified state, an alarm is signalled. Both audible and visual signals are used.

Accounts of alarm systems include those by E. Edwards and Lees (1973), Andow and Lees (1974), Hanes (1978), Swain and Guttman (1983), Schellekens (1984), Shaw (1985) and the Center for Chemical Process Safety (CCPS, 1993/14). There have also been investigations of the operation of alarm systems, as described below.

14.8.1 Basic alarm systems

The traditional equipment used for process alarms is a lightbox annunciator. This consists of a fascia, or array, of separate small rectangular coloured glass panels, behind each of which there is a lamp that lights up if the alarm is active. Each panel is inscribed with an alarm message. The panels are colour coded, usually with red being assigned the highest priority. This visual display is complemented by a hooter. When a new alarm occurs, the hooter sounds and the fascia light flashes until the operator acknowledges receipt by pressing a button. The panel then remains lit until the alarm condition is cleared by operator action or otherwise, as described below.

There are a number of variations on this basic system. An account of some of these is given by Kortland and Kragt (1980a). One is a two-level hierarchical arrangement in which there is a central fascia and a number of local

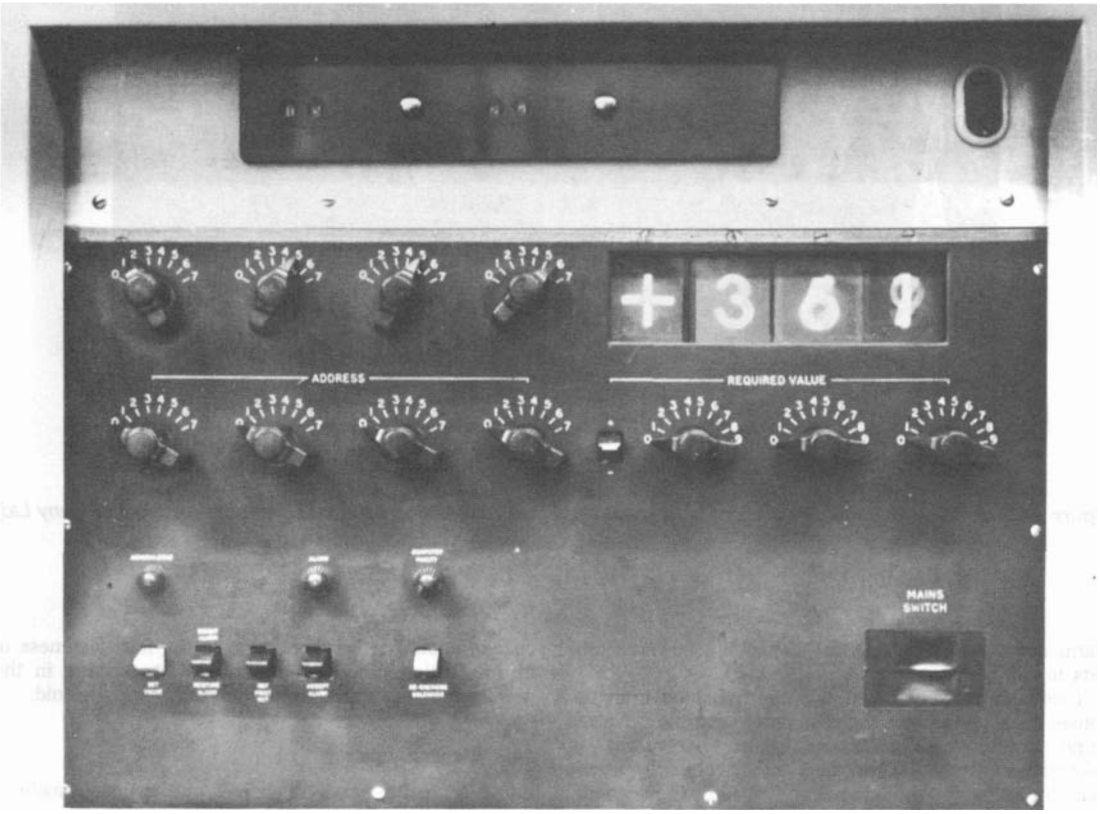

Figure 14.5(a) *Control panel of the direct digital control (DDC) computer on ICIs ammonia soda plant at Fleetwood, 1961 (Courtesy of Ferranti Ltd and Imperial Chemical Industries Ltd)*

Figure 14.5(b) *Control panel and display of Foxboro Intelligent Automation computer system (Foxboro Company Ltd)*

fascias, the light on the former indicating the number of the local fascia on which the alarm has occurred. These authors also describe hierarchical systems with additional levels. Another arrangement is a mimic panel with alarms located at the relevant points on the flow diagram.

In computer-controlled systems alarms are generally printed out on hard copy in the time sequence in which they occur and are also displayed on the VDU. On the latter there are numerous display options, some of which are detailed by Kortlandt and Kragt. One is the use of a dedicated VDU in which the alarms come up in time sequence, as on the printer. Another is a group display in which all the alarms on an item of equipment are shown with the active alarms(s) highlighted. Another is a mimic display akin to the hardwired mimic panel.

The occurrence of an alarm is normally accompanied by an audible warning in the form of the sounding of the hooter and a visual warning in the form of a flashing light. On a computer system, the sound of the printer serves as another form of audible signal. The operator 'accepts' the alarm by depressing the appropriate pushbutton.

Annunciator sequences are given in ISA Std S18.1: 1975 *Annunciator Sequences and Specifications,* which recognizes three types: (1) automatic reset (A), (2) manual reset (M) and (3) ringback (R). Automatic reset returns to the normal state automatically once the alarm has been acknowledged and the process variable has returned to its normal state. Manual reset is similar except that return to the normal state requires operation of the manual reset pushbutton. Ringback gives a warning, audible and/or visual, that the process condition has returned to normal.

There are alarms on the trips in the Safety Interlock System (SIS). Operation of a trip is signalled by an alarm. The SIS alarm system, like the rest of the SIS, should be separate from the basic process control system (BPCS).

In a conventional instrument system, the hardware used to generate an alarm consists of a sensor, a logic module and the visual display. The sensor and the logic elements may be separate or may be combined in an alarm switch. Such combined switches are referred to as flow switches, level switches and so on.

In a computer-based system there are two approaches that may be used. In one, the computer receives from the sensor an analogue signal to which the program applies logic to generate the alarm. In the other, the signal enters in digital form. The latter can provide a cheaper system, but reduces the scope for detection of instrument malfunction.

Some basic requirements for an alarm are that it attracts the attention of the operator, that it be readily identifiable and that it indicate unambiguously the variable which has gone out of limit.

14.8.2 Alarm system features

As just described, an alarm system is a normal feature of process computer control. The scanning of large numbers of process variables for alarm conditions is a function very suitable for a computer. Usually the alarm system represents a fairly straightforward translation of a conventional system on to the computer. Specified limits of process variables and states of equipment are scanned and resulting alarms are displayed on a typewriter, necessarily in time order, and also on a VDU, where time order is one of a number of alarm display options.

The process computer has enormous potential for the development of improved alarm systems, but also brings with it the danger of excess. There is first the choice of variables which are to be monitored. It is no longer necessary for these to be confined to the process variables measured by the plant sensors. In addition, 'indirect' or 'inferred' measurements calculated from one or more process measurements may be utilized. This considerably increases the power of the alarm system.

Then there are a number of different types of alarm which may be used. These include absolute alarms, relative, deviation or set-point alarms, instrument alarms and rate-of-change alarms, in which the alarm limits are, respectively, absolute values of the process variable, absolute or proportional deviations of the process variable from the loop set-point, zero or full-scale readings of the instrument and rate of change of the process variable.

The level at which the alarm limits are set is another important feature. Several sets of alarm limits may be put on a single variable to give different degrees of alarms such as early warning, action or danger alarms. The alarms so generated may be ordered and displayed in various ways, particularly in respect of the importance of the variable and the degree of alarm.

The conventional alarm system, therefore, is severely limited by hardware considerations and is relatively inflexible. The type of alarm is usually restricted to an absolute alarm. The computer-based alarm system is potentially much more versatile.

The alarm system, however, is frequently one of the least satisfactory features of the control system. The most common defect is that there are too many alarms and that they stay active for too long. As a result, the system tends to become discredited with the operator, who comes to disregard many of the alarm signals and may even disable the devices which signal the alarms.

Computer-based alarm systems also have some faults peculiarly their own. It is fatally easy with a computer to have a proliferation of types and degrees of alarm. Moreover, the most easily implemented displays, such as time-ordered alarms on a typewriter or a VDU, are inferior to conventional fascias in respect of aspects such as pattern recognition.

The main problem in alarm systems is the lack of a clear design philosophy. Ideally, the alarm system should be designed on the basis of the information flow in the plant and the alarm instrumentation selected and located to maximize the information available for control, bearing in mind instrumentation reliability considerations. In fact, an alarm system is often a collection of subsystems specified by designers of particular equipment with the addition of some further alarms.

An alarm system is an aid for the operator. An important but often neglected question is therefore what action he is required to take when an alarm is signalled.

There are also specific problems which cause alarms to be numerous and persistent. One is the confusion of alarms and statuses. A status merely indicates that an equipment is in a particular state, for example that an agitator is not running. An alarm, by contrast, indicates that an equipment is in a particular state and should be in a different one, for example, that an agitator is not running but should be. On most plants there are a number of statuses that need to be displayed, but there is frequently no separate status display and so the alarm display has to be used. As a result, if a whole section of plant is not in use, a complete block of alarms may be permanently up on a display, even though these are not strictly alarm conditions. The problem can be overcome by the use of separate types of display, for example yellow for alarms, white for statuses, in conventional systems and by similar separate displays in computer systems, but often this is not done.

A somewhat similar problem is the relation of the alarms to the state of the process. A process often has a number of different states and a signal which is an alarm in one state, for example normal operation, is not a genuine alarm in another, as with, say, start-up or maintenance. It may be desirable to suppress certain alarms during particular states. This can be done relatively easily with a computer but not with a conventional system. It should be added, however, that suppression of alarms needs to be done with care, each case being considered on its merits.

On most plants there is an element of sequential control, for example start-up. As long as no fault occurs, control of the sequence is usually straightforward, but the need to allow for faults at each stage of the sequence can make sequential control quite complex. With sequential operations, therefore, the sequential control and alarm systems are scarcely separable. A computer is particularly suitable for performing sequential control.

The state of the art in alarm system design is not satisfactory, therefore. In conventional systems this may be ascribed largely to the inflexibility of the hardware, but the continuance of the problem in computer systems suggests that there are also deficiencies in design philosophy.

The process computer provides the basis for better alarm systems. It makes it possible to monitor indirect measurements and to generate different types and degrees of alarm, to distinguish between alarms and statuses and to adapt the alarms to the process state. It is also possible to provide more sophisticated facilities such as analysis of alarms, as described below. However, there is scope for great improvement in alarm systems even without the use of such advanced facilities.

14.8.3 Alarm management

It will be apparent from the foregoing that in many systems some form of alarm management is desirable. Alarm management is discussed by the CCPS (1993/14). Approaches to the problem include (1) alarm prioritization and segregation, (2) alarm suppression and (3) alarm handling in sequential operations.

Alarms may be ranked in priority. The CCPS suggests a four level system of prioritization in which critical alarms are assigned to Level 1 and important but non-critical alarms to Level 2, and so on. The alarms are then segregated by level.

With regard to alarm suppression, the CCPS describes two methods. One is conditional suppression, which may be used where an alarm does not indicate a dangerous situation and where it is a symptom which can readily be deduced from the active alarms. The other is flash suppression, which involves omitting the first stage in the alarm annunciation sequence, namely the sounding of the hooter and flashing of the fascia lamp. Instead, the alarm is shown illuminated, as if already acknowledged.

As already discussed, sequential operations such as plant start-up tend to activate some alarms. With a computer-based system arrangements may be made for appropriate suppression of alarms during such sequences.

Alarm management techniques need to be approached with caution, taking account of the overall information needs of the operator, of the findings of research on the operation of alarm systems and of other factors such as the fact that an alarm which is less important in one situation may be more so in another.

14.8.4 Alarm system operation

Studies of the operation of process alarm systems have been conducted by Seminara, Gonzalez and Parsons (1976) and Kragt and co-workers (Kortlandt and Kragt, 1980a,b; Kragt, 1983, 1984a,b; Kragt and Bonten, 1983; Kragt and Daniels, 1984).

The work of Seminara, Gonzalez and Parsons (1976) was a wide-ranging study of various aspects of control room design. On alarms, two features found by these authors are of particular interest. One is that, in some cases, the number of alarms was some 50–100 per shift, and in one case 100 in an hour. The other is the proportion of false alarms, for which operator estimates ranged from 'occasional', through 15% and 30%, up to 50%.

Kortland and Kragt (1980a,b) studied five different control room situations, by methods including questionnaire and observation, two of the principal investigations being in the control rooms of a fertilizer plant and a high pressure polyethylene plant. On both plants, the authors identified two confusing features of the alarms. One was the occurrence of oscillations in which the measured values moved back and forth across the alarm limit. The other was the occurrence of clusters of alarms. The number of alarms registered on the two plants was as follows:

	Fertilizer plant	*Polyethylene plant*
Observation period (h)	63	70
Single alarms, not occurring during clusters or oscillations	816	1714
Single alarms during clusters or oscillations	280[a]	325[a]
Signals during oscillations	410[a]	NA
Signals from clusters	1288[a]	1300[a]
Total	2794	3339

[a] Estimated from analysis of the data.

The authors suggest that oscillations can be overcome by building in hysterisis, which is indeed the normal approach, and that clusters may be treated by grouping and suppression of alarms. The intervals between successive signals, disregarding oscillations and clusters, were analysed and found to fit a log–normal distribution. The response of the operators to the alarms was as follows:

	Fertilizer plant	*Polyethylene plant*
Signal followed by action (%)	47	43
Action followed by signal (%)	46	50
No action (%)	7	7

Thus about half the alarms were actually feedback cues on the effects of action taken by the operators, who in many cases would have been disturbed not to receive such a signal. Further evidence for this is given by the fact that on the fertilizer plant 55% of the alarm signals were anticipated. On this plant, the operators judged the importance of the signals as follows: important 13%, less important 36%, not important 43% and unknown 8%.

Kragt (1984a) has described an investigation of the operator's use of alarms in a computer-controlled plant. The main finding was that sequential information presentation is markedly inferior to simultaneous presentation.

14.9 Fault Administration

As already stated, it is the function of the control system to avert the development of conditions which may lead to shut-down, but if necessary to execute shut-down. Generally, there are automatic trip systems to shut the plant down, but the responsibility of avoiding this situation if at all possible falls to the operator.

Fault administration can be divided into three stages: fault detection, fault diagnosis and fault correction or shut-down. For the first of these functions, the operator has a job aid in the form of the alarm system, while fault correction in the form of shut-down is also frequently automatic, but for the other two functions, fault diagnosis and fault correction less drastic than shut-down, he is largely on his own.

14.9.1 Fault detection

The alarm system represents a partial automation of fault detection. The operator still has much to do, however, in detecting faults. This is partly a matter of the additional sensory inputs such as vision, sound and vibration that the operator possesses. But it is also partly due to his ability to interpret information, to recognize patterns and to detect instrument errors.

14.9.2 Fault diagnosis

Once the existence of some kind of fault has been detected, the action taken depends on the state of the plant. If it is in a safe condition, the next step is diagnosis of the cause. This is usually left to the operator. The extent of the diagnosis problem may vary considerably with the type of unit. It has been suggested, for example that whereas on a crude distillation unit the problem is quite complex, on a hydrotreater it is relatively simple (Duncan and Gray, 1975a).

There are various ways in which the operator may approach fault diagnosis. Several workers have observed that an operator frequently seems to respond only to the first alarm which comes up. He associates this with a particular fault and responds using a rule-of-thumb. This is an incomplete strategy, although it may be successful in quite a high proportion of cases, especially where a particular fault occurs repeatedly.

An alternative approach is pattern recognition from the displays on the control panel. The pattern may be static or dynamic. The static pattern is obtained by instantaneous observation of the displays, like a still photograph. The operator then tries to match this pattern with model patterns or templates for different faults. Duncan and Shepherd (1975b) have developed a technique for training in fault diagnosis in which some operators use this method. The alternative, and more complex, dynamic pattern recognition involves matching the development of the fault over a period of time.

Another approach is the use of some kind of mental decision tree in which the operator works down the paths of the tree, taking particular branches, depending on the instrument readings. Duncan and Gray (1975a) have used this as the basis of an alternative training technique. Yet another method is the active manipulation of the controls and observation of the displays to determine the reaction of the plant to certain signals. Closely related to this is the situation where no fault has been detected, but the operator is already controlling the process when he observes some unusual feature and continues his manipulation to explore this condition.

Whatever approach is adopted by the operator, fault diagnosis in the control room is very dependent on the instrument readings. It is therefore necessary for the operator to check whether the instruments are correct. The problem of checking to detect malfunctions is considered later, but attention is drawn here to its importance in relation to fault diagnosis.

These different methods of fault diagnosis have important implications for aspects such as displays and training. The conventional panel assists the recognition of static patterns, whereas computer consoles generally do not. Chart recorders aid the recognition of dynamic patterns and instrument faults. The question of training for fault diagnosis is considered later.

Fault diagnosis is not an easy task for the operator. There is scope, therefore, for computer aids, if these can be devised. Some developments on these lines are described below.

14.9.3 Fault correction and shut-down

When, or possibly before, a fault has been diagnosed, it is usually possible to take some corrective action which does not involve shutting the plant down. In some cases, the fault correction is trivial, but in others, such as operating a complex sequence of valves, it is not. Operating instructions are written for many of these activities, but otherwise this is a relatively unexplored area.

Fault correction is one of the activities for which interlocks may be provided. Conventional interlocks were described in the previous chapter and developments in computer software interlocks are outlined below.

Some fault conditions, however, require plant shutdown. Although fault administration has been described in terms of successive stages of detection, diagnosis and correction, in emergency shut-down usually little diagnosis is involved. The shut-down action is triggered directly when it is detected that a critical process limit has been passed.

There are differing philosophies on the problem of allocation of responsibility for shutting down the plant under fault conditions. In some plants, the operator deals with fault conditions with few automatic aids and is thus required to assure both safety and economic operation. In others, automatic protective systems are provided to shut the plant down if it is moving close to an unsafe condition and the operator thus has the economic role of preventing the development of conditions which will cause shut-down.

In a plant without protective systems the operator is effectively given the duty of keeping the plant running if he can, but shutting it down if he must. This tends to create in his mind a conflict of priorities. Usually, he will try to keep the plant running if he possibly can and, if shut-down becomes necessary, he may tend to take action too late. Mention has already been made of the human tendency to gamble on beating the odds. There are numerous case histories which show the dangers inherent in this situation (Lees, 1976b).

The alternative approach is the use of automatic protective systems to guard against serious hazards in the plant. The choice is made on the basis of quantitative assessment of the hazards. This philosophy assigns to the operator the essentially economic role of keeping the plant running.

Although the use of protective systems is rapidly increasing, the process operator usually retains some responsibility for safe plant shut-down. There are a number of reasons for this. In the first place, although high integrity protective systems with 2/3 voting are used on particularly hazardous processes (R.M. Stewart, 1971), the majority of trip systems do not have this degree of integrity. The failure rate of this simple 1/1 trip system has been quoted as 0.67 faults/year (Kletz, 1974d).

Protective systems have other limitations that apply even to high integrity systems. One is that it is very difficult to foresee and design for all possible faults, particularly those arising from combinations of events. It is true, of course, that even if a process condition arises from an unexpected source a protective system will usually handle it safely. But there remains a residual of events, usually of low probability, against which there is no protection, either because they were unforeseen or because their probability was estimated as below the designer's cut-off level.

Another problem is that a protective system is only partially effective against certain types of fault, particularly failure of containment. In such an event, the instrumentation can initiate blowdown, shut-off and shut-down sequences, but while this may reduce the hazardous escape of materials, it does not eliminate it.

Yet another difficulty is that many hazards occur not during steady running but during normal start-up and shut-down or during the period after a trip and start-up from that condition. A well designed protective system caters, of course, for these transitional regimes as well as continuous operations. Nevertheless, this remains something of a problem area. Even with automatic protective systems, therefore, the process operator tends to retain a residual safety function. His effectiveness in performing this is discussed later.

14.10 Malfunction Detection

Another aspect of the administration of fault conditions by the control system is the detection of malfunctions, particularly incipient malfunctions in plant equipment and instruments. These malfunctions are distinguished from alarms in that although, they constitute a fault condition of some kind, they have not as yet given rise to a formal alarm.

Malfunction detection activities are not confined to the control system, of course. Monitoring of plant equipment by engineers, as described in Chapter 19, is a major area of work, usually independent of the control system. Insofar as the control system does monitor malfunctions, however, this function is primarily performed by the operator. The contribution of the computer to malfunction detection is considered later.

Detection of instrument malfunction by the operator has been investigated by Anyakora and Lees (1972a). In general, malfunction may be detected either from the condition of an instrument or its performance. Detection from condition is illustrated by observation on the plant of a leak on the impulse line to a differential pressure transducer or of stickiness on a control valve. Detection from performance is exemplified by observation in the control room of an excessively noise-free signal from the transducer or of an inconsistency between the position of a valve stem and the measured flow for the valve. Most checks on instrument condition require the operator to visit the equipment and use one of his senses to detect the fault. Most performance checks can be made from the control room by using instrument displays and are based on information redundancy.

Some of the ways in which the operator detects malfunction in instruments are illustrated by considering the way in which he uses for this purpose one of his principal detection aids – the chart recorder. Some typical chart records are shown in Figure 14.6. The operator detects error in such signals by utilizing some form of redundant information and making a comparison. Some types of redundant information are (1) *a priori* expectations, (2) past signals of instrument, (3) duplicate instruments, (4) other instruments and (5) control valve position.

Thus it may be expected *a priori* that an instrument reading will not go 'hardover' to zero or full scale, that it will give a 'live' rather than a 'dead' zero, that it will exhibit a certain noise level, that its rate of change will not exceed a certain value and that it is free to move within the full scale of the instrument. On the basis of such expectations, the operator might diagnose malfunction in the signals shown in Figures 14.6(b–f). However, the firmness of such expectations may vary with the plant operating conditions. For example, during start-up, zero readings on some instruments may be correct.

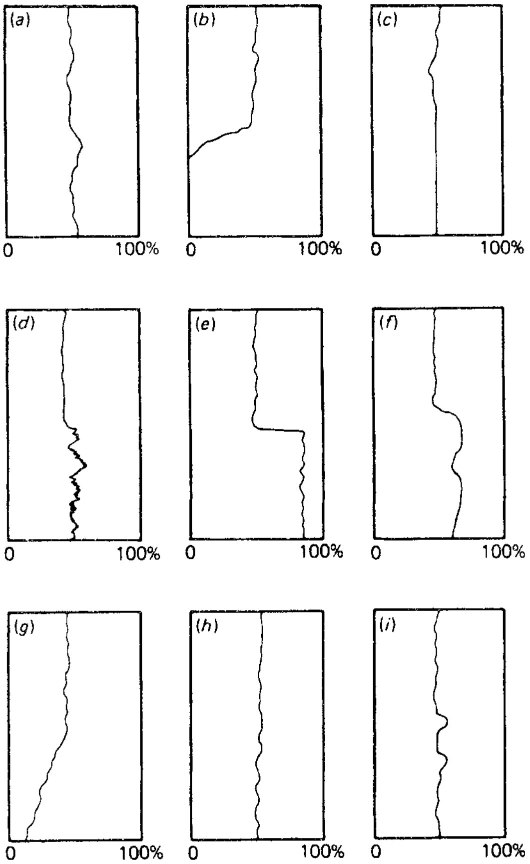

Figure 14.6 *Typical chart recorder displays of measurement signals (Anyakora and Lees, 1972a): (a) normal reading; (b) reading zero; (c) reading constant; (d) reading erratic; (e) reading suddenly displayed; (f) reading limited below full scale; (g) reading drifting; (h) reading cycling; (i) reading with unusual features (Courtesy of the Institution of Chemical Engineers)*

It may not be possible to decide *a priori* what constitutes a reasonable expectation. The level of noise, for example tends to vary with the individual measurement. In this case, the operator must use his knowledge of the range of variation of the noise on a particular instrument in the past. Thus, Figures 14.6(c) and 14.6(d) might or might not indicate malfunction.

If there is a duplicate instrument, then detection of the fact that one of the instruments is wrong is straightforward, although it may not be possible to say which. However, duplication is not usual in the normal instrument systems that are of primary concern here. On the other hand, near duplication is quite common. For example, the flow of a reactant leaving a vaporizer and entering two parallel reactors may be measured at the exit of both the vaporizers and the reactors, and the flow measurement systems provide a check on each other.

What constitutes a reasonable signal may depend on the signals given by other instruments. Thus, although a signal that exhibits drift, such as that in Figure 14.6(g), may appear incorrect, a check on other instruments may show that it is not.

Some types of variation in a signal, such as a change in the noise level, appear easy to detect automatically. Others, such as that shown in Figure 14.6(i), are probably more difficult, especially if their form is not known in advance. Here the human operator with his well developed ability to recognize visual patterns has the advantage.

There are a number of ways in which the readings of other instruments can serve as a check. Some of these are (1) near-duplication, (2) mass and heat balances, (3) flow–pressure drop relations and (4) consistent states. This last check is based on the fact that certain variables are related to each other and at a given state of operation must lie within certain ranges of values.

The position of control valves also provides a means of checking measurements. This is most obvious for flow measurement but it is by no means limited to this.

These remarks apply essentially to measuring instruments, but checks can also be developed for controllers and control valves. A general classification of instrument malfunction diagnoses by the operator is shown in Table 14.6.

Many of the checks described do not show unambiguously that a particular instrument is not working properly; often they indicate merely that there is an inconsistency that needs to be explored further. However, this information is very important.

Another kind of information that the operator also uses in checking instruments is his knowledge of the probabilities of failure of different instruments. He usually knows which have proved troublesome in the past.

The detection of instrument malfunction by the process operator is important for a number of reasons. Instrument malfunctions tend to degrade the alarm system and introduce difficulties into loop control and fault diagnosis. Their detection is usually left to the operator and it is essential for him to have the facilities to do this. This includes appropriate displays and may extend to computer aids.

Table 14.6 *General classification of methods of instrument malfunction detection (Anyakora and Lees, 1972a) (Courtesy of the Institution of Chemical Engineers)*

Measuring instruments	
M1	Measurement reading zero or full scale
M1.1	Reading zero
M1.2	Reading full scale
M2	Measurement reading noise or dynamic response faulty
M2.1	Reading constant
M2.2	Reading erratic
M2.3	Reading sluggish
M3	Measurements reading displaced suddenly
M3.1	Reading fell suddenly
M3.2	Reading rose suddenly
M4	Measurement reading limited within full scale
M4.1	Reading limited above zero
M4.2	Reading limited below full scale
M5	Measurement reading drifting
M5.1	Reading falling
M5.2	Reading rising
M6	Measurement reading inconsistent with duplicate measurement
M7	Measurement reading inconsistent with one other measurement
M7.1	Reading inconsistent with near-duplicate measurement
M7.2	Reading inconsistent with level-flow integration
M7.3	Reading otherwise inconsistent
M8	Measurement reading inconsistent with simple model
M8.1	Reading inconsistent with mass balance
M8.2	Reading inconsistent with heat balance
M8.3	Reading inconsistent with flow–pressure drop relations
M8.4	Reading otherwise inconsistent
M9	Measurement reading inconsistent with plant operating state
M9.1	Reading zero but variable not zero
M9.2	Reading not zero but variable zero
M9.3	Reading low
M9.4	Reading high
M9.5	Reading otherwise inconsistent
M10	Measurement reading inconsistent with control valve position
M10.1	Reading (flow) zero with valve open
M10.2	Reading (flow) not zero with valve closed
M10.3	Reading otherwise inconsistent
M11	Measurement reading periodic or cycling
M12	Measurement reading showing intermittent fault
M13	Measurement reading faulty
M14	Measurement instrument tested by active tests
M15	Measuring instrument condition faulty
Control action and controllers	
C1	Control action faulty
C1.1	Control erratic
C1.2	Control sluggish
C1.3	Control cycling
C1.4	Control unstable

14.11 Computer-based Aids

There are some functions that the computer can perform automatically, whereas there are others which at present are performed by the operator, but for which computer aids have been, or may be, developed to assist him. Some computer-based aids to assist the operator which have been described include:

(1) system state display;
(2) alarm diagnosis;
(3) valve sequencing;
(4) malfunction detection.

The provision of such an aid is not solely a matter of engineering. There is an essential human factors angle also. A facility that is intended to assist the operator to perform a particular function, as opposed to replacing him by executing that function automatically, must conform to the requirements of the operator.

The main account of computer-based aids is given in Chapter 30. The treatment at this point is confined to consideration of one particular aid, computer-based alarm diagnosis. This, is in its own right, one of the most

  - C1.5 Control error excessive
  - C1.6 Control otherwise faulty
- C2 Controller performance faulty
- C3 Controller tested by active tests
- C4 Controller condition faulty

Control valves and valve positioners

- V1 Valve position inconsistent with signal to valve (this requires independent measurement of position)
- V2 Valve position inconsistent with flow (but not necessarily flow measurement)
  - V2.1 Valve passing fluid when closed
  - V2.2 Valve not passing fluid when open
  - V2.3 Valve position otherwise inconsistent with flow measurement
  - V2.4 Valve position inconsistent with one other measurement
  - V2.5 Valve position inconsistent with simple model
- V3 Valve not moving
  - V3.1 Valve stays closed
  - V3.2 Valve stays open
  - V3.3 Valve stays part open
- V4 Valve movement less than full travel
  - V4.1 Valve not closing fully
  - V4.2 Valve not opening fully
  - V4.3 Valve travel otherwise limited
- V5 Valve movement faulty
  - V5.1 Valve movement erratic
  - V5.2 Valve movement sluggish
  - V5.3 Valve movement otherwise faulty
- V6 Valve movement cycling
- V7 Valve or positioner performance faulty
- V8 Valve or positioner tested by active tests
- V9 Valve or positioner condition faulty

significant aids, but in addition it also illustrates the human factors problems which can arise.

14.11.1 Alarm analysis

In some process systems, the number of alarms that can be generated is large and it seems desirable to help the operator to assimilate these by an analysis of the alarms using a process computer. The problem is most acute in nuclear power stations and alarm analysis has been pioneered by the nuclear industry. Computer-based alarm systems, which include alarm analysis, were installed on the nuclear reactors at Oldbury (Kay, 1966; Kay and Heywood, 1966; Patterson, 1968) and at Wylfa (Jervis and Maddock, 1965; Welbourne, 1965, 1968).

The number of alarms in the systems described is very large. At Wylfa, for example, there are two reactors with some 6000 fuel channels, 2700 mixed analogue inputs and 1900 contacts on each reactor. These systems, therefore, represent an extreme form of the problem of potential information overload that is always encountered when a wide span of control is concentrated in one centralized control station. Some kind of information reduction is required if overload is to be avoided. Thus, alarm analysis was undertaken not as a desirable optional facility but rather as a matter of necessity. There are two possible objectives of alarm analysis that are related but distinct. The weaker one is to interpret fresh alarms as they appear in the real-time situation, whilst the stronger one is to identify the original, usually mechanical, cause.

On the Oldbury system, as described by Patterson (1968), the method of analysis is 'alarm tree analysis' in which the propagation of a fault is followed up through successively higher levels of the tree. A prime cause alarm is an active alarm at the lowest level. All important alarms are displayed together, with the cause alarm at the head of the group and the effect alarms beneath it. Other associated effect alarms that are not considered important for the operator's understanding of the fault are not displayed but are 'suppressed' or 'inhibited' by 'darkening'.

Initially, the alarms displayed were the prime cause alarms and the uninhibited alarms; the highest level alarm reached was not shown, unless it was an uninhibited alarm. It was found, however, that this system led to an excessive demand for more uninhibited alarms. It was, therefore, modified so that the highest alarm reached is always displayed. The operator thus knows how far the fault has propagated.

The analysis method at Wylfa, as described by Welbourne (1965, 1968) is rather similar. When a fresh alarm occurs, it is classed as a prime cause alarm, unless it could have been caused by an existing prime cause alarm, in which case it is classed merely as a new alarm. There are separate VDU displays for prime cause and new alarms. There is, however, no suppression of intermediate alarms.

At Oldbury, in addition to real process alarms based on plant sensors, messages may be generated based on such alarms. If the message relates to a fault, it is in effect a 'deduced alarm'. Similarly, at Wylfa there are 'synthetic' alarms. The number of alarms to be displayed at Oldbury proved to be rather larger than expected. It was necessary to increase the number of 32-line pages of alarms from 3 to 9. The number of alarms is also large at Wylfa, where there is no suppression of alarms.

It is apparent that there are a number of problems in the provision and use of an alarm analysis facility. They fall into two broad categories: those that are concerned with the engineering work involved in conducting a comprehensive analysis, and those that concern the use of the analysis by the operator.

The method of conducting the analysis in the systems described is that a team of experienced engineers studies systematically and in detail the various situations which can occur on the plant and the alarms to which these give rise. The engineering effort in the system described by Patterson was a team of five for 2 years.

As far as concerns process plants, an early exploration was undertaken by Barth and Marleveld (1967), but was not apparently followed through.

One of the main obstacles to the use of an aid such as alarm analysis is the large effort required to create the alarm data structure. It is clear that progress in its application to process plants would be greatly assisted by the development of a systematic and economical method of creating the alarm data structure. By the mid-1970s, there were indications of work in this area (Andow, 1973; Powers and Tompkins, 1974b; Andow and Lees, 1975).

Since that time, as described in Chapter 30, the development of real-time aids to assist the operator in handling fault conditions, including expert system aids, has been an active area of investigation, but progress is perhaps best described as sporadic.

Turning to the human factors aspects, alarm analysis is a facility to assist the operator. It is essential, therefore, to give the fullest consideration to the human factors problems that arise. Otherwise, the engineering effort is largely wasted.

The objective of alarm analysis is principally to assist the operator in handling rarely occurring but seriously hazardous situations. These occur typically as a result not of a single fault but of a combination of faults. If an analysis is to be useful, it must be sufficiently comprehensive to include these low probability but hazardous conditions, and it must do this in such a way as to convince the operator, who may be disinclined initially to believe in the existence of a low probability event or combination of events until he has exhausted the more familiar high probability causes. The point is well put by Rasmussen (1968b):

> It may be extremely difficult, if not impossible, for the designer of a large plant to carry through an analysis that takes into account not only all failures in the plant itself and the instrumentation, but also the combination of failures.
>
> One has to realize that direct automatic identification of the primary fault based on a not completely comprehensive analysis, which assumes that the operator critically evaluates the results of the analysis, involves a great risk of further decreasing that probability that the operator takes into consideration very improbable but hazardous failures not dealt with in the simplified analysis of the designer and thus of the instrumentation.
>
> If one utilizes a simplified analysis of failure conditions in this way, one may therefore be in the paradoxical situation that it is as risky for the operator to trust the analysis too much when it indicates a probable cause of failure as to incline towards distrusting it when it indicates an *a priori* improbable cause.

In addition to this problem of the confidence that the operator can place in the analysis, there is the question of the way in which the results are to be displayed. Moreover, the display of the analysis itself is not the whole of the display problem. A knowledge of the current state of the process is also necessary to the operator when a fault is detected. Both his own diagnosis and his corrective action depend very much on this background information. It is not satisfactory that he should have to begin his evaluation of the process state *ab initio* on detection of a fault before he can take action.

An additional aspect is the phenomenon of operator indecision. It has been found by several workers that an operator may have difficulty in bringing himself to actually take a control action. Thus Bainbridge (1974) describes this situation, which in her work occurred even in a simulation study:

> Another type of poor performance, independent of ability to think about the task, is shown by the subjects who can choose the action to take, considering more and more refined dimensions of this choice, but have difficulty in committing themselves to making it.

It seems reasonable to assume that this inability to come to the point of decision is largely a matter of the confidence that the operator has in his assessment of the situation and in his intended remedial action. This in turn depends to a considerable extent on his knowledge of the state of the process, on information redundancy in the displays, and so on.

14.12 Human Information Processing

At this point, it is necessary to devote some consideration to the topic of human information processing, some appreciation of which is essential to the understanding of modern developments in areas such as training and human error. The task of the process operator is largely one of processing information. An understanding of the characteristics of human information processing in such a task is therefore crucial to the design of his work situation. In particular, it can contribute to the design of the interface and to assessment of human error. The process operator as an information processor is described in *Information Processing and Human–Machine Interaction* (Rasmussen, 1986). The following is a simplified account of this work.

14.12.1 Cognitive task analysis

An account has already been given of the use of task analysis as an aid to understanding the task of the process operator and its role in design of the system and provision of assistance to the operator. Figure 14.7 shows a generalized framework for task analysis in process operation in the form of information processing activities required to pass from one state of knowledge to the next. The left-hand, upwards ladder gives the activities leading to evaluation of some plant state which requires action. The activities are (1) detection, (2) observation, (3) identification, (4) interpretation and (5) evaluation. The right-hand, downwards ladder gives the activities leading to action in response to that state. They are (1) evaluation, (2) interpretation, (3) definition of task, (4) formulation of procedure and (5) execution of procedure. Also shown in the diagram are some of the links that allow bypassing of intermediate stages.

Several different types of information processing are involved. There is analysis of the current state of the system, evaluation both of the current state and of the ultimate goal and planning of the task to be undertaken in response to that state.

14.12.2 Level of abstraction

The operator may think about the system at several different levels of abstraction: (1) physical form, (2) physical function, (3) generic function, (4) abstract function and (5) functional purpose. Consider the example of a pump. The level of physical form corresponds to the appearance of the pump. A typical representation at this level might be the symbol for a pump on the flow diagram. The level of physical function corresponds to the pumping function of the pump. The level of generic function corresponds to the maintenance of flow and that of abstract function to the maintenance of the mass and/or heat balance. These functions in turn contribute to the ultimate functional purpose of the plant. The levels of abstraction constitute a means–ends hierarchy, with the functional end at the top and the physical means of fulfilling this at the bottom.

In making decisions about the system, the operator may need to move between the different levels of abstraction. In an emergency situation, for example, he may have to step back and consider the ultimate functional purpose. If he decides that this is best served by maintaining the heat balance, he may consider whether to reconfigure the system. This is a decision at a lower level of abstraction. He may then decide to effect this by altering a flow and may alter this flow by making a physical change to a pump system. This takes the decision-making to still lower levels.

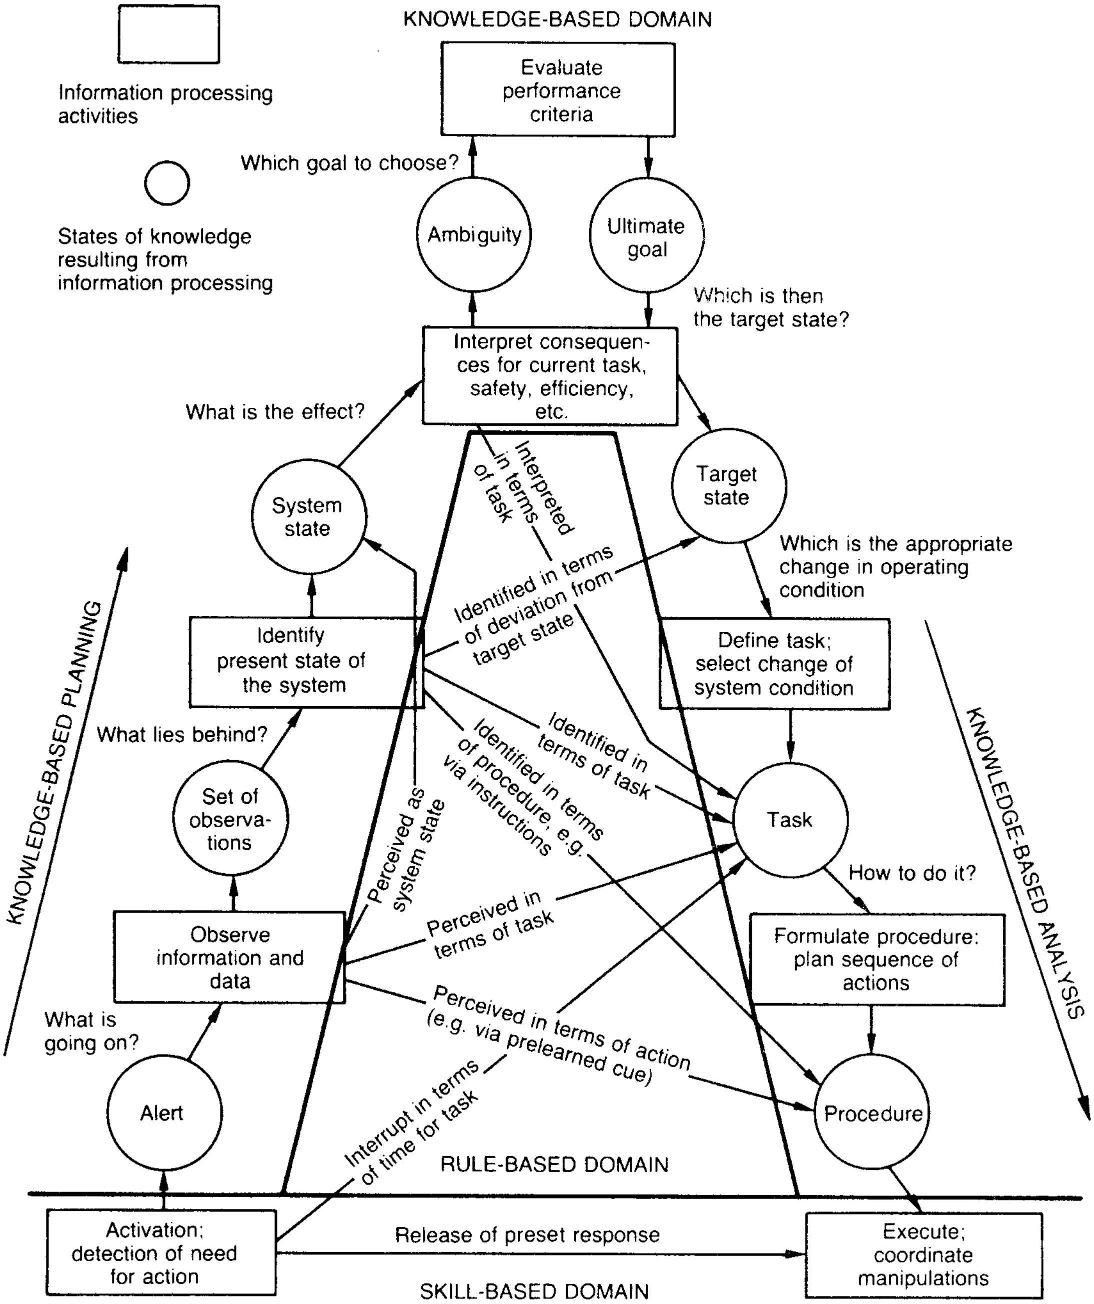

Figure 14.7 *The information processing activities of the operator in making a control decision represented as a ladder diagram (Rasmussen, 1986), The diagram also shows (a) bypassing of certain stages and (b) the domains of skill-based, rule-based and knowledge-based behaviour (Reproduced with permission of John Wiley & Sons Ltd from Information Processing and Human–Machine Interaction by J. Rasmussen, 1986, Copyright ©)*

14.12.3 Human behaviour in diagnostic tasks

One of the principal functions of the process operator is diagnosis. On a process plant, however, diagnosis is not entirely straightforward. If an equipment is known to have a fault, the response required from the maintenance technician is relatively simple. It is to identify the fault and repair it. With a fault on a process plant, fault matters are not quite so simple. The identification of the fault is typically not the first priority. The priority is generally to evaluate the situation, decide whether the ultimate goal is to be modified, decide the new target state of the plant and define the tasks, and formulate and execute the procedures required to bring the plant to that state. Only if diagnosis of the fault is necessary to this sequence need it be undertaken at this stage.

A study of trouble-shooting in electronic equipment was undertaken by Rasmussen and Jensen (1973, 1974) as an example of human behaviour in a diagnostic task. They identified two broad search strategies:

(1) functional search;
(2) topographic search.

Functional search involves detailed observation of the specific characteristics of the fault, followed by interpretation in the light of a model of the system. It requires relatively few items of data but a possibly quite complex model. It is characteristic of the expert designer.

Topographic search is quite different. It involves a search through the system making a rapid sequence of good/bad checks until the fault is located. It requires a large number of items of data, on average, but only simple good/bad decisions. It is characteristic of the expert maintenance technician.

The maintenance technician is able to operate successfully a topographic search strategy using a rather general search procedure that is not dependent on the specific equipment or fault. The task is viewed not as one of solving a problem but of locating a faulty item. Aspects of the search strategy include search along the main flow path and hierarchical ordering of the search. The technician is also able to make do with a very generalized model of the system. In electronic trouble-shooting, the circuit diagram is used for simple purposes such as identification of the main signal paths rather than to obtain a full functional understanding.

In performing topographic search, the maintenance technician follows a strategy that he finds to be broadly optimal in terms of time and trouble. It may not appear optimal in terms of the conventional measures. He will tend to follow the line of least resistance and to take apparently impulsive decisions.

Behaviour in topographic search may sometimes appear to display a fixation. The search may come to an impasse. Even in these circumstances there is relatively little tendency to resort to the use of functional reasoning. The technician is likely to take a break and then to resume using a topographic search strategy again.

Functional search is often used to identify the subsystem that is faulty, prior to the use of topographic search on the subsystem. A common example is trouble-shooting on a TV set where the behaviour of the 'picture' may provide an indication of the type of fault and the associated faulty subsystem.

This work provides background to the diagnostic tasks performed by the process operator. The operator may utilize one of two broad strategies:

(1) topographic search;
(2) symptomatic search:
    (a) pattern recognition,
    (b) sequential decision-making.

The topographic search is based on a map of the system that shows the location of items the state of which can be observed and subjected to a good/bad check.

The symptomatic search may take two forms. It may involve assessment of the state of the system by some form of pattern recognition. Or it may involve a sequential process of decision-making equivalent to logical forms such as truth tables, fault trees and event trees. An alternative sequential approach is search by hypothesis and test.

These considerations have implications for various aspects affecting the operator such as information display, computer aiding and training.

14.12.4 Design of overall control system

Design of the overall control system for a process plant is seen by Rasmussen as involving three principal stages:

(1) definition of control requirements;
(2) analysis of the decision tasks;
(3) cognitive task analysis and design.

The designer defines the control requirements by moving down through the levels of abstraction, defining at each level the context of the control task, including the task specification from the level above and the resources available at the level below. The decision tasks implied in this scheme of control are then analysed. The decision ladder diagram given in Figure 14.7 provides a framework for such analysis.

In the cognitive task analysis, the designer formulates the possible information-processing strategies that the operator may use. System design does not require knowledge of the detailed mental models used by the operator. Rather it can be based instead on knowledge of the higher level, more generic, models which operators can and do use. The fact that different operators may use different detailed models also argues for a higher level approach.

Rasmussen gives several ladder diagrams illustrating the decision task analysis for different tasks and in different systems. These all have the same broad structure but differ in detail. For example, different diagrams apply for fully and partially automated systems.

14.12.5 Human behaviour in cognitive tasks

Rasmussen distinguishes three types, or levels, of human behaviour in tasks such as process control. Such behaviour may be:

(1) skill-based;
(2) rule-based;
(3) knowledge-based.

The relation between the three types is shown in Figure 14.8.

This description of operator behaviour by Rasmussen is frequently referred to as the skill-rule-knowledge, or SRK model. Skill-based, or skilled, behaviour occurs without conscious attention and is data-driven. Rule-based behaviour is consciously controlled and goal-oriented. Knowledge-based behaviour is also conscious and involves reasoning. These three types of behaviour apply to both parts of the decision ladder diagram, as shown in Figure 14.7.

Another, closely related distinction is that between (1) a signal, (2) a sign and (3) a symbol, illustrated in Figure 14.9. The distinction lies in the way in which the input is perceived. A signal is an input perceived simply as a continuous quantitative indicator of system state. A sign is perceived as an indication of some discrete state and often of the need for action. A symbol relates to some functional

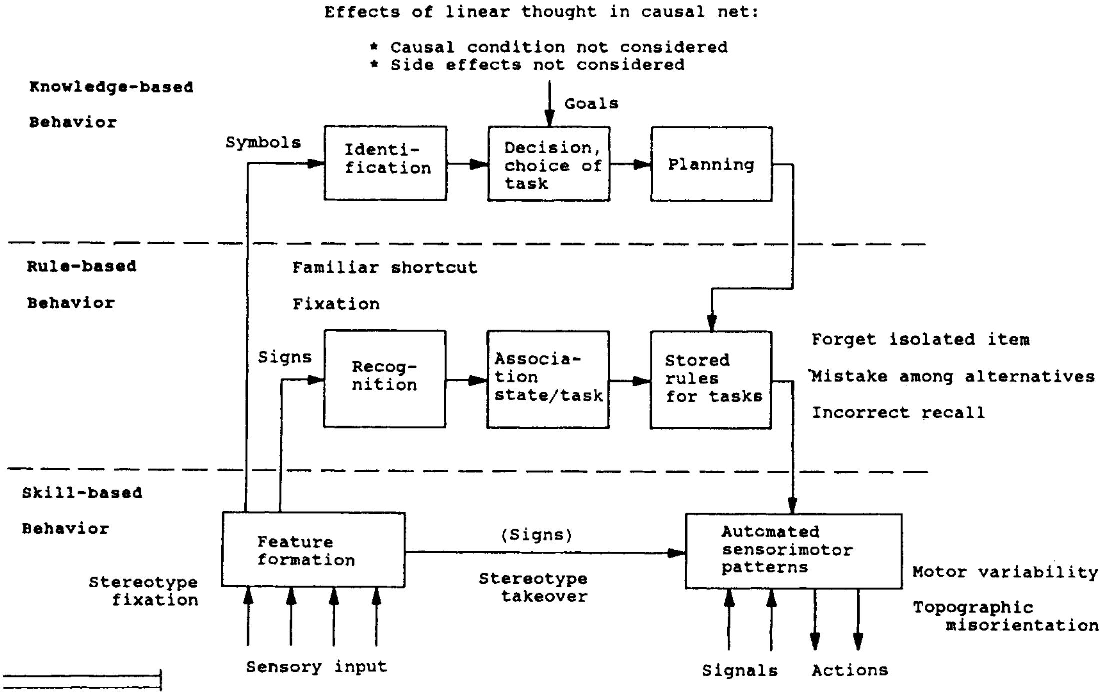

Figure 14.8 *The three levels of control of human actions: skill-based, rule-based and knowledge-based behaviour (Rasmussen, 1986) (Reproduced with permission of John Wiley & Sons Ltd from Information Processing and Human–Machine Interaction by J. Rasmussen, 1986, Copyright ©)*

property of the system. A sign cannot be used for functional reasoning about the system, which is the province of the symbol. Signs belong essentially to the domain of rule-based behaviour, and symbols to that of knowledge-based behaviour, as shown in Figure 14.8.

14.12.6 Human as control system component

Much work has been done on human behaviour in control tasks generally and in process control tasks in particular, and various characterizations have been developed of man as a component in a control system.

Rasmussen discusses the behaviour of the human as a component in a control loop, and his needs for aiding, in relation to the successively more difficult tasks of (1) direct manipulation, (2) indirect manipulation, (3) remote manipulation and, finally, (4) remote process control. In the first three cases, the operator receives information in analogue form and exercises a basic sensorimotor skill in a relatively simple space-time loop. This may not be so in the fourth case, where the signals on both the input, or sensory, channel and the output, or manipulative, channel, are likely to be symbolic and therefore to require translation. Such translation is a relatively high-level activity and therefore breaks the simple space-time loop.

In this light, the aim of the designer should be to restore to the operator the ability to apply to the task the basic sensorimotor skill. This requires that the designer do at least two things. On the sensory channel, the information presented should be based on symbols directly related to the function to be controlled. On the manipulative channel, the information presented should provide symbols and structure which allow the symbolic representation of the space-time feature to be directly manipulated.

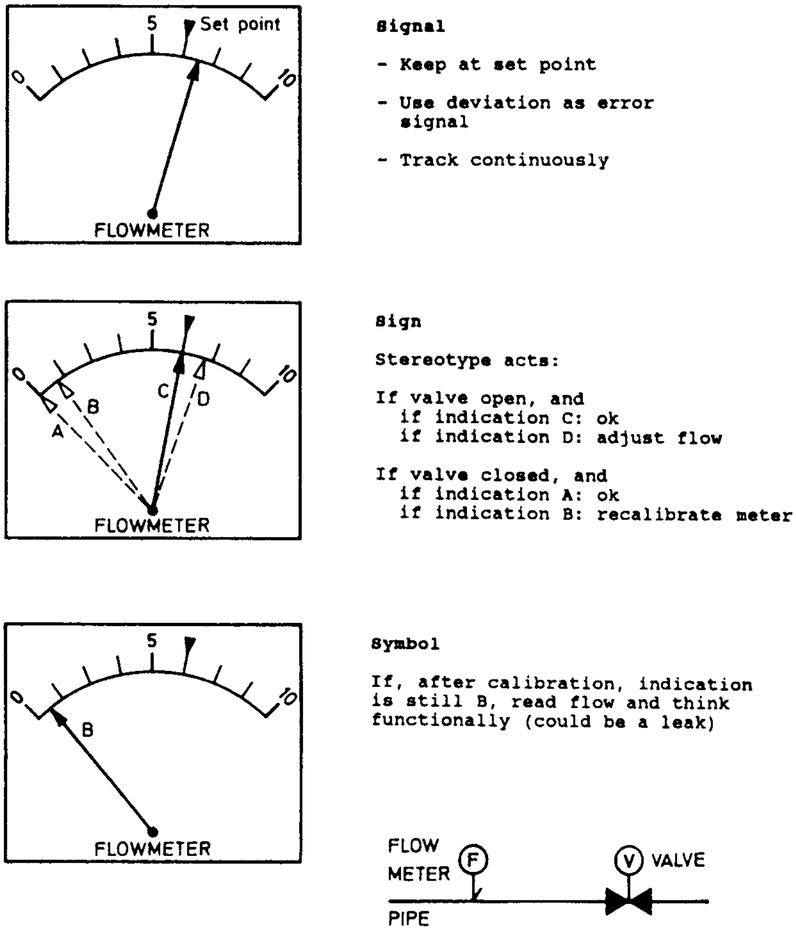
14.12.7 Mental models used in cognitive tasks

At the level of knowledge-based behaviour, the operator requires to effect transformation between different types of model. Rasmussen identifies three strategies which he uses to do this: (1) aggregation, (2) abstraction and (3) analogy.

If a system is viewed with a high degree of resolution, it may appear complex. This complexity, however, is not an inherent property. If the elements of the system are aggregated into a larger whole by reducing the degree of resolution, a simplification may be achieved.

The apparent complexity of a typical control system is largely due to the one-sensor-one indicator technology. Given this technology, the operator has to transform the information by aggregation in order to reduce the complexity. Alternative forms of display can be devised which effect this aggregation for him. Another basic transformation strategy is shifting the level of abstraction. The operator moves between different levels of abstraction, as already discussed. The third strategy is analogy. This may be regarded as a special case of shifting the level of abstraction. Since systems that are physically different may have the same higher level model, a shift to this higher level may provide a useful analogy.

These considerations have implications for the decision support systems provided for the operator. Traditionally, displays consist mainly of measured values and some



Signal

- Keep at set point
- Use deviation as error signal
- Track continuously

Sign

Stereotype acts:

If valve open, and
  if indication C: ok
  if indication D: adjust flow

If valve closed, and
  if indication A: ok
  if indication B: recalibrate meter

Symbol

If, after calibration, indication is still B, read flow and think functionally (could be a leak)

Figure 14.9 *Three perceptions of the same indication (Rasmussen, 1983): as a signal; as a sign; and as a symbol (Courtesy of the Institute of Electrical and Electronic Engineers)*

structural information such as mimic diagrams. There is relatively little that relates directly to the various levels of the means–ends hierarchy. There is need for displays to support decision-making at the different levels.

Lind (1981) has developed a description of process systems in terms of the mass and energy balances which has several levels and maps well onto the means–ends hierarchy. Goodstein (1984) has done work on multilevel displays. The provision at a higher level of abstraction of displays which give a one-to-one mapping between the appearance of the display and the properties of the process to be controlled allows rule- and skill-based behaviour to be extended to this higher level.

A functional representation can serve as a set of prescriptive signs. Cuny and Boy (1981) have shown that an electrical circuit diagram can be analysed as a set of signs controlling activities in design, installation and repair. A closely associated topic is co-operative decision-making where the computer supports human decision-making by undertaking parts of the information processing.

With regard to the form of mental models, the model used by man tends to be based on common-sense reasoning, or causal reasoning. As a model at the purely physical level, this does not have the precision of a formal mathematical model such as a set of differential equations, but it is serviceable and can be extended to higher levels of reasoning.

14.12.8 Human error in cognitive tasks

The causes of unsatisfactory system performance are technical faults and human error. The tracing of the causes of poor performance by an investigator is arbitrary to a degree. Rasmussen points out that there is a strong tendency for the trace to terminate if it reaches a human; it does not often pass through.

He discusses human error mainly in terms of human variability and of human–machine mismatch. This variability is a desirable characteristic. It is an important ingredient in human adaptability. In particular, it plays an important part in the learning processes. Small excursions outside limits are needed in order to learn where limits lie.

Similar experimentation underlies the development of rules-of-thumb.

If the environment is unforgiving, however, so that if such excursions prove to have bad effects it is not possible to recover, error becomes a problem. Overall, it is generally more fruitful both for error prevention and error prediction to concentrate on recovery from error than on the initial error.

At the level of knowledge-based behaviour, error may occur due to selection of an inappropriate goal or selection of an appropriate goal followed by incorrect implementation.

At the level of rule-based behaviour a prime cause of error is a change in the environment. Practice of a task leads to a tendency for knowledge-based behaviour to be replaced by rule-based behaviour and use of signs. If the environment changes so that the signs do not alter but the rules are no longer appropriate, error is liable to occur. This may be compounded by the tendency to utilize convenient, informal signs instead of formal signs and to modify rules to give more convenient sequences.

Human error may occur in a normal situation in the execution of familiar tasks. Some of the mechanisms include (1) motor variability, (2) topographic misorientation, (3) stereotype take-over, (4) forgetting an isolated item and (5) selecting an incorrect alternative.

Motor variability is exemplified by an operator applying different degrees of force to a set of valves so that one of them is not leak-tight. Selecting the wrong pump in a set of pumps is an example of topographic misorientation. Stereotype take-over is illustrated by switching during an emergency shut-down sequence to the regular shut-down sequence.

Forgetting an isolated item can take many forms. A typical form is omission of an isolated act. An analysis of nuclear plant test and calibration reports by Rasmussen (1980b) found that this category accounted for 50% of errors. Precisely because the act is an isolated one, the probability of initial error tends to be high and that of recovery low. Another form of forgetting an isolated item is incorrect recall of a number. Insertion by an operator of a wrong set-point is an example. An example of incorrect selection between alternatives is adding to a figure a correction factor which should in fact be subtracted.

Other types of human error occur in off-normal situations. Skill-based behaviour is appropriate to the normal situation, but if the situation changes it may no longer be appropriate. Generally, however, adaptation tends not to take place until a mismatch has occurred.

Rule-based behaviour is liable to two types of mismatch: (1) stereotype fixation and (2) stereotype take-over. An example of stereotype fixation is execution of a sequence of operations appropriate to normal dusts when in fact the dust being handled is radioactive and calls for additional precautions. Stereotype take-over, by contrast, is exemplified by an operator initially conscious of the need to vary a sequence of operations to suit the particular circumstances, such as the dust-handling task just described, but then relapsing into the normal sequence. Such interference is more likely to occur in situations where the mind is occupied by forward planning of other activities before the action concerned has been executed.

Another form of failure in rule-based behaviour is failure to switch to knowledge-based behaviour even though this is what the situation warrants. If the system has changed but the signs remain unchanged, rule-based behaviour based on the signs may no longer be appropriate.

An operator is typically faced with the display of a set of measurements. It is apparently the expectation of the designer that he will interpret them using knowledge-based behaviour. In fact, an operator relies not so much on sets of relationships between variables as on linear sequences of events. He does not derive states and events from sets of relations but utilizes state and event indicators. Thus, if the system changes, the operator is required not only to shift to knowledge-based behaviour but also to cease interpreting information as signs and to interpret it instead as symbols. His difficulty is compounded if the information sources are attended to sequentially.

Once the domain of knowledge-based behaviour is entered, it becomes much more difficult to characterize the mechanisms leading to mismatch. Some types of human error which may occur in this situation include the following: (1) slips, mistakes and interference; (2) premature selection of a hypothesis; and (3) inappropriate testing of a hypothesis and (4) failure to map/match resource to goal. Rasmussen concludes that given current types of display, the situation is generally too unstructured to permit the development of a model of the problem-solving process and hence the identification of typical error modes.

The taxonomy for description and analysis of events involving human malfunction given by Rasmussen is shown in Figure 14.10. Human malfunctions are classified as external or internal malfunctions. An external malfunction relates to omission or commission of acts that affect the state of plant equipment. An internal malfunction relates to decisions made at some level on the decision ladder. The scheme is not hierarchical. It allows quite a high degree of resolution. It is based on internal rather then external malfunctions, which retains the internal structure of the error, allows a reasonably economical description of it and avoids the combinatorial explosion that is liable to occur in a scheme based on external malfunctions.

One of the factors which affect the probability of error is stress. However, although much work has been done on the effects of stress, relatively little is applicable to cognitive tasks. An abnormal situation tends to result in a modification of behaviour even if there is little stress. But frequently in an abnormal situation, there is an increase in stress. Apart from the effect of anxiety, there are some specific effects related to the cognitive task itself. The need to apply functional reasoning to a disturbed function increases the workload and reduces the time available for general monitoring of the state of the system. At the same time, the existence of abnormal conditions means that familiar indicators may be less reliable as guides to the state of the system. There is a tendency for the operator to focus on the disturbed function and thus to exhibit the cognitive tunnel effect. The need for shifts of strategy is another factor increasing stress.

Work on pilot performance by Bartlett (1943) indicates that under stress the tendency is for skilled subroutines to be retained but for the higher level co-ordination of these routines to deteriorate.

14.12.9 Models of human information processing

There exist a variety of models of human information processing activities which may have a contribution to make in the present context. These are reviewed by Rasmussen in respect of the characteristics of each model and of its relationships with the other models. The models are summarized in Table 14.7.

14.13 Task Analysis

The analysis of the task to be done logically precedes other stages of the design process, such as interface or training design, as shown in Figure 14.1. Insofar as any analysis of the operator's task is made in the process industries, this has traditionally tended to be done implicitly in the course of writing the plant operating instructions. Increasingly, however, use is being made of more fundamental approaches, mainly based on the various forms of task analysis.

14.13.1 Hierarchical task analysis

Early work was given in *Task Analysis* (Annett *et al.,* 1971). The method described by these authors is hierarchical task analysis (HTA), in which the task is broken down into a hierarchy of task elements. The hierarchical task analysis method of Annett *et al.* has been developed by Duncan and co-workers (Duncan, 1974; Duncan and Gray, 1975a,b; Duncan and Shepherd, 1975a,b).

The method adopted is to break the task down into a hierarchy. The elements of the hierarchy are a goal, plans and operations. The task involves a goal and this is then redescribed in terms of the plans and operations necessary to achieve it. Operations are units of behaviour, typically with an action–information feedback structure. The main operations in the task of controlling an acid purification plant are shown in Figure 14.11, the full hierarchy of operations in Figure 14.12 and representative subordinate operations in a start-up procedure in Figure 14.13.

One of the difficulties in any task analysis is to know when to stop. Unless there is a suitable stopping rule, the redescription gets out of hand. The rule used is that redescription stops when the product of the probability p and the cost c of failure is acceptably low. The application of the rule is shown by the underlining in Figure 14.11. Double underlining indicates that this product has an acceptably low value. This is usually because the action required is trivial and does not call for training. Single underlining denotes a possible difficulty and perhaps need for training.

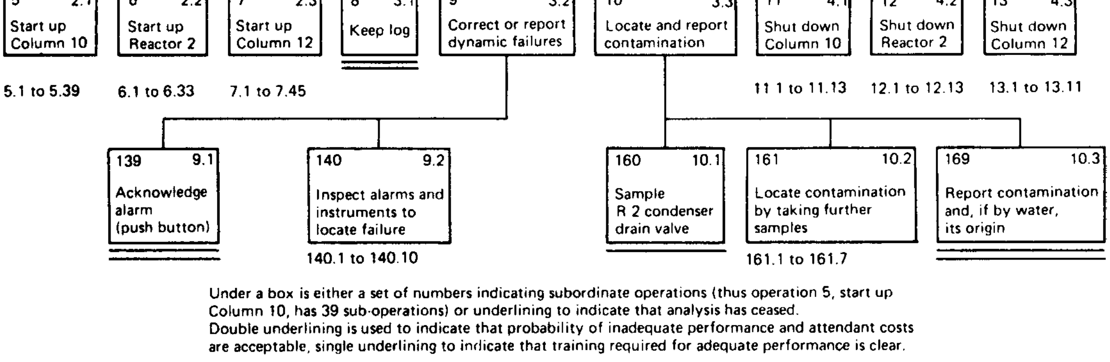
Thus, as mentioned in Chapter 8, this method is a type of hazard identification procedure and should take its place along with other such techniques. It conforms to the loss prevention approach of taking into account both the magnitude and probability of the hazard. Although the technique is intended primarily to assist in the design of training, it is not assumed that training is in all cases the right solution. On the contrary, in some instances other measures such as design alteration may be more appropriate.

The type of material that the method produces is shown in Table 14.8. The numbers in the left-hand column identify the operation in the corresponding box diagram of Figure 14.12. Thus 3/1.2 (Run plant) is operation 3, which is the second subdivision of operation 1. The column on the extreme right refers to further breakdown. Thus operation 4 is broken down into operations 11–13, which are detailed further down the table. The notes in the main body describe the operation, mentioning particularly any constraints or tolerance limits and also tentative suggestions for a training method. The columns headed I or F, and A, are checked with a cross if any difficulty has been found in the input or feedback to the operator (that is a sensory or perceptual difficulty) or if an action difficulty (inability to perform the motor act) has been found. The letter R indicates that the operation is redescribed elsewhere in the table.

The task analysis breaks the task down into operations which are carried out according to a plan. The simplest plan is a fixed sequence, but variable sequences may be handled, and training may be particularly important for these. One problem that task analysis studies reveal is the identification of equipment, such as bypass and isolation valves around control valves. Figure 14.14 shows a typical plant control valve and Figure 14.15 some representative bypass and isolation configurations, the variety of which can lead to confusion. Another problem is fault diagnosis, which is considered below.

14.13.2 Development of task analysis

Task analysis has now developed into a family of techniques, undertaken for a variety of purposes and employing different methodologies. Thus, for example, task analysis may be used as an aid to identifying information requirements, writing operating procedures, defining training



Under a box is either a set of numbers indicating subordinate operations (thus operation 5, start up Column 10, has 39 sub-operations) or underlining to indicate that analysis has ceased.
Double underlining is used to indicate that probability of inadequate performance and attendant costs are acceptable, single underlining to indicate that training required for adequate performance is clear.

Figure 14.11 *Main operations in an acid purification task (Duncan, 1974) (Courtesy of Taylor & Francis Ltd)*

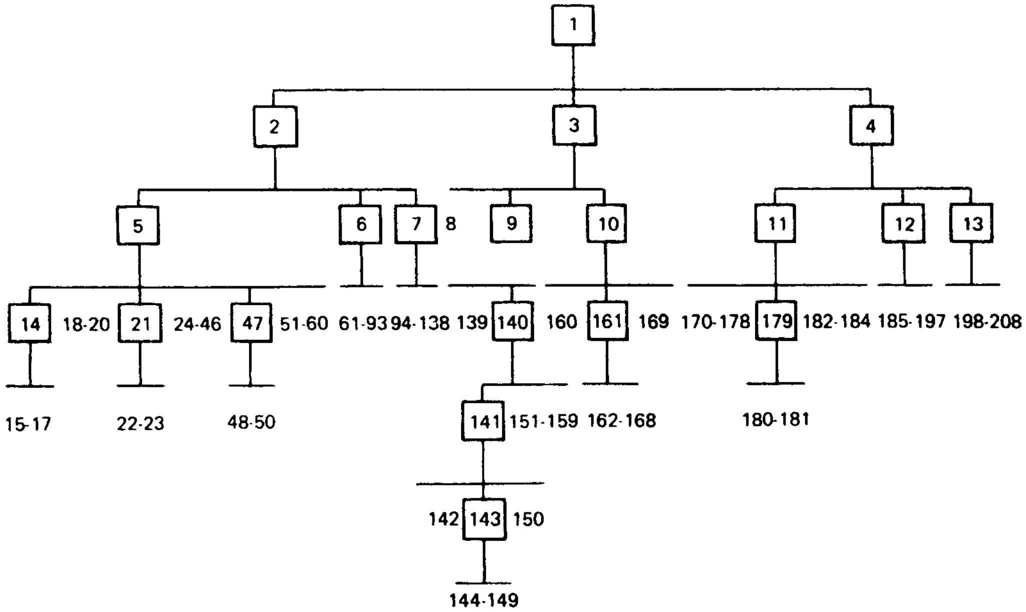


Figure 14.12 *Hierarchy of operations in an acid purification task (Duncan, 1974) (Courtesy of Taylor & Francis Ltd)*

needs, specifying manning levels, estimating human reliability in probabilistic safety assessment and investigating problems.

As far as concerns the methods, there are some 25 or more major techniques available. In effect, therefore, in many areas of human factors in the process industries, task analysis has become an indispensable tool.

14.13.3 Hierarchical task analysis: standard task elements

An approach to rendering hierarchical task analysis more systematic has been described by A. Shepherd (1993), with special reference to the information requirements of the process operator, as described below. In HTA, the task is decomposed into a set of subgoals for each of which there is a set of information requirements, which the author calls ‘subgoal templates’ (SGTs). He identifies five broad classes of task element:

(1) sequence elements (S);
(2) action elements (A);
(3) communications elements (C);
(4) monitoring elements (M);
(5) decision-making elements (D).

He further divides each class of element into subclasses to give the scheme shown in Table 14.9.

Shepherd illustrates the translation of a conventional HTA into his standard form by reference to the simple example shown in Figure 14.16. The original plan is:

> *Upon instructions from supervisor, do 1, then do 2, then when temperature = 100 degrees, do 3. Then if pH is within specification, do 4, otherwise do 5.*

This plan is translated into standard task elements as follows, where the left-hand side shows the plan and the right-hand side the standard elements:

Upon instruction from supervisor	–receive instruction (C4)
do	–then do (S1)
1 (Establish feeds)	–redescribed
then do	–then do (S1)
2 (Open steam valve to 7 psi)	–redescribed
then	–then do (S1)
when temperature = 100 degrees	–monitor to anticipate change (M2)
do	–then do (S1)
3 (Switch steam to ‘automatic’)	–activate (A1)
then	–then do (S1)
If pH is within specification	–monitor to anticipate change (M2)
do	–then do . . . either (S2)
4 (Switch feeds to ‘automatic’)	–activate (A1)
otherwise do	–then do . . . or (S2)
5 (Adjust feeds)	–redescribed

In this method sequence elements need to be introduced between each of the other elements. This serves to clarify for each subgoal in the task the information required and the time when it is needed. Another feature is that monitoring elements and decision-making elements need to be introduced within sequences to handle contingencies that may arise. Frequently in task analyses these elements are not made explicit.

14.13.4 Applications of task analysis: operator information requirements

A methodology for the definition of the information requirements of the process operator where he is part of a

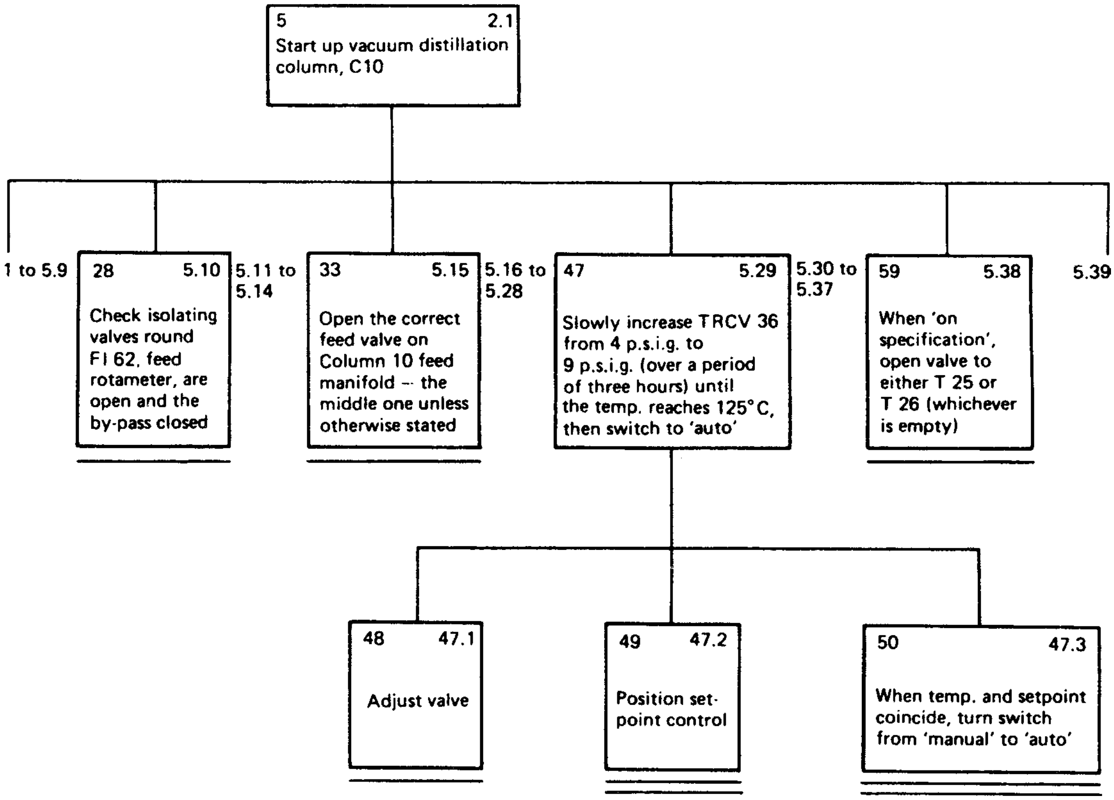

Figure 14.13 *Representative subordinate operations in a start-up procedure (Duncan, 1974) (Courtesy of Taylor & Francis Ltd)*

control loop has been described by A. Shepherd (1993) in the work just referred to. He describes a number of operator information acquisition problems found in industrial studies. One is 'breaking the loop'. In one case, the display of information on the effect of control actions was distant from the controls to be manipulated, being two floors up from the controls. In another, the problem was that the control actions on a rather sensitive distillation process on a batch plant had to be performed by interrupting work on preparation of batches and going to another part of the plant, with the result that the operators tended to adopt a rather conservative and uneconomic control strategy. In a third example, the target information and the controls – required to effect changes were shown on different VDUs because the VDUs were arranged to display information by geographical area on the plant and the equipments were in different areas, with the result that in order to make a change, two operators, each viewing one screen, had to shout across the control room to each other.

Another problem identified was 'information fragmentation'. This can arise where the operator has to examine several items of information before making a decision. In one case the operator was required to deal with disturbances in a particular part of the plant but in order to do so required information from points throughout the plant. This was not too difficult to do using the original conventional control panel but with a new VDU system it became very difficult, because the menu hierarchy was organized geographically and considerable search activity was involved in order to locate the necessary data.

14.13.5 Applications of task analysis: emergency stand-by system

Umbers and Reiersen (1994) have described the application of task analysis to assessment of an emergency stand-by system. This arose as part of the long-term safety review (LTSR) of the UK Magnox nuclear reactors, which includes the installation of a new, tertiary feed water system as stand-by for the two existing systems. Several task analysis techniques were used, including hierarchical task analysis and timeline analysis.

Information for the work was drawn from a wide variety of sources. The documentation consulted included the outline design specification, summary of safety arguments, fault study results, station operating procedures, site drawings and plant system drawings. Discussions were held with operations staff, the feed system designers and fire service teams. A timed walk-through was done.

Also of interest are the topics on which assumptions had to be made, including: plant status following a fault; system

***Table 14.8** Extracts from the analysis of an acid purification task (Annett et al., 1971) (Courtesy of HM Stationery Office)*

No.	*Description of operation and training notes*	*I or F*	*A redescribed*
1	Operate acid purification plant. R Instructions when to start-up or shut-down the whole process given by supervisor	–	X 2 to 4
2/1,1	Start-up plant. R Must memorize order of units, i.e. C10, R2, C12	–	X 5 to 7
3/1,2	Run plant. R Log keeping and sampling tests for contamination at intervals fixed by supervisor. Alarms signal dynamic failure	–	X 8 to 10
4/1,3	Shut-down plant. R Must memorize order of units for *routine* shut-down, i.e. C10, R2, C12. In an *emergency* units may be shut-down in any order depending on instructions, and an abbreviated procedure is followed	–	X 11 to 13
5/2,1	Start-up vacuum distillation column, C10. R Invariant order 5,1 to 5,39. Very long fixed procedure. Use job aid? Group steps under headings and learn order of headings? Few opportunities to practise in a continuous process plant. Delays due to plant response could be avoided and practice speeded on a simulator	–	X 14 18 to 21 24 to 47 51 to 60
6/2,2	Start-up hydrogenerator reactor, R2. R Invariant order 6,1 to 6,35. *See* 5	–	X 61 to 93
7/2,3	Start-up final water distillation column, C12. R Invariant order 7,1 to 7,45. *See* 5	–	X 94 to 138
8/3,1	Keep log		–
9/3,2	Locate and correct or report dynamic failures. R Acknowledge – first accept responsibility – then locate	–	X 139 and 140
10/3,3	Locate and report product contamination. R *Only report* contaminants other than water; *report and locate* water contamination	–	X 160, 161 and 169
11/4,1	Shut-down C10. R Invariant order 11,1 to 11,13. *See* 5. In emergency, procedure is abbreviated to suboperations 172, 170, 171, 174 *in that order*. This procedure and locations of console instruments must be overlearned	–	X 170 to 179 182 to 184
12/4,2	Shut-down R2. R Invariant order 12,1 to 12,13. *See* 5. In emergency, procedure is abbreviated to suboperations 188 to 193 *in that order. See* 11	–	X 185 to 197
13/4,3	Shut-down C12. R Invariant order 13,1 to 13,11. *See* 5. In emergency, procedure is abbreviated to suboperations 198 to 203 *in that order. See* 11	–	X 198 to 208
23/21,2	Turn switch from 'manual' to 'auto'		
25/5,7	Open inlet valve to reflux pump in use and check outlet, drain and valves about stand-by pump are closed (P66/67). I Must find way through plant to pump plinth 66/67 – 'landmarks' for learning plant geography? Pumps are labelled but inlet valve is one of six unlabelled hand valves on pump lines. Rote learn which is which, OR learn generalization and discrimination of classes of valves, i.e. *inlet, outlet or discharge*, and *drain!* Sketch to indicate relevant valves and lines against cluttered plant background?	X	– –
48/47,1	Adjust valve. A Compensatory tracking of pen movements to produce an acceptable slope on recorder. Plant control law might be simulated, but expense justifiable? Practice on the job under supervision feasible, but would be infrequent. F Examples of 'acceptable' and 'unacceptable' slopes could easily be provided	X	X –
78/6,18	Set up a pressure of 1 psig on the gauge after the block valve. Then check that there is a purge through the system by putting a hand over the outlet vent. F Must find way through plant to outlet valve. Once pointed out, vent is easily identified	X	– –
161/10,2	Locate origin of water contamination by taking further samples from other points on the plant. R The number and order of samples taken, i.e. suboperations, varies. Given (a) a relative cost index for each of 7 sampling points and (b) for each of 8 plant components, estimated probability of failure (i.e. contaminating product), the operator must apply a search strategy which minimizes sampling costs. Need flow	–	X 162 to 168

design aspects; maintenance and testing aspects; and the number, training and responsibilities of personnel.

The study had a number of outcomes. It gave estimates of the time to commission the tertiary feed water system in an emergency. It highlighted the importance of avoiding delay in establishing loss of the primary and secondary feeds and identified the indications of such loss, some of which varied as between one plant and another. It showed up potential errors and simple design enhancements to avoid them.

The work included a comparison of the commissioning times predicted by the task analysis with those found in

***Table 14.9** Standard task elements for hierarchical task analysis (A. Shepherd, 1993) (Courtesy of Taylor & Francis Ltd)*

Code	*Label*	*Description*	*Information suggestion*
S1	then do	Fixed sequence – where the first operation of REMAINDER is carried out upon completion of the previous operation	
S2	then do either . . . or . . .	Choice – where the first operation of REMAINDER varies in accordance with a specified condition detected in the first operation	
S3	Then do together . . . and . . .	Time sharing – where the first operation of REMAINDER is carried out at the same time as the previous operation	
S4	do in any order . . .	Sometimes it does not matter which order suboperations are carried out in. This is the case in setting-up operations, e.g. prior to plant start-up	
A1	Prepare equipment	The operator sets items of equipment, e.g. valves, in readiness for subsequent operations	Indication of alternative operating states. Feedback that equipment is set to required state
A2	Activate	The operator carries out an act locally on plant or on a central or local control panel to bring an item of equipment on-line or take it off-line, e.g. open valve, switch on centrifuge	Auditory or mechanical feedback that the action has been effective
A3	Adjust	The operator carries out an act locally or on a central or local control panel to adjust an item of equipment to modify operating rates, e.g. increase amps, adjust valve controller, decrease feed-pump rate	Feedback confirming controller position
A4	De-activate	The converse of A1	Auditory or mechanical feedback that the action has been effective
C1	Read	The operator reads a value of a parameter or listens to a sound, e.g. read pressure indicator	Indication of item
C2	Record	The operator records items of information for managerial purposes or to provide data for later stages in processing (e.g. remember, record)	Location of record for storage and retrieval
C3	Wait for instruction	The operator waits for an instruction before commencing the next action	Project wait time. Contact point
C4	Receive	The operator receives instructions pertinent to operation, e.g. to proceed or not proceed, adjustment to targets, priorities, running conditions, potential hazards	Channel for confirmation
C5	Give instruction/ information	The operator gives instructions or provides information (e.g. to management, other operators in plant, operators on other plants outside, suppliers, customers, services)	Feedback of receipt
C6	Remember	The operator commits information to memory (e.g. times to act, operating values, operating constraints)	
C7	Retrieve	The operator may be required to retrieve previously stored information to provide current operating information	Location of information for retrieval
M1	Monitor to detect deviance	Target values of particular parameters are to be maintained through specified	Key parameters to monitor

Table 14.9 *(continued)*

Code	*Label*	*Description*	*Information suggestion*
		phases of processing, usually as a precautionary action. This form of monitoring is usually intermittent, with low expectancy of deviation, unless certain preconditions have occurred. Often this form of monitoring is dealt with by attention grabbing alarms	
M2	Monitor to anticipate change	The operator anticipates change to detect a cue for a subsequent action. In contrast to M1, the operator expects change, usually after the passing of some time or the occurrence of an intermediate event	Key parameters
M3	Monitor rate of change	Where the current plant status is changing over time (e.g. during a plant start-up or other change of operating conditions), the operator may have to ensure that rates of change are within tolerance	Key parameters to monitor Change rates
M4	Inspect plant and equipment	The satisfactory state of equipment may only be determined by human inspection via the human senses	Access to symptoms
D1	Diagnose process problems	Operators must diagnose situations judged out of tolerance to determine a course of compensatory or corrective action	Information requirements must be identified in conjunction with training strategies
D2	Plan adjustment	The operator must observe conditions and work out a sequence of steps to move to a desired (safe) state in an acceptable fashion. Planning must anticipate the consequence of choices of intermediate actions and select only those which lead to acceptable conditions	Planning information deriving from analysis of typical cases
D3	Locate contaminant	In plants where there may be problems associated with contaminants entering pipework, through impure feeds or leaks in heat exchangers, there may be a need for examination of samples at various points in order to detect the site of the problem	Sample points in the system enabling the problem, eventually to be bracketed between a clean input and a contaminated output
D4	Judge adjustment	Often operators are required to make an adjustment to an item of equipment to affect processing conditions. The degree of adjustment must be judged prior to the action	The target indicator Adjustment values

demonstration exercises. The differences were attributable mainly to pessimistic assumptions made by the analysis.

14.13.6 Task Analysis Guide

A full treatment of the topic is given in *A Guide to Task Analysis* (Kirwan and Ainsworth, 1992) (the *Task Analysis Guide*). Other accounts include those by Drury *et al.* (1987) and A. Shepherd (1992).

The *Task Analysis Guide* divides task analysis methods into five broad categories: (1) task data collection, (2) task description, (3) task simulation, (4) task behaviour assessment and (5) task requirement evaluation. The *Guide* gives short accounts of a number of techniques under each of these headings. For task data collection the techniques are (1) activity sampling, (2) critical incident technique, (3) observation, (4) questionnaire, (5) structured interview and (6) verbal protocol. The task description techniques are (1) charting and networking methods, (2) decomposition methods, (3) hierarchical task analysis, (4) link analysis, (5) operational sequence diagram and (6) timeline analysis.

Task simulation is represented by (1) computer modelling and simulation, (2) simulator and mock-up, (3) table top analysis and (4) walk-through and talk-through. Techniques considered under task behaviour assessment are (1) barrier and works safety analysis, (2) event tree, (3) failure modes and effects analysis, (4) fault tree, (5) hazard

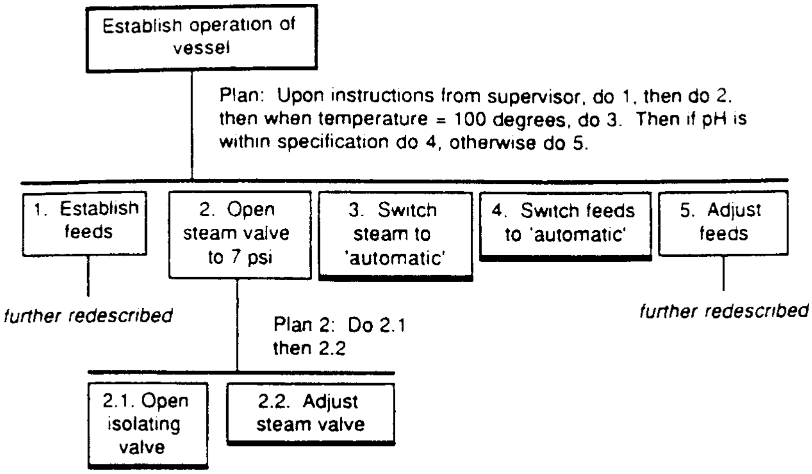

Figure 14.16 *Hierarchical task analysis of part of a process control operation (A. Shepherd, 1993) (Courtesy of Taylor & Francis Ltd)*

and operability (hazop) study, (6) influence diagram and (7) management oversight and risk tree (MORT). The task requirement techniques treated are (1) ergonomics checklists and (2) interface surveys.

The *Guide* also gives some 10 case histories of the application of task analysis to (1) allocation of function between humans and automatic systems, (2) preliminary communications system assessment, (3) plant local panel review, (4) staffing assessment for a local control room, operator workload assessment in a command system, (5) analysis of operator safety actions, (7) maintenance training, (8) quantification of effectiveness of ultrasonic inspection, (9) operations safety review and (10) a task analysis programme for a large plant.

14.13.7 CCPS *Guidelines*

Other task analysis methods are described in the *Human Error Prevention Guidelines* (CCPS, 1994/17), described in Section 14.38. Under the heading of 'action oriented techniques' they give an account of hierarchical task analysis, operator action event trees, decision/action flow diagrams, operational sequence diagrams and signal flow graph analysis. The two cognitive task analysis techniques given are the critical action and decision evaluation technique (CADET) and the influence modelling and assessment system (IMAS).

14.14 Job Design

Job design involves the arrangement of the individual tasks which the man has to do into a job which he is capable of doing and from which he obtains satisfaction. An account of job design is given by L.E. Davis and Wacker (1987).

As the control system becomes more automatic, the active control work of the operator is reduced and his function is increasingly one of monitoring. Such passive monitoring, however, is not a function to which man is well suited.

There is, therefore, a potential problem of job design. An entry to this problem is to consider why man is part of the control system at all. To a large extent, he is there as the component used by the designer to give the system a self-repairing capability. An approach to job design that starts from this fact is to develop explicitly those functions of the operator that are concerned with handling faults and keeping the plant running, notably fault administration and malfunction detection. These are tasks for which, in general, man has the ability and the motivation and they are entirely in line with the aims of loss prevention.

Such an approach requires more attention to be given to these functions of the operator and that he be given the necessary training and job aids. Training should emphasize the importance of running a tight ship and not tolerating degraded equipment. Job aids, including computer-based aids, should assist him in fault administration and malfunction detection.

Other aspects of job design such as workload and organization and social factors have been considered above.

14.15 Personnel Selection

There does not appear to be very much guidance available on selection methods for process operators. This is no doubt largely due to the difficulty of defining criteria for operator performance.

One of the first studies of the process operator was in fact that by Hiscock (1938), who described the development of a set of selection tests, but subsequent work by D.G. Davies (1967) showed little correlation between performance assessed by a selection test battery and by the judgement of supervisors.

It is probably true that enough is now known about process control skill to offer a better prospect of success in developing selection tests. The abilities that an operator needs are better understood. They include signal detection, signal filtering, probability estimation, system state evaluation, manual control and fault diagnosis. Tests may be devised to measure these abilities, using perhaps a computer-based simulator.

It is also important, however, to take into account in selection personal qualities. Crossman (1960) suggested that it is desirable that a process operator should be:

(1) Responsible – able to make satisfactory judgements on matters of discretion, so that his work does not need frequent checking by superiors.

(2) Conscientious – ready to take extra trouble and care, without direct instructions, when the situation demands it.
(3) Reliable – never making mistakes, forgetting instructions, overlooking important indications, etc., or otherwise failing in his prescribed duties.
(4) Trustworthy – honest and truthful in reporting to superiors; not concealing the facts when his own actions may have had adverse effects.

Other important factors are temperament, motivation and social skills. Temperament includes response to monotony and to stress. Motivation is partly an individual matter, but is also influenced by job design. Social skills cover the wide range of communication activities that the work entails.

The operator's job requires a reasonably high level of intelligence, particularly on large plants, but it is not necessary to look for a high intelligence score or university degree. The graduate sometimes makes a rather poor operator. The question of education is considered below together with that of training. A further account of personnel selection is given by Osburn (1987).

Selection for process control tasks is touched on in a study by the Advisory Committee on the Safety of Nuclear Installations (ACSNI, 1990) in relation to testing for trainability. The authors emphasize the need for the formulation of criteria for operator performance applicable to both training and selection, and thus imply that full development of selection tests must wait on the availability of such criteria. They do, however, consider it practical to select out individuals who have chronic stress problems or are unable to cope with high levels of stress. This aspect is also addressed by Weisaeth (1992), who describes the variability of individual response to the stress of emergency conditions.

The elimination of completely unsuitable individuals is probably the most useful feature of selection tests in other fields, such as those for aircraft pilots, which might appear to be a suitable model for some process situations.

A review of the state of knowledge and current practice on operator selection has been published by the HSE (1993 CRR 58).

14.16 Training

The training of process operators is an area in which more can be achieved and, in general, industry devotes considerable effort to this. An overview of training applicable to the process industries is given in *Training* (Patrick, 1992).

14.16.1 Training and education

There is a distinction to be made between training and education: the former is specific to a particular task or job, the latter is more general. The difference may be seen clearly in the evolution of training for electronic maintenance technicians in the US armed services (Shriver, Fink and Trexler, 1964). Initially, this involved a general education in electronics, but this did not prove very effective in training people to repair equipment. Latterly, the emphasis has been on specific training for the diagnostic tasks involved.

The question of the operator's mental model of the process and of his need for a scientific understanding of it was raised in the work of Crossman and Cooke (1962) on manual control and has been extensively discussed by subsequent workers (Attwood, 1970; Kragt and Landeweerd, 1974). Investigations in fairly simple manual control tasks do tend to suggest that it is better to train the operator in control strategies, controller settings, etc., but it is not clear how far this can be generalized to other tasks such as fault diagnosis.

In the United Kingdom, the City and Guilds Institute runs a Chemical Technicians Certificate (1972) that constitutes a substantial education in chemical processes. Such an educational background probably is beneficial, but it is not a substitute for specific training in process tasks.

General guidance on the training of process operators is given in the publications of the former Industry Training Boards (ITBs), in particular the Chemical and Allied Products ITB (CAPITB) and the Petroleum ITB (PITB). For example, CAPITB *Training Recommendation 12* (1971/9) contains *Information Papers* which represent outline approaches to job analysis, training needs, training programmes and fault analysis which the user should apply to his own plant, while other *Information Papers* such as that on distillation (1972/6) represent outline subject syllabuses. Another *Information Paper* (1971/5) deals with safety training. The work of Duncan and his colleagues has been supported by the CAPITB and has been published partly as reports of that body (Duncan and Shepherd, 1975a).

14.16.2 Training principles

> The job of the trainer is to observer and analyse, and to arrange to supply the right amount of the right kind of information to the learner at the right time. He must know a great deal about the task being trained, but the kind of knowledge needed is what comes from careful, objective analysis of the job and of the necessary skill rather than from the experience of becoming personally proficient. His task is to find out what factors affect the learning of the skill with which he is concerned, to watch the effects of varying them and to try to arrange the best combination.

This account by Holding (1965) highlights some of the important features in training. It brings out clearly the importance of the prior task analysis to determine where the operator may have difficulty and where training may be necessary. The content of training should be appropriate, which in effect means it should be related to these difficulties. The training should be at a suitable pace. It should provide feedback of results, since this is essential for learning.

Motivation of the trainee is another important factor and this can be strengthened by recognizing successful performance and treating failures objectively by explaining the cause in a non-condemnatory manner.

There are a number of classic problems in training. The training period may be spaced out or massed together. The task may be learned whole or in parts. The task may have to be done under some form of stress and this may need to be taken into account.

A particularly important question is the transfer of skill from one task to another. It is possible, for example, to achieve good performance in a particular task using methods such as decision trees that leave relatively little to the operator, but the penalty tends to be that he cannot transfer the skill to other tasks.

Many of these problems are discussed in the specific context of process control in the work of Duncan and his colleagues (Duncan, 1974; Duncan and Shepherd, 1975a,b). A further account of concepts of training is given by Holding (1987). The relationship between training goals and training systems is described by Goldstein (1987) and the use of training simulators by Flexman and Stark (1987).

14.16.3 Process operator training

The process operator needs to have the safety training received by other employees also, but in addition has certain specific needs of his own. In this section, consideration is given to the content of training for process operators. A further account of operator training is given in Section 14.17. Safety training is considered in Chapter 28. Some topics for training are listed in Table 14.10.

In general, it is usually a mistake to provide numerous lectures on areas such as details of the process design or of the process computer program. It is better to stick fairly closely to the operator's own problems. Nevertheless, he does need to understand the process flow diagram, the unit operations which compose it and the control system. In addition, a basic understanding of the goals and constraints with which the plant manager operates and the possible changes of priorities that may occur is necessary.

The operator also requires some knowledge of the plant equipment and the instrumentation. In particular, he needs to be able to identify items and to carry out the manipulations for which he is responsible.

There are numerous operating procedures with which he has to become familiar. These include start-up, shut-down, batch operation and all other sequential routines.

The operator needs to learn to administer faults and, in particular, to interpret the alarm system, to diagnose faults and to detect incipient malfunction. He must also be thoroughly conversant with the emergency procedures.

The system of permits-to-work on a plant is extremely important and the operator requires to have a full grasp of the system used.

Training in fire fighting is a particularly important aspect of emergency work. The best training is provided by realistic fire fighting exercises in a training area dedicated to this purpose.

Operational malpractices develop on most plants. A typical example is the operation of furnaces at temperatures that drastically reduce creep life. If this can be foreseen, training may be given to counter this.

The operator has quite an important role to play in communicating information about plant operation to other people and it may be appropriate to include this in training.

14.16.4 Fault diagnosis

Fault diagnosis is a particularly important activity of the process operator. It has been studied in detail by Duncan and his co-workers (Duncan, 1974; Duncan and Gray, 1975a,b; Duncan and Shepherd, 1975a,b) and is considered here as an example of training in a specific task.

Fault diagnosis is usually carried out by the operator at the control panel. Frequently, therefore, use is made of a panel simulator for training. The simulator used at the beginning of Duncan's work is shown in Figure 14.17. It represents a typical panel and the trainer sets up manually combinations of instrument readings corresponding to particular process conditions. The training is interrupted, however, by the rather slow process of resetting the simulator to represent the next set of conditions. Duncan and Shepherd (1975b) have overcome this problem by using a mock-up of the panel, shown in Figure 14.18, and back-projecting this on to a full-size screen in front of which the trainee operator can stand. Different sets of instrument readings can be brought up by projection without delay.

Using this device, Duncan and Shepherd have studied the training of operators to recognize different fault patterns on the panel. A cumulative part-training method was used in which the number of sets of faults was progressively increased. The subjects achieved encouragingly high rates of success in diagnosing faults. Debriefing of the subjects suggested that different diagnosis strategies were used. One was a pattern recognizer, looking first at the alarms and then considering possible failures consistent with these. Another examined first the instruments and then used hueristics based on plant functions.

An alternative approach is the use of decision trees as described by Duncan and Gray (1975a). Figures 14.19 and 14.20 show for a crude distillation column the decision tree and fault-symptom matrix, respectively. The operators were taught to use the decision tree to diagnose faults. Again a high success rate was achieved.

There are various ways in which the information in the decision tree in Figure 14.19 may be presented and learned. The tree as shown gives the faults in the 'natural' grouping. An alternative tree can be constructed in which the maximum number of decisions is reduced from 8 to 3, but the rationale of such a tree is no longer apparent, and the tree would be more difficult to remember. The method actually adopted was to retain the tree in its natural form and to use the 'linked lists' shown in Figure 14.21 to assist in learning it.

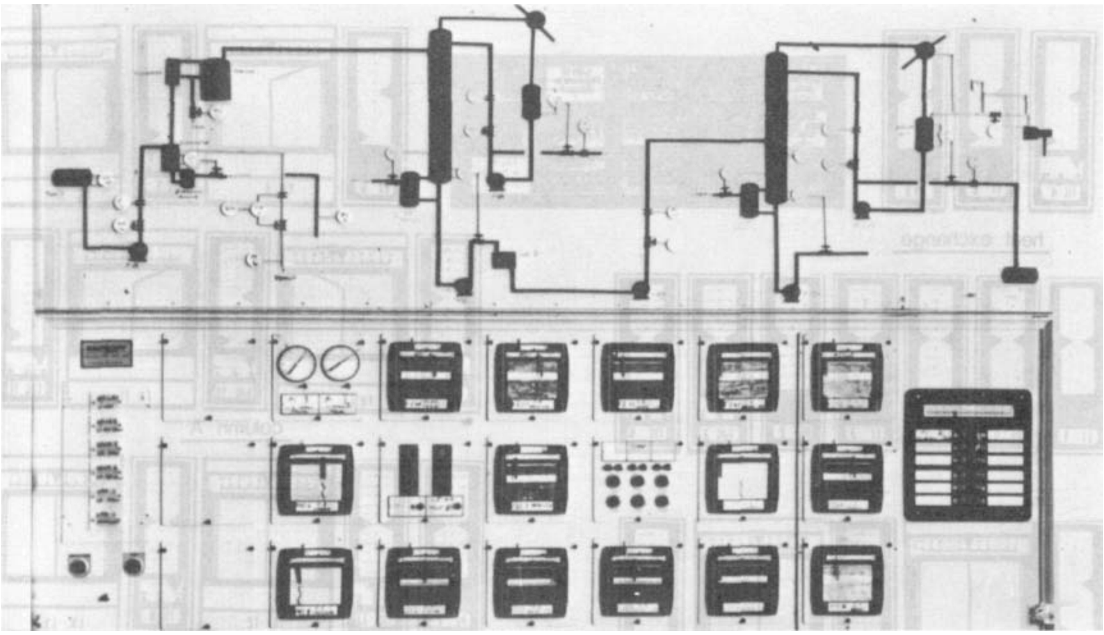

Figure 14.17 *The Carmody 'Universal Process Trainer' (Courtesy of Taylor & Francis Ltd; photograph courtesy of BP Chemicals (International) Ltd)*

Some of the decisions in the tree depend on the instrument readings, which may be in error. Training in the checking of instruments was therefore developed also. The emphasis here was on determining the true value of a parameter rather than on deciding the instrument failure. The following general principles were evolved for checking:

(1) Direct observation – represents truth.
(2) An outside report, such as a sight glass reading, is a direct observation only if the correct procedure for reading is followed.
(3) Two control instruments that agree represent truth.
(4) The costs (time, effort, danger) must be taken into account, and the cheapest route to truth taken.
(5) Only independent indicators of the same parameter can be used for checking.
(6) Where only two indicators of a parameter are available, the more reliable of the two is to be believed.
(7) An individual instrument may show itself to be faulty by deviant behaviour; for example, a straight line on a pen record.

This work brings out the importance of verifying the instrument readings before embarking on the main diagnosis. The need for this in the automated equivalent of computer alarm analysis was mentioned earlier.

This work also included the development of programmed learning texts to assist the operator to learn both the linked lists of the main decision tree and the instrument verification procedures. These developments in training do not of course solve the problem of diagnosing very rare but very hazardous fault conditions. It is doubtful if training is the proper approach to this problem. Such faults are better dealt with by the protective system; since they are very rare, the shut-downs involved are probably acceptable.

14.17 Training: ACSNI *Study Group Report*

A review of training is given in the *First Report: Training and Related Matters* of the ACSNI (1990). Although this is a report to the nuclear industry, it is applicable in large part to the process industries also. The report starts from the point that human error is the major source of accidents and refers to the cases of Three Mile Island and Chernobyl.

The authors treat the topic under the following headings: (1) definition of training, (2) the safety culture, (3) initiation of training, (4) internal monitoring, (5) training needs analysis, (6) criteria for operator performance, (7) standards for training, (8) methods of training, (9) central vs site-based simulators, (10) individual vs team training, (11) training for stress, (12) training of management, instructors, etc., (13) certification and (14) privatization. They state:

> It is misleading to think of training solely in terms of the transfer of items of verbal knowledge or technical skill from instructor to pupil. Although both knowledge and skill are necessary, they are not on their own sufficient to assure safety. They must be augmented by different qualities: habits of forethought and precaution that place minimization of risk first, and other goals such as short term performance or convenience, second.

The main purpose of training is to create a safety culture. The report rehearses some of the elements of this, which have already been described in Chapter 6. It is necessary that senior management give a lead and take certain specific measures. Line management should have operational

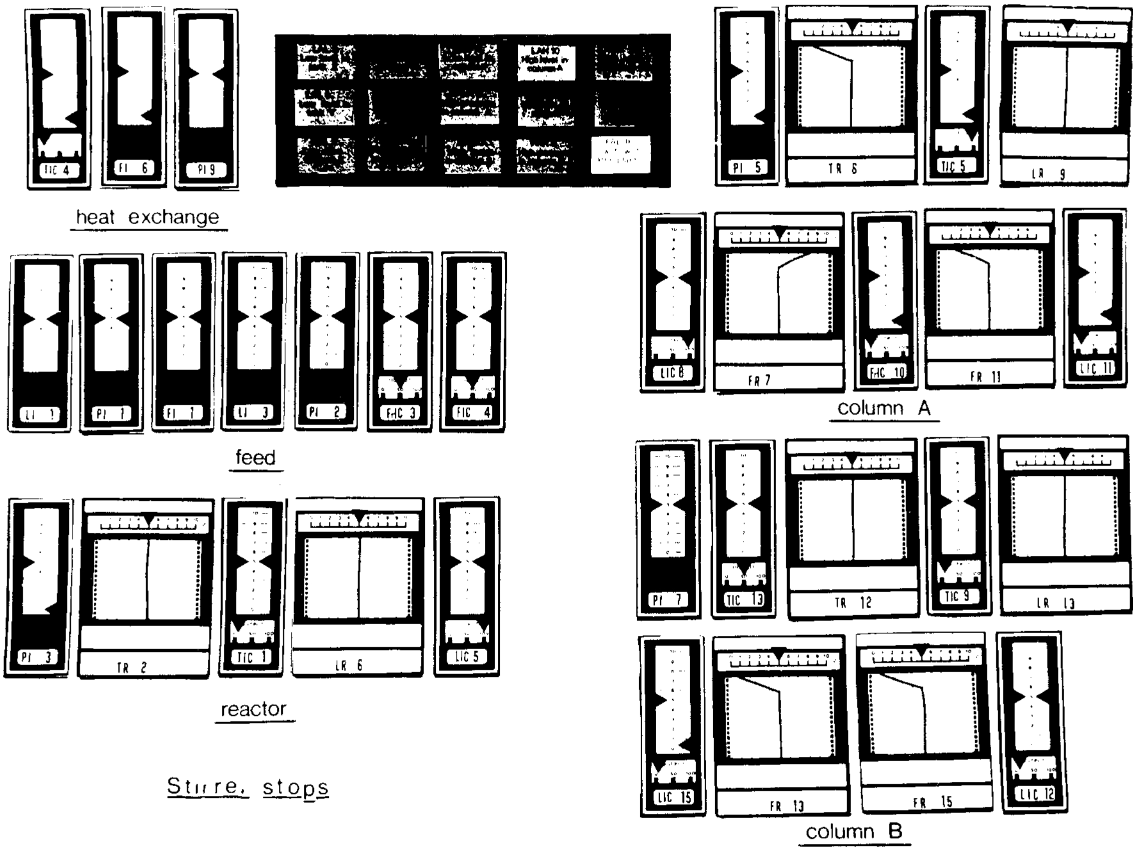

Figure 14.18 *Control panel display used for operator training (Duncan and Shepherd, 1975b) (Courtesy of Taylor & Francis Ltd)*

responsibility *inter alia* for safety and training. There should be monitoring of the safety culture using objective measures and independent assessment and a policy of continuous improvement with specific targets and with feedback to the workforce. Training should aim to rehearse the individual's experience deliberately so as to reinforce compliance and self-monitoring and awareness and reporting of hazards. Senior management should ensure not only that the organization has a suitable formal training system, but that it is operating effectively in practice.

Training should be monitored. One method of monitoring is the use of objective measures such as the frequency of accidents, incidents, operational deviations, trips, etc. Another method is to sample regularly what people say about the safety culture and about their own attitudes. The monitoring should be done by an assessor who is independent both of the local line management and of the training specialists.

Task analysis should be used to establish training needs. The analysis should specify in concrete terms the information to be supplied, the alternative actions that can be taken, and the quality of calculation or judgement the task requires. It may reveal different needs such as knowledge about equipment or practice in control skills, and thus point to different types of training such as lectures or use of a simulator.

Evidence from a number of industries shows that, even after quite thorough training, an individual may have little idea of the hazards of the job. The training should aim to raise the awareness of these hazards.

The report states that performance on the job should be not only monitored but also measured. This implies that there should be criteria of operator performance. Closely related to this is standards for training. The report accepts that it may be unrealistic to seek totally objective measures. Where these are not practical, it suggests that the assessment take the form of two independent assessments by supervisory staff using carefully defined rating scales and that these staff themselves receive training to ensure that the criteria used are consistent.

With regard to methods of training, the report refers to the distinction between skill-based, rule-based and knowledge-based behaviour and between responses to signal and to signs. Control skills such as making adjustments to maintain constant a single variable have become relatively less important on automated plant, but there are a range of control room skills which still need to be learned. Skills used in normal operation may perhaps be adequately learned on the job, but this is not so for skills required in

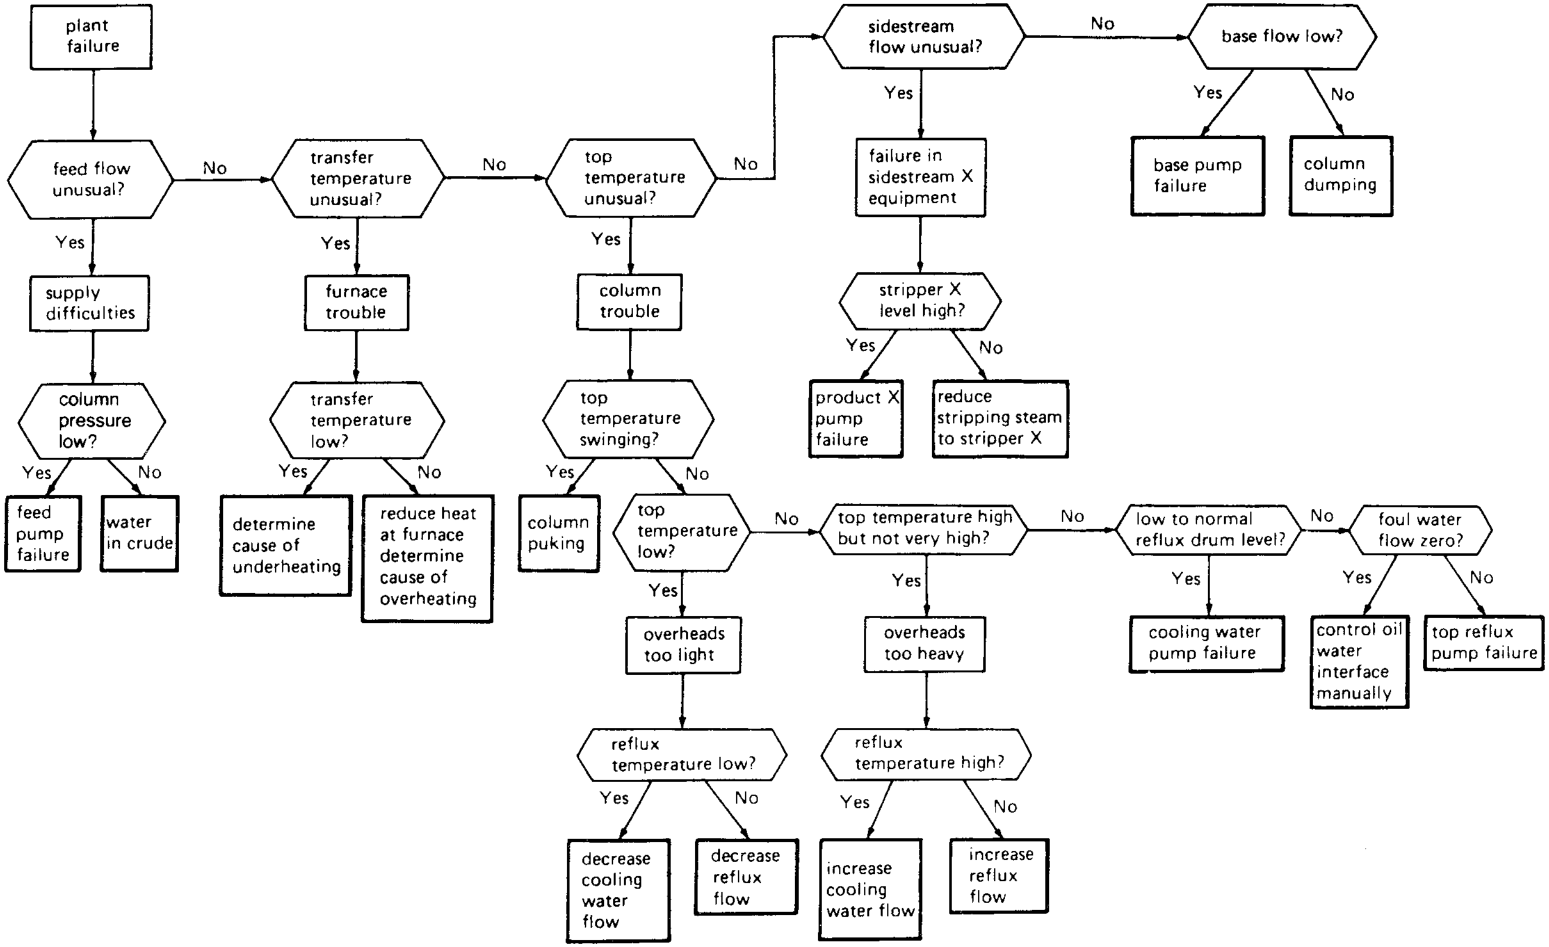

Figure 14.19 *Decision tree for fault diagnosis on a crude oil distillation unit (Duncan and Gray, 1975a) (Courtesy of the Journal of Occupational Psychology)*

an emergency situation, for which simulator training is appropriate.

The report argues that for the control of nuclear plants, an average level of performance is not good enough. It follows that training may have to seek to change certain patterns of highly learned skilled-based behaviour.

The report places particular emphasis on the rule-based level of control. Here the operator responds to signs rather than signals and has to categorize the situation. Whilst rules may be learned to some degree in the classroom, practice in the use of rules to categorize the situation is most effectively given on a simulator.

The report gives high priority to the provision of simulators for each type of control room, since there are aspects of task that cannot readily be taught without them. It discusses the merits of local vs off-site simulators, but regards this question as less important that clear specification of the skills to be learned and the level of competence to be achieved.

With regard to individual vs team training, the authors suggest that the initial emphasis should be on individual training, with team training introduced later. Simulator training is treated as a form of team training.

Operator performance is affected by the level of stress experienced. It is not desirable that any operator of a nuclear plant should have to carry out the job under an abnormal degree of stress. This has implications for selection and for monitoring of individuals. The individual should be free from chronic stress symptoms and be able to tolerate acute stress. Given this, the training should give practice in performing the task in realistic conditions and with a raised level of stress so that the trainee learns to handle it. Factors that affect stress include the level of demand and the degree of control over the task that the person feels he has. The individual's confidence that he is in control may be built up by experience of successful handling of similar problems. This experience can be given using a simulator. The level of demands should be built up until it reaches that experienced in real operation.

Another aspect of stress is the danger inherent in a major incident. The reports acknowledge that this aspect is difficult to simulate in an exercise, but refers to the expectation of possible criticism. In a healthy safety culture criticism of the performance of an individual or team can be made and accepted constructively. The report urges that management

at all levels should be periodically assessed for training need and that no-one should be 'above it.'

The report devotes considerable attention to the question of certification, which is supported by some and opposed by others. In order to disentangle the argument, it is necessary to assign a clear meaning to the word 'certification'. The report gives some eight possible definitions, together with comments. These may be summarized as follows: (1) specification of the content of training and clear responsibility for authorization of an individual to undertake certain actions; (2) separation between individuals who undertake (1) and line management; (3) a requirement that line management accept without further question separate assessment of the individual competence; (4) a requirement that line management authorize only persons from amongst those who have satisfied a separate assessment; (5) a rule that (3) or (4) apply only at the stage common to all reactors with different procedures thereafter; (6) a requirement that separate assessment should not mean simply testing by the training function but by another part of the organization; (7) a requirement that separate assessment should not be carried out by the licensee's organization at all but by a separate body and (8) a requirement that assessment should include observation of performance on the job and not merely verbal knowledge.

The report suggests that the first two interpretations would attract widespread consent. Opponents of certification may understand it in the third sense, but the authors doubt whether this view has proponents. A more serious argument turns on the fourth definition. Here opponents of certification argue that the trend is towards more involvement by line management in any matter which affects production and that there are dangers if it is not involved in training, whilst proponents emphasize that line management is liable to develop blind spots. The authors suggest that this points to the need for a 'two key' system, in which an operator needs to satisfy both an independent assessment and local line management. They argue that given the wide variety of reactor types in Britain the fifth definition would effectively rule out independent assessment. With regard to the sixth and seventh definitions, the report supports an assessment of the trainee performed by assessors who are independent both of the local line management and of the training function, but is unconvinced that the independent assessors need to come from outside the licensee. The authors support the type of assessment

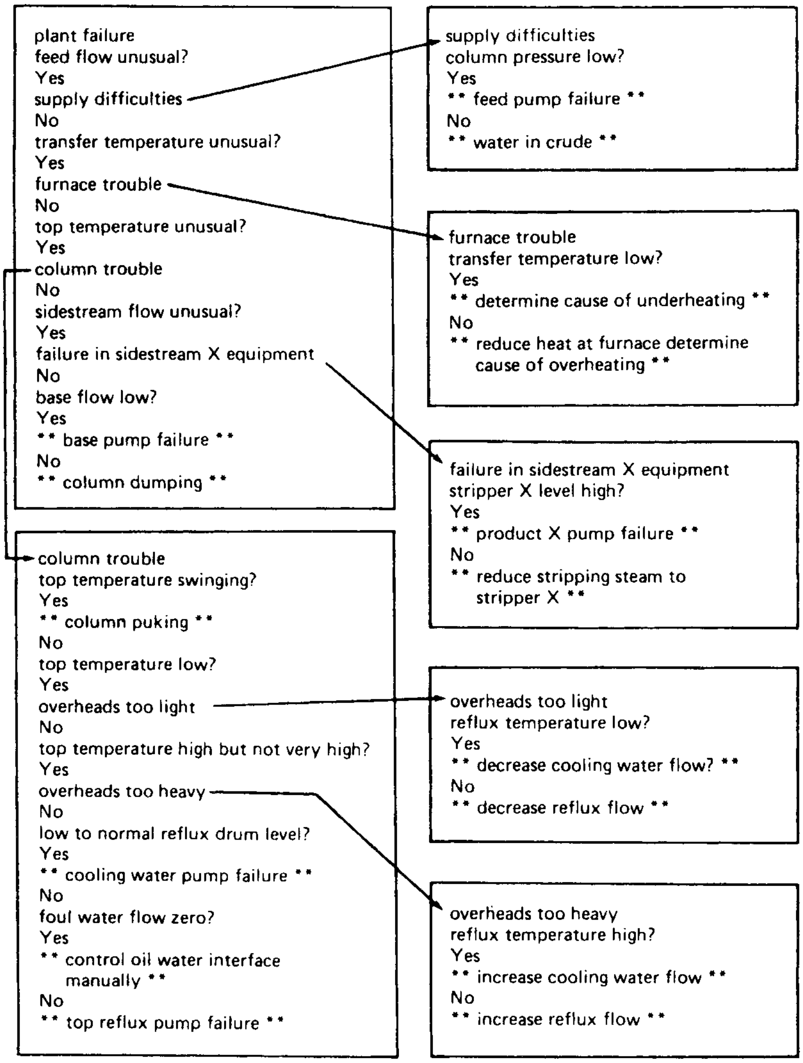

Figure 14.21 *Linked lists for learning fault diagnosis on a crude oil distillation unit (Duncan and Gray, 1975a) (Courtesy of the Journal of Occupational Psychology)*

given in the eighth definition. With regard to privatization, the report makes the point that, in order to support the type of training envisaged, a certain minimum size of training establishment is required.

The framework for training developed in the report is therefore broadly on the following lines. The starting point is task analysis. On the basis of this a specification for training is formulated by line management and the training is carried out by the training function. It is monitored by assessors independent of both local line management and the training establishment. Assessment of the trainee contains a component of actual or simulated performance. The trainee first has to satisfy the independent assessors and is then authorized by line management. Assessment is a continuing process.

The report deals particularly with the training of process operators. However, it emphasizes that training should not be confined to process operators but should also cover instrument artificers, maintenance personnel, etc.

Under the guise of trainability testing, the report touches on the question of personnel selection. It states:

> The Study Group believes it is important to find a valid way of deciding the relative success of different individuals, and that thereby it will become possible to devise satisfactory selection procedures. In other occupations it has frequently been found that systematic assessment of individuals can significantly improve trainability and subsequent performance. The potential of such methods should be explored further.

14.18 Human Factors and Industrial Safety

An account of the role of human factors in safety is given in *Human Factors in Industrial Safety* (HSE, 1989 HS(G) 48). This study sets out the factors that emerge most frequently from accident investigations and gives numerous case histories to illustrate the points made. Some of these case histories are given in Appendix 1.

It refers to the disaster at Chernobyl as an illustration. The background to the incident was serious defects in the management culture and in the regulatory system. The personnel conducting the test on the reactor were under pressure to complete the test in a short time. They failed to distinguish between small and large risks. They removed layer upon layer of protection and violated operational rules. The incident has many lessons, but the authors warn against treating it as a universal model.

The study starts from the viewpoint that the human operator is basically a positive rather than a negative factor in process plants. The operator gives the system a much enhanced ability to deal with abnormal situations. But it is necessary to design systems which protect against, and are tolerant of, human error and to train operators to improve their decision-making in these situations. Above all, the operator needs the support of a good safety culture.

The authors describe case histories that illustrate three aspects of human factors in particular: inadequate information, inadequate design and minimization of the consequences of human error. Human error is classified, with examples, under the headings of slips and lapses, mistakes, misperceptions, mistaken priorities and violations.

Measures for the prevention of human error, and an overall strategy for this, are considered under the headings of the organization, the job and personal factors. In this strategy, the organization is considered in terms of the safety climate, standard setting, monitoring, supervision and incident reports; the job is considered in terms of task analysis, decision-making, man–machine interfaces, procedures and operating instructions, the working environment, tools and equipment, work patterns and communication; and personal factors are considered in terms of personnel selection, training, health assessment and monitoring. Checklists are given under each of these headings.

Many of the examples given in this study are drawn from the process industries. The application of human factors to the process industries specifically is treated in *Human Factors in Process Operations* (Mill, 1992). This is a report of the Human Factors Study Group of the Loss Prevention Panel of the European Federation of Chemical Engineering (CEFIC).

The study covers a number of topics dealt with elsewhere in the present text, notably: management; accident models; control room design; operator control, mental models and workload; operating and emergency procedures; and human error.

A five-step strategy is described for modification of human behaviour in relation to accidents and hazards. These steps are: (1) identification and analysis of accidents and hazards; (2) revision of safety rules concerning working behaviour; (3) development of a plan of measures; (4) implementation of the plan and (5) follow-up – assessing the effectiveness of the measures taken.

14.19 Human Error

The topic of human error as such is a vast one and beyond the scope of the present work. The treatment here is limited to consideration of the effect of human error on the performance of process systems and on methods of dealing with it.

Accounts of human error include *Handbook of Human Reliability Analysis with Emphasis on Nuclear Power Plant Applications* (Swain and Guttmann, 1983), *Information Processing and Human-Machine Interaction* (Rasmussen, 1986), *Human Reliability* (Park, 1987), *Human Reliability Analysis* (Dougherty and Fragola, 1988), *Human Error* (Reason, 1990) and *An Engineers View of Human Error* (Kletz, 1991e). Selected references on human error and operator error are given in Table 14.11.

14.19.1 Engineering interest in human error

Engineering interest in human error derives from two principal sources. One is accident investigation, where the apparent salience of human error gives rise to concern. The other is hazard assessment, where the requirement to quantify the effect of human error on system performance creates a demand for a methodology capable of doing this.

In certain areas, such as an aircraft flightdeck, the prime emphasis has been on the application of human factors in system design to improve performance and reduce human error. In the nuclear field, however, there has been a much greater emphasis on the development of methodology for the assessment of the effect of human error on system performance. This has been the case in the process industries also.

There are, therefore, two distinct sources of interest in human error in engineering. Design seeks to improve the work situation and should not too readily accept the inevitability of human error. Assessment must to a considerable extent accept the situation as it is and seek to evaluate human error.

Work both on features that cause human error and on the methods of assessing it is a well established aspect of human factors.

14.19.2 Human error as a cause of accidents

Human error often figures as a major factor in analyses of incidents. Such an attribution appears in large part to derive from the nature of the investigative process. Reference has already been made to the comment by Rasmussen that in the investigation of accidents the tracing of the causes is generally terminated when it reaches a human, as if this was a stopping rule of the tracing process.

When a failure occurs, there is frequently an administrative requirement to determine the cause, and allocation to human error is notorious. In fact, the incident has occurred in a specific set of circumstances involving men, machines, systems and procedures, physical and social factors, and their interactions. Often the error is more truly that of another party who is responsible for some aspect of the work situation. This point is important because, whereas assignment to human error suggests little can be done, recognition of the effect of the work situation does tend to indicate the possibilities for improvement.

It is relevant to remember that experimental psychologists frequently conduct experiments in which various aspects of the work situation are altered and the subject's error rate is evaluated. This demonstrates clearly the importance of these factors in determining human error.

The reporting of errors in man–machine systems is often deficient, because reporting systems are frequently designed essentially to give information on equipment failure. The reporting of malfunctions in missile systems was studied by J. Cooper (1961), who found that, whilst the reporting system did reveal failures involving equipment only, it was deficient in discovering those involving man as well. He found that man appeared to be involved in 20–53% of all malfunctions for the systems studied, and this result is probably typical.

Thus, other investigations of the contribution of man to system failure have been made – in aerospace by Cornell (1968), on nuclear reactors by R.L. Scott (1971) and on industrial boilers by Ovenu (1969). These studies too attribute a large proportion of failures in the system to human error.

The contribution of human error to major accidents appears to be greater than it is to less serious failures. It has been estimated by Rasmussen (1978) that whereas human error probably contributes about 10% to general failures, it contributes about 50–80% to major accidents.

14.19.3 Approaches to human error

In recent years, the way in which human error is regarded, in the process industries as elsewhere, has undergone a profound change. The traditional approach has been in terms of human behaviour, and its modification by means such as exhortation or discipline. This approach is now being superseded by one based on the concept of the work situation. This work situation contains error-likely situations. The probability of an error occurring is a function of various kinds of influencing factors, or performance shaping factors.

The work situation is under the control of management. It is therefore more constructive to address the features of the work situation that may be causing poor performance. The attitude that an incident is due to 'human error', and that therefore nothing can be done about it, is an indicator of deficient management. It has been characterized by Kletz (1990c) as the 'phlogiston theory of human error'.

There exist situations in which human error is particularly likely to occur. It is a function of management to try to identify such error-likely situations and to rectify them. Human performance is affected by a number of performance shaping factors. Many of these have been identified and studied so that there is available to management some knowledge of the general direction and strength of their effects.

The approach to the work situation has itself undergone development. Three phases may be distinguished. In the first phase, the concern was with error-likely situations and performance shaping factors in general and on the application of ergonomic and human factors principles. The second phase saw greater emphasis on cognitive and decision-making aspects of the task. The third phase seeks the root causes in the organizational and, more generally, socio-technical background.

The approaches taken to human error may therefore be summarized as:

(1) behavioural approach;
(2) work situation approach:
  (a) general work situation,
  (b) cognitive features,
  (c) organizational features.

Any approach that takes as its starting point the work situation, but especially that which emphasizes organizational factors, necessarily treats management as part of the problem as well as of the solution. Kipling's words are apt: 'On your own heads, in your own hands, the sin and the saving lies!'

14.20 Models and Classifications of Human Error

A systematic approach to human error must involve the classification of errors and must, therefore, be based on appropriate models, either explicitly or implicitly. The classification is not necessarily along a single dimension. Most workers in the field have found it necessary to classify in terms of at least two dimensions: (1) human behaviour and (2) task characteristics.

An early detailed classification of operator error, which was developed for use in analysing licensee event reports (LERs) for nuclear plants by Rasmussen, quoted by J.R. Taylor (1979), is shown in Table 14.12. Also shown in the table is an analysis of 200 such reports. A more comprehensive version of this analysis is given by Rasmussen (1980). This classification includes categories both of behaviour and of task.

14.20.1 Task analysis framework and model

The general framework in which most models and classifications of human error are applied is that of task analysis. That is to say, the task is decomposed into elements such as plans and actions and the errors associated with these are modelled and classified. The extent of the decomposition varies, some approaches being highly decompositional and others more holistic, as discussed below.

In addition to being a general framework within which particular models are applied, task analysis, particularly hierarchical task analysis, may be regarded as a model in its own right. One common classification of human error is in terms of actions. This type of classification refers to acts of omission, acts of commission, and also delays in taking action and so on. It does not attempt to explain them in terms of any other model, such as one involving skills or absentmindedness, although it make take into account various types of influencing factor. This approach has much in common with hazop in the way in which action errors are classified. The similarity between the task analysis scheme and the human error classification shown in Tables 14.9 and 14.18 respectively, makes the point.

14.20.2 Work situation framework and models

Another general framework in the modelling of human error is the work situation, which covers the task itself and the various influencing factors including the ergonomic, the cognitive and the organizational. Where an approach is adapted to human error which accords a central role to the work situation, or some aspect of it such as communication, the work situation virtually becomes the model. In such a model, the emphasis tends to be on identifying, classifying and quantifying the strength of the factors influencing human error rather than on seeking a more fundamental explanation.

14.20.3 Demand-capacity mismatch model

Turning now to other models of human error, or human reliability, one early model views it as a mismatch between the demands of the task and the capacity of the human to perform the task. The mismatch may arise in various ways. It may be due, for example, to physical incapacity. Or it may arise from lack of training.

A particular case, which is properly regarded as involving human reliability rather than human error, is where sudden death or incapacity, such as a heart attack, occurs. This may need to be taken into account in relation to crucial functions.

14.20.4 Tolerance-variability model

Another early model starts from the viewpoint that fundamental to human error is variability, both of people and of tasks. Variability in performance is associated with the desirable human feature of adaptability. Variability is also present in the task. Even a standardized assembly operation involves some variability. More complex industrial tasks are much more variable.

***Table 14.12** Classification of operator error in 200 licensee event reports (J.R. Taylor, 1979; after Rasmussen)*

	No.
Task condition	
Routine task on schedule	89
Routine task on demand	11
Special task on schedule	51
Ad hoc, improvization	21
Various, not mentioned	27
Task control	
Paced by system dynamics	9
Paced by program, orders	4
Self-paced	166
Various, not mentioned	21
Error situation	
Spontaneous error in undisturbed task	93
Change in condition of familiar task	27
Operator distracted in task, preoccupied	10
Unfamiliar task	22
Various, not mentioned	48
Task	
Monitoring and inspection	3
Supervisory control	13
Manual operation, manual control	17
Inventory control	30
Test and calibration	47
Repair and modification	60
Administrative, recording	4
Management, staff planning	13
Various, not mentioned	13
Effect from	
Specified act not performed	103
Positive effect of wrong act	65
Extraneous effect	15
Sneak path	12
Various, not mentioned	6
Potential for recovery	
Effect not immediately reversible	29
Effect not immediately observable	137
Various, not mentioned	34
Error categories	
Absent-mindedness	3
Familiar association	6
Capability exceeded	1
Alertness low	10
Manual variability, lack of precision	10
Topographic, spatial orientation inadequate	10
Familiar routine interference	0
Omission of functionally isolated act	56
Omission of administrate act	12
Omission, other	9
Mistake, interchange among alternative possibilities	11
Expect, assume rather than observe	10
System knowledge, insufficient	2
Side-effects of process not adequately considered	15
Latent causal condition or relations not adequately considered	20
Reference data recalled wrongly	1
Sabotage	1
Various, not mentioned	17

Some variations in the performance of the task can be tolerated. It is only when some limit is overstepped that error is said to occur. The definition of error is therefore critical. The limits may be defined in various ways such as physical barriers, warning signs, operating procedures, production tolerances and standards, process conditions, and social and legal codes.

Swain (1972) distinguishes between random, systematic or sporadic errors. Random and systematic errors can usually be corrected by reducing, respectively, the variance and the bias in the performance of the task, but it may be more difficult to understand and correct sporadic errors, which typically involve sudden and often large excursions out of limits.

14.20.5 Time availability model

Another type of model is based on the premise that human reliability in certain tasks, particularly emergency response, increases with the time available to perform the task. This model might be regarded as a particular case of the demand–capacity mismatch model.

14.20.6 Skills-rules-knowledge model

The skills-rules-knowledge (SRK) model, developed by Rasmussen (1986), treats the human as operating on the three levels of skills, rules and knowledge. Each level has its characteristic types of error. An account of this model has been given in Section 14.12.

14.20.7 Absentmindedness model

The absentmindedness model, developed by Reason (1990), distinguishes between slips, lapses and mistakes. A slip is either (1) an error in implementing a plan, decision or intention, where the plan is correct but the execution is not or (2) an unintended action. A lapse is an error in which the intended action is not executed due to a failure of memory. A mistake is an error in establishing a course of action such as an error in diagnosis, decision-making or planning. This model is described more fully in Chapter 26.

14.20.8 Organizational model

The organizational, or socio-technical system, model stresses the contribution of organizational and wider socio-technical factors to human error. It may be regarded as a version of the work situation model that puts particular emphasis on these factors.

14.20.9 Violations

It is recognized that some actions are not strictly human errors but outright violations. There appears to be no developed model for violations. Whilst it is now accepted that human error is something that is under the influence of management, this is less so for violations. In this respect, the treatment of violations seems to be at the point where that of human error was some two or three decades ago. There is a need for a better understanding of why violations occur and how they may be designed out.

14.20.10 Decompositional and holistic approaches

Along a different dimension, approaches to human error may be characterized either as decompositional or as holistic. In the decompositional approach, also referred to as 'reductionist', 'mechanistic' or 'atomistic', the task is decomposed into its constituent elements, and for each element the probability of failure is estimated. The probability of failure for the task overall is taken as the product of the individual probabilities. Allowance may be made for certain features such as dependent failure, but for the most part other aspects of task failure such as errors in decision-making are not well handled. The holistic approach by contrast takes high level elements of the work and thus covers features such as decision-making.

14.20.11 Classifications of human error

Classifications of human error flow from the above described models. A common distinction, based essentially on the task analysis model, is between errors of omission, transformation or commission. A human may fail to execute a required action, or he may execute it but incorrectly or out of sequence or too slowly, or he may execute an unwanted action. Errors of omission may involve failures of attention or memory, and errors of commission failures in identification, interpretation or operation. Error classifications along these lines have been given by Lincoln (1960) and Swain (1970).

Classifications related to the work situation model are typically in terms of the influencing factors. The SRK model of Rasmussen gives rise to a classification based on distinction between errors arising at the levels of skill, rules and knowledge. The classification deriving from Reasons's absentmindedness model is into slips, lapses and mistakes.

Another classification of human error is based on the relationship in time of the error to the initiating event in an incident sequence. If the error precedes the initiating event, it is a latent, or enabling, error. If it is the direct cause of the event, it is an initiating error. And if it follows the event, it is a response or recovery error.

14.21 Human Error in Process Plants

14.21.1 Human error in general and in plant operation

An overview of human error in process plants is given in *An Engineer's View of Human Error* (Kletz, 1991e). This work provides a useful account of the practicalities of human error in the various activities occurring on such plants. Kletz describes the following types of human error:

(1) simple slips;
(2) errors due to poor training or instructions;
(3) errors due to lack of physical or mental ability;
(4) wrong decisions;
(5) management errors.

He treats human error in:

(6) design;
(7) construction;
(8) operation;
(9) maintenance.

Kletz also gives numerous examples.

The basic approach that he adopts is that already described. The engineer should accept people as they are and should seek to counter human error by changing the work situation. In his words: 'To say that accidents are due to human failing is not so much untrue as unhelpful. It does not lead to any constructive action'.

In designing the work situation the aim should be to prevent the occurrence of error, to provide opportunities to observe and recover from error, and to reduce the consequences of error.

Some human errors are simple slips. Kletz makes the point that slips tend to occur not due to lack of skill but rather because of it. Skilled performance of a task may not involve much conscious activity. Slips are one form of human error to which even, or perhaps especially, the well trained and skilled operator is prone. Generally, therefore, additional training is not an appropriate response. The measures that can be taken against slips are to (1) prevent the slip, (2) enhance its observability and (3) mitigate its consequences.

As an illustration of a slip, Kletz quotes a incident where an operator opened a filter before depressurizing it. He was crushed by the door and killed instantly. Measures proposed after the accident included: (1) moving the pressure gauge and vent valve, which were located on the floor above, down to the filter itself; (2) providing an interlock to prevent opening until the pressure had been relieved; (3) instituting a two-stage opening procedure in which the door would be 'cracked open' so that any pressure in the filter would be observed and (4) modifying the door handle so that it could be opened without the operator having to stand in front of it. These proposals are a good illustration of the principles for dealing with such errors. The first two are measures to prevent opening while the filter is under pressure; the third ensures that the danger is observable; and the fourth mitigates the effect.

One area of process operation where slips are liable to occur is in the emptying and filling of equipment. It is often necessary to drain a vessel or other equipment such as a pump. Not infrequently, fluid is admitted to the equipment while the drain valve is still open. In some applications, an interlock may be the appropriate solution, as described in Chapter 13.

Misidentification of the equipment to be worked on is another fertile source of error. Kletz gives as an example a plant that had an alarm and trip on the same process variable and where the technician who intended to work on the alarm in fact disabled the trip. He also gives a number of examples of the operation of the wrong press button or the wrong valve caused by inconsistent labelling. The identification of equipment for maintenance is considered in more detail in Chapter 21.

Another type of slip is failure to notice. This is particularly liable to occur if some item is similar but not identical. A case in point is where an operator draws from a drum which contains the wrong chemical but where the drums containing the right and the wrong chemicals have similar markings.

The need to calculate some process quantity introduces a further opportunity for error. In some cases, the result may be sufficiently unusual as to highlight the error, but in others it may not.

Many human errors in process plants are due to poor training and instructions. In terms of the categories of skill-, rule- and knowledge-based behaviour, instructions provide the basis of the second, whilst training is an aid to the first and the third, and should also provide a motivation for the second. Instructions should be written to assist the user rather than to hold the writer blameless. They should be easy to read and follow, they should be explained to those who have to use them, and they should be kept up to date.

Problems arise if the instructions are contradictory or hard to implement. A case in point is that of a chemical reactor where the instructions were to add a reactant over a period of 60–90 min, and to heat it to 45°C as it was added. The operators believed this could not be done as the heater was not powerful enough and took to adding the reactant at a lower temperature. One day there was a runaway reaction. Kletz comments that if operators think they cannot follow instructions, they may well not raise the matter but take what they believe is the nearest equivalent action. In this case, their variation was not picked up as it should have been by any management check. If it is necessary in certain circumstances to relax a safety-related feature, this should be explicitly stated in the instructions and the governing procedure spelled out.

Certain features of the operation and maintenance of process plants should be covered in elementary training. Incidents occur because operators do not fully appreciate the basic properties and hazards of flammable and toxic chemicals and the precautions necessary in handling them, the operation and hazards of pressure systems, the reasons for the principal procedures and the importance of adherence to all procedures. This elementary training is discussed in more detail in Chapter 28.

There are a number of hazards which recur constantly and which should be covered in the training. Examples are the hazard of restarting the agitator of a reactor and that of clearing a choked line with air pressure.

Training should instil some awareness of what the trainee does not know. The modification of pipework that led to the Flixborough disaster is often quoted as an example of failure to recognize that the task exceeded the competence of those undertaking it.

Kletz illustrates the problem of training by reference to the Three Mile Island incident. The reactor operators had a poor understanding of the system, did not recognize the signs of a small loss of water and they were unable to diagnose the pressure relief valve as the cause of the leak.

Installation errors by contractors are a significant contributor to failure of pipework. Details are given in Chapter 12. Kletz argues that the effect of improved training of contractors' personnel should at least be more seriously tried, even though such a solution attracts some scepticism.

Human error may occur due to physical or mental inability to perform the task. Even if there is not total inability, the task may be very difficult and therefore liable to error. Physical difficulties can arise in the manipulation of controls and valves. The task may require the operator to observe a display whilst manipulating a control, but the display may be too far from the control to do this. Manual valves on the plant may be inaccessible or stiff to turn. The need to use protective equipment such as breathing apparatus may introduce physical difficulties.

There are a number of situations that may create mental difficulties. Mental overload is one such situation that may come in various forms. The operator may suffer overload due to an excessive number of alarms. A supervisor may be overloaded by the number of permits-to-work. Another type of mental difficulty occurs where the operator is required to undertake tasks that are not his *forte*. One case is detection of rare events. Another is taking over in an emergency from a totally automated system.

Another category of human error is the deliberate decision to do something contrary to good practice. Usually it involves failure to follow procedures or taking some other form of short-cut. Kletz terms this a 'wrong decision'. W.B. Howard (1983, 1984) has argued that such decisions are a major contributor to incidents, arguing that often an incident occurs not because the right course of action is not known but because it is not followed: 'We ain't farmin' as good as we know how'. He gives a number of examples of such wrong decisions by management.

Other wrong decisions are taken by operators or maintenance personnel. The use of procedures such as the permit-to-work system or the wearing of protective clothing are typical areas where adherence is liable to seem tedious and where short-cuts may be taken.

A powerful cause of wrong decisions is alienation.

Wrong decisions of the sort described by operating and maintenance personnel may be minimized by making sure that rules and instructions are practical and easy to use, convincing personnel to adhere to them and auditing to check that they are doing so.

Responsibility for creating a culture that minimizes and mitigates human error lies squarely with management. The most serious management failing is lack of commitment. To be effective, however, this management commitment must be demonstrated and made to inform the whole culture of the organization.

There are some particular aspects of management behaviour that can encourage human error. One is insularity, which may apply in relation to other works within the same company, to other companies within the same industry or to other industries and activities. Another failing to which management may succumb is amateurism. People who are experts in one field may be drawn into activities in another related field in which they have little expertise.

Kletz refers in this context to the management failings revealed in the inquiries into the Kings Cross, *Herald of Free Enterprise* and Clapham Junction disasters. Senior management appeared unaware of the nature of the safety culture required, despite the fact that this exists in other industries.

14.21.2 Human error and automation

The automation of functions previously performed by the human operator can give rise to certain characteristic problems. These ironies of automation have been discussed by Bainbridge (1983), who identifies four areas of concern. One is the potential for deterioration of the skills of the process operator. Another is the need for the operator to monitor the functioning of the automatic equipment, a role to which he is not particularly well suited. The third is the difficulty for the operator of maintaining an up-to-date mental model of the status of the process in case he has to intervene. The fourth is the tendency of automated systems to reduce small variations at the price of occasionally introducing very large ones.

These characteristics of automated systems were discussed in general terms in the early part of this chapter. Here attention is drawn to their potential to induce human error.

14.21.3 Human error in plant maintenance

Much of the literature on human error in process plants is devoted to the process operators. However, a large proportion of serious incidents is attributable to errors in maintenance work. Maintenance errors may endanger those doing the work, the plant, or both.

Several treatments of human error in maintenance work have been published by the Health and Safety Executive (HSE). Accounts illustrated with case histories are given in *Deadly Maintenance* (HSE, 1985b) and *Dangerous*

Maintenance (HSE, 1987a). *Human Factors in Industrial Safety* (HSE, 1989 HS(G) 48) gives general guidance on human factors relevant *inter alia* to maintenance work.

Here again it is appropriate to start with the designer. If it is practical to design out the need for maintenance, the problem disappears.

One cause of error in maintenance is lack of understanding either of the process and chemicals or of the equipment. This is exemplified by a number of incidents where the wrong bolts have been loosened on a valve, resulting in a release.

Maintenance is an area where poor practices can easily creep in. An example is breaking a flange the wrong way. Maintenance personnel on process plants spend a large proportion of their time dealing with heavy, dirty equipment. It is not easy to make the transition required when they have to work on relatively delicate items. A case in point is leaving flameproof equipment with loose screws and an excessive gap so that it is no longer flameproof.

In some cases defects of workmanship in maintenance are gross. Kletz cites a case where a fitter had to remake a flanged joint using a new spiral wound gasket. Since it was too large, he ground depressions in the outer metal ring of the gasket so that it would fit between the bolts. He made matters worse by making only three depressions so that the gasket did not fit centrally between the bolts.

Maintenance is an activity which can often be frustrating and short-cuts may be taken. Use of protective clothing, isolation procedures and the permit-to-work system are areas where such short-cuts tend to be taken.

Reference has already been made to errors in identification of equipment. Measures need to be taken to ensure effective identification.

An overview of the management of maintenance to ensure safe working is given in Chapter 21.

14.21.4 Human error in pipework failure

In construction, errors in the installation of pipework loom large. The problem was highlighted in a survey by Kletz (1984k), who has given a checklist aimed at eliminating such defects. Two of the measures proposed by Kletz to reduce pipework construction errors are improved training of the construction workforce, as already described, and the use of the barrier principle. A more detailed treatment of Kletz' work on pipework errors is given in Chapter 12.

This theme has been taken up again in the study of pipework failure, and human error as cause of such failure, described by Bellamy and co-workers (Bellamy, Geyer and Astley, 1989; Geyer *et al.*, 1990; Geyer and Bellamy, 1991; Hurst *et al.*, 1991). This study has already been referred to in Chapter 12 in dealing with failure of pipework, where a number of tables are given based on this study.

A total of 921 incidents from incident data bases were reviewed, some analysis was done on all 921 incidents and further analysis on some 502 incidents. Incidents were classified in three ways: (1) 'direct cause', (2) 'origin of failure' or underlying cause and (3) 'recovery failure' or preventive mechanism.

The crude data showed that operator error contributed 18.2% to the direct causes of pipework failure, whilst defective pipe or equipment contributed 31.9% and unknown causes 9.1%. If the last two categories are removed from consideration, operator error then contributes 30.9%. Table 14.13, Section A, shows the contribution to the direct causes of operator error and of two other human errors. Sections B and C of the table give the distribution of human error among the underlying causes and the recovery failures, respectively. For the former, the predominant errors are in maintenance and for the latter, in human factors review and task checking.

Table 14.13 *Human error as a cause of pipework failure (after Bellamy, Geyer and Astley, 1989) (Courtesy of the Health and Safety Executive)*

A Direct causes

Cause	*Contribution of human error* (%)
Operator error	30.9
Wrong or incorrectly located in-line equipment	4.5
Human-initiated impact	5.6
Total	41.0

B Underlying cause

Cause	*Distribution of human error between underlying causes* (%)
Design	8
Manufacture	2
Construction	8
Operation	22
Maintenance	59
Sabotage	1
Total	100

C Recovery failures

Failure	*Distribution of human error between recovery failures* (%)
Not recoverable	1
Hazard study	6
Human factors review	60
Task checking	31
Routine checking	2
Total	100

14.21.5 Human error and plant design

Turning to the design of the plant, design offers wide scope for reduction both of the incidence and consequences of human error. It goes without saying that the plant should be designed in accordance with good process and mechanical engineering practice. In addition, however, the designer should seek to envisage errors that may occur and to guard against them.

The designer will do this more effectively if he is aware from the study of past incidents of the sort of things that can go wrong. He is then in a better position to understand, interpret and apply the standards and codes, which are one of the main means of ensuring that new designs take into account, and prevent the repetition of, such incidents.

A significant contribution can be made by the designer to the elimination of errors leading to pipework failures.

One is to remove situations vulnerable to an operator error such as opening the wrong valve so that the plant suffers overpressure or undertemperature. Another is to counter errors in construction and maintenance by applying the barrier principle so that it is literally impossible to assemble an item in a manner other than the correct one.

Another area where the designer has a large contribution to make is in facilitating maintenance activities on the plant. This includes: provision of access to equipment, pipework and valves; pipework arrangements which assist isolation of sections of plant; and measures to prevent of misidentification of equipment.

An aspect of operation that provides a new field for human error is computer control of process plants. This is considered in Chapter 13.

14.21.6 Human error and organizational factors

At a fundamental level human error is largely determined by organizational factors. Like human error itself, the subject of organizations is a wide one with a vast literature, and the treatment here is strictly limited.

It is commonplace that incidents tend to arise as the result of an often long and complex chain of events. The implication of this fact is important. It means in effect that such incidents are largely determined by organizational factors. An analysis of 10 incidents by Bellamy (1985) revealed that in these incidents certain factors occurred with the following frequency:

Interpersonal communication errors	9
Resources problems	8
Excessively rigid thinking	8
Occurrence of new or unusual situation	7
Work or social pressure	7
Hierarchical structures	7
'Role playing'	6
Personality clashes	4

The role of organizational factors is a principal theme in the work of Kletz, who has described a number of incidents that appear to arise from failures which at the superficial level might be assigned to hardware or humans, but which on deeper investigation can be attributed to organizational aspects. He describes the process of seeking out these more fundamental causes as 'peeling the onion'.

Organizational factors are to a degree taken into account in current methods of human reliability analysis (HRA) in several ways. In particular, allowance is made for these factors in relation to oral and written procedures and to factors that influence task performance.

14.21.7 Human error in communications

One aspect of organizational factors is interpersonal communication. Communications is one of the relatively few topics in human error in process plants that has been the subject of study. Work on communication errors has been described by Bellamy (1983, 1984, 1985). She found that interpersonal communication errors played a part in nine out of the ten incidents which she studied (Bellamy, 1985). The errors might be associated with either enabling or initiating events.

Incidents studied by Bellamy (1983) include the explosion at Flixborough, the explosion at Houghton Main colliery and the radioactive release at Sellafield. Figure 14.22 shows her analysis of the chain of events at Houghton Main in which communication errors were prominent.

It is normal to place considerable reliance on communication as a line of defence. Where this is the case it is necessary to take steps to ensure that the communication is effective. In order to ensure the integrity of communication, there is need for a considerable degree of formality in the communication procedures. In certain fields, such as air traffic control, this is normal practice. In the process industries, the degree of formality in communication tends to be variable. Two important features include the handover procedures and permit-to-work system. Other aspects of communication may be less formal.

Table 14.14 is a list given by Bellamy (1983) of some of the errors that may occur in interpersonal communications. One feature prominent in the incidents that she describes is ambiguous or incomplete messages occurring within a formal system. The existence of a formal system such as handover with associated logbooks may not, therefore, be sufficient if in practice the quality of communication within it is poor.

Two central features of the system of communication on a plant are the permit-to-work system and the handover system. It is not surprising, therefore, that many communications errors are associated in some way with one or other of these systems. Kletz (1991e) gives as an illustration the instance of the failure of a permit-to-work system, described in Chapter 20.

14.22 Prevention and Mitigation of Human Error

There exist a number of strategies for prevention and mitigation of human error. Essentially these aim to:

(1) reduce frequency;
(2) improve observability;
(3) improve recoverability;
(4) reduce impact.

Some of the means used to achieve these ends include:

(1) design-out;
(2) barriers;
(3) hazard studies;
(4) human factors review;
(5) instructions;
(6) training;
(7) formal systems of work;
(8) formal systems of communication;
(9) checking of work;
(10) auditing of systems.

The *Guide to Reducing Human Error in Process Operation* compiled by the Human Factors in Reliability Group (HFRG), (1985 SRD R347) gives guidance in check-list form. The checklists cover (1) operator-process interface, (2) procedures, (3) workplace and working environment, (4) training and (5) task design and job organization.

14.22.1 Role of engineering measures

There is some danger that emphasis on the apparently dominant role of human error in major incidents may induce in the engineer a feeling of helplessness. This is misplaced. As this chapter indicates, there is a variety of methods, from the managerial to the technical, which can

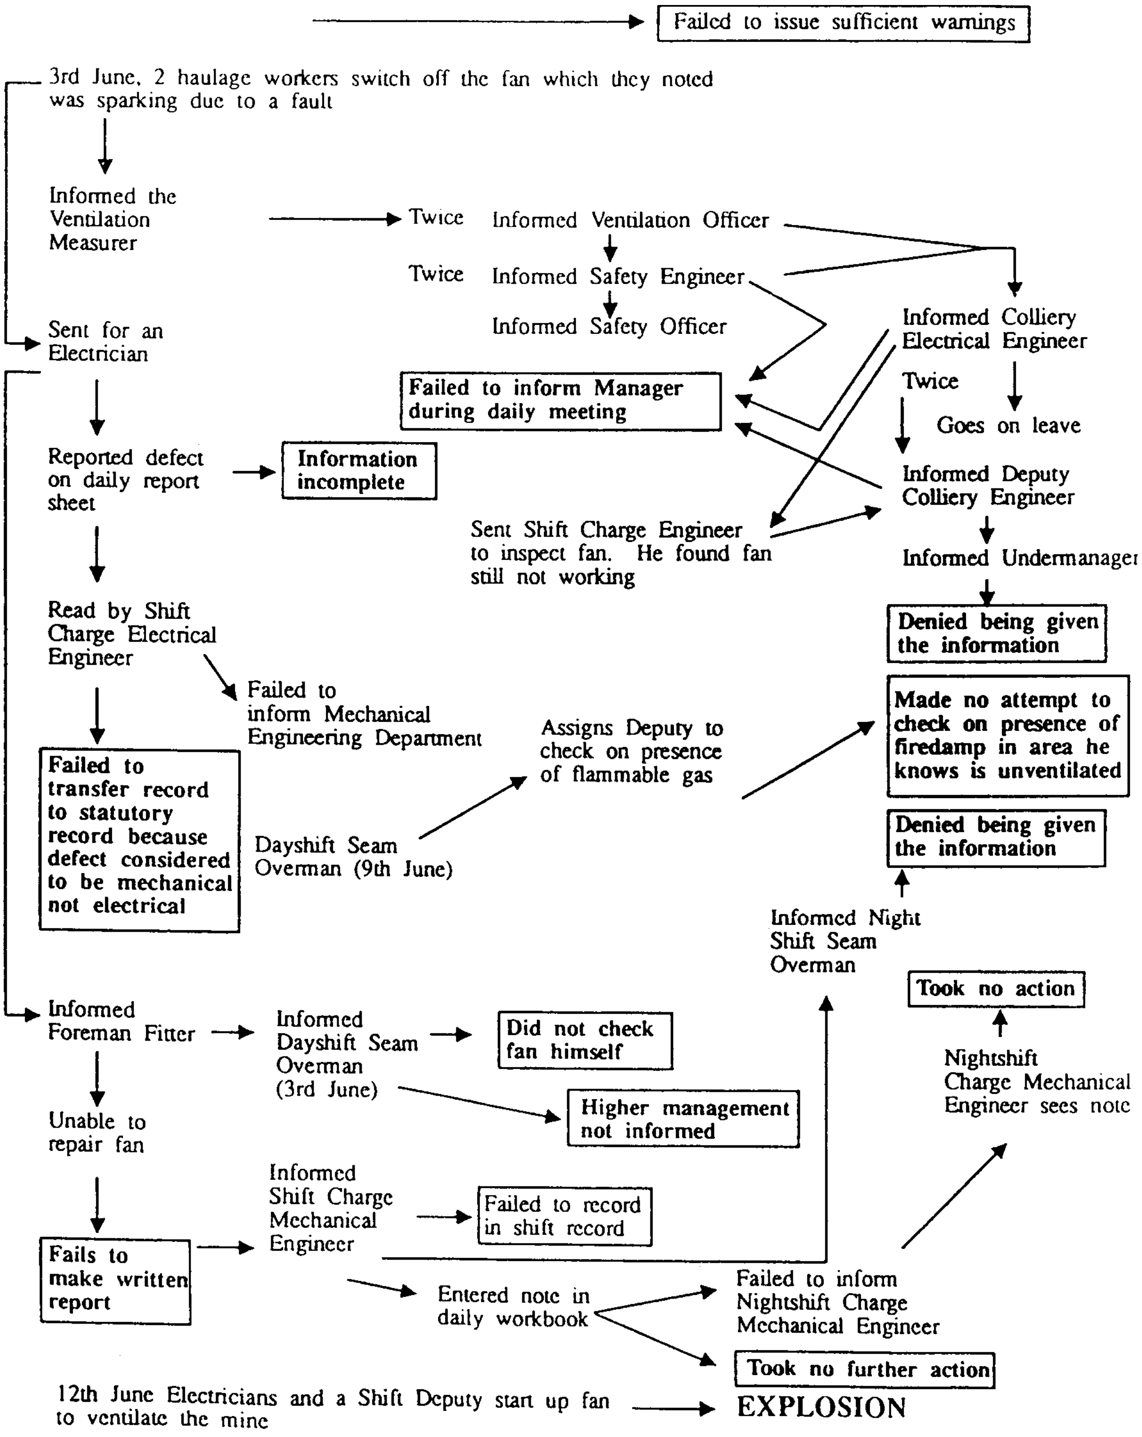

Figure 14.22 Chain of events in the Houghton Main colliery accident illustrating communication errors (Bellamy, 1983. Reproduced by permission.)

Table 14.14 *Some human errors in interpersonal communication (Bellamy, 1983. Reproduced with permission.)*

1. *Sender errors*
   (a) *In encoding information*
   - Information not encoded (e.g. message contains no information)
   - Information ambiguous (e.g. semantic ambiguity)
   - Information incomplete (e.g. details omitted)
   - Information or code incorrect (e.g. wrong values given, wrong terms used)
   - Code inappropriate (e.g. code foreign to intended receiver)

   (b) *In transmitting information*
   - Information not transmitted (e.g. not sent, not recorded)
   - Information not transmitted in time (e.g. too late for action to be taken)
   - Information transmitted via incorrect channel (e.g. standard channel not used)
   - Unacknowledged transmission not repeated (e.g. repeat not possible)
   - Acknowledged transmission not corrected (e.g. error in the acknowledgement not noticed)

2. *Receiver errors*
   - Failure to acquire message (e.g. does not read record book, ignores message)
   - Incomplete decoding of message (e.g. forgets details)
   - Incorrect decoding of message (e.g. misinterprets meaning)
   - Receipt of message not acknowledged (does not give feedback to sender)
   - Receipt of message acknowledged but no feedback of decoded message (e.g. does not repeat back interpreted content of message)
   - Feedback of decoded message is ambiguous (e.g. semantic ambiguity)

3. *Errors in additional recording of sent or received messages*
   - Sent information not recorded (e.g. not written down)
   - Received information not recorded (e.g. not written down)
   - Information recorded but poorly encoded (*see* l(a)) (e.g. in written report)

be used to reduce the frequency with which human error gives rise to an initiating event. But it may well be in his contribution to the mitigation of the consequences that the engineer comes into his own.

14.23 Assessment of Human Error

Turning now to the assessment of human error, the growing use of quantitative risk assessment has created a demand for the development of techniques for the assessment of human error to complement those available for the assessment of hardware failures.

In the following sections an account is given of developments in the assessment of human error. First, the task analytic approach is described in which a task is decomposed into its elements and error rates are assigned to each of these elements (Section 14.24). Next, an overview is given of early attempts to decompose the process control task into elements for which there might be available information on human error probabilities (Section 14.25). The account then reverts to qualitative methods developed to ensure that the analyst has a sound understanding of the problem before embarking on quantification (Section 14.26). There follow descriptions of some of the principal methods of estimating human reliability (Sections 14.27–14.32), of performance shaping factors (Section 14.33) and of human error data (Sections 14.34). Treatments are then given of certain guides and overviews, including a benchmark exercise, and of applications at Sizewell B (Sections 14.35–14.39). The topic of human reliability assessment is replete with acronyms and the account here necessarily reflects this.

14.24 Assessment of Human Error: Task Analytic Approach

Turning then to the methods available for making a quantitative assessment of human error in process plant operation, the starting point is analysis of the task.

14.24.1 Task analysis

Early work on discrete tasks generally took as its starting point some form of task analysis in which the task was broken down into its component parts. The probabilities of error in the performance of these component subtasks were then estimated and the probability of error in the complete task then assessed.

A methodology based on the task analytical approach, the technique for human error rate prediction (THERP), developed by Swain and co-workers is described below. An overview of this type of approach is given here based on an early account by Swain (1972).

Estimates of the probability of success in a planned discrete task may be made at different levels of sophistication. At one extreme, an average task error rate of, say, 0.01 is sometimes quoted. This is apparently based on the assumption that the average element error rate is 0.001 and that there are, on average, 10 elements per task. At the other extreme is the collection and application of experimental data on error rates as a function of the performance shaping factors.

An important aspect of task reliability is the possibility of recovery by detection and correction of the error. If an error is retrievable in this way, the error rate for the task may be reduced by orders of magnitude. The probability of recovery depends very much on the cues available concerning the error, whether from displays and controls or from the system generally.

The effect of an error is also relevant, since only a proportion of errors have significant effects. Swain suggests that if the probability that an error will occur is between 10^{-4} and 10^{-3}, that it will be corrected is between 0.02 and 0.2 and that it will have a significant effect is between 0.2 and 0.3, then the probability that an error will occur, will remain undetected and will have a significant effect is of the order 0.4×10^{-6} to 60×10^{-6}.

The application of task reliability calculation to process control is exemplified by the work of Ablitt (1969 UKAEA AHSB(S) R160) on the estimation of the reliability of execution of a schedule of trip and warning tests involving some 55 items.

14.25 Assessment of Human Error: Process Operation

It was recognized early on that the above approach, based as it is on routine tasks such as equipment assembly, was of dubious applicability to the overall task of process control, and attempts were made to classify tasks in process control so as to make the links between these tasks and relevant areas of research in human factors.

One such classification is that given by Lees (1973a, 1980b), who breaks the overall process control tasks down into three categories on which information is available: (1) simple tasks, (2) vigilance tasks and (3) emergency behaviour – and two further more difficult categories – (4) complex tasks and (5) control tasks. In this classification, simple tasks are essentially the planned, usually routine, discrete tasks of the type just described, whereas complex tasks are those which are not routine but require some element of decision-making. The control task is essentially the residual of the operator's overall task in supervising the process, after exclusion of the specific simple and complex tasks, the vigilance, or monitoring, task and emergency response. The classification was an early attempt to decompose the process control task into categories that are recognized in work on human factors and on which there is therefore some prospect of obtaining data, or at least guidance.

A more recent but somewhat similar classification is that given by Dougherty and Fragola (1988). They give the following analogy between hardware failures and human error:

Hardware failure	*Human activity*
Demand failure	Plan-directed behaviour
Stand-by failure	Vigilance behaviour
Running failure	Event-driven behaviour

To the above list might be added, for hardware, emergency response failure and, for human activity, emergency response behaviour.

Other techniques which take a more holistic approach to complex tasks are the goal-directed activity (GDA) technique and success likelihood index method (SLIM) of Embrey and the human error assessment and reduction technique (HEART) of Williams, described below.

14.25.1 Routine tasks

As described above, the usual approach to the estimation of human error rates in simple, or routine, tasks is to break the task down into its constituent elements and to derive an estimate of the reliability of the task from that of its constituent elements. The deficiencies of this rather mechanistic approach have long been recognized for any task that involves decision-making, but it may serve to the degree that a routine task may be defined as one that does not require decision-making so that errors are confined to slips rather than mistakes. Given this restriction, the methods developed in THERP may be used. Alternatively, use may be made of the methods developed for complex, or non-routine tasks, as described below.

14.25.2 Vigilance tasks

A vigilance task involves the detection of signals. There is a large body of work on the performance of vigilance tasks. Some of the factors that affect performance in such tasks are:

(1) sensory modality;
(2) nature of signal;
(3) strength of signal;
(4) frequency of signal;
(5) expectedness of signal;
(6) length of watch;
(7) motivation;
(8) action required.

Sight and hearing are the main channels for receiving the signal. The signal itself may be a simple GO–NO GO one or a complex pattern. In this latter case, the out-of-limit condition may not be well defined in advance, but may have to be judged by the subject at the time. The signal may be strong and noise-free or weak and noisy, it may be frequent or infrequent and it may be an expected or unexpected type. The performance of the subject is affected by such factors as length of watch, degree of motivation and the action required on receipt of the signal.

Some general conclusions may be drawn from the work on vigilance. In general, the auditory channel is superior to the visual for simple GO–NO GO signals such as alarms. The probability of detection of a signal varies greatly with signal frequency; detection is much more probable for frequent than for infrequent signals. A vigilance effect exists so that performance tends to fall off with time.

There is an appreciable amount of data on vigilance tasks such as scanning displays, responding to alarms, and so on. A typical piece of work on vigilance in process control is that described by A.E. Green (1969 UKAEA AHSB(S) R172, 1970). The equipment used was the Human Response Analyser and Timer for Infrequent Occurrences (HORATIO), which automatically produces signals that are reasonably representative in form and time distribution of certain types of fault indication, and measures the time interval between the onset of the signal and the operator's response to it. Experiments were conducted in nuclear reactor control rooms in which operators were asked to respond to a simultaneous visual indication and an audible alarm signal by pressing a button. The signal rates were between 0.35 and 1.5 events/h. The probability of failure to respond to signals within the allowed response time was about 10^{-3}.

Another related type of task is inspection, which has also been much studied. In general, there is a greater probability of error in an inspection task where it is rather passive, the discrimination required is simple, the defect rate is low and the inspection is continuous. If there are more active features, such as taking measurements to detect the defect, the defect rate is high and inspection is alternated with another task, the error rate is reduced. A survey by McCornack (1961) suggests that with a defect probability of 0.01 the average inspection error is about 0.15, but inspection error probabilities vary widely and Swain (1972) quotes the range 0.01–0.6.

14.25.3 Emergency behaviour

Another definable task is response to an emergency. This is treated here as a situation which requires decision-making under stress. Here a certain amount of information is available from military and aerospace sources. One source of information is the critical incident technique that involves debriefing personnel who have been involved in critical incidents.

Two studies in particular on behaviour in military emergencies have been widely quoted. One is an investigation described by Ronan (1953) in which critical incidents were obtained from US Strategic Air Command aircrews after they had survived emergencies, for example loss of engine on take-off, cabin fire or tyre blowout on landing. The probability of a response which either made the situation no better or made it worse was found to be, on average, 0.16.

The other study, described by Berkun (1964), was on army recruits who were subjected to emergencies, which were simulated but which they believed to be real, such as increasing proximity of mortar shells falling near their command posts. As many as one-third of the recruits fled rather than perform the assigned task, which would have resulted in a cessation of the mortar attack.

Information is also available from work on simulators. In process control, a typical study is the bounding study on operator response to emergencies done with reactor operators on a process simulator in the UKAEA and described by Lees and Sayers (1976). The simulation involved typical faults, for example control rod runout, blower failure and gas temperature rise. The fault rate was high at 10 faults/h. The response was to push a single button. These conditions were favourable and the result may therefore be regarded as an upper limit to the operator reliability that can be expected. For response times in the range 0–30 s the error probability was 0.24, and for those in the range 60–90 s it was zero.

14.25.4 Non-routine tasks

For complex, or non-routine, tasks the mechanistic approach of subdividing the task into its constituent elements is inappropriate. The appropriate approach is to treat the task in a more holistic way. Using this approach, it is necessary to obtain estimates for the reliability of the whole task.

One method of doing this is to obtain estimates of task reliability from the judgement of experts. Early work on this was done by Rook (1964), who developed a method in which tasks were ranked by experts in order of their error-likeliness, and ranking techniques were used to obtain error rates.

Embrey (1979b) has developed this line of approach in his work on GDA. Whole tasks which are undertaken in process control are identified and estimates made of task reliability by a combination of data collection and expert judgement.

The other main method of determining the reliability of the whole task is the use of simulation. The information from simulation is generally a correlation between the probability of failure and the time available to perform the task.

14.25.5 Overall control task

There remains an overall control task that is essentially the residual remaining after the above activities have been treated. The effect of progress in the treatment of human error in process control has been to reduce this undefined residue.

14.25.6 Isolated acts of commission

There is a finite possibility that in performing his overall control task the operator will intervene unnecessarily, with unfortunate results. Such an event is not brought out by analyses that consider only activities which the operator is required to perform.

There are also other possibilities, including deliberate damaging action by the operator. One such action is suicide by destruction of the plant which is discussed by Ablitt (1969 UKAEA AHSB(S) R190):

> The probability per annum that a responsible officer will deliberately attempt to drop a fuel element into the reactor is taken as 10^{-3} since in about 1000 reactor operator years there have been two known cases of suicide by reactor operators and at least one case in which suicide by reactor explosion was a suspected possibility. The typical suicide rate for the public in general is about 10^{-4} per year although it does vary somewhat between countries.

The report on the underground tube train crash at Moorgate Station in London (DoE, 1976/7) drew attention to the possibility of suicide by the driver. Sabotage is another type of action by the operator that is not unknown in process plants.

14.25.7 Time–reliability correlations

Error in executing a task is in general, a function of the time available to perform it. There has been a growing tendency to use time as a principal correlator of operator error.

Thus error in vigilance situations depends very much on the response time that is allowed. Ablitt (1969 UKAEA AHSB(S) R190) tentatively proposed the following estimates of the error probability q for operator action in response to an alarm signal as a function of response time t:

t	1 s	10 s	60 s	5 min	10 min	>10 min
q	1	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}–10^{-6}

A similar type of correlation underlies the estimates of the general probability of ineffective behaviour in emergencies used in studies such as the *Rasmussen Report*. In that study the error probability q used for operator action in response to an emergency as a function of response time t is:

t	60 s	5 min	30 min	Several hours
q	1	0.9	10^{-1}	10^{-2}

14.25.8 Human error probabilities: *Rasmussen Report*

One of the earliest sets of estimates for the probability of human error was that given in the *Rasmussen Report* as shown in Table 14.15. These estimates are mostly of the type used in THERP, but they include the time reliability correlation just referred to.

14.25.9 Human error probabilities: hazard analysis

Estimates of human error probability (HEP) are given in a number of fault trees. Operator error occurs in the tree as errors that either initiate or enable to the fault sequence and as errors that constitute failures of protection. Table 14.16 is a summary by Lees (1983a) of the estimates used in two fault trees published by Lawley (1974b, 1980). Errors that result in failure of protection (expressed as probabilities) predominate over errors that initiate or enable the fault sequence (expressed as frequencies). Initiating and enabling errors tend to be associated with an item of

Table 14.15 *General estimates of error probability used in the Rasmussen Report (Atomic Energy Commission, 1975)*

Estimated error probability	*Activity*
10^{-4}	Selection of a key-operated switch rather than a non-key switch (this value does not include the error of decision where the operator misinterprets situation and believes key switch is correct choice)
10^{-3}	Selection of a switch (or pair of switches) dissimilar in shape or location to the desired switch (or pair of switches), assuming no decision error. For example, operator actuates large-handled switch rather than small switch
3×10^{-3}	General human error of commission, e.g. misreading label and therefore selecting wrong switch
10^{-2}	General human error of omission where there is no display in the control room of the status of the item omitted, e.g. failure to return manually operated test valve to proper configuration after maintenance
3×10^{-3}	Errors of omission, where the items being omitted are embedded in a procedure rather than at the end as above
3×10^{-2}	Simple arithmetic errors with self-checking but without repeating the calculation by re-doing it on another piece of paper
$1/x$	Given that an operator is reaching for an incorrect switch (or pair of switches), he selects a particular similar-appearing switch (or pair of switches), where x = the number of incorrect switches (or pairs of switches) adjacent to the desired switch (or pair of switches). The $1/x$ applies up to 5 or 6 items. After that point, the error rate would be lower because the operator would take more time to search. With up to 5 or 6 items he does not expect to be wrong and therefore is more likely to do less deliberate searching
10^{-1}	Given that an operator is reaching for a wrong motor operated valve (MOV) switch (or pair of switches), he fails to note from the indicator lamps that the MOV(s) is (are) already in the desired state and merely changes the status of the MOV(s) without recognizing he had selected the wrong switch(es)
~ 1.0	Same as above, except that the state(s) of the incorrect switch(es) is (are) *not* the desired state
~ 1.0	If an operator fails to operate correctly one of two closely coupled valves or switches in a procedural step, he also fails to correctly operate the other valve
10^{-1}	Monitor or inspector fails to recognize initial error by operator. *Note:* With continuing feedback of the error on the annunciator panel, this high error rate would not apply
10^{-1}	Personnel on different work shift fail to check condition of hardware unless required by checklist or written directive
5×10^{-11}	Monitor fails to detect undesired position of valves, etc., during general walk-around inspections, assuming no checklist is used
0.2–0.3	General error rate given very high stress levels where dangerous activities are occurring rapidly
$2^{(n-1)}x$	Given severe time stress, as in trying to compensate for an error made in an emergency situation, the initial error rate, x, for an activity doubles for each attempt, n, after a previous incorrect attempt, until the limiting condition of an error rate of 1.0 is reached or until time runs out. This limiting condition corresponds to an individual's becoming completely disorganized or ineffective
~ 1.0	Operator fails to act correctly in first 60 s after the onset of an extremely high stress condition, e.g. a large LOCA
9×10^{-1}	Operator fails to act correctly after the first 5 min after the onset of an extremely high stress condition
10^{-1}	Operator fails to act correctly after the first 30 min in an extreme stress condition
10^{-2}	Operator fails to act correctly after the first several hours in a high stress condition
x	After 7 days after a large LOCA, there is a complete recovery to the normal error rate, x, for any task

Notes:
(1) Modifications of these underlying (basic) probabilities were made on the basis of individual factors pertaining to the tasks evaluated.
(2) Unless otherwise indicated, estimates or error rates assume no undue time pressures or stresses related to accidents.

equipment, and protection errors with a process variable. Such a variable may have (1) no measurement, (2) measurement only or (3) measurement and alarm, and this is an important feature influencing the error rate.

The great majority of figures given are assumed values, with a few values being obtained from the literature and a few from the works. Engineering judgement is used in arriving at these values and the values selected take into account relevant influencing factors such as variable measurement and alarm and time available for action. The way in which allowance is made for these influencing factors is illustrated by the following extracts from the supporting notes:

> There is therefore a very high probability that the operator would be made aware of a spurious Slowdown condition by the alarms and this would be augmented by observation of excessive flaring and header noise that would highlight the cause of the problem. Because alarms will be set quite close to normal operating pressure and

Crystallizer plant

	Probability
Operator fails to observe level indicator or take action	0.04
Operator fails to observe level alarm or take action	0.03 *Frequency* (events/year)
Manual isolation valve wrongly closed (p)	0.05 and 0.1
Control valve fails to open or misdirected open	0.5
Control valve fails shut or misdirected shut (l)	0.5

Propane pipeline

	Time available	*Probability*
Operator fails to take action:		
To isolate pipeline at planned shut-down		0.001
To isolate pipeline at emergency shut-down		0.005
Opposite spurious tank blowdown given alarms and flare header signals	30 min	0.002
Opposite tank low level alarm		0.01
Opposite tank level high given alarm with	5–10 min	
(a) controller misdirected or bypassed when on manual		0.025
(b) level measurement failure		0.05
(c) level controller failure		0.05
(d) control valve or valve positioner		0.1
Opposite slowly developing blockage on heat exchanger revealed as heat transfer limitation		0.04
Opposite pipeline fluid low temperature given alarm	5 min	0.05
Opposite level loss in tank supplying heat transfer medium pump given no measurement (p)	5 min	0.2
Opposite tank blowdown without prior pipeline isolation given alarms which operator would not regard as significant and pipework icing	30 min	
(a) emergency blowdown		0.2
(b) planned blowdown		0.6
Opposite pipeline fluid temperature low given alarm		0.4
Opposite pipeline fluid temperature low given alarm	Limited	0.8
Opposite backflow in pipeline given alarm	Extremely short	0.8
Opposite temperature low at outlet of heat exchanger given failure of measuring instrument common to control loop and alarm		1
Misvalving in changeover of two-pump set (stand-by pump left valved open, working pump left valved in)		0.0025/changeover
Pump in single or double operation stopped manually without isolating pipeline		0.01/shut-down
Low pressure steam supply failure by fracture, blockage or isolation error (p)		0.1/year
Misdirection of controller when on manual (assumed small proportion of time)		1/year

[a] l, Literature value; p, plant value; other values are assumptions.

> level, there would be almost 30 min available for action before the pipeline is chilled to −15°C.

and

> The probabilities quoted are based on experience assuming that 5 min would be available for action, and including allowance for failure of the alarm. They take into account factors such as whether or not the operator would be in close attendance at the time of the fault, ease of diagnosis of the problem, whether or not the fault could be corrected from the control room or only by outside action, reluctance to shut-down the export pumps until correction of the fault has been attempted because back-up trip protection is provided, etc.

14.26 Assessment of Human Error: Qualitative Methods

The foregoing account has described some early approaches to human reliability assessment in support of probabilistic risk assessment (PRA). It is now necessary to backtrack a little and revert to a consideration of qualitative methods for analysis of human error.

Methods are available which may be utilized to identify and so reduce error-likely situations and also to support incident investigation. The elements of such methods are the underlying model of human reliability, the taxonomy of human error and the analysis technique.

These methods may be used in their own right to reduce error or as a stage in a human reliability assessment method. Their significance in the latter application is that they provide a structured approach to gaining understanding of the problem. In the absence of a high quality technique for this essential preliminary stage, quantification is premature.

Task analysis may be regarded as the prime technique, or rather family of techniques, but there are also a number of others. Early work in this area was that of J.R. Taylor (1979), who described a variety of approaches.

A method based on hierarchical task analysis is predictive human error analysis, described below. Another method is the work analysis technique described by Pedersen (1985).

A fuller discussion of human error analysis methods is given by Kirwan (1990) and the CCPS (1994/17).

14.26.1 Some error analysis strategies

Against the background of a long-term programme of work on human error, J.R. Taylor (1979) has developed a set of four error analysis strategies:

(1) action error method;
(2) pattern search method;
(3) THERP;
(4) sneak path analysis.

The third of these has already been outlined and is considered further below. The others are now described.

14.26.2 Action error method

The action error method is applicable to a sequence of operator actions that constitute intervention on the plant. The structure of the sequence takes the form: action/effect on plant/action/effect on plant. An outline of the structure of the procedure in the form of a cause-consequence diagram is shown in Figure 14.23. The range of errors handled is shown in Table 14.17.

Usually it is found that for any reasonably large operating procedure, it is practical to take into account only single initial errors, although in a few cases it may be possible to use heuristic rules to identify double errors that it is worthwhile to explore. For example, one error may result in material being left in a vessel, while a second error may result in an accident arising from this.

Taylor states that the method is not suitable for quantitative assessment, because the spread of error rates on the individual elements is considered to be too wide. Factors mentioned as influencing these error rates are cues, feedback and type of procedure (freely planned, trained).

14.26.3 Pattern search method

The pattern search method is addressed to the problem that an accident is typically the result of a combination of operator errors. For such cases, detailed analysis at the task element level is impractical for two reasons. One is the combinatorial explosion of the number of sequences. The other is that the error rates, and above all the error rate dependencies, are not determinable.

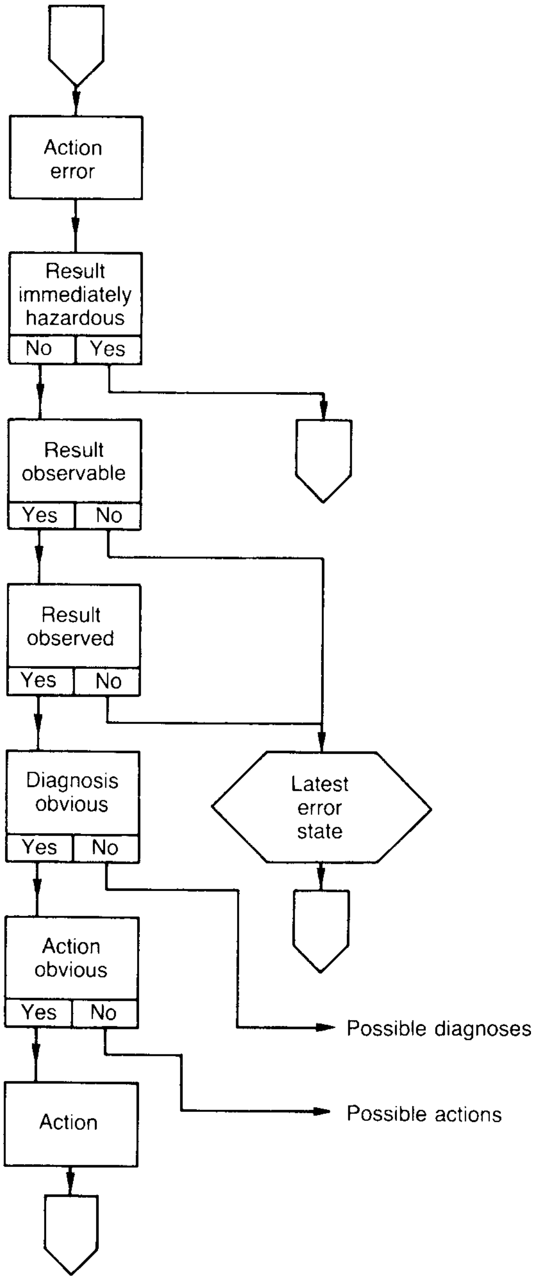

Figure 14.23 *Outline structure of action error method (J.R. Taylor, 1979. Reproduced by permission.)*

An important feature of such accidents is that they may have a relatively long sequence of errors, say 3–5, which have a common cause, such as error in decision-making, in work procedure or in plant state assessment. Often the sequence is associated with an unrevealed plant failure.

Table 14.17 *Operator errors addressed in action error method (J.R. Taylor, 1979. Reproduced by permission.)*

Cessation of a procedure
Excessive delay in carrying out an action or omission of an action
Premature execution of an action – too early
Premature execution of an action – preconditions not fulfilled
Execution on wrong object of action
Single extraneous action
In making a decision explicitly included in a procedure, taking the wrong alternative
In making an adjustment or an instrument reading, an error outside tolerance limits

The pattern search method is based on identifying a common cause error, developing its consequence, perhaps using an event tree, and using the results to 'steer' the construction of the fault tree.

14.26.4 Sneak path analysis

Sneak path analysis is concerned with the identification of potential accident situations. It is so called by analogy with sneak circuits. It seeks to identify sources of hazard such as energy or toxins and targets such as people, critical equipment or reactive substances. The standpoint of the analysis is similar to the accident process model of Houston (1971) described in Chapter 2.

For an accident to occur, it is necessary for there to be some operator action, operator error, equipment failure or technical sequence. A search is made to determine whether any of these necessary events can occur. In examining operator error, attention is directed particularly to actions that are 'near' to the necessary error. Nearness may be temporal, spatial or psychological. Often such an action is very near to the normal operator action.

14.26.5 Predictive human error analysis (PHEA)

Predictive human error analysis (PHEA) is described by Embrey and co-workers (e.g. Murgatroyd and Tait, 1987; Embrey, 1990) and by the CCPS (1994/17). PHEA uses hierarchical task analysis to discover the plan involved in the task, combined with the error classification shown in Table 14.18. The task is then analysed step by step in terms of the task type, error type, task description, consequences, recovery and error reduction strategy.

In a validation study of PHEA, Murgatroyd and Tait (1987) found that the proportion of errors with potentially significant consequences that actually occurred in an equipment calibration task over a 5-year-period was 98%.

14.26.6 System for predictive error analysis and reduction (SPEAR)

The system for predictive error analysis and reduction (SPEAR) is a set of qualitative techniques, of which PHEA is one. It is described by the CCPS (1994/17). SPEAR comprises the following techniques: (1) task analysis, (2) performance influencing factor (PIF) analysis, (3) PHEA, (4) consequence analysis and (5) error reduction analysis.

Consequence analysis involves consideration not just of the consequences of failure to perform the task but also of the consequences of any side-effects that may occur whether or not the task is executed. Error reduction analysis is concerned with measures to reduce those errors that do not have a high probability of recovery. Task analysis and PHEA have already be described and PIF analysis is treated in Section 14.33.

14.27 Assessment of Human Error: *Human Reliability Analysis Handbook*

The first systematic approach to the treatment of human error within a PRA was the Technique for Human Error Rate Prediction (THERP). An early account of THERP was given by Swain (1972). Its origins were work done at Sandia Laboratories on the assessment of human error in assembly tasks. This work was then extended to human error in process control tasks, with particular reference to nuclear reactors. This extension to nuclear reactor control was used in the *Rasmussen Report,* or WASH-1400 (AEC, 1975), which contains generic PRAs for US commercial nuclear reactors.

The accident at Three Mile Island gave impetus to work in this area and led to the publication of the *Handbook of Human Reliability Analysis with Emphasis on Nuclear Power Plant Applications. Final Report* (the *HRA Handbook*) by Swain and Guttmann (1983). This report was widely circulated in draft form in 1980 and many literature references are to the draft. Further work is described in *Accident Sequence Evaluation Program. Human Reliability Analysis Procedure* (Swain, 1987a).

The *HRA Handbook* gives a complete methodology for addressing the human error aspects of a PRA, but THERP is central to the approach, and the methodology as a whole is generally referred to by that acronym. However, the *Handbook* represents a considerable extension of the original THERP methodology, particularly in respect of its adoption of the time reliability correlation method.

A further review of HRA and THERP is given by P. Miller and Swain (1987). Table 14.19 gives the contents of the *HRA Handbook* and Figure 14.24 shows the structure of the principal data tables. An account is now given of THERP. The *HRA Handbook* should be consulted for a more detailed treatment.

14.27.1 Overall approach

The overall approach used in the *Handbook* is shown in Figure 14.25. The tasks to be performed are identified as part of the main PRA. The HRA involves the assessment of the reliability of performance of these tasks.

14.27.2 Technique for human error rate prediction (THERP)

The starting point is a task analysis for each of the tasks to be performed. The method is based on the original THERP technique and uses a task analytic approach in which the task is broken down into its constituent elements along the general lines described above. The basic assumption is that the task being performed is a planned one.

The task is described in terms of an event tree as shown in Figure 14.26. This figure gives the event tree for two tasks A and B which are performed sequentially and which constitute elements of a larger overall task. In reliability terms, the relationship between the two constituent tasks to the overall task may be a series or a parallel one.

The probability that task A will be performed successfully is a and the probability that it will not be performed successfully is A. Since task A is the first in the sequence it is assumed to be independent of any other task and the probabilities a and A are therefore unconditional probabilities. The probability that task B will be performed successfully is b and the probability that it will not be performed successfully is B. Since task B is performed after task A it is assumed to be dependent in some degree on task A and the probabilities b and B are therefore conditional probabilities. Thus for b it is necessary to distinguish between $b \mid a$ and $b \mid A$ and for B between $B \mid a$ and $B \mid \mathrm{A}$. The probabilities to be used are therefore as shown in Figure 14.26.

The structure of the tree is the same whether the configuration is a series or parallel one but the status of the outcomes is different. As shown in Figure 14.26 for a series system in which it is necessary for both tasks to be successful, there is only one which rates as a success, whilst for a parallel system in which it is sufficient for only one of the tasks to be successful, there are three outcomes which rate as success.

A distinction is made between step-by-step tasks and dynamic tasks. The latter involve a higher degree of decision-making. The approach just described is most readily justified for step-by-step tasks.

14.27.3 Human error probability

The event tree so produced, and the corresponding equations, are then used to determine the probability of failure for the overall task. For this estimates are required of the HEP for each of the constituent tasks.

Several different human error probabilities are distinguished: nominal, basic, conditional and joint. A nominal HEP is a generic value before application of any performance shaping factors. A basic HEP (BHEP) is the basic unconditional HEP after application of performance shaping factors. A conditional HEP (CHEP) is a BHEP adjusted to take account of dependency. A joint HEP (JHEP) is the HEP for the overall task.

The simple application of HEP values that make no allowance for dependence tends to give very low probabilities of failure which do not accord with experience and carry little conviction. Allowance for dependence is therefore important. There is in any event some value of the HEP below which the estimate is no longer credible. A cut-off

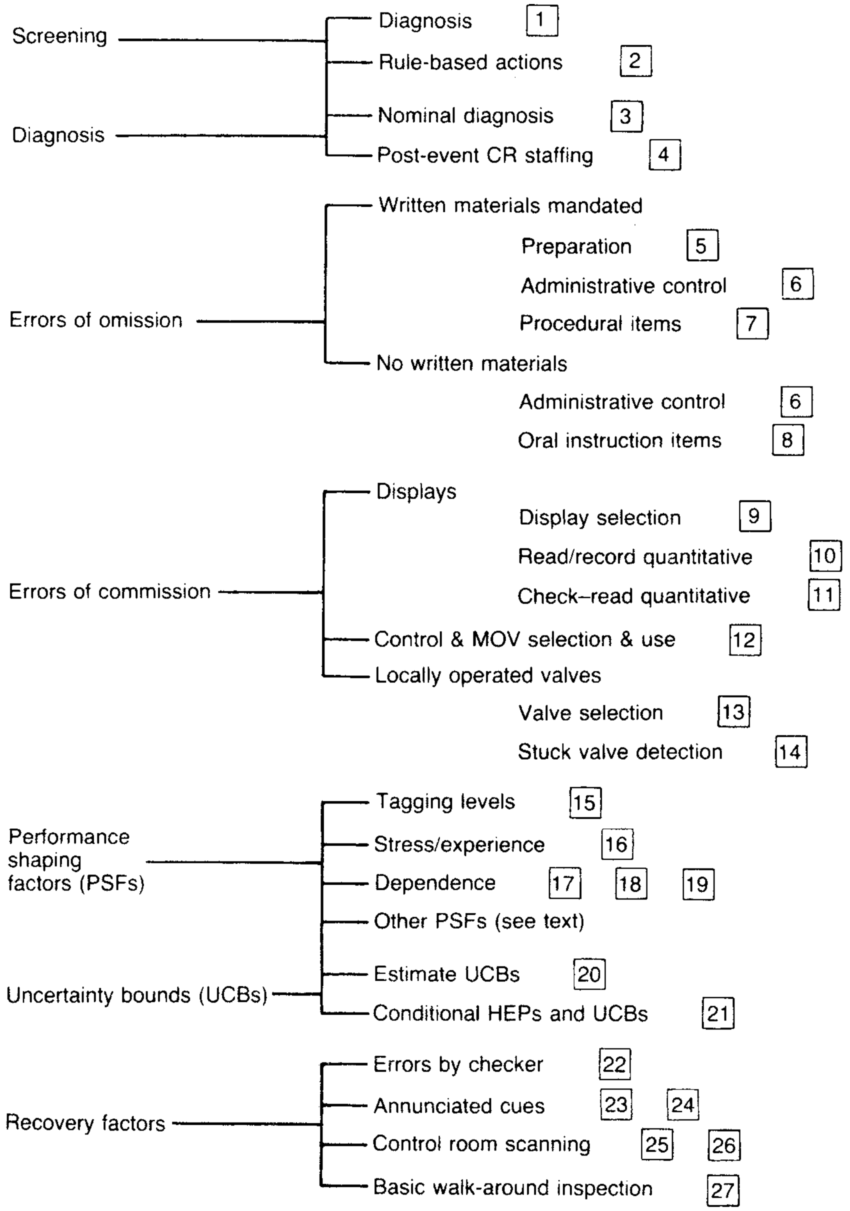

Figure 14.24 *HRA Handbook: structure of principal data tables (Swain and Guttmann, 1983). CR, control room; HEP, human error probability; MOV, motor operated valve*

value is therefore applied. Reference is made to a cut-off of about 5×10^{-5}.

Many of the HEPs in the *Handbook* are expressed as log–normal distributions, quoted in terms of the two parameters – median and error factor (EF).

14.27.4 Dependence model

The dependence model is an important feature of the methodology. A significant proportion of the *Handbook* is concerned with dependency. There are two basic forms of dependence: dependence between tasks and dependence between people.

Where two tasks are performed in sequence the second task may be influenced by the first. Dependence is likely, for example, where an operator has to change two valves one after the other.

The other situation is where two people are involved in the same task. The form of the involvement may vary.

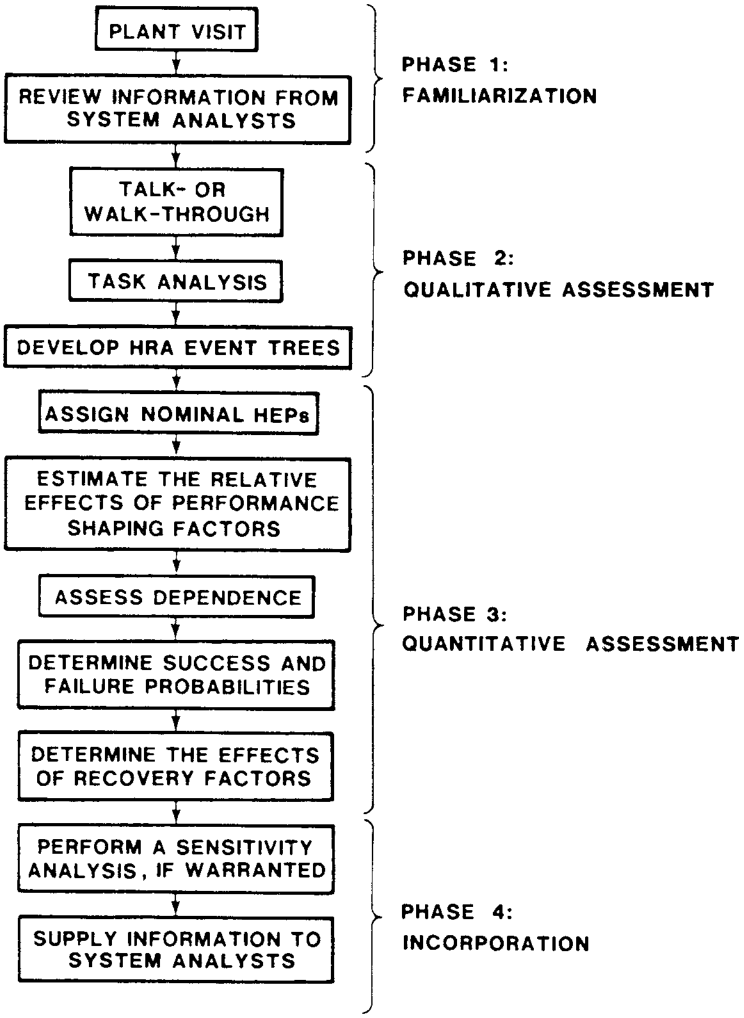

Figure 14.25 *HRA Handbook: methodology for human reliability analysis (Swain and Guttmann, 1983)*

The two persons may be involved in a joint task such as calibrating an instrument. They may perform separate but closely linked functions such as those of two operators sharing a control room but controlling different sections of the plant. The work of one person may be subject to the general supervision of another person. Or it may be formally checked by another.

There are various approaches that may be used to quantify dependence, including data and expert judgement. There are few relevant data. Expert judgement can be used to a limited extent. An example is given of the use of expert estimates of dependence in a calibration task.

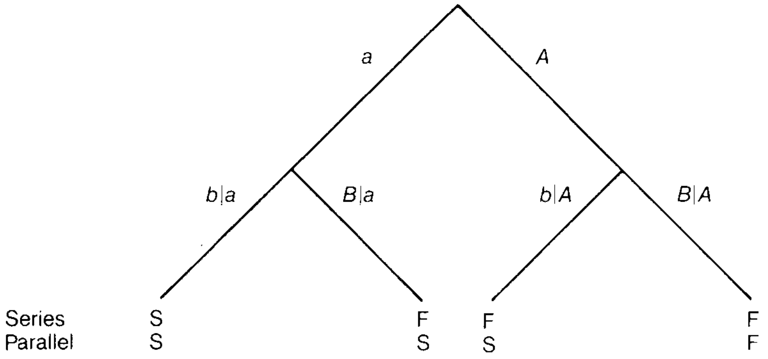
The approach used in the *Handbook*, therefore, is the development of a generalized dependence model. The degrees of dependence used are zero, low, medium, high and complete. The determination of the appropriate degree of dependence depends on the situation under consideration. The *Handbook* gives quite extensive guidance. Here it is possible only to give a few examples.

In some cases, there may be judged to be zero dependence. An example given of a situation where zero dependence between two tasks would be assumed is check-reading of one display followed by check-reading of another display as part of periodic scanning of the displays. Zero dependence is not normally assumed for persons working as a team or for one person checking another's performance.

The assumption of even a low level of dependence tends to result in an appreciably higher HEP than that of zero dependence. If there is any doubt, it is conservative to use low dependence rather than zero dependence.

A level of dependence between people that would be assessed as low is illustrated by the checking of the work of a new operator by a shift supervisor. In this situation, the shift supervisor has an expectation that the new operator may make errors and is more than usually alert.

A moderate level of dependence is usually assessed between the shift supervisor and the operators for tasks where the supervisor is expected to interact with them.



Task A = The first task
Task B = The second task
a = Probability of successful performance of task A
A = Probability of unsuccessful performance of task A
$b|a$ = Probability of successful performance of task B given a
$B|a$ = Probability of unsuccessful performance of task B given a
$b|A$ = Probability of successful performance of task B given A
$B|A$ = Probability of unsuccessful performance of task B given A

FOR THE SERIES SYSTEM:
$\Pr[S] = a(b|a)$
$\Pr[F] = 1 - a(b|a) = a(B|a) + A(b|A) + A(B|A)$

FOR THE PARALLEL SYSTEM:
$\Pr[S] = 1 - A(B|A) = a(b|a) + a(B|a) + A(b|A)$
$\Pr[F] = A(B|A)$

***Figure 14.26** HRA Handbook: event tree for two tasks in sequence illustrating conditional probabilities (Swain and Guttmann, 1983); F, failure; S, success*

A high level of dependence, or even complete dependence, would be assigned for the case where the shift supervisor takes over a task from a less experienced operator, since the latter may well defer to the supervisor both because of his greater experience and his seniority.

The other aspect of the dependence model is the quantification of the adjustment to be made given that the degree of dependency has been determined. The adjustment is made to the BHEP. The relation used is:

$$P_c = (1 - kP_b)/(k + 1) \qquad [14.27.1]$$

where P_b, is the BHEP and P_c is the CHEP, k is a constant which has the following values: low dependency $k = 19$; medium dependency $k = 6$; high dependency $k = 1$.

Equation 14.27.1 and the values of the constant k are selected to give CHEPs of approximately 0.05, 0.15 and 0.50 of the BHEP for low, medium and high dependency, respectively, where BHEP ≤ 0.01. Where BHEP > 0.01, the effective multiplying factor is slightly different. Thus, for example, for a BHEP of 0.1 the values of the CHEP are 0.15, 0.23 and 0.55, respectively, for these three levels of dependency.

14.27.5 Displays, annunciators and controls

Common tasks in process control are obtaining information from displays, responding to annunciators and manipulating controls. This is very much the home ground of human factors and there is a good deal of information available on response times and probabilities of error in such tasks. The *Handbook* gives a number of tables for HEPs for these tasks.

For unannunciated displays, the *Handbook* gives the following HEP values for selection of a display (Table 20.9). The HEP depends on the existence of similar adjacent displays. It is assumed to be negligible if the display is dissimilar to adjacent displays and the operator knows the characteristics of the display he requires. The HEP is taken as 0.005 (EF 10) if it is from a group of similar displays on a panel with clearly drawn mimic lines which include the displays; as 0.001 (EF 3) if it is from a group of similar displays which are part of a well-delineated functional group on the panel; and as 0.003 (EF 3) if it is from an array of similar displays identified by label only. These HEP values do not include recovery from any error. The probability that this will occur is high if the reading obtained is grossly different from that expected.

For check reading from displays the HEPs given are as follows (Table 20.11). The HEP is taken as 0.001 for digital displays and for analogue meters with easily seen limit marks; as 0.002 for analogue meters with limits marks which are difficult to see and for analogue chart recorders with limits marks; as 0.003 for analogue meters without limit marks; and as 0.006 for analogue chart recorders without limit marks. In all cases, the EF is taken as 3. The HEP for confirming a status change on a status lamp and that for misinterpreting the indications an indicator lamp are assumed to be negligible. These HEPs apply to the individual checking of a display for some specific purpose.

14.27.6 Oral instructions and written procedures

Communication in process control includes both oral instructions and written procedures. For oral instructions, a distinction is made between general and detailed instructions. Table 14.20 gives some HEP estimates for these two cases.

For written instructions, the types of HEP treated include error in the preparation of the instructions, failure to refer to them and error in their use. Table 14.21 gives some HEP estimates for these three cases, respectively.

14.27.7 Locally operated valves

Another common task in process control is the manipulation of locally operated valves (LOVs). This task, therefore, receives special treatment in the *Handbook*. The valves concerned are manually operated. They include valves with or without a rising stem and with or without position indicators.

Three principal errors are distinguished. One is selection of the wrong valve. Here the base case is a single isolated valve. Where there are other valves present, the possibility exists that the wrong valve will be selected. Another type of error is reversal, or moving the valve in the wrong direction. The operator opens it instead of closing it, or vice versa. One form of this error is to reverse the state of a valve, which is in fact already in the desired state. The third type of error is failure to detect that the valve is stuck. A common form of this error is to fail to effect complete closure of a valve. Table 14.22 gives some HEP estimates for selection of a valve, for detection of a stuck valve and for checking a valve. The manipulation of valves is a particular case where there may exist a strong dependence, or coupling, between two tasks. This case is one that was taken into account in the *Rasmussen Report*. An operator may be required to cut off flow by closing two valves, closure of either of which is sufficient to stop the flow. If the probability of error in closing one valve is 10^{-2} and there is zero dependence, the probability of error in the overall task is 10^{-4} ($10^{-2} \times 10^{-2}$). On the other hand, if there is complete coupling, the probability of error is 10^{-2} ($10^{-2} \times 1$). These two cases represent the two extremes and constitute lower and upper bounds on the probability of failure. For the more realistic case of loose coupling, the approach used in WASH-1400 was to take for the probability of error the log–normal median or square root of the product of the two bounds: $(10^{-2} \times 10^{-4})^{1/2} = 10^{-3}$. The dependence model

Table 14.20 *HRA Handbook: human error probability (HEP) estimates and error factors (EFs) for oral instructions*[a] *(after Swain and Guttmann, 1983)*

Item[b]	*Number of oral instruction items or perceptual units*	*(a) Pr(F) to recall item 'N', order of recall not important*		*(b) Pr(F) to recall all items, order of recall not important*		*(c) Pr(F) to recall all items, order of recall is important*	
		HEP	*EF*	*HEP*	*EF*	*HEP*	*EF*
Oral instructions are detailed:							
(1)	1[c]	0.001	3	0.001	3	0.001	3
(2)	2	0.003	3	0.004	3	0.006	3
(3)	3	0.01	3	0.02	5	0.03	5
(4)	4	0.03	5	0.04	5	0.1	5
(5)	5	0.1	5	0.2	5	0.4	5
Oral instructions are general:							
(6)	1[c]	0.001	3	0.001	3	0.001	3
(7)	2	0.006	3	0.007	3	0.01	3
(8)	3	0.02	5	0.03	5	0.06	5
(9)	4	0.06	5	0.09	5	0.2	5
(10)	5	0.2	5	0.3	5	0.7	5

[a] It is assumed that if more than five oral instruction items or perceptual units are to be remembered, the recipient will write them down. If oral instructions are written down, use Table 20.5 in the *Handbook* for errors in preparation of written procedures and Table 20.7 for errors in their use.

The first column of HEPs (a) is for individual oral instruction items, e.g. the second entry, 0.003 (item 2a), is the Pr(F) to recall the second of two items, given that one item was recalled, and order is not important. The HEPs in the other columns for two or more oral instruction items are joint HEPs, e.g. the second 0.004 in the second column of HEPs is the Pr(F) to recall both of two items to be remembered, when order is not important. The 0.006 in the third column of HEPs is the Pr(F) to recall both of two items to be remembered in the order of performance specified. For all columns, the EFs are taken from Table 20.20.

[b] The term 'item' for this column is the usual designator for tabled entries and does *not* refer to an oral instruction item.

[c] The Pr(F) values in rows 1 and 6 are the same as the Pr(F) to initiate the task.

Table 14.21 *HRA Handbook; human error probability (HEP) estimates and error factors (EFs) for written procedures (after Swain and Guttmann, 1983)*

A Preparation of written procedures[a]

Item	*Potential errors*	*HEP*	*EF*
(1)	Omitting a step or important instruction from a formal or *ad hoc* procedure[b] or a tag from a set of tags	0.003	5
(2)	Omitting a step or important instruction from written notes taken in response to oral instructions[c]	Negligible	
(3)	Writing an item incorrectly in a formal or *ad hoc* procedure or a tag	0.003	5
(4)	Writing an item incorrectly in written notes made in response to oral instructions[c]	Negligible	

[a] Except for simple reading and writing errors, errors of providing incomplete or misleading technical information are not addressed in the *Handbook*. The estimates are exclusive of recovery factors, which may greatly reduce the nominal HEPs.

[b] Formal written procedures are those intended for long-time use; *ad hoc* written procedures are one-of-a-kind, informally prepared procedures for some special purpose.

[c] A maximum of five items is assumed. If more than five items are to be written, use 0.001 (EF = 5) for each item in the list.

B Neglect of written procedures

Item	*Task*	*HEP*	*EF*
(1)	Carry out a plant policy or scheduled tasks such as periodic tests or maintenance performed weekly, monthly or at longer intervals	0.01	5
(2)	Initiate a scheduled shiftly checking or inspection function[a]	0.001	3
	Use written operations procedures under:		
(3)	Normal operating conditions	0.01	3
(4)	Abnormal operating conditions	0.005	10
(5)	Use a valve change or restoration list	0.01	3
(6)	Use written test or calibration procedures	0.05	5
(7)	Use written maintenance procedures	0.3	5
(8)	Use a checklist properly[b]	0.5	5

[a] Assumptions for the periodicity and type of control room scans are discussed in Chapter 11 of the *Handbook* in the section, 'General Display Scanning Model'. Assumptions for the periodicity of the basic walk-around inspection are discussed in Chapter 19 of the *Handbook* in the section, 'Basic Walk-around Inspection'.

[b] Read a single item, perform the task, check off the item on the list. For any item in which a display reading or other entry must be written, assume correct use of the checklist for that item.

C Use of written procedures[a]

Item[b]	*Omission of item*	*HEP*	*EF*
When procedures with check-off provisions are correctly used:[c]			
(1)	Short list, ≤ 10 items	0.001	3
(2)	Long list, >10 items	0.003	3
When procedures without check-off provisions are used, or when check-off provisions are incorrectly used:[d]			
(3)	Short list ≤ 10 items	0.003	3
(4)	Long list, >10 items	0.01	3
(5)	When written procedures are available and should be used but are not used[d]	0.05[e]	5

[a] The estimates for each item (or perceptual unit) presume zero dependence among the items (or units) and must be modified by using the dependence model when a nonzero level of dependence is assumed.

[b] The term 'item' for this column is the usual designator for tabled entries and does *not* refer to an item of instruction in a procedure.

[c] Correct use of check-off provisions is assumed for items in which written entries such as numerical values are required for the user.

[d] Table 20.6 in the *Handbook* lists the estimated probabilities of incorrect use of check-off provisions and of non-use of available written procedures.

[e] If the task is judged to be 'second nature', use the lower uncertainty bound for 0.05, i.e. use 0.01 (EF = 5).

given in the *Handbook* allows the use of more levels of dependence.

14.27.8 Time ± reliability correlation

As already mentioned, there has been an increasing tendency, associated mainly with experimental work with operators on simulators, to correlate the probability of operator failure with time. In particular, use is made of the time–reliability correlation (TRC) to obtain human error probabilities for complex, or non-routine, tasks, including handling an emergency. The assumption underlying such a TRC is that, although there are in principle other factors

***Table 14.22** HRA Handbook; human error probability (HEP) estimates and error factors (EFs) for manipulation and checking of locally operated valves (after Swain and Guttmann, 1983)*

A Selection of valve

Item	*Potential errors*	*HEP*	*EF*
	Making an error of selection in changing or restoring a locally operated valve when the valve to be manipulated is:		
(1)	Clearly and unambiguously labelled, set apart from valves that are similar in *all* of the following: size and shape, state and presence of tags[a]	0.001	3
(2)	Clearly and unambiguously labelled, part of a group of two or more valves that are similar in *one* of the following: size and shape, state or presence of tags[a]	0.003	3
(3)	Unclearly or ambiguously labelled, set apart from valves that are similar in *all* of the following: size and shape, state and presence of tags[a]	0.005	3
(4)	Unclearly or ambiguously labelled, part of a group of two or more valves that are similar in *one* of the following: size and shape, state or presence of tags[a]	0.008	3
(5)	Unclearly or ambiguously labelled, part of a group of two or more valves that are similar in *all* of the following: size and shape, state and presence of tags[a]	0.001	3

[a] Unless otherwise specified, level 2 tagging is presumed. If other levels of tagging are assessed, adjust the tabled HEPs according to Table 20.15 in the *Handbook*.

B Detection of stuck valves

Item	*Potential errors*	*HEP*	*EF*
	Given that a locally operated valve sticks as it is being changed or restored,[a] the operator fails to notice the sticking valve, when it has:		
(1)	A position indicator[b] only	0.001	3
(2)	A position indicator[b] and a rising stem	0.002	3
(3)	A rising stem but no position indicator[b]	0.005	3
(4)	Neither rising stem nor position indicator[b]	0.01	3

[a] Equipment reliability specialists have estimated that the probability of a valve's sticking in this manner is approximately 0.001 per manipulation, with an error factor of 10.

[b] A position indicator incorporates a scale that indicates the position of the valve relative to a fully opened or fully closed position. A rising stem qualifies as a position indicator if there is a scale associated with it.

C Checking, including valves[a]

Item	*Potential errors*	*HEP*	*EF*
(1)	Checking routine tasks, checker using written materials (includes over-the-shoulder inspections, verifying position of locally operated valves, switches, circuit breakers, connectors, etc., and checking written lists, tags or procedures for accuracy)	0.1	5
(2)	Same as above, but without written materials	0.2	5
(3)	Special short-term, one-of-a-kind checking with alerting factors	0.05	5
(4)	Checking that involves active participation, such as special measurements	0.01	5
	Given that the position of a locally operated valve is checked (item (1) above), noticing that it is not completely opened or closed:	0.5	5
(5)	Position indicator[b] only	0.1	5
(6)	Position indicator[b] and a rising stem	0.5	5
(7)	Neither a position indicator[b] nor a rising stem	0.9	5
(8)	Checking by reader/checker of the task performer in a two-man team, *or* checking by a second checker, routine task (no credit for more than 2 checkers)	0.5	5
(9)	Checking the status of equipment if that status affects one's safety when performing his tasks	0.001	5
(10)	An operator checks change or restoration tasks performed by a maintainer	Above HEPs/2	5

[a] This table applies to cases during normal operating conditions in which a person is directed to check the work performed by others either as the work is being performed or after its completion.

[b] A position indicator incorporates a scale that indicates the position of the valve relative to a fully opened or fully closed position. A rising stem qualifies as a position indicator if there is a scale associated with it.

that affect operator performance in such tasks, time is the dominant one.

An aspect of operator performance of particular concern to the nuclear industry is behaviour following the initial event. One of the main methods used to study such behaviour is the use of simulators. Work on simulators has shown that the probability of success in post-event behaviour correlates strongly with time. Early work on this was done by R.E. Hall, Fragola and Wreathall (1982). A number of TRC models have since been produced based on simulator results.

Figure 14.27 shows some TRCs given by Hall, Fragola and Wreathall for operator vigilance and for particular events to which a nuclear reactor operator may have to respond.

14.27.9 Nominal diagnosis model

The task analysis approach on which THERP is based is not well adapted to handling the behaviour of the operators in an abnormal situation. For this, use is made of the TRC approach. Several TRCs are given in the *Handbook*. Two are used for screening: one for diagnosis and one for post-diagnosis performance. The main TRC is the nominal diagnosis model that is applicable to diagnosis only and not to post-diagnosis performance. This TRC is shown in Figure 14.28. In contrast to the other HEP relations, which refer to individuals, the TRCs refer to the behaviour of a team. The nominal diagnosis model, therefore, implies a particular manning model. This is described in the next section.

Figure 14.28 includes curves for the upper and lower bounds. The *Handbook* gives guidance on the choice of curve. Essentially the lower bound is applicable if the event is a well-recognized one and the operators have practised on a simulator and demonstrate by interview that they know how to handle it. The upper bound is applicable if the event is not covered by training or is covered only in initial training or if the operators demonstrate by interview that they do not know how to handle it. The main, or nominal, curve is applicable if the operators have practised the event only on simulator requalification exercises or if none of the rules for the lower or upper bound apply.

The nominal diagnosis TRC does not itself fit a log–distribution, but it may be approximated by such a distribution. The parameters of the log–normal distribution approximating to this TRC have been estimated by Dougherty and Fragola (1988), who obtain values for the median and the EF of $m = 4$ and $f = 3.2$, respectively. The relation between the nominal diagnosis TRC and the approximating log–normal distribution is:

Time (min)	*Human error probability*	
	Nominal diagnosis TRC	*Approximating log–normal distribution*
5	0.9	0.4
10	0.1	0.1
20	0.01	0.01
30	0.001	0.002
60	0.0001	0.00006

14.27.10 Manning model

The nominal diagnosis TRC just described applies to a whole team and is in fact postulated on a particular team composition. In other words there is an implied manning model.

The manning model used is shown in Table 14.23. The team consists of operators 1 and 2, the shift supervisor and the shift technical advisor. At 10 min into the incident for operator 1 the BHEP is 0.1. Operator 2 has complete dependency. The shift supervisor has high dependency. At this stage, no credit is taken for the shift technical advisor. For operator 1, the BHEP remains constant at 0.1. At 20 min for operator 2, the dependency reduces to the high level and

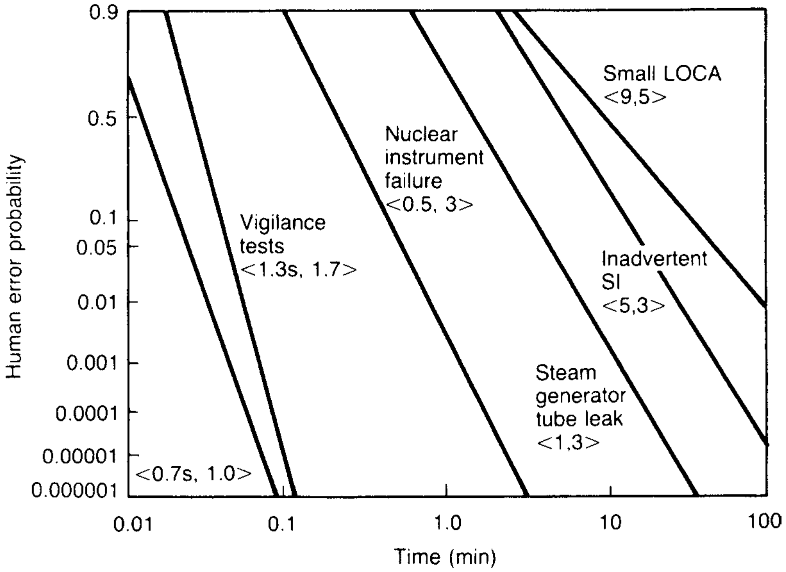


Figure 14.27 *Some time–reliability correlations relevant to nuclear power plants (R.E. Hall, Fragola and Wreathall, 1982). LOCA, loss of coolant accident; SI, safety interlock. Notation <x, y> denotes median m, error factor f of log–normal distribution*

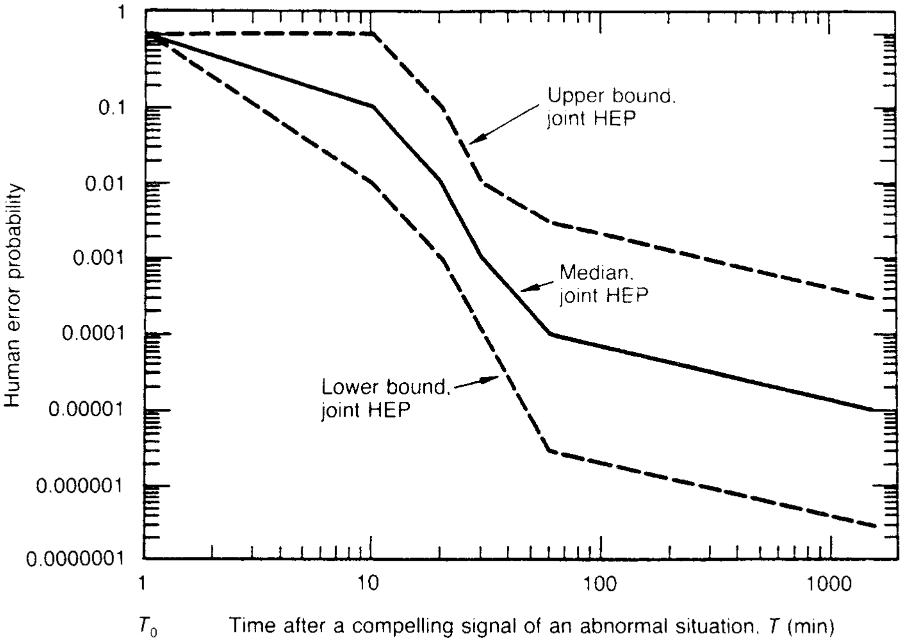

Figure 14.28 *HRA Handbook: nominal diagnosis model (Swain and Guttmann, 1983): human error probability (HEP) of diagnosis of one abnormal event by control room personnel*

Table 14.23 *HRA Handbook: manning model for nominal diagnosis model – illustrative example (after Dougherty and Fragola, 1988, from Swain and Guttmann, 1983)*

Time (min)	*Conditional probability of error*		*Joint probability of error*	*TRC value*
10	Operator 1 Operator 2 Shift supervisor Shift technical adviser	0.1 (basic probability) 1.0 (complete dependence) 0.55 (high dependency) 1.0 (no credit)	0.055	0.1
20	Operator 1 Operator 2 Shift supervisor Shift technical adviser	0.1 (basic probability) 0.55 (high dependency) 0.23 (moderate dependency) 1.0 (high dependency)	0.007	0.01
30	Operator 1 Operator 2 Shift supervisor Shift technical adviser	0.1 (basic probability) 0.55 (high dependency) 0.15 (low dependency) 0.15 (low dependency)	0.0012	0.001

for the shift supervisor it reduces to medium level. The shift technical advisor is now taken into account with a high dependency. At 30 min for operator 2, the dependency remains at the high level but for the shift supervisor it reduces again to the low level. For the shift technical advisor, the dependency reduces to the low level. The CHEPs shown are those given by Equation 14.27.1. The JHEPs shown are the products of the BHEP for operator 1 and the CHEPs for the other members of the team. These JHEPs are then rounded to give the actual values used in the nominal diagnosis TRC.

14.27.11 Recovery model

Some errors are not recoverable, but many are and the recovery model is therefore another important feature of the methodology. The probability of recovery depends on the opportunities for detection, the use made of these opportunities and the effectiveness of the recovery action. Recovery mechanisms include:

(1) human actions – checking;
(2) plant states – panel indications;
(3) equipment states – inspections.

Recovery is treated under the headings:

(1) human redundancy;
(2) annunciated indications;

(3) active inspections;
(4) passive inspections.

Human redundancy is essentially the checking of one person's work by another person. For checking, the *Handbook* gives the following HEP values (Table 20.22). The HEP for checking is taken as being determined by two distinct errors, failure to execute the check at all and error in performing it. The HEP is taken as 0.1 if a written procedure is used; as 0.2 if a written procedure is not used; as 0.05 if the check is a one-off with alerting factors; and as 0.01 if the check involves active participation. The HEP is taken as 0.5 for checking by a second member of a two-man team or by a second checker. It is taken as 0.001 for checking of equipment which affects the safety of the checker. In all cases, the EF is taken as 5. These HEPs apply where a person is directed to check the work of others, either as the work is being performed or after its completion. Credit for checking is limited to the use of two checkers. The HEP of the second checker in a routine task is taken as 0.5.

Recognition is given to a number of problems associated with checking. Checking is particularly affected by psychological considerations. There is an expectation that an experienced person will not make errors. Conversely, there is an expectation that an inexperienced person may well do so.

It is often suggested that if a person knows that his work is to be checked he may perform it with less care and that the end result may be a lower task reliability than if checking were not employed. This view is rejected. It is argued that for any credible values of the BHEP and the CHEP for checking the JHEP will be lower with checking.

The possibility exists that on a particular plant checking may have fallen into disuse. This is one feature in particular which it is prudent for the analyst to observe and check. There is a tendency in some situations for the task and its checking to become elided and for the whole to become a joint operation. Where this occurs, there is no longer an independent check.

Annunciated indicators, or alarms, are treated at two levels. The HEP for taking the prescribed corrective action in response to a single alarm is 0.0001, but this may be drastically modified for other alarm situations.

An annunciator response model is used which applies to multiple alarms and is expressed by two equations. The probability P_i of failure to initiate action in response to the ith alarm in a group of n alarms is:

$$P_i = 10^{-4} \qquad i = 1 \tag{14.27.2a}$$

$$P_i = 2^{i-2} \times 10^{-3} \qquad 1 < i \leq 10 \tag{14.27.2b}$$

$$P_i = 0.25 \qquad i > 10 \tag{14.27.2c}$$

The probability P_r of failure to initiate action in response to a randomly selected alarm in a group of alarms and is:

$$P_\mathrm{r} = \sum_{i=1}^{n} P_i/n \tag{14.27.3}$$

Active inspection is defined as inspection for a specific purpose. The main forms are prescribed periodic logging of readings and prescribed audit of indications with written instructions, both in the control room, and a walk-around inspection on the plant with instructions. The inspection may be based on oral instructions or written instructions. The HEP for an active inspection is that applicable to oral instructions and written procedures, already described.

Passive inspection is defined as a casual type of inspection. There are no written instructions and no instructions to look for any particular feature. The main forms are scanning of the control room displays and a walk-around on the plant.

As described above, HEPs are given for detection of deviant unannunciated displays in a periodic scan.

For passive inspection by walk-around, the *Handbook* gives the following HEP values (Table 20.27). The event concerned is failure to detect a particular deviant state within 30 days. It is assumed that there is one inspection per shift. The HEPs are taken as 0.52, 0.25, 0.05, 0.003, 0.002, 0.001 and 0.001 for periods between walk-around of 1, 2, 3, 4, 5, 6 and 7 days, respectively.

For a planned task recovery may be introduced into the task event tree. This is illustrated in the event tree shown in Figure 14.29, which shows recoveries from error represented by tasks C and G. C is a recovery from failure at task B. G is a recovery from failure at task E and also at task H.

14.27.12 Performance shaping factors

The performance shaping factors (PSFs) are divided into the following classes:

(1) external factors:
    (a) situational characteristics,
    (b) task and equipment characteristics,
    (c) job and task instructions,
(2) internal factors;
(3) stressors.

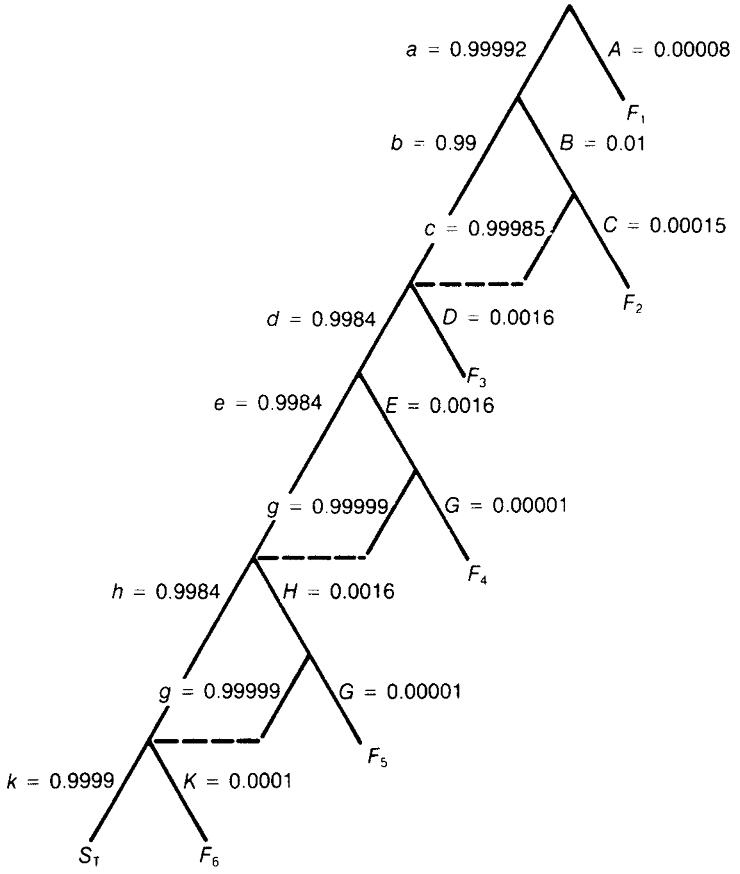
Stressors are treated separately and are considered in the next section.

The PSFs used listed in the *Handbook* are shown in Table 14.24. Each PSF is discussed in some detail. The *Handbook* does not, however, appear to give any simple method of adjusting the nominal HEPs by way of a multiplying factor or otherwise. It is evidently up to the analyst to judge the quality of a particular PSF for the situation concerned and to make a suitable adjustment.

However, some estimates, described as speculative and conservative, are given of the potential benefit of the adoption of good ergonomic practices. The authors state that in nuclear power plants violations of conventional human factors practices are the rule rather than the exception. The *Handbook* indicates that a reduction in HEP by a factor in the range 2–10 might be attained by adoption of good human factors practices in the design or displays and controls, and a similar reduction can be achieved by the use of checklists and well-written procedures instead of narrative procedures (Table 3.8). The EFs given alongside the nominal HEPs also provide further guidance for the analyst.

14.27.13 Stress

As already described, stress is an important determinant of performance and must be taken into account. It is one of the PSFs, but is accorded special treatment. Stress may be caused by both external and internal factors. Some of these



JHEP	EVENTS	JOINT HEPs FOR 3 OPERATORS
A	Fail to initiate action to annunciators	0.00008
B	Misdiagnosis	0.01
C	Fail to initiate action to annunciator	0.00015
D	Omit step 2.4	0.0016
E	Omit step 2.5	0.0016
G	Fail to initiate action to annunciator	0.00001
H	Omit step 2.6	0.0016
K	Fail to initiate high-pressure injection	0.0001

Figure 14.29 *HRA Handbook: event tree for task of handling loss of steam generator feed in a nuclear power plant, illustrating recovery from error (Swain and Guttmann,1983)*

stressors are listed in Table 14.24 for stress that could potentially be rather complex.

The approach adopted in the *Handbook* is to simplify and to treat stress as a function of workload. The assumption underlying this approach is that, although there are in principle other factors that affect stress, workload is the dominant one.

At a very low workload, performance is less than optimal. There is some higher workload at which it is optimal. At a higher workload yet, performance again deteriorates. Finally, the situation may induce threat stress, which is qualitatively different and is accorded separate treatment.

The four levels of stress are therefore defined as:

(1) very low task load;
(2) optimum task load;
(3) heavy task load;
(4) threat stress.

A heavy task load is one approaching the limit of human capacity.

For the first three levels of stress, the *Handbook* gives multiplying factors which are applied to the nominal HEP (Table 20.16). The multiplying factors for an experienced

Table 14.24 *HRA Handbook: some performance shaping factors (PSFs)*[a] (after Swain and Guttmann, 1983)

External PSFs		*Stressor PSFs – psychological stressors: PSFs which directly affect mental stress*	*Internal PSFs – organismic factors: characteristics of people resulting from internal and external influences*
Situational characteristics: those PSFs general to one or more jobs in a work situation	*Task and equipment characteristics: those PSFs specific to tasks in a job*

			Group identifications

Job and task instructions: single most important tool for most tasks Procedures required (written or not written) Written or oral communications Cautions and warnings Work methods Plant policies (shop practices)		*Physiological stressors: PSFs which directly affect physical stress* Duration of stress Fatigue Plain or discomfort Hunger or thirst Temperature extremes Radiation G-force extremes Atmospheric pressure extremes Oxygen insufficiency Vibration Movement constriction Lack of physical exercise Disruption of circadian rhythm	

[a] Some of the tabled PSFs are not encountered in present-day nuclear power plants (e.g. *g*-force extremes), but are listed for application to other man–machine systems.

operator are: 2 for a very low task load and for a heavy task load of a step-by-step task; and 5 for a heavy task load of a dynamic task and for a threat stress condition of a step-by-step task. The multiplier for optimum workload is unity. Different factors are given for an inexperienced operator.

A situation that can arise is where an error is made and recognized and an attempt is then made to perform the task correctly. Under conditions of heavy task load the probability of failure tends to rise with each attempt as confidence deteriorates. For this situation the doubling rule is applied. The HEP is doubled for the second attempt and doubled again for each attempt thereafter, until a value of unity is reached. There is some support for this in the work of Siegel and Wolf (1969) described above.

For a dynamic task or for diagnosis under threat stress the approach is different. A multiplier is not used, but instead a HEP value is given. The HEP for these cases is taken as 0.25 for an experienced operator and as 0.5 for an inexperienced one (both EF 5). The *Handbook* gives guidance on the assignment of the levels of workload, and hence stress.

The basis of the HEP value of 0.25 is the work on behaviour in emergencies by Ronan and Berkun already described. The probability of ineffective behaviour from the work on in-flight emergencies is about 0.15. The training of a pilot is particularly intensive. Operators are not expected to perform as well. Hence, the HEP value of 0.25 is used for operators.

This HEP for threat stress conditions applies to dynamic tasks and to diagnosis, not to step-by-step tasks, for which, as already stated, a multiplier of 5 is used.

A different treatment again is applied to a loss-of-coolant accident (LOCA).

14.27.14 Sources of human performance estimates

Ideally, the data on human performance used in this study would have been obtained from the nuclear industry alone. In fact, the data from this source were very limited and a much wider range of sources was used, as follows: nuclear power plants (NPPs); NPP simulators; process plants; other industrial and military sources; experiments and field studies on real tasks; and experiments on artificial tasks. This list is in order of decreasing relevance but, unfortunately, of increasing data availability. Some 29 'experts' on human error were approached for assistance in providing HEP estimates, but virtually none were forthcoming.

For the nuclear industry the main potential source of human error data is licensee events reports (LERs). These contain an entry 'Personnel error'. HEPs were determined from these LERs for tasks involving operation, maintenance and testing of manual isolation valves, motor operated valves (MOVs) and pumps. The HEP values obtained were low. Work by Speaker, Thompson and Luckas (1982) on valves has shown, however, that for every LER classification of 'Personnel error', there were some 5–7 additional reportable events that in their judgement involved human error. Multiplication of the original HEP estimates by a correction factor of 6 brought them much closer to those from other sources.

Most studies on NPP and other simulators have not yielded usable human error data. The first systematic study found which does was that of Beare *et al.* (1983). This work came too late for incorporation in the *Handbook* but was used as a cross-check. Extensive use was made of HEP data from the process industries given by Kletz and Whitaker (1973), E. Edwards and Lees (1974) and the *ICI Safety Newsletter* (1979). Other industrial HEP data mentioned are those of Rook (1962), Rigby and Edelman (1968a,b) and Rigby and Swain (1968, 1975) on the production and testing of military systems.

A number of field studies and experiments in industrial settings were conducted and yielded usable data. These were subject, however, to the usual caution that the very fact that an experiment is being conducted tends to distort the results.

There is a large amount of experimental data on artificial tasks such as those conducted in laboratories. This work suffers from the fact that not only is it artificial, but also the limits of acceptable performance are often very narrow. It tends to be a poor indicator of absolute performance in real situations, but is a much more reliable guide to comparative performance. The correction that needs to be applied to such data to allow for the broader tolerances in industrial situations was the subject of a study by Payne and Altaian (1962), who obtained an average correction factor of 0.008. The *Handbook* states that using this factor the HEP values obtained are similar to those found in field operations.

Expert judgement was utilized extensively to obtain HEP estimates where hard data were not available. Use was made of scaling techniques to calibrate HEPs for tasks estimated by the experts against known task HEPs. For the HEP in an emergency or highly stressed situation use was made of the work of Ronan (1953) and Berkun and co-workers (Berkun *et al.,* 1962; Berkun, 1964).

The *Handbook* discusses the estimation of HEPs where these are a function of time. For such tasks the three relevant features are: the time to begin the task, essentially the response time and the time required for diagnosis, if any; the time required to do the task correctly; and the time available to do the task correctly. Data on the time to perform the task were obtained from operating records and from experts. The time available was often determined by the characteristics of the plant.

The *Handbook* also gives an account of the determination of HEPs for: displays and controls; LOVs; oral instructions and written procedures; administrative controls; and abnormal events.

14.27.15 Human performance estimates from expert judgement

The estimates of human performance given in the *Handbook*, whether for human error probabilities or performance shaping factors, are based on expert judgement. A discussion of expert judgement techniques applicable to human factors work is given in the *Handbook* by Weston (1983). He discusses the following methods: (1) paired comparisons, (2) ranking and rating procedures, (3) direct numerical estimation and (4) indirect numerical estimation. In dealing with estimates of human error, it is particularly important to give a full definition of the task for which the estimate is to be made. If the definition is poor, the estimates obtained are liable to exhibit wide differences.

A study is quoted by Seaver and Sitwell (1983) in which these methods were compared in respect of six criteria. For the three criteria selected by Weston (quality of judgements, difficulty of data collection and empirical support) the rankings obtained by these workers were as follows: (1, best; 4, worst):

Criterion	*Type of procedure*			
	Paired comparisons estimation	*Ranking/ rating estimation*	*Direct numerical*	*Indirect numerical*
Quality of judgement	1	2	4	3
Difficulty of data collection	4	1	2	3
Empirical support	3	4	1	1

14.27.16 Uncertainty bounds and sensitivity analysis

It is normal to include in a hazard assessment a sensitivity analysis and this creates a requirement to express an estimate of HEP not just as a point value but as a distribution. The distribution that is generally used is the log–normal distribution. As described in Chapter 7, the log–normal distribution is characterized by the two parameters m^* and σ Alternatively, it may be defined instead in terms of the log–normal median m and the EF f. Often only a point value is available, and generalized values of σ or f are used to give the spread.

The log–normal distribution is that used in the *Handbook*. It is admitted that the basis for preferring this distribution is not strong. The experimental support that exists relates to distributions of response times. On the other hand, it is argued that the choice of distribution does not appear critical. It is also the case that the log–normal distribution is a convenient one to use. Uncertainty arises from (1) lack of data, (2) deficiencies in the models used, (3) the effects of the PSFs and (4) the variable quality of analysts.

Using the log–normal distribution, characterized by the log–normal median m and the EF f the uncertainty bounds (UCBs) are expressed in terms of the error factor. As an illustration, consider the following case:

Nominal HEP $= 0.01$
Lower UCB $= 0.003$
Upper UCB $= 0.03$
Error factor $f = (0.03/0.003)^{1/2} \approx 3$

For the most part symmetrical UCBs are used, but there are exceptions. If the median value is low, the use of symmetrical UCBs may give a lower bound which is below the HEP cut-off, whilst at the other extreme for an HEP ≥ 0.25 it may give an upper bound which exceeds unity. In these cases asymmetrical bounds are used.

The general guidelines given in the *Handbook* for estimating the EF (Table 20.20) are given in Table 14.25.

14.27.17 Validation

A methodology of the type just described is clearly difficult to validate. There is a good deal of information provided in the *Handbook* in support of individual HEP estimates and some of this is described above. An account is also given of validation exercises carried out in support of the original THERP methodology, but these relate to tasks such as calibration and testing rather than process control.

14.28 Assessment of Human Error: Success Likelihood Index Method (SLIM)

A method of obtaining HEP estimates based on PSFs is the success likelihood index (SLI) which is incorporated in the SLI method (SLIM). Accounts are given in *SLIM-MAUD: An Approach to Assessing Human Error Probabilities using Structured Judgement* by Embrey *et al.* (1984 NUREG/CR-3518) and by Embrey (1983a,b) and Kirwan (1990).

SLIM treats not only the quality of the individual PSFs but also the weighting of these in the task. It is thus a complete method for assessing of human error, and not merely a technique for determining values of the PSFs. The basic premise of SLIM is that the HEP depends on the combined effects of the PSFs. A systematic approach is used to obtain the quality weightings and relevancy factors for the PSFs, utilizing structured expert judgement. From these PSFs the SLI for the task is obtained.

As defined by Embrey (1983a) the SLI for n PSFs is:

$$\mathrm{SLI} = \sum_{i=1}^{n} r_i w_i \qquad [14.28.1]$$

where r is a relevancy factor and w a quality weighting. Thus, the SLI approach makes explicit the distinction between quality and relevance.

The quality weighting is obtained from the judgement of a panel of experts and is assigned a value on the scale 1–9.

Table 14.25 *HRA Handbook: general guidelines on estimation of the error factor (EF)*[a] *(after Swain and Guttmann, 1983)*

Item	*Task and HEP guideline*[b]	*EF*[c]
	Task consists of performance of step-by-step procedure[d] conducted under routine circumstances (e.g. a test, maintenance or calibration task); stress level is optimal:	
(1)	Estimated HEP < 0.001	10
(2)	Estimated HEP 0.001–0.01	3
(3)	Estimated HEP > 0.01	5
	Task consists of performance of step-by-step procedure[d] but carried out in non-routine circumstances such as those involving a potential turbine/reactor trip; stress level is moderately high:	
(4)	Estimated HEP$<$0.001	10
(5)	Estimated HEP$\geq$0.001	5
	Task consists of relatively dynamic[d] interplay between operator and system indications, under routine conditions, e.g. increasing or reducing power; stress level is optimal:	
(6)	Estimated HEP < 0.001	10
(7)	Estimated HEP ≥ 0.001	5
(8)	Task consists of relatively dynamic[d] interplay between operator and system indications but carried out in non-routine circumstances; stress level is moderately high	10
(9)	Any task performed under extremely high stress conditions, e.g. large LOCA, conditions in which the status of ESFs is not perfectly clear, or conditions in which the initial operator responses have proved to be inadequate and now severe time pressure is felt (see text of *Handbook* for rationale for EF = 5)	5

[a] The estimates in this table apply to experienced personnel. The performance of novices is discussed in Chapter 18 of the *Handbook*.

[b] For UCBs for HEPs based on the dependence model, see Table 7.3 of the *Handbook*.

[c] The highest upper UCB is 1.0.
See Appendix A to calculate the UCBs for $P_T(F_T)$, the total-failure term of an HRA event tree.

[d] See Table 18.1 of the *Handbook* for definitions of step-by-step and dynamic procedures.

The relevancy factor, which again is obtained from the judgement of the expert panel, is a measure of the contribution of that PSF, the sum of the relevancy factors being unity. The SLI so obtained is a relative value.

In order to convert an SLI into a HEP, it is necessary to calibrate it against tasks for which the HEP is known. The relation used is:

$$\log_{10}(\mathrm{HEP}) = a\mathrm{SLI} + b \qquad [14.28.2]$$

where a and b are constants. These constants are obtained from two tasks of known HEP. Due to the logarithmic relationship, SLI values that do not differ greatly (e.g. 5.5 and 5.75) may correspond to very different HEPs.

The SLI methodology has two modules. The first is the multi-attribute utility decomposition (MAUD), usually referred to as SLIM-MAUD. The second is the systematic approach to the reliability assessment of humans (SARAH). The former is used to obtain the SLI and the latter to perform the calibrations. Both are embodied in computer programs. Accounts of work done to validate this approach have been given by Embrey (1983a) and Embrey and Kirwan (1983). Illustrative examples of SLIM are given by Dougherty and Fragola (1988), as described below, and Kirwan (1990).

14.29 Assessment of Human Error: Human Error Assessment and Reduction Technique (HEART)

In the HEART, described by J.C. Williams (1986, 1988a,b, 1992), the HEP of the task is treated as a function of the type of task and of associated error producing conditions (EPCs), effectively PSFs. The method is based on a classification of tasks into the generic types shown in Section A of Table 14.26, which also gives the proposed nominal human unreliabilities for execution of the tasks. There is an associated set of EPCs, for each of which is given an estimate of the maximum predicted normal amount by which the unreliability might change going from ‘good’ to ‘bad’. Section B of the table shows the first 17 EPCs listed, those with the strongest influence; entries 18–38 list further EPCs with a weaker influence.

In applying an EPC use is made of a weighting for the proportion of the EPC that is effective. Thus, for a task of type D with a nominal unreliability of 0.09, a single EPC of 4 and a weighting of 0.5, the resultant unreliability is:

$$0.09[(4 - 1) \times 0.5 + 1] = 0.23 \qquad [14.29.1]$$

The method also includes a set of associated remedial measures to be applied to improve the reliability.

HEART has been designed as a practical method, and is easy to understand and use. It was on of the principal techniques used in the quantitative risk assessment for Sizewell B, as described in Section 14.39.

14.30 Assessment of Human Error: Method of Dougherty and Fragola

The deficiencies of THERP in respect of non-routine behaviour have led to the development of alternative methods. One of these methods is that described in *Human Reliability Analysis* by Dougherty and Fragola (1988). Like THERP, this method has been developed essentially as an adjunct to fault tree analysis, but the approach taken is rather different.

The earlier approach associated human errors essentially with equipment or procedure failures. One effect was the generation of a large number of human events linked to the equipment failures. Another was the neglect of more significant but complex human errors. The approach taken in the HRA of Dougherty and Fragola is to concentrate on a smaller number of more significant failures and human errors. There is also strong emphasis on integrating the HRA into the PRA.

14.30.1 Overall approach

The HRA process is shown in Figure 14.30. The generation of the human events to be considered is part of the PRA. As with physical hazards, identification has a good claim to be the most difficult stage of the process. Error classification schemes have been developed as an aid, but give no guarantee of completeness.

The human events are identified, characterized and quantified according to the scheme shown in Figure 14.31.

Certain principles have been identified to guide the development of the PRA so that there is compatibility with the HRA. In broad outline these guidelines include the following:

(1) The description of the human event should refer to failure of a function rather than to some lower level of abstraction.
(2) The human events should be confined to the three categories of pre-initiator (or latent) events, human-induced initiator events and post-initiator events.
(3) Human events in the latent category should be incorporated in the fault tree at the highest appropriate level.
(4) A human-induced initiator event should be subsumed in the initiator type which includes the human event. The data required should be expressed as a probability and not as a frequency.
(5) A human event in the post-initiator category which relates to failure of a system should be modelled as a single event under the gate below the top event of the fault tree for that system, the gate being (a) an OR gate if the system is manually activated or (b) an AND gate if the system is automatically activated.

14.30.2 Task analysis

The starting point is again a task analysis. A typical task analysis is outlined in Table 14.27.

14.30.3 Response and recovery events

Human events that occur in the post-initiator period are treated as either response or recovery events. The nuclear industry has gone to some pains to provide a rather comprehensive set of emergency response guidelines. Following such guidelines, a planned activity is classed as a response, whilst an unplanned activity is classed as a recovery. Recovery activity is applicable only to those events from which recovery is possible; there are some events for which there is no recovery.

The incorporation of recovery is not undertaken during the development of the main fault tree but is deferred until the tree, and its cut sets, are available. There are two reasons for this. One is that introduction of recovery during the main synthesis tends to result in an undue increase in the size of the tree. The other is that recovery analysis is an iteration through much of the PRA/HRA process, embraces system and human aspects, and tends to be highly specific to the set of events from which the recovery is to be made. It is therefore better to consider the set of events and the associated recovery as a separate exercise at the end.

14.30.4 Operator action event trees

Some of the activity of the operator consists of planned tasks, but he may also have to respond to an abnormal condition on the plant. Thus, although some events can be incorporated into the main fault tree of the PRA, post-initiator events involving action by the operator require the introduction of a specific event tree – the operator action event tree (OAET).

Table 14.26 Classification of generic tasks and associated unreliability estimates (J.C. Williams, 1986)

A Generic classifications

Generic task		*Proposed nominal human unreliability (5th–95th percentile boundaries)*
A	Totally unfamiliar, performed at speed with no real idea of likely consequences	0.55 (0.35–0.97)
B	Shift or restore system to a new or original state on a single attempt without supervision or procedures	0.26 (0.14–0.42)
C	Complex task requiring high level of comprehension and skill	0.16 (0.12–0.28)
D	Fairly simple task performed rapidly or given scant attention	0.09 (0.06–0.13)
E	Routine, highly practised, rapid task involving relatively low level of skill	0.02 (0.007–0.045)
F	Restore or shift a system to original or new state following procedures, with some checking	0.003 (0.0008–0.007)
G	Completely familiar, well-designed, highly practised, routine task occurring several times per hour, performed to highest possible standards by highly motivated, highly trained and experienced person, totally aware of implications of failure, with time to correct potential error, but without the benefit of significant job aids	0.0004 (0.00008–0.009)
H	Respond correctly to system command even when there is an augmented or automated supervisory system providing accurate interpretation of system stage	0.00002 (0.000006–0.00009)
M	Miscellaneous task for which no description can be found. (Nominal 5th to 95th percentile data spreads were chosen on the basis of experience suggesting log-normality)	0.03 (0.008–0.11)

B Error-producing conditions[b]

Error-producing condition		*Maximum predicted nominal amount by which unreliability might change going from 'good' conditions to 'bad'*
1.	Unfamiliarity with a situation which is potentially important but which only occurs infrequently or which is novel	× 17
2.	A shortage of time available for error detection and correction	× 11
3.	A low signal-to-noise ratio	× 10
4.	A means of suppressing or overriding information or features which is too easily accessible	× 9
5.	No means of conveying spatial and functional information to operators in a form which they can readily assimilate	× 8
6.	A mismatch between an operator's model of the world and that imagined by the designer	× 8
7.	No obvious means of reversing an unintended action	× 8
8.	A channel capacity overload, particularly one caused by simultaneous presentation of non-redundant information	× 6
9.	A need to unlearn a technique and apply one which requires the application of an opposing philosophy	× 6
10.	The need to transfer specific knowledge from task to task without loss	× 5.5
11.	Ambiguity in the required performance standards	× 5
12.	A mismatch between perceived and real risk	× 4
13.	Poor, ambiguous or ill-matched system feedback	× 4
14.	No clear direct and timely confirmation of an intended action from the portion of the system over which control is to be exerted	× 3
15.	Operator inexperienced (e.g. a newly qualified tradesman, but not an 'expert')	× 3
16.	An impoverished quality of information conveyed by procedures and person–person interaction	× 3
17.	Little or no independent checking or testing of output	× 3

Table 14.26 *(continued)*

18.	A conflict between immediate and long-term objectives.	× 2.5
19.	No diversity of information input for veracity checks	× 2.5
20.	A mismatch between the educational achievement level of an individual and the requirements of the task	× 2
21.	An incentive to use other more dangerous procedures	× 2
22.	Little opportunity to exercise mind and body outside the immediate confines of the job	× 1.8
23.	Unreliable instrumentation (enough that it is noticed)	× 1.6
24.	A need for absolute judgements which are beyond the capabilities or experience of an operator	× 1.6
25.	Unclear allocation of function and responsibility	× 1.6
26.	No obvious way to keep track of progress during an activity	× 1.4
27.	A danger that finite physical capabilities will be exceeded	× 1.4
28.	Little or no intrinsic meaning in a task	× 1.4
29.	High-level emotional stress	× 1.3
30.	Evidence of ill-health amongst operatives, especially fever	× 1.2
31.	Low workforce morale	× 1.2
32.	Inconsistency of meaning of displays and procedures	× 1.2
33.	A poor or hostile environment (below 75% of health or life-threatening severity)	× 1.15
34.	Prolonged inactivity or highly repetitious cycling of low mental workload tasks	× 1.1 for first half-hour × 1.05 for each hour thereafter
35.	Disruption of normal work-sleep cycles	× 1.1
36.	Task pacing caused by the intervention of others	× 1.06
37.	Additional team members over and above those necessary to perform task normally and satisfactorily	× 1.03 per additional man
38.	Age of personnel performing perceptual tasks	× 1.02

[a] If none of the task descriptions A–H fits the task under consideration, the values given under M may be taken as reference points.

[b] Conditions 18–38 are presented simply because they are frequently mentioned in the human factors literature as being of some importance in human reliability assessment. To a human factors engineer, who is sometimes concerned about performance differences of as little as 3%, all these factors are important, but to engineers who are usually concerned with differences of more than 300%, they are not very significant. The factors are identified so that engineers can decide whether or not to take account of them after the initial screening.

The response of the operator to an abnormal condition may be described in terms of an event tree. The use of event trees for this purpose has been formalized as the OAET or, simply, the operator action tree (OAT) technique.

The OAET method has been described by R.E. Hall, Fragola and Wreathall (1982). Three basic features are recognized: (1) perception, (2) diagnosis and (3) response. Figure 14.32 shows a typical OAET for a nuclear reactor coolant pump seal LOCA. The OAET tends to be used in conjunction with a time–reliability correlation.

14.30.5 Modelling of human events

The classification of human events and the associated event models used in the HRA are shown in Figure 14.31. The human activity is divided into three classes which are specifiable and one that is not. The three definable activities are planned tasks, response and recovery. Each of these definable activities is further divided into slips and mistakes, and these in turn are divided into errors of omission or commission.

In each case a slip is modelled using a modified version of THERP. Mistakes of response and recovery are modelled using TRCs. Other mistakes are not modelled, except that response mistakes of commission may be modelled. Recovery mistakes of commission may be estimated as described below.

14.30.6 Filtering of human events

The human events identified are subjected to both a qualitative and a quantitative filter. This process is assisted if the analysis of the hardware and human aspects proceeds simultaneously. This is the most effective way to apply a qualitative filter to the large proportion of the human events identified.

A quantitative filter is then applied. This means that an approximate estimate is made of the probability of each human event and, if at this level of probability the event has negligible effect on the fault tree, it is not pursued.

The approach used draws on THERP. A probability of 0.001 is used as a basic screening value for the probability of a human event for latent or human-induced initiator failures. If there is redundancy so that a second error must occur for the failure to occur, a conditional probability of value of 0.1 is used, corresponding to moderate dependency. For post-initiator events, use is made of the appropriate TRC, taking the probability at 5 min as the screening value.

14.30.7 Modelling of slips

Slips are errors in an activity that has to some degree been planned. This applies even to recovery, where the operator first formulates and then executes a plan. The method used to model slips is a modified version of THERP. One modification is to consider only one slip per task. The probability of the slip is taken as a basic value of 0.001 or, if there is

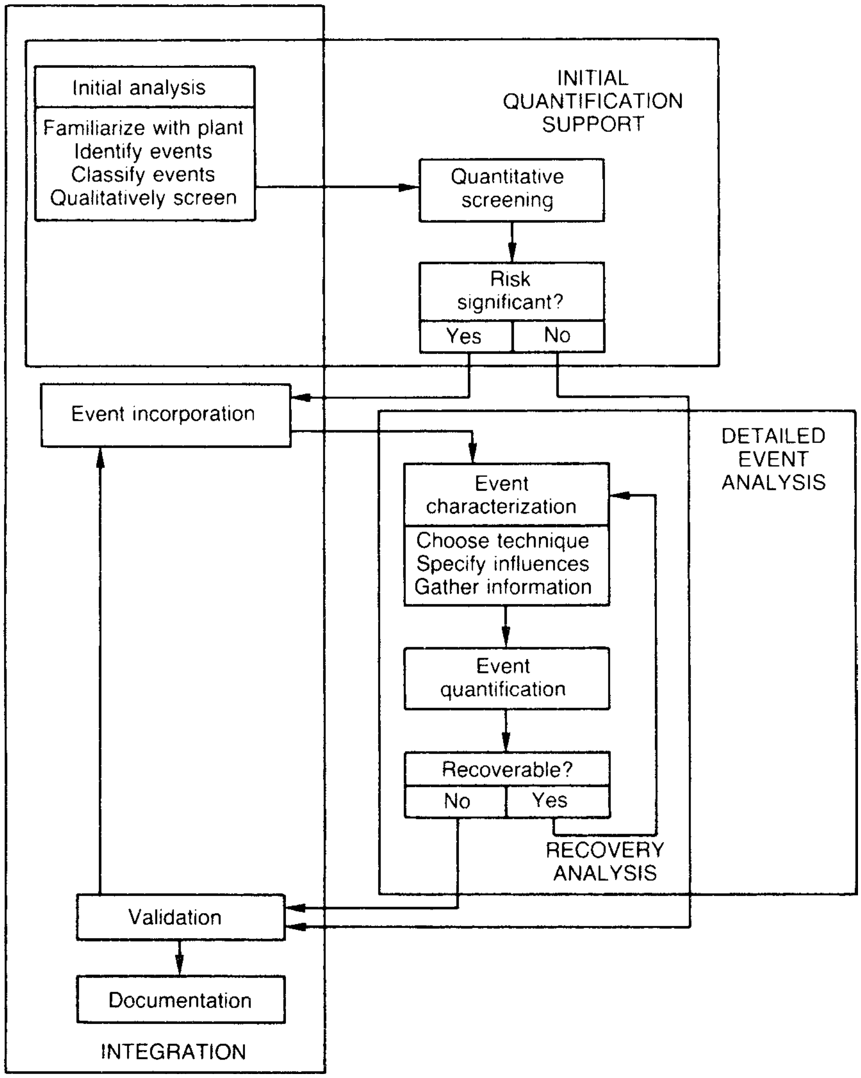

Figure 14.30 *Method of Dougherty and Fragola: methodology for human reliability analysis (Dougherty and Fragola, 1988) (Reproduced with permission of John Wiley & Sons Ltd from Human Reliability Analysis by E.M. Dougherty and J.R. Fragola, 1988, copyright ©)*

redundancy, 0.0001. These values are the same as those used for screening. They are then adjusted using appropriate performance shaping factors. The authors also describe alternative, more complex methods of estimating the probability of slips.

14.30.8 Modelling of mistakes

Response and recovery mistakes are modelled using time–reliability correlations. The underlying assumption in this approach is that, although the probability of success depends, in principle, on many factors, the time available is the dominant one. Four separate TRCs are used. These are for the cases

(1) response without hesitancy;
(2) response with hesitancy;
(3) recovery without hesitancy;
(4) recovery with hesitancy.

Hesitancy is associated with the burden of the task that in turn depends on a number of factors as described below. Account is also taken of the effect of PSFs. The incorporation of these two features into the TRCs is described below.

14.30.9 Time–reliability correlations

It is found empirically that response times tend to fit a log–normal distribution. The TRC models used are based

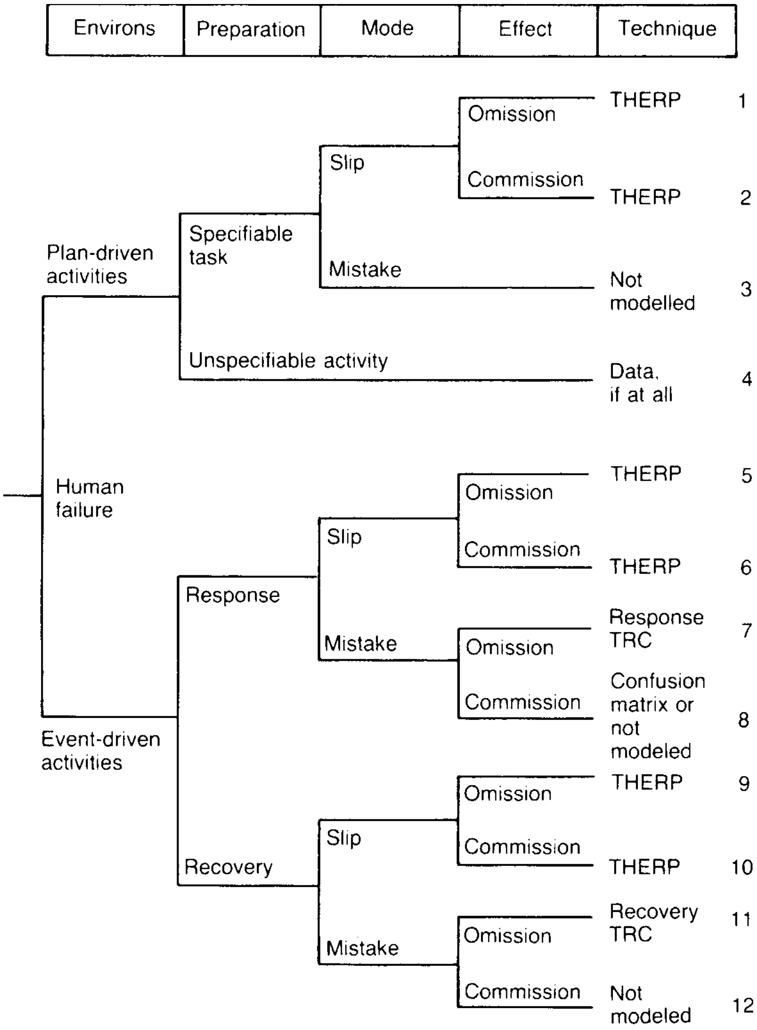

Figure 14.31 *Method of Dougherty and Fragola: classification of human events (Dougherty and Fragola, 1988) (Reproduced with permission of John Wiley & Sons Ltd from Human Reliability Analysis by E.M. Dogherty and J.R. Fragola, 1988, Copyright ©)*

on the assumption that the log-normal distribution is applicable. They are characterized by a log–normal median m and an EF f and give a straight line when plotted on log–probability paper. The basic response time τ is given by:

$$\tau_r = k_1 k_2 \tau \qquad [14.30.1]$$

where τ is the median response time, τ_r is the adjusted median response time and k_1 and k_2 are adjustment factors. The value of m used is the adjusted median response time.

The first factor k_1 takes account of the availability or otherwise of a rule, in other words of the difference between response and recovery. It has the values:

$k_1 = 1$ Rule available [14.30.2a]

$k_1 = 0$ no rule available [14.30.2b]

The second factor k_2 takes account of the performance shaping factor as measured by the SLI. It is assumed that at best (SLI = 1), the median response time is halved and at worst (SLI = 0), it is doubled. The factor is defined as:

$$k_2 = 2^{(1-2x)} \qquad [14.30.3]$$

where x is the SLI.

The base TRC is the nominal diagnosis curve given in THERP. This curve has a median m of 4 and an EF f of 3.2. It, therefore, has a relatively high median and low EF. The high median corresponds to a recovery rather than a response and the low error factor to absence of hesitancy. On this basis this curve is taken as that for recovery without hesitancy.

The other TRC curves are then obtained from this basic curve. The curve for response without hesitancy has the

***Table 14.27** Task analysis in support of a human reliability analysis for a task in nuclear power plant operation (Dougherty and Fragola, 1988) (Reproduced with permission of John Wiley & Sons Ltd from Human Reliability Analysis by E.M. Dougherty and J.R. Fragola, 1988, Copyright ©)*

Goal
Obtain reactor core system water make-up and cooling following a small loss of coolant accident (LOCA)

Step	*Means*
Diagnose event	
Detect plant upset condition	Several alarms
Observe RCS level indicator	Pressurizer or reactor level
Observe decreasing RCS pressure	Pressure indicator
Observe sump level increasing	Level indicator
Observe containment pressure increasing	Pressure indicators
Observe no secondary side radiation	Radiation monitors
Isolate the LOCA	
Close PORV block valve 1	One valve control
Close PORV block valve 2	Another valve control
Close letdown line	One valve control
Close RCP seal isolation valve 1	One valve control
Close RCP seal isolation valve 2	Another valve control
Verify safety system actuation	
Observe HPI pump meters	Two flow indicators
Start HPI pumps	Two pump start controls
Observe AFW pump meters	Two flow indicators
Start AFW pumps	Two pump start controls
Obtain long-term cooling	
Await low level tank alarm	One level indicator
Open sump valve 1	One valve control
Open sump valve 2	One valve control
Open tank valve 1	One valve control
Open tank valve 2	One valve control

AFW, auxiliary feed water; HPI, high pressure injection; PORV, power operated relief valve; RCP, reactor coolant pump; RCS, reactor cooling system.

parameters $m = 2$ and $f = 3.2$; that for response with hesitance $m = 2$ and $f = 6.4$; and that for recovery with hesitance $m = 4$ and $f = 6.4$.

The TRC curves so derived are shown in Figure 14.33. These curves already incorporate the factor k_1 but not the factor k_2. The response time obtained from the curves should be multiplied by k_2.

14.30.10 Performance shaping factors

PSFs are treated using SLIM. In the format given by the authors the SLI is defined as:

$$\mathrm{SLI} = \sum_{i=1}^{n} r_{ni} q_i \qquad [14.30.4]$$

with

$$r_{ni} = r_i \Big/ \sum_{i=1}^{n} r_i \qquad [14.30.5]$$

where q is the quality, r the rank and r_n the normalized rank.

In general, q has a value in the range 0–1. This is so if the PSF can have either a bad or a good influence. If it can have only a bad influence, the range of q is restricted to 0–0.5 and if it can have only a good influence the range is restricted to 0.5–1.

The determination of the SLI is illustrated in Table 14.28, which gives the SLI for a human error in a recovery mistake. The SLI is can be used to adjust probabilities of slips or mistakes. In the latter case it is applied to the median response time of the TRC, as described below.

14.30.11 Recovery mistakes of commission

In an incident situation, the possibility exists that the operator will take some action which actually makes the situation worse. As so far described, the methodology does not include a model for such an action which is called a 'recovery mistake of commission'.

A method is given, however, for estimating the probability that such an error will occur. This probability is the product of three probabilities. The first is the probability of a significant and extended commission error, the second the probability that the emergency response guidelines (ERGs) do not cover the resulting situation, and the third the probability that the senior reactor operator (SRO) or other personnel fail to recover the situation.

The values of these three probabilities are estimated as follows. At the time of writing there had been 10,000 reactor scrams. Two involved misdiagnoses that led to core melt, including Chernobyl. The probability of a significant and extended commission error is thus estimated as 0.0002 (2/10,000). It is assumed that ERGs would effect a reduction in probability of between one and three orders of magnitude and a reduction of two orders of magnitude is selected so that the second probability is estimated as 0.01. The action of the SRO, whose function is to stand back and monitor plant status, is assumed to have only low dependency with that of the crew and the probability that he will fail to effect recovery is estimated as 0.05. From these figures the authors derive a figure for the frequency of unrecovered mistakes of commission.

14.30.12 Computer aids

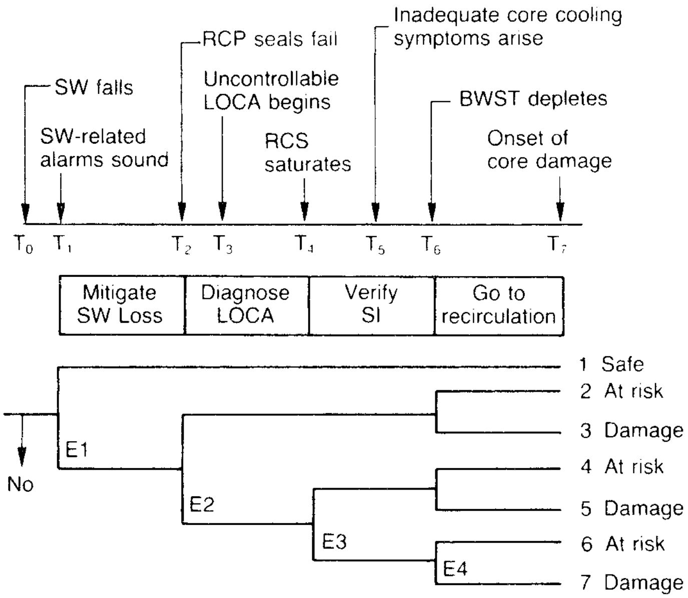
The documentation required of the HRA by the PRA is quite extensive and a computer program ORCA (Operator Reliability and Assessment) has been developed to assist in producing it. Table 14.29 shows a typical document for a recovery mistake.

14.30.13 Application to nuclear power plants

Detailed illustrations of the application of the HRA technique to particular nuclear power plants are given by the authors.

14.30.14 Validation

The HRA method just outlined is described by its authors as speculative. In other words, it lacks validation. In this it is on a par with most of the techniques used for quantifying human error in nuclear and process plants. Nevertheless,



Event	**Most likely error modes**
E1	Fail to recover SW in time
E2	Cannot stop LOCA in time
E3	Fail to follow ICC rule
E4	Fail to respond to low level alarm

Figure 14.32 *Operator action event tree for a nuclear reactor pump seal loss-of-coolant accident (LOCA) (Dogherty and Fragola, 1988). BWST, borated water storage tank; RCP, reactor coolant pump; RCS, reactor cooling system; SI, safety interlock; SW, seal water (Reproduced with permission of John Wiley & Sons Ltd from Human Reliability Analysis by E.M. Dougherty and J.P. Fragola, 1988, Copyright ©)*

this general type of approach represents the most systematic method currently available for the treatment of the human error aspects of a PRA.

14.31 Assessment of Human Error: CCPS Method

Another methodology for human reliability assessment is that described in the CCPS *Human Error Prevention Guidelines* (1994/17). The structure of the method is shown in Figure 14.34. The core is the four stages of (1) critical human interaction identification and screening, (2) qualitative prediction of human error, (3) representation of event development and (4) quantification of significant human errors.

The qualitative error prediction stage utilizes the SPEAR method involving task analysis, PIF analysis, PHEA, consequence analysis and error reduction analysis. The representation of event development typically takes the form of fault trees and event trees. The techniques described for the quantitative error prediction stage are THERP, SLIM and influence diagram analysis (IDA). The latter is described in the next section.

The CCPS HRA methodology has the important characteristic that it requires the analyst to start by acquiring a thorough understanding of the system first by critical human interaction identification and then by detailed qualitative analysis. Only then does the work progress to the use of the quantitative methods.

14.32 Assessment of Human Error: Other Methods

The following methods also merit mention. A brief account of each is given in the *Second Report* of the Study Group on Human Factors of the ACSNI (1991). Accounts are also given by J.C. Williams (1985), Waters (1989) and Brazendale (1990 SRD R510).

14.32.1 TESEO method

A simple model for the estimation of the probability of operator error is that used in TESEO (Tecnica Empirica

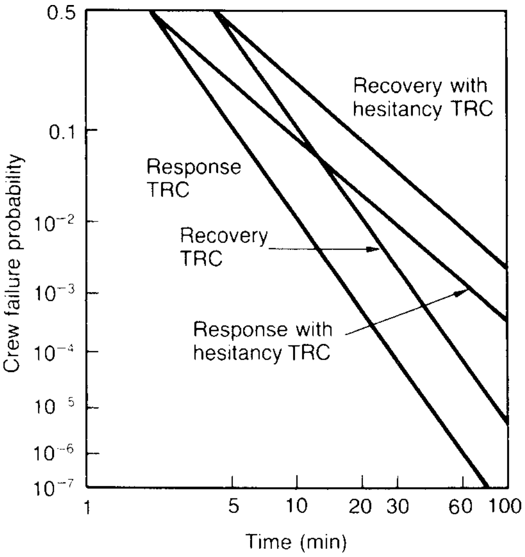


***Figure 14.33** Method of Dougherty and Fragola: time–reliability correlations (Dougherty and Fragola, 1988) (Reproduced with permission of John Wiley & Sons Ltd from Human Reliability Analysis by E.M. Dougherty and J.R. Fragola, 1988, Copyright ©)*

Stima Errori Operatori) developed by Bello and Colombari (1980). The probability, q, of error is assumed to be the product of five parameters K_1--K_5 as follows:

$$q = K_1K_2K_3K_4K_5 \qquad [14.32.1]$$

Definitions and values of the parameters are given in Table 14.30.

An illustration of the use of TESEO has been given by Kletz (1991e). He considers a daily task of filling a tank by watching the level and closing a valve when the tank is full. He suggests that a reasonable estimate of failure is 1 in 1000, or once in 3 years. In practice, men operate such systems without incident for periods of 5 years. Using the TESEO approach he sets K_1 as 0.001, K_2 as 0.5 and the other parameters as unity, obtaining a probability of failure of 1 in 2000, or once every 6 years.

14.32.2 Absolute probability judgement (APJ) method

In the absolute probability judgement (APJ) method, described by Seaver and Sitwell (1983), experts are asked to make direct estimates of human error probabilities for the task.

14.32.3 Method of paired comparisons (PCs)

The use of the method of paired comparisons (PCs) in expert judgement was outlined in Chapter 9. It may be applied to the estimation of HEPs, as described by Blanchard *et al.* (1966) and Hunns (1980, 1982).

14.32.4 Influence diagram approach (IDA)

Influence diagram analysis is a tool developed in the context of decision analysis (R.A. Howard and Matheson, 1980). It has been adapted for work on human factors by L.D. Phillips, Humphreys and Embrey (1983). Essentially, it is a form of logic tree showing the relations between particular performance shaping factors. As such it may be used to obtain quantitative estimates based on expert judgement of the effects of these factors.

14.32.5 Human Cognitive Reliability (HCR) correlation

The human cognitive reliability (HCR) correlation of Hannaman and co-workers (Hannaman *et al.*, 1985; Hannaman and Worledge, 1987) is a method in which the actions of the operating crew are represented in the form of an extended operator action tree and the probability of failure to respond is assessed using a set of three time–reliability correlations.

14.32.6 Systematic human error reduction and prediction approach (SHERPA)

The systematic human error reduction and prediction approach (SHERPA), and its application to human performance in ultrasonic inspection, has been described by Murgatroyd *et al.* (1986). SHERPA involves the three stages of identification of the set of tasks, hierarchical task analysis and human error analysis. HTA is used to identify the two main types of task element handled: those involving manual skills, and those involving the application of condition–action rules. The human error analysis utilizes a flowchart technique to identify the external error modes of the actions comprising the task and the psychological error mechanisms which give rise to these modes. Other types of task element are dealt with by some other appropriate method.

SHERPA is one of the two methods cited in the SRDA *Operating Procedures Guide* (Bardsley and Jenkins, 1991 SRDA-R1) for the treatment of human error in the development of operating procedures.

14.32.7 Critical action and decision approach (CADA)

The other method quoted by these authors is the critical action and decision approach (CADA) of Gall (1990). This is a technique for systematic examination of decision-making tasks and is thus complementary to SHERPA. CADA utilizes checklists to classify and examine decision errors and to assess their likelihood.

14.32.8 Maintenance personnel performance simulator (MAPPS)

The maintenance personnel performance simulator (MAPPS) method is concerned principally with the effect of manning levels on maintenance tasks. The basic premise is that the probability of failure is a function of the loading on the personnel.

14.32.9 Comparative evaluations

Comparative evaluations of sets of human reliability techniques have been given by several authors, including Brune, Weinstein and Fitzwater (1983), J.C. Williams (1983, 1985a), Bersini, Devooght and Smidts (1988), Humphreys (1988a,b) and Kirwan (1988). J.C. Williams (1985b) has compared six methods of human reliability assessment, including the AIR data bank, APJ, PC and SLIM.

The methods treated in the comparative evaluation by Humphreys (1988a,b), described more fully in Section 14.35, are APJ, PC, TESEO, THERP, HEART, IDA, SLIM

and HCR. Another account of this work is given by Kirwan (1988).

A comparative evaluation was also made in the Benchmark Exercise described in Section 14.36.

14.33 Assessment of Human Error: Performance Shaping Factors (PSFs)

14.33.1 THERP method

The use of PSFs in the THERP methodology as given in the *HRA Handbook* has been outlined above. The factors are listed and described but a formal quantitative method of determining for each PSF an adjustment factor to be applied to the human HEP does not appear to be used.

14.33.2 SLIM

PSFs are the basis of SLIM, as described above. In this method the value, or quality, of a PSF is determined by structured expert judgement. The influence diagram technique is used to show the structure of the relationship between PSFs.

14.33.3 HEART

HEART is another method in which PSFs play a central role. The classification of the generic tasks is itself based on PSF-like distinctions and the EPCs that are applied to the basic generic task reliability estimates are in effect PSFs.

14.33.4 White method

R.F. White (1984 SRD R254) has described a form of PSF, the observable operational attribute (OOA) in which, as the name implies, the emphasis is on the observability of the attribute. He provides a checklist of attributes, broken down into (1) plant attributes and (2) main- tenance attributes. Examples of attributes listed as observable are:

(1) What is the time-scale of a filling operation of one tank (or two at a time)? (e.g. Within one shift? Longer than one shift?)
(2) Is formal training given at instrument fitter level?

14.33.5 Whalley model

A methodology for identifying error causes and making the link between them and the PSFs has been developed by

Whalley (1987). The classification structure of the PSFs used is shown in Figure 14.35. A total of 146 PSFs is defined. The PSFs influence the error causes. Each error cause may be affected by several PSFs and each PSF may affect several error causes.

The method utilizes classifications of (1) task types, (2) response types, (3) error types, (4) error mechanisms and (5) error causes. There are seven task types (TTs), which are shown in Table 14.31, Section A. There are also seven response types (RTs) as shown in Section B of the table. The ten error types (ETs) are shown in Section C. The error mechanisms and error causes are shown in Figure 14.36. There are 10 error mechanisms (EMs) and 37 error causes (ECs) (including causes 23a and 30a).

The task types may be summarized as follows. TT 1 is response to a familiar input and requires essentially no decision-making. TT 2 is response to several familiar inputs, matches the mental model and requires no decision-making. TT 3 is interpretation of, and response to, a developing situation using the mental model. TT 4 is a predetermined response to a recognized situation. TT 5 is a self-determined activity that may involve planning. TT 6 is selection of one of several alternative plans. TT 7 is correction of error, and thus differs from the other types. For the response types the primary classification is into discrete or sequence responses, the former involving a single unit of performance, the latter a sequence. The secondary classification is into action and communication activities. The error types are cast as guidewords that are broadly similar to those used in Hazop studies.

The overall structure of the method is shown in Figure 14.37. The primary linkages are from TT, RT and ET to possible ECs. Each TT can be mapped to a set of ECs, either through an information processing chain (IPC) (TT → IPC → EC) or through a set of error mechanisms (TT → EM → EC). Each response type can be mapped to a set of error causes either through a set of error types (RT → ET → EC) or directly (RT → EC).

The analyst uses these various routes to identify the ECs for the task under consideration and then determines for each cause the relevant PSFs and their impact. A computer aid has been developed to assist in identifying the ECs, linking these to the PSFs and quantifying the effect of the latter.

14.33.6 CCPS method

Another set of PSFs are those given in the *Human Error Prevention Guidelines* by the CCPS (1994/17), which refers to them as performance influencing factors (PIFs). The PIF classification structure is shown in Table 14.32. The *Guidelines* give a detailed commentary on each of these factors.

14.34 Assessment of Human Error: Human Error Data

The various methods described for quantitative assessment of human reliability give rise to a demand for data on human error. Some aspects of this are now considered. Human error data and its acquisition has been discussed by a number of workers. The account given in *Human Error Prevention Guidelines* by the CCPS (1994/17) deals with the essentials.

14.34.1 Human error data

Data on human error may be acquired by a number of methods. One approach involves study of the task from

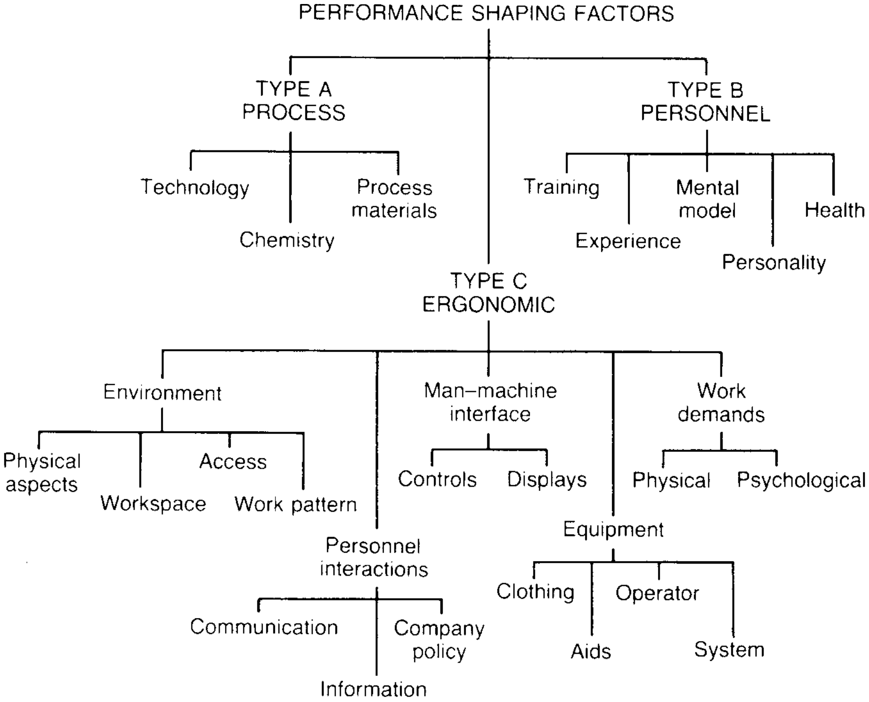

Figure 14.35 *Classification structure of performance shaing factors (Whalley, 1987. Reproduced by permission.)*

Table 14.31 Some classifications of task, response and error for the human operator (Whalley, 1987. Reproduced with permission.)

documentation, which may be aided by task analysis. Another group of methods are those based on some form of direct observation. This may be informal or may utilize formal techniques such as activity sampling, verbal protocol, or withholding of information.

A third group of methods are based on debriefing. One technique here is the critical incident technique, originally used by Flanagan (1954), in which a person who has experienced a near miss is debriefed. Debriefing may also be used to gain information about more normal tasks and situations. A fourth approach is the elicitation of information from experts.

The situation studied may be that on real plant or on a simulator. Simulation is widely used to present situations representative of real life in a compressed time-scale. A review of these and other methods of acquisition of data on human error is given by the CCPS.

14.34.2 Human error data collection

The acquisition of high quality data on human error is clearly of central importance. Human error data collection and data collection systems are also treated by the CCPS. The account deals with (1) types of data collection system, (2) design principles for data collection systems, (3) organizational and cultural aspects of data collection, types of data collected, (5) methods of data collection and storage and (6) data interpretation.

The CCPS distinguishes between consequence-driven and causally oriented systems. The traditional reporting system in the process industries is one triggered by incidents. It is often largely a matter of chance, however, whether or not an error has significant consequences. For this reason the *Guidelines* concentrate on causally oriented systems. Some types of data collection system that are described are (1) the incident reporting and investigation system (IRIS), (2) the root cause analysis system (RCAS), (3) the near miss reporting system (NMRS) and (4) the quantitative human reliability data collection system (QHRDCS).

It is primarily the latter type of system that has the potential to generate data for HRA. There is little evidence of the development of such systems. The CCPS sees them as most likely to emerge in the first instance at in-house level.

The type of data collected will depend on the perspective dominant in the organization, on the human error model implied and on the associated error classification. The CCPS list the following types of causal data. Data may refer to (1) event sequence and structure, (2) human error tendencies, (3) performance-influencing factors and (4) organizational issues.

14.34.3 Human reliability data banks

Human error data banks were a relatively early development. The data entered into these data banks were of the type necessary to support techniques such as THERP. One such data bank is the American Institute for Research (AIR) data bank developed by Altaian and co-workers (Payne and Altaian, 1962; Altaian, 1964) and also described by Meister (1964) and others (Swain, 1968; De Greene, 1970). The store provides data for the execution time and probability of success of task ‘elements’ or ‘steps’. Each step has an input, a mediating and an output component. Typical input components are indicators such as scales and lights; typical output components are controls such as knobs and push buttons, and the two mediating components are identification/recognition and manipulation. Each component has several parameters. Those for a light include size, number and brightness. Each parameter has several discrete levels or ‘dimensions’. Data on time and reliability for each parameter are recorded as functions of its dimensions. The time and reliability of the component are estimated by summing and multiplying, respectively, the time and reliability of the parameters. The time and reliability of the element are obtained from those of the components in a similar way.

Two other data banks from this era are the Aerojet-General data bank, described by Irwin and co-workers (Irwin, Levitz and Ford, 1964; Irwin, Levitz and Freed, 1964), and the Bunker-Ramo data bank, described by Meister (1967). These three data banks have been reproduced in Topmiller, Eckel and Kozinsky (1982). Another somewhat similar data bank is the Sandia Human Error Rate Bank (SHERB) described by Rigby (1967) and Swain (1970).

It will be clear that the development of these data banks was largely driven by the needs of the defence and aerospace industries.

Work on the cognitive and socio-technical aspects of human error is almost certainly too recent for the emergence of data banks utilizing classifications based on these approaches. Nor is it clear whether the needs of the process industries are perceived as sufficiently urgent to support

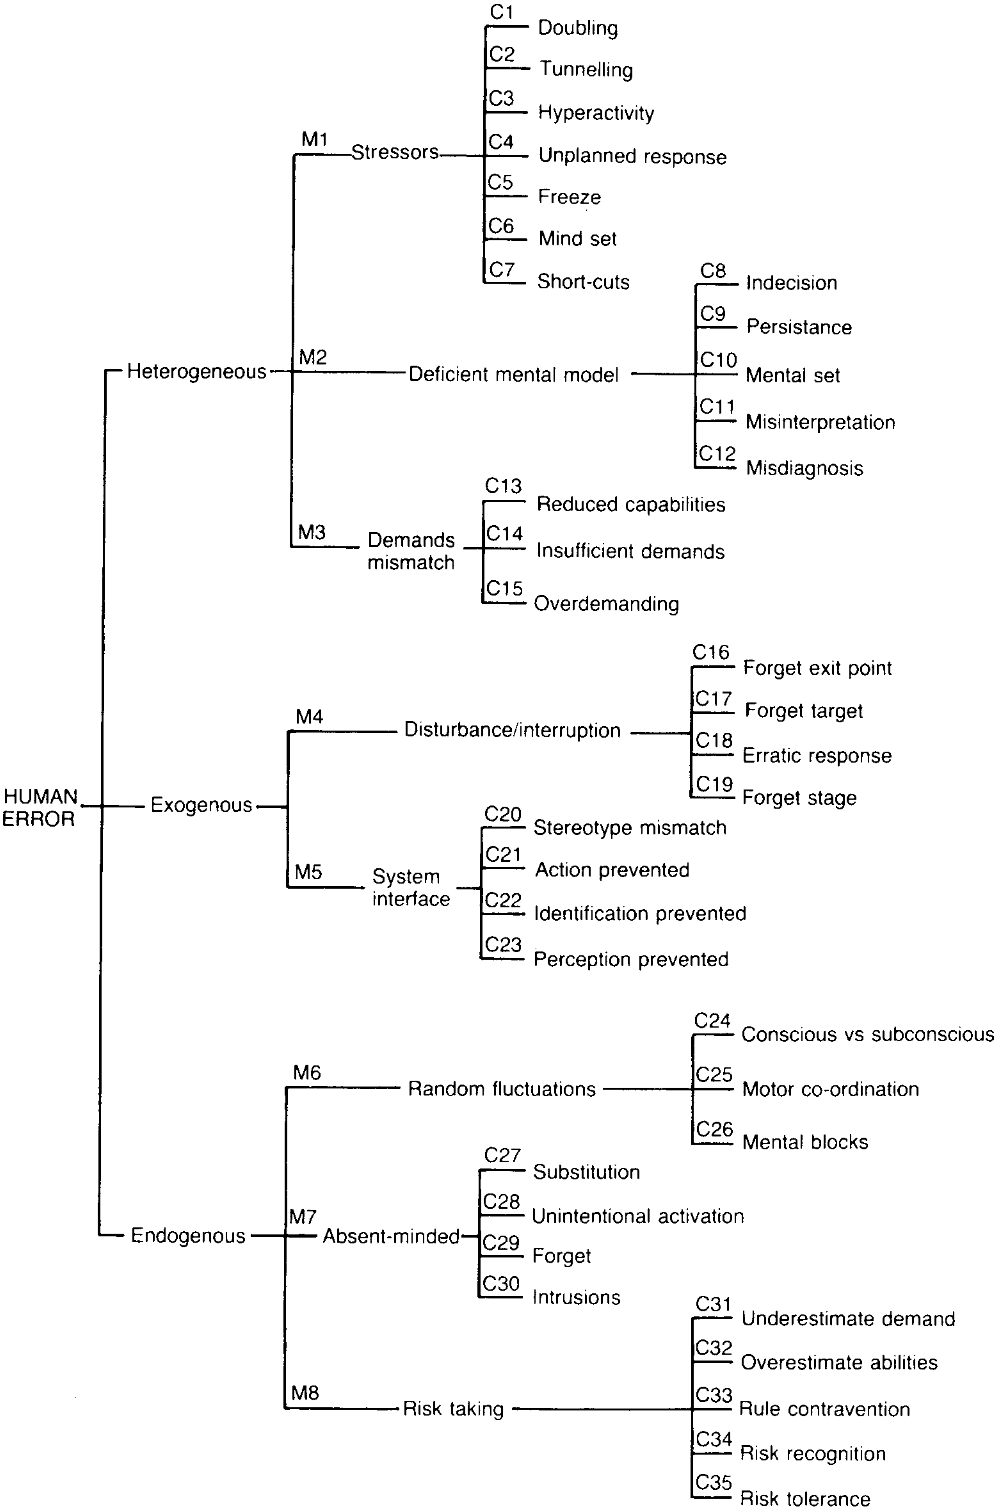

Figure 14.36 *Structure of error mechanisms and error causes (Whalley, 1987. Reproduced by permission.)*

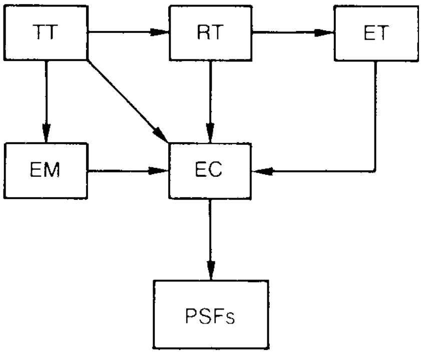

Figure 14.37 *Relations between task and response types, error causes and other quantities (Whalley, 1987. Reproduced by permission.)*

the creation of data banks which are both based on this more recent work and applicable to those industries.

14.34.4 Human error database (HED)

The Human Error Database (HED), described by Kirwan (1988), is based on the HEP data given in the *Rosmussen Report*, tempered by expert judgement. In that it derives from that report, it has similarities to THERP, but it is less decompositional and is not dependent on any specific model.

14.34.5 Accident and human error classification system (TAXAC)

A design for an accident and human error classification system, TAXAC, as the basis of a human error data bank, has been given by Brazendale (1990 SRD R510). The accident classification is obtained as a function of the accident signature (a skeletal account) S, and the accident causes and conducive factors. The features which contribute to the latter are grouped under the headings: activity A, man M, organization O, and plant P. Accidents are also categorized by industry I. Checklists are given for features I, S, A, M, O and P. The author also reviews the requirements and prospects for a human error data bank. Such a venture should not be an isolated entity but should be part of a wide activity on human performance.

14.35 Assessment of Human Error: SRD Human Error Guides

Guidance on several aspects of human error in design and assessment has been issued by the Safety and Reliability Directorate (SRD).

Design is dealt with in *Guide to Reducing Human Error in Process Operation (short version)* by the Human Factors in Reliability Group (HFRG) (1985 SRD R347) (the *HFRG Guide*) and *The Guide to Reducing Human Error in Process Operation* by P. Ball (1991 SRDA-R3), the short and full versions.

The treatment of human error in hazard assessment is covered in *A Suggested Method for the Treatment of Human Error in the Assessment of Major Hazards* by R.F. White (1984 SRD R254), *Human Reliability Assessors Guide* by Humphreys (1988a) and *Human Error in Risk Assessment* by Brazendale (1990 SRD/HSE/510).

A related publication is *Developing Best Operating Procedures* by Bardsley and Jenkins (1991 SRDA-R1). This is considered in Chapter 20.

The *HFRG Guide* (1985 SRD R347), as its title indicates, is concerned with qualitative measures for reducing human error rather than with predicting it. It is essentially a collection of checklists under the following headings: (1) operator–process interface, (2) procedures, (3) workplace and working environment, (4) training and (5) task design and job organization.

The *Guide* distinguishes three meanings of procedure: (1) general guidance, (2) an aid and (3) prescribed behaviour. With regard to the latter, it states the following principles: (1) there should be no ambiguity about when a procedure is to be used, (2) if a procedure is mandatory there should be no incentive to use another method, (3) where possible a procedure should support the operator's skill and discretion rather than replace them and (4) a procedure should be easy to understand and to follow.

R.F. White (1984 SRD R254) describes the use of event tree and fault tree methods to identify the points at which a human action occurs which has an effect on the outcomes. As described earlier, he uses a form of PSF, the OOA, which is distinguished by the fact that it is observable and for which he provides a checklist. He gives as an illustrative example the analysis of the filling of an liquefied natural gas tank.

The *Human Reliability Assessors Guide* (Humphreys, 1988a), given in overview by Humphrey (1988b), is in two parts, the first of which gives a summary of eight techniques for human reliability assessment and the second evaluation criteria for selection and a comparative evaluation based on these criteria. The eight techniques are APJ, PC, TESEO, THERP, HEART, IDA, SLIM and HCRM. For each technique the *Guide* gives a description and a statement of advantages and disadvantages. The evaluation criteria used relate to (1) accuracy, (2) validity, (3) usefulness, (4) effective use of resources, (5) acceptability and (6) maturity. Accuracy has to do with correspondence with reality and with consistency; validity with incorporation of human factors knowledge and of the effect of appropriate PSFs.

The report by Brazendale (1990 SRD/HSE/510) presents a taxonomy for an accident classification scheme, TAXAC, intended for use in connection with a human error data bank. The classification is preceded by a discussion of models of human error. An account of this work is given in Section 14.34.

14.36 Assessment of Human Error: Benchmark Exercise

A benchmark exercise of human reliability is described in *HF-RBE: Human Factors Reliability Benchmark Exercise: Summary Contributions of Participants* (Poucet, 1989). The study is one of a series of benchmark exercises conducted by the Commission of the European Communities (CEC) and organized by the Joint Research Centre (JRC) at Ispra, Italy. The exercise was carried out over 1986–88 with 13 participants. The system studied was the emergency feedwater system (EFS) on a nuclear reactor at the Kraftwerk Union (KWU) site at Grohnde. Two studies were performed: a routine test and an operational transient.

The study carried out by SRD is described in Poucet's volume by Waters. The work showed the importance of the

qualitative modelling stage prior to any quantification and the value of event trees as a tool for such modelling. Methods investigated included APJ, TESEO, THERP, HEART and SLIM. No single method appeared superior in all applications.

14.37 Assessment of Human Error: ACSNI *Study Group Report*

The accounts given of attempts to assess human error illustrate the difficulties and raise the question of whether such assessment is even feasible. The use of quantitative risk assessment has created a demand for the development of techniques for the assessment of human error and this demand has been satisfied by the development of methods, which have just been described, but the validation of these methods leaves much to be desired.

This problem is addressed in *Second Report* of the ACSNI (1991) entitled *Human Reliability Assessment – A Critical Review.* The study deals with the control of the process, but emphasizes that the question is wider than this, embracing also maintenance and other activities. Although it is a report to the nuclear industry, its findings are in large part applicable to the process industries also.

As systems become more automated and reliable, but still vulnerable to human error, the relative importance of human error increases.

The report quotes the view expressed to the Sizewell B Inquiry by the Nuclear Installations Inspectorate (HSE, 1983e) that it was 'considered that comprehensive quantification of the reliability of human actions was not, with current knowledge, meaningful or required', and considers how far the situation has changed since that time.

The report describes the basic procedure of HRA. This is the breakdown of the task into a series of events, each of which has two alternative outcomes and the assignment to these events of basis error probabilities (HEPs). These HEPs are then modified in respect of dependencies and of PSFs. The HEP for the task is then determined. The robustness of the result is assessed by means of a sensitivity analysis.

The variations on this basic procedure lie in the areas of the data sources, the rules for combination and the handling of time. The different techniques vary in the use which they make of field data, data banks, and expert judgement. They also differ in the way in which they combine the influencing factors. In one method some factors may be taken into account by making distinctions in the basic tasks, whilst in another they may be handled as PSFs. The effect of time may be taken into account by treating it simply as another PSF, or, alternatively, it may be accorded a special status. In this latter case the favoured method is the time response correlation, in which time is the principal independent variable determining the HEP, the HEP decreasing as the time available increases.

The report examines some of the areas of HRA in which problems arise or over which care must be taken. The include (1) classification of errors, (2) modelling and auditing, (3) operator error probabilities, (4) maintenance error probabilities, (5) interaction between PSFs, (6) sensitivity analysis and (7) changes in management and organization.

It adopts the distinction between skill-based, rule-based and knowledge-based behaviour and that between slips and mistakes. Essentially it argues that slips, associated with skilled behaviour, are amenable to prediction, but mistakes, associated with rule-based behaviour, are harder to predict, whilst for errors in knowledge-based behaviour there is currently no method available. It also draws attention to wilful actions, or violations, which again are not well covered in current methods.

The first step in an assessment of HEPs is the modelling of the task. There is evidence that for skill-based errors at least, the variability between techniques is less than that between analysts. This points to the need for training of analysts and for an independent check. For auditing it is necessary that the analyst record sufficient detail on his procedures and reasoning.

The report cites estimates of HEPs given in the literature such as the *Rasmussen Report*, described below. It draws attention to the importance of dependency between human actions. It is characteristic of human error that the probability of a further error following an initial one is often not independent but conditional on, and increased by, the occurrence of the first error. On the other hand, humans have the capability to recover from error. It is also necessary to consider the HEP for tasks where more than one operator is involved.

With regard to maintenance error, the report makes the point that hardware failure rate data already include the effects of maintenance errors. Nevertheless, it is prudent to make some assessment of the maintenance error. In particular, there is the possibility that such errors may be a source of dependent failures, as described in Chapter 9.

Most methods make the assumption that the PSFs are independent of each other. Yet, the effects of lack of supervision and of training, for example, are likely to be greater when they occur in combination. An exception is SLIM, which does allow for this effect. The HEP estimates should be explored using sensitivity analysis.

The HRA is likely to more affected than the PRA as a whole by changes in the management and organization of the company, but the assessment of such changes on HEPs is not straightforward. It seems likely that certain types of error will be more affected than others and, therefore, that their relative importance will change. Skill-level errors may be less influenced by management changes than by knowledge-level ones. Violations might well be sensitive to such changes.

The report reviews the strengths and limitations of HRA. It is accepted that PRA has an essential role to play in improving reliability; HRA is a logical and vital extension. Its use has been given impetus by the retrospective assessments conducted after the Three Mile Island incident. A HRA contributes to system design in three ways: it provides a benchmark for designs and safety cases; it gives a quantitative assessment of alternative design or organizational solutions; and it provides a means and a justification for searching out the weak points in a system.

The limitations of HRA principally considered are those of HEP data and of validation. There is a wealth of data from various kinds of human factors experiments, but the situations in which they are obtained are usually to a degree artificial and their applicability is questionable. They provide guidance on the relative importance of different PSFs but generally need to be supplemented by information from other sources. The quantity and quality of field data are relatively low. Those data that do exist are predominantly for slips rather than mistakes or violations. Again they are a guide to the relative importance of different PSFs, but need to be supplemented. A third source of data is expert judgement. The methods for maximizing the quality of assessments and avoiding pitfalls are discussed. The importance is emphasized of the experts having full information on the operational context, such as normal operation or abnormal conditions.

The report addresses the question of the lack of validation of HRA methods. It quotes the following critique of J.C. Williams (1985b): 'It must seem quite extraordinary to most scientists engaged in research in other areas of the physical and technological world that there has been little or no attempt made by human reliability experts to validate the human reliability assessment techniques which they so freely propagate, modify and disseminate'.

Four kinds of validity are considered by the authors: (1) predictive validity, (2) convergent validity, (3) content validity and (4) construct validity. Essentially, for the prediction of a given analyst, predictive validity is concerned with agreement with the real situation, convergent validity is concerned with agreement with the predictions of other analysts, content validity is concerned with agreement between the elements of the model and the features which are critical in real life, and construct validity is concerned with agreement between the structure of the model and that of the real-life situation.

A study of predictive validity has been made by Kirwan (1988). He compared six HRA methods in respect of their ability to predict accident data from experimental, simulator and plant sources, and found that on some criteria some methods seemed reasonably successful. The work was limited, however, to the assessment of the HEP for specified errors and did not deal with modelling of tasks. Two studies of convergent validity, by Brune, Weinstein and Fitzwater (1983) and Bersini, Devooght and Smidts (1988), have found that different assessors give widely differing estimates, even when using the same method. Content validity is probably best assessed by peer review. A study by Humphreys (1988a) based on a comparison of eight methods against a checklist concluded that the relative performance of the methods depends on the problem and that few are completely comprehensive. The report states that construct validity does not appear to have been applied in HRA and that it may not be applicable at this stage of development.

Considering the areas where work is required, the report suggests that one important topic is the development of an improved model of operator behaviour. Here it is the high level decision-making processes which are of prime importance, since it is failures at this level which have the most serious consequences. There is a hierarchy of patterns of learned behaviour, highly learned at the lower levels and but less so towards the upper ones. It is the conservatism of these processes which is responsible for behaviour such as 'mind set' and switch to 'automatic pilot' and for slips when the mind 'jumps the points' and then continues with a whole series of inappropriate actions. Another area where work is needed is the creation of a data set which may be used for validation studies.

The report supports the development and use of methods of HRA. It is an essential element of PRA and is beneficial in its own right. But the techniques available for predicting slips are better than those for mistakes, and particular caution should be exercised with the latter. It should be recognized that HRA is still in its infancy.

It rejects the view that HRA in the nuclear industry should be optional and supports a requirement for its use. HRA provides a structured and systematic consideration of human error. It is already a valuable tool and has the potential to become an invaluable one. A requirement for its use is necessary to provide the necessary impetus for this. The report emphasizes, however, that effort should not be concentrated exclusively on assessment; there is equal need for a systematic approach to the reduction of human error.

The report contains appendices (Appendices 1–4) on HRA methods and their evaluation, dependability of human error data, attempts to establish validity of HRA methods, and approaches to reducing human error. Some of the procedures reviewed in Appendix 1 are APJ, IDA, TESEO, THERP, HEART, SLIM, TRCs, MAPPS and HED.

Appendix 4 of the report gives guidance on approaches to the reduction of human error. It discusses accident chains and latent and active (enabling and initiating) failures and gives the accident model shown in Figure 2.5 which shows the 'shells of influence' for the PSFs. The approach is based on the identification by the HRA, including the sensitivity analysis, of the features where human error is critical, the application of human factors methods and the implementation of the improvements indicated by these methods. The role of human factors both in system design and in the design of the man–machine interface and the workplace is described.

14.38 CCPS *Human Error Prevention Guidelines*

14.38.1 CCPS *Guidelines for Preventing Human Error in Process Safety*

The prevention of human error on process plants is addressed in the *Guidelines for Preventing Human Error in Process Safety* edited by Embrey for the CCPS (1994/17) (the CCPS *Human Error Prevention Guidelines*).

The *Human Error Prevention Guidelines* are arranged under the following headings: (1) the role of human error in chemical process safety, (2) understanding human performance and error, (3) factors affecting human performance in the chemical industry, (4) analytical methods for predicting and reducing human error, (5) qualitative and quantitative prediction of human error in risk assessment, (6) data collection and incident analysis methods, (7) case studies and (8) setting up an error reduction program in the plant.

14.38.2 Approaches to human error

The *Guidelines* distinguish four basic perspectives on human error, which they term: (1) the traditional safety engineering approach, which treats the problem as one of human behaviour and seeks improvement by attempting to modify that behaviour; (2) the human factors engineering and ergonomics (HF/E) approach, which regards human error as arising from the work situation which it therefore seeks to improve; (3) the cognitive engineering approach, which again accords primacy to the work situation, but places its main emphasis on the cognitive aspects; and (4) the socio-technical systems approach, which treats human error as conditioned by social and management factors. Until quite recently, it has been the HF/E approach which has made the running. In the last decade, however, the last two approaches, cognitive engineering and socio-technical systems, have emerged strongly.

The stance of the *Guidelines* is one of system-induced error. This is akin to the work situation approach but enhanced to encompass the cognitive and socio-technical approaches.

14.38.3 Performance influencing factors

The factors shaping human performance are referred to in the *Guidelines* as PIFs. They give a PIF classification structure and a detailed commentary on each factor.

14.38.4 Methods of predicting and reducing human error

The *Guidelines* deal with methods for predicting and reducing human error in terms of (1) data acquisition techniques, (2) task analysis, (3) human error analysis and (4) ergonomics checklists.

They describe a number of methods of task analysis, grouped into action-oriented techniques and cognitive techniques. The former include HTA and operation action event trees (OAETs). The two representatives of the latter are the critical action and decision evaluation technique (CADET) and the influence modelling and assessment system (IMAS). A critical review is given of each method.

Human error analysis is represented by PHEA and work analysis. The PHEA method is that utilized in the *Guidelines'* methodology for HRA.

14.38.5 Methods of predicting HEP for risk assessment

The *Guidelines* describe a methodology for HRA, as part of quantitative risk assessment, utilizing both qualitative and quantitative methods for predicting human error. They begin with an illustrative example of fault tree analysis in which the prime contributors are human error events.

The HRA methodology presented in the *Guidelines* is that already described in Section 14.31 and outlined in Figure 14.34. A detailed commentary is given on each of the stages involved. The core of the method is the four stages of (1) critical human interaction identification and screening, (2) qualitative prediction of human error, (3) representation of event development and (4) quantification of significant human errors.

It is a feature of this HRA methodology that it directs the analyst to acquire understanding of the system and its problems by critical human interaction identification and to undertake a detailed qualitative analysis to further enhance this understanding before embarking on the use of the quantitative methods. It is this rather than the introduction of any new quantitative technique which is its most distinctive characteristic of the method.

14.38.6 Methods for data collection and incident analysis

The *Guidelines* review the collection of data on human error. The treatment given is outlined in Section 14.34.

The *Guidelines* give a number of methods of incident analysis. They are (1) the causal tree/variation diagram, (2) the management oversight and risk tree (MORT), (3) the sequentially timed events plotting procedure (STEP), (4) root cause coding, (5) the human performance investigation process (HPIP) and (6) change analysis. They also refer to the CCPS *Incident Investigation Guidelines*, where most of these techniques are described. A relatively detailed account is given of HPIP by Paradies, Unger and Ramey-Smith (1991); HPIP is a hybrid technique combining several of those just mentioned. The CCPS treatment of incident investigation both in these *Guidelines* and in the *Incident Investigation Guidelines* is described Chapter 27.

14.38.7 Case studies

A feature of the *Human Error Prevention Guidelines* is the number of case histories given. The section on case studies gives five such studies: (1) incident analysis of a hydrocarbon leak from a pipe (Piper Alpha); (2) incident investigation of mischarging of solvent in a batch plant; (3) design of standard operating procedures for the task in Case Study 2; (4) design of VDUs for a computer controlled plant; and (5) audit of offshore emergency blowdown operations. Other case studies occur throughout the text. One illustrates system induced error. Other scene-setting case studies cover (1) errors occurring during plant changes and stressful situations, (2) inadequate human–machine interface design, (3) failures due to false assumptions, (4) poor operating procedures, (4) routine violations, (5) ineffective organization of work, (6) failure explicitly to allocate responsibility and (7) organizational failures. There are case studies illustrating the application of models of human error such as the step ladder and sequential models.

The importance of human error in QRA is illustrated by the case study, already mentioned, dealing with the prevalence of human error in fault trees. Other case studies illustrate HTA, SPEAR, THERP and SLIM.

14.38.8 Error reduction programmes

The *Guidelines* provide guidance on the implementation of an error reduction programme in a process plant. A necessary precondition for such a programme is a management culture that provides the background and support for such initiatives. The general approach is essentially that given in the CCPS *Process Safety Management Guidelines* described in Chapter 6.

Since both safety-related and quality-related errors tend to have the same cause, an error reduction programme may well run in parallel with the quality programme. An error reduction programme should address both existing systems and system design. The tools for such a programme given in the *Human Error Prevention Guidelines* include (1) critical task identification, (2) task analysis, (3) PIE analysis and (4) error analysis, as described in Sections 14.38.3 and 14.38.4. System design should also address allocation of function. Error reduction strategies for these two cases are presented in the *Guidelines*.

14.39 Human Factors at Sizewell B

14.39.1 Sizewell B Inquiry

The potential contribution of human factors to the design and operation of nuclear power stations was urged in evidence to the Sizewell B Inquiry by the Ergonomics Society, as described by Whitfield (1994).

The Society saw this contribution as being in the areas of: (1) setting operational goals; (2) allocation of function between humans, hardware and software; (3) definition of operator tasks; (4) job design; (5) overall performance assessment and monitoring of operational experience; (6) operator-plant interface and workplace conditions; (7) pperator support documentation; (8) selection and training of operating staff; (9) human reliability assessment; and (10) construction and quality assurance. The Nuclear Installations Inspectorate also laid emphasis on human factors aspects (HSE, 1983e).

The report of the Inquiry Inspector (Layfield, 1987) states: ‘I regard human factors as of outstanding significance in assessing the safety of Sizewell B since they impinge on all stages from design to manufacture, construction, operation and maintenance.’ (paragraph 25.90). It recommended the involvement of the discipline.

The plan put forward by the Central Electricity Generating Board in support iof its licence application included commitments to an extensive schedule of training and to the use of probabilistic safety assessment, including quantification of human error.

14.39.2 Human factors studies

A review of the applicability of ergonomics at Sizewell B was undertaken by Singleton (1986), who identified applications in control room design, use of VDU displays, documentation, fault diagnosis, maintenance and task analysis. He stated: ‘We know that human operators can achieve superb performance if they are given the right conditions. Appropriate conditions in this context can be listed within the four categories: the information presentations, the training, the support systems and the working conditions and environment’.

An overview of the application of human factors at Sizewell B has been given by Whitfield (1994).

Human factors specialists are involved in extensive work on training, supported by task analysis, as described below. In the main control room one feature is the use of a plant overview panel, separate from the other displays, for the monitoring of safety critical parameters. Another area of involvement is in operating instructions. Use is made of ‘event-based’ instructions to diagnose a fault and to initiate recovery. But in addition, for safety critical functions, there are ‘function-based’ procedures, which assist in restoring the plant to a safe condition if for some reason the event-based instructions are inappropriate. Further details are given by McIntyre (1992).

HRA within the PSA utilizes OAETs and the HEART method, with some use of THERP. An account is given by Whitworth (1987). The application of task analysis at Sizewell B is described by Ainsworth (1994). The programme for this comprised five stages:

(1) preliminary task analysis of critical tasks;
(2) task analysis of selected safety critical tasks;
(3) preliminary talk-through/walk-through evaluations of procedures in a control room mock-up;
(4) validation of procedures on a control room simulator;
(5) task analysis of tasks outside the main control room.

One crucial task on which task analysis was performed was the cooling down and depressurization of the reactor. This was a major study involving some 60 task elements and taking some 44 person-weeks. Time line analysis was used to address issues such as manning.

A review of procedures revealed a number of defects. Besides obvious typographical errors, they included: (1) incorrect instrument numbering (in procedures); (2) incorrect instrument labelling (on panels and in procedures); (3) omission of important clarifiers such as 'all', 'or', 'either' and 'if available'; (4) omission of important cautions and warnings; (5) requirements for additional information; and (6) lack of consistency between procedures, panels and VDU displays. Overall, the task analyses identified a number of mismatches between task requirements and man–machine interfaces.

Ainsworth makes the point that the ergonomists were often better at identifying problems than in devising solutions, those which they proposed often being impractical, but that it is possible to achieve a mode of working in which these problems are communicated to the designers who take them on board and come up with effective solutions.

14.40 Notation

Section 14.3

$H(s)$	operator transfer function
K	gain
τ_d	reaction time (s)
τ_I	compensatory lag time constant (s)
τ_L	lead time constant (s)
τ_N	neuromuscular lag time constant (s)

Section 14.27

Subsection 14.27.4

k	constant
P_b	basic human error probability
P_c	conditional human error probability

Subsection 14.27.11

n	number of alarms in group
P_i	probability of failure to initiate action in response to ith alarm
P_r	probability of failure to initiate action in response to a randomly selected

Section 14.28

a, b	constants
HEP	human error probability
n	number of performance shaping factors
r	relevancy factor
SLI	Success Likelihood Index
w	quality weighting

Section 14.30

f	error factor
k_1, k_2	constants
m	median
q	quality
r	rank
r_n	normalized rank
x	Success Likelihood Index
τ	mean response time
τ_r	adjusted median response time

Emission and Dispersion

Contents

The three major hazards – fire, explosion and toxic release – usually involve the emission of material from containment followed by vaporization and dispersion of the material. The treatment given here is relevant to all three hazards; in particular, the development of the emission and dispersion phases is relevant to such situations as:

(1) Escape of flammable material, mixing of the material with air, formation of a flammable cloud, drifting of the cloud and finding of a source of ignition, leading to (a) a fire and/or (b) a vapour cloud explosion, affecting the site and possibly populated areas.
(2) Escape of toxic material, formation of a toxic gas cloud and drifting of the cloud, affecting the site and possibly populated areas.

15.1 Emission

There is a wide range of circumstances which can give rise to emission. The situation which appears to be most frequently discussed is a failure of plant integrity, but it is important to consider other occurrences, including escape from valves which have been deliberately opened and forced venting in emergencies. Thus on a low pressure refrigerated liquefied petroleum gas (LPG) installation, for example, a large quantity of flammable vapour may be released by failure of a pressure vessel or of pipework. But loss of refrigeration with resultant forced venting could also give a large release of vapour. Finally, emissions caused by terrorist acts are of growing concern.

In view of the many different situations which can give rise to emission, it is peculiarly difficult to obtain meaningful estimates of the quantity and duration of emissions. The emission stage is therefore subject to great uncertainty. It is nevertheless very important, because the way in which emission occurs can greatly influence the nature and effect of the release, and particularly of any vapour cloud which is formed.

Emission flows may be determined by the basic relations of fluid mechanics. Fundamentals of fluid flow are treated in such texts as *Hydraulics* (Lewitt, 1952), *Thermodynamics Applied to Heat Engines* (Lewitt, 1953), *The Dynamics and Thermodynamics of Compressible Flow* (Shapiro, 1953–), *Chemical Engineering* (Coulson and Richardson, 1955–, 1977–), *Machanics of Fluids* (Massey, 1968–) and *Chemical Engineers Handbook* (Perry and Green, 1984). Selected references on emission are given in Table 15.1.

Fugitive emissions (*see* Table 15.70)

15.1.1 Emission situations

Emission situations may be classified as follows:

(1) Fluid
  (a) gas/vapour,
  (b) liquid,
  (c) vapour–liquid mixture;
(2) Plant
  (a) vessel,
  (b) other equipment,
  (c) pipework;
(3) Aperture
  (a) complete rupture,
  (b) limited aperture;
(4) Enclosure
  (a) in building,
  (b) in open air;
(5) Height
  (a) below ground level,
  (b) at ground level,
  (c) above ground level;
(6) Fluid momentum
  (a) low momentum,
  (b) high momentum.

Some typical emission situations are shown in Figure 15.1.

The fluid released may be gas, vapour, liquid or a two-phase vapour–liquid mixture, as shown in Figure 15.1(a). If the escape is from a container holding liquid under pressure, it will normally be liquid if the aperture is below the liquid level and vapour or vapour–liquid mixture if it is above the liquid level. For a given pressure difference the mass of release is usually much greater for a liquid or vapour–liquid mixture than for a gas or vapour.

The plant on which the release occurs may be a vessel, other equipment such as a heat exchanger or a pump, or pipework, as shown in Figure 15.1(b). The maximum amount which can escape depends on the inventory of the container and on the isolation arrangements.

The aperture through which the release occurs may range from a large fraction of the envelope of the container in the case of complete rupture of a vessel to a limited aperture such as a hole, as shown in Figure 15.1(c). An aperture on a vessel may be (1) a sharp-edged orifice, (2) conventional pipe branch, (3) a rounded nozzle branch, or (4) a crack. The flow through a rounded nozzle is greater than through a conventional pipe branch, but it is the latter which is generally used. Other apertures on vessels, equipment and pipework include: (5) drain and sample points; (6) pressure relief devices – (a) pressure relief valves, (b) bursting discs, and (c) liquid relief valves; (7) seals; (8) flanges and (9) pipe ends.

The relief may take place from plant in a building or in the open air, as shown in Figure 15.1(d). This greatly affects the dispersion of the material. A large proportion of escapes to the open air are dispersed without incident.

The height at which the release occurs also has a strong influence on the dispersion, as shown in Figure 15.1(e). A liquid escape from plant below ground level may be completely contained. An escape of gas or vapour from above ground level may be dispersed over a considerable distance.

Dispersion is further affected by the momentum of the escaping fluid, as shown in Figure 15.1(f). Low and high momentum releases of gas or vapour form a plume and a turbulent momentum jet, respectively. Low and high momentum releases of liquid form a liquid stream and a high 'throw' liquid jet, respectively, both of which then form a liquid pool.

A generalized chart for the calculation of the discharge of liquids and gases under pressure has been given by Pilz and van Herck (1976) and is reproduced in Figure 15.2.

15.1.2 Elementary relations

For flow of a single fluid

$$W = Q\rho \qquad [15.1.1]$$

$$Q = uA \qquad [15.1.2]$$

$$G = W/A \qquad [15.1.3]$$

$$G = u\rho \qquad [15.1.4a]$$

$$G = u/v \qquad [15.1.4b]$$

where A is the cross-sectional area of the pipe, G is the mass flow per unit area, Q is the total volumetric flow, u is the velocity, v is the specific volume of fluid, W the total mass flow, and ρ is the density of the fluid.

The general differential form of the energy balance for the flow of unit mass of fluid is

$$-\mathrm{d}q + \mathrm{d}W_s + \mathrm{d}H + \mathrm{d}\left(\frac{u^2}{2}\right) + g\,\mathrm{d}z = 0 \qquad [15.1.5]$$

where g is the acceleration due to gravity, H is the enthalpy, q is the heat absorbed from the surroundings, W_s is the work done on the surroundings (shaft work), and z is the height.

It is often convenient to eliminate H from Equation 15.1.5 using the relation:

$$\mathrm{d}H(= T\,\mathrm{d}S + v\,\mathrm{d}P) = \mathrm{d}q + \mathrm{d}F + v\,\mathrm{d}P \qquad [15.1.6]$$

where F is the mechanical energy irreversibly converted to heat (frictional loss) and P is the absolute pressure.

Then, combining Equations 15.1.5 and 15.1.6 gives

$$\mathrm{d}W_s + v\,\mathrm{d}P + \mathrm{d}F + \mathrm{d}\left(\frac{u^2}{2}\right) + g\,\mathrm{d}z = 0 \qquad [15.1.7]$$

For the discharge processes considered here, the work done on the surroundings W_s is zero. Then Equation 15.1.7 becomes:

$$v\,\mathrm{d}P + \mathrm{d}F + \mathrm{d}\left(\frac{u^2}{2}\right) + g\,\mathrm{d}z = 0 \qquad [15.1.8a]$$

or, alternatively,

$$v\,\mathrm{d}P + \mathrm{d}F + u\,\mathrm{d}u + g\,\mathrm{d}z = 0 \qquad [15.1.8b]$$

In some applications the friction loss and potential energy terms may be neglected, in which case Equation 15.1.8b reduces to:

$$v\,\mathrm{d}P + u\,\mathrm{d}u = 0 \qquad [15.1.9]$$

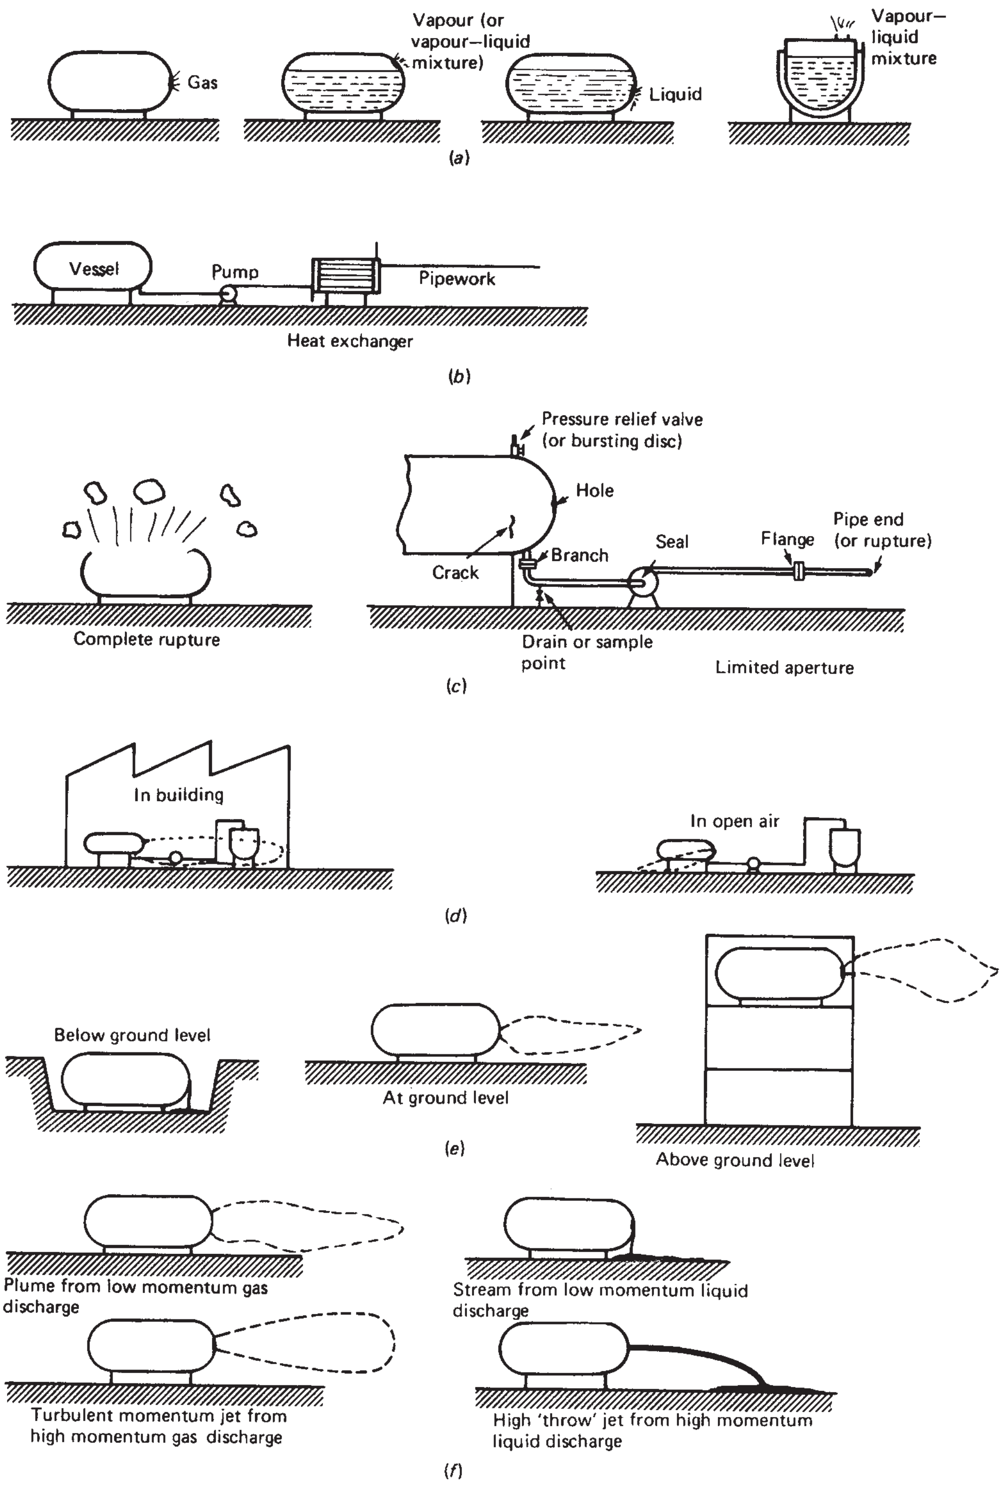

Figure 15.1 *Some emission situations*

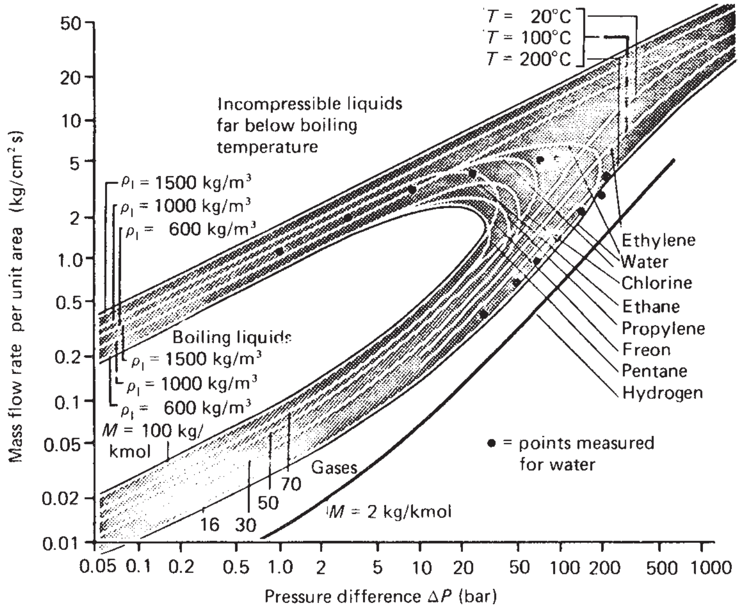

Figure 15.2 *Mass flow vs pressure difference for flow of gases, vapours and liquids through an orifice (Pitz and van Herck, 1976; reproduced by permission)*

Equation 15.1.8b may also be expressed in the form of a pressure drop relation:

$$\frac{dP}{dl}+\frac{1dF}{v\,dl}+G\frac{du}{dl}+\frac{g\,dz}{v\,dl}=0 \qquad [15.1.10a]$$

or

$$\frac{dP}{dl}+\rho\frac{dF}{dl}+G\frac{du}{dl}+\rho g\frac{dz}{dl}=0 \qquad [15.1.10b]$$

or

$$\frac{dP}{dl}+\frac{1dF}{v\,dl}+\frac{u\,du}{v\,dl}+\frac{g\,dz}{v\,dl}=0 \qquad [15.1.10c]$$

where l is the distance along the pipe.

A relation for pressure drop may also be obtained from the momentum balance:

$$\frac{dP}{dl}+\frac{S}{A}R_o+G\frac{du}{dl}+\rho g\frac{dz}{dl}=0 \qquad [15.1.11]$$

where R_o is the shear stress at the pipe wall and S is the perimeter of pipe. The term dz/dl in Equations 15.1.10 and 15.1.11 is often replaced by the term $\sin\theta$, where θ is the angle between pipe and horizontal.

Comparing Equations 15.1.10b and 15.1.11, which each give the pressure drop, it follows that:

$$\frac{S}{A}R_o=\rho\frac{dF}{dl} \qquad [15.1.12]$$

The pressure drop dP/dl may also be expressed in terms of its constituent elements:

$$-\frac{dP}{dl}=-\frac{dP_f}{dl}-\frac{dP_a}{dl}-\frac{dP_g}{dl} \qquad [15.1.13]$$

where dP_f/dl is the frictional pressure change, dP_a/dl is the accelerational pressure change and dP_g/dl is the gravitational pressure change.

For flow in pipes, the friction term dF is:

$$dF=4\phi\frac{dl}{d}u^2 \qquad [15.1.14a]$$

$$=8\phi\frac{dl}{d}\frac{u^2}{2} \qquad [15.1.14b]$$

with

$$\phi=\frac{R}{\rho u^2} \qquad [15.1.15]$$

where d is the diameter of the pipe, R is the shear stress at the pipe wall and ϕ is the friction factor.

The most commonly used friction factor f is twice the friction factor ϕ:

$$f=2\phi \qquad [15.1.16]$$

Hence from Equations 15.1.14b and 15.1.16

$$dF=4f\frac{dl}{d}\frac{u^2}{2} \qquad [15.1.17]$$

Another form of the pressure drop equation which is derived from Equation 15.1.10b together with Equations 15.1.14 and 15.1.17 is:

$$\frac{dP}{dl} + G^2\left(\frac{dv}{dl} + \frac{4fv}{2d}\right) + \frac{g}{v}\frac{dz}{dl} = 0 \qquad [15.1.18]$$

The equations just given are in differential form. In order to obtain relations useful in engineering, they need to be integrated. Integrating the energy balance Equation 15.1.8a

$$\int_1^2 v\,dP + F + g\Delta z + \Delta\left(\frac{u^2}{2}\right) = 0 \qquad [15.1.19]$$

where limit 1 is the initial state and limit 2 is the final state.

Integration of the first term in Equation 15.1.19 requires a relation between pressure P and specific volume v. Three principal relations are those for incompressible, isothermal and isentropic flow:

$$v = \text{Constant} \quad \text{Incompressible flow} \qquad [15.1.20a]$$

$$Pv = \text{Constant} \quad \text{Isothermal flow} \qquad [15.1.20b]$$

$$P\gamma = \text{Constant} \quad \text{Isentropic flow} \qquad [15.1.20c]$$

where γ is the ratio of the gas specific heats. Also, for an adiabatic expansion:

$$Pv^k = \text{Constant} \quad \text{Adiabatic flow} \qquad [15.1.20d]$$

where k is the expansion index.

Then it can be shown that for these flow regimes:

$$\int_1^2 v\,dP = v(P_2 - P_1) \quad \text{Incompressible flow} \qquad [15.1.21a]$$

$$= P_1 v_1 \ln\left(\frac{P_2}{P_1}\right) \quad \text{Isothermal flow} \qquad [15.1.21b]$$

$$= \frac{\gamma}{\gamma - 1} P_1 v_1 \left[\left(\frac{P_2}{P_1}\right)^{(\gamma-1)/\gamma} - 1\right] \quad \text{Isentropic flow} \qquad [15.1.21c]$$

$$= \frac{k}{k - 1} P_1 v_1 \left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \quad \text{Adiabatic flow} \qquad [15.1.21d]$$

It is frequently convenient to work in terms of the head h rather than the pressure P of the fluid. The relation between the two is:

$$P = h\rho g \qquad [15.1.22]$$

It is generally necessary to define the flow regime. The principal criterion of similarity is the Reynolds number Re which is

$$\text{Re} = \frac{Gd}{\mu} \qquad [15.1.23]$$

where d is the diameter of the orifice or pipe, and μ is the viscosity of the fluid.

The discharge of liquids and of gases and vapours is now considered.

15.1.3 Liquid or incompressible fluid discharge

For the flow of a liquid, or incompressible fluid, the term $\int_1^2 (1/\rho)\,dP$ is given by Equation 15.1.21a. Substituting this term in Equation 15.1.19 gives

$$\frac{1}{\rho}(P_1 - P_2) + g(z_1 - z_2) = \Delta\left(\frac{u^2}{2}\right) + F \qquad [15.1.24]$$

When flow is on a horizontal axis, the left-hand side simplifies to $(P_1 - P_2)/\rho$. When flow is not on a horizontal axis, variation in elevation can be incorporated in subsequent equations by replacing P with $P + \rho gz$ where z is based on a common reference height. The first term on the right hand side of Equation 15.1.24, $\rho\,(u^2/2)$, represents the increase in kinetic energy of (final) state 2 from (initial) state 1. Many authors include a coefficient on the kinetic energy term correcting for non-uniform velocity distributions

$$\left\{\frac{\text{kinetic energy}}{\text{mass of fluid}}\right\} = \frac{\int u^3\,da}{2\int u\,da} = \alpha\left(\frac{u^2}{2}\right) \qquad [15.1.25]$$

where integration is over the cross-sectional area of the flow and u is defined by Equation 15.1.2. For laminar flow in pipes, $\rho = 2$, and McCabe, Smith and Harriott (1956–) state that ρ is about 1.05 for fully developed turbulent flow in pipes.

For the flow of liquid through a pipe, the frictional loss F is given by

$$F = F_c + F_f + F_{ft} \qquad [15.1.26]$$

where F is the total frictional loss, F_c is the frictional loss due to sudden contraction, F_f is the frictional loss due to the pipe (or skin friction), and F_{ft} is the frictional loss due to fittings. In this expression, expansion losses have been ignored, but expressions for the expansion loss can be found in standard texts. Expansion losses cannot exceed the kinetic energy of the fluid and do not apply at the point of discharge to the atmosphere.

McCabe, Smith and Harriott (1956–) give the friction loss from contraction as

$$F_c = 0.4\left(1 - \frac{A_2}{A_1}\right)\left(\frac{u^2}{2}\right) \qquad [15.1.27]$$

where u is the velocity in the (smaller) pipe with cross-sectional area A_2. The frictional loss due to the pipe is:

$$F_f = \frac{4fl}{d}\left(\frac{u^2}{2}\right) \qquad [15.1.27]$$

The friction coefficient f is described in Section 15.1.5. The friction loss from pipe fittings is usually expressed as a number of velocity heads:

$$F_{ft} = K_{ft}\left(\frac{u^2}{2}\right) \qquad [15.1.28]$$

where K_{ft} is the friction coefficient for pipe fittings (expressed as the number of velocity heads) and is discussed in Section 15.1.5.

All of the frictional losses can be expressed in terms of the number if velocity heads. For flow from a vessel through a pipe of a single diameter, the total number K of velocity heads lost, excluding any exit, is

$$K = K_c K_f + K_{ft} \qquad [15.1.30]$$

where K_c is the number of velocity heads lost at the contraction (pipe entrance), K_f is the number of velocity heads lost due to skin friction and K_{ft} is the number of velocity heads lost due to fittings. Comparing with Equation 15.1.27, K_c is

$$K_c = 0.4\left(1 - \frac{A_2}{A_1}\right) \qquad [15.1.31]$$

and K_f is

$$K_f = \frac{4fl}{d} \qquad [15.1.32]$$

15.1.4 Liquid discharge rates

Equation 15.1.24 can be used to predict the discharge rate from a vessel at (stagnation) pressure $P_1(+\rho gz)$ to ambient pressure $P_2(+\rho gz)$. As discussed above, the frictional loss due to a sudden pipe expansion does not apply at pipe openings to the atmosphere. This section discusses liquid discharge rates through an orifice, an external mouthpiece, and a constant diameter pipe system.

For discharge through an orifice or nozzle, changes in elevation are negligible, and frictional losses are much less than the flow kinetic energy. Based on vessel (stagnation) pressure P_1, Equation 15.1.24 shows that the velocity of a liquid through an orifice with a cross-sectional area A, which is small relative to that of the vessel, is

$$u = C_D\left[\frac{2}{\rho}(P_1 - P_2)\right]^{1/2} \qquad [15.1.33]$$

or, in terms of the mass rate W,

$$W = C_D A[2\rho(P_1 - P_2)]^{1/2} \qquad [15.1.34]$$

where C_D is the coefficient of discharge.

For orifice flow, the coefficient of discharge C_D is the ratio of the actual to the theoretical discharge. This actual discharge is the product of the actual cross-sectional area of the jet and the actual velocity of the jet. Then defining a coefficient of contraction C_c as the ratio of the actual to the theoretical area, and a coefficient of velocity C_v ($= 1/\rho$ in Equation 15.1.25) as the correction factor for non-uniform velocity profile at the actual cross-sectional area of the jet gives

$$C_D = C_c C_v \qquad [15.1.35]$$

The coefficient of contraction C_c is defined as

$$C_c = A_c/A_o \qquad [15.1.36]$$

where A_o is the cross-sectional area of the orifice and A_c is the cross-sectional area of the vena contracta. For a sharp-edged orifice in the side of a vessel there are available theoretical expressions for the coefficient of contraction. Thus for a two-dimensional sharp-edged orifice for liquid

$$C_c = \frac{\pi}{\pi + 2} = 0.61 \qquad [15.1.37]$$

and for gas

$$C_c = \frac{\pi}{\pi + 2(\rho_2/\rho_1)} \qquad [15.1.38]$$

where the subscripts 1 and 2 refer to stagnation and outlet conditions, respectively.

An average experimental value of C_c for sharp-edged orifices for liquids is 0.64. The difference between the actual and theoretical velocities for a sharp-edged orifice for liquid is very small. An average experimental value of C_v for sharp-edged orifices for liquids is 0.97. Thus for a sharp-edged orifice for liquids an average experimental value of the coefficient of discharge C_D is 0.62 ($= 0.97 \times 0.64$).

Studies on the coefficient of discharge from sharp-edged orifices for water have been described by Lea (1930). The coefficient of discharge for sharp-edged orifices for gases has been studied by Perry (1949). He found that the coefficient of discharge is a function of the ratio of the outlet to the stagnation pressure, or pressure ratio, as shown in Figure 15.4. The limiting values of the coefficient are 0.6 and 0.84 at high and low pressure ratios, respectively. Similar results have been obtained for short pipe outlets by Arnberg (1962). Values of the coefficient of discharge used in hazard assessment work range between 0.6 and 1.0. A value of 0.6 is frequently used for orifices. Coefficients of discharge are treated in more detail in standard texts (e.g. Lewitt, 1952; Coulson and Richardson, 1977–).

Another common discharge situation is that of an external mouthpiece on the side of a vessel, such as a short nozzle or pipe stub, as shown in Figure 15.3.

For short pipe stubs with l/d at least about 10, the frictional loss can be approximated as that of a flow contraction per Equation 15.1.27 or 15.1.31. Based on vessel (stagnation) pressure P_1, Equation 15.1.24 shows that the liquid velocity through an opening with cross-sectional area A which is small relative to that of the vessel is

$$u = \frac{[(2/\rho)(P_1 - P_2)]^{1/2}}{(1 + K_c)^{1/2}} \qquad [15.1.39]$$

In a similar fashion to Equations 15.1.33 and 15.1.34, the discharge rate can be calculated using an effective

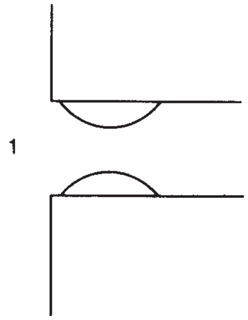

Figure 15.3 *External mouthpiece*

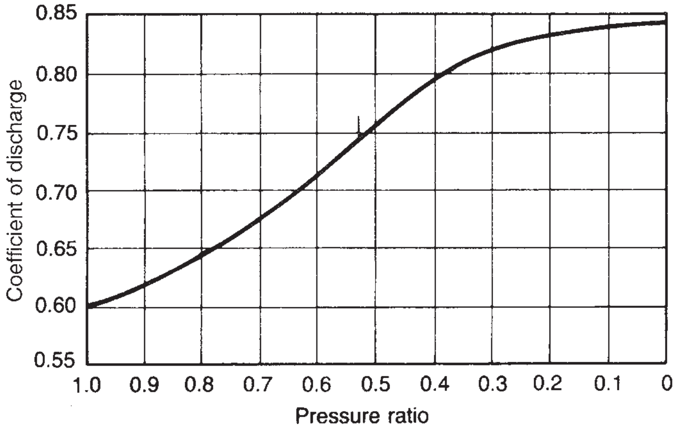

Figure 15.4 *Coefficient of discharge for gas flow through an orifice (after J.A. Perry, 1949) (Courtesy of the American Society of Mechanical Engineers)*

discharge coefficient, and using the number of velocity heads lost, the effective discharge coefficient is

$$C_D = \frac{1}{(1+K_c)^{1/2}} \qquad [15.1.40]$$

Using Equation 15.1.31 and considering discharge from a small opening in a large vessel,

$$C_D = \frac{1}{(1+0.4)^{1/2}} = 0.85 \qquad [15.1.41]$$

An average experimental value of the coefficient of discharge is 0.81 that applies to mouthpieces for which the length/diameter ratio of the pipe is not less than 3. A value of 0.8 is frequently used for short nozzles and pipe stubs.

Similarly for constant diameter pipe systems, an effective coefficient of discharge C can be defined as

$$C = \frac{1}{(1+K)^{1/2}} \qquad [15.1.42]$$

where K is given by Equation 15.1.30.

15.1.5 Friction, friction factor and fittings loss

The friction loss in a pipe is given by Equation 15.1.27, where the friction factor f is obtained from Equations 15.1.15 and 15.1.16. The relationship between the friction factors θ and f is given by Equation 15.1.16.

Relationships between the principal friction factors used are given by Churchill (1977). The friction factor f as defined above is identical to the Fanning friction factor f_F so that

$$f_F = 2\phi \qquad [15.1.43]$$

Another friction factor is the Darcy friction factor f_D. This is related to the other friction factors as follows:

$$f_D = 8\phi \qquad [15.1.44a]$$

$$= 4f \qquad [15.1.44b]$$

$$= 4f_F \qquad [15.1.44c]$$

Graphs of the friction factor are available based primarily on the work of Stanton and Pannell (1914) and of L.F. Moody (1944) and are given in standard texts (e.g. Coulson and Richardson, 1977–, Perry and Green, 1984).

It is also desirable to have equations for the friction factor, and a number of these are available. Some of the equations are implicit, others explicit. Some are more convenient for use if the flow is known, others if the pressure drop is known.

The friction factor depends on the flow regime, the three regimes being those of laminar, transitional and turbulent flow. In the laminar regime the friction factor may be obtained from the Poiseuille equation and may be written as:

$$\phi = \frac{8}{\mathrm{Re}} \qquad [15.1.45]$$

In the other regimes the friction factor is, in general, a function of the Reynolds number Re and of the roughness ratio e/d, where e is the pipe roughness.

A correlation of the friction factor for these regimes has been given by Colebrook (1939) as follows:

$$\frac{1}{f_D^{1/2}} = -2\log_{10}\left(\frac{e}{3.7d} + \frac{2.51}{\mathrm{Re}\, f_D^{1/2}}\right) \qquad [15.1.46]$$

He states that Equation 15.1.46 reduces for smooth pipes to

$$\frac{1}{f_D^{1/2}} = 2\log_{10}\left(\frac{\mathrm{Re}\, f_D^{1/2}}{2.51}\right) \qquad [15.1.47]$$

and for rough pipes to

$$\frac{1}{f_D^{1/2}} = 2\log_{10}\left(\frac{3.7d}{e}\right) \qquad [15.1.48]$$

Colebrook also gives as an alternative to Equation 15.1.47 which avoids the implicit formulation by means of the following approximate equation:

$$\frac{1}{f_D^{1/2}} = 1.8\log_{10}(\mathrm{Re}/7) \qquad [15.1.49]$$

Coulson and Richardson (1977–) state that the transition regime occurs at $2000 < \mathrm{Re} < 3000$ and give the following equations for the turbulent regime.

Smooth pipes:

$$\phi = 0.0396/\mathrm{Re}^{0.25} \quad 2.5 \times 10^3 < \mathrm{Re} < 10^5 \qquad [15.1.50]$$

$$\phi^{-0.5} = 2.5 \ln (\mathrm{Re}\,\phi^{0.5}) + 0.3 \quad 10^5 < \mathrm{Re} < 10^7 \qquad [15.1.51]$$

Rough pipes:

$$\phi^{-0.5} = -2.5 \ln [0.27e/d + 0.885/(\mathrm{Re}\,\phi^{-0.5})] \qquad [15.1.52]$$

$$\phi^{-0.5} = 3.2 - 2.5 \ln (e/d) \quad (e/d)\mathrm{Re}\,\phi^{0.5} \gg 3.3 \qquad [15.1.53]$$

Equation 15.1.50 is the Blasius equation.

Churchill (1977) has given an explicit equation for the friction factor ϕ for all three regimes as follows:

$$\phi = \left[\left(\frac{8}{\mathrm{Re}}\right)^{12} + \frac{1}{(A+B)^{3/2}}\right]^{1/12} \qquad [15.1.54]$$

with

$$A = \left[2.457 \ln\left(\frac{1}{(7/\mathrm{Re})^{0.9} + 0.27e/d}\right)\right]^{16} \qquad [15.1.55]$$

$$B = (37530/\mathrm{Re})^{16} \qquad [15.1.56]$$

where A and B are constants. Elsewhere, Churchill (1980) states that the transition regime occurs at $1800 < \mathrm{Re} < 4000$.

Another explicit equation for the friction factor for all three regimes, expressed this time in terms of the Darcy friction factor, is that of N.H. Chen (1979):

$$\frac{1}{f_\mathrm{D}^{1/2}} = -2.0 \log\left\{\frac{e}{3.7065d} - \frac{5.0452}{\mathrm{Re}} \times \log\left[\frac{1}{2.8257}\left(\frac{e}{d}\right)^{1.1098} + \frac{5.8506}{\mathrm{Re}^{0.8991}}\right]\right\} \qquad [15.1.57]$$

The relative merits of the equations for the friction factor are considered in the discussion on the work of N.H. Chen (1980).

Tabulations are available for the pressure drop across the various types of pipe fitting such as elbows, tees, valves, etc. A prime source is *Flow of Fluids through Valves, Fittings and Pipe* (Crane Company, 1986), which gives the loss in terms of the number of velocity heads. Tables are given in standard texts (e.g. Perry and Green, 1984) and appear mostly to be based on the data given in the various editions of the Crane Company publication.

An alternative formulation of fittings loss is in terms of number of pipe diameters. A table giving for selected fittings both the number of velocity heads and the number of pipe diameters is given by Coulson and Richardson (1977–). For many of the entries in this table the number of pipe diameters equivalent to one velocity head is about 50.

15.1.6 Critical flow

For compressible fluids, including gases and two-phase mixtures, it is necessary to consider critical flow. If, for such a fluid, the upstream pressure is high relative to the downstream pressure, the flow is choked. The flow is then no longer a function of the pressure difference but is a function of the upstream pressure alone and has a maximum or critical value. This is the condition of critical or choked flow. For a gas this flow is then sonic and the condition is also referred to as sonic flow.

The measure of approach to sonic conditions is the Mach number Ma which is

$$\mathrm{Ma} = \frac{u}{c} \qquad [15.1.58]$$

where c is the velocity of sound. For sonic flow the Mach number is unity and the velocity u of the fluid equals the velocity of sound c. The velocity of sound in a gas of absolute pressure P and specific volume v is given by the relation

$$c = (kPv)^{1/2} \qquad [15.1.59]$$

where k is the expansion index. Hence under critical conditions

$$u = (kP_1v_1)^{1/2} \qquad [15.1.60]$$

where subscript 1 indicates upstream (stagnation) conditions. A pressure ratio η may be defined

$$\eta = \frac{P_2}{P_1} \qquad [15.1.61]$$

Then it can be shown that the critical pressure ratio η_c is

$$\eta_\mathrm{c} = \left(\frac{2}{k+1}\right)^{k/(k-1)} \qquad [15.1.62]$$

Equation 15.1.62 is often used to determine the downstream, or choke, pressure under critical conditions.

For a given upstream pressure, the flow is zero both when $\eta = 0$ and when $\eta = 1$. At some intermediate value of η, and P, the flow passes through a maximum, which occurs when

$$\frac{\mathrm{d}G}{\mathrm{d}P} = 0 \qquad [15.1.63a]$$

or

$$\frac{\mathrm{d}G}{\mathrm{d}\eta} = 0 \qquad [15.1.63b]$$

Differentiating Equation 15.1.4b with respect to P and applying Equation 15.1.63a gives for the critical flow G_c

$$\frac{\mathrm{d}u}{\mathrm{d}P} = G_\mathrm{c}\frac{\mathrm{d}v}{\mathrm{d}v} \qquad [15.1.64]$$

Then from Equations 15.1.64 and 15.1.9

$$G_\mathrm{c}^2 = -\frac{\mathrm{d}P}{\mathrm{d}v} \qquad [15.1.65]$$

Critical flow is discussed further in the following sections.

15.1.7 Gas and vapour discharge

For the flow of a gas, or compressible fluid, through an orifice it is necessary to define the type of fluid and the type of expansion. For an ideal gas

$$P_{\mathrm{v}} = \frac{RT}{M} \qquad [15.1.66]$$

and for a non-ideal gas

$$P_{\mathrm{v}} = \frac{ZRT}{M} \qquad [15.1.67]$$

where M is the molecular weight, R is the universal gas constant, T is the absolute temperature, and Z is the compressibility factor.

The flow of an ideal gas may be calculated using Equation 15.1.21 with a suitable expression for $\int_1^2 v\,\mathrm{d}P$. The flow of a non-ideal gas may be obtained from Equation 15.1.5 using enthalpy values from thermodynamic tables.

The expansions which take place in discharge situations are normally throttling expansion or free expansion. Throttling expansion occurs when gas issues through a very narrow aperture or crack. There is high frictional resistance and low kinetic energy. When applied to vapour, the process is sometimes called 'wire-drawing'.

The frictional resistance of a fluid passing through a pipe varies inversely with the fifth power of the pipe diameter. Similarly, as an aperture becomes larger a situation is quickly reached where there is free expansion. The frictional resistance is low and the kinetic energy is high. In the present context it is free expansion which is of prime interest and which is considered in the treatment given below.

The free expansion of an ideal gas is usually treated as an approximately adiabatic expansion with some degree of irreversibility. The entropy change $\mathrm{d}S$ for the expansion is

$$\mathrm{d}S = \frac{\mathrm{d}q}{T} + \frac{\mathrm{d}F}{T} \qquad [15.1.68]$$

If the expansion is adiabatic $\mathrm{d}q = 0$, and if it is reversible $\mathrm{d}F = 0$. If the expansion is reversible adiabatic $\mathrm{d}S = 0$. The free expansion of an ideal gas is usually treated by the use of the Equation 15.1.21d.

If the expansion process is reversible and adiabatic or intermediate between adiabatic and isothermal, Equation 15.1.21d is applicable. If the expansion is not reversible, it may not be possible to give a continuous function for the relation between pressure and volume, but Equation 15.1.21d is often applied over a limited range of conditions. If the expansion is isentropic, then the index k is equal to the ratio of specific heats γ. If the expansion is not isentropic, then k is less than γ.

If the absolute upstream pressure P_1 is only slightly greater than the absolute downstream pressure P_2, in other words for low values of the pressure ratio P_1/P_2, it may be adequate to assume an isothermal expansion according to Equation 15.1.20b. For isothermal flow of an ideal gas ($Pv = P_1v_1$)

$$\int_1^2 v\,\mathrm{d}P = P_1v_1\int_1^2 \frac{1}{P}\,\mathrm{d}P \qquad [15.1.69a]$$

$$= P_1v_1 \ln\frac{P_2}{P_1} \qquad [15.1.69b]$$

Then, assuming flow on a horizontal axis ($\Delta z = 0$) and using a coefficient of discharge C_{D} to take account of the friction term F in Equation 15.1.19, it can be shown from Equations 15.1.4a, 15.1.19 and 15.1.76b that for the flow of an ideal gas through an orifice with a cross-sectional area A which is small relative to that of the vessel

$$u = C_{\mathrm{D}}\left[2P_1v_1\ \ln\left(\frac{P_1}{P_2}\right)\right]^{1/2} \qquad [15.1.70]$$

$$G = C_{\mathrm{D}}\left[\frac{2P_2^2}{P_1v_1}\ \ln\left(\frac{P_1}{P_2}\right)\right]^{1/2} \qquad [15.1.71]$$

For adiabatic flow of an ideal gas ($Pv^k = P_1{v_1}^k$),

$$\int_1^2 v\,\mathrm{d}P = \int_1^2\left(\frac{P_1v_1^k}{P}\right)^{1/k}\mathrm{d}P \qquad [15.1.72a]$$

$$= \frac{k}{k-1}P_1v_1\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \qquad [15.1.72b]$$

$$= \frac{k}{k-1}(P_2v_2 - P_1v_1) \qquad [15.1.72c]$$

Following the same approach, it can be shown from Equations 15.1.4, 15.1.19 and 15.1.72b that for the adiabatic flow case

$$G = \frac{C_{\mathrm{d}}}{v_2}\left\{\frac{2P_1}{v_1}\cdot\frac{k}{k-1}\left[1 - \left(\frac{P_2}{P_1}\right)^{(k-1)/k}\right]\right\}^{1/2} \qquad [15.1.73]$$

Introducing the pressure ratio η from Equation 15.1.61 in Equation 15.1.73 gives

$$G = C_{\mathrm{d}}\left\{\frac{2P_1}{v_1}\cdot\frac{k}{k-1}\left[\eta^{2/k} - \eta^{(k+1)/k}\right]\right\}^{1/2} \qquad [15.1.74]$$

If the ratio of the upstream pressure P_1 to that downstream P_2 is sufficiently high, the flow is choked, or sonic. Under these conditions Equation 15.1.62 applies. Then, taking friction into account the maximum discharge G_{c} under these conditions is

$$G_{\mathrm{c}} = C_{\mathrm{d}}\left[\frac{P_1}{v_1}k\left(\frac{2}{k+1}\right)^{(k+1)/(k-1)}\right]^{1/2} \qquad [15.1.75]$$

Equation 15.1.75 shows that, under sonic conditions, the flow depends on the upstream pressure P_1, but is independent of the downstream pressure P_2.

Equations 15.1.73 and 15.1.75, for subsonic and sonic flow of gas, respectively, are those normally required here for the calculation of high pressure gas discharges both from vents and pressure relief valves and from ruptures.

Equation 15.1.20d and the expressions based on it should be used only within the range of their validity. The equation is based on a modification of the equations for isentropic expansion of an ideal gas, in which the index k is equal to the ratio of specific heats γ. The index k is used instead of γ to take account of a degree of non-ideal behaviour. The value of

k is obtained from thermodynamic charts by fitting Equation 15.1.20d to the appropriate constant entropy line. In addition, the index k is also used to take into account a degree of friction energy loss in expansion. In this case the value of k is determined empirically for the system concerned. The use of Equation 15.1.20d is not suitable for gases at very high pressures. These require separate treatment, as discussed in standard texts (e.g. Shapiro, 1953–; Massey, 1968–).

The use of Equation 15.1.20d is less appropriate for vapour which becomes wet when expanded. This case may be treated by the direct use of Equation 15.1.5. The work done on the surroundings is zero, and neglecting potential energy changes ($dz = 0$) along with heat transfer to the fluid, for finite changes, Equation 15.1.5 becomes

$$\Delta H + \Delta\left(\frac{u^2}{2}\right) = 0 \qquad [15.1.76]$$

Hence for negligible upstream velocity,

$$G = \rho_2[2(H_1 - H_2)]^{1/2} \qquad [15.1.77]$$

In order to solve Equation 15.1.77 it is necessary to determine the mass fraction constituted by the vapour phase, or quality, x. This can be obtained from the assumption of isentropic expansion which from the entropy balance gives

$$S_1 = S_2 \qquad [15.1.78a]$$

$$S_1 = S_{v2}x + S_{l2}(1 - x) \qquad [15.1.78b]$$

where subscripts l and v refer to the liquid and the vapour, respectively. The enthalpy after expansion H_2 is then given by:

$$H_2 = H_{v2}x + H_{l2}(1 - x) \qquad [15.1.79]$$

The effect of friction may be taken into account by applying to the enthalpy change $(H_1 - H_2)$ an efficiency factor. Efficiencies of orifices and nozzles are discussed in standard texts (e.g. Lewitt, 1953).

If the vapour flow is sonic, as determined by Equations 15.1.61 and 15.1.62, then, as for a gas, the flow is independent of the downstream pressure. In this case, the pressure P_2 for the calculation of the terminal conditions of the fluid is that obtained from Equation 15.1.61 with $\eta = \eta_c$. An illustrative example is given by Lewitt (1953, p. 275).

A vapour undergoing sudden expansion tends, however, to be supersaturated with less than the equilibrium quantity of condensed liquid droplets. It is frequently assumed that such a vapour does in fact follow a path given by Equation 15.1.20d.

A calculation which is sometimes required is the flow of vapour from a liquid vaporizing adiabatically in a vessel. The pressure in the vessel decreases as the temperature of the liquid falls due to the removal of the latent heat of vaporization.

Further discussions of methods of calculating the expansion of gases and vapours are given in the *High Pressure Safety Code* (E.G. Cox and Saville, 1975) and by Lapple (1943).

15.1.8 Temperature effects

For an adiabatic expansion the absolute temperature after expansion T_2 is

$$\frac{T_2}{T_1} = \left(\frac{P_2}{P_1}\right)^{(k-1)/k} \qquad [15.1.80]$$

For sonic flow the pressure ratio P_2/P_1 is given by Equation 15.1.62. Hence for this case

$$\frac{T_2}{T_1} = \frac{2}{k+1} \qquad [15.1.81]$$

15.1.9 Vessel discharge: gas flow through pipe

It is sometimes necessary to calculate the flow of high pressure gas from a vessel. The pressure in the vessel decreases as the mass of gas decreases. Equation 15.1.82, for sonic flow, can be used until the upstream pressure falls to the value at which flow becomes subsonic, at which point Equation 15.1.80 is used. An illustrative example is given by Coulson and Richardson (1977–, vol. 1, p. 110).

Another problem that may occur is the flow of gas from a vessel through a pipe, as shown in Figure 15.5. In this case, the calculation involves simultaneous solution of the equations for flow through the aperture at the entrance to the pipe and through the pipe itself.

Charts to facilitate the calculation have been constructed by Lapple (1943) and are widely used. It has been pointed out by Levenspiel (1977), however, that this work is in error due to the assumption that sonic flow can be isothermal. Corrected charts given by Levenspiel are reproduced in Figure 15.6. The parameters used in the charts are the pressures shown in Figure 15.5 and

d = diameter of pipe (m)
f_F = Fanning friction factor
G = mass velocity of gas (kg/m^2 s)
G^* = critical mass velocity of gas through an adiabatic nozzle (kg/m^{2}s)
k = expansion index (= ratio of gas specific heats)
L = length of pipe (m)
N = pipe resistance factor ($= (4f_F L)/d$)
P = absolute pressure (N/m^2)

Figure 15.6(a) is useful for finding the length of pipe for a given flow rate and Figure 15.6(b) for finding the flow rate for a given length of pipe. Note that the pipe resistance factor does not include entrance loss effects. Also, this method relies on the pipe having a uniform diameter. Changes in pipe diameter may result in multiple shocks in the discharge pipe.

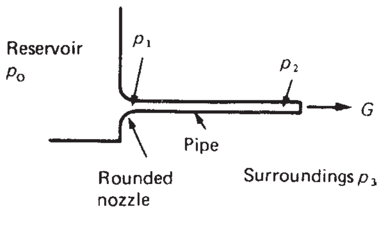

***Figure 15.5** Vessel with connected discharge pipe (Levenspiel, 1977) (Courtesy of the American Institute of Chemical Engineers)*

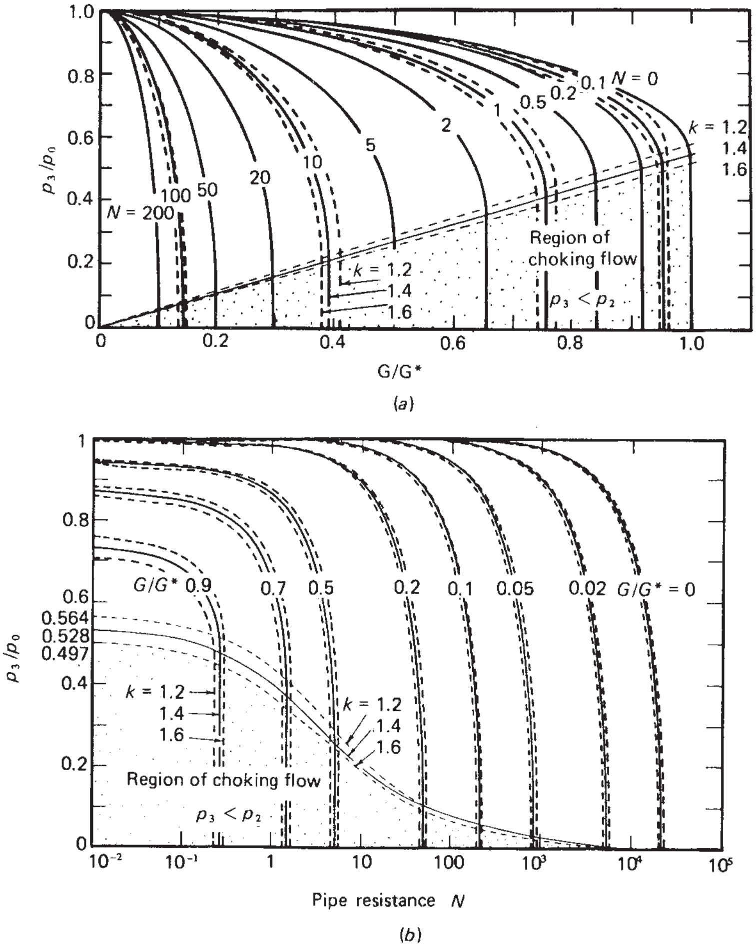

Figure 15.6 Charts for calculation of adiabatic flow of gas from a vessel to atmosphere (Levenspiel, 1977): (a) chart useful for finding the allowable length of pipe for a given flow rate; (b) chart useful for finding the flow rate for a given length of pipe (Courtesy of the American Institute of Chemical Engineers)

Expressions exist for the calculation of the fraction of fluid left in a vessel after a given discharge time. Such relations are given in the Rijnmond Report and by Mecklenburgh (1985).

15.1.10 Vessel discharge: liquid discharge time

It is convenient to have expressions for the time taken for a vessel containing liquid to discharge its contents. Treatments of liquid discharge times for vessels have been given in the Rijnmond Report and by Lewitt (1952), T.C. Foster (1981), Mecklenburgh (1985), Loiacono (1987), Sommerfeld and co-workers (Schwartzhoff and Sommerfeld, 1988; Sommerfeld, 1990; Papas and Sommerfeld, 1991; Hart and Sommerfeld, 1993; Sommerfeld and Stallybrass, 1993; K.S. Lee and Sommerfeld, 1994), Crowl and Louvar (2002), J.L. Woodward and Mudan (1991) and Crowl (1992b).

In the most elementary case, the vessel is of simple geometry and the outflow is through a hole at the bottom and is due solely to the head of liquid. Complexity is introduced by the following features: (1) pressure above the liquid in the vessel, (2) hole at an arbitrary height in the liquid space and (3) outflow through a pipe rather than an orifice.

The basic relations for liquid outflow, taking account of the pressure on the liquid surface and for a hole of arbitrary height, are

$$-A\frac{\mathrm{d}h}{\mathrm{d}t} = Q \qquad [15.1.82]$$

$$Q = C_D A_o\{2[g(h - h_0) + \Delta P/\rho]$$

where A is the cross-sectional area of the vessel at height h (m^2), A_o is the cross-sectional area of the orifice (m^2), C_D is the coefficient of discharge, g is the acceleration due to gravity (m/s^2), h is the height of the liquid above the bottom of the vessel (m), h_o is the height of the orifice above the bottom of the vessel (m), Q is the outflow through the orifice (m^3/s), ΔP is the pressure difference between the liquid surface and atmosphere, or gauge pressure (Pa), t is the time (s) and ρ is the density of the liquid (kg/m^3).

Rearranging and integrating Equations 15.1.82 and 15.1.83 gives the general relation for the time for discharge, or efflux time t_e (s), as:

$$t_e = \frac{1}{C_D A_o (2)^{1/2}} \int_{h_o}^{h_i} \frac{A(h)}{[g(h-h_o)+\Delta P/\rho]^{1/2}} \mathrm{d}h \qquad [15.1.84]$$

for liquid with initial height above the bottom of the vessel h_i (m). The solution of this equation requires the specification of the terms $A(h)$ and $\Delta P/\rho$. The function $A = f(h)$ depends on the geometry of the vessel; specific cases are given below.

As for the term $\Delta P/\rho$, this is zero for the case where there is no imposed pressure on the liquid surface. The other simple case is where the pressure is maintained constant, as with an inert gas padding system, so that the term may be expressed as $\Delta P/\rho = gh_p$, where h_p is an equivalent liquid head (m).

Some expressions for the vessel cross-sectional area $A(h)$ are:

$$A = \frac{\pi}{4}D^2 \quad \text{vertical cylindrical vessel} \qquad [15.1.85]$$

$$A = 2L(hD-h^2)^{1/2} \quad \text{horizontal cylindrical vessel (flat ends)} \qquad [15.1.86]$$

$$A = \frac{\pi}{4}C^2 \quad \text{spherical vessel} \qquad [15.1.87]$$

with

$$C = 2(hD-h^2)^{1/2} \qquad [15.1.88]$$

$$A = \pi h^2 \tan^2\theta \quad \text{vertical conical vessel, tip down} \qquad [15.1.89]$$

where L is the length of the vessel (m) and θ is the half-angle of the vessel tip(°).

It may sometimes be helpful to derive the cross-sectional area from the volume using the relation

$$A = \frac{\mathrm{d}V}{\mathrm{d}h} \qquad [15.1.90]$$

where V is the volume of the vessel (m^3). A number of specific cases are now considered.

Vertical cylindrical vessel, finite imposed pressure

Crowl and Louvar (2002) have treated the case of a vertical cylindrical vessel with a finite imposed pressure on the liquid surface. For this case, Equation 15.1.84 yields

$$t_e = \frac{1}{C_D g}\left(\frac{A}{A_o}\right)\left(\frac{2\Delta P}{\rho}\right)^{1/2}\left[\left(1+\frac{\rho g(h_i-h_o)}{\Delta P}\right)^{1/2} - 1\right] \qquad [15.1.91]$$

where A is given by Equation 15.1.85. For the case where there is no imposed pressure $\Delta P = 0$:

$$t_e = \frac{1}{C_D g}\left(\frac{A}{A_o}\right)[2g(h_i-h_o)]^{1/2} \qquad [15.1.92]$$

And for the case where the hole is at the bottom of the vessel ($h_o = 0$)

$$t_e = \frac{1}{C_D}\left(\frac{A}{A_0}\right)\left(\frac{2h_i}{g}\right)^{1/2} \qquad [15.1.93]$$

Horizontal cylindrical vessel, no imposed pressure

The alternative case of a horizontal cylindrical vessel has been treated by Sommerfeld and Stallybrass (1993), who consider the case of a vessel with flat ends and no imposed pressure. Then from Equations 15.1.84 and 15.1.86

$$t_e = \frac{2L}{C_D A_o (2g)^{1/2}} \int_{h_o}^{h_i} \frac{[(D-h)h]^{1/2}}{(h-h_o)^{1/2}} \mathrm{d}h \qquad [15.1.94]$$

The authors obtain an analytical solution, albeit a somewhat complex one.

Spherical vessel, no imposed pressure

The case of a spherical vessel with no imposed pressure has been described by Hart and Sommerfeld (1993). For this case, from Equations 15.1.94 and 15.1.87

$$t_e = \frac{2\pi}{15 C_D A_o (2g)^{1/2}}(5Dh_i + 10Dh_o - 3h_i^2 - 4h_i h_o - 8h_o^2)(h_i-h_o)^{1/2} \qquad [15.1.95]$$

For the case where the hole is at the bottom of the vessel ($h_o = 0$):

$$t_e = \frac{2\pi}{3 C_D A_o (2g)^{1/2}}\left[\left(D - \frac{3h}{5}\right)h_i^{3/2}\right] \qquad [15.1.96]$$

Vessels with other geometries

K.S. Lee and Sommerfeld (1993) have obtained analytical solutions for vessels with a number of other geometries with no imposed pressure. These are conical, paraboloid and ellipsoid vessels, both with the tapering end at the bottom and with it at the top.

Vessel drainage times and flows

Expressions have just been given for vessel drainage time. The average drainage flow is then obtained as the initial volume of liquid in the vessel divided by the drainage time. Expression of the drainage relations in dimensionless form allows some more general conclusions to be drawn. K.S. Lee and Sommerfeld (1993) define a dimensionless drainage time τ as the ratio of the time to drain the vessel with the liquid at the actual height h and the hole at the actual height h_o to the time to drain a full vessel with the hole at the bottom ($h_a = 0$). They also define a dimensionless hole height x as the ratio of the hole height h_o to the vessel diameter D or height H.

They show that for certain vessel geometries the variation of the dimensionless drainage time τ with the dimensionless hole height x is such that it passes through a maximum. The geometries where this occurs are those where the cross-sectional area of the vessel $A(h)$ decreases as the height h_a decreases. They give a tabulation of values of the maximum dimensionless drainage time $\tau_{\max}$, which includes the following:

Vessel geometry	*Dimensionless drainage time maximum, $\tau_{\max}$*	*Corresponding dimensionless height of hole, x*
Vertical cylindrical	None	–
Horizontal cylinidrical	1.161	0.17
Spherical	1.299	0.25
Cone, tip down	1.776	0.683
Paraboloid, tip down	1.414	0.50
Vertical ellipsod	1.299	0.25
Horizontal ellipsoid	1.299	0.25

The sphere may be considered a special case of the ellipsoid.

The authors state that in no case does the maximum dimensionless drainage time attain a value of 2.

Vessels with pipe attached

Treatments for the case where the outflow is through a pipe attached to the vessel are given by Loiacono (1987), Sommerfeld (1990), Papas and Sommerfeld (1991) and Sommerfeld and Stallybrass (1992).

15.1.11 Model systems

There are available a number of model systems for determining the emission of fluid from vessels. These include those of the two *Canvey Reports* and the *Rijnmond Report* and of the Committee for the Prevention of Disasters (CPD), (1992a), Solberg and Skramstad (1982), Considine and Grint (1985), Mecklenburgh (1985) and Napier and Roopchand (1986). There are also the model systems associated with computer codes for hazard assessment such as WHAZAN and SAFETI.

15.2 Two-phase Flow

In some cases the fluid is neither a pure gas (or vapour) nor a pure liquid, but is a vapour–liquid mixture, and it is then necessary to use a correlation for two-phase flow.

The behaviour of fluids in two-phase flow is complex and by no means understood. Of the large literature on the topic mention may be made of the accounts in *One Dimensional Two-Phase Flow* (Wallis, 1969), *Two-Phase Flow and Heat Transfer* (Butterworth and Hewitt, 1977), in *Two-Phase Flow in Pipelines and Heat Exchangers* (Chisholm, 1983) and *Emergency Relief Systems for Runaway Reactions and Storage Vessels: A Summary of Multiphase Flow Methods* (AIChE, 1992/149) and of the work of Benjaminsen and Miller (1941), Burnell (1947), Lockhart and Martinelli (1949), Pasqua (1953), Schweppe and Foust (1953), O. Baker (1954, 1958), Isbin, Moy and da Cruz (1957), Zaloudek (1961), Fauske (1962, 1963, 1964), Isbin *et al.* (1962), Fauske and Min (1963), Dukler, Wicks and Cleveland (1964), Levy (1965), F.J. Moody (1965), Baroczy (1966), Chisholm and Watson (1966), Chisholm and Sutherland (1969–70), R.E. Henry and Fauske (1971), M.R.O, Jones and Underwood (1983, 1984), van den Akker, Snoey and Spoelstra (1983), Nyren and Winter (1983), B. Fletcher (1984a,b), B. Fletcher and Johnson (1984), Leung (1986a, 1990a,b, 1992a) and S.D. Morris (1988a,b, 1990a,b).

Work on two-phase flow, particularly in pipelines, has been carried out by the American Institute of Chemical Engineers (AIChE) Design Institute for Multiphase Processing (DIMP). An important distinction in two-phase flow is that between one-component systems, such as steam and water, and two-component systems, such as air and water. It is the former which is of prime concern here and, unless otherwise stated, it is to these systems that the account given here refers. Two situations which are of particular interest in the present context are the escape of a superheated, flashing liquid and the venting of a chemical reactor. Selected references on two-phase flow are given in Table 15.2.

15.2.1 Experimental studies

Much work on two-phase flow has been done on two-component systems, for example, air and water, but for the two cases mentioned the more relevant work is that on one-component systems, for example, steam and water. The bulk of the experimental work has been done on small pipes, often 25 mm diameter or less, but more recent work has been done on pipes of larger diameter. Details of some of the experimental work are given in Table 15.3.

15.2.2 Two-phase flow phenomena

Some characteristic features of, and problems in, two-phase flow are:

(1) flow pattern;
(2) phase equilibrium;
(3) phase velocity;
(4) critical flow;
(5) friction factor.

There are a variety of flow patterns in two-phase flow, the pattern depending on the mass flow and on the mass fraction of vapour, or quality, and also on whether the pipe is horizontal or vertical. The flow patterns are considered in the next section.

For very short flow outlets, there may be insufficient time for relaxation to occur and equilibrium between the liquid and vapour phase to be established. In this case it is necessary to make some assumption about the degree of equilibrium attained. One limiting assumption is that of frozen flow in which there is no interchange between the phases. The alternative limiting assumption is that equilibrium is attained.

Another principal feature is the relative velocity between the two phases. One limiting assumption is that of zero slip in which the relative velocity of the two phases is the same.

Critical flow occurs in two-phase flow but it is a much more complex phenomenon than in gas flow, and it tends not to be well defined. The essential feature, however, is that, as in gas flow, the flow is independent of the downstream pressure.

For flow in long pipes, it becomes necessary to take friction into account. Pressure drop due to friction is characterized in two-phase as in single-phase flow by a friction factor, but again this is somewhat more complex than in single-phase flow.

The types of two-phase flow calculation which are of interest here are primarily releases from plant and venting of reactors and vessels. An assumption which is conservative for one of these cases is not necessarily conservative for the other.

15.2.3 Two-phase flow patterns

There are a number of different flow patterns in two-phase flow. Among the numerous descriptions are those by O. Baker (1954, 1958), D.S. Scott (1963), Schicht (1969), Choe and Weisman (1974), Butterworth and Hewitt (1977), Chisholm (1983), and Cindric, Gandhi and Williams (1987).

The flow patterns for horizontal two-phase flow in pipelines were identified and correlated by O. Baker (1954, 1958). Figure 15.7, after Coulson and Richardson (1977–), shows a set of flow patterns denoted in accordance with Baker's terminology.

Figure 15.8 shows the correlation of flow patterns given by Baker in terms of the gas and liquid mass velocities G and L and the parameters λ and ψ, where the latter are defined as

$$\lambda = \left[\frac{\rho_g \rho_l}{\rho_a \rho_w}\right]^{0.5} \qquad [15.2.1]$$

$$\psi = \frac{\sigma_w}{\sigma_l}\left[\frac{\mu_l}{\mu_w}\left[\frac{\rho_w}{\rho_l}\right]^2\right]^{0.33} \qquad [15.2.2]$$

where μ is the viscosity, ρ is the density, σ is the surface tension, and the subscripts a, g, l, and w denote air, gas, liquid and water, respectively.

[a] See also work of Fauske and coworkers (Section 15.3) and work on relaxation length (Table 15.4), on pressure relief valves (Section 15.6), on vessel blowdown (Section 15.7) and in the DIERS project (Chapter 17).

[b] Single-component systems are those with a single saturated or superheated liquid, typically water. Two-component systems are those with a gas and a liquid, typically air and water.

The Baker curves have been widely used to correlate the flow patterns in two-phase flow. A set of equations for the Baker curves has been given by Yamashiro, Espiell and Farina (1986).

The flow patterns for horizontal two-phase flow given by Butterworth and Hewitt are similar except that they omit dispersed flow. Figure 15.9 shows the flow patterns for vertical two-phase flow and Figure 15.10 a flow pattern map given by Butterworth and Hewitt.

There is a considerable variation in the terminology used for the flow patterns in two-phase flow. A summary of the terminology and a classification has been given by Chisholm (1983).

A simplified classification scheme for horizontal two-phase flow has been proposed by Choe and Weisman (1974), following earlier work by Hubbard and Dukler (1968). They identify four flow patterns, which correlate as follows with mass velocity G and with mass fraction of vapour, or quality, x.

Flow pattern	*Mass velocity, G* (kg/m^2 s)	*Quality, x*
Homogeneous	$G > 2700$	0–1.0
Intermittent	$94 < G < 2700$	0–0.8
Annular	$94 < G < 2700$	>0.8 (±0.1)
Separated	$G < 94$	0–1.0

In terms of the relations given by Chisholm between the usual terms and those of Choe and Weisman, homogeneous flow corresponds to bubble flow, intermittent flow to plug and slug flow and separated flow to stratified flow; annular flow is the same in both cases.

Olujic (1985) has given a classification of flow patterns in horizontal two-phase flow based on a distinction between high and low quality. He defines parameters α and β:

$$\alpha = \left(1 + \beta \frac{u_g}{u_l}\right)^{-1} \qquad [15.2.3]$$

$$\beta = \frac{1-x}{x}\frac{\rho_g}{\rho_l} \qquad [15.2.4]$$

where u is the velocity. In the β regime, the velocity of the two phases is approximately equal, while in the α regime that of the gas is much higher. The β regime corresponds to bubble and slug flows, and the α regime to wavy, slug and annular flows. The author gives a map of the two regimes, plotting $1/\beta$ vs the Froude number Fr.

Cindric, Gandhi and Williams (1987) discuss the work of DIMP and present flow pattern maps, one for horizontal and one for vertical two-phase flow. The former is a plot of certain flow parameters vs the Martinelli parameter (described below), and the latter a plot of superficial liquid velocity vs superficial gas velocity.

15.2.4 Modelling of two-phase flow

Two-phase flow is a complex phenomenon and has given rise to a large number of models. Of particular interest here are models for critical two-phase flow. A review of such models has been given by Wallis (1980). Wallis distinguishes essentially three types of model for critical two-phase flow:

(1) homogeneous equilibrium model;
(2) models incorporating limiting assumptions
  (a) frozen flow models,
  (b) slip flow models,
  (c) isentropic stream tube models;
(3) equilibrium models,
  (a) empirical models,
  (b) physically based models for thermal equilibrium,
  (c) two fluid models.

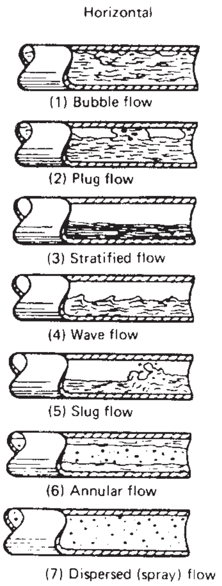

Figure 15.7 *Flow patterns in two-phase flow: horizontal flow (Coulson and Richardson, 1977–) (Courtesy of Pergamon Press)*

The homogeneous equilibrium model (HEM) is based on the two limiting assumptions: that the flow is homogeneous, that is, there is no slip between the two phases; and that the flow is in equilibrium, that is, there is effectively perfect transfer between the two phases.

This is a well-established and widely used model; it is used in a number of computer codes. Wallis states that the model gives reasonably good predictions for the mass velocity under conditions where the pipe is long enough for equilibrium to be established and the flow pattern is such as to suppress relative motion. For short pipes where there is insufficient relaxation time the flow can be in error by a factor of about 5. For longer pipes with a flow pattern which allows large relative velocity, such as annular flow, the error factor tends to be somewhat less than 2.

The homogeneous equilibrium model is based on limiting assumptions. The second group of models are based on alternative limiting assumptions. The limiting assumption made in the frozen flow model is that there is no transfer between phases so that flow is effectively frozen and quality remains constant. This assumption is most nearly met if the outlet is short. While no interphase transfer is the key assumption in this model it may be combined with other assumptions such as those of no slip or isentropic expansion.

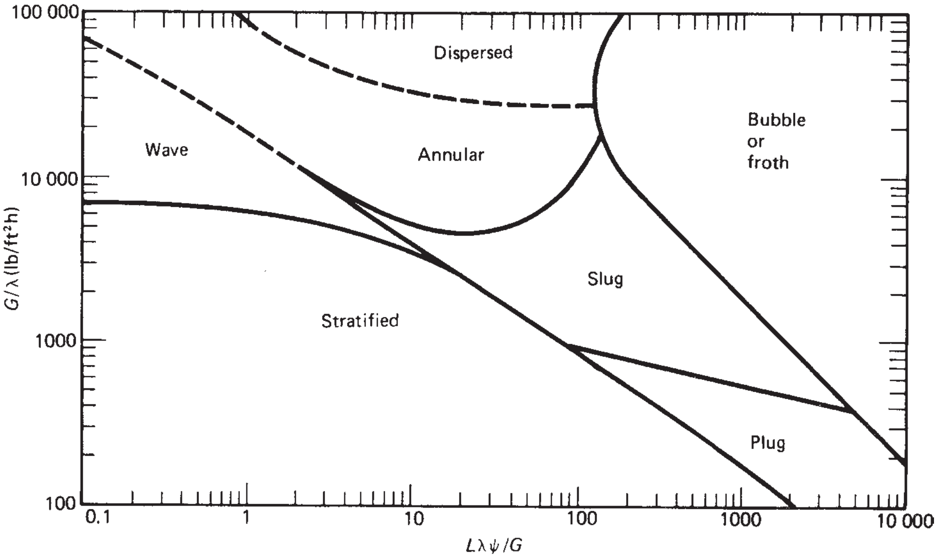

Figure 15.8 *Regimes in two-phase flow; the Baker diagram (O. Baker, 1954) (Courtesy of the Oil and Gas Journal)*

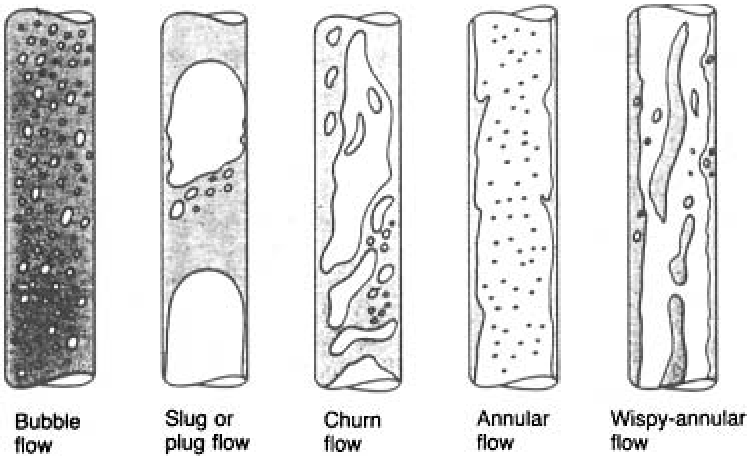

Figure 15.9 *Flow patterns in two-phase flow: vertical flow (Butterworth and Hewitt, 1977) (Courtesy of Oxford University Press)*

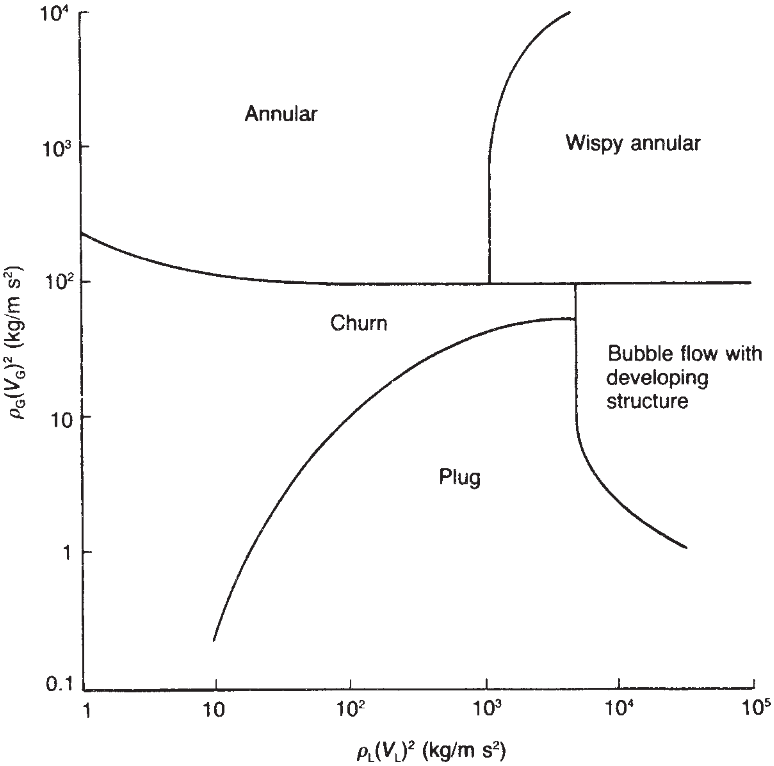

Figure 15.10 *Regimes in two-phase flow: flow patterns map for vertical flow (Butterworth and Hewitt, 1977) V_G velocity of gas (m/s); V_L, velocity of liquid (m/s); ρ_G density of gas (kg/m^3); ρ_L density of liquid (kg/m^3). (Courtesy of Oxford University Press)*

The limiting assumption made in the slip equilibrium model is that there is equilibrium between the phases, which is the opposite of the previous case. Two principal slip equilibrium models are those by Fauske (1962, 1963) and F.J. Moody (1965). These two models differ in terms of the way in which the exit condition is determined. In the Moody model, the exit conditions are determined by an energy balance and the maximum flow occurs at a slip ratio

$k = (\rho_l/\rho_g)^{1/3}$, while in the Fauske model the exit conditions are determined by a momentum balance and the maximum flow occurs at $k = (\rho_l/\rho_g)^{1/2}$.

The slip equilibrium models just described treat the velocity ratio k as a parameter to be adjusted to obtain the maximum flow, without indicating how this condition is actually achieved. Wallis and Richter (1978) have described an isentropic stream tube model, based on isentropic expansion of individual stream tubes originating from the vapour–liquid interface, which attempts to address this point.

The third group of models incorporate non-equilibrium effects. One approach used to handle such effects is the use of empirical correction factors. This is the basis of the model by RE. Henry and Fauske (1971).

Other non-equilibrium models are based on physical descriptions of the processes of bubble nucleation and vapour generation. Wallis concludes that the development of such models is not such as to offer much improvement on the purely empirical models.

Another type of non-equilibrium model is the two fluid, or separated flow, model, in which effects such as interphase drag are taken into account, but again Wallis concludes that the stage of development is not such as to make these models more useful than the empirical ones.

15.2.5 Elementary relations

For a two-phase system the following equations apply for continuity and other relations:

$$W_g = Wx \qquad [15.2.5]$$

$$W_l = W(1-x) \qquad [15.2.6]$$

$$G_g = u_g\rho_g \qquad [15.2.7]$$

$$G_g = \frac{Gx}{\alpha} \qquad [15.2.8]$$

$$G_l = \frac{G(1-x)}{1-\alpha} \qquad [15.2.9]$$

$$Q_g = \frac{W_x}{\rho_g} \qquad [15.2.10]$$

$$Q_l = \frac{W(1-x)}{\rho_l} \qquad [15.2.11]$$

$$u_g = \frac{Gx}{\alpha\rho_g} \qquad [15.2.12]$$

$$u_l = \frac{G(1-x)}{(1-\alpha)\rho_l} \qquad [15.2.13]$$

$$k = \frac{u_g}{u_l} \qquad [15.2.14]$$

$$k = \frac{x}{1-x}\,\frac{1-\alpha}{\alpha}\,\frac{\rho_l}{\rho_g} \qquad [15.2.15]$$

$$\alpha = \left(1 + \frac{1-x}{x}k\,\frac{\rho_g}{\rho_l}\right)^{-1} \qquad [15.2.16a]$$

$$\alpha = \left(1 + \frac{1-x}{x}k\,\frac{v_l}{v_g}\right)^{-1} \qquad [15.2.16b]$$

$$\beta = \frac{Q_g}{Q_l + Q_g} \qquad [15.2.17]$$

$$\beta = \left(1 + \frac{1-x}{x}\,\frac{\rho_g}{\rho_l}\right)^{-1} \qquad [15.2.18]$$

where Q is the volumetric flow, v is the specific volume, W is the mass flow, ρ is the fraction of volume occupied by vapour, or void fraction, and β is the vapour phase volumetric flow fraction.

The pressure drop derived from the energy balance for two-phase flow, analogous to Equation 15.1.10b for single phase flow, is

$$\frac{dP}{dl} + \rho_h\frac{dF}{dl} + G\frac{du}{dl} + \rho_h g\frac{dz}{dl} = 0 \qquad [15.2.19]$$

with

$$\rho_h = \left[\frac{x}{\rho_g} + \frac{1-x}{\rho_l}\right]^{-1} \qquad [15.2.20]$$

where F is the friction loss, g is the acceleration due to gravity, l is the distance along the pipe, P is the absolute pressure, z is the vertical distance, and subscript h denotes homogeneous flow.

The pressure drop derived from the momentum balance for two-phase flow, analogous to Equation 15.1.11 for single phase flow, may be written as

$$\begin{aligned}&\frac{dP}{dl} + \frac{S}{A}R_0 + \frac{d[G_g\alpha u_g + G_l(1-\alpha)u_l]}{dl}\\ &\quad + g[\alpha\rho_g + (1-\alpha)\rho_l]\frac{dz}{dl} = 0\end{aligned} \qquad [15.2.21]$$

where A is the cross-sectional area of the pipe, R_0 is the shear stress at the pipe wall and S is the perimeter of the pipe.

Comparing Equations 15.2.19 and 15.2.21, which each give the pressure drop, it follows that, in a manner analogous to the derivation of Equation 15.1.12,

$$\frac{S}{A}R_0 = \rho_h\frac{dF}{dl} \qquad [15.2.22]$$

As with Equation 15.1.19 for single-phase flow, the pressure drop given in Equation 15.2.19 may also be expressed in terms of its constituent elements, as given in Equation 15.1.13.

15.2.6 Homogeneous flow

If the gas and liquid velocities are equal and the slip ratio k therefore unity, the flow is said to be homogeneous. The specific volume for homogeneous flow v_h is defined as

$$v_h = \frac{Q_g + Q_l}{W} \qquad [15.2.23]$$

and hence

$$v_h = \frac{x}{\rho_g} + \frac{1-x}{\rho_l} \qquad [15.2.24]$$

or

$$v = v_g x + v_l(1-x) \qquad [15.2.25]$$

where v is the specific volume.

The density for homogeneous flow ρ_h is defined as the reciprocal of the specific volume

$$\rho_h = 1/v_h \qquad [15.2.26a]$$

$$= \left[\frac{x}{\rho_g} + \frac{1-x}{\rho_l}\right]^{-1} \qquad [15.2.26b]$$

It may be noted that Equation 15.2.26b is the same as Equation 15.2.20. This is the reason for the use of the symbol ρ_h to define the density in Equation 15.2.20. In that case, however, there was no implication that Equation 15.2.20 is restricted to homogeneous flow. Also for homogeneous flow:

$$\alpha = \left(1 + \frac{1-x}{x}\frac{\rho_g}{\rho_l}\right)^{-1} \qquad [15.2.27a]$$

$$\alpha = \left(1 + \frac{1-x}{x}\frac{v_l}{v_g}\right)^{-1} \qquad [15.2.27b]$$

$$\beta = \left(1 + \frac{1-x}{x}\frac{\rho_g}{\rho_l}\right)^{-1} \qquad [15.2.28]$$

$$\beta = \alpha \qquad [15.2.29]$$

For homogeneous flow, since $\rho_h = 1/v_h$, Equation 15.2.19 may be written as

$$\frac{dP}{dl} + \frac{1}{v_h}\frac{dF}{dl} + G\frac{du}{dl} + \frac{g}{v_h}\frac{dz}{dl} = 0 \qquad [15.2.30]$$

15.2.7 Non-homogeneous flow

If the gas and liquid velocities are different, the flow is non-homogeneous. For non-homogeneous flow the specific volume of the two-phase mixture v_m is not equal to the reciprocal of the density of the two-phase mixture ρ_m:

$$v_m \neq 1/\rho_m \qquad [15.2.31]$$

The specific volume for non-homogeneous flow is often defined as

$$v_m = [\rho_g\alpha + \rho_l(1-\alpha)]^{-1} \qquad [15.2.32]$$

The use of this relationship for specific volume has been criticized by Fauske (1962). His alternative treatment is described in the following section.

15.2.8 Critical flow

As an introduction to critical two-phase flow, the condition is derived for critical flow in homogeneous flow. The acceleration pressure drop term in Equation 15.1.13 may be written as

$$-\frac{dP_a}{dl} = G^2\frac{dv_h}{dl} \qquad [15.2.33]$$

But

$$v_h = f(P, x) \qquad [15.2.34]$$

Hence

$$\frac{dv_h}{dl} = \frac{dv_h}{dP}\frac{dP}{dl} + \frac{dv_h}{dx}\frac{dx}{dl} \qquad [15.2.35]$$

But, from Equation 15.2.25.

$$\frac{dv_h}{dx} = v_g - v_l \qquad [15.2.36]$$

Then, from Equations 15.2.30, 15.2.33 and 15.2.36

$$-\frac{dP}{dl} = -\frac{dP_f}{dl} + G^2\left[\frac{dv_h}{dP}\frac{dP}{dl} + (v_g - v_l)\frac{dx}{dl}\right] + \frac{g}{v_h}\frac{dz}{dl} \qquad [15.2.37a]$$

$$= -\frac{dP_f/dl + G^2(v_g - v_l)(dx/dl) + (g/v_h)(dz/dl)}{1 + G^2\left(\frac{dv_h}{dP}\right)}$$

where dP_f/dl is the pressure drop due to friction.

The critical condition occurs where the pressure gradient becomes infinite

$$1 + G^2\frac{dv_h}{dP} \qquad [15.2.38a]$$

$$-\frac{dv_h}{dP} = \frac{1}{G^2} \qquad [15.2.38b]$$

15.2.9 Empirical friction correlations

The solution of the equations for pressure drop in two-phase flow requires a relation for the friction loss term. Much effort has been devoted to obtaining a correlation for this. Typically, the two-phase pressure drop has been correlated in terms of some single phase pressure drop. One pair of relations used for correlation is

$$\frac{dP_f}{dl} = \phi_g^2\left(\frac{dP_f}{dl}\right)_g \qquad [15.2.39a]$$

$$\frac{dP_f}{dl} = \phi_l^2\left(\frac{dP_f}{dl}\right)_l \qquad [15.2.39b]$$

where dP_f/dl is the actual two-phase pressure drop, $(dP_f/dl)_g$ is the pressure drop which would occur if the gas phase were flowing alone in the pipe, $(dP_f/dl)_l$ is the pressure drop which would occur if the liquid phase were flowing alone and ϕ_g^2 and ϕ_l^2 are friction parameters.

Another pair of relations are

$$\frac{dP_f}{dl} = \phi_{go}^2\left(\frac{dP_f}{dl}\right)_{go} \qquad [15.2.40a]$$

$$\frac{dP_f}{dl} = \phi_{lo}^2\left(\frac{dP_l}{dl}\right)_{lo} \qquad [15.2.40b]$$

where $(dP_f/dl)_{go}$ is the pressure drop which would occur if the whole fluid were flowing as gas in the pipe, $(dP_f/dl)_{lo}$ is the pressure drop which would occur if the whole fluid were flowing as liquid ϕ_{go}^2 and ϕ_{lo}^2 are further friction parameters.

Lockhart and Martinelli (1949) introduced the parameter

$$X^2 = \frac{(dP_f/dl)_l}{(dP_f/dl)_g} \qquad [15.2.41]$$

Chisholm and Sutherland (1969–70) utilized the parameter

$$\Gamma^2 = \frac{(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)_\mathrm{go}}{(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)_\mathrm{lo}} \qquad [15.2.42]$$

This parameter was also used by Baroczy (1966) in the form

$$\frac{1}{\Gamma^2} = \frac{\rho_\mathrm{g}}{\rho_\mathrm{l}}\left(\frac{\mu_\mathrm{l}}{\mu_\mathrm{g}}\right)^{0.2} \qquad [15.2.43]$$

The friction factor may be expressed in a generalized form of the Blasius equation

$$f \propto \mathrm{Re}^{-n} \qquad [15.2.44]$$

where n is an index. Then the parameters X and Γ are related to the quality x as follows:

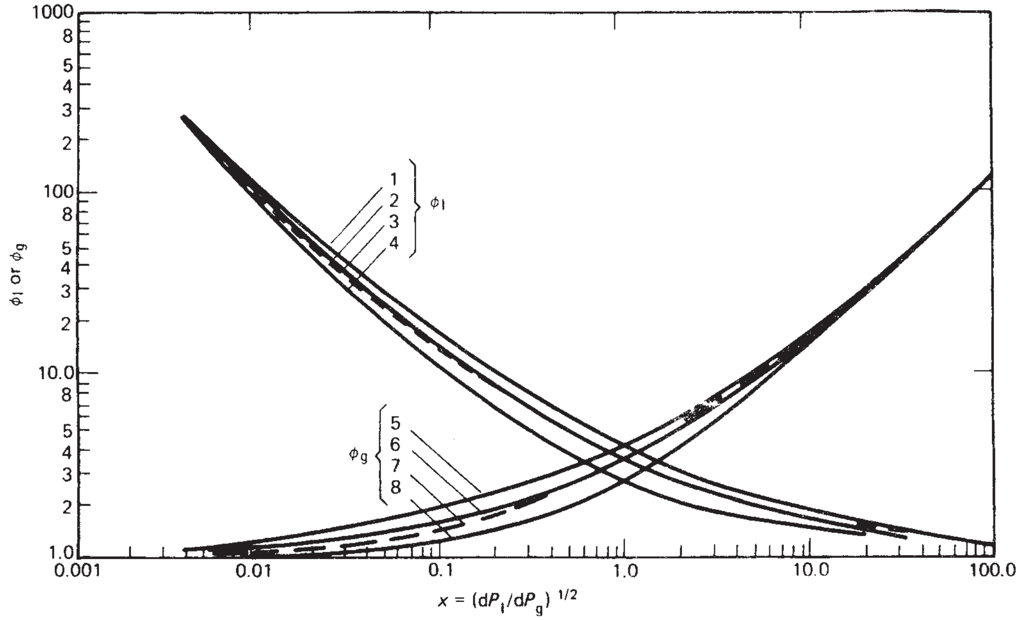
$$X^2 = \frac{1}{\Gamma^2}\left[\frac{1-x}{x}\right]^{2-n} \qquad [15.2.45]$$

15.2.10 Lockhart–Martinelli model

A method for determining the pressure drop in two-phase, two-component flow has been given by Lockhart and Martinelli (1949), who correlated ϕ_g^2 and ϕ_l^2 with X^2. The equations of the model are Equations 15.2.39 and 15.2.41. The relations given by Lockhart and Martinelli between the parameters ϕ_g, ϕ_l and X are shown in Figure 15.11.

The method is to calculate the single-phase gas and liquid Reynolds numbers Re_g and Re_l and pressure drops $(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)_\mathrm{g}$ and $(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)_\mathrm{l}$, to calculate X from Equation 15.2.41, to obtain from Figure 15.11 either ϕ_g or ϕ_l, depending on the value of X, and then to calculate $(\mathrm{d}P_\mathrm{f}/\mathrm{d}l)$ from Equation 15.2.39a or 15.2.39b. The curves given in Figure 15.11 for ϕ_g and ϕ_l depend, as shown, on whether the gas and liquid flow regimes are viscous or turbulent.

Equations for the Lockhart–Martinelli parameters, which may be used instead of Figure 15.11, have been given by Degance and Atherton (1970). Although it is one of the earlier two-phase flow correlations, the method of Lockhart and Martinelli remains one of the most widely used.



Reynolds No.	Regime Turbulent–turbulent	Viscous–turbulent	Turbulent–viscous	Viscous–viscous
Re_l	>2000	<1000	>2000	<1000
Re_g	>2000	>2000	<1000	<1000
Curve for ϕ_l	1	2	3	4
Curve for ϕ_g	5	6	7	8

If $X \geqslant 1.0$ use ϕ_l
If $X < 1.0$ use ϕ_g

Figure 15.11 *Pressure gradient in two-phase flow: the Lockhart–Martinelli correlation (after Lockhart and Martinelli, 1949) (Courtesy of the American Institute of Chemical Engineers)*

15.2.11 Other friction correlation methods

Baroczy (1966) obtained a correlation in terms of ϕ_{lo}, x, and the group which is defined as $1/\Gamma^2$ in Equation 15.2.43. A further more economical correlation was derived by Chisholm and Sutherland (1969–70). The correlation depends on the value of n in relation 15.2.44. For the case of $n = 0$ their correlation is

$$\phi_{\mathrm{g}}^2 = 1 + CX + X^2 \tag*{[15.2.46a]}$$

$$\phi_{\mathrm{l}}^2 = 1 + \frac{C}{X} + \frac{1}{X^2} \tag*{[15.2.46b]}$$

with

$$C = \frac{1}{k}\left(\frac{\rho_{\mathrm{l}}}{\rho_{\mathrm{g}}}\right)^{1/2} + k\left(\frac{\rho_{\mathrm{g}}}{\rho_{\mathrm{l}}}\right)^{1/2} \tag*{[15.2.47]}$$

The parameter C is a function of the mass velocity G and the parameter Γ.

15.2.12 Friction factor

The friction factor to be used in two-phase flow equations depends on the particular correlation. Use is often made of a single-phase flow friction factor, obtained from one of the relations given in Section 15.1. In some cases, the approach taken is even simpler. The friction factor recommended by Perry and Green (1984) for use with Equation 15.2.48 below is the single value of 0.003.

15.2.13 DIMP project

A study of non-flashing two-phase flow has been conducted by the Design Institute for Multi-phase Processing (DIMP) of the AIChE. An account of the DIMP work has been given by Cindric, Gandhi and Williams (1987).

15.2.14 Homogeneous flow models

Much of the recent development in two-phase flow which is of interest here relates to homogeneous equilibrium flow models.

15.2.15 Homogeneous equilibrium flow model

The homogeneous equilibrium model has been described by a number of workers. The minimal assumptions in this model are that the phase velocities are equal and that thermal equilibrium exists.

From Equation 15.1.18 but substituting v_{h} for v it is possible to derive for a horizontal pipe

$$G = \left[\frac{-1}{\mathrm{d}v_{\mathrm{h}}/\mathrm{d}P + (4fv_{\mathrm{h}})/2d(\mathrm{d}P/\mathrm{d}l)}\right]^{1/2} \tag*{[15.2.48]}$$

This appears to be the form most commonly quoted (e.g. Perry and Green, 1984).

For critical flow the following relation is given by Fauske (1962). From Equation 15.2.38b utilizing the definition of v_{h} in Equation 15.2.25 and assuming isentropic expansion, the critical mass velocity G_{c} is

$$G_{\mathrm{c}} = \left[\frac{-1}{x(\mathrm{d}v_{\mathrm{g}}/\mathrm{d}P)_{\mathrm{s}} + (v_{\mathrm{g}} - v_{\mathrm{s}})(\mathrm{d}x/\mathrm{d}P)_{\mathrm{s}} + (1-x)(\mathrm{d}v_1/\mathrm{d}P)_{\mathrm{g}}}\right]^{1/2} \tag*{[15.2.49]}$$

where subscript s indicates constant entropy.

A third form of the model is that given by Starkman *et al.* (1964), as quoted by R.E. Henry and Fauske (1971). Again, the additional assumption of isentropic expansion is made:

$$G_{\mathrm{c}} = \frac{\{2[h_{\mathrm{o}} - (1 - x_{\mathrm{E}})h_{\mathrm{lE}} - x_{\mathrm{E}}h_{\mathrm{gE}}]\}^{1/2}}{(1 - x_{\mathrm{E}})v_{\mathrm{lE}} + x_{\mathrm{E}}v_{\mathrm{gE}}} \tag*{[15.2.50]}$$

where h is the specific enthalpy and subscripts c, E and o indicate critical, equilibrium, and stagnation conditions, respectively.

15.2.16 Homogeneous frozen flow model

The homogeneous frozen flow model has also been described by a number of workers. In the form given by R.E. Henry and Fauske (1971), the model is based on the two necessary assumptions for this type of model, that the phase velocities are equal and that there is no transfer between phases so that thermal equilibrium does not exist, but also on the assumption that the vapour expansion is isentropic and that the critical flow is determined by gas dynamic principles. The expression for the critical mass velocity is

$$G_{\mathrm{c}} = \frac{1}{v}\left[2x_{\mathrm{o}}v_{\mathrm{go}}P_{\mathrm{o}}\frac{\gamma}{\gamma - 1}\left(1 - \eta_{\mathrm{c}}^{(\gamma-1)/\gamma}\right)\right]^{1/2} \tag*{[15.2.51]}$$

where γ is the ratio of gas specific heats, η_{c} is the critical pressure ratio and subscript o indicates the stagnation condition. The critical pressure ratio is the ratio of the throat pressure to the downstream pressure, and the expression given for it is relatively complex.

15.2.17 Two-phase flashing flow

The two-phase flow which is of particular interest here is single-component, two-phase flashing flow. This is the type of flow which occurs when liquefied gas is released to the atmosphere, whether in a controlled manner through a relief device or due to an accident. A number of models have been developed for two-phase flashing flow, particularly through the work of Fauske and co-workers in the DIERS project, as described below.

The type of model characteristic of this work is a homogeneous equilibrium model for a very short pipe. The presence of the pipe makes it possible to assume equilibrium conditions, but the pipe is sufficiently short that frictional effects can still be neglected. Allowance is then made for frictional pressure drop by the use of empirical correlations.

The assumption of negligible pipe length leads to much simpler expressions for the critical flow. Initially, the length of pipe at which equilibrium is established was assumed to be defined by a length/diameter, or l/d, ratio. As described below, it has been shown that equilibrium is reached as a fixed length of some 0.1 m.

Two models, or rather families of models, of the type described are those of Fauske and of Leung. These are described in Sections 15.3 and 15.4, respectively.

15.2.18 Maximum critical flow

The maximum possible flow of a two-phase fluid in a pipe is obtained if it is assumed that friction can be neglected and that the energy released by the drop in pressure is converted to kinetic energy. At the critical flow conditions $\mathrm{d}G/\mathrm{d}P = 0$ or, alternatively, $\mathrm{d}G/\mathrm{d}\eta = 0$.

For a horizontal pipe Equation 15.1.77 yields $v\,\mathrm{d}P = u\,\mathrm{d}u$ ($\mathrm{d}W_{\mathrm{s}} = \mathrm{d}F = \mathrm{d}z = 0$). Noting that the velocity $u = Gv$, it can readily be shown that at the critical flow conditions ($\mathrm{d}G/\mathrm{d}P = 0$) the maximum, or critical, mass velocity G_{c} is given by the relation $G_{\mathrm{c}}^2 = -(\mathrm{d}P/\mathrm{d}v)$, where the pressure P and the specific volume v refer to the inlet conditions.

Critical flow conditions can occur at quite a high value of the ratio of the downstream pressure to the upstream pressure, or critical pressure ratio. A value as high as 0.7 in some cases is quoted by Coulson and Richardson (1977–, p. 95). The Leung model, described below, includes correlations for the critical pressure ratio.

15.2.19 Relaxation length

As already mentioned, it was initially believed that in two-phase flow the length of pipe over which equilibrium becomes established, or relaxation length, is a function of the length/diameter ratio. However, it has been shown in a number of studies that it is the absolute length which matters.

Work designed specifically to elucidate this point has been described by B. Fletcher (1984a,b) and B. Fletcher and Johnson (1984). Experiments were carried out on discharges of Refrigerant 11 through sharp edged orifices and tubes in the diameter range 3.2–10.8 mm and length/diameter ratio (l/d) range 0.88–200. In this work it was found that the onset of flashing was favoured by higher excess pressure, and hence superheat, and by increased tube length. It was also found that as the tube length was increased the flow at first decreased rapidly but then much more gradually. The transition point marking the end of the rapid decrease in flow with length occurred at a length of about 75 mm. Figure 15.12 shows the jet in some of Fletcher and Johnson's experiments.

At the time when this work was done one of the most widely used models for two-phase flow was the empirical model of Fauske (1964)

$$G = C_{\mathrm{d}}[2\rho_{\mathrm{l}}(P_0 - P_{\mathrm{c}})]^{1/2} \quad l/d < 3 \qquad [15.2.52]$$

where C_{d} is the coefficient of discharge, P_{c} is the absolute critical outlet pressure and P_0 is the absolute upstream pressure.

As described below, Fletcher and Johnson are somewhat critical of Equation 15.2.52. The correlation preferred is based on the assumption that for a given length

$$G \propto C_{\mathrm{d}}P_0^{1/2} \qquad [15.2.53]$$

Figure 15.13 shows the results of discharge experiments correlated in this way. Figure 15.13(a) shows Fletcher's own results for Refrigerant 11 and Figure 15.13(b) shows the results of other workers. Thus, in this work, relation 15.2.53 is used for excess pressures in the range 1–102 bar.

Fletcher points out that the transition distance of 75 mm found in his work corresponds in Fauske's work to a length/diameter ratio of 12, a ratio which Fauske treats as a transition point.

Fletcher discusses the point at which all liquid flow ceases and flashing begins. He refers to the assumption in the Rijnmond Report that all liquid flow can be assumed to exist for $l/d < 2$ and states that he has observed flashing at $l/d < 1$ if the excess pressure is sufficiently high.

In presenting their own correlation, Fletcher and Johnson state certain criticisms of Equation 15.2.52. Two of these have already been discussed: the use of l/d instead of l as a correlator and the assumption of all liquid flow for $l/d < 2$. Another is the assumption that $P_{\mathrm{c}} = 0.55P_{\mathrm{d}}$ for all fluids. They refer to the use in the *Second Canvey Report* of Equation 15.2.52, but point out that this applies strictly only to the all gas, or vapour, condition.

Confirmation that the relaxation length is a function of the absolute length of pipe for large pipe diameters is provided by the work at Marviken by S. Levy Inc. (1982). The available data on relaxation length has been reviewed by Fauske (1984c), who quotes the data shown in Table 15.4. The later models of Fauske incorporate the absolute length method of correlation. This method is now generally adopted. The value of the relaxation length is taken as 0.1 m.

15.2.20 Critical pressure ratio

As the foregoing account indicates, a crucial parameter in two-phase flow is the critical pressure ratio (CPR), defined as the ratio of the critical pressure to the upstream, or stagnation pressure. A review of the CPR is given by Hardekopf and Mewes (1988).

For the fluid, they distinguish between a saturated liquid, a two-phase mixture and a superheated vapour and for the outlet between an orifice, a pipe, and a nozzle. They state that for orifices and long pipes there is no single CPR, but that for nozzles, including outlets with short pipes, a CPR can be calculated. They refer particularly to the work of Schiller (1933) and Friedrich and Vetter (1962), as well as that of Fauske and coworkers.

For an orifice with saturated liquid or two-phase flow there is no readily calculable CRP, whilst for superheated vapour they give the CPR as zero. For a pipe with any of the three fluid conditions the CPR is a function of pipe length; they suggest that for two-phase flow use be made of the model by R.E. Henry and Fauske (1971), described in the next section, or of the homogeneous equilibrium model (HEM). For a nozzle with saturated liquid or two-phase flow, they again refer to these two models and quote typical values for a saturated liquid of CPR $\sim$ 0.85 and for two-phase flow of $0.85 < \mathrm{CPR} < 0.55$, whilst for superheated vapour they give the adiabatic expansion equation with a typical CPR of 0.55.

15.2.21 Two-phase flow transients

The two-phase flow models described apply to steady-state conditions. The steady state is preceded and followed by transients. A treatment of such transients in pipelines is given by Seynhaefve *et al.* (1994).

15.2.22 DIERS project

Two-phase flow was a major aspect of the project by the Design Institute for Emergency Relief Systems (DIERS) of the AIChE. Although it was not intended that the project should produce new relations for two-phase flow, much work was done to investigate the suitability of the various correlations, and new methods have resulted. This work is described in the DIERS Technical Summary and in a series of papers by Fauske, Epstein, Grolmes, Leung and co-workers.

15.2.23 Choice of model

With regard to choice of model, it is relevant to distinguish between one-component, two-phase flashing flow, mainly in controlled or accidental releases from plant, and two-component, two-phase non-flashing flow, mainly of fluids in pipelines. It is the former which is of prime interest here.

Guidance on the choice of model for non-flashing two-phase flow based on the work of DIMP has been given by

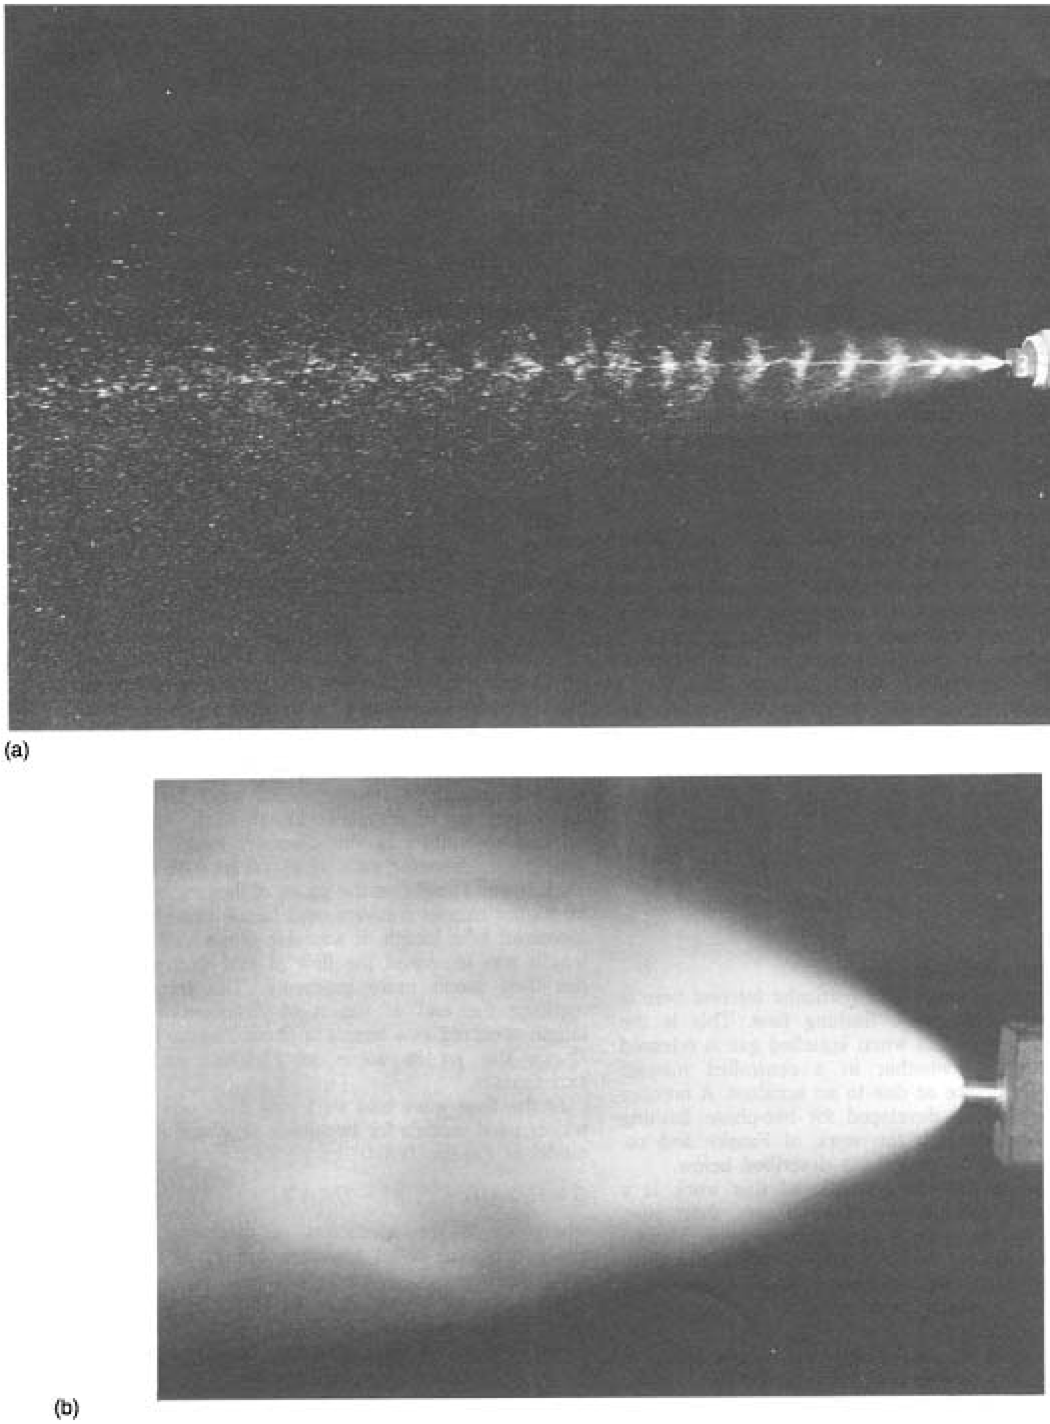


Figure 15.12 Discharge of Refrigerant 11 through 3.2 mm pipe (B. Fletcher and Johnson, 1984): (a) excess pressure of 0.7 bar; (b) excess pressure of 2.5 bar (Courtesy of HM Stationery Office)

Cindric, Gandhi and Williams (1987). For horizontal flow the following models are recommended:

Flow	*Model*	
Stratified	Stratified	Taitel and Dukler (1976)
Stratified wavy	Stratified	Taitel and Dukler (1976)
Intermittent slug	Horizontal slug	Dukler and Hubbard (1975) Nicholson, Aziz and Gregory (1978)
Intermittent elongated bubble	Similarity	Dukler, Wicks and Cleveland (1964)
Annular	Similarity	Dukler, Wicks and Cleveland (1964)
Dispersed bubble	Similarity	Dukler, Wicks and Cleveland (1964)

The choice of model for two-phase flashing flow is discussed below, in particular in Sections 15.3 and 15.4 which deal with families of models of Fauke and Leung, Section 15.6 which treats the model given by Leung for pressure relief valves and Chapter 17 which covers venting of reactors.

For reactor venting, Fauske (1985b) suggests: for orifices, the non-equilibrium model; for short outlets, the equilibrium rate model (ERM); and for longer outlets, where friction is significant, the homogeneous equilibrium model (HEM).

15.2.24 Design conservatism

In considering what constitutes a conservative assumption, it is necessary to make a number of distinctions. In determining the flow through a relief such as a pressure relief valve or a reactor vent, for the purpose of sizing the relief, it is conservative to use a method which tends to underestimate the flow. However, this approach is not conservative with respect to aspects such as the reaction forces on the vessel, the pressure drop in the relief header or the flow through the relief disposal train, for all of which it is conservative to use a method which tends to overestimate the flow.

For an accidental release to atmosphere, it is generally conservative to use a method which tends to overestimate the flow. However, this may not always be true. For example, if the release gives a jet flame, a smaller flame of longer duration could be a worse case.

15.2.25 Two-phase flow in valves

Two-phase flashing flow occurs in valves, both control valves and pressure relief valves. Accounts of methods used to calculate such flow through control valves have been given by W.F. Allen (1952–), Ziegler (1957), Hanssen (1961), Sheldon and Schuder (1965) and Romig, Rothfus and Kermode (1966). Flow through pressure relief valves is considered in Section 15.6.

15.2.26 Two-phase flow through cracks

It is convenient to deal at this point with flow, particularly two-phase flow of a flashing liquid, through cracks in pressure vessels such as may be relevant to the leak-before-break condition. A number of workers have studied the leak rate through such cracks and have modelled it using various two-phase flow models (e.g. Amos *et al.*, 1983; Abdo Uahian *et al.*, 1984; R.P. Collier, 1984; John *et al.*, 1986; Kefer *et al.*, 1986). The two-phase flow models used by the workers cited are principally those of R.E. Henry (1970), Pana (1976) and Levy (1982).

The work has been reviewed by Friedel (1987b) and Friedel and Westphal (1987, 1988, 1989). They observe that there are a number of features, such as viscosity changes, surface tension and wetting effects, and non-equilibrium conditions, which current models tend not to account for and that no model can be regarded as universally valid, even for water.

15.3 Two-phase Flow: Fauske Models

15.3.1 Fauske empirical model

An early empirical model for two-phase flow was that described by Fauske (1964). The model is relatively simple and readily adaptable, and has been widely used. The general form of the model is

$$G = C_\mathrm{d}[2\rho_\mathrm{l}(P_\mathrm{o} - P_*)]^{1/2} \qquad [15.3.1]$$

where C_d is the coefficient of discharge, G is the mass velocity, P_o is the absolute stagnation pressure, P_* is the effective downstream pressure and ρ_l is the density of the liquid.

A correlation for the transition from single-phase to two-phase flow in fluid flowing from a vessel through an aperture or short pipe to atmosphere has been given by Min, Fauske and Petrick (1966). The transition is correlated in terms of a modified cavitation number C'_a:

$$C'_\mathrm{a} = \frac{2\Delta P}{\rho_\mathrm{l} U^2}\frac{l}{d} \qquad [15.3.2]$$

where d is the diameter of the pipe, l is the length of the pipe, ΔP is the pressure difference, U is the average velocity of fluid and ρ_l is the density of the saturated or subcooled fluid in the vessel. Flow is single-phase for values of C'_a less than 9 and two-phase for values greater than 15. At values between 9 and 15, unstable transitional flow occurs.

The empirical model given by Fauske (1964) is based on experimental work on the flow of a saturated liquid from a vessel through an aperture or an aperture connected to a short pipe to atmosphere. For a system in which the aperture was a sharp edged orifice, the following equations were obtained:

$$G = C_\mathrm{d}[2\rho_\mathrm{l}(P_\mathrm{o} - P_\mathrm{b})]^{1/2} \qquad [15.3.3a]$$

$$G = C_\mathrm{d}[2\rho_\mathrm{l}(P_\mathrm{o} - P_\mathrm{c})]^{1/2}, \quad l/d < 3 \qquad [15.3.3b]$$

where subscripts b and c denote the downstream and critical values, respectively. The value of the coefficient of discharge was 0.61.

Equation 15.3.3a applies to an orifice without a pipe and Equation 15.3.3b to an orifice with a pipe attached. For this latter case the critical exit pressure P_c was found to be a function of the length/diameter ratio l/d of the pipe. Fauske considered separately the regions $3 < l/d < 12$ and $12 < l/d < 40$. He found that in the latter region there was very little decrease in flow with l/d, indicating a relatively small friction effect. His data over the two regions may be represented by the approximate equation

$$\frac{P_\mathrm{c}}{P_\mathrm{o}} = 0.55[1 - \exp(-\mathrm{l}/3d)] \qquad [15.3.4]$$

Equation 15.3.3 was derived from experiments on saturated water flowing through a sharp-edged orifice of 0.25 in.

diameter with an upstream pressure of up to 2000 psi. This model has been used extensively in industry to determine the two-phase flow from pipe ruptures. An account of such application has been given by Simpson (1971).

Equation 15.3.3 is that used in the *Second Canvey Report* for estimation of two-phase flow from pipe ruptures. The report uses for the critical pressure ratio Equation 15.1.69.

15.3.2 Relaxation length

As described earlier, Fauske (1964) correlated his results in terms of the length/diameter ratio. Subsequent work indicates, however, that it is the absolute length l rather than the length/diameter ratio l/d which is the appropriate correlator and this position has been adopted by Fauske.

15.3.3 Jones and Underwood model

The Fauske empirical model has been widely used and has been subject to various adaptations. M.R.O. Jones and Underwood (1983) refer to Fauske's empirical model and point out that the use of an average density ρ_m implies the assumption of homogeneous equilibrium flow. They present as an alternative relations derived from the theory for critical annular flow given by Fauske (1961):

$$G = C_{DM}\left[\frac{\rho_l\rho_n}{\rho_l - \rho_n}(P_0 - P_c)\right]^{1/2} \qquad [15.3.5]$$

with

$$\rho_n = \left[\frac{x_c^2}{\rho_g R_g} + \frac{(1-x_c)^2}{\rho_l(1-R_g)}\right]^{-1} \qquad [15.3.6]$$

$$R_g = \left[\frac{(1-x_c)}{x_c}\left(\frac{\rho_g}{\rho_l}\right)^{1/2} + 1\right]^{-1} \qquad [15.3.7]$$

where C_{DM} is the modified coefficient of discharge, R_g is the fraction of the cross-sectional area occupied by vapour, x is the mass fraction of the vapour, and subscripts c, g, l, and n denote the pipe exit, vapour, liquid and two-phase annular value, respectively.

The authors describe experimental work on Freons 12, 22, and 114 discharging through pipes of diameter 0.5 and 4 mm and length/diameter ratios between 10 and 617. The authors found that the coefficient of discharge C_{DM} in Equation 15.3.5 was a function of the length/diameter ratio and obtained the relation

$$C_{DM} = 5.46\left(\frac{l}{d}\right)^{-0.77} + 0.29 \qquad [15.3.8]$$

Equation 15.3.8 actually gives a coefficient of discharge greater than unity for $l/d < 15$ and the coefficient so obtained should be treated as a purely empirical one.

In a further study, M.R.O. Jones and Underwood (1984) investigated releases from apertures rather than full bore ruptures. Experiments were carried out using Freons and propane with pipes 4.3–4.5 mm in diameter and ending in a ball valve followed by one of the following apertures:

1. circular aperture, $d = 0.5–4.4$ mm, $l/d < 3$;
2. circular aperture, $d = 0.5$ mm, $l/d = 10$;
3. rectangular aperture, height/width ratio 5.5, 10.2 and 25.6.

It might be expected that for pipes of cross-sectional area A_p and apertures of area A_a the flow would be proportional to the area ratio A_a/A_p, but the correlation obtained was in fact in terms of $(A_a/A_p)^{1/2}$. Three regions were observed:

$0 < (A_a/A_p)^{1/2} < 0.25$ Flow effectively metastable.

$0.25 < (A_a/A_p)^{1/2} < 0.9$ Ratio of actual flow to maximum flow proportional to $(A_a/A_p)^{1/2}$. Constant of proportionality 1.15.

$0.9 < (A_a/A_p)^{1/2} < 1.0$ Flow equal, or close, to maximum flow.

The authors warn, however, that their experiments were small scale and that caution should be exercised in extrapolating the results to the large scale.

15.3.4 Henry–Fauske non-equilibrium model

A non-equilibrium model for outlets with short pipes has been given by R.E. Henry and Fauske (1971). The model receives frequent mention. The assumption is made that flow is homogeneous but not that it is in equilibrium. The expansion of the vapour is assumed to be polytropic. The model gives the flow in terms of the stagnation conditions.

For critical two-phase flow the authors derive the relation

$$G_c^2 = \left(\frac{-\mathrm{d}}{\mathrm{d}P}\left\{\frac{[xk + (1-x)]}{k}[(1-x)kv_l + xv_g]\right\}\right)_t^{-1} \qquad [15.3.9]$$

where k is the slip ratio, v is the specific volume and subscript t indicates the throat. The equations of the model are:

$$G_c^2 = \frac{(1-x_o)v_{lo}(P_o - P_t) + [x_o\gamma/(\gamma-1)](P_o v_{go} - P_t v_{gt})}{[(1-x_o)v_{lo} + x_o v_{gt}]^2/2} \qquad [15.3.10]$$

$$\frac{\eta = [((1-\alpha_o)/\alpha_o)(1-\eta) + \gamma/(\gamma-1)]^{\gamma/(\gamma-1)}}{1/(2\beta\alpha_t^2) + \gamma/(\gamma-1)} \qquad [15.3.11]$$

$$\beta = \left\{\frac{1}{n} + \left(1 - \frac{v_{lo}}{v_{gt}}\right)\left[\frac{(1-x_o)NP_t}{x_o(s_{gE} - s_{lE})_t}\frac{\mathrm{d}s_{lE}}{\mathrm{d}P}\right]_t - c_{pg}\frac{1/n - 1/\gamma}{s_{go} - s_{lo}}\right\} \qquad [15.3.12]$$

$$\alpha_o = \frac{x_o v_{go}}{(1-x_o)v_{lo} + x_o v_{go}} \qquad [15.3.13]$$

$$\alpha_t = \frac{x_o v_{gt}}{(1-x_o)v_{lo} + x_o v_{gt}} \qquad [15.3.14]$$

$$v_{gt} = v_{go}\eta^{-1/\gamma} \qquad [15.3.15]$$

$$\eta = \frac{(1-x)\mathrm{c}_l/c_{pg} + 1}{(1-x)\mathrm{c}_l/c_{pg} + 1/\gamma} \qquad [15.3.16]$$

$$N = \frac{x_{Et}}{0.14} \quad x_{Et} \le 0.14 \qquad [15.3.17a]$$

$$N = 1 \quad x_{Et} > 0.14 \qquad [15.3.17b]$$

$$x_E = \frac{s_o - s_{lE}}{s_{gE} - s_{lE}} \qquad [15.3.18]$$

where c is the specific heat, n is the polytropic index, N is a non-equilibrium parameter, s is the specific entropy, α is the void fraction, γ is the isentropic index and the subscript E denotes equilibrium (corresponding to local static pressure).

For $N = 1$ the model reduces approximately to the homogeneous equilibrium model, while for $N = 0$ it reduces approximately to the homogeneous frozen model. For inlet quality greater than $x_o = 0.1$, corresponding to throat quality x_{Et} in the range 0.125–0.155, with an assumed average of 0.14, the homogeneous equilibrium model is assumed, so that $N = 1$, as given in Equation 15.3.17b. For inlet qualities less than $x_o = 0.1$, Equation 15.3.17a is used.

15.3.5 Fauske slip equilibrium model

In the models described so far, the usual assumptions are thermal equilibrium and homogeneous flow. Fauske (1962, 1963) has developed a slip equilibrium model in which the latter assumption is relaxed. The model is applicable essentially to annular flow, in which the vapour and liquid flows are largely separate so that the vapour velocity is likely to exceed that of the liquid. The starting point of the model is the momentum balance:

$$\mathrm{d}P + \mathrm{d}F' + \mathrm{d}(G_g u_g + G_l u_l) = 0 \qquad [15.3.19]$$

where $\mathrm{d}F'$ is the friction term. Differentiating Equation 15.3.19 with respect to the quality x gives

$$\frac{\mathrm{d}P}{\mathrm{d}x} + \frac{\mathrm{d}F'}{\mathrm{d}x} + \frac{\mathrm{d}(G_g u_g + G_l u_l)}{\mathrm{d}x} = 0 \qquad [15.3.20]$$

It is assumed that the friction term can be expressed as

$$\mathrm{d}F' = \frac{f^* G^2 v\, \mathrm{d}l}{2d} \qquad [15.3.21]$$

where f^* is a friction factor for two-phase flow.

Substituting for u_g, u_l and $\mathrm{d}F'$ in Equation 15.3.20 from Equations 15.2.12, 15.2.13 and 15.3.21 gives, eventually,

$$\frac{\mathrm{d}P}{\mathrm{d}l} + G^2\left\{\frac{\mathrm{d}}{\mathrm{d}l}\left[\frac{x^2 v_g}{\alpha_g} + \frac{(1-x)^2}{(1-\alpha_g)}\frac{v_l}{\rho_l}\right] + \frac{fv}{2d}\right\} = 0 \qquad [15.3.22]$$

But the corresponding equation for single-phase flow is

$$\frac{\mathrm{d}P}{\mathrm{d}l} + G^2\left[\frac{\mathrm{d}v}{\mathrm{d}l} + \frac{fv}{2d}\right] = 0 \qquad [15.3.23]$$

where f is the friction factor.

Equations 15.3.22 and 15.3.23 become identical because the specific volume v is defined as

$$v = \frac{v_g x^2}{\alpha_g} + \frac{v_l(1-x)^2}{1-\alpha_g} \qquad [15.3.24]$$

This definition of the specific volume is a crucial feature of the model.

In the model, the slip ratio k is treated as a variable to be adjusted to obtain the maximum flow. The specific volume v can be expressed as a function of k by combining Equations 15.2.16b and 15.3.24 to give

$$v = \frac{[(1-x)v_l k + x v_g][1 + x(k-1)]}{k} \qquad [15.3.25]$$

Differentiating Equation 15.3.22 with respect to k gives

$$G^2\left[\frac{\delta}{\delta l}\left(\frac{\delta v}{\delta k}\right) + \frac{f}{2d}\frac{\delta v}{\delta k} + \frac{v}{2d}\frac{\delta f}{\delta k}\right] = 0 \qquad [15.3.26]$$

In order to obtain from Equation 15.3.26 an expression for the maximum flow it is necessary to make some limiting assumptions. One limit is that of isentropic flow ($f = 0$, $\delta v/\delta k = 0$), but this is rejected because of the irreversibilities inherent in different phase velocities. Instead, the assumption made is isenthalpic flow ($\delta f/\delta k = 0$, $\delta v/\delta k = 0$).

Differentiating Equation 15.3.25 with respect to k gives

$$\frac{\delta v}{\delta k} = (x - x^2)\left(v_l - \frac{v_g}{k^2}\right) \qquad [15.3.27]$$

Then the values of k for which Equation (15.3.27) is equal to zero are

$$k = 1 \quad x = 0, 1 \qquad [15.3.28a]$$

$$k = \left(\frac{v_g}{v_l}\right)^{1/2} \quad 0 < x < 1 \qquad [15.3.28b]$$

Integrating Equation 15.3.22 over the length l of the pipe gives

$$\int_{P_o}^{P}\frac{\mathrm{d}P}{v} + G^2\left(\frac{\ln v}{v_o} + \frac{f_m l}{2d}\right) = 0 \qquad [15.3.29]$$

with

$$f_m = \int_{P_o}^{P} f \frac{\mathrm{d}}{\mathrm{d}P}(1/l)\,\mathrm{d}P \qquad [15.3.30]$$

where f_m is the average friction factor.

Differentiating Equation 15.3.30 with respect to P and setting $\mathrm{d}G/\mathrm{d}P = 0$ and then combining the result with Equation 15.3.29 gives

$$G_c = \left[\frac{-1}{v[\mathrm{d}\ln v/\mathrm{d}P + (1/2d)\,\mathrm{d}f_m/\mathrm{d}P]}\right]^{1/2} \qquad [15.3.31]$$

But

$$\left(\frac{\delta f_m}{\delta P}\right)_c = \frac{\delta f_m}{\delta k}\frac{\delta k}{\delta P} \qquad [15.3.32]$$

and, since, $\delta f_m/\delta k = 0$, it follows that $\delta f_m/\delta P = 0$.

Then from Equations 15.3.31 and 15.3.25

$$G_c = \left(\frac{-k}{\mathrm{d}/\mathrm{d}P\{[(1-x)v_l k + x v_g][1 + x(k-1)]\}}\right)^{1/2} \qquad [15.3.33]$$

Completing the differentiation of the denominator of Equation (15.3.33) with respect to P gives

$$G_c = (-k/\zeta)^{1/2} \tag{15.3.34}$$

with

$$\begin{aligned}\zeta = {} & [(1 - x + kx)x]\frac{dv_g}{dP} \\ & + [v_g(1 + 2kx - 2x) + v_l(2xk - 2k - 2xk^2 + k^2)]\frac{dx}{dP} \\ & + [k(1 + x(k-2) - x^2(k-1)]\frac{dv_l}{dP}\end{aligned} \tag{15.3.35}$$

Equation 15.3.34 is the required relation for the critical two-phase flow.

The derivative terms in Equation 15.3.35 are calculated under isenthalpic conditions as follows:

$$\frac{dv_g}{dP} \approx \left(\frac{\Delta v_g}{\Delta P}\right)_h \tag{15.3.36}$$

$$\frac{dv_l}{dP} \approx \left(\frac{\Delta v_l}{\Delta P}\right)_h \tag{15.3.37}$$

$$\frac{dx}{dP} \approx -\frac{1}{h_{fg}}\left(\frac{dh_f}{dP} + x\frac{dh_{fg}}{dP}\right) \tag{15.3.38a}$$

$$\frac{dx}{dP} \approx -\frac{1}{h_{fg}}\left(\frac{\Delta h_f}{\Delta P} + \frac{\Delta h_{fg}}{\Delta P}\right) \tag{15.3.38b}$$

where the subscripts f, fg and h denote the liquid, the liquid–vapour transition and constant enthalpy, respectively.

The method of calculation is as follows. For a given pressure P and given value of the quality x, the quantities v_g, v_l, h_{fg}, $\Delta v_g/\Delta P$, $\Delta v_l/\Delta P$, $\Delta h_f/\Delta P$ and $\Delta h_{fg}/\Delta P$ are obtained from thermodynamic tables. As an illustration, consider the calculation (in British units) given by Fauske for the maximum mass velocity of a steam–water mixture at a pressure of 600 psi. From steam tables

$$v_g = 0.7698$$
$$v_l = 0.0201$$
$$h_{fg} = 731.6$$

and for $\Delta P = 40$

$$\Delta v_g = 0.7440 - 0.7973$$
$$\Delta v_l = 0.0202 - 0.0201$$
$$\Delta h_f = 727.2 - 736.1$$
$$\Delta h_{fg} = 475.2 - 467.4$$

Hence

$$\frac{dx}{dP} = \frac{10^{-6}}{4.214}(-8.3 + 8.9x)$$
$$\frac{dv_g}{dP} = -9.2535 \times 10^{-6}$$
$$k = 6.19$$

Then the maximum mass velocity G_c for different values of quality x is

x	G_c
0.01	8960
0.05	7605
0.10	6510
0.20	5100
0.40	3570
0.60	2740
0.80	2235

The term (dv_l/dP) can often be neglected. In the calculation given for a value of the pressure P of 600 psi, the error in neglecting the term is 3%. At 400 psi the error reduces to 1%.

A further illustrative calculation has been given by Ramskill (1986 SRD R352) for an ammonia flow problem.

In the Fauske slip-equilibrium model, the friction factor defined is relatively complex and is unique to that model, although this does not present a problem since it is eliminated in the manipulations and does not appear in the final equation for the critical mass velocity.

15.3.6 Fauske non-equilibrium model

A model for critical two-phase flow in short outlets which has both non-equilibrium and equilibrium versions has been given by Fauske (1985b). The model is suitable for venting of vessels such as reactors and storage vessels where the outlet is sufficiently short for friction to be neglected. The general, or non-equilibrium, form of the model is:

$$G \approx \frac{h_{fg}}{v_{fg}}\left(\frac{1}{NTC}\right)^{1/2} \tag{15.3.39}$$

with

$$N \approx \frac{h_{fg}^2}{2\Delta P \rho_l K^2 v_{fg}^2 TC} + l/l_e \quad 0 < l/l_e < 1 \tag{15.3.40}$$

where C is the specific heat of the liquid, K is the coefficient of discharge, l_e is the equilibrium or relaxation length, N is a non-equilibrium parameter and ΔP is the total available pressure drop. The discharge coefficient K is the usual coefficient of discharge; it is given by Fauske variously as 0.6 and 0.61. The relaxation length l_e is 0.1 m.

Equation 15.3.39 is applicable over the range $0 < l/l_e < 1$. For $l/l_e = 0$, it reduces to

$$G = K(2\Delta P \rho_l)^{1/2} \tag{15.3.41}$$

with

$$\Delta P = P_o - P_a \tag{15.3.42}$$

where P_a is the absolute atmospheric pressure.

15.3.7 Fauske equilibrium rate model

If, on the other hand, the pipe length is sufficient for equilibrium to be reached, which occurs at $l/l_e > 1$, then in Equation 15.3.39 $N = 1$, and hence

$$G \approx \frac{h_{fg}}{v_{fg}}\left(\frac{1}{TC}\right)^{1/2} \tag{15.3.43}$$

Fauske (1985b) terms Equation 15.3.43 the equilibrium rate model (ERM).

An alternative form of Equation 15.3.43 which is often more convenient is

$$G \approx \frac{\mathrm{d}P}{\mathrm{d}T}\left(\frac{T}{C}\right)^{1/2} \qquad [15.3.44]$$

Equation 15.3.44 gives a good estimate of two-phase flashing flow, provided the mass fraction x of vapour does not exceed a limiting value. The condition for its validity is given by Fauske and Epstein (1989) as

$$x < \frac{Pv_{\mathrm{fg}}}{h_{\mathrm{fg}}^2} TC \qquad [15.3.45]$$

This condition implies a corresponding value of the void fraction α, since

$$\alpha = \frac{xv_{\mathrm{g}}}{(1-x)v_{\mathrm{f}} + xv_{\mathrm{fg}}} \qquad [15.3.46]$$

15.3.8 Flow through a pipe

The equilibrium rate model applies essentially to flow through a nozzle just long enough for equilibrium conditions to be established but sufficiently short that frictional effects can be neglected. The flow is only weakly dependent on the length of the outlet, but if it is necessary to take friction into account, Fauske suggests two approaches.

One is the use of the homogeneous equilibrium model. discussed in Section 15.2.15.

The other approach given by Fauske (1989a) is the use of a flow correction factor F to the ERM so that Equation 15.3.44 becomes

$$G = F\frac{\mathrm{d}P}{\mathrm{d}T}\left(\frac{T}{C}\right)^{1/2} \qquad [15.3.47]$$

with

$$F = f(l/d) \qquad [15.3.48]$$

In the context of venting of reactors with vapour pressure, or tempered systems, Fauske (1989a) has reported the values of F given here in Table 15.5.

15.3.9 Subcooled liquids

For flow of a liquefied gas which is initially subcooled, Fauske (1985b) gives the following relations. For a liquid with a large degree of subcooling:

$$G = K[2(P_{\mathrm{o}} - P_{\mathrm{a}})\rho_{\mathrm{l}}]^{1/2} \qquad [15.3.49]$$

For a liquid with a small degree of subcooling, and thus in the transition zone between a saturated and strongly subcooled liquid:

$$G = \{2[P_{\mathrm{o}} - P_{\mathrm{v}}(T_{\mathrm{o}})]\rho_l + G_{\mathrm{ERM}}^2\}^{1/2} \quad l/l_{\mathrm{e}} \geq 1 \qquad [15.3.50]$$

with

$$G_{\mathrm{ERM}} = \frac{P_{\mathrm{v}}}{P}\frac{\mathrm{d}P}{\mathrm{d}T}\left(\frac{T}{C}\right)^{1/2} \qquad [15.3.51]$$

where P_{v} is the absolute vapour pressure.

Equation 15.3.50 reduces to Equation 15.3.44 for zero subcooling and to Equation 15.3.49 for strong subcooling.

15.3.10 Source term models

From this family of models, Fauske (1985b) and Fauske and Epstein (1988) have summarized those which may be used for the source term of an accidental release. They are:

Liquid condition		*Equation*
Saturated stagnation	Orifice (non-equilibrium, frictionless, $l/l_{\mathrm{e}} = 0$)	15.3.41
	Nozzle (non-equilibrium, frictionless, $0 < l/l_{\mathrm{e}} < 1$)	15.3.39
	Nozzle/short pipe (equilibrium, frictionless, $l/l_{\mathrm{e}} > 1$)	15.3.44
	Longer pipe (equilibrium, frictional effecs, $l/l_{\mathrm{e}} > 1$)	15.3.47
Week subcooling	Nozzle (non-equilibrium, $l/l_{\mathrm{e}} < 1$)	15.3.50 (with G_{ERM} replaced by G from 15.3.39)
	Longer pipe (equilibrium, $l/l_{\mathrm{e}} > 1$)	15.3.50 (with G_{ERM} from 15.3.51)
Strong subcooling	Nozzle/longer pipe	15.3.49

15.4 Two-phase Flow: Leung Models

Another family of models for two-phase flow is that given by Leung, another contributor to the DIERS project. The model of particular interest here is the homogeneous equilibrium model (HEM) for one-component two-phase flashing flow (Leung, 1986a). In addition to the basic model, the author has treated two-phase flashing flow in a horizontal duct (Leung, 1990a; Leung and Grolmes, 1987–), in an inclined duct (Leung, 1990a; Leung and Epstein, 1990a), with a subcooled liquid (Leung and Grolmes, 1988) and with non-condensable gas (Leung and Epstein, 1991), has presented a unified approach for nozzles and pipes (Leung, 1990b) and an overall comparison of flashing flow methods (Leung and Nazario, 1990). He has also given a model for two-phase non-flashing flow (Leung and Epstein, 1990b) and has shown the similarity between the flashing and non-flashing flow models (Leung, 1990a).

***Table 15.5** Flow correction factor for Fauske equilibrium rate model (after Fauske, 1989a)*

l/d	F
0	1.0
50	0.85
100	0.75
200	0.65
400	0.55

Applications of the model given by Leung include its use for: two-phase flow in storage vessels (Leung, 1986b); pressure relief valves (Leung, 1992a); and venting of reactors (Leung and Fauske, 1987; Leung and Fisher, 1989). These applications are described in Sections 15.5, 15.6 and Chapter 17, respectively.

15.4.1 Flow through a nozzle

The homogeneous equilibrium flow model of Leung (1986a) follows on from an earlier model by Grolmes and Leung (1984) which was restricted to an inlet condition of all liquid flow. This has been generalized by Leung to allow the handling of two-phase flow at the inlet.

The basic momentum and energy balance relations are:

$$v\,\mathrm{d}P + G^2\left(v\,\mathrm{d}v + 4fv^2\frac{\mathrm{d}L}{2D}\right) = 0 \qquad [15.4.1]$$

$$h_\mathrm{o} = h + \frac{G^2v^2}{2} \qquad [15.4.2]$$

where D is the diameter of the pipe, f is the friction factor, h is the specific enthalpy, L the length of the pipe and subscript o denotes stagnation. The situation considered is frictionless flow through a nozzle. This is treated as an isentropic process.

For a nozzle ($L = 0$), Equation 15.4.1 becomes

$$G = (-\mathrm{d}v/\mathrm{d}P)^{-1/2} \qquad [15.4.3]$$

The relations for specific enthalpy h, specific entropy s and specific volume v are:

$$h = h_\mathrm{f} + xh_\mathrm{fg} \qquad [15.4.4]$$

$$s = s_\mathrm{f} + xs_\mathrm{fg} \qquad [15.4.5]$$

$$v = v_\mathrm{f} + xv_\mathrm{fg} \qquad [15.4.6]$$

where subscripts f and fg indicate the liquid and the liquid–vapour transition, respectively.

Equation 15.4.2 for the energy balance can be written as

$$G = \frac{[2(h_\mathrm{o} - h)]^{1/2}}{v} \qquad [15.4.7]$$

But

$$h_\mathrm{o} - h = -\int_{P_\mathrm{o}}^{P} v\,\mathrm{d}P \qquad [15.4.8]$$

Then from Equations 15.4.7 and 15.4.8

$$G = \frac{(-2\int_{P_\mathrm{o}}^{P} v\,\mathrm{d}P)^{1/2}}{v} \qquad [15.4.9]$$

In order to solve Equation 15.4.9, use is made of an equation of state proposed by M. Epstein *et al.* (1983) for isentropic expansion from (all) liquid stagnation conditions:

$$\frac{v}{v_\mathrm{fo}} = \omega\left(\frac{P_\mathrm{o}}{P} - 1\right) + 1 \qquad [15.4.10]$$

where ω is a parameter. Grolmes and Leung (1984) utilized Equation 15.4.10 to obtain the flow through a nozzle for an all liquid inlet condition.

For isentropic expansion, the correlating parameter ω in Equation 15.4.10 is

$$\omega = \frac{C_\mathrm{fo}T_\mathrm{o}P_\mathrm{o}}{v_\mathrm{fo}}\left(\frac{v_\mathrm{fgo}}{h_\mathrm{fgo}}\right)^2 \qquad [15.4.11]$$

where C_f is the specific heat of the liquid and T is the absolute temperature.

The critical mass velocity G_c is

$$G_\mathrm{c} = \eta_\mathrm{c}\left(\frac{P_\mathrm{o}}{\omega v_\mathrm{fo}}\right)^{1/2} \qquad [15.4.12]$$

where η_c is the critical pressure ratio. The pressure ratio η is defined as

$$\eta = \frac{P}{P_\mathrm{o}} \qquad [15.4.13]$$

The critical pressure ratio η_c was found to be the value of η satisfying the relation

$$\eta^2 + (\omega^2 - 2\omega)(1-\eta)^2 + 2\omega^2\ln\eta + 2\omega^2(1-\eta) = 0 \qquad [15.4.14]$$

Further, for the all liquid inlet condition

$$\omega = \frac{P_\mathrm{o}}{v_\mathrm{fo}G_\mathrm{lm}^2} \qquad [15.4.15]$$

and hence from Equations 15.4.11 and 15.4.15

$$G_\mathrm{lm} = \left(\frac{1}{C_\mathrm{fo}T_\mathrm{o}}\right)^{1/2}\frac{h_\mathrm{fgo}}{v_\mathrm{fgo}} \qquad [15.4.16]$$

where G_lm is the mass velocity at this limiting condition. Starting from these relations, Leung extends the treatment to the case of a two-phase inlet condition. Equation 15.4.10 becomes

$$\frac{v}{v_\mathrm{o}} = \omega\left(\frac{P_\mathrm{o}}{P} - 1\right) + 1 \qquad [15.4.17]$$

which is also given as

$$\omega = \frac{(v/v_\mathrm{o} - 1)}{(P_\mathrm{o}/P - 1)} \qquad [15.4.18]$$

and Equation 15.4.12 becomes

$$G_\mathrm{c} = \eta_\mathrm{c}\left(\frac{P_\mathrm{o}}{\omega v_\mathrm{o}}\right)^{1/2} \qquad [15.4.19]$$

Introducing a dimensionless mass velocity G^*

$$G^* = \frac{G}{(P_\mathrm{o}/v_\mathrm{o})^{1/2}} \qquad [15.4.20]$$

the critical value G_c^* becomes

$$G_\mathrm{c}^* = \frac{G_\mathrm{c}}{(P_\mathrm{o}/v_\mathrm{o})^{1/2}} \qquad [15.4.21]$$

At this point, the assumption is made that the process is isenthalpic. This approximation allows ω to be expressed more readily in terms of the stagnation properties. The relations for the specific enthalpy, specific entropy and specific volumes are:

$$h_o = h_{fo} + x_o h_{fgo} \qquad [15.4.22]$$

$$s_o = s_{fo} + x_o s_{fgo} \qquad [15.4.23]$$

$$v_o = v_{fo} + x_o v_{fgo} \qquad [15.4.24]$$

where x is the mass fraction of the vapour.

It is shown that with the isenthalpic assumption and certain other approximations:

$$\omega = \frac{x_o v_{fgo}}{v_o} + \frac{C_{fo} T_o P_o}{v_o}\left(\frac{v_{fgo}}{h_{fgo}}\right)^2 \qquad [15.4.25]$$

Starting from Equation 15.4.19 and utilizing data for two-phase flow of water and nine other fluids, Leung obtains the following empirical correlation:

$$\frac{G_c}{(P_o/v_o)^{1/2}} = \frac{\eta_c}{\omega^{0.5}} \quad \omega > 4.0 \qquad [15.4.26a]$$

$$= \frac{0.66}{\omega^{0.39}} \quad \omega < 4.0 \qquad [15.4.26b]$$

The critical pressure ratio η_c was found to be the value of η satisfying the following relations. For a stagnation pressure of $P_o = 5$ bara (absolute bar)

$$\eta = 0.6055 + 0.1356 \ln\omega - 0.131(\ln\omega)^2 \qquad [15.4.27]$$

and for $P_o = 15$ bara (absolute bar)

$$\eta = 0.55 + 0.217 \ln\omega - 0.046(\ln\omega)^2 + 0.004(\ln\omega)^3 \qquad [15.4.28]$$

This correlation was found to apply up to a reduced temperature $T_r = 0.9$ and reduced pressure $P_r = 0.5$.

The most general formulation of the parameter ω is:

$$\omega = \alpha_o + (1 - \alpha_o) p_{fo} C_{fo} T_o P_o \left(\frac{v_{fgo}}{h_{fgo}}\right)^2 \qquad [15.4.29]$$

where α is the void fraction. For the all liquid condition $\alpha_o = 0$, and for the all vapour condition $\alpha_o = 1$. The parameter ω takes the following values:

$x_o = 1 \quad \alpha_o = 1$ all vapour $\omega = 1$
$0 < x_o < 1 \quad \alpha_o < 1$ but flashing $\omega > 1$
$0 < x_o < 1 \quad \alpha_o < 1$ but non-flashing $\omega = \alpha_o < 1$

The larger the value of ω, the greater the increase in specific volume upon depressurization and the more readily the flow attains the choking condition.

15.4.2 Flow through a pipe

The case of flow through a horizontal pipe as opposed to a nozzle has been treated by Leung and Grolmes (1987–), whilst Leung and Epstein (1990a) have considered flow through a pipe inclined upwards. The results of this work have been summarized by Leung (1990a).

For the inclined pipe, use is made of the flow inclination number Fi defined as:

$$\mathrm{Fi} = \frac{gD\cos\theta}{4fP_o v_o} \qquad [15.4.30]$$

where g is the acceleration due to gravity and θ is the angle between the pipe axis and the vertical.

Figure 15.14 shows the ratio G/G_o of the mass velocity through a pipe G to that through a nozzle G_o, or flow reduction factor. Figure 15.14(a) is for a horizontal pipe ($\mathrm{Fi} = 0$) and Figure 15.14(b) for an inclined pipe with $\mathrm{Fi} = 0.1$.

For the case of all liquid inlet flow ($\omega = 0$):

$$\frac{G}{G_o} = \left(\frac{1 - N\mathrm{Fi}}{1 + N}\right)^{1/2} \qquad [15.4.31a]$$

$$= \frac{1}{(1 + N)^{1/2}} \quad \mathrm{Fi} = 0 \text{ (horizontal pipe)} \qquad [15.4.31b]$$

$$\rightarrow 0 \quad N\mathrm{Fi} = 1 \qquad [15.4.31c]$$

with

$$N = 4f\frac{L}{D} \qquad [15.4.32]$$

where N is the pipe resistance factor.

15.4.3 Subcooled liquids

The case of flashing critical flow of an initially subcooled liquid is considered by Leung and Grolmes (1988). A more general relation which applies to such flow as well as flow of an initially two-phase mixture is

$$G^* = \frac{G}{(P_o/v_o)^{1/2}} = \frac{\{2(1 - \eta_s) + 2[\omega\eta_s \ln(\eta_s/\eta) - (\omega - 1)(\eta_s - \eta)]\}^{1/2}}{\omega((\eta_s/\eta) - 1) + 1} \qquad [15.4.33]$$

with

$$\eta_s = \frac{P_s}{P_o} \qquad [15.4.34]$$

where the subscript s denotes saturation.

Setting $\mathrm{d}G^*/\mathrm{d}\eta = 0$ gives for the critical mass velocity

$$G_c^* = \frac{\eta_c}{(\omega\eta_s)^{1/2}} \qquad [15.4.35]$$

The flow behaviour depends on the degree of subcooling. The critical value η_{sc} separating the two regimes is

$$\eta_{sc} = \frac{2\omega - 1}{2\omega} \qquad [15.4.36]$$

For low subcooling ($\eta_s \geq \eta_{sc}$), the fluid attains flashing before reaching the choked location. For high subcooling

$$\eta_c = \eta_s \qquad [15.4.37]$$

$$G_c^* = [2(1 - \eta_s)]^{1/2} \qquad [15.4.38]$$

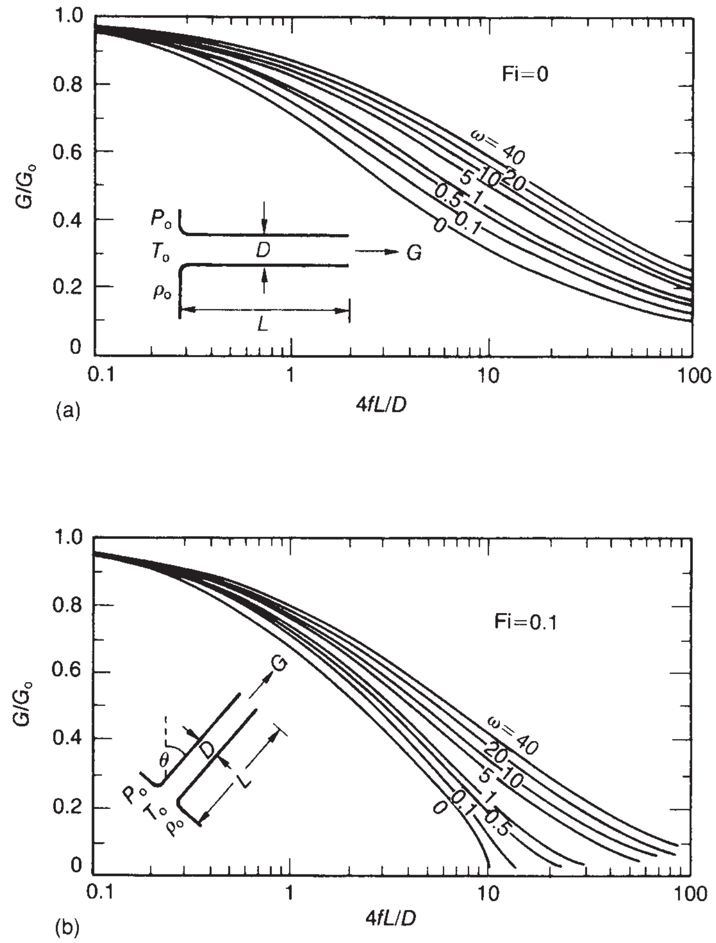

Figure 15.14 Leung homogeneous equilbrium flow model: critical flow for discharge through a pipe (Leung, 1990a): (a) horizontal pipe; and (b) inclined pipe Fi = 0.1 (Courtesy of the American Institute of Chemical Engineers)

or, from a relation similar to Equation 15.4.21 but with v_{fo} instead of v_o,

$$G_c = [2\rho_{fo}(P_o - P_s)]^{1/2} \qquad [15.4.39]$$

which is the usual equation for liquid flow through an orifice.

15.4.4 Subcritical flow

The case of flashing subcritical flow is treated by Leung (1992a). A more general relation which applies to such flow as well as critical flow is

$$G^* = \frac{G}{(P_o/v_o)^{1/2}} = \frac{\{-2[\omega \ln \eta + (\omega - 1)(1 - \eta)]\}^{1/2}}{\omega(1/\eta - 1) + 1} \qquad [15.4.40]$$

Setting $dG^*/d\eta = 0$ gives for the critical mass velocity

$$G_c^* = \frac{\eta_c}{\omega^{1/2}} \qquad [15.4.41]$$

15.4.5 Non-flashing flow

The case of non-flashing critical flow has been dealt with by Leung and Epstein (1990b). Non-flashing two-phase flow is exemplified by two-phase flow of a two-component mixture such as air and water. A comparison of flashing and non-flashing flows is given by Leung (1990a).

Figure 15.15 shows the correlation given by Leung (1990a) for the dimensionless mass velocity G_c^* and the critical pressure ratio η_c in two-phase critical flow in both the flashing and non-flashing regimes.

15.5 Vessel Depressurization

Some of the most complex fluid flow problems arise in the depressurization or venting of vessels, particularly reactors and storage vessels. In order to specify the venting arrangements for a vessel, it is necessary to determine the flow, the phase condition of fluid and the vent area required for this flow. The venting of vessels is complicated by the fact that in many situations the flow is likely to be two-phase. It is necessary therefore, to be able both to estimate

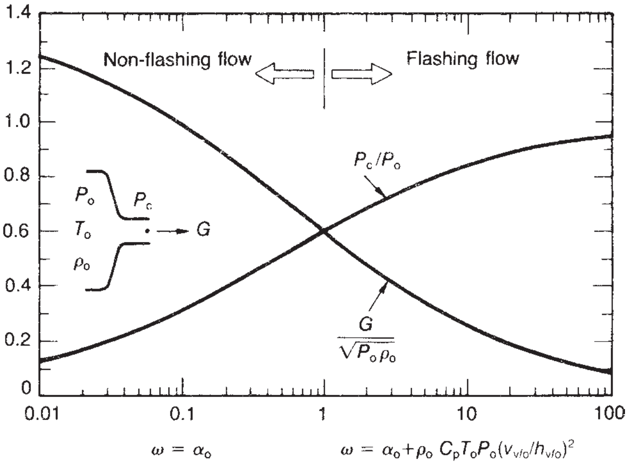

Figure 15.15 *Leung homogeneous equilibrium flow model: critical flow for discharge through a frictionless nozzle (Leung, 1990a) (Courtesy of the American Institute of Chemical Engineers)*

the vapour mass fraction, or quality, of the fluid entering the vent and the flow through the vent.

The need to determine the quality of the fluid vented has been highlighted during the work of the DIERS project. The quality of the fluid entering the vent is determined by liquid swell and vapour disengagement. There are two principal regimes that are recognized as occurring when a vessel is depressurized. If the liquid is non-foaming the regime tends to be churn turbulent, whereas if it is foaming the regime is bubbly.

For a non-foaming liquid, methods have been developed to predict the onset of two-phase flow. In the depressurization of a vessel containing such a liquid there will, in general, be a region in which the flow is all vapour and another region in which it is two-phase. A large initial vapour space, or freeboard, will favour all vapour flow. For a foaming liquid it is necessary to assume two-phase flow. Broadly, a pure liquid held in a storage vessel may well be non-foaming. It is to this situation that the methods developed principally apply.

An otherwise non-foaming liquid may be rendered foaming by the presence of impurities. Quite small quantities of a surface active agent may suffice to effect this. Since impurities are likely to be present in the liquid in a reactor, it is usual to treat a reaction mass as foaming.

In this section an account is given of models of liquid swell and vapour disengagement. Models have been given in the DIERS Technical Summary and by Fauske, Grolmes and Henry (1983), Swift (1984) and Grolmes and Epstein (1985). The application of these models to venting, particularly of storage vessels, is described in Chapter 17.

15.5.1 Liquid swell

Depressurization of a vessel containing superheated liquid or addition of heat to liquid in a vessel gives rise to the formation of vapour bubbles, which results in liquid swell. If this is severe, the level of the swollen liquid may reach the vent. But even if this is not so, there may be carryover of droplets into the vent. Liquid swell and vapour disengagement therefore affect the vapour mass fraction entering the vent. Some of the flow regimes that can occur on operation of the relief are shown in Figure 15.16.

For a liquid subject to swell, the average void fraction is

$$\bar{\alpha} = 1 - \frac{H_o}{H} \qquad [15.5.1]$$

with

$$H_o = \frac{V_l}{A_x} \qquad [15.5.2]$$

where A_x is the cross-sectional area of the vessel (m^2), H is the height of the liquid (m), H_o is the height of the liquid without swell (m), V_l is the volume of the liquid (m^3) and $\bar{\alpha}$ the average void fraction. A distinction is made between the average void fraction $\bar{\alpha}$ and the local void fraction α.

The initial void fraction in the vessel, or freeboard, α_o is

$$\alpha_o = 1 - \frac{H_o}{H_x} \qquad [15.5.3]$$

where H_x is the height of the vessel (m).

15.5.2 Gas or vapour generation

Gas or vapour may be present in the liquid because gas is injected into the liquid or because gas or vapour is generated in the liquid, due either to exothermic reaction or to an external heat source. The first case is that of uniform flux (UF) and the second that of a uniform volumetric source (VS). It is the latter that is of principal interest here.

The vapour superficial velocity above the height of the swelled liquid is

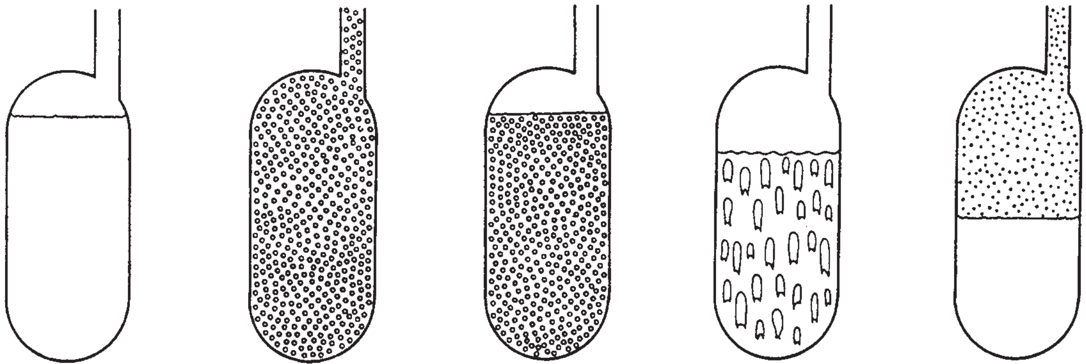
$$j_{g\infty} = \frac{S}{A_x} \qquad [15.5.4]$$

where j_g $\alpha$is the vapour superficial velocity (m/s) and S is the volumetric source strength (m^3/s).

A dimensionless source strength ψ is defined as

$$\psi = \frac{j_{g\infty}}{U_\infty} \qquad [15.5.5]$$

where U_∞ is the bubble rise velocity (m/s). The parameter ψ is also referred to as the 'dimensionless velocity'.



(a) Gas flow

(b) Two-phase flow

(c) Bubbly flow

(d) Churn turbulent flow

(e) Droplet flow

Figure 15.16 *Some flow regimes in venting of vessels (Swift, 1984) (Courtesy of the Institution of Chemical Engineers)*

The volumetric source strength is a function of the heat input. For an external heat source

$$q = \frac{FQ_{\mathrm{ex}}}{\rho_{\mathrm{l}} D} \qquad [15.5.6]$$

where D is the vessel diameter (m), q is the heat input per unit mass (kW/kg), Q_{ex} is the external heat input flux (kW/m^2), ρ_{l} is the density of the liquid (kg/m^3) and F is a geometric factor. For the geometric factor F the *Technical Summary* gives for a sphere $F = 6$, for a vertical cylinder $F = 4$ and for a horizontal cylinder with hemispherical ends $F = (L/D + 1)/(3L/D + 2)$, where L/D is the length/diameter ratio.

15.5.3 Drift flux

A drift flux model for the behaviour of the liquid in a vessel subject to vapour generation has been described in the *Technical Summary*. The concept of drift flux has been described in work by Zuber and Findlay (1965) and Wallis (1969). The local gas and liquid superficial velocities are:

$$j_{\mathrm{g}} = \alpha U_{\mathrm{g}} \qquad [15.5.7]$$

$$j_{\mathrm{l}} = (1 - \alpha) U_{\mathrm{l}} \qquad [15.5.8]$$

$$j = j_{\mathrm{g}} + j_{\mathrm{l}} \qquad [15.5.9]$$

where j is the total volume flux, or superficial velocity (m/s), j_{g} is the superficial gas velocity (m/s), j_{l} is the superficial liquid velocity (m/s), U_{g} is the area average gas velocity (m/s), and U_{l} is the area average liquid velocity (m/s).

From these relations is derived the expression for the drift flux:

$$j_{\mathrm{gl}} = j_{\mathrm{g}}(1 - \alpha) - \alpha j_{\mathrm{l}} \qquad [15.5.10]$$

where j_{gl} is the superficial drift velocity, or drift flux (m/s).

It has been shown by Wallis that the drift flux j_{gl} can be expressed as a function of the bubble rise velocity U_∞. The particular relation adopted in the *Technical Summary* differs slightly from that of Wallis and is

$$j_{\mathrm{gl}} = \frac{\alpha(1 - \alpha)^n U_\infty}{1 - \alpha^m} \qquad [15.5.11]$$

where U_∞ is the bubble velocity (m/s) and m and n are indices. The velocity U_∞ is also variously termed the 'particle velocity' and the 'characteristic velocity'. The bubble velocity is given by

$$U_\infty = \frac{k[\sigma g(\rho_{\mathrm{l}} - \rho_{\mathrm{g}})]^{1/4}}{\rho_{\mathrm{c}}^{1/2}} \qquad [15.5.12]$$

where $U\rho$ is the density (kg/m^3), σ is the surface tension of the liquid (N/m), k is a constant, and subscript c denotes the continuous phase.

The values of the indices m and n and of the constant k depend on the regime as follows:

	n	m	k
Bubbly regime	2	3	1.18
Churn turbulent regime	0	$\to \infty$	1.53

Substituting these values in Equation 15.5.11 gives

$$j_{\mathrm{gl}} = \frac{\alpha(1 - \alpha)^2}{1 - \alpha^3} U_\infty \quad \text{bubbly regime} \qquad [15.5.13]$$

$$j_{\mathrm{gl}} = \alpha U_\infty \quad \text{churn turbulent regime} \qquad [15.5.14]$$

A further drift flux is defined j_{lg}, complementary to j_{gl}, such that

$$j_{\mathrm{gl}} + j_{\mathrm{lg}} = 0 \qquad [15.5.15]$$

The two drift fluxes are given by

$$j_{\mathrm{gl}} = \alpha(1 - \alpha)(U_{\mathrm{g}} - U_{\mathrm{l}}) \qquad [15.5.16a]$$

$$j_{\mathrm{lg}} = -\alpha(1 - \alpha)(U_{\mathrm{g}} - U_{\mathrm{l}}) \qquad [15.5.16b]$$

where j_{lg} is the superficial drift velocity of the liquid phase relative to the gas phase (m/s).

The foregoing treatment does not take account of the radial distribution of the void fraction. In order to obtain better correlations Zuber and Findlay (1965) introduced the distribution parameter C_{o}. Equation 15.5.10 for the drift flux then becomes

$$j_{\mathrm{gl}} = (1 - C_{\mathrm{o}}\alpha) j_{\mathrm{g}} - C_{\mathrm{o}}\alpha j_{\mathrm{l}} \qquad [15.5.17]$$

For the case of no radial void distribution C_o is unity. In general, the value of C_o used tends to lie in the range 1.0–1.5. For C_o a best estimate is 1.2 and 1.5 for the bubbly and churn turbulent regimes, respectively, and a conservative estimate is 1.0 for both regimes.

This drift flux model is now applied to three situations: (1) an open system with a uniform gas injection flow, (2) an open system with uniform volumetric gas generation and (3) a closed system with a uniform volumetric gas generation.

15.5.4 Superficial velocity: open system with uniform injection flow

For an open system with uniform gas injection at the bottom of the vessel, the steady state condition is $j_l = 0$ and Equation 15.5.17 with Equation 15.5.11 then gives

$$j_g = \frac{\alpha(1-\alpha)^n U_\infty}{(1-\alpha^m)(1-C_o\alpha)} \qquad [15.5.18]$$

But, since the gas flow is constant throughout the height, $j_g = j_{g\infty}$, and hence from Equation 15.5.5:

$$\psi = \frac{\alpha(1-\alpha)^n}{(1-\alpha^m)(1-C_o\alpha)} \qquad [15.5.19]$$

Then for the two regimes

$$\psi = \frac{\alpha(1-\alpha)^2}{(1-\alpha^3)(1-C_o\alpha)} \quad \text{bubbly regime} \qquad [15.5.20]$$

$$\psi = \frac{\alpha}{1-C_o\alpha} \quad \text{churn turbulent regime} \qquad [15.5.21a]$$

$$\psi \to \alpha \quad \text{churn turbulent regime; } \alpha \ll 1 \qquad [15.5.21b]$$

15.5.5 Superficial velocity: open system with uniform volume source

For an open system with uniform volumetric gas generation throughout the liquid, the vapour flux varies with height. The energy balance is:

$$\rho_g h_{fg} dj_g = q\rho_l(1-\alpha)\, dH \qquad [15.5.22]$$

where h_{fg} is the latent heat of vaporization (kJ/kg). Limiting the treatment to the churn turbulent regime, differentiation of Equation 15.5.18 with respect to α and combination with Equation 15.5.22 yields

$$\psi \frac{dH^*}{d\alpha} = (1-\alpha)^{-3} \qquad [15.5.23]$$

with

$$H^* = H/H_o \qquad [15.5.24]$$

$$\psi = \frac{q(\rho_l/\rho_g - 1)H_o}{h_{fg}U_\infty} \qquad [15.5.25]$$

where H^* is the dimensionless liquid height. Equation 15.5.23 may then be integrated:

$$\psi H^* = \int_0^\alpha (1-\alpha)^{-3}\, d\alpha \qquad [15.5.26]$$

Two successive integrations are then performed. The first gives α as a function of H^*:

$$\alpha = 1 - (1 + 2\psi H^*)^{-1/2} \qquad [15.5.27]$$

The second gives α as a function of H^*, subject to the condition

$$H^*_{\max} = 1/(1-\bar{\alpha}) \qquad [15.5.28]$$

This second integration yields

$$\bar{\alpha} = \frac{\psi}{2+\psi} \qquad [15.5.29a]$$

or

$$\psi = \frac{2\bar{\alpha}}{1-\bar{\alpha}} \qquad [15.5.29b]$$

Introducing the distribution parameter C_o, Equation 15.5.29 becomes

$$\bar{\alpha} = \frac{\psi}{2+C_o\psi} \qquad [15.5.30a]$$

$$\psi = \frac{2\bar{\alpha}}{1-C_o\bar{\alpha}} \qquad [15.5.30b]$$

The corresponding equation for bubbly flow is

$$\psi = \frac{\bar{\alpha}(1-\bar{\alpha})^2}{(1-\bar{\alpha}^3)(1-C_o\bar{\alpha})} \qquad [15.5.31]$$

15.5.6. Superficial velocity: closed system with uniform volume source

The case of a closed system is also relevant, since it represents the condition just before the relief device operates. It is used for the analysis of transient conditions. For this case j_l is not equal to zero.

For a closed system with uniform volumetric gas generation throughout the liquid, the treatment is as follows. Continuity of flow gives:

$$j_l = aj_g \qquad [15.5.32]$$

with

$$a = \frac{1-x_e}{(\rho_l/\rho_g)^{x_e}} \qquad [15.5.33]$$

where a is a parameter and x_e is the mass fraction of vapour at the vent. Then from Equations 15.5.11, 15.5.17 and 15.5.32:

$$j_g = \frac{\epsilon\lambda U_\infty}{1-C_o\lambda a} \qquad [15.5.34]$$

with

$$\epsilon = \frac{(1-\alpha)^n}{1-\alpha^m} \qquad [15.5.35]$$

$$\lambda = \frac{\alpha}{1-C_o\alpha} \qquad [15.5.36]$$

where ϵ and λ are parameters.

For the two regimes, the values of the parameters, α, ϵ and λ are as follows. For the bubbly regime:

$$\alpha = \bar{\alpha} \qquad [15.5.37]$$

$$\epsilon = \frac{(1-\alpha)^2}{1-\alpha^3} \qquad [15.5.38]$$

$$\lambda = \frac{\bar{\alpha}}{1+C_o\bar{\alpha}} \qquad [15.5.39]$$

For the churn turbulent regime:

$$\alpha = \frac{2\bar{\alpha}}{1+C_o\bar{\alpha}} \qquad [15.5.40]$$

$$\epsilon = 1 \qquad [15.5.41]$$

$$\lambda = \frac{2\bar{\alpha}}{1-C_o\bar{\alpha}} \qquad [15.5.42]$$

A mass balance on the vapour at the vent gives:

$$j_g = \frac{Gx_e\Omega}{\rho_g} \qquad [15.5.43]$$

with

$$\Omega = A/A_x \qquad [15.5.44]$$

where A is the area of the vent (m^2) and Ω is the ratio of the vessel area to the vent area. Then from Equations 15.5.34–15.5.43:

$$\frac{Gx_e\Omega}{U_\infty\rho_g} = \frac{\epsilon\lambda}{1-C_o\lambda a} \qquad [15.5.45]$$

Equation 15.5.45 provides an expression coupling between the vessel and the vent line description. As described by Grolmes and Leung (1985), it is used for this purpose in numerical models of vessel venting.

The value of ψ at the all vapour flow condition with $x_e = 1$ may be obtained as follows. Noting that Equation 15.5.43 is for the vent point and hence $j_g = j_{g\infty}$, then Equations 15.5.43 and 15.5.5 give

$$\psi = \frac{G\Omega}{U_\infty\rho_g} \qquad [15.5.46]$$

15.5.7 Vapour generation by external heat

From Equations 15.5.3, 15.5.6 and 15.5.25 it may be shown that for an externally heated vessel

$$\psi = \frac{FQ_{ex}(1-\alpha_o)H_x}{U_\infty h_{fg}\rho_g D} \qquad [15.5.47]$$

15.5.8 Criterion for two-phase flow

These relations may be used to indicate the boundary between all vapour venting and two-phase venting. The criterion for two-phase flow into the vent is that the average void fraction is greater than the vessel freeboard

$$\bar{\alpha} > \alpha_o \qquad [15.5.48]$$

The value of the average void fraction $\bar{\alpha}$ for use in relation 15.5.48 is obtained as follows. The actual value of the dimensionless velocity ψ is determined from the appropriate equation. The corresponding value of $\bar{\alpha}$ is then determined from the appropriate relation between ψ and $\bar{\alpha}$. For example, for an externally heated vessel with a churn turbulent regime, Equation 15.5.47 gives ψ and Equation 15.5.30a the corresponding value of $\bar{\alpha}$.

Alternatively, the criterion for two-phase flow to occur may be formulated in terms of the dimensionless velocity ψ. The criterion is then

$$\psi(\bar{\alpha}) > \psi(\alpha_o) \qquad [15.5.49]$$

For example, for the externally heated vessel with churn turbulent regime ($\bar{\alpha}$) is obtained as before from Equation 15.5.47 $\psi(\alpha_o)$ and from Equation 15.5.30b with α_o instead of $\bar{\alpha}$.

15.5.9 Criterion for two-phase flow: illustrative example

An illustrative example of the determination of the quality of the vapour entering the vent is given in Table 15.6. The case considered is a vertical cylindrical vessel with external heating. The calculation shows that the flow entering the vent is two-phase.

15.5.10 Vapour carryunder

A model based on vapour carryunder has been developed and applied to an externally heated vessel by Grolmes and Epstein (1985). A dimensionless heat flux J_o is defined as

$$J_o = \frac{Q_{ex}}{U_\infty h_{fg}\rho_g} \qquad [15.5.50]$$

The external heating at the vessel walls creates a boiling two-phase boundary layer in the liquid which generates vapour bubbles that rise. This rise is balanced by liquid downflow in the centre of the vessel, which creates the potential for vapour carryunder. Vapour carryunder is assumed to occur if the downward recirculating velocity U_c exceeds the bubble rise velocity U_∞. The conditions which can occur are shown in Figure 15.17, where Figure 15.17(a) shows no vapour carryunder ($U_c < U_\infty$ throughout) and Figure 15.17(b) shows vapour carryunder to a level H_{BL} (where $U_c = U_\infty$).

The downward liquid recirculating velocity U_c is related to the upward liquid superficial velocity U_s, evidently the same as the bubble rise velocity U_∞, by a geometric factor ϵ:

$$U_c = \epsilon U_s \qquad [15.5.51]$$

The geometric factor ϵ is the ratio of the area for downward recirculation flow to the boundary layer area for upward flow. It is a function of the boundary layer thickness $\delta(H)$ measured at the height H of the liquid, which itself is a function of the heat flux:

$$\epsilon = f[\delta(H)] \qquad [15.5.52]$$

$$\delta(H) = f(J_o) \qquad [15.5.53]$$

The interface height H_{BL} below which there is no vapour carryunder is determined as the height at which $U_c = U_s$ or $\epsilon = 1$.

Table 15.6 *Illustrative calculation for occurrence of two-phase flow of fluid entering the vent of an externally heated storage vessel*

A Scenario

Liquid density, $\rho_l = 750\ \mathrm{kg/m^3}$
Vapour density, $\rho_g = 4.5\ \mathrm{kg/m^3}$
Latent heat of vaporization, $h_{fg} = 900\ \mathrm{kJ/Kg}$
Surface tension, $\sigma = 0.02\ \mathrm{N/m}$
Vessel type: vertical cylindrical
Vessel diameter, $D = 1.0\ \mathrm{m}$
Vessel height, $H_x = 2.0\ \mathrm{m}$
Vessel freeboard, $\alpha_o = 0.16$
Vessel geometric factor, $F = 4$
External heat input, $Q_{ex} = 60\ \mathrm{kJ\ W/m^2}$
Vessel regime: churn turbulent
$k = 1.53$
$C_o = 1$

B Fluid phase

From Equation 15.5.12:
$U_\infty = 1.53[0.02 \times 9.81(750 - 4.5)]^{1/4}/750^{1/2} = 0.19\ \mathrm{m/s}$
From Equation 15.5.47

$$\psi = \frac{4 \times 60(1 - 0.16) \times 2.0}{0.19 \times 900 \times 4.5 \times 1.0} = 0.51$$

From Equation 15.5.5

$j_{g\infty} = 0.51 \times 0.19 = 1.097\ \mathrm{m/s}$

From Equation 15.5.29a

$$\bar{\alpha} = \frac{0.51}{2 + 0.51} = 0.20$$

But

$\alpha_o = 0.16$

Hence $\bar{\alpha} > \alpha_o$, indicating that flow entering vent is two phase. Alternatively, from Equation 15.5.29b with α_o instead of $\bar{\alpha}$:

$$\psi(\alpha_o) = \frac{2 \times 0.16}{1 - 0.16} = 0.38$$

Hence $\psi(\bar{\alpha}) > \psi(\alpha_o)$, again indicating that flow entering vent is two phase.

The authors give a graphical relation of the form

$$U_s = f(J_o, z) \qquad [15.5.54]$$

where z is the height (m). Using this relation, the height H_{BL} can be determined.

Using this model, the authors derive the following results for the fraction H_{BL}/H of vessel height where there is no vapour carryunder:

Heat flux, J_o	*Vessel diameter* (m)			
	0.61	1.52	3.05	6.1
0.310	0.41	0.32	0.26	0.22
0.062	0.62	0.48	0.39	0.33
0.006	1	0.86	0.69	0.58

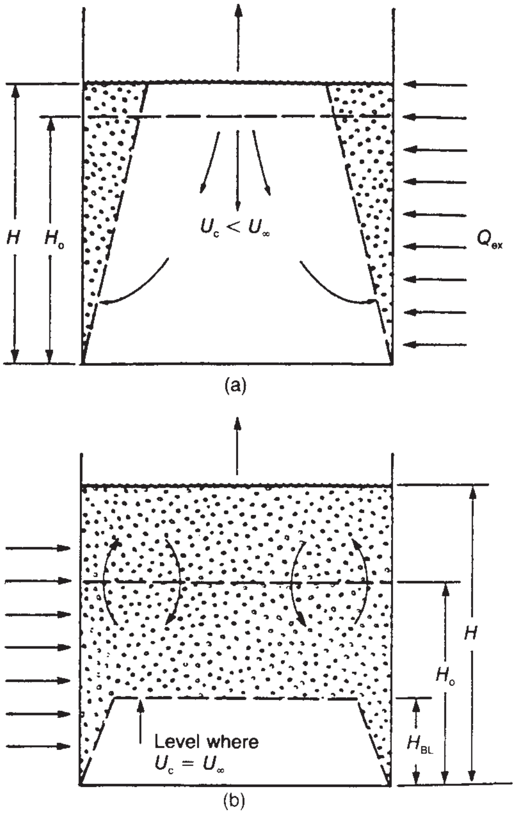


Figure 15.17 *Vapour carryunder in venting of a vessel (Grolmes and Epstein, 1985): (a) case where the recirculating liquid velocity U_c is less than the bubble rise velocity U_∞ throughout the vessel; and (b) case where the recirculating liquid velocity U_c is not less than the bubble rise velocity U_∞ throughout the vessel (Courtesy of the American Institute of Chemical Engineers)*

The results show that the proportion of the liquid subject to vapour carryunder increases with heat flux and with vessel size. Thus large vessels are more prone than small ones to vapour carryunder.

The potential significance of these models for large atmospheric storage tanks is discussed by Fauske *et al.* (1986). Assuming that vapour carryunder could cause sufficient liquid swell to give a two-phase mixture at the vent inlet, then since in such tanks the permissible overpressure is very low, the ratio of the vent area required for two-phase flow to that for all vapour flow is, to first order, proportional to $(\rho_g/\rho_l)^{1/2}$, which implies augmentation by a factor of 10–30.

The authors suggest, however, that while vapour carryunder is possible hydrodynamically, the vapour bubbles will in fact tend to collapse as they are carried down into liquid, the subcooling of which increases with depth, and state that, to first order, liquid swell is determined by the boiling two-phase boundary layer without vapour carryunder.

They describe experimental work on the measurement of liquid swell in vessels heated externally. The measured liquid swells agree well with those predicted neglecting vapour carryunder. They suggest, therefore, that in the sizing of vents for atmospheric storage tanks for liquids that are not highly viscous or foaming, the assumption of all vapour flow will normally be valid.

For reactors, the situation is quite different, as discussed by Fauske (1985a). He states that it is a hopeless task to seek to generalize the results just described to reacting systems, or indeed to any system with traces of impurities. For such systems, the appropriate assumption is that there will be two-phase homogeneous flow at the vent inlet.

15.6 Pressure Relief Valves

As components of a pressure system, pressure relief valves have been treated in Chapter 12. In this section some further consideration is given in respect of the flow through such devices. Dispersion of the discharge is considered in Section 15.20 and, for dense gases in Section 15.43.

15.6.1 Single-phase flow

Relations for single-phase flow of gases and liquids have been presented in Section 15.1. Formulae derived from these are given in the codes for pressure relief. The API and BS formulae are stated in Chapter 12.

15.6.2 Two-phase flow

Two-phase vapour–liquid flow has been discussed in Sections 15.2–15.4, from which it will be apparent that this is a much more complex topic. The various models for two-phase flow do not lend themselves to formulae for calculating the area of the pressure relief valve orifice that are comparable in simplicity with those for single-phase flow. Moreover, with two-phase flow the determination of the flow through the valve orifice by no means exhausts the problem. The flows in the inlet and outlet lines are also complex.

The treatment here deals primarily with flow through the valve orifice and is confined to an account of the widely used American Petroleum Institute (API) method and of a method given by Leung which has gained some acceptance, together with a overview of the wider aspects of the design.

15.6.3 Two-phase flow: API method

API RP 520 Part 1: 1990 gives the following method for sizing a two-phase gas–liquid relief. It describes the method as reasonably conservative. The method is to calculate separately the cross-sectional areas required for the vapour and the liquid flows. The quantity of vapour formed is determined by assuming an adiabatic, isenthalpic expansion from the relieving condition down to the critical downstream pressure or the back pressure, whichever is the greater. The area for the vapour flow is then obtained using the equations given for all vapour flow, supercritical or subcritical, as the case may be. Likewise, the area for liquid flow is obtained from the equation for liquid flow, taking as the downstream pressure the back pressure. The areas for vapour and for liquid flow are then summed to give the required area of the valve orifice. The valve selected will have an area greater than or equal to this required area. The quantity of vapour formed downstream of the orifice of the actual valve should then be rechecked.

Whilst this method is probably the most widely used, it is commonly criticized by workers in the field as lacking theoretical basis and experimental validation. Critiques of the API method have been given by Leung and Nazario (1989) and Leung (1992a).

15.6.4 Two-phase flow: Leung method

As described in Section 15.4, a comprehensive set of models for two-phase flow has been developed by Leung. These have been applied by the author to the problem of two-phase flow through a safety relief valve (Leung, 1992a).

The treatment described by Leung is essentially the application of his homogeneous equilibrium model (HEM) to the safety relief valve (SRV) design requirements of API RP 520: 1990 and RP 521: 1990. The equations used are a subset of those given in Section 15.4, based mainly on Leung (1986a). For clarity, this subset is given again here together with an explanation of their use in SRV system design and with the illustrative examples given by Leung.

In his method, Leung distinguishes four initial states of the liquid in the vessel:

(1) saturated liquid;
(2) two-phase gas–liquid mixture;
(3) subcooled liquid
 (a) low subcooling,
 (b) high subcooling.

Each of these cases is treated differently.

The model utilizes the parameter ω which determines the equation of state

$$\frac{v}{v_o} = \omega\left(\frac{P_o}{P} - 1\right) + 1 \qquad [15.6.1]$$

and is given by

$$\omega = \frac{x_o v_{go}}{v_o} + \frac{C_{fo} T_o P_o}{v_o}\left(\frac{v_{fgo}}{h_{fgo}}\right)^2 \qquad [15.6.2]$$

where C is the specific heat (J/kg K), h is the specific enthalpy (J/kg), P is the absolute pressure (Pa), T is the absolute temperature (K), v is the specific volume (m^3/kg), x is the mass fraction of vapour, and subscripts f, fg, g and o indicate the liquid, the liquid–vapour transition, the vapour and stagnation, respectively. The inlet void fraction α_o is

$$\alpha_o = \frac{x_o v_{go}}{v_o} \qquad [15.6.3]$$

The specific volume of the fluid is

$$v_o = x_o v_{go} + (1 - x_o) v_{fo} \qquad [15.6.4]$$

The following pressures are defined: P the pressure, P_b the back pressure at the orifice, P_c the critical pressure, P_o the stagnation pressure in the vessel and P_s the saturation pressure of the liquid (all pressures absolute in Pa). Subscripts 1 and 2 denote upstream and downstream ends of the outlet line, respectively. The corresponding pressure ratios are:

$$\eta = \frac{P}{P_o} \qquad [15.6.5]$$

$$\eta_c = \frac{P_c}{P_o} \qquad [15.6.6]$$

$$\eta_s = \frac{P_s}{P_o} \qquad [15.6.7]$$

where the subscripts c and s denote critical and saturation, respectively.

For the outlet line the following expression is used for the critical pressure at the downstream end:

$$P_{2c} = \frac{W_{act}}{A_2}\left(\frac{P_o\omega}{\rho_o}\right)^{1/2} \qquad [15.6.8]$$

where A_2 is the cross-sectional area of the outlet line (m^2), W is the mass flow (kg/s), ρ is the density (kg/m^3) and the subscript act indicates actual.

Saturated liquid

For the case where the inlet fluid condition is a saturated liquid, the vapour fraction $x_o = 0$.

A value of the parameter ω is calculated from Equation 15.6.2. This value is then used in the following equation to determine the critical pressure ratio η_c:

$$\eta_c^2 + (\omega^2 - 2\omega)(1 - \eta_c)^2 + 2\omega^2 \ln \eta_c + 2\omega^2(1 - \eta_c) = 0 \qquad [15.6.9]$$

From the value of η_c so obtained, the critical pressure P_c is calculated using Equation 15.6.6.

If $P_c < P_b$ the flow is not choked, and P is set equal to P_b. The mass flux is then calculated from the following equation:

$$\frac{G}{(P_o/v_o)^{1/2}} = \frac{(-2\{\omega \ln(P/P_o) + (\omega - 1)[1 - (P/P_o)]\})^{1/2}}{\omega(P_o/P - 1) + 1} \qquad [15.6.10]$$

where G is the mass velocity (kg/m^2 s). If $P_c > P_b$ the flow is choked and the mass flux may be obtained either from Equation 15.6.10 or from

$$\frac{G_c}{(P_o/v_o)^{1/2}} = \frac{\eta_c}{\omega^{1/2}} \qquad [15.6.11]$$

Two-phase mixture

For the case where the inlet fluid condition is a two-phase gas–liquid mixture, the vapour fraction x_o has a finite value. Otherwise the calculation procedure is essentially the same as for the case of a saturated liquid.

Subcooled liquid

For the case where the inlet fluid condition is a subcooled liquid, a distinction is made between a low degree of subcooling and high subcooling.

A form of the parameter ω appropriate to the saturated condition is defined as

$$\omega_s = \frac{C_{fo} T_o P_s}{v_{fo}}\left(\frac{v_{fgo}}{h_{fgo}}\right)^2 \qquad [15.6.12]$$

The condition for low subcooling is

$$\eta_s \geq \frac{2\omega_s}{1 + 2\omega_s} \qquad [15.6.13]$$

If the case is one of low subcooling, the fluid flashes in the throat.

The value of the parameter ω_s is then used to determine the critical pressure ratio η_c:

$$\frac{\omega_s + (1/\omega_s) - 2}{2\eta_s}\eta_c^2 - 2(\omega_s - 1)\eta_c + \omega_s\eta_s \ln\left(\frac{\eta_c}{\eta_s}\right) + \frac{3}{2}\omega_s\eta_s - 1 = 0 \qquad [15.6.14]$$

From the value of η_c so obtained, the critical pressure P_c is calculated using Equation 15.6.6.

The mass flux is calculated from the following equation:

$$\frac{G}{(P_o/v_{fo})^{1/2}} = \frac{\{2(1-\eta_s)+2[\omega_s\eta_s\ln(\eta_s/\eta)-(\omega_s-1)(\eta_s-\eta)]\}^{1/2}}{\omega_s(\eta_s/\eta-1)+1} \qquad [15.6.15]$$

As the condition of a saturated liquid is approached $P_o \rightarrow P_s$ and $\eta_s \rightarrow 1$, so that Equations 15.6.14 and 15.6.15 reduce to Equations 15.6.9 and 15.6.10.

If the case is one of high subcooling, no flashing occurs at the throat. The critical pressure ratio is

$$\eta_c = \frac{P_s}{P_o} \qquad [15.6.16]$$

and the critical pressure is the saturation pressure P_s.

The mass flux is given by Equation 15.6.15, which for this case reduces to

$$\frac{G_c}{(P_o/v_{fo})^{1/2}} = [2(1 - \eta_s)]^{1/2} \qquad [15.6.17]$$

or

$$G_c = [2\rho_{fo}(P_o - P_s)]^{1/2} \qquad [15.6.18]$$

This completes the set of expressions for the mass flow through the valve orifice. It remains to consider the valve sizing and selection and the effect of the inlet and outlet lines.

Valve sizing

The pressure relief requirement is specified as a required mass flow. The actual mass flux is obtained by the methods just described. The required area of the valve orifice is then

$$A_{req} = \frac{W_{req}}{KG_{act}} \qquad [15.6.19]$$

where A is the cross-sectional area of the valve (m^2), K is the valve discharge coefficient and the subscript req denotes required.

A valve size is then selected. Since, in general, this will have an orifice cross-sectional area slightly larger than that required, the actual mass flow will also be larger:

$$W_{act} = KA_{act}G_{act} \qquad [15.6.20]$$

It is this actual mass flow, which is used in the piping calculations which follow.

Inlet line

The treatment of the inlet and outlet piping conforms to the API requirements. For the inlet piping, these are that the piping be as short as possible with the recommendation that the line losses be limited to 3% of the gauge set pressure.

The pressure drop in the inlet line is determined from the equation

$$\Delta P_{\text{in}} = \frac{1}{2}\bar{v}_{\text{in}}\left(\frac{W_{\text{act}}}{A_{\text{in}}}\right)^2\left[4f\left(\frac{L_{\text{in}}}{D_{\text{in}}}\right)\right] + \frac{gH}{\bar{v}_{\text{in}}} \qquad [15.6.21]$$

where A_{in} is the cross-sectional area of the inlet pipe (m^2), D_{in} is the diameter of the inlet pipe (m), f is the Fanning friction factor, g is the acceleration due to gravity (m/s^2), H is the change in elevation (m), L_{in} is the length of the inlet pipe (m), ΔP_{in} is the total pressure difference across the inlet pipe (Pa) and $\bar{v}_{\text{in}}$ is the average specific volume in the inlet pipe (m^3/kg). The value of K is taken as 0.95.

The average specific volume in the inlet is evaluated at 0.98 of the stagnation pressure, so that

$$\bar{v}_{\text{in}} = v_{\text{fo}}\left[\omega\left(\frac{1}{0.98} - 1\right) + 1\right] \qquad [15.6.22]$$

However, if the liquid is subcooled and $P_{\text{s}}/P_{\text{o}} < 0.98$, then $v_{\text{in}} = v_{\text{fo}}$.

Outlet piping

For the outlet piping, a calculation is made to determine the maximum allowable length of the pipe. This is governed by the maximum allowable back pressure on the valve. This back pressure is specified by the SRV manufacturer and is typically 10% of the differential set pressure for unbalanced valves and up to 50% for balanced valves.

The maximum allowable length of the outlet line is determined from the equation

$$4f\left(\frac{L_2}{D_2}\right) = 2\frac{P_{\text{o}}\rho_{\text{o}}}{(W_{\text{act}}/A_2)^2}\left\{\frac{\eta_1-\eta_2}{1-\omega} - \frac{\omega}{(1-\omega)^2} \times \ln\left[\frac{(1-\omega)\eta_1+\omega}{(1-\omega)\eta_2+\omega}\right]\right\} + 2\ln\left[\frac{(1-\omega)-\eta_1+\omega}{(1-\omega)\eta_2+\omega}\left(\frac{\eta_2}{\eta_1}\right)\right] \qquad [15.6.23]$$

with

$$\eta_1 = \frac{P_1}{P_{\text{o}}} \qquad [15.6.24]$$

$$\eta_2 = \frac{P_2}{P_{\text{o}}} \qquad [15.6.25]$$

where D_2 is the diameter of the outlet pipe (m) and L_2 is the length of the outlet pipe (m).

Illustrative example

As an illustration of this method, consider the example given by Leung, which is the design of an SRV for the venting of liquefied ammonia. The example is given in two parts, Part A being the determination of the mass flux for the specified liquid condition and Part A the sizing of the valve itself and of the inlet and outlet lines.

Part A: mass flux

The initial, or stagnation, state of the liquid is

$P_{\text{o}} = 1 \times 10^6$ Pa
$T_{\text{o}} = 298$ K
$v_{\text{fo}} = 0.001658\ \text{m}^3/\text{kg}$
$v_{\text{go}} = 0.1285\ \text{m}^3/\text{kg}$
$v_{\text{fgo}} = 0.1268\ \text{m}^3/\text{kg}$
$C_{\text{fo}} = 4806$ J/kg K
$h_{\text{fgo}} = 1165430$ J/kg

The mass flux is calculated for two liquid conditions: (1) saturated liquid, $x_{\text{o}} = 0$; and (2) two-phase gas–liquid mixture, $x_{\text{o}} = 0.1$. The latter is included to illustrate how this liquid condition is tackled, but is not strictly relevant to the main problem.

Case 1: saturated liquid

$x_{\text{o}} = 0$
$v_{\text{o}} = 0.001658\ \text{m}^3/\text{kg}$
$\rho_{\text{o}} = 603\ \text{kg/m}^3$
$\alpha_{\text{o}} = 0$
$\omega = 10.2$ (from Equation 15.6.2)
$\eta_{\text{c}} = 0.85$ (from Equation 15.6.9)
$G_{\text{c}} = 6510\ \text{kg/m}^2\ \text{s}$ (from Equation 15.6.11)

Case 2: two-phase mixture

$x_{\text{o}} = 0.1$
$v_{\text{o}} = 0.014\,34\ \text{m}^3/\text{kg}$ (from Equation 15.6.4)
$\rho_{\text{o}} = 69.7\ \text{kg/m}^3$
$\alpha_{\text{o}} = 0.9$ (from Equation 15.6.3)
$\omega = 2.1$ (from Equation 15.6.2)
$\eta_{\text{c}} = 0.7$ (from Equation 15.6.9)
$G_{\text{c}} = 6010\ \text{kg/m}^2\ \text{s}$ (from Equation 15.6.11)

Part B: sizing of valve and piping

The pressures around the SRV are:

Atmospheric pressure = 0.101 MPa (a)
Backpressure = 0.0101 MPa (a)
Set pressure = 0.915 MPa (a) = 1.016 (g)
Differential set pressure = 0.915 − 0.101 = 0.814 MPa
Relieving pressure = 1.0 MPa (a)

The gauge relieving pressure is 110% of the differential set pressure ($1.1 \times 0.814 = 0.90$) and thus the absolute relieving pressure is 1.0 MPa. The details of the SRV piping are:

Elevation of valve, $H = 1$ m
Length of inlet pipe, $L_{\text{in}} = 1$ m
Equivalent length of outlet pipe, $L_2 = 20$ m
Outlet pipe Fanning friction factor, $f = 0.005$

The SRV is sized for the saturated liquid condition. The valve is required to vent a mass flow W_{req} of 1.0 kg/s, the actual mass flux G_{act} is 6510 kg/s and the value of the valve coefficient K is 0.95. Then from Equation 15.6.19 the required area A_{req} of the valve orifice is $1.62 \times 10^{-4}\ \text{m}^2$. Consulting the table of standard valve orifice sizes, the next size up is an F size valve with an actual area A_{act} of $1.98 \times 10^{-4}\ \text{m}^2$. This is the valve size selected.

Then from Equation 15.6.20 the actual mass flow is $W_{\text{act}} = 1.22$ kg/s.

For the size-F valve the diameter D_{in} and cross-sectional area A_{in} of the inlet are 0.0409 m and $1.313 \times 10^{-3}\,\text{m}^2$, respectively. An inlet line of the same diameter is used and a check is made that the inlet line losses do not exceed 3% of the gauge set pressure. Then Equation 15.6.22 with $\omega = 10.2$ and $v_o = 0.001658\,\text{m}^3/\text{kg}$ yields $\bar{v}_{\text{in}} = 0.002\,\text{m}^3/\text{kg}$.

The pressure drop ΔP_{in} in the inlet line is calculated from Equation 15.6.21. For the vertical line the length L_{in} and the elevation H are identical at 1 m. The value obtained for ΔP_{in} is 5328 Pa. The inlet line losses are thus much less than 3% of the gauge set pressure of 1.016×10^6 Pa.

For the outlet line, the calculation required is to establish that the equivalent length of 20 m is within the maximum allowable length of the line. The first step is to determine the values to be used for the pressures P_1 and P_2 at the inlet and outlet of the line, respectively. For P_1 the value is 10% of the gauge set pressure and is thus 0.183 MPa. For P_2, from Equation 15.6.8 $P_{2c} = 5.64 \times 10^4$ Pa. The back pressure P_b is 10.1×10^4 Pa. Hence $P_{2c} < P_b$ and thus P_2 is set equal to P_b. Then from Equations 15.6.24 and 15.6.25 $\eta_1 = 0.183$ and $\eta_2 = 0.101$.

The line diameter D_2 is taken as that of the valve outlet, which is 0.0629 m, giving a corresponding cross-sectional area A_2 of $3.089 \times 10^{-3}\,\text{m}^2$. Then with a value of the Fanning friction factor f of 0.005, Equation 15.6.23 yields a maximum allowable line length of 28 m. The actual equivalent line length is 20 m, which is within the allowable range.

15.6.5 Two-phase flow: overall system

As indicated earlier, there is more to the design of a pressure relief for a two-phase vapour–liquid mixture than the sizing of the valve orifice. Accounts of overall design for pressure relief include those by Crawley and Scott (1984) and S.D. Morris (1988b). An overview, with particular reference to offshore systems, has been given by Selmer-Olsen (1992).

Selmer-Olsen identifies a number of difficulties: (1) there is no accepted method of deciding when two-phase flow needs to be considered; (2) there is no accepted design method for two-phase flow; (3) the widely used API method may be inadequate; (4) the methods available are generally not sufficiently validated by experimental work, particularly on the large scale and (5) there is a strong coupling between the thermohydraulic behaviour of the fluid system and the flow through the pressure relief device for which the commonly used modular approach may be inappropriate.

The occurrence of two-phase flow can completely alter the characteristics of the relief system, in particular the behaviour of the fluid in the pipework downstream of the pressure relief valve. This can result in increased back pressure or in choking in the relief header, possibly with oscillating location of the choking throat between the valve and the pipe – the multiple choke effect. Potential consequences of such flow effects are prolonged depressurization times, intermittent flows, high header pressures and blowback to lower pressure sources, and high thermal and mechanical loads.

The author identifies the following work relevant to the design of a pressure relief system for two-phase flow. Work on the sizing of the valve itself includes that of Simpson, Rooney and Grattan (1979), Sallet and co-workers (Sallet, 1984, 1990b,c; Sallet and Somers, 1985), Campbell and Medes (1985), Friedel and Kissner (1985, 1987, 1988), S.D. Morris (1988b, 1990a,b), Morley (1989a,b), Alimonti, Fritte and Giot (1990), Curtelin (1991), M.R. Davis (1991), Simpson (1991) and Leung (1992a).

Treatments of the inlet line to the valve are given by O.J. Cox and Weirick (1980), Zahorsky (1985), S.D. Morris (1988b) and Leung (1992a) and treatments of the outline line are given by Richter (1978b), Friedel and Lohr (1982), S.D. Morris (1988b, 1990b) and Leung (1992a).

The author states that the method of Leung (1992a), based on the homogeneous equilibrium model (HEM) of two-phase flow appears to be the increasingly preferred choice for flow through the valve, for which it is said to be reasonably conservative. He comments, however, that it may well not be conservative for the associated inlet and outlet lines and downstream tanks.

The effects of non-equilibrium assumptions are discussed by Bilicki and Kestin (1990) and Lemonnier *et al.* (1991).

Experimental work on the flows through a configuration relevant to pressure relief has been done by Selmer-Olsen (1991, 1992), using a converging–diverging nozzle with inlet and outlet lines. For short nozzles and low pressures the flows exceeded those predicted by the HEM by a factor of up to 2. As the throat length and pressure were increased the predictions of the HEM were approached, but never reached. The concomitant of this is that the flows in the inlet and outlet lines may be higher than predicted by the HEM.

15.6.6 Two-phase flow: computer codes

A number of computer codes have been developed for pressure relief flows. An account is given by Selmer-Olsen (1992).

One of these codes is BLOW-DOWN by Nylund (1983 DnV Rep. 83-1317, 1984). Another is the BLOWDOWN code of Haque, Richardson and Saville (1992), described in the next section. Other codes include those by Middleton and Lloyd (1984), Bayliss (1987), Klein (1987), Evanger *et al.* (1990) and the NEL code PIPES.

A benchmark exercise on vessel depressurization methods is described by Skouloudis (1990 CEC EUR 12602 EN).

15.7 Vessel Blowdown

Emergency shut-down of a hydrocarbon processing plant may involve the depressurization of major process vessels by blowdown to the flare. On offshore production platforms blowdown is a normal part of emergency shut-down.

In many cases, blowdown will be two-phase. One aspect of the treatment of blowdown is therefore the estimation of the flow. The account of flow in relief systems given in the previous section is applicable to blowdown. The other aspect is the hazards associated with blowdown, particularly the fall in the temperature of the gas.

15.7.1 BLOWDOWN

A treatment which covers both aspects has been given by Richardson, Saville and co-workers (S.M. Richardson, 1989; Haque *et al.*, 1990; Haque, Richardson and Saville, 1992; S.M. Richardson and Saville, 1992).

The hazards arise essentially due to the large temperature drop associated with the sudden depressurization of a vessel containing gas or vapour. Thus, for example, if nitrogen at 150 bar and atmospheric temperature is expanded adiabatically down to atmospheric pressure the isentropic expansion gives a final gas temperature of 78 K.

The type of vessel of interest is one that retains, under pressure, a vapour space, a layer of liquid hydrocarbon and beneath that a layer of water. The potential effects of the temperature drop associated with sudden depressurization are chilling of the vessel walls, condensation of vapour to form droplets with carryover of these droplets into the flare header and formation of hydrates in the hydrocarbon liquid. It is therefore of practical interest to be able to predict the temperature profiles of the fluid phases and of the vessel walls.

An account of a model for vessel blowdown has been given by Haque, Richardson and Saville (1992). The model is embodied in the code BLOWDOWN. For a non-condensable gas, an acceptable estimate of the time profiles of pressure in and of flow from the vessel can generally be obtained assuming choked adiabatic flow. For this case the authors give:

$$P = P_{\mathrm{o}}\left[1 + \frac{\gamma - 1}{2}\frac{A}{V}t\left(\frac{\gamma R T_{\mathrm{o}}}{M}\right)^{1/2}\left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/(2\gamma-2)}\right]^{-2\gamma/(\gamma-1)} \qquad [15.7.1]$$

$$W = A\rho_{\mathrm{o}}\left(\frac{\gamma R T_{\mathrm{o}}}{M}\right)^{1/2}\left(\frac{2}{\gamma+1}\right)^{(\gamma+1)(2\gamma-2)}\left(\frac{P}{P_{\mathrm{o}}}\right)^{(\gamma+1)/2\gamma} \qquad [15.7.2]$$

where A is the cross-sectional area of the choke (m^2), M is the molecular weight of the gas, R is the absolute pressure in the vessel (Pa), R is the universal gas constant (J/kg mole K), T is the absolute temperature of the gas (K), V is the volume of the vessel (m^3), W is the mass flow from the vessel (kg/s), γ is the ratio of the gas specific heats, ρ is the density of the gas (kg/m^3), and the subscript o indicates initial conditions in the vessel.

Since in this model the conditions are adiabatic, it excludes heat transfer between the gas and the wall of the vessel. By definition, therefore, it cannot be used to determine the temperature of the vessel wall. On these grounds alone a fuller model is needed. Moreover, it turns out that this model is also inadequate for the representation of the more complex vessel blowdown scenarios of the kind described earlier. The BLOWDOWN model has been developed to meet this requirement. It consists of a thermophysical model in combination with relationships for heat, mass and momentum and for flow through the choke. The thermophysical properties are calculated using the computer package PREPROP.

The vessel is modelled as a set of three fluid zones (gas, liquid hydrocarbon and water), three corresponding vessel wall zones, and the outflow system consisting of the pipework between the vessel and the choke, the choke itself and the pipework downstream of the choke.

The outflow from the vessel is modelled as follows. It is assumed that the pressure drop at the orifice is such that the flow is critical. For a gas the flow is choked and is determined by its velocity through the choke which is equal to the velocity of sound in the gas:

$$a = \left[\left(\frac{\partial P}{\partial \rho}\right)_{\mathrm{s}}\right]^{1/2} \qquad [15.7.3]$$

where a is the velocity of sound in the gas at the choke (m/s), P is the absolute pressure at the choke (Pa), ρ is the density of the gas at the choke (kg/m^3) and subscript s denotes isentropic conditions. The expansion is isentropic so that

$$S_{\mathrm{i}} = S_{\mathrm{c}} \qquad [15.7.4]$$

where S is the entropy of the gas (kJ/kmol K) and the subscripts c and i denote choke and vessel, respectively. The energy balance is

$$H_{\mathrm{i}} = H_{\mathrm{c}} + a^2/2 \qquad [15.7.5]$$

where H is the enthalpy of the gas (J/kg). These three equations are solved simultaneously using the thermophysical package. The mass flow is then obtained as

$$W = C_{\mathrm{D}} A a \rho_{\mathrm{c}} \qquad [15.7.6]$$

where C_{D} is the coefficient of discharge. The value of C_{D} at the choke is generally taken as 0.8.

For a gas–liquid, thus two-phase, fluid the flow is again assumed to be critical, but in this case the velocity does not equal the speed of sound. Consider changes in the overall pressure difference caused by, say, decreasing the downstream pressure. At small overall pressure differences the liquid is in the metastable condition and does not flash as it passes through the orifice. As the overall pressure difference increases, the limit of meta-stability is reached. There is then no further change either in the flow through the orifice or the pressure at the orifice. The fluid downstream of the orifice undergoes flashing. The behaviour of the fluid is therefore analogous to that of a gas in that a critical condition is reached, but differs from it in that the speed of sound plays no role.

For the pressure at which metastability can no longer be supported, the authors give the following relation, generalized from the work of Abuaf, Jones and Wu (1983):

$$P_{\mathrm{s}} - P_{\mathrm{ms}} = 1.1 \times 10^{11}\,\frac{\sigma^{1.5}(T/T_{\mathrm{c}})^{8}(1 + 2.2 \times 10^{-8}\Pi^{0.8})^{0.5}}{T_{\mathrm{c}}^{0.5}[1 - (\rho_{\mathrm{g}}/\rho_{\mathrm{l}})]}$$

$$T < 0.85T_{\mathrm{c}} \qquad [15.7.7]$$

where P_{ms} is the absolute pressure at which metastability is no longer supported (Pa), P_{s} is the absolute saturated vapour pressure of the liquid at temperature T (Pa), T is the absolute temperature of the liquid upstream of the orifice (K), T_{c} is the absolute critical temperature of the liquid (K), Π is the depressurization rate (N/m^2 s), ρ_{g} is the density of the gas (kg/m^3), ρ_{l} is the density of the liquid (kg/m^3), is the surface tension of the liquid (N/m), and subscripts g and l denote the gas and liquid, respectively. The depressurization rate Π is approximated as the pressure difference across the orifice divided by the time required to traverse twice the diameter of the orifice.

The flow conditions are then as follows. For the range

$P_{\mathrm{u}} > P_{\mathrm{s}},\ P_{\mathrm{d}} < P_{\mathrm{s}}$:

$P_{\mathrm{d}} > P_{\mathrm{ms}}$ flow unchoked

$P_{\mathrm{d}} \le P_{\mathrm{ms}}$ flow choked

where subscripts d and u denote downstream and upstream, respectively. The mass flow through the orifice is given by

$$W = C_{\mathrm{D}} A[2\rho_{\mathrm{l}}(P_{\mathrm{u}} - P_{\mathrm{x}})]^{1/2} \qquad [15.7.8]$$

where C_D is the coefficient of discharge and P_x is an appropriate absolute orifice pressure (Pa). The pressure P_x is the greater of P_{ms} and P_d. The coefficient of discharge is taken as approximately 0.65 for an orifice and unity for a properly formed nozzle.

The situations treated in this work are complex and it is not practical to construct a model that represents in equal detail all the relationships involved. Rather, the authors proceeded by seeking to identify the more significant phenomena and to model these accurately.

Experiments done to validate the model are described by Haque *et al.* (1990, 1992) and S.M. Richardson and Saville (1992). Two vessels were utilized, one 1.52 m long and the other 3.24 m long. In some tests the fluid used was nitrogen, in others it was a mixture of light hydrocarbons. The papers cited present for selected experiments a number of time profiles of the pressure in the vessel and of the temperatures of the gas and the vessel walls.

Some of these time profiles for tests of blowdown through a top outlet are shown in Figure 15.18. Figures 15.18(a) and

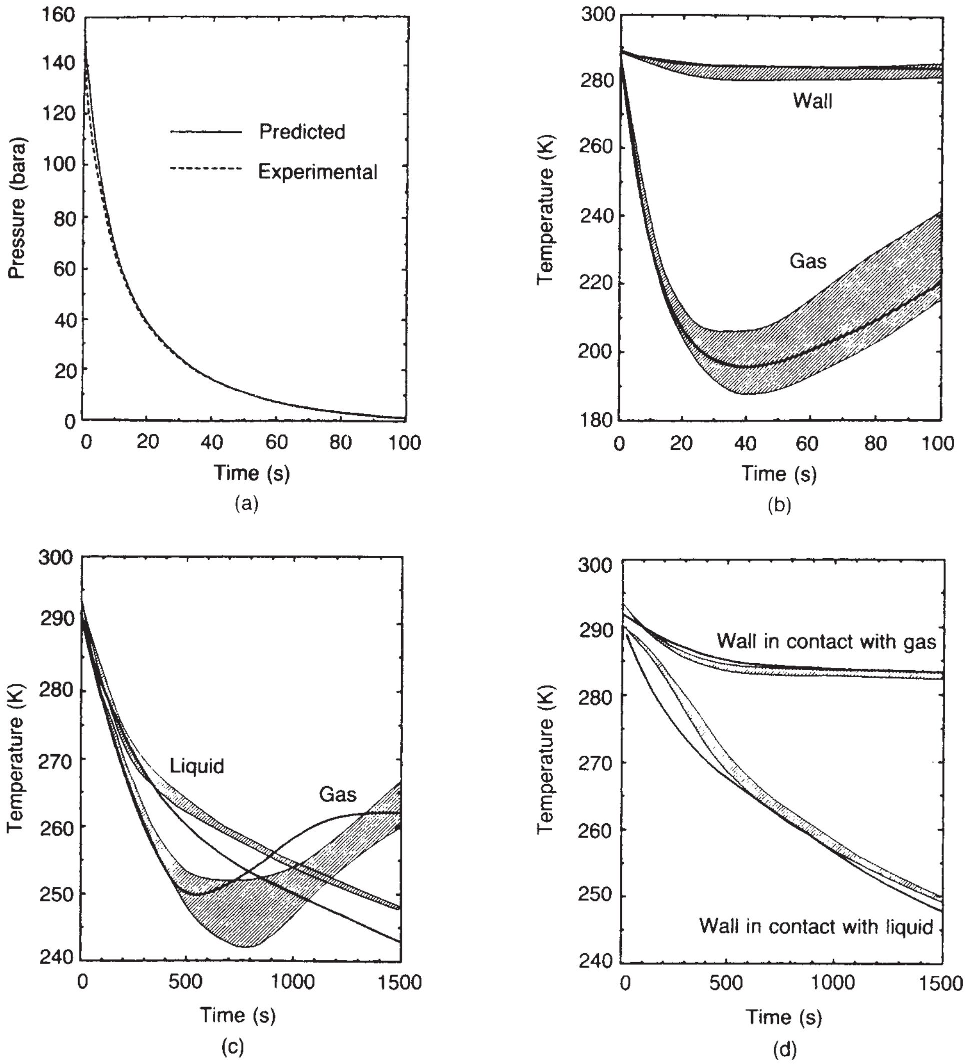

Figure 15.18 Profiles of pressure and temperature in blowdown of a vessel (Haque et al., 1992): (a) pressure in vessel for nitrogen; (b) temperatures of bulk gas and of vessel wall for nitrogen; (c) temperatures of bulk gas and of bulk liquid for hydrocarbon mixture (C_1, 66.6%; C_2, 3.5%; and C_3, 30.0%); (d) temperature of sections of vessel inside wall in contact with (1) gas and (2) liquid for hydrocarbon mixture (C_1, 66.6%; C_2, 3.5%; and C_3, 30.0%). Vertical vessels, top outlets. Hatched regions span experimental measurements; solid lines are predictions (Courtesy of the Institution of Chemical Engineers)

(b) are for a vessel containing nitrogen; the first shows the profiles of the vessel pressure, the second those of the temperatures of the gas and of the vessel wall Figures 15.18(c) and (d) are for a vessel containing hydrocarbons with the composition C_1 66.5%, C_2 3.5% and C_3 30.0%; the first shows the profiles of the gas and the liquid and the second those of the vessel wall in contact with these two phases.

Case studies of the application of the model are also described. One is for the blowdown of the suction scrubber of a gas compressor and another for the blowdown of a gas–condensate separator. The model is also applicable to the prediction of an accidental release from a vessel.

15.8 Vessel Rupture

In certain circumstances a vessel may rupture completely. If vessel rupture occurs, a large vapour cloud can be formed very rapidly. Accounts of vessel rupture include those by Hardee and Lee (1974, 1975), Hess, Hoffmann and Stoeckel (1974), J.D. Reed (1974), Maurer *et al.* (1977), A.F. Roberts (1981/82) and B. Fletcher (1982).

15.8.1 Vaporization

If a vessel containing a superheated liquid under pressure ruptures, a proportion of the liquid vaporizes. This initial flash fraction is determined by the heat balance, the latent heat of vaporization being supplied by the fall in the sensible heat of the liquid. The rapid formation of vapour bubbles also generates a spray of liquid drops so that typically most or all of the remaining liquid becomes airborne, leaving little or no residue in the vessel.

This effect has been demonstrated by J.D. Reed (1974), who carried out experiments on sudden vessel depressurization. In one series of experiments, 3.5 kg of liquid ammonia contained at an absolute pressure of 3 bar and a temperature of −9°C in a vessel 15 cm diameter and 45 cm high was released using a quick release lid. One of the experiments is shown in Figure 15.19, in which the time interval between the first and last frame is one-sixth of a second. In all the experiments at least 90% of the liquid ammonia was vaporized.

Similarly, Maurer *et al.* (1977) have carried out experiments (described below) on the rapid release of propylene held at pressures of 22–39 bar and temperatures of 50–80°C. The flash fraction of vapour was 50–65% and the remaining liquid formed spray.

An investigation of the extent of vapour and spray formation and of retained liquid has been made by B. Fletcher (1982), who carried out experiments, principally in a vertical vessel of 127 × 47 mm cross-section, in which a charge of superheated Refrigerant 11 was depressurized and the liquid residue was determined. The results are correlated in terms of the ratio (h_b/h_o) of the height reached by the liquid on depressurization h_b to the initial height of the liquid h_o, as shown in Figure 15.20. The parameter in the figure is the ratio K of the vent area to the vessel cross-sectional area. The mass of retained liquid is given by the relation

$$\frac{m_r}{m_o} = \frac{1}{K}\left[\frac{m_v \rho_l}{m_o \rho_v} + \left(1 - \frac{m_v}{m_o}\right)\right]^{-1} \qquad [15.8.1]$$

where m is the mass of fluid, ρ is the density, and subscripts l, o, r and v denote the liquid, initial, retained and vapour, respectively. For a full bore release the value of the constant K is unity.

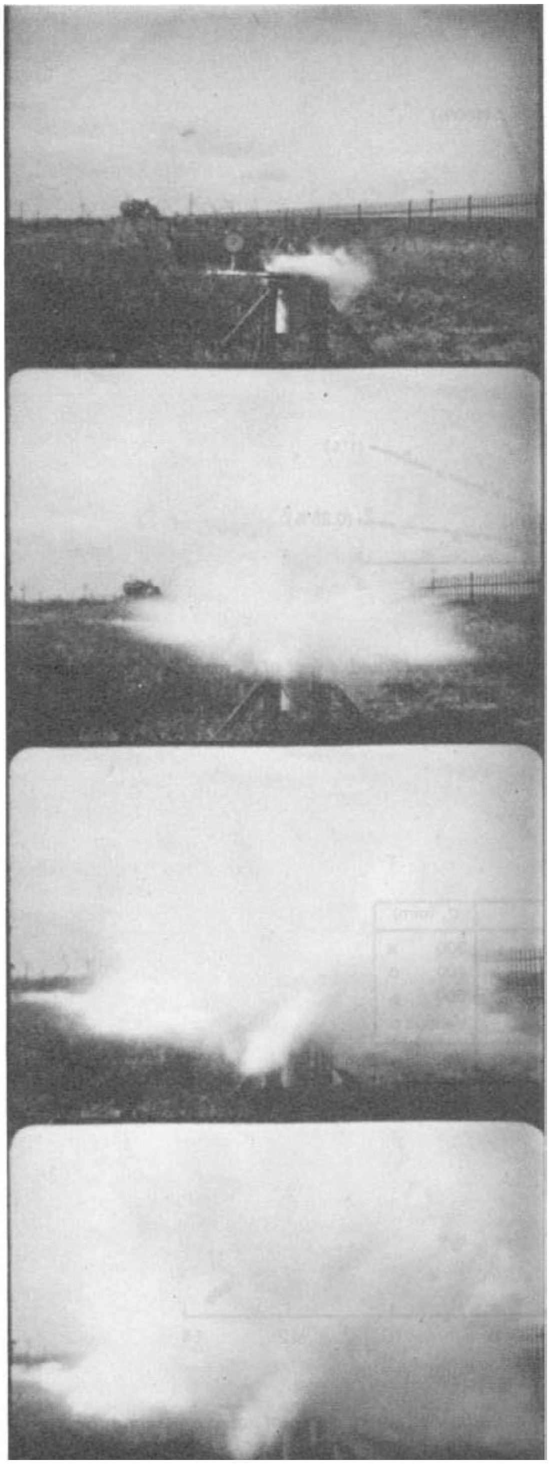

Figure 15.19 *Sudden depressurization of a vessel containing liquid ammonia under pressure (J.D. Reed, 1974) (Courtesy of Elsevier Publishing Company)*

Further correlation of the results is given in terms of the superheat ΔT_{onb} required for vapour nucleation, and hence nucleate boiling. The expression for superheat is

$$\Delta T \approx \frac{4RT_{\mathrm{sat}}\sigma}{\Delta H_{\mathrm{v}} M \delta P_{\mathrm{l}}} \quad \rho_{\mathrm{l}} \gg \rho_{\mathrm{v}};\ 4\sigma/P_{\mathrm{l}}\delta \ll 1 \qquad [15.8.2]$$

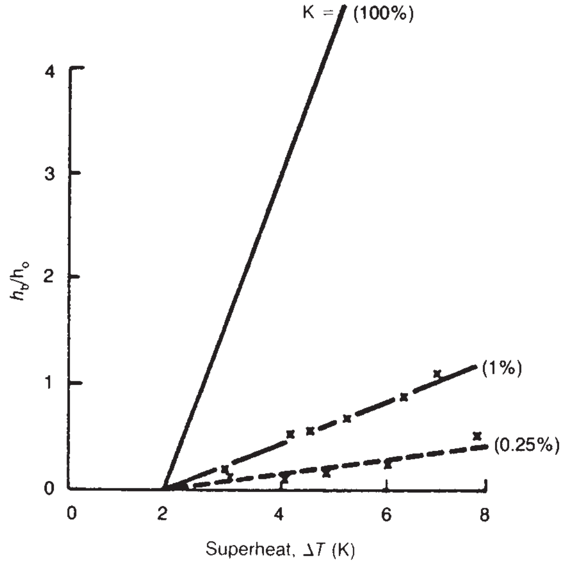

***Figure 15.20** Sudden depressurization of a vessel containing superheated liquid: effect of a restriction on the height to which the liquid rises (B. Fletcher, 1982) (Courtesy of the Institution of Chemical Engineers)*

where ΔH_{v} is the latent heat of vaporization, M is the molecular weight, P is the absolute pressure, R is the universal gas constant, T is the absolute temperature, ΔT is the superheat, δ is the diameter of the vapour nucleus, σ is the surface tension and subscripts onb and sat denote onset of nucleate boiling and saturation, respectively.

The proportion of retained liquid was expressed in terms of the ratio (h/h_{v}) of the height h of the liquid residue to the height h_{v} of the vessel. The limiting value of the superheat, or value at the onset of nucleate boiling $(\Delta T_{\mathrm{onb}})$, corresponds to the situation where all the liquid is retained and thus $h/h_{\mathrm{v}} = 1$.

For Refrigerant 11 the value of ΔT_{onb} is about 1.9 K. Using this value in Equation 15.8.2 with the appropriate physical value for Refrigerant 11 a value of δ can be obtained. Then, utilizing this value, the superheat ΔT_{onb} for other substances can be obtained.

The correlation given by Fletcher for the superheat effect is shown in Figure 15.21. The proportion of retained liquid h/h_v falls off rapidly with increase in the ratio $\Delta T/\Delta T_{\mathrm{onb}}$ and for values in excess of about 12 falls to less than 5%.

A comparison of the proportion of liquid retained in the tank cars in several transport incidents with that estimated from Equation 15.8.1 is given as:

Incident	*Liquid*	*Mass fraction retained* (%)	
		Reported	*Estimated*
Pensacola	Ammonia	50	40
Mississauga	Chlorine	10	13
Youngstown	Chlorine	44	37

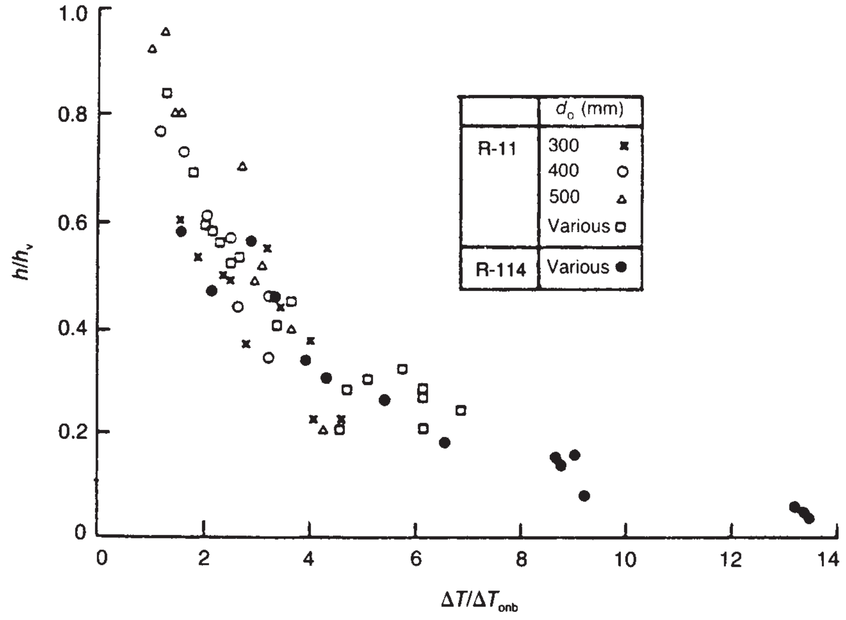

***Figure 15.21** Sudden depressurization of a vessel containing superheated liquid: depth of liquid remaining (B. Fletcher, 1992) (Courtesy of the Institution of Chemical Engineers)*

Further work on vaporization following vessel rupture has been described by Schmidli, Bannerjee and Yadigaroglu (1990).

15.8.2 Hardee and Lee model

An investigation of the rapid depressurization of a vessel containing a superheated liquid has been described by Hardee and Lee (1975). The growth of the cloud is considered to occur in three stages, as shown in Figure 15.22. The first stage is the expansion of the fluid from the original vessel pressure to atmospheric pressure, the second the entrainment of air, and the third the dispersion of the cloud.

For the first stage, the expansion is assumed to be isentropic and the flash fraction at the end of the expansion is given by the entropy balance

$$x_1 s_{v1} + (1 - x_1)s_{f1} = x_2 s_{v2} + (1 - x_2)s_{f2} \qquad [15.8.3]$$

where s is the specific entropy, x is the mass fraction of vapour and subscripts f and v denote liquid and vapour and 1 and 2 initial and final states, respectively.

The velocity of the expanding fluid may then be obtained from the energy balance. Taking the initial velocity u_1 of the liquid as zero,

$$x_1 h_{v1} + (1 - x_1)h_{f1} = x_2 h_{v2} + (1 - x_2)h_{f2} + u_2^2/2 \qquad [15.8.4]$$

where h is the specific enthalpy and u is the velocity.

The first stage is evidently to be regarded as virtually instantaneous. At the end of this stage the fluid consists of vapour and spray. In the second stage air is entrained, the spray is vaporized and the cloud grows. At the end of this stage the cloud has attained a height that thereafter does not increase. In the third stage the cloud grows, but only in the radial direction.

In the second stage, the momentum of the cloud increases linearly with time until the end of the stage is reached at the depressurization, or dump, time t_d. In the third stage, the momentum remains constant. For the second stage the volume of the expanding fluid is

$$V_2 = u_2 A_2 t \qquad [15.8.5]$$

where A_2 is the area of cloud perpendicular to direction of expansion at end of the second stage, t is the time and V is the volume of fluid; subscript 2 denotes the value at the end of expansion down to atmospheric pressure. At the end of the second stage, and hence at time t_d

$$V_2 = u_2 A_2 t_d \qquad [15.8.6]$$

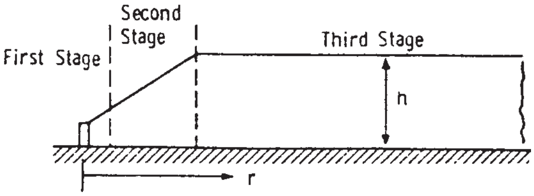

Figure 15.22 *Rupture of a vessel containing superheated liquid: cloud expansion process (Hardee and Lee, 1975) (Courtesy of Pergamon Press)*

The initial mass of fluid W may be expressed in terms of the volume given in Equation 15.8.6 as follows:

$$W = \rho_2 V_2 \qquad [15.8.7a]$$

$$= \rho_2 u_2 A_2 t_d \qquad [15.8.7b]$$

where ρ is the density. Then, during the second stage, the momentum ψ is

$$\psi = \rho_2 u_2^2 A_2 t \quad t < t_d \qquad [15.8.8a]$$

$$= \rho_2 u_2^2 A_2 t_d \quad t > t_d \qquad [15.8.8b]$$

$$= W u_2 \qquad [15.8.8c]$$

The momentum may be obtained via the momentum balance from the initial pressure P_1 and final pressure P_2 as follows:

$$(P_1 - P_2)A_1 = \rho_2 u_2^2 A_2 \qquad [15.8.9]$$

where A_1 is the area of the vessel aperture. Also, from Equations 15.8.8 and 15.8.9

$$\frac{A_1 t_d}{W} = \frac{u_2}{P_1 - P_2} \qquad [15.8.10]$$

For the momentum of a general moving vortex

$$\psi = c\rho u V \qquad [15.8.11]$$

where c is a constant. The value of the constant c is shown by the authors to be approximately 3/2. Then, from Equation 15.8.11:

$$\frac{dr}{dt} = u \qquad [15.8.12]$$

$$= \frac{2\psi}{3\rho V} \qquad [15.8.13]$$

where r is the radius of the cloud.

For a hemispherical cloud

$$V = \frac{2}{3}\pi r^3 \qquad [15.8.14]$$

Hence substituting from Equations 15.8.8a and 15.8.14 in Equation 15.8.13 and integrating

$$r = \left(\frac{2\rho_2 u_2^2 A_2}{\rho\pi}\right)^{1/4} t^{1/2} \qquad [15.8.15]$$

or, from Equation 15.8.8b

$$r = \left(\frac{2\psi}{\rho\pi t_d}\right)^{1/2} t^{1/2} \qquad [15.8.16]$$

At the end of this stage

$$r = \left(\frac{2\psi}{\rho\pi t_d}\right)^{1/4} t_d^{1/2} \qquad [15.8.17]$$

For the third stage, the height h of the cloud is constant at the value of the radius r reached at the end of the second stage. Then for a cylindrical cloud

$$V = \pi r^2 h \qquad [15.8.18]$$

Since the cloud is now relatively dilute it is possible to set, $\rho \approx \rho_a$, where ρ_a is the density of air. Then from Equations 15.8.13 and 15.8.18:

$$\frac{dr}{dt} = \frac{2\psi}{3\rho_a \pi r^2 h} \qquad [15.8.19]$$

and integrating

$$r = \left(\frac{2\psi}{\rho_a \pi h}\right)^{1/3} t^{1/3} \qquad [15.8.20]$$

The use of the model is assisted by the graphs given in Figures 15.23 and 15.24, which give the momentum and the dump time, respectively.

For a hazardous release there will be some concentration, corresponding to a cloud volume V, below which the cloud no longer presents a hazard. The model may be used to

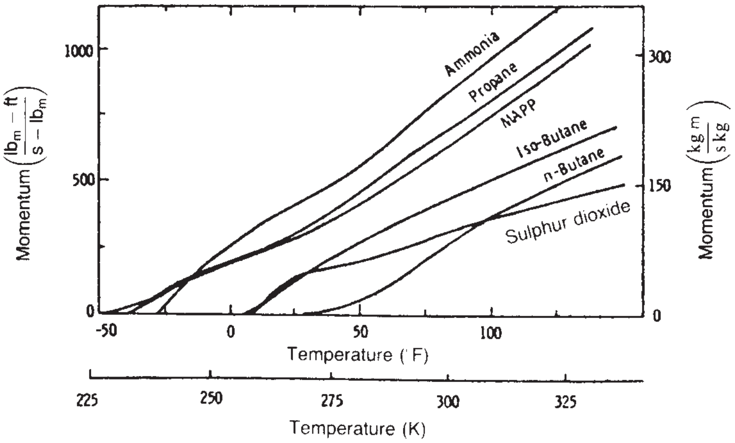

Figure 15.23 *Rupture of a vessel containing superheated liquid: momentum release per pound of fuel (Hardee and Lee, 1975) (Courtesy of Pergamon Press)*

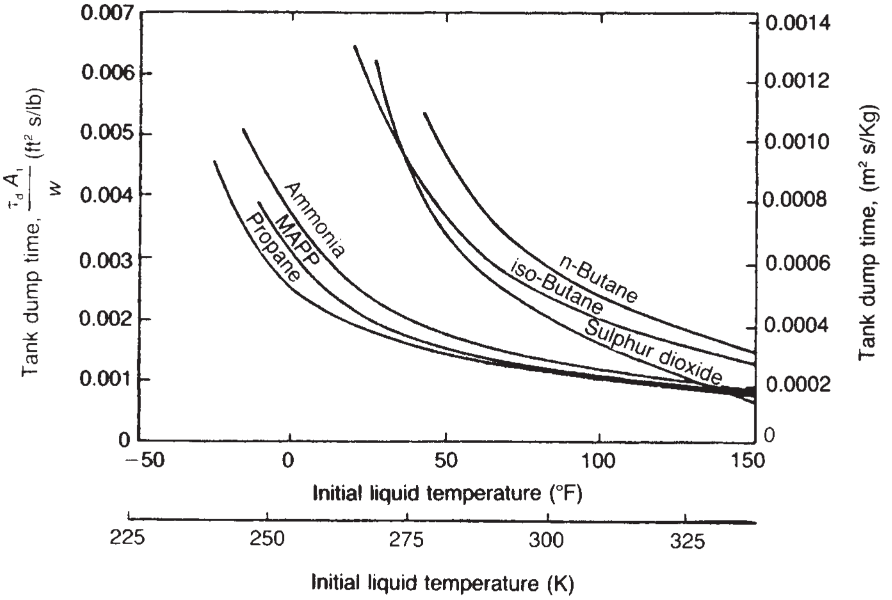

Figure 15.24 *Rupture of a vessel containing superheated liquid: vessel dump time (Hardee and Lee, 1975) (Courtesy of Pergamon Press)*

determine the range r and time t at which the concentration falls below this critical value.

The authors carried out experiments in which vessels containing up to 422 kg of propane and 436 kg of a methyl acetylene–propylene–propadiene (MAPP) mixture were suddenly depressurized and obtained good agreement for the increase of the cloud radius with time and for the cloud height.

Thus for a release of 29 kg of MAPP at a temperature of 284 K through an aperture of 0.728 m^2 the relation for the growth of the cloud radius, derived from Equation (15.8.20), is

$$r = 8.84t^{1/3} \qquad [15.8.21]$$

where r is the radius (m) and t the time (s). The cloud height is 2.74 m.

Hardee and Lee also describe the use of the model to determine cloud growth for the incidents of propane release at Lynchburg, Virginia, and of ammonia at Crete, Nebraska.

15.8.3 Model of Hess, Hoffman and Stoeckel

Another model for vessel rupture has been given by Hess, Hoffmann and Stoeckel (1974). The situation modelled is again the depressurization of a superheated liquid.

After the vessel burst the growth of the cloud is considered to occur in three stages. The first stage is expansion down to atmospheric pressure with flash-off of vapour and formation and partial evaporation of spray and some admixture of air. The second stage is the evaporation of the remaining spray and entrainment of air into the cloud. The third stage is the further entrainment of air and, if the fluid is flammable, the formation of a flammable mixture.

The model deals primarily with this third stage. For this stage, using spherical symmetry, the basic equation describing the variation of concentration c with radial distance r and time t is:

$$\frac{dc}{dt} = \epsilon\left[\frac{d^2c}{dr^2} + \frac{2}{r}\frac{dc}{dr}\right] \qquad [15.8.22]$$

where ϵ is eddy diffusion coefficient. Time zero is taken as the start of the third stage. The boundary conditions used are as follows: $0 < r < a,\ t = 0,\ c = c_0$; $r > a,\ t = 0,\ c = 0$. Then from a standard solution given by Carslaw and Jaeger (1959, p. 257), Equation 15.8.22 can be integrated to give

$$\frac{c}{c_o} = \frac{a^3}{6(\epsilon t)^{3/2}\pi^{1/2}}\exp\left(\frac{-r^2}{4\epsilon t}\right) \qquad [15.8.23]$$

where a is the radius of the initial cloud formed on completion of the bursting process and c_o is the concentration of vapour in the initial cloud.

The authors carried out experiments in which 40 and 60 mm diameter cylindrical vessels with a length/diameter ratio of 3.5 : 1, filled with liquid propane, were heated until they burst. The bursting of the vessels was recorded by high speed photography. They describe in detail the bursting of a 40 mm cylinder. The time for the vessel itself to burst was less than 1 ms. Following bursting the vapour cloud formed in two phases. In the first phase the propane expanded to ambient pressure and about half the liquid flashed off as vapour with the temperature dropping to about 230 K. It was estimated that without admixture of air the vapour would form a hemisphere with a radius of about 20 cm, but the actual radius was somewhat larger, implying that some air had already been mixed in. This phase was complete within about 3 ms. In the second phase the remaining liquid propane vaporized on mixing with air, from which it obtained the necessary heat of vaporization. It was estimated that from the energy balance the vapour–air mixture would form a hemisphere with a radius of about 46 cm. The average concentration of propane was then 20%. This phase was complete in about 8 ms.

The concentrations of vapour obtained following this bursting process were compared with those predicted by using Equation 15.8.23. The radius of and concentration in the initial cloud were obtained from the experiment. The eddy diffusion coefficient ϵ was obtained from the Prandtl mixing length formula:

$$\epsilon = lu' \qquad [15.8.24]$$

where l is the mixing length and u' the fluctuating velocity. The mixing length l was taken as the average eddy diameter and the fluctuating velocity u' was taken as the speed at which the eddies moved, both quantities being obtained from photographs. The parameters required for solution of Equation 15.8.23 were then

$c_o = 20\%$
$a = 46$ cm
$\epsilon = 0.52$ m^2/s

Using these values in the model, good agreement was obtained with the results of this experiment.

15.8.4 Model of Maurer *et al.*

A development of the model of Hess, Hoffman and Stoeckel has been described by Maurer *et al.* (1977). In the second model it is again assumed that there is a central highly mixed core at uniform concentration and that the concentration outside this core decays in a Gaussian manner, but the second model differs in that it allows for the variability of the eddy diffusion coefficient, which in the first model is assumed to be constant.

For the air entrainment stage, using spherical symmetry, the basic equations given are:

$$\frac{c}{c_c} = \exp\left\{X_c^2\left[1 - \left(\frac{r}{r_g}\right)^2\right]\right\} \quad r > r_g \qquad [15.8.25]$$

$$c_c = f(X_c)\frac{V_g}{(4\epsilon t)^{1.5}} \qquad [15.8.26]$$

$$r_g = X_c(4\epsilon t)^{1/2} \qquad [15.8.27]$$

where V_g is the effective volume of vapour, X_c is a parameter characterizing the mass fraction of gas in the core, and subscripts c and g denote the core concentration and the core radius, respectively. The volume V_g is taken as twice the mass divided by the density at standard pressure and temperature; this allows for the use of spherical symmetry to model a hemispherical cloud.

The parameter $f(X_c)$ is obtained experimentally. The value used is 1.36, which corresponds to a fraction of vapour in the core of 50%.

In addition, as observed by A.F. Roberts (1981/82), the following additional relation for the eddy diffusion coefficient may be obtained from a graph of experimental results given by the authors:

$$\epsilon = 0.75V_g^{1/3}\left(\frac{t}{V_g^{1/3}}\right)^{-1/4} \qquad [15.8.28]$$

Experiments were carried out in which cylindrical vessels containing propylene were heated up and then made to burst by mechanical means or by a small explosive charge. The quantities of propylene used ranged from 0.124 to 452 kg, the vessel in this latter case being 0.7 m diameter × 2.8 m long. The propylene was heated to temperatures of 50–80°C corresponding to pressures of 22–39 bar. After rupture and flash evaporation the vapour was ignited and overpressure generated was recorded. Some 50–65% of the liquid vaporized and the rest formed spray. The propagation velocity of the cloud boundary was followed by the condensation contours, which correspond to vapour concentrations of 1–3%.

The expansion velocities obtained, and the turbulence generated, were high. Only a very small proportion of the mechanical energy available was required to generate this turbulence.

The authors correlate their results in terms of a reduced time, $t/V_g^{1/3}$, a dimensionless time $\tau = \epsilon t/V_g^{2/3}$ and a scaled distance $r/V_g^{1/3}$. Some of these results are shown in Figures 15.25 and 15.26. Figure 15.25 shows the propagation velocity w of the cloud boundary. The plateau at short times corresponds to the expansion velocities predicted thermodynamically, which ranged from 240 to 370 m/s for vessel preheats of 35 and 80°C, respectively. Figure 15.26 gives the overpressures measured due to flash evaporation.

Figure 15.27 shows the concentration profiles and contours predicted by the model. Figure 15.28 shows the ratio $V_{g,ign}/V_g$ of the flammable volume $V_{g,ign}$ to the total volume V_g as a function of t. The maximum flammable fraction is 70% and the period during which a flammable mixture exists at all is $0.15 < t < 0.4$ s.

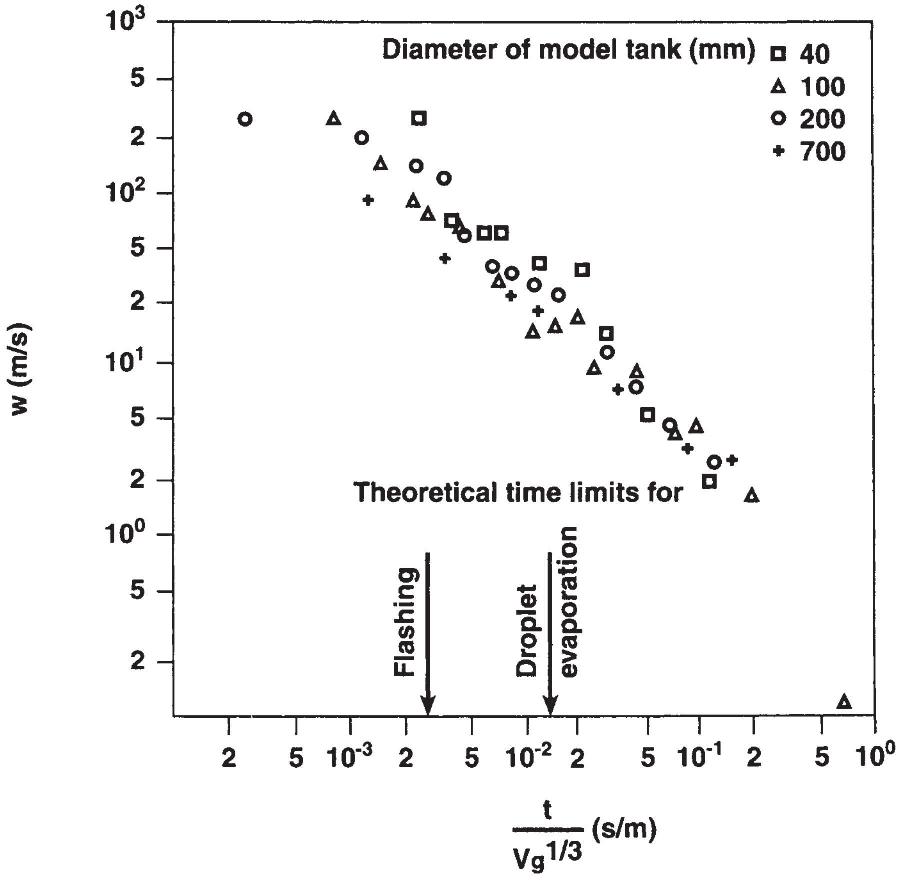

Figure 15.25 *Rupture of a vessel containing superheated liquid (Maurer et al., 1977): propagation velocity of vapour cloud boundary due to condensation from humid air (Courtesy of DECHEMA)*

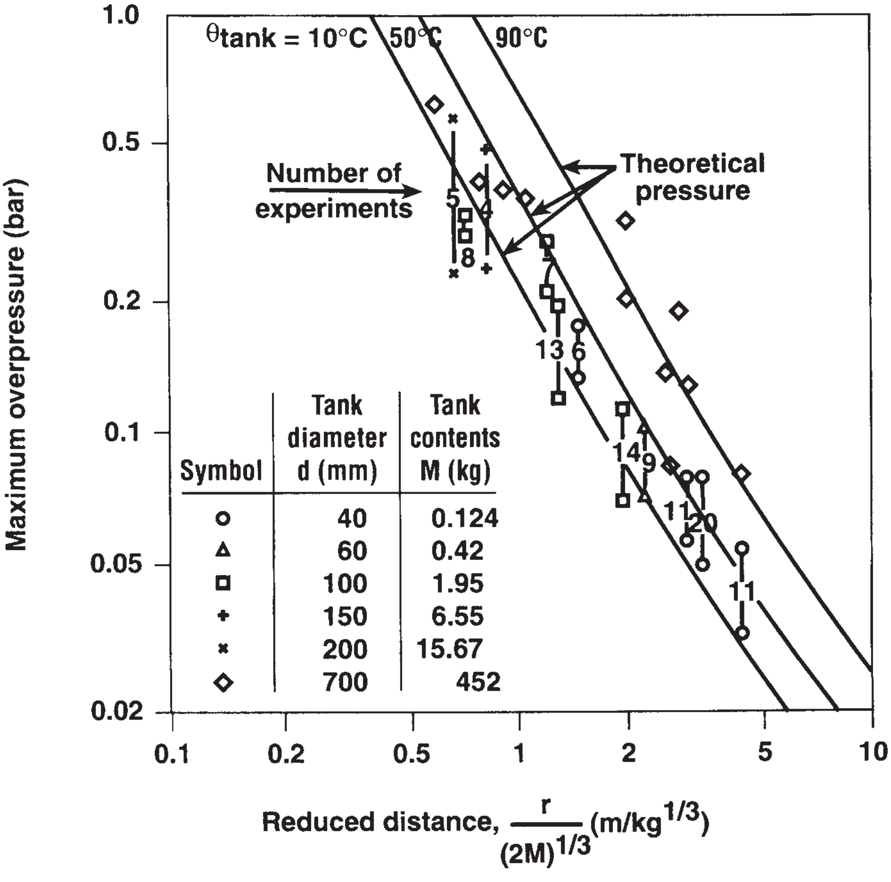

Figure 15.26 *Rupture of a vessel containing superheated liquid: blast wave overpressure due to flash expansion (Maurer et al., 1977) (Courtesy of DECHEMA)*

The flammable mixture showed considerable unmixedness, as evidenced by the afterburning of the cloud subsequent to the pressure-generating combustion. Investigation revealed that only some 30–50% of the macromixed gas participated in the pressure-generating combustion. Then taking the maximum flammable fraction as 70% and the fraction of the latter participating in pressure-generating combustion as 40%, the maximum fraction of the original contents participating in pressure-generating combustion is 0.28 (= 0.4 × 0.7). The authors therefore quote a round figure for this fraction of 30%.

15.8.5 Roberts model

A discussion of vessel rupture in the context of the fireballs has been given by A.F. Roberts (1981/82). Roberts compares the models of Hardee and Lee and of Maurer *et al.* in respect of the predictions of the transition from control by diffusion to control by gravity slumping, using the transition criterion – proposed by Jagger and Kaiser (1981):

$$N = \frac{gr\Delta}{(\mathrm{d}r/\mathrm{d}t)^2} \qquad [15.8.29]$$

with

$$\Delta = \frac{\rho_\mathrm{v} - \rho_\mathrm{a}}{\rho_\mathrm{a}} \qquad [15.8.30]$$

where g is the acceleration due to gravity, r is the radial distance, Δ is a relative density, ρ is the density, and subscripts a and v denote air and vapour, respectively. The value of N at the transition point is taken to be unity. For the Hardee and Lee model, Roberts obtains

$$N = \frac{6g\Delta \cdot t}{\alpha} \qquad [15.8.31]$$

and for the model of Maurer *et al.*

$$N = 0.6\frac{\rho_\mathrm{v}^{5/6}}{\rho_\mathrm{a}}\left(1 - \frac{\rho_\mathrm{a}}{\rho_\mathrm{v}}\right)M^{1/6}t^{1/2} \qquad [15.8.32]$$

where M is the initial mass of liquid and α is the momentum per unit mass.

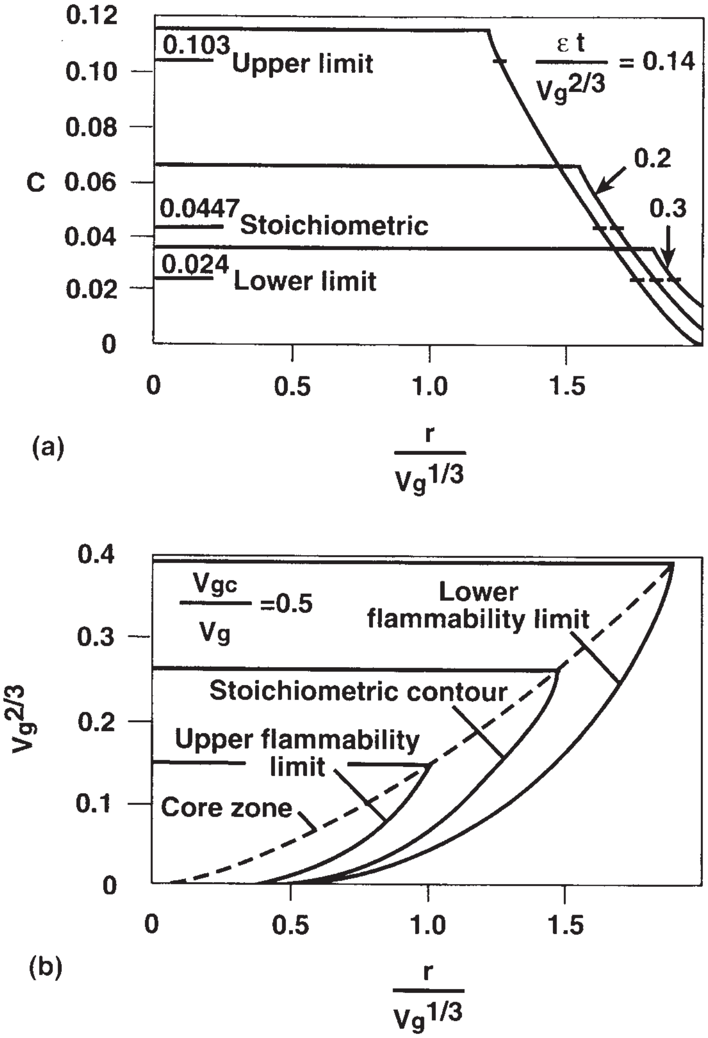

Figure 15.27 Rupture of a vessel containing superheated liquid – model predictions (Maurer et al., 1977): (a) concentration profiles; (b) concentration contours (Courtesy of DECHEMA)

Then, for a transition with $N = 1$, Roberts obtains for propane for the time t_g to transition for the Hardee and Lee model

$$t_g = 0.05\alpha \quad [15.8.33]$$

and for that of Maurer *et al.*

$$t_g = 10M^{-1/3} \quad [15.8.34]$$

Also in the Hardee and Lee model the concentration c at transition is

$$c = 22M^{1/4}\alpha^{-3/2} \quad [15.8.35]$$

Thus, in both models gravity slumping becomes more important as the release size increases. With increase in release size the concentration at transition to gravity slumping also increases.

Roberts also gives the following expression for the radial velocity w in the Hardee and Lee model:

$$w = \left(\frac{\alpha\rho_v}{128\pi\rho_a}\right)^{1/4}\left(\frac{t}{V_g^{1/3}}\right)^{-3/4} \quad [15.8.36]$$

with

$$V_g = 2M/\rho_v \quad [15.8.37]$$

where V_g is the volume of vapour released and the factor of 2 is included to allow for the hemispherical symmetry. Substituting values for propane of $\rho_v/\rho_a = 2$ and $\alpha = 220$ m/s gives

$$w = 1.0 - \left(\frac{t}{V_g}\right)^{-3/4} \quad [15.8.38]$$

He comments that this also agrees well with the data of Maurer *et al.*

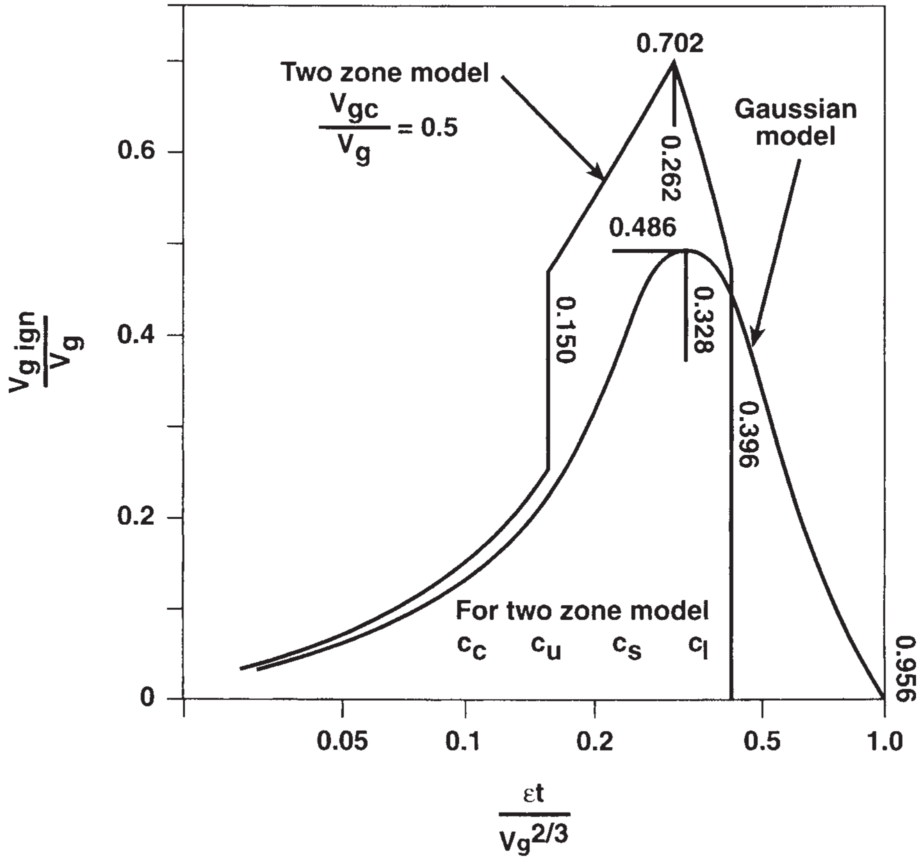

Figure 15.28 *Rupture of a vessel containing superheated liquid – model predictions (Maurer et al., 1977): fractions of flammable and reacting gas (Courstey of DECHEMA)*

15.8.6 Other treatments

A further discussion of vessel rupture has been given by Appleton (1984 SRD R303).

15.8.7 Entrainment of air

The cloud formed from a vessel rupture entrains air. The determination of the amount of air entrained is important, because the cloud constitutes the source term for dispersion models and these models are rather sensitive to the degree of air entrainment. The air entrained may be estimated using the models just described. Alternatively, use may be made of empirical relations.

Air entrainment has been discussed by Griffiths and Kaiser (1979 SRD R154) in relation to rupture of vessels containing liquefied ammonia. They propose for ammonia the rule-of-thumb that in such a release the ammonia mixes with ten times as much air by mass. They also state: ‘to the accuracy that is possible here, this is also equivalent to mixing in about ten times as much air by volume’.

This estimate is based partly on the incident at Potchefstroom in which a horizontal pressure vessel burst, releasing 38 te of ammonia through a hole some 7 m^2. From eyewitness accounts the immediate resulting gas cloud was ‘about 150 m in diameter and about 20 m in depth’. They also refer to the work of van Ulden (1974) in which 1 te of Freon 12 was poured onto water, giving immediate vigorous boiling and rapid formation of a gas cloud in which the volume of air was about 10 times that of the Freon.

The rule-of-thumb that for a vessel rupture the volume of air entrained is some 10 times that of the gas released has been widely used in the modelling of heavy gas dispersion.

Griffiths and Kaiser give an example of a release of 20 te of liquefied ammonia, giving 4 te of vapour and 16 te of spray. If sufficient dry air is entrained at 20°C just to evaporate the drops, this requires 400 te of air, or a factor of 20 on the mass of ammonia released. This gives a cloud at a temperature of −33°C and a relative density of 1.18. The density of the cloud is greatly in excess of that of air and the cloud will exhibit heavy gas behaviour.

15.8.8 Storage tank rupture

A quite different problem arises when rupture of an atmospheric storage tank occurs. If the rupture is sufficiently sudden and complete, a wave of liquid surges outwards and may overflow the bund. This hazard is considered further in Chapter 22.

15.9 Pipeline Rupture

Another situation that can lead to a large release of gas or vapour is rupture of a pipeline. Pipelines that may give rise to such a release are principally those carrying either high pressure gas or liquefied gas. In each case, while the determination of the initial emission rate is relatively straightforward, the situation then becomes rather more complex.

15.9.1 Gas pipelines

Accounts of emission from pipelines containing high pressure gas have been given by R.P. Bell (1978), D.J. Wilson (1979b), Picard and Bishnoi (1988, 1989) and J.R. Chen, Richardson and Saville (1992).

An empirical model for flow from a pipeline rupture has been given by R.P. Bell (1978). This model may be written as

$$m = \frac{m_o}{m_o + m_r}[m_o \exp(-t/\tau_2) + m_r \exp(-t/\tau_1)] \qquad [15.9.1]$$

with

$$m_r = A\left(\frac{2P\rho d}{flN}\right)^{1/2} \qquad [15.9.2]$$

$$\tau_1 = \frac{W_o}{m_r} \qquad [15.9.3]$$

$$\tau_2 = \frac{W_o m_r}{m_o^2} \qquad [15.9.4]$$

where A is the cross-sectional area of the pipeline, d is the diameter of the pipeline, f is the friction factor, l is the length of the pipeline, m_o is the initial mass flow from the pipeline, m_r is a steady-state, or reference, flow from the pipeline defined by Equation 15.9.2, N is a correction factor, P is the absolute pressure, W_o is the initial mass holdup in the pipeline, ρ is the density and τ_1 and τ_2 are time constants. The friction factor f is evidently the Darcy friction factor f_D (=8ϕ).

For the correction factor N, Bell gives the empirical formula

$$N = 8[1 - \exp(-26400d/l)] \qquad [15.9.5]$$

He also states that he used a value of 0.02 for the friction factor f.

Bell also discusses the dispersion from the pipeline.

D.J. Wilson (1979b) has derived a rather more complex model, but also states that Bell's model compares quite well.

A formulation of the Bell model has been given by the CCPS (1987/2) and this may be put in the following form:

$$m = \frac{m_o}{1+\psi}[\exp(-t/\tau_2) + \psi \exp(-t/\tau_1)] \qquad [15.9.6]$$

with

$$\psi = m_r/m_o \qquad [15.9.7a]$$

$$\psi = W_o/m_o\tau_1 \qquad [15.9.7a]$$

$$\tau_1 = W_o/m_r \qquad [15.9.8]$$

$$\tau_2 = \psi^2\tau_1 \qquad [15.9.9]$$

where ψ is a parameter. Furthermore,

$$\tau_1 = 0.67\left(\frac{\gamma fl}{d}\right)^{1/2}\frac{1}{u_s} \qquad [15.9.10]$$

with

$$u_s = \left(\frac{\gamma RT}{M}\right)^{1/2} \qquad [15.9.11]$$

where M is the molecular weight, R is the universal gas constant, T is the absolute temperature, u_s is the velocity of sound and γ is the ratio of the gas specific heats.

More complex treatments are given by Picard and Bishnoi (1988, 1989) and J.R. Chen, Richardson and Saville (1992). The work of the latter authors is treated in Section 15.9.3.

15.9.2 Liquefied gas pipelines

Accounts of emission from pipelines containing liquefied gas are given by Inkofer (1969), Westbrook (1974) and T.B. Morrow, Bass and Lock (1982).

Inkofer (1969) discusses the factors determining the rate of emission in a liquid ammonia pipeline rupture. He envisages an initial spurt of liquid followed by a period of prolonged and spasmodic ejection of liquid and vapour due to the effect of vapour locks at humps along the pipeline.

Estimates of the rate of emission from a rupture in a chlorine pipeline have been given by Westbrook (1974). These estimates are an initial escape rate of 60.3 ton/h from each of two 4 in. orifices and a total escape of 28.4 ton in 24 min.

T.B. Morrow, Bass and Lock (1982) have given a method of estimating the flow from a pipeline containing liquefied gas. They consider two cases: complete rupture and partial rupture. For the two-phase critical flow at the rupture point the method utilizes Fauske's slip equilibrium model. Upstream of the rupture point it is assumed that there is a transition, or interface, point at which the flow changes from liquid flow to two-phase flow and that this point is that at which the pressure corresponds to the bubble point of the liquid. The basic equation for the two-phase pressure drop is

$$\frac{dP}{dz} = \frac{\phi_g^2 4fu_{fs}}{2dv_f} \qquad [15.9.12]$$

where f is the friction factor, u is the velocity, v is the specific volume, z is the distance along the pipe from the rupture point, ϕ_g is a parameter, and subscripts f and fs denote liquid and superficial value for liquid, respectively. The friction factor f is the Fanning friction factor (=2ϕ).

The actual liquid velocity u_f is

$$u_f = \frac{u_{fs}}{1-Y} \qquad [15.9.13]$$

where Y is the void fraction. The parameter ϕ_g is

$$\phi_g^2 = \frac{1}{(1-Y)^2} \qquad [15.9.14]$$

Then from Equations 15.9.12–15.9.14

$$\frac{dP}{dz} = \frac{2fu_f^2}{dv_f} \qquad [15.9.15]$$

Using the same assumption for slip as made by Fauske in the derivation of the slip equilibrium model, namely

$$\frac{u_g}{u_f} = \left(\frac{v_g}{v_f}\right)^{1/2} \quad [15.9.16]$$

where subscript g denotes vapour. Expressing the quality in terms of the fluid enthalpies, and hence of pressure, the authors obtain

$$\left(\frac{mv_f}{Au_f}\right)^2 = f(P) \quad [15.9.17]$$

Hence

$$\frac{dP}{dz} = \frac{2fm^2v_f}{A^2df(P)} \quad [15.9.18]$$

In order to integrate Equation 15.9.18 the mass flow m is expressed as a function of the distance z from the rupture point:

$$m = m_e\left(\frac{m_e - m_i}{z_i}\right)z \quad [15.9.19]$$

where subscript e denotes the rupture point, or exit, and i denotes the transition, or interface, point. Expressions are also given for the volume of the vapour space, and hence of the liquid removed, between the transition and rupture points. The model allows the mass flow from the rupture point and the position of the transition point to be determined as a function of time.

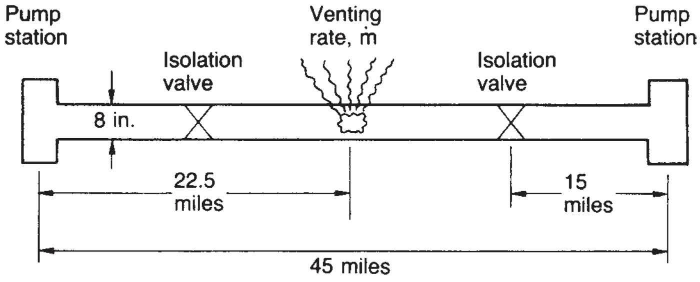
The authors have used the model to study ruptures in the propane pipeline system shown in Figure 15.29. They investigated different pumping station distances, valve spacings and shut-down times of the upstream pump, with valves shut down 5 min after the pump. Typical results for the flow profiles given by ruptures are shown in Figure 15.30. Curve A shows the flow for a complete rupture. This flow is for some time unaffected by pump shut-down and valve closure, since the two-phase interface moves relatively slowly. For example, for a spacing between pumps of 15 miles the interface is estimated to reach the isolation valves at 7½ miles only after some 25 min. Curve B in Figure 15.30 shows the flow for a partial rupture. In this case the pressure is maintained at the value before rupture until the pump shuts off, then falls, and finally reaches a new steady value corresponding to the bubble point. The fall may approximate to a ramp or may change to a steeper slope as the isolation valve shuts.

A description of the actual pipeline break at Port Hudson has been given by the NTSB (1972 PAR-72-01) and Burgess and Zabetakis (1973 BM RI 7752). The event is described in Case History A52.

15.9.3 BLOWDOWN

An account has been given in Section 15.8 of the model BLOWDOWN developed for the prediction of conditions during blowdown of, or release from, a vessel. This model has also been adapted for use in the determination of conditions arising during outflow of fluid from a pipeline, whether as intentional blowdown or accidental release.

One of the topics in which the Piper Alpha Inquiry was interested was the explanation of the change in pressure that occurred during the accident in the gas pipelines connected to the platform. Evidence on this topic, based on the use of the BLOWDOWN code, was presented to the inquiry by Richardson (1989b).



• Pipeline flow rate	40 000 bbl/day
• Isolation valve spacing	45, 15 and 5 miles
• Pump stations	45 miles apart
• Pump shut-off time	5 min and 20 min after rupture
• Valve closure time	5 min after pump shut-off time
• Break sizes	Complete break (venting from both ends), and partial break (initial venting rate 10 000 bbl/day)

Figure 15.29 *Emission from an LPG pipeline: configuration of pipeline studied (T.B. Morrow, Bass and Lock, 1982) (Courtesy of the American Society of Mechanical Engineers)*

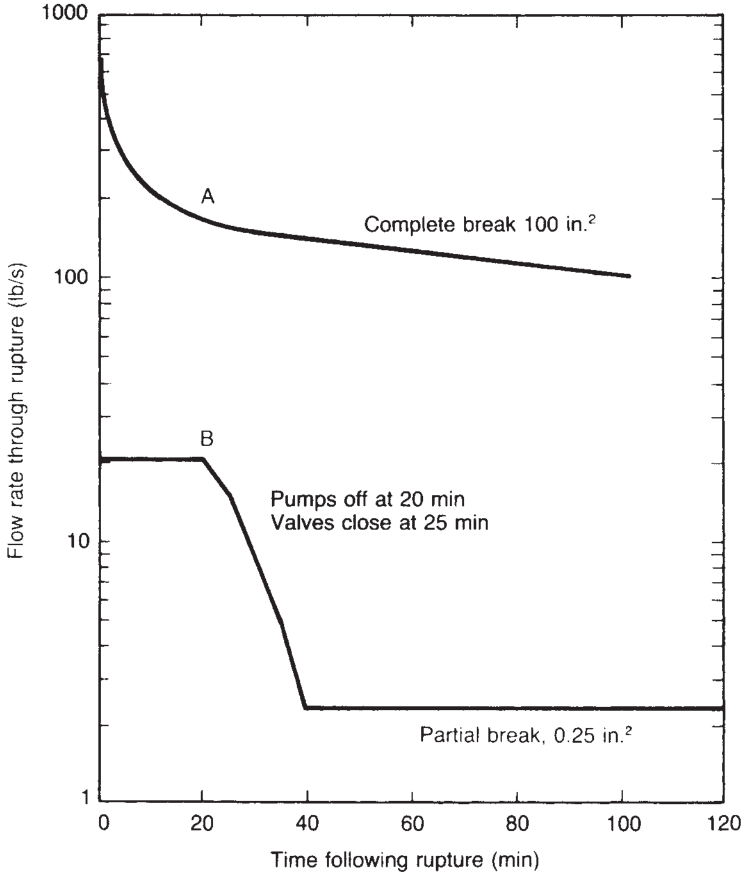


Figure 15.30 *Emission from an LPG pipeline: flow of propane for partial and complete ruptures. Isolation value spacing = 45 miles (T.B. Morrow, Bass and Lock, 1982) (Courtesy of the American Society of Mechanical Engineers)*

An account of the extensions made to the BLOWDOWN model to allow it to be applied to a gas pipeline has been given by J.R. Chen, Richardson and Saville (1992). The basic model comprises the unsteady one-dimensional Euler equations supplemented by friction and heat transfer relations. Chen *et al.* describe the investigation of a number of methods for the solution of these equations, including finite difference methods (FDMs), the method of characteristics (MOC), a hybrid method and a wave tracing method. The technique found to be most efficient and accurate was the multiple wave tracing method.

The investigation made use of the test problem of Picard and Bishnoi (1989) and of data on the depressurization of the pipeline between Piper Alpha and MCP-01 on the night of the accident. Results are presented which include values of the intact end pressure, the open end pressure and the release rate.

15.9.4 Pipeline isolation

The quantity of material released from a pipeline rupture depends on whether the section of line is isolated or not. The arrangements for line break detection and isolation are therefore of the greatest importance in minimizing escapes.

15.10 Vaporization

If the fluid that escapes from containment is a liquid, then vaporization must occur before a vapour cloud is formed. The process of vaporization determines the rate at which material enters the cloud. It also determines the amount of air entrained into the cloud. Both aspects are important for the subsequent dispersion. Selected references on vaporization are given in Table 15.7

15.10.1 Vaporization situations

In considering the generation of a vapour cloud from the liquid spillage, the following situations can be distinguished:

(1) A volatile liquid at atmospheric temperature and pressure, for example, acetone.
(2) A superheated liquid
  (a) at ambient temperature and under pressure, for example, butane;
  (b) at high temperature and under pressure, for example, hot cyclohexane.
(3) A refrigerated liquefied gas at low temperature but at atmospheric pressure, for example, cold methane.

The vaporization of the liquid is different for these three cases. In the first case the liquid after spillage is approximately at equilibrium and evaporates relatively slowly. In the second case the liquid is superheated and flashes off when spilt, and then undergoes slower evaporation. The first category of a superheated liquid, at ambient temperature but under pressure, is that of a liquefied gas, while the second, at high temperature and under pressure, is that of a liquid heated above its normal boiling point. The third case is that of a refrigerated liquefied gas that on spillage evaporates rapidly at first and then more slowly.

15.10.2 Vaporization of a superheated liquid

If the liquid released from containment is superheated, a proportion flashes off as vapour. The remaining liquid is cooled by the removal of the latent heat of vaporization and falls to its atmospheric boiling point.

The theoretical adiabatic flash fraction (TAFF) of vapour so formed is usually determined by the simple heat balance

$$\phi = \frac{c_{\mathrm{pl}}}{\Delta H_{\mathrm{v}}}(T_{\mathrm{i}} - T_{\mathrm{b}}) \quad T_{\mathrm{i}} > T_{\mathrm{b}} \qquad [15.10.1]$$

where c_{p} is the specific heat, T is the absolute temperature, ΔH_{v} is the latent heat of vaporization, ϕ is the fraction of liquid vaporized and subscripts b, i and l denote boiling point, initial and liquid, respectively.

An alternative expression that takes account of the differential nature of the vaporization is

$$(1 - \phi)c_{\mathrm{pl}}(-\mathrm{d}T) = \Delta H_{\mathrm{v}}\,\mathrm{d}\phi \qquad [15.10.2]$$

and hence

$$\phi = 1 - \exp\left[-\frac{c_{\mathrm{pl}}}{\Delta H_{\mathrm{v}}}(T_{\mathrm{i}} - T_{\mathrm{b}})\right] \quad T_{\mathrm{i}} > T_{\mathrm{b}} \qquad [15.10.3]$$

Equations 15.10.1 and 15.10.3 give the theoretical fraction of vapour formed. The sudden growth and release of vapour bubbles also results in the formation of liquid droplets, or spray. The mass of liquid in spray form is generally of the same order as that in the initial vapour flash and may exceed it.

This spray then either vaporizes, increasing the vapour cloud, or rains out as liquid, forming a pool on the ground. The total amount of vapour formed, both that from the initial flash and that from the evaporation of spray, constitutes the ultimate flash.

For the fraction of liquid which forms spray a rule-of-thumb frequently used is that it is equal to the initial vapour flash (Kletz, 1977J). Another rule-of-thumb is that if the fraction flashing off is small it may be appropriate to assume that the spray fraction is two or three times the initial vapour flash-off (W.G. High, 1976).

A discussion of spray and rainout following the discharge of a flashing liquid, with particular reference to liquid ammonia, has been given by Wheatley (1986). Two discharge situations may be distinguished: meta-stable flow of a superheated liquid and choked two-phase flow. These two cases have been modelled by Wheatley. As shown in Table 15.8, the flow characteristics obtained are significantly different.

In the non-choked liquid flow case there is a large increase in diameter of the flow at the outlet. Such large increases have been observed in the Desert Tortoise tests (Koopman *et al.*, 1986). In the choked two-phase flow case the flow velocity is much higher. The flash fraction is similar in the two cases.

The drops formed are subject to shear stress and there is a maximum size of drop given by the drop Weber number:

$$\mathrm{We_d} = \frac{u_d^2 d \rho_d}{\sigma_d} \qquad [15.10.4]$$

where d is the diameter of the drop, u is the velocity, ρ is the density, σ is the surface tension and subscript d denotes drop. Table 15.8 shows the drop sizes obtained for the two cases.

The extent to which rainout of the drops occurs depends on a balance between the inertial and gravity forces. The drops will have higher inertia than the vapour but will be more affected by gravity. Wheatley treats rainout in terms of the inclination of the bounding drop trajectory, which is obtained from the ratio of the settling velocity to the horizontal velocity of the drops. The settling velocity and inclination of the drops for the cases considered are shown in Table 15.8. Both for the superheated liquid flow and the choked two-phase flow the inclinations are too small to give significant rainout, but for the refrigerated liquid flow the inclination is much larger and rainout could be significant.

Following flash-off, the residual liquid is at its normal boiling point. Vaporization then continues as a rate-limited process. This secondary stage of rate-limited vaporization is usually regarded as relatively less important compared with the initial flash-off, particularly with respect to the formation of flammable gas clouds.

The spray fraction from a ruptured vessel was considered in Section 15.7. Frequently, very little liquid is left in the vessel. The spray fraction in fireballs is discussed in Chapter 16.

15.10.3 Mass and heat transfer for a pool

In general, vaporization from a pool is a mass and heat transfer limited process, but in a specific case there may be one dominant transfer mode. Thus for vaporization of a cryogenic liquid it is the heat transfer from the ground to the pool which governs the rate of vaporization.

For a pool there is only one mode of mass transfer, that between the liquid surface and the atmosphere. By contrast, for heat transfer there are several modes, namely heat transfer by convection between the liquid surface and the atmosphere, by conduction between the liquid and the ground, and by radiation, both solar and between the liquid surface and the atmosphere.

The heat balance on the pool is thus

$$wc_{\mathrm{pl}}\frac{\mathrm{d}T}{\mathrm{d}t} = -A_{\mathrm{p}}(q_{\mathrm{v}} - q_{\mathrm{cn}} - q_{\mathrm{cd}} - q_{\mathrm{r}}) \qquad [15.10.5]$$

with

$$q_{\mathrm{r}} = q_{\mathrm{rs}} + q_{\mathrm{ra}} - q_{\mathrm{rl}} \qquad [15.10.6]$$

$$q_{\mathrm{v}} = m_{\mathrm{v}}\Delta H_{\mathrm{v}} \qquad [15.10.7]$$

where A_{p} is the area of the pool, c_{pl} is the specific heat of the liquid, m_{v} is the mass vaporization rate per unit area, q_{cd} is the heat flow per unit area by conduction from the ground to the pool, q_{cn} is the heat flow per unit area by convection from the atmosphere to the pool, q_{r} is the net heat flow per unit area by radiation to the pool, q_{ra} is the heat flow per unit area by radiation from the atmosphere to the pool, q_{rl} is the heat flow per unit area by radiation from the pool to the atmosphere, q_{rs} is the heat flow per unit area by solar radiation to the pool, q_{v} is the heat required per unit area for vaporization, t is the time and w is the mass of liquid.

The mass balance on the pool is

$$-\frac{\mathrm{d}w}{\mathrm{d}t} = A_{\mathrm{p}}m_{\mathrm{v}} \qquad [15.10.8]$$

Table 15.8 *Flow characteristics of discharge of liquid ammonia (after Wheatley, 1986) (Courtesy of the Institution of Chemical Engineers)*

Storage temperature (°C)	*Flow type*	*Axial velocity* (m/s)	*Flow diameter* (cm)	*Flash fraction* (%)	*Spray characteristics*		*Inclination* (°)
					Drop size (μm)	*Settling velocity* (m/s)	
20	Liquid	154	13	17.6	25	0.013	0.0048
20	Two-phase	37.7	61	18.7	420	1.4	2.1
−34	Liquid				1900	5.2	16

with

$$m_v = \frac{k_m M(p^o - p_\infty)}{RT} \qquad [15.10.9]$$

where k_m is the mass transfer coefficient, p° is the vapour pressure of the liquid and p_∞ is the partial pressure of the liquid outside the influence of the pool. The partial pressure p_∞ can usually be set equal to zero. For a multi-component liquid Drivas (1982) has modified Equation 15.10.9 as follows:

$$m_v = \frac{k_m M_T^o}{RTn_T} \frac{\sum x_i^o M_i p_{is}}{\sum x_i^o M_i} \exp(-kp_{is}t) \qquad [15.10.10]$$

with

$$k = \frac{k_m A_p}{RTn_T} \qquad [15.10.11]$$

where M_i is the molecular weight of component i, M_T^o is the initial mass of the liquid, n_T is the number of moles of the liquid, p_{is} is the vapour pressure of component i, x_i^o is the initial mole fraction of component i in the liquid and k is a constant.

In general, heat transfer may be correlated by the factor j_h of Chilton and Colburn (1934) and mass transfer by the corresponding factor j_m. For a geometry where the characteristic dimension is the diameter d these j factors are defined as

$$j_h = \mathrm{St}\,\mathrm{Pr}^{0.67} \qquad [15.10.12]$$

$$j_m = \frac{k_m}{u}\frac{C_{Bm}}{C_T}\mathrm{Sc}^{0.67} \qquad [15.10.13]$$

where C_{Bm} is the log mean concentration difference, C_T is the total concentration and k_m is the mass transfer coefficient. The term C_{Bm}/C_T is the drift factor.

The definitions of, and relations between, the Reynolds number Re, the Prandtl number Pr, the Nusselt number Nu, the Schmidt number Sc and the Stanton number St are

$$\mathrm{Re} = \frac{ud\rho}{\mu} \qquad [15.10.14]$$

$$\mathrm{Pr} = \frac{c_p\mu}{k} \qquad [15.10.15]$$

$$\mathrm{Nu} = \frac{hd}{k} \qquad [15.10.16]$$

$$\mathrm{Sc} = \frac{\mu}{\rho D} \qquad [15.10.17]$$

$$\mathrm{St} = \frac{h}{c_p\rho} \qquad [15.10.18]$$

$$\mathrm{St} = \frac{\mathrm{Nu}}{\mathrm{RePr}} \qquad [15.10.19]$$

where d is the pool diameter, D is the diffusion coefficient, k is the thermal conductivity and μ is the viscosity.

Given a correlation for j_h, the heat transfer coefficient h may be obtained from the definition of j_h in Equation 15.10.12. Then, using the approximate equality,

$$j_m \approx j_h \qquad [15.10.20]$$

and using the definitions of j_h, and j_m in Equations 15.10.12 and 15.10.13

$$k_m = \frac{hC_T}{c_p\rho C_{Bm}}\left(\frac{\mathrm{Pr}}{\mathrm{Sc}}\right)^{0.67} \qquad [15.10.21]$$

Alternatively, if the correlation available is for j_m this may be used to obtain j_h. For other geometries the diameter d is replaced by the characteristic length.

A number of workers have measured mass transfer from a plane liquid surface to a gas stream above, particularly in the evaporation of water. An account is given by Coulson and Richardson (1977–). Their results have been correlated by T.K. Sherwood (1940) in terms of a point Reynolds number Re_x where the characteristic dimension is the distance across the liquid surface to the point considered. His results may be expressed as

$$j_m = 0.0415\mathrm{Re}_x^{-0.21} \qquad [15.10.22]$$

over the approximate range $10^4 < \mathrm{Re}_x < 10^5$. Equation 15.10.22 may be used, in conjunction with Equation 15.10.20, to obtain both the mass and heat transfer coefficients.

The mass transfer coefficient may also be correlated directly in terms of the Sherwood number Sh:

$$\mathrm{Sh} = \frac{k_m d}{D} \qquad [15.10.23]$$

Fleischer (1980) has given the following correlation for the Sherwood number over a plane liquid surface:

$$\mathrm{Sh} = 0.037\mathrm{Sc}^{1/3}(\mathrm{Re}^{0.8} - 15,200) \qquad [15.10.24]$$

The transition from the laminar to the turbulent regime is taken here to occur at $\mathrm{Re} = 320{,}000$.

In the case of the plane liquid surface there is also available for the mass transfer a specific correlation for the evaporation rate derived by Sutton and Pasquill. This is described in Section 15.10.4.

Heat transfer from the ground is complex, because it involves an unsteady-state process. An account of unsteady-state heat transfer, including many standard cases, is given by Carslaw and Jaeger (1959). The basic equation is

$$\frac{d^2\theta}{dz^2} = \frac{1}{\alpha_s}\frac{d\theta}{dt} \qquad [15.10.25]$$

with

$$\theta = T - T_s \qquad [15.10.26]$$

$$\alpha_s = \frac{k_s}{\rho_s c_{ps}} \qquad [15.10.27]$$

where α is the thermal diffusivity, θ the temperature above the datum, or soil, temperature and subscript s denotes soil.

For the case of constant liquid temperature, Equation 15.10.25 may be solved with the boundary conditions $z = 0$, $\theta = \theta_1$; $z = \infty$, $\theta = \theta_s$. For temperature this gives

$$\frac{\theta}{\theta_l} = \mathrm{erf}\,c\left[\frac{z}{2(\alpha_s t)^{1/2}}\right] \quad [15.10.28]$$

where z is the vertical distance down into the ground and subscript l denotes liquid.

For the heat flow per unit area q

$$q = -k\frac{\mathrm{d}\theta}{\mathrm{d}z} \quad [15.10.29]$$

Then from Equations 15.10.28 and 15.10.29 and

$$q = \left(\frac{k_s\rho_s c_{ps}}{\pi}\right)^{1/2}\frac{\theta_1}{t^{1/2}} \quad [15.10.30]$$

For the total heat transferred per unit area Q

$$Q = \int_0^t q\,\mathrm{d}t \quad [15.10.31]$$

and from Equations 15.10.30 and 15.10.31

$$Q = 2\left(\frac{k_s\rho_s c_{ps}}{\pi}\right)\theta_1 t^{1/2} \quad [15.10.32]$$

For the more complex case of varying liquid temperature, Equation 15.10.25 may be solved with the boundary conditions $t = 0$, $\theta = 0$; $z = 0$, $\theta = \theta_l(t)$; $z = \infty$, $\theta = 0$. For temperature this gives

$$\theta = \frac{z}{2(\pi\alpha_s)^{1/2}}\int_0^t \frac{\theta_l}{(t-\tau)^{3/2}}\exp\left[-\frac{z^2}{4\alpha_s(t-\tau)}\right]\mathrm{d}\tau \quad [15.10.33]$$

The decrease in temperature of a vaporizing pool will be approximately exponential. An analytical solution of Equation 15.10.33 for the case $\theta_l = \exp(-\lambda t)$, where λ is a constant, is given by Carslaw and Jaeger.

For heat transfer by radiation the net heat radiated to the pool is given by Equation.15.10.6. The individual terms in the equation are given by

$$q_{rs} = \psi(1-a) \quad [15.10.34]$$

$$q_{ra} = \epsilon_a\sigma T_a^4 \quad [15.10.35]$$

$$q_{rl} = \epsilon_l\sigma T_l^4 \quad [15.10.36]$$

where a is the albedo of the liquid surface, ϵ is the emissivity, σ is the Stefan–Boltzmann constant, ψ is the solar constant and subscript a denotes atmosphere. The value of the solar constant is 1373 W/m^2 (Lide, 1994).

The albedo and emissivities have been discussed by Mackay and Matsugu (1973), who propose for the albedo a value of 0.14 and for the emissivities of the atmosphere and of the liquid values of 0.75 and 0.95, respectively.

The albedo of a plane water surface has also been discussed by Shaw and Briscoe (1978 SRD R100). The albedo is actually a function of the sun's elevation. They give the following values:

Elevation (°)	90	50	40	20	10	0
Albedo	0.02	0.025	0.034	0.134	0.348	1.0

Data on the albedo for different surfaces are given by Oke (1978). A further discussion of albedo is given by Byrne *et al.* (1992 SRD R553).

15.10.4 Sutton–Pasquill model

A model for mass transfer in evaporation from a liquid surface at constant temperature has been derived by O.G. Sutton (1934). Sutton's model was subsequently modified by Pasquill (1943) and the modification was accepted by O.G. Sutton (1953). In the form given by Pasquill, the relations for evaporation from a rectangular and a circular pool are:

$$E = Ku_1^{(2-n)/(2+n)}x_o^{2/(2+n)}y_o \quad \text{rectangular pool} \quad [15.10.37]$$

$$E = K'u_1^{(2-n)/(2+n)}r^{(4+n)/(2+n)} \quad \text{circular pool} \quad [15.10.38]$$

with

$$K = \chi_o\left(\frac{2+n}{2-n}\right)^{(2-n)/(2+n)}\left(\frac{2+n}{2\pi}\right)\sin\left(\frac{2\pi}{2+n}\right)\Gamma\left(\frac{2}{2+n}\right)\times \mathrm{a}^{2/(2+n)}z_1^{-n^2/(4-n^2)} \quad [15.10.39]$$

$$K' = \frac{2^{2+n}\pi^{1/2}\Gamma(3+n/2+n)K}{\Gamma(8+3n/2(2+n))} \quad [15.10.40]$$

$$a = \left|\frac{[(\pi/2)]^{1-n}(2-n)^{1-n}n^{1-n}}{(1-n)(2n-2)^{2(1-n)}}\right|k^{2(1-n)}\lambda^n z_1^{(n^2-n)/(2-n)} \quad [15.10.41]$$

$$\chi_o = \frac{Mp^o}{RT} \quad [15.10.42]$$

where E is the evaporation rate (g/s), k is the von Karman' constant, M is the molecular weight, n is the diffusion index, p^o is the vapour pressure of the liquid (dyn/cm^2), r is the radius of the pool (cm), R is the universal gas constant (erg/gmol K), T is the absolute temperature (K), u_1 is the wind speed at height z_1 (cm/s), x_o is the downwind length of the pool (cm), y_o is the crosswind width of the pool (cm), z_1 is the height at which the wind speed u_1 is measured (cm), λ is a parameter (cm^2/s), χ_o is the concentration (g/cm^3) and a, K and K' are constants. The constant K may be written as:

$$K = \chi_o f_1(n)\mathrm{a}^{2/(2+n)}z_1^{-n^2/(4-n^2)} \quad [15.10.43]$$

$$= \chi_o f_1(n)^{2/(2+n)}f_2(n)^{2/(2+n)}k^{4(1-n)/(2+n)} \times \lambda^{2n/(2+n)}z_1^{-n/(2+n)} \quad [15.10.44]$$

with

$$f_1(n) = \left[\frac{2+n}{2-n}\right]^{(2-n)/(2+n)} \left[\frac{2+n}{2\pi}\right] \sin\left[\frac{2\pi}{2+n}\right] \Gamma\left[\frac{2}{2+n}\right] \qquad [15.10.45]$$

$$f_2(n) = \frac{(\pi/2)^{1-n}(2-n)^{1-n}n^{1-n}}{(1-n)(2-2n)^{2-2n}} \qquad [15.10.46]$$

Sutton's treatment is based on the wind velocity profile:

$$\frac{u}{u_1} = \left[\frac{z}{z_1}\right]^{n/(2-n)} \qquad [15.10.47]$$

where u is the wind speed (cm/s) and z is the height (cm).

Sutton identified the parameter λ with the kinematic viscosity of the air ν. Pasquill gives a table of values for the constants K and K' for the following case:

$k = 0.4$

$\lambda = \nu = 0.147\ \mathrm{cm^2/s}$

$\chi_o = 1\ \mathrm{g/cm^3}$

$z_1 = 1\ \mathrm{cm}$

$u_1 = 500\ \mathrm{cm/s}$

Hence

n	K	K'
0.20	0.0094	0.0283
0.25	0.0180	0.0537
0.30	0.0313	0.0926

He also gives the results of an experiment for which

$M = 157$

$T = 290\ \mathrm{K}$

$x_o = 10\ \mathrm{cm}$

$y_o = 20\ \mathrm{cm}$

$n = 0.219$

Hence

$K = 0.0122\chi_0$

and

$$\frac{E}{p^o} = 1.89 \times 10^{-6}\ (\mathrm{g/s})/(\mathrm{dyn/cm^2})$$

However, Pasquill argued that the parameter should properly be the diffusion coefficient D of the vapour in air and this argument was accepted by O.G. Sutton (1953). Hence in Equations 15.10.39–15.10.44, λ should be set equal to D.

Equations for the Sutton–Pasquill model have been given by V.J. Clancey (1974a) in the following form. For a rectangular pool set square to the wind direction:

$$E = 1.2 \times 10^{-10}\frac{Mp^o}{T}u^{0.78}x_o^{0.89}y_o \quad \text{rectangular pool} \qquad [15.10.48]$$

$$E = 3.6 \times 10^{-10}\frac{Mp^o}{T}u^{0.78}r^{1.89} \quad \text{circular pool} \qquad [15.10.49]$$

Clancey states that in deriving Equations 15.10.48 and 15.10.49 he has used values $\lambda = 0.147\ \mathrm{cm^2/s}$ and $D \approx 0.075\ \mathrm{cm^2/s}$, the latter being typical for hydrocarbons. In determining K from Equation 15.10.39 he appears to have included both the terms $\lambda^{2n/(2+n)}$ and $D^{2n/(2+n)}$, which for $n = 0.25$ have the values 0.653 and 0.56, respectively. Equations 15.10.48 and 15.10.49 may be corrected for this by dividing by 0.653.

Relations for the Sutton–Pasquill model in SI units are given in the *Rijnmond Report*. The report gives Equations 15.10.37 and 15.10.38 together with the equations

$$K = a\chi_o D^{2n/(2+n)} z_1^{-n/(2+n)} \qquad [15.10.50]$$

$$K' = a'\chi_o D^{2n/(2+n)} z_1^{-n/(2+n)} \qquad [15.10.51]$$

where D is the diffusion coefficient of vapour in air ($\mathrm{m^2/s}$), E is the evaporation rate (kg/s), r is the radius of the pool (m), x_o is the downwind length of the pool (m), y_o is the crosswind width of the pool (m), χ_o is the concentration of the vapour in the air ($\mathrm{kg/m^3}$), u is the wind speed at height z_1(m/s), z_1 is the height at which the wind speed is measured (m) and a and a' are constants. The constant a is different from that given in Equation 15.10.41. The following values are given for the groups K/χ_o and K'/χ_o:

n	K/χ_o	K'/χ_o
0.20	1.278×10^{-3}	3.846×10^{-3}
0.25	1.579×10^{-3}	4.685×10^{-3}
0.30	1.786×10^{-3}	5.285×10^{-3}

15.10.5 Vaporization of a volatile liquid

Vaporization of a volatile liquid is governed by the mass and heat transfer rate processes described in Section 15.10.3. If the vaporization rate is low so that the heat transfer to the pool is sufficient to prevent a fall in the temperature of the liquid, the vaporization is a mass transfer limited process that depends on the vapour pressure of the liquid and the wind flow across the pool. At higher vaporization rates, where the heat transfer to the pool is insufficient to prevent chilling, the liquid temperature will fall, approaching asymptotically to a steady-state value. The approach will generally be approximately exponential.

It has been shown theoretically by Flothmann, Heudorfer and Langbein (1980) that for pools of liquids such as hydrogen cyanide and acrolein, neglect of heat transfer from the ground can lead to appreciable error in the estimation of the vaporization rate, particularly under conditions of low solar radiation and/or low wind speeds. Vaporization from a pool of a volatile liquid constitutes a steady, continuous source of vapour.

Higher vaporization rates still occur where the liquid is at or close to its boiling point. There is relatively little information available on vaporization under these conditions. This situation has been discussed by Shaw and Briscoe (1978 SRD R100), who consider the vaporization of a liquid such as butane (b.p. −0.5°C) on a cold surface at 0°C. The liquid boils and the vaporization is limited by heat transfer, the heat transfer being by convection from the air and by radiation, that from the ground being minimal.

They propose the use of the relations of Mackay and Matsugu (1973), given in Section 15.10.6, both for convective heat transfer from the air to the pool and for the net radiative heat transfer. For the former the heat transfer coefficient may be obtained from the expression for the mass transfer coefficient. They also discuss the question of the concentration and temperature at which the necessary physical properties should be determined.

A correlation for the vaporization rate for a liquid at a temperature above ambient has been given by the Centre for Chemical Process Safety (CCPS, 1987/2):

$$m_v = C_D u(\rho_{gs} - \rho_g) \qquad [15.10.52]$$

where C_D is the drag coefficient, u is the wind speed, ρ_g is the density of gas 10 m above the pool and ρ_{gs} is the saturation density of the gas at ambient conditions. The value of C_D is about 10^{-3} if u is measured 10 m above the pool.

15.10.6 Mackay and Matsugu model

A model for the vaporization of a volatile liquid from a circular pool has been given by Mackay and Matsugu (1973). The authors carried out experiments on the evaporation of water, gasoline and cumene from 4 × 4 ft and 4 × 8 ft pans.

In their model the heat balance on the pool is given by Equation 15.10.5, except that the term for heat conduction from the ground is omitted. For mass and heat transfer between the pool and the atmosphere:

$$N = \frac{k_m(p - p_\infty)}{RT_l} \qquad [15.10.53]$$

$$q_{cn} = h(T_a - T_l) \qquad [15.10.54]$$

with

$$k_m = Cu^{0.78}x^{-0.11} \qquad [15.10.55]$$

$$h = k_m \rho_v c_v (\mathrm{Sc}/\mathrm{Pr})^{0.67} \qquad [15.10.56]$$

$$C = k\mathrm{Sc}^{-0.67} \qquad [15.10.57]$$

where c is the specific heat, h is the heat transfer coefficient, k_m is the mass transfer coefficient, N is the mass transferred per unit area, p is the partial pressure of the vapour, q_{cn} is the heat flow per unit area by convection from the atmosphere to the pool, u is the wind speed, x is the diameter of the pool, C and k are constants and subscripts a, l, v and ∞ are air, liquid, vapour and atmosphere beyond influence of pool, respectively. In SI units, the value of k is $0.00482\ \mathrm{m}^{0.33}/\mathrm{s}^{0.22}$.

Equation 15.10.55 is based on the Sutton–Pasquill model with the diffusion index $n = 0.25$. The authors state that in terms of the factor j_m their correlation for the mass transfer coefficient is equivalent to

$$j_m = 0.0565\mathrm{Re}^{-0.22} \qquad [15.10.58]$$

where Re is in the range $7 \times 10^4 - 4.6 \times 10^5$.

For the net radiation the authors use Equations 15.10.34–15.10.36 with the values of the parameters quoted in Section 15.10.3.

As stated earlier, the model given by these authors does not include a term for heat transfer from the surface beneath the pool. This term was presumably not significant in their particular experiments, which involved evaporation pans.

15.10.7 Spreading of a liquid

Accounts of the spreading of liquids are given in *Water Waves* (Stoker, 1957) and *Oil on Sea* (Hoult, 1969) and by Abbott (1961) and Webber and Brighton (1986). Much of the work is concerned with the spreading of oil slicks, which is treated by Fay (1969, 1973) and by Hoult (1969, 1972b).

If the liquid is not confined within a hollow or a bund, but is free to spread, it is usually necessary to take account of such spreading and to use a treatment based on simultaneous spreading and vaporization. Spreading of a liquid on land and on sea differ somewhat and may require separate treatment.

The volume V of the liquid pool is a function of its radius r and height h

$$V = \pi r^2 h \qquad [15.10.59]$$

The growth of the pool may be expressed in terms either of the velocity u of the pool edge

$$\frac{dr}{dt} = u \qquad [15.10.60]$$

or of its acceleration.

As the pool spreads, it passes through different spreading regimes. Initially the frictional resistance may be negligible so that the gravity force is balanced by the inertia force. At a later stage, the inertia may be negligible so that the gravity force is balanced by the resistance force.

The pool growth has most commonly been modelled by the energy balance relation

$$\frac{dr}{dt} = (2g'h)^{1/2} \qquad [15.10.61a]$$

or, more generally,

$$\frac{dr}{dt} = c(g'h)^{1/2} \qquad [15.10.61b]$$

with

$$g' = g \quad \text{on land} \qquad [15.10.62a]$$

$$g' = g\Delta \quad \text{on water} \qquad [15.10.62b]$$

$$\Delta = \frac{\rho_w - \rho_l}{\rho_w} \qquad [15.10.63]$$

where g is the acceleration due to gravity, g' is the reduced gravity, Δ is the reduced density, c is a constant and subscripts l and w denote liquid and water, respectively.

The value of the constant c in Equation 15.10.61b has been extensively treated in the literature. A value of c of 1.4 is often used. This value is close to the value of $2^{1/2}$ implied in Equation 15.10.61a.

It may be noted that Equations 15.10.59 and 15.10.61 give

$$\frac{\mathrm{d}r}{\mathrm{d}t} \propto r^{-1} \qquad [15.10.64]$$

A treatment which takes account of both the gravity–inertia and gravity–viscous regimes has been given by Raj and Kalelkar (1974). In the former the gravity force F_g is opposed by the inertial force F_i

$$F_\mathrm{g} = \pi \rho g' h^2 r \qquad [15.10.65]$$

$$F_\mathrm{i} = -C\pi\rho h r^2 \frac{\mathrm{d}^2 r}{\mathrm{d}t^2} \qquad [15.10.66]$$

where C is a constant. The constant C represents the ratio of the inertia of the liquid system to the inertia that would exist if all the liquid were moving at the acceleration of the spill edge. The value given for C is 0.754.

Then, equating the two forces F_g and F_i gives

$$r\frac{\mathrm{d}^2 r}{\mathrm{d}t^2} = -\frac{g'h}{C} \qquad [15.10.67]$$

The authors also give a treatment of the gravity–viscous regime.

A relation that takes account of the frictional resistance has been given by Webber and Brighton (1986). They suggest that the natural model to use for the spreading of a thin layer of liquid is the shallow water, or shallow layer, equations (Stoker, 1957). From these equations they derive the relation

$$\frac{\mathrm{d}^2 r}{\mathrm{d}t^2} = \frac{4g'h(1-s)}{r} - F \qquad [15.10.68]$$

where F is a friction term and s is a shape factor. The friction factor is

$$F = C_\mathrm{L}\frac{u^2}{h} + \left(\frac{3}{2}\right)^5 \frac{\nu u}{h^2} \quad \text{on land} \qquad [15.10.69a]$$

$$F = C_\mathrm{W}\frac{u^2}{h} + 1.877\frac{\nu u}{h^2}(1-f) \quad \text{on water} \qquad [15.10.69b]$$

where ν is the kinematic viscosity and C_L and C_W are constants for land and sea, respectively. The factor f allows for the effect on the shear stress on the pool of the radial motion in the water beneath it. In Equation 15.10.69 the right-hand side contains both a turbulent and a laminar term.

In a further treatment, Webber and Brighton (1986 SRD R371) have expressed their results in the form

$$\frac{\mathrm{d}^2 r}{\mathrm{d}t^2} = -\frac{gV}{\pi}\frac{\beta}{r^3} \qquad [15.10.70]$$

where β is a shape factor. The shape factor β determines the edge height of the pool and its value depends on the pool boundary conditions. Relevant factors include the surface tension of the liquid and the resistance of the ambient medium. For a convex pool $\beta < 0$, for a concave pool $\beta > 0$, for a cylindrical pool $\beta = 0$. A value of $\beta = -4$ corresponds to a pool with zero edge height (zero surface tension) and one of $\beta = 4$ corresponds to a pool with its centre tending to zero thickness. Hence from Equation 15.10.70

$$\frac{\mathrm{d}^2 r}{\mathrm{d}t^2} \propto r^{-3} \qquad [15.10.71]$$

15.10.8 Vaporization of a cryogenic liquid

In the general case of vaporization of a cryogenic liquid, or refrigerated liquefied gas, it is necessary to consider simultaneous spreading and vaporization. Considering initially just the vaporization, this is governed by heat transfer from the ground to the liquid. There is a short period of very rapid vaporization followed by a relatively steady lower rate of vaporization.

The rate of vaporization is obtained from the heat flux as given by Equation 15.10.30:

$$q = \left(\frac{k_\mathrm{s}\rho_\mathrm{s}c_\mathrm{ps}}{\pi}\right)^{1/2}\frac{\theta_1}{t^{1/2}} \qquad [15.10.72]$$

Equation 15.10.72 may be written as

$$q = A_\mathrm{v} t^{1/2} \qquad [15.10.73]$$

with

$$A_\mathrm{v} = \left(\frac{k_\mathrm{s}\rho_\mathrm{s}c_\mathrm{ps}}{\pi}\right)^{1/2}\theta_1 \qquad [15.10.74]$$

where A_v is the vaporization parameter. Equation 15.10.73 has been confirmed experimentally.

It should be noted that for zero time Equation 15.10.72 gives an infinite heat transfer rate and is not applicable, but the period over which the heat transfer rate is overestimated is very short.

Most studies of the vaporization of cryogenic liquids have been concerned with liquefied natural gas (LNG) or liquefied ammonia. These are considered in the following sections.

Large-scale tests on the vaporization of refrigerated liquid ethylene have been conducted in Japan by a working group headed by Professor Hikita Tsuyoshi under the auspices of the Ministry of International Trade and Industry (MITI) (1976) and other bodies. This work was part of a programme of tests on various aspects of hazards of liquid ethylene.

In one test, 392 kg of liquid ethylene at a temperature of −104°C was poured into a 2.5 m diameter bund with a pebble floor. There was violent boiling of the liquid that caused an estimated 66% of it to vaporize or form spray within the first minute. The spillage gave rise to a cloud of ethylene with regions of mist and vapour.

The contours of the mist and of the vapour concentrations corresponding to lower explosive limit were similar, but not identical. The maximum distances reached by vapour concentrations of 2.7% (the lower explosive limit), 2.0% and 1.0% were 60, 80 and 86 m, respectively, all attained after 70 s. The mean wind speed was approximately 2.5 m/s.

The initial vaporization rate of the liquid ethylene over the first minute was fitted by the equation

$$v = 0.625\exp(-0.0507t) \qquad [15.10.75]$$

where t is the time (s) and v is the regression rate (cm/s). After the first minute the rate of vaporization was much reduced.

A collection of experimental data for the validation of models of spills of cryogenic liquids on land and water has been made by Prince (1985 SRD R324).

Vaporization from a pool of a cryogenic liquid constitutes initially a near-instantaneous source of vapour followed by steady, continuous source.

15.10.9 Spreading and vaporization of LNG

Accounts of the spreading and vaporization of LNG have been given by a number of workers including Burgess, Murphy and Zabetakis (1970 BM RI 7448), Humbert-Basset and Montet (1972), Kneebone and Boyle (1973), Feldbauer *et al.* (1972), Raj and Kalelkar (1973), the American Gas Association (AGA) (1974), Drake and Reid (1975), Opschoor (1977, 1980), Shaw and Briscoe (1978 SRD R100) and Raj (1979, 1981).

A general account of the spreading of a liquid such as LNG has been given in Section 15.10.7. In this section a description is given of work on the vaporization rate of a pool of LNG of fixed area on land or on water and of some simple treatments of simultaneous spreading and vaporization of LNG. Some principal models for the latter are given in the following sections.

Evaporation of liquid methane on common surfaces such as soil has been investigated by Burgess and Zabetakis (1962 BM RI 6099). They found that initially the vaporization rate v was limited by the rate of heat transfer from the substrate and was given by the relation

$$v = \frac{k_s}{\rho_l \Delta H_v}\frac{T_s - T_l}{(\pi\alpha_s t)^{1/2}} \qquad [15.10.76]$$

Equation 15.10.76 applied only to the initial rapid vaporization period, which did not exceed 1 min.

Values of the thermal conductivity and thermal diffusivity for different substrates are given by Carslaw and Jaeger (1959), as described below. There is relatively little difference between the values for average soil and normal concrete.

During the initial period the vaporization rate for liquid methane is high. Thereafter it decays and becomes dependent on the wind speed and is thus convection controlled. It approaches a constant value of approximately 0.02 in./min at low wind speeds after periods of 0.25–2 h. A log – log plot of vaporization rate vs time gives a straight line.

The evaporation of LNG on various surfaces has been investigated by Drake and Reid (1975). These authors describe experimental work at MIT and refer also to other experimental work by the American Gas Association (AGA) (1974) and work done by Gaz de France (Humbert-Basset and Montet, 1972). They found that the initial transfer and vaporization rates are in accordance with Equation 15.10.73, but that they vary considerably, depending on the nature of the substrate.

Drake and Reid quote both calculated and experimental values of the vaporization parameter A_v in Equation 15.10.73. Values of the parameters ρ_s, c_{ps} and k_s for various substrates are given by Carslaw and Jaeger (1959). From these parameters the corresponding values of A may be calculated. It is assumed that the substrate is at 16°C (60°F) and the LNG is at −162°C (−260°F) so that ($T_s - T_l$) is 178°C. These calculated values of A_v are compared by Drake and Reed with experimental values for LNG spills obtained in the AGA and Gaz de France tests, as shown in Table 15.9. By contrast the value of A given for insulating concrete is 0.61.

Drake and Reid state that the rate of vaporization of LNG is greater than that of pure methane. It is greater on surfaces such as crushed rock or pebbles than on compacted soil. On soils, the vaporization rate is enhanced by percolation if the soil is dry. The extent of percolation in most soils is limited by the formation of a frozen barrier. Foaming is another factor that may increase the vaporization rate of LNG. A marked reduction in the vaporization rate of LNG may be obtained by the use of insulating concrete.

V.J. Clancey (1974a) has developed equations for the vaporization of a cryogenic liquid such as LNG. For the initial rapid vaporization

$$E_i = \frac{k_1(T_s - T_l)^2}{\Delta H_v} \qquad [15.10.77]$$

Table 15.9 *Vaporization parameters for LNG on different substrates (after Drake and Reid, 1975) (Courtesy of the American Institute of Chemical Engineers)*

	ρ_s (g/cm)	c_{ps} (cal/g°C)	k_s (cal/s cm°C)	A_v (cal/s$^{1/2}$cm^2)
Carslaw and Jaeger (1959, p. 497)				
Soil (average)	2.5	0.2	0.0023	3.41
Soil (sandy, dry)	1.65	0.19	0.00063	1.40
Soil (sandy, 8% moist)	1.75	0.24	0.0014	2.45
Concrete (1 : 2 : 4)	2.3	0.23	0.0022	3.39
AGA tests				
Soil (compacted)				8.5
Gaz de France				
Soil (dry, 15°C)				18.2
Soil (wet, 50°C)				12.7
Soil (wet, 15°C)				5.68

and for the steady continuous vaporization

$$E_s = \frac{k_2(T_s - T_l)}{\Delta H_v} \quad [15.10.78]$$

where E_i is the mass vaporized per unit area within 1 min (g/cm^2), E_s is the steady-state mass vaporization rate per unit area (g/cm^2 min), ΔH_V is the latent heat of vaporization (cal/g) and k_1 and k_2 are constants. The values of the constants k_1 and k_2 are as follows:

Substrate	k_1	k_2
Average soil	7.1×10^{-4}	1.5×10^{-2}
Concrete	7.5×10^{-4}	1.5×10^{-2}
Sandstone	1.3×10^{-3}	2.6×10^{-2}

Equation 15.10.77 is applicable where the temperature difference $(T_s - T_l)$ is large, as for a spillage of liquid methane. It is assumed in Equation 15.10.77 that the depth of ground which gives up heat to the pool is proportional to $(T_s - T_l)$; this accounts for the occurrence in Equation 15.10.77 of the term $(T_s - T_l)^2$.

For a large spillage the time that elapses before the vaporization rate reaches a quasi-steady state may be an hour or more. Clancey suggests that the values of the vaporization rate in this intermediate period may be obtained by logarithmic interpolation between the initial and steady vaporization rates.

Vaporization rates of LNG on water are relatively high. Work has been carried out by a number of investigators, including Burgess, Murphy and Zabetakis (1970 BM RI 7448), Kneebone and Boyle (1973), Feldbauer *et al.* (1972), Germeles and Drake (1975) and Opschoor (1977, 1981).

Burgess, Murphy and Zabetakis obtained a mass vaporization rate of 0.18 kg/m^2 s and Feldbauer *et al.* (1972) one of 0.20 kg/m^2 s. The First *Canvey Report* states that the vaporization rate obtained in such work is of the order of 0.19 kg/m^2 s.

For the vaporization rate, Opschoor (1980) quotes the following relation of J.S. Turner (1965):

$$q_w = 0.085 k_w \left(\frac{g\beta\Delta T^4}{\alpha_w \nu_w}\right)^{1/3} \quad [15.10.79]$$

where q_w is the heat flow per unit area by conduction from the water to the spill, ΔT is the temperature difference between the water and the liquid, β is the coefficient of cubical expansion and ν is the kinematic viscosity. For LNG, taking $\Delta T = 47.4$ K, Equation 15.10.79 gives

$$q_w = 2.3 \times 10^4 \ \mathrm{W/m^2}$$

which corresponds to a mass vaporization rate of

$$m_v = 0.045 \ \mathrm{kg/m^2\,s}$$

This value agrees well with the experimental results of Kneebone and Boyle (1973). Opschoor gives a preferred value of 0.05 kg/m^2 s.

Shaw and Briscoe (1978 SRD R100) use a regression rate based on the Esso work of 4.7×10^{-4} m/s. The regression rate used by Raj (1979) is 6.5×10^{-4} m/s.

Opschoor also gives relations for the estimation of the mass vaporization rate with ice formation beneath the LNG. It is found that an ice layer forms in about 20 s. Before the ice forms, film boiling pertains; once the film has formed heat transfer is by conduction through the ice. He gives for these two regimes the following mass vaporization rates:

$$m_v = 0.008t \quad 0 \le t \le 25 \quad [15.10.80a]$$

$$m_v = \frac{0.517}{(t-20)^{1/2}} \quad t > 25 \quad [15.10.80b]$$

where m_v is the mass vaporization rate per unit area (kg/m^2 s) and t is the time (s).

For simultaneous spreading and vaporization of LNG, Burgess, Murphy and Zabetakis (1970) have given the relations

$$r = k_3 t \quad [15.10.81]$$

$$\frac{\mathrm{d}m}{\mathrm{d}t} = \pi\rho v r^2 \quad [15.10.82]$$

$$m = \pi\rho v \int_0^t r^2(t)\,\mathrm{d}t \quad [15.10.83]$$

$$m = \frac{\pi}{3}\rho v k_3^2 t^3 \quad [15.10.84]$$

where m is the total mass vaporized, r is the radial distance and k_3 is a constant. The value of the constant k_3 is 0.381. Then, taking the density of LNG as 416 kg/m^3, Equation 15.10.84 becomes

$$m = 63.2 v t^3 \quad [15.10.85]$$

Lind (1974) has given a similar treatment but uses a value of k_3 of 0.635 based on the Esso experiments described by Feldbauer *et al.* (1972). From Equation 15.10.84 this gives

$$m = 175.7 v t^3 \quad [15.10.86]$$

Fay (1973) has used Equations 15.10.59 and 15.10.61a, integrating the latter with the boundary conditions $t = 0$ and $r = 0$ to obtain

$$r = \left(\frac{8g'V}{\pi}\right)^{1/4} t^{1/2} \quad [15.10.87]$$

Equation 15.10.87 may be used with Equation 15.10.83 to determine the mass vaporized. Fay assumes in his treatment that ice forms beneath the spill, and that this determines the vaporization rate. Raj and Kalelkar (1973) obtained the relation

$$m = 1.712\pi\rho v A^{1/2} t^2 \quad [15.10.88]$$

where A is the volume of liquid for an instantaneous spill.

These and other models have been reviewed by Shaw and Briscoe (1978 SDR R100).

15.10.10 Shaw and Briscoe model

A series of models for simultaneous spreading and vaporization of continuous and instantaneous spills of LNG on land and on water has been given by Shaw and Briscoe (1978 SRD R100).

For the vaporization of LNG on land in a fixed area such as a bund they give

$$\frac{\mathrm{d}m}{\mathrm{d}t} = \frac{A_{\mathrm{p}} X k_{\mathrm{s}} (T_{\mathrm{s}} - T_{\mathrm{b}})}{\Delta H_{\mathrm{v}} (\pi \alpha_{\mathrm{s}})^{1/2} t^{1/2}} \qquad [15.10.89]$$

where A_{p} is the area of the pool, ΔH_{v} is the latent heat of vaporization, k is the thermal conductivity, m is the total mass vaporized, α is the thermal diffusivity, and subscripts b and s denote the boiling point and soil, respectively. The factor X takes account of surface roughness. In the tests by the Japan Gas Association, after 1 s the regression rate was some three times the theoretical value ($X = 1$), and on this basis the authors suggest a value for X of 3.

In general, for an LNG spill the volume V of the pool is

$$V = A + Bt - m/\rho \qquad [15.10.90]$$

where A is the volume of liquid for instantaneous spill and B is the volumetric flow for a continuous spill.

From Equations 15.10.59 and 15.10.61

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \left(\frac{2g'V}{\pi r^2}\right)^{1/2} \qquad [15.10.91]$$

where r is the radius of the pool.

Analytical solutions of Equation 15.10.91 are obtained by neglecting the term m/ρ in Equation 15.10.90.

For an LNG spill on water the heat transfer rate, and hence the vaporization rate, is taken as constant and is characterized by the regression rate v. The authors use Equations 15.10.90 and 15.10.91 together with the relation

$$\frac{\mathrm{d}m}{\mathrm{d}t} = \pi r^2 \rho v \qquad [15.10.92]$$

For an instantaneous spill on water, Equation 15.10.91 is solved with the condition $B = 0$ (and hence $V = A$), $t = 0$ and $r = r_{\mathrm{o}}$, where r_{o} is the initial radius of the pool. Then, integrating Equation 15.10.91

$$r = \left[\left(\frac{8g'A}{\pi}\right)^{1/2} t + r_{\mathrm{o}}^2\right]^{1/2} \qquad [15.10.93]$$

and using Equations 15.10.92 and 15.10.93 and integrating the former

$$m = \pi \rho v \left[\left(\frac{2g'A}{\pi}\right)^{1/2} t^2 + r_{\mathrm{o}}^2 t\right] \qquad [15.10.94]$$

For a continuous spill on water, Equation 15.10.91 is solved with the condition $A = 0$ (hence $V = Bt$), $t = 0$ and $r = 0$. Then, as before, integrating Equation 15.10.91 followed by Equation 15.10.92 gives

$$r = \left(\frac{2}{3}\right)^{1/2} \left(\frac{8g'B}{\pi}\right)^{\frac{1}{8}} t^{3/2} \qquad [15.10.95]$$

$$m = \frac{4}{15} \pi \rho v \left(\frac{8g'B}{\pi}\right)^{1/2} t^{5/2} \qquad [15.10.96]$$

For an LNG spill on land the vaporization rate is determined by the heat transfer, and hence the vaporization rate decreases with time. The relation used for the vaporization rate is

$$\frac{\mathrm{d}m}{\mathrm{d}t} = 2\pi\theta \int_0^{r_2} \frac{r_1}{(t_2 - t_1)^{1/2}}\, \mathrm{d}r_1 \qquad [15.10.97]$$

with

$$\theta = \frac{X k_{\mathrm{s}} (T_{\mathrm{s}} - T_{\mathrm{b}})}{\Delta H_{\mathrm{v}} (\pi \alpha_{\mathrm{s}})^{1/2}} \qquad [15.10.98]$$

where r_1 is the radius at time t_1, r_2 is the radius at time t_2 ($t_2 > t_1$) and θ is a parameter. Equations 15.10.90 and 15.10.91 are again used.

For an instantaneous spill on land, Equation 15.10.91 is solved with the conditions $B = 0$ (hence $V = A$), $t = 0$ and $r = r_{\mathrm{o}}$ Also on land, $g = g'$. Then, integrating Equation 15.10.91 gives

$$r = \left[\left(\frac{8gA}{\pi}\right)^{1/2} t + r_{\mathrm{o}}^2\right]^{1/2} \qquad [15.10.99]$$

For small r_{o}, Equation 15.10.99 becomes

$$r^2 \approx \left(\frac{8gA}{\pi}\right)^{1/2} t \qquad [15.10.100]$$

Hence

$$t = \beta_1 r^2 \qquad [15.10.101]$$

with

$$\beta_1 = \left(\frac{\pi}{8gA}\right)^{1/2} \qquad [15.10.102]$$

where β_1 is a constant.

Utilizing Equation 15.10.101 and integrating Equation 15.10.97 gives

$$m = \frac{8}{3} \theta (2\pi g A)^{1/2} t^{3/2} \qquad [15.10.103]$$

For a continuous spill on land, Equation 15.10.91 is solved with the conditions $A = 0$ (hence $V = Bt$), $t = 0$ and $r = 0$. Then, as before, integrating Equation 15.10.91 gives

$$r = \frac{2}{3}\left(\frac{8gB}{\pi}\right)^{1/4} t^{3/4} \qquad [15.10.104]$$

Hence

$$t = \beta^2 r^{4/3} \qquad [15.10.105]$$

with

$$\beta^2 = \left(\frac{9}{32} \frac{\pi}{gB}\right)^{1/3} \qquad [15.10.106]$$

where β^2 is a constant.

Utilizing Equation 15.10.105 and integrating Equation 15.10.97 gives

$$m = \pi^{3/2}\theta\left(\frac{gB}{2}\right)t^2 \qquad [15.10.107]$$

As stated above, the authors use for the regression rate for LNG on water the value from the Esso work of 4.7×10^{-4} m/s.

The authors also performed numerical integration of the full equations and obtained for the radius r_e and time t_e at the end of evaporation:

$$\ln r_e = 1.5 \ln t_e - 2.45 \qquad [15.10.108]$$

$$\ln t_e = 0.25(\ln M_s + 6) \qquad [15.10.109]$$

where M_s is the mass of the spill.

They also confirmed that it is justifiable to neglect the term m/ρ.

15.10.11 Raj model

Another series of models for simultaneous spreading and vaporization of continuous and instantaneous spills of LNG on land and on water has been given by Raj (1981), developing the earlier work of Raj and Kalelkar (1974). For a continuous spill on land the basic equation is

$$\frac{\mathrm{d}q}{\mathrm{d}t} = \frac{k_s \Delta T}{(\pi\alpha_s)^{1/2}(t - t_1)^{1/2}} 2\pi r_1 \mathrm{d}_r \qquad [15.10.110]$$

with

$$\Delta T = T_s - T_l \qquad [15.10.111]$$

where k is the thermal conductivity, q is the heat flux per unit area, r is the radial distance, ΔT is the temperature difference between the liquid and the soil at distance r_1, and subscript 1 denotes at distance r_1.

Then, equating the steady-state vaporization rate per unit area and the volumetric flow of liquid into the spill V_c:

$$V_c = \frac{2\pi k_s \Delta T}{\Delta H_v \rho_l (\pi\alpha_s t)^{1/2}} \int_0^{r(t)} \frac{r_1}{(1 - t_1/t)^{1/2}} \mathrm{d}r_1 \qquad [15.10.112]$$

where subscript l denotes the liquid.

Integration of Equation 15.10.112 gives

$$r(t) = \left(\frac{2\Delta H_v \rho_l V_c}{\pi^2 S \Delta T}\right)^{1/2} t^{1/4} \qquad [15.10.113]$$

with

$$S = \left(\frac{k_s \rho_s c_s}{\pi}\right)^{1/2} \qquad [15.10.114]$$

where c is the specific heat and ρ is the density.

Raj also shows that

$$V_c = \frac{\pi r^2 S \Delta T}{(2/\pi)\Delta H_v \rho_l} t^{1/2} \qquad [15.10.115]$$

The regression rate v is

$$v = \frac{V_c}{\pi r^2} \qquad [15.10.116]$$

For a continuous spill of finite size on land, using the result just given in Equation 15.10.115

$$V(t) + \frac{\pi^2 S \Delta T}{2\Delta H_v \rho_l} \int_0^t \frac{r^2}{t^{1/2}} \mathrm{d}t = V_c t \quad t \le t_{sp} \qquad [15.10.117a]$$

$$= V_c t_{sp} \quad t > t_{sp} \qquad [15.10.117b]$$

where V is the volume of the pool and the subscript sp denotes the spill duration. The first term on the left-hand side of Equation 15.10.117 is the volume of liquid remaining and the second the volume vaporized.

Raj utilizes the liquid spreading relations 15.10.59 and 15.10.61b to obtain a numerical solution of Equation 15.10.117. For an instantaneous spill of LNG on land the basic equation is

$$V(t) + \int_0^t v(t)\pi r^2(t)\,\mathrm{d}t = V_i \qquad [15.10.118]$$

with

$$v(t) = \frac{S \Delta T}{(2/\pi)\Delta H_v \rho_l t^{1/2}} \qquad [15.10.119]$$

where V_i is the volume of liquid in the instantaneous spill.

The relations utilized for the liquid spreading are Equations 15.10.59 and 15.10.67, together with Equation 15.10.118. From these relations are obtained for the final evaporation radius r_e and time t_e:

$$r_e = 1.248\left(\frac{\Delta H_v \rho_l}{S \Delta T}\right)^{1/3} V_i^{4/9} \qquad [15.10.120]$$

$$t_e = 0.639\left(\frac{\Delta H_v \rho_l}{S \Delta T}\right)^{2/3}\left(\frac{1}{g}\right)^{1/2} V_i^{7/18} \qquad [15.10.121]$$

For a continuous spill on water the basic equation is

$$\dot{V}(t) + \pi r^2 v = V_c \qquad [15.10.122]$$

The relations utilized for liquid spreading are Equations 15.10.59 and 15.10.61. The following relation is obtained for the final evaporation radius r_e:

$$r_e = \left(\frac{V_c}{\pi v}\right)^{1/2} \qquad [15.10.123]$$

For an instantaneous spill on water the basic equation is

$$V(t) + \pi \int_0^t v(t) r^2(t)\,\mathrm{d}t = V_i \qquad [15.10.124]$$

The relation utilized for spreading is Equation 15.10.67.

The following relations are obtained for the final evaporation radius and time:

$$r_e = \left(\frac{V_i^3 g'}{v^2}\right)^{1/8} \quad [15.10.125]$$

$$t_e = 0.6743\left(\frac{V_i}{g' v^2}\right)^{1/4} \quad [15.10.126]$$

Raj (1979) has also given a criterion for classifying a spill of LNG on water as instantaneous or continuous. He defines the following dimensionless quantities:

$$L = V_i^{1/3} \quad [15.10.127]$$

$$t_{ch} = L/v \quad [15.10.128]$$

$$\xi = r/L \quad [15.10.129]$$

$$\tau = t/t_{ch} \quad [15.10.130]$$

where L is a characteristic length, t_{ch} is a characteristic evaporation time, ξ is a dimensionless maximum spread and τ is a dimensionless time.

Utilizing Equations 15.10.123 and 15.10.125 for the final spill radii for the two types of spill together with the fact that $V_c = V_i/t$, he obtains

$$\xi = \left(\frac{Lg'}{v^2}\right)^{1/8} \quad \text{instantaneous spill} \quad [15.10.131]$$

$$\xi = \frac{1}{(\pi\tau)^{1/2}} \quad \text{continuous spill} \quad [15.10.132]$$

Then from Equations 15.10.131 and 15.10.132 a value of τ may be obtained for the point at which the value of ξ is the same for the two equations.

Using a typical value of the regression rate v of LNG on water of 6.5×10^{-4} m/s gives a value of τ of 2×10^{-3} s. Then for the crossover time t_{cr} Raj gives the following values:

Volume spilled (m^3)	1000	10,000	25,000	50,000
Crossover time (s)	31	68	92	116

15.10.12 Opschoor model

A model for the simultaneous spreading and vaporization of an instantaneous spill of LNG on water has been given by Opschoor (1977, 1980).

For an instantaneous spill of LNG on water

$$V(t)\rho_l + \pi \int_0^t m_v r^2(t)\mathrm{d}t = V_i \rho_l \quad [15.10.133]$$

where m_v is the mass rate of vaporization per unit area.

Integration of Equation 15.10.133 gives

$$r = \left[0.44 \frac{m_v g'}{\rho_l} t^3 + 1.3 (g' V_i)^{1/2} t\right]^{1/2} \quad [15.10.134]$$

For the final evaporation radius and time

$$r_e = 1.02\left(\frac{g' \rho_l^2 V_i^3}{m_v^2}\right)^{1/8} \quad [15.10.135]$$

$$t_e = 0.67\left(\frac{\rho_l^2 V_i}{g' m_v^2}\right)^{1/4} \quad [15.10.136]$$

Opschoor also considers an LNG spill on a water surface of limited area A_o. Using Equation 15.10.134, but neglecting the first term on the right-hand side, the following relation is obtained for the time t_o for a water surface of area A_o to be fully covered:

$$t_o = 0.24\left(\frac{A_o^2}{g' V_i}\right)^{1/2} \quad [15.10.137]$$

The work of Opschoor on the mass vaporization rate of LNG on water has already been described in Section 15.10.9.

15.10.13 Spreading and vaporization of ammonia

Work on the spreading and vaporization of liquefied ammonia (LNH$_3$) on water has been described by Raj, Hagopian and Kalelkar (1974). Experiments were carried out in which quantities of ammonia up to 50 US gal were spilled on water.

When ammonia is spilled on water, part of it vaporizes and part goes into solution in the water. Defining a partition coefficient p as the proportion that dissolves, the authors obtained a value of $p \approx 0.6 \pm 0.1$. The remainder $(1 - p)$ vaporizes.

The authors modelled the release assuming that the ammonia was at a temperature of $-33°$C, there was no initial entrainment of air and no spray formation. Under these conditions the cloud is buoyant. They treated the dispersion in terms of a buoyant plume model. For the final evaporation radius and time they give:

$$r_e = 2.5 V^{0.375} \quad [15.10.138]$$

and

$$t_e = 0.674\left(\frac{V}{g' v^2}\right)^{1/4} \quad [15.10.139]$$

where r_e is the final evaporation radius (ft), t_e is the final evaporation time (s), v is the regression rate (ft/s), and V is the volume spilled (US gal). The authors obtained a regression rate of 2.8 in./min.

Using a thermodynamic analysis, Raj and Reid (1978a) have shown that it is possible to determine the point at which further addition of water simply dilutes the solution without causing any further evolution of ammonia and to obtain the value of the partition coefficient. For the illustrative example considered the experimental partition coefficient was 0.73 and the theoretical value 0.715.

Griffiths (1977 SRD R67) has criticized the interpretation given by Raj, Hagopian and Kalelkar and gives an alternative interpretation of the results assuming that spray formation occurs and that the plume is not buoyant.

15.10.14 Computer codes

A number of computer codes have been written for vaporization. A review of these has been given by the CCPS (1987/2). The Safety and Reliability Directorate (SRD) code SPILL is based on the model of Shaw and Briscoe (1978 SRD R100). It has been described by Prince (1981 SRD R210). Another program is the Shell SPILLS code which is described by Fleischer (1980).

15.11 Dispersion

Emission and vaporization are followed by dispersion of the vapour to form a vapour cloud.

Accounts of gas dispersion of particular relevance here include those given in *Micrometeorology* (O.G. Sutton, 1953), *Atmospheric Diffusion* (Pasquill, 1962a, 1974) *Meteorology and Atomic Energy* (Slade, 1968), *An Evaluation of Dispersion Formulas* (Anderson, Hippler and Robinson, 1969), *Recommended Guide for the Prediction of the Dispersion of Airborne Effluents* (ASME, 1969/1, 1973/2, 1979/4), *Workbook of Atmospheric Dispersion Estimates* (D.B. Turner, 1970), *Turbulent Diffusion in the Environment* (Csanady, 1973) and *Handbook on Atmospheric Diffusion* (Hanna, Briggs and Hosker, 1982), and those given by Pasquill and Smith (1983).

Dispersion models used in the nuclear industry are described in the Nuclear Regulatory Commission (NRC) *Regulatory Guide 1.111 Methods for Estimating Atmospheric Transport and Dispersion of Gaseous Effluents in Routine Releases from Light-water-cooled Reactors* (1974) and the NRC *Regulatory Guide 1.145 Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear Power Plants* (1979a). The NRC has also published an account of the basis for *Regulatory Guide 1.145* (1981 NUREG/CR-2260). Another nuclear industry dispersion model is *A Model for Short and Medium Range Dispersion of Radionuclides into the Atmosphere* by Clarke (1979 NRPB R91).

Work on dispersion is primarily concerned with the dispersion of pollutants from industrial chimney stacks. Most of the fundamental work on dispersion relates to this problem. There is, however, an increasing amount of work on dispersion of hazardous releases from process plant.

Selected references on dispersion are given in Table 15.10.

Topics common to passive and dense gas dispersion, including source terms, mitigation systems and hazard assessment (*see* Table 15.42)

15.11.1 Dispersion situations

Dispersion situations may be classified as follows. The fluid and the source may be classified as:

(1) Fluid buoyancy
  (a) neutral buoyancy,
  (b) positive buoyancy,
  (c) negative buoyancy.
(2) Momentum
  (a) low momentum,
  (b) high momentum.
(3) Source geometry
  (a) point source,
  (b) line source,
  (c) area source.
(4) Source duration
  (a) instantaneous,
  (b) continuous,
  (c) intermediate.
(5) Source elevation
  (a) ground level source,
  (b) elevated source.

The dispersion takes place under particular meteorological and topographical conditions. Some principal features of these are as follows:

(1) Meteorology
  (a) wind,
  (b) stability.
(2) Topography
  (a) surface roughness,
  (b) near buildings and obstructions,
  (c) over urban areas,
  (d) over coastal zones and sea,
  (e) over complex terrain.

These aspects of the dispersion situation are now considered.

15.11.2 Buoyancy effects

The fluid may have neutral, positive or negative buoyancy. Neutral density is generally the default assumption and applies where the density of the gas–air mixture is close to that of air. This is the case where the density of the gas released is close to that of air or where the concentration of the gas is low. In determining the density of the gas it is necessary to consider not only molecular weight but also the temperature and liquid droplets. Gases with positive buoyancy include those with low molecular weight and hot gases. Many hazardous materials, however, form negatively buoyant gases, or heavy gases.

Much of the fundamental work on dispersion, and the models derived from this work, relate to the dispersion of gas of neutral density, or neutral buoyancy. This work is relevant to dispersion from stacks once buoyancy effects have decayed. There are separate models that treat gases of positive buoyancy, which apply to releases close to stacks, and gases of negative buoyancy. Dispersion of gases that do not exhibit positive or negative buoyancy is generally referred to as 'passive dispersion'.

15.11.3 Momentum effects

A continuous release of material with low kinetic energy forms a plume that tends to billow. If the kinetic energy is high, however, a momentum jet is formed which has a well-defined shape.

The momentum of the release has a marked effect on the extent of air entrainment. If the kinetic energy is high, large quantities of air are entrained. The degree of air entrainment affects the density of the cloud and is important in its further dispersion.

15.11.4 Source terms

The principal types of source used in idealized treatments of dispersion are the point source, the line source and the area source. An escape from a pipe is normally treated as a point source, while vaporization from a pool may be treated as an area source. There may also be some situations that may be modelled as an infinite or semi-infinite line source.

A very short and a prolonged escape may approximate to an instantaneous release and to a continuous release, respectively. An escape of intermediate duration, however, may need to be treated as a quasi-instantaneous or, alternatively, quasi-continuous release.

The most common scenarios considered are an instantaneous release from a point source, or 'puff', and a continuous release from a point source, or 'plume'.

It will be apparent that the source terms described are idealizations of the actual situation.

15.11.5 Source elevation

Another distinction is the elevation of the source. Sources are classed as ground level or elevated. Most hazardous escapes are treated as ground level sources. Stacks are the principal elevated sources.

15.11.6 Meteorology and topography

The two main meteorological conditions that affect the dispersion are the wind direction and speed and the stability conditions.

The stability of the atmosphere determines the degree of mixing. The simplest classification of stability is:

(1) unstable;
(2) neutral;
(3) stable.

Dispersion is greatest in unstable conditions and least in stable conditions.

With respect to topography the default condition may be regarded as dispersion over flat grassland of moderate roughness, but there are many other situations, including dispersion over surfaces with very low or very high roughness, at buildings or other obstacles, over urban areas, over coastal zones and sea, and over other complex terrain.

Meteorology and topography are discussed further in Sections 15.12 and 15.13, respectively.

15.11.7 Dispersion of passive gas plume

As already mentioned, the dispersion situation that has been studied most extensively is the dispersion of a plume of neutral density gas from a continuous point source. It is convenient at this point to consider some basic features of gas dispersion in relation to this source term.

It has frequently been shown by experiment that for such a plume both the crosswind and vertical concentration distributions are approximately Gaussian, as illustrated in Figure 15.31(a).

By convention, the boundaries of a cloud are defined in dispersion work as the locus of the points at which the concentration has fallen to 1/10 of that at the centre. For a plume at ground level the horizontal and vertical cloud boundaries are given by the envelope at which the concentrations are 1/10 of those down the centre line. This defines the cloud width w, the lateral spread θ and the cloud height h, as shown in Figure 15.31(b).

Since the concentration distribution is Gaussian, the cloud spread may also be defined in terms of the standard deviations of concentration in the crosswind y and vertical z directions σ_y and σ_z. The relation between the cloud height h and vertical standard deviation σ_z is

$$h = 2.15\sigma_z \qquad [15.11.1]$$

The factor of 2.15 derives from the Gaussian distribution and corresponds to the 1/10 maximum value.

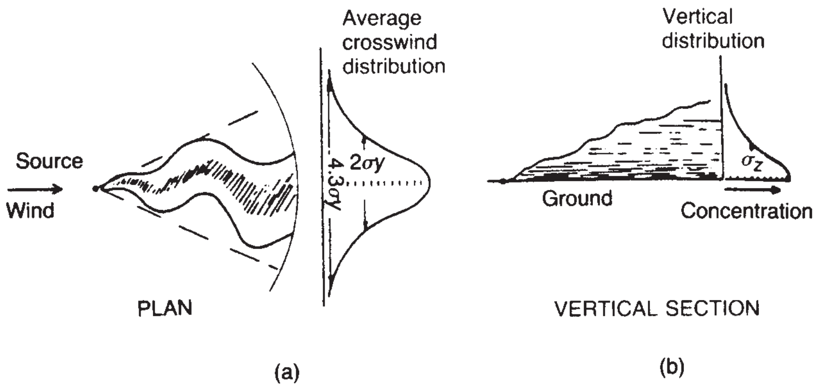

Figure 15.31 *Plume from a continuous release: definition of plume (Pasquill and Smith, 1983; reproduced by permission)*

15.11.8 Co-ordinate systems for gas dispersion

Three widely used co-ordinate systems are (1) the rectangular, (2) the spherical and (3) the cylindrical systems. A treatment of their use in chemical engineering is given by Bird, Stewart and Lightfoot (1960).

Most gas dispersion modelling utilizes rectangular coordinates (x, y, z). For dispersion of instantaneous releases it is sometimes convenient to use spherical coordinates (r, θ). Models for instantaneous releases may use a coordinate system moving with the cloud. Some use is made of special coordinate systems. An example is that used in the DRIFT model described in Section 17.35.

15.11.9 Concentration fluctuations and sampling

It is found experimentally that if the concentration in a gas cloud from a continuous point source under near neutral conditions is measured at points along an arc across wind, the distribution of concentration obtained is Gaussian, but the shape of the distribution depends on the sampling interval. If the sample is virtually instantaneous, the distribution has a relatively narrow spread and a high maximum, while if the sample is averaged over a time period the distribution has a wider spread and a lower maximum. This behaviour is illustrated in Figure 15.32.

Typically, at 100 m the total width of the cloud as measured by instantaneous samples is about 20 m, but the width as measured by time mean samples is about 35 m. The width of the cloud increases rapidly as the interval over which the sample is averaged increases from zero to 2 min. For intervals greater than 3 min the concentration distribution remains fairly constant, provided the wind direction does not alter.

Over longer periods, however, the wind does alter direction and there is a further but more gradual increase in the spread of the concentration distribution. The variation of concentration with sampling period may be taken into account using a relation of the form

$$\frac{\chi}{\chi_r} = \left(\frac{t_r}{t}\right)^{\rho} \qquad [15.11.2]$$

where t is the sampling period which yields concentration χ, p is an index and subscript r denotes the reference value.

There can be considerable differences between peak and time-mean concentrations. Values of the peak/mean ratio of 50 or more have been reported in some investigations. The concentrations given by the common dispersion models for passive dispersion gas are time-mean values. In some applications it is necessary also to consider the peak values.

15.11.10 Models for passive gas dispersion

The modelling of dispersion, particularly that of neutral density gas, and passive gas dispersion models are discussed further in Sections 15.15 and 15.16, respectively. Passive gas dispersion over particular surfaces and in particular conditions is considered in Sections 15.17 and 15.18, while dispersion parameters for passive gas dispersion models are described in Section 15.19.

15.11.11 Models for dense gas dispersion

For high concentration releases of many of the *hazardous* materials of interest in process plants the assumption of neutral density gas behaviour is not valid. In particular, the gas cloud is often heavier than air. In this situation the common neutral density gas models are not applicable. However, the behaviour of dense gases has been the subject of much work in recent years and dense gas dispersion models have been developed. Dispersion of dense gas is discussed further in Section 15.22 and succeeding sections.

15.11.12 Other topics

Other topics in gas dispersion considered below include dispersion of buoyant plumes and momentum jets, concentration fluctuations, dispersion over short distances, transformation and removal mechanisms, flammable and toxic clouds, infiltration into buildings, fugitive emissions, dispersion by fluid curtains and leaks and spillages.

15.12 Meteorology

Gas dispersion depends on meteorology and, in particular, on turbulence. Both the form of the models used to describe dispersion and the values of the parameters in them derive from meteorological considerations.

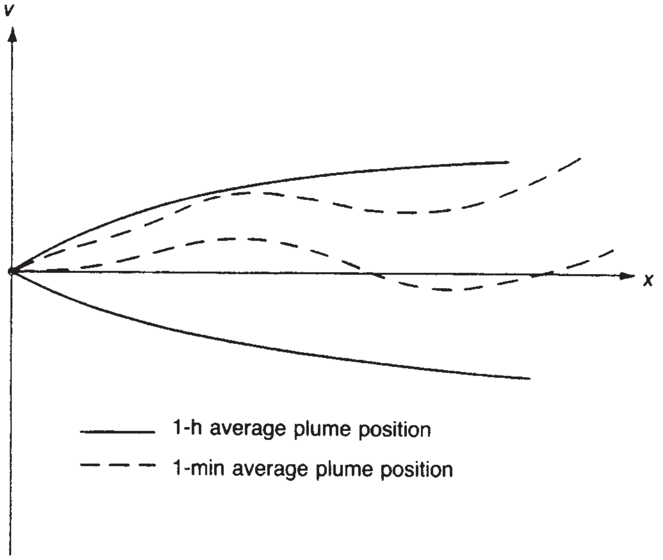

Figure 15.32 *Plume from a continuous release: effect of meandering of plume (S.R. Hanna, Briggs and Hosker, 1992)*

Accounts of meteorology include those given in *Physical and Dynamical Meteorology* (Brunt, 1934), *The Climate Near the Ground* (Geiger, 1950–), *Micrometeorology* (O.G. Sutton, 1953), *The Challenge of the Atmosphere* (O.G. Sutton, 1962), *Elementary Meteorology* (G.F. Taylor, 1954), *Exploring the Atmosphere's First Mile* (Lettau and Davidson, 1962), *Natural Aerodynamics* (Scorer, 1958), *Environmental Aerodynamics* (Scorer, 1978), *General Meteorology* (Byers, 1959), *Atmospheric Diffusion* (Pasquill, 1962a, 1974; Pasquill and Smith, 1983), *An Introduction to Climate* (Trewartha, 1968), *Essentials of Meteorology* (McIntosh and Thorn, 1969), *Evaporation into the Atmosphere* (Brutsaert, 1982), *CRC Handbook of Atmospherics* (Volland, 1982), *Engineering Meteorology* (Plate, 1982) and *Meteorological Glossary* (McIntosh, 1972), *Dynamics in Atmospheric Physics* (Lindzen, 1990), and in the *Meteorological Glossary* (McIntosh, 1972). An account specific to the United Kingdom is available in *Climate in the United Kingdom* (Page and Lebens, 1986).

Works on turbulence and related phenomena include *Massenaustausch in freier Luft and verwandte Erscheinungen* (Schmidt, 1925), *Turbulence* (Hinze, 1959), *Turbulent Transfer in the Lower Atmosphere* (Priestley, 1959), *Boundary Layer Theory* (Schlichtling, 1960), *Turbulence: Classic Papers on Statistical Theory* (Friedlander and Topper, 1961), *The Structure of Atmospheric Turbulence* (Lumley and Panofsky, 1964), *Introduction to Turbulence and Its Measurement* (Bradshaw, 1971), *Statistical Fluid Mechanics: Mechanics of Turbulence* (Monin and Yaglom, 1971), *Turbulence Phenomena* (J.T. Davies, 1972), *A First Course in Turbulence* (Tennekes and Lumley, 1972), *Turbulent Diffusion in the Environment* (Csanady, 1973), *Buoyancy Effects in Fluids* (U.S. Turner, 1973), *Mathematical Modelling of Turbulent Diffusion in the Environment* (C.J. Harris, 1979) and *Turbulence and Diffusion in Stable Environments* (Q.C.R. Hunt, 1985).

Treatments of gas dispersion, with particular emphasis on air pollution, include those given in *Atmospheric Pollution: Compendium of Meteorology* (Hewson, 1951), *Air Pollution* (Scorer, 1968), *Contemporary Problems of Atmospheric Diffusion and Pollution in the Atmosphere* (Beryland, 1975), *Atmospheric Motion and Air Pollution* (Dobbins, 1979), *Air Pollution Modelling and its Application* (de Wispelaere, 1981, 1983, 1984, 1985; de Wispelaere, Schiermeier and Gillani, 1986), *Atmospheric Diffusion* (Pasquill and Smith, 1983), and *Atmospheric Turbulence and Air Pollution Modelling* (Nieuwstadt and van Dop, 1982).

15.12.1 Atmospheric boundary layer

The meteorological conditions that are of prime relevance here are those within the atmospheric boundary layer (ABL), or planetary boundary layer (PEL). In unstable, or convective, conditions this layer is also known as the convective boundary layer (CBL).

The ABL has an outer and an inner region, as shown in Figure 15.33. The outer region, or defect layer, has a height of some 10^2–10^3 m and the inner region, or surface layer, one of some 10 m. There is within the surface sublayer a dynamic sublayer with a height of 1–10 m. Between the dynamic sublayer and the surface is the interfacial layer, the height of which depends on the surface roughness.

Within the PEL, the surface layer is of particular importance. Within this layer stress is virtually constant and it is also termed the constant stress layer, or surface stress layer. Considering the PEL over land, conditions in the layer depend on the stability conditions. The simplest case is that of neutral conditions where buoyancy forces are negligible. It is to this case that the classical treatments primarily apply.

In the neutral PEL turbulent energy derives from two main sources. One is due to the mechanical drag of the wind over the surface, and the other to the turning of the wind direction with height. In the unstable boundary layer

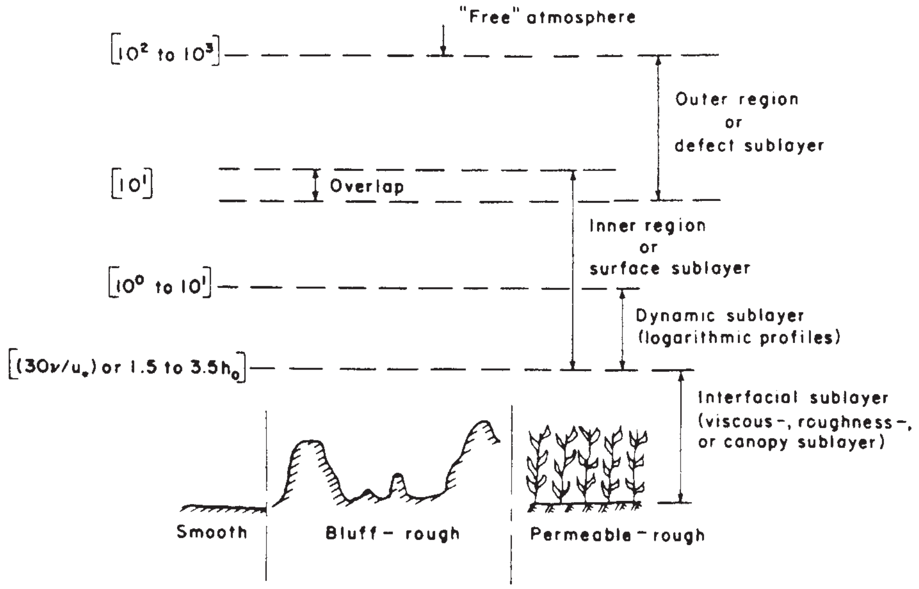

Figure 15.33 *Atmospheric boundary layer: orders of magnitude of the heights of the sublayers (Brutsaert, 1982). The vertical scale (m) is distorted; h_o is the height of the roughness obstances (Courtesy of Reidel Publishing Company)*

a further source of turbulent energy is that due to buoyancy. Over land, such buoyancy is mainly caused by vertical flux of sensible heat into the air at the surface. Over sea, vertical flux of latent heat associated with water vapour plays a significant role.

Stable conditions occur mainly at night. In the stable boundary layer the surface is cool relative to the air and the vertical heat flux is in the reverse direction so that the mechanical and buoyancy forces are opposed. At some height above the surface turbulence becomes very weak and is virtually suppressed.

15.12.2 Wind characteristics

Wind is a main factor in determining dispersion. Some principal wind characteristics are:

(1) direction;
(2) speed
  (a) at surface,
  (b) above ground;
(3) persistence;
(4) turbulence.

Wind direction is defined as the direction from which the wind is blowing. Information on wind direction and speed at a given location is conveniently summarized in the form of a 'wind rose'. This is a polar diagram in which the length of the sections of the spokes is proportional to the observed frequencies of wind direction and speed. The period for which the wind rose is drawn is typically a month or a year. Some monthly wind roses show a marked degree of seasonal variation, others do not. The degree of symmetry in wind roses also varies considerably. A table of percentage frequency of wind direction and speed and corresponding wind rose for Watnall is shown in Figure 15.34.

The predominant wind direction is usually called the 'prevailing wind'. This wind direction only applies, however, for a relatively limited proportion of the time, and it is usually necessary in dispersion calculations to consider other directions also.

Persistence of the wind direction is important in assessing dispersion. This is often expressed in the form of a persistence table such as that shown for Watnall in Table 15.11, which gives the number of occasions during the given period in which the wind remained within the sectors indicated for the number of hours in sequence indicated.

Alternatively, the persistence of wind direction may be expressed in terms of the constancy, which is based on the ratio of the vector and scalar winds and has a value of 1 for an invariant wind direction and 0 for a completely uniform distribution of wind directions. This measure has the advantage that, unlike persistence, it is relatively little affected by brief excursions outside the 45° sector.

Localized variations of wind direction and speed can occur and may affect dispersion. Features that can give rise to these variations include irregularities in terrain and differences in surface temperature. Where there is a marked slope, a drainage wind can occur. This is a downhill flow of air cooled by radiation at night and it may be in a direction quite different from the gradient wind. In well-defined valleys there are usually complex flow patterns. Typically, at night there is a drainage wind from the sides and down the bottom of the valley and during the day a tendency for wind to flow up the valley bottom. On the coast the land is warmer in daytime and the sea at night. Hence during the day there tends to be a sea breeze blowing onto the land and during the night a land breeze blowing towards the sea.

Turbulence is another feature of wind variation. In the present context turbulence includes wind fluctuations with

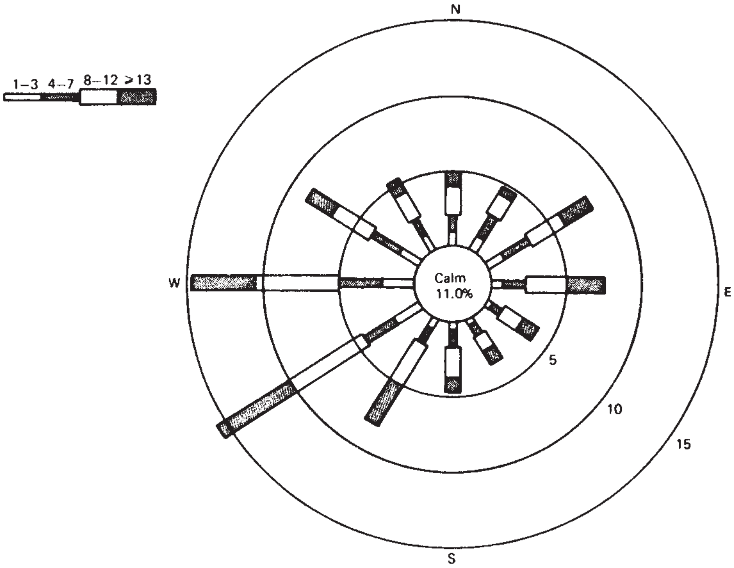

Figure 15.34 *Table of percentage frequency of wind direction and speed and corresponding wind rose for Watnall, 1959–68 (Meteorological Office, 1977; reproduced by permission)*

Table 15.11 *Table of wind persistence for Watnall, 1974–76 (Meteorological Office, 1977; reproduced by permission)*

No. of hours in sequence	*Direction*							
	N	*NE*	*E*	*SE*	*S*	*SW*	*W*	*NW*
1	756	565	510	411	587	1043	1087	721
7	91	110	64	29	82	176	202	46

>49	0	5	0	0	0	2	3	0
Total no. of hours	3374	4007	2404	1190	3106	6503	6153	2202

Watnall: latitude 53° 01′ N, longitude 01° 15′ W

a frequency of more than 2 cycle/h, the most important fluctuations lying in the range 0.1–1 cycle/s. The main factors that determine the turbulence are the gradient wind speed and the roughness of the terrain, and the temperature differences between the surface and the air. Turbulence tends to increase as the gradient wind speed increases, or as the temperature of the air close to the surface increases, relative to that of the air aloft. A measure of turbulence is given by the standard deviation, or, σ, value of the wind fluctuations over a 1 h period. These wind speed σ values can be related to the dispersion σ values in the models of gas dispersion.

Before leaving wind characteristics, it is convenient to give at this point the method of characterizing high wind speeds. This is the Beaufort scale, developed originally for use at sea. It is shown in Table 15.12. The scale is not used in work on gas dispersion, but is relevant to wind hazard.

15.12.3 Geostrophic wind and Ekman spiral

In the free atmosphere above the PEL it is usual to assume that the wind is horizontal and free from friction. In this situation the wind velocity becomes a function of the pressure gradient and of the forces arising from the rotation of the Earth. The wind that satisfies these conditions is known as the gradient level wind.

Where the lines of constant pressure, or isobars, are straight so that any centripetal acceleration is negligible, the gradient level wind is known as the geostrophic wind. The direction of the geostrophic wind is not the same as the surface wind. An idealized representation of the wind velocity vectors at different heights is given by the Ekman spiral, developed originally in relation to ocean currents, as shown in Figure 15.35. The Ekman spiral is the locus of the end points of the wind velocity vectors. These vectors approach the geostrophic wind velocity at the mixed layer

Table 15.12 *The Beaufort Scale*

Force	*Wind speed*[a] (mile/h)		*Description*	*Specification (land)*	*Weather forecast*
	Average	*Limits*			
0	<1		Calm	Calm; smoke rises vertically	Calm
1	2	1–3	Light air	Wind shown by smoke drift, not wind vanes	Light
2	5	4–7	Light breeze	Wind felt on face; leaves rustle	Light
3	10	8–12	Gentle breeze	Leaves and small twigs in constant motion	Light
4	15	13–18	Moderate breeze	Raises dusts and loose paper	Moderate
5	21	19–24	Fresh breeze	Small trees in leaf begin to sway	Fresh
6	28	25–31	Strong breeze	Large branches in motion; whistling heard in telegraph	Strong
7	35	32–38	Near gale	Whole trees in motion; inconvenience when walking against the wind	Strong
8	42	39–46	Gale	Breaks twigs off trees; generally impedes progress	Gale
9	50	47–54	Strong gale	Slight structural damage	Severe gale
10	59	55–63	Storm	Trees uprooted; considerable structural damage	Storm
11	68	64–72	Violent storm	Very rarely experienced; accompanied by widespread damage	Violent storm
12	>73		Hurricane	As Force 11	Hurricane

[a] Wind speeds are average speeds measured at a height of 10 m.

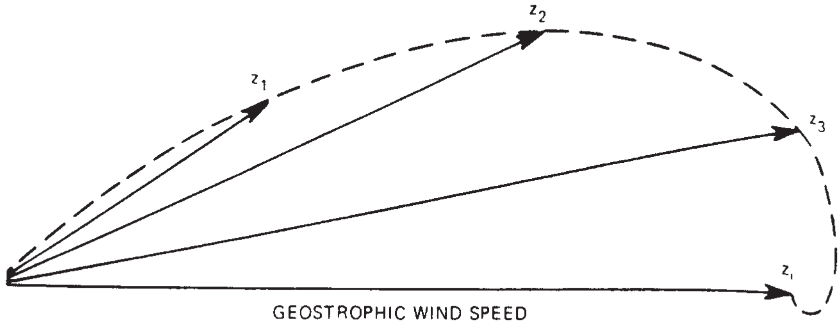

Figure 15.35 *Geostrophic wind and Ekman spiral (S.R. Hanna, Briggs and Hosker, 1982). The wind velocity vectors (z_1, z_2, z_3) approach the geostrophic wind velocity vector at the top of the mixed layer z_i*

height. The angle of a vector is the angle by which it is backed from the direction of the geostrophic wind. The angle of the surface wind vector is backed 45° from this direction. Actual observed angles between the geostrophic and surface winds are typically 5–10°, 15–20° and 30–50° for unstable, neutral and stable conditions, respectively.

Wind direction shear affects dispersion, particularly over large distances, where the top and bottom of a plume can move with a difference of direction of some 40–50°, which gives a much larger plume spread than would be obtained by diffusion alone.

15.12.4 Force balance equation

The balance of forces acting horizontally on the air in free stream conditions is given by the relations

$$\frac{\partial u}{\partial t} + fv = \frac{1}{\rho}\frac{\partial p}{\partial x} + X \qquad [15.12.1a]$$

$$\frac{\partial v}{\partial t} + fu = \frac{1}{\rho}\frac{\partial p}{\partial y} + Y \qquad [15.12.1b]$$

where f is the Coriolis force, p is the pressure, t is the time, u and v are the wind velocity components in the downwind and crosswind directions, respectively, X and Y are accelerations representative of forces not due to pressure and gravity, and ρ is the air density. The Coriolis force, or parameter, f is

$$f = 2\omega \sin \phi \qquad [15.12.2]$$

where ϕ is the latitude and ω is the angular velocity of the Earth. The Coriolis force has a value of approximately $10^{-4}\,\mathrm{s}^{-1}$ at intermediate latitudes and tends to zero at the equator.

15.12.5 Turbulent exchange, momentum flux, eddy viscosity and mixing length

The theory of turbulence derives from the work of Schiller (1932), Nikuradse (1933), Prandtl (1933) and Schlichtling (1936) on the boundary layer for flow in pipes. The extension of this theory for flow over open ground is described by O.G. Sutton (1953) and Pasquill (1962a). The theories of turbulence which describe the mixing that occurs when wind passes over a surface are complex. The treatment given here is limited to the description of a few simple concepts and relations. The momentum flux is given by the equation

$$\frac{\tau}{\rho} = (\nu + K_{\mathrm{M}})\frac{\mathrm{d}u}{\mathrm{d}z} \qquad [15.12.3a]$$

The eddy viscosity K_{M} is generally much greater than the kinematic viscosity ν, and hence

$$\frac{\tau}{\rho} = K_{\mathrm{M}}\frac{\mathrm{d}u}{\mathrm{d}z} \quad \nu \ll K_{\mathrm{M}} \qquad [15.12.3b]$$

where K_{M} is the eddy viscosity, u is the mean wind speed, z is the height, ν is the kinematic viscosity of air, ρ is the density of air and τ the mean momentum flux per unit area.

The constant K_{M} is variously described as the coefficient of exchange for momentum, the eddy diffusivity for momentum, or the eddy viscosity. In terms of the mixing length theory of Prandtl,

$$K_{\mathrm{M}} = l^2\frac{\mathrm{d}u}{\mathrm{d}z} \qquad [15.12.4]$$

where l is the mixing length. The momentum flux is then

$$\frac{\tau}{\rho} = l^2\left(\frac{\mathrm{d}u}{\mathrm{d}z}\right)^2 \qquad [15.12.5]$$

On the assumption that the mixing length is proportional to the distance from the surface,

$$l = kz \qquad [15.12.6]$$

where the constant k is von Karman's constant. The value usually quoted for von Karman's constant is 0.4. A value of 0.35 has been given by Businger *et al.* (1971).

From Equation 15.12.3b and the relation $u_*^2 = \tau/\rho$, described below,

$$K_{\mathrm{M}} = \frac{u_*^2}{\mathrm{d}u/\mathrm{d}z} \qquad [15.12.7]$$

Then from Equations 15.12.7 and the 'law of the wall' Equation 15.12.15, given below,

$$K_{\mathrm{M}} = ku_*z \qquad [15.12.8]$$

In terms of mixing length theory, using Equation 15.12.6, Equation 15.12.15 may be rewritten as

$$\frac{l}{u_*}\frac{\mathrm{d}u}{\mathrm{d}z} = \frac{1}{l} \qquad [15.12.9]$$

and Equation 15.12.8 as

$$K_{\mathrm{M}} = u_*l \qquad [15.12.10]$$

15.12.6 Friction velocity

Closely related to the momentum flux is the friction velocity u, defined by the relations

$$\frac{\tau}{\rho} = u_*^2 \qquad [15.12.11a]$$

or

$$u_* = (\tau/\rho)^{1/2} \qquad [15.12.11b]$$

The friction velocity may be obtained from the geostrophic wind velocity using the relation

$$u_* = c_{\mathrm{g}}u_{\mathrm{g}} \qquad [15.12.12]$$

where c_{g} is the drag coefficient and u_{g} is the geostrophic wind speed.

An empirical relation for the drag coefficient c_{g} in neutral conditions has been given by Lettau (1959) as follows:

$$c_{\mathrm{g}} = \frac{0.16}{\log_{10}\mathrm{Ro} - 1.8} \qquad [15.12.13]$$

with

$$\mathrm{Ro} = \frac{u_{\mathrm{g}}}{fz_{\mathrm{o}}} \qquad [15.12.14]$$

where Ro is the Rossby number and z_{o} is the roughness length.

For other stability conditions Lettau uses the following approximate ratios of the drag coefficient to that in neutral conditions:

Unstable	1.2
Slightly stable	0.8
Stable	0.6

The value of the friction velocity u_* varies between about 3 and 12% of the mean wind speed, the lower values being associated with smooth surfaces. It is often taken as one-tenth of the wind speed. The friction velocity is generally tabulated together with the surface roughness as a function of the type of surface, as described below.

15.12.7 Law of the wall

On the assumption that the flow at the surface depends only on the shear stress and the distance from the wall

$$\frac{\mathrm{d}u}{\mathrm{d}z} = \frac{u_*}{kz} \qquad [15.12.15]$$

This is the so-called 'law of the wall'. The term $(kz\mathrm{d}u/u_*\mathrm{d}z)$ is a non-dimensional wind shear. Equation 15.12.15 is applicable to adiabatic, or neutral, conditions.

15.12.8 Empirical vertical wind velocity profile

The gradient wind is, by definition, uninfluenced by friction effects, but at lower heights the wind velocity is reduced by such effects. Figure 15.36 illustrates some vertical profiles of wind speed.

A widely used empirical relation for the vertical wind velocity profile is

$$u = u_{\mathrm{r}}\left(\frac{z}{z_{\mathrm{r}}}\right)^p \quad z < z_{\mathrm{r}} \qquad [15.12.16]$$

where u is the wind speed, u_{r} is the wind speed at the reference height, z is the height, z_{r} the reference height and p is an index.

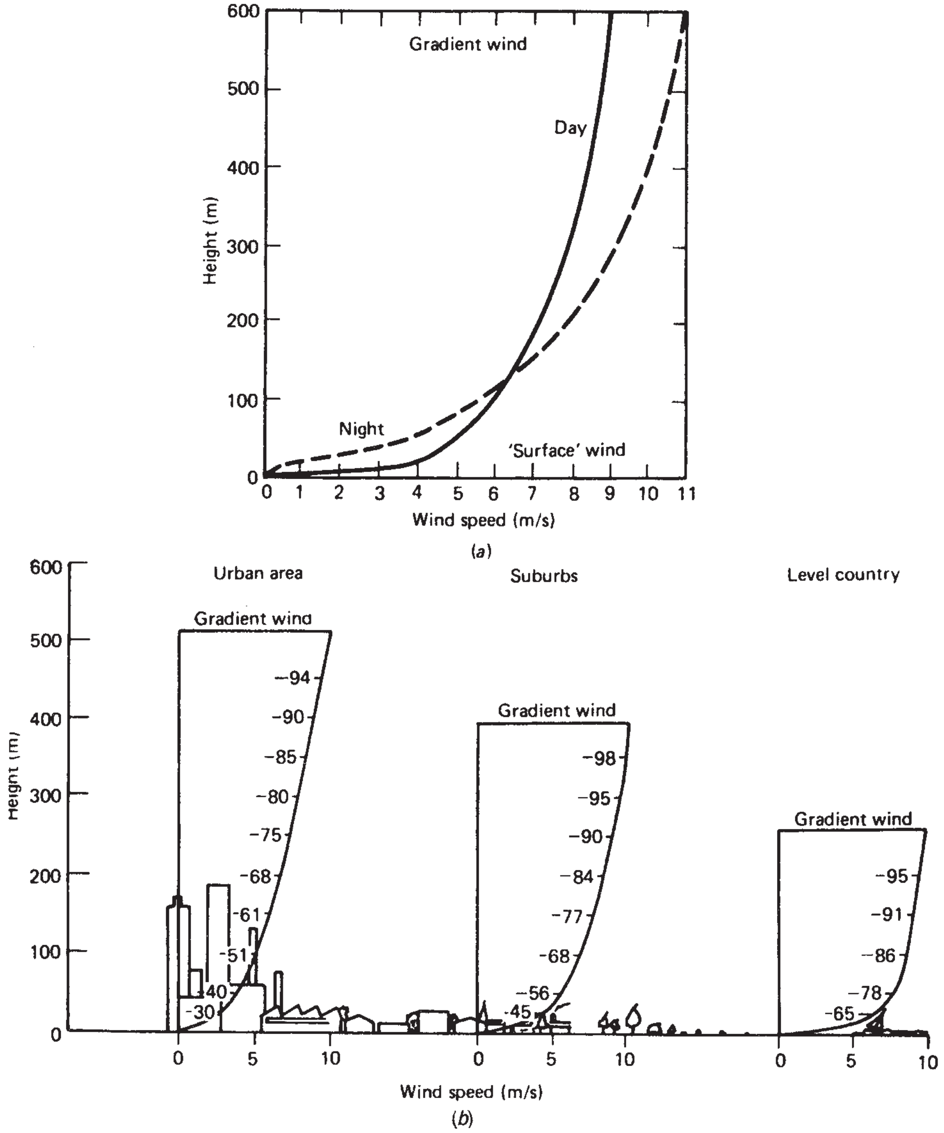

Figure 15.36 *Wind speed vs height above ground (American Society of Mechanical Engineers, 1973/2): (a) effect of stability conditions on wind speed; (b) effect of terrain on wind speed*

The gradient level reference height z_r lies approximately in the range 300–750 m, being typically 300 m over level ground and 500 m over an urban area.

The value of the index p generally lies in the range $0.11 < p < 0.65$, and invariably in the range $0 < p < 1$. Range values obtained include: $0.145 < p < 0.77$ by Frost (1947); $0.10 < p < 0.63$ by Touma (1977); and $0.11 < p < 0.65$ by Hanafusa, Lee and Lo (1986).

As pointed out by O.G. Sutton (1953), the generally accepted value of the index p for the turbulent boundary layer of a flat plate in a wind tunnel is 1/7 (0.142).

Touma states that in the absence of measured values the wind speed is generally estimated using the 1/7 wind profile and assuming neutral stability conditions. He presents experimental data, however, which indicate that the index p has a value of about 0.10 at Pasquill stability category A, may pass at some sites through a weak minimum and then increases markedly through categories D–F to a value of up to 0.62.

In further experimental work in Japan by Hanafusa, Lee and Lo (1986), the value of the index p varied with the Pasquill stability categories approximately as follows:

Pasquill stability category	*Index, p*
A	0.33
B	0.26
C	0.20
D, E	0.38
F	0.42
G	0.57

The strong increase in the index p with stability categories D–F broadly confirmed that found by Touma, but the values of p for categories A and B were higher than those obtained by the latter. The authors suggest that the difference may be due to the different methods used to define the stability category. The index p may also be written as

$$p = n/(2 - n) \qquad [15.12.17]$$

where n is an index. This index is one of the parameters in the Sutton model for neutral density gas dispersion, as described below.

15.12.9 Empirical vertical wind velocity profile: Deacon relation

An empirical relation for the vertical wind velocity gradient was formulated by Deacon (1949) as follows:

$$\frac{\mathrm{d}u}{\mathrm{d}z} = az^{-\beta} \qquad [15.12.18]$$

where a is a constant and β an index. He gave the following values of the index β:

$\beta > 1$ superadiabatic conditions
$\beta = 1$ adiabatic conditions, or small temperature gradients
$\beta < 1$ inversion conditions

Then for $\beta = 1$

$$\frac{\mathrm{d}u}{\mathrm{d}z} = \frac{a}{z} \qquad [15.12.19]$$

Equation 15.12.19 is an alternative form of the law of the wall given above as Equation 15.12.15.

15.12.10 Logarithmic vertical wind velocity profile

Another vertical wind velocity profile is the logarithmic profile. This is applicable to adiabatic, or neutral, conditions. The logarithmic vertical wind velocity profile is obtained by integration of Equation 15.12.15 to give

$$u = \frac{u_*}{k}\ \ln\left(\frac{z}{z_o}\right) \qquad [15.12.20]$$

where z_o is a constant of integration. This constant is termed the 'roughness length'.

15.12.11 Modified logarithmic vertical wind velocity profiles

For non-adiabatic, or diabatic, conditions a different treatment is required. The analysis is complicated by buoyancy effects. For diabatic conditions Equation 15.12.15 may be modified by the inclusion of the similarity factor introduced by Monin and Obukhov (1954). It then becomes

$$\frac{\mathrm{d}u}{\mathrm{d}z} = \frac{u_*}{kz}\phi_{\mathrm{M}} \qquad [15.12.21]$$

where ϕ_{M} is the similarity factor. These authors take

$$\phi_{\mathrm{M}} = f(z/L) \qquad [15.12.22]$$

They also use the relation

$$\phi_{\mathrm{M}} = 1 + \alpha\frac{z}{L} \qquad [15.12.23]$$

which yields for Equation 15.12.21

$$\frac{\mathrm{d}u}{\mathrm{d}z} = \frac{u_*}{kz}\left(1 + \alpha\frac{z}{L}\right) \qquad [15.12.24]$$

where L is a characteristic length (the Monin–Obukhov length), and α is the Monin–Obukhov coefficient. Integrating Equation 15.12.24

$$u = \frac{u_*}{k}\left[\mathrm{In}(z/z_o) + \alpha\,\frac{z - z_o}{L}\right] \qquad [15.12.25]$$

and taking $z \gg z_o$ yields

$$u = \frac{u_*}{k}\left[\mathrm{ln}(z/z_o) + \alpha\,\frac{z}{L}\right] \qquad [15.12.26]$$

This is the log–linear vertical wind velocity profile. The log–linear velocity profile is applicable over a limited range of unstable conditions and a wide range of stable conditions. In a further treatment Ragland (1973) has given

$$\phi_{\mathrm{M}} = 1 \quad \text{neutral conditions} \quad z < (ku_*/f) \qquad [15.12.27a]$$

$$= 1 + \alpha\frac{z}{L} \quad \text{stable conditions} \quad 0 < \frac{z}{L} < 1 \qquad [15.12.27b]$$

$$= 1 + \alpha \quad \text{neutral conditions} \quad 1 < \frac{z}{L} < 6 \qquad [15.12.27c]$$

$$= \left(1 - 15\frac{z}{L}\right)^{-0.25} \quad \text{stable conditions} \quad -2 < \frac{z}{L} < 0 \qquad [15.12.27d]$$

He quotes for α the value of 5.2 given by Webb (1970).

15.12.12 Surface roughness and roughness length

A surface is aerodynamically rough when the flow is turbulent down to the surface itself. Over such a surface the velocity profile and surface drag are independent of viscosity and depend on the roughness length. In meteorology, nearly all surfaces are aerodynamically rough for any significant wind speed. The roughness length depends on the height and spacing of the roughness elements.

From work on pipe roughness, the roughness length z_o and the mean height ϵ of the roughness elements are related approximately as follows:

$$z_o = \epsilon/30 \qquad [15.12.28]$$

Roughness of flow may be defined in terms of the roughness Reynolds number $u_* z/\nu$. For fully rough flow the criterion obtained from Nikuradse's work is

$$\frac{u_*\epsilon}{\nu} > 75 \qquad [15.12.29a]$$

or, using Equation 15.12.28,

$$\frac{u_* z_o}{\nu} > 2.5 \qquad [15.12.29b]$$

Paeschke (1937) correlated roughness length z_o with the mean height ϵ of roughness elements on a larger scale and obtained for various grass and field surfaces

$$z_o = \epsilon/7.35 \qquad [15.12.30]$$

Other workers have obtained similar results, while yet others have found it to be a more complex function. Some typical values of the roughness length given in the literature are shown in Table 15.13.

For very rough surfaces the logarithmic wind profile of Equation 15.12.20 may be extended using the empirical modification

$$u = \frac{u_*}{k}\ln\left(\frac{z-d}{z_o}\right) \quad z > (d + z_o) \qquad [15.12.31]$$

where d is the zero plane displacement, or displacement height.

The displacement height d is the datum level above which normal turbulent exchange occurs. Using the displacement height concept the base of the roughness elements is at $z = 0$.

Table 15.13 *Some values of roughness length*

A Values given by O.G. Sutton (1953)

Type of surface	z_o (cm)	$u*$ (cm/s)
Very smooth (mud flats, ice)	0.001	16
This grass upto 10 cm high	0.7	36
Thick grass upto 50 cm high	9	63

B Values given by Pasquill and Smith (1983)

Type of surface	z_o (m)
Grass: closely mown	10^{-3}
short (*c.* 10 cm)	10^{-2}
long	3×10^{-2}
Agricultural–rural complex	0.2
Towns, forests	1

15.12.13 Vertical temperature profile

The stability of the atmosphere is essentially the extent to which it allows vertical motion by suppressing or assisting turbulence. One source of turbulence is the mechanical turbulence due to wind movement. Another is the turbulence associated with the vertical temperature gradient. Traditionally stability has been expressed primarily in terms of the latter.

If a small volume of air is taken vertically upward in the atmosphere, it meets lower pressure and therefore expands and cools. The rate of decrease of temperature with height is known as the lapse rate. If the air were dry and the process adiabatic, then the rate of decrease would have a particular value which is known as the dry adiabatic lapse rate of temperature. Although such a process does not occur in the atmosphere, the dry adiabatic lapse rate provides a standard of comparison for real atmospheric conditions.

The rate of change of temperature with height $\mathrm{d}T/\mathrm{d}z$ under adiabatic, or neutral, conditions is approximately -0.01°C/m. The definition of lapse rate as a rate of decrease of temperature, and thus as a positive quantity under adiabatic conditions, is a potential source of confusion. It is appropriate, therefore, to quote the following statement by O.G. Sutton (1953, p. 9): '$\mathrm{d}T/\mathrm{d}z = -1$°C per 100 m. This particular rate of decrease of temperature with height, known as the dry adiabatic lapse rate and denoted by the symbol Γ (gamma), is one of the fundamental constants of meteorology'.

The potential temperature θ of dry air is the temperature attained if a small volume of the air is taken adiabatically from its existing pressure to a standard pressure, usually that at the surface. Then

$$\theta = T\left(\frac{p_o}{p}\right)^{(\gamma-1)/\gamma} \qquad [15.12.32]$$

where p is the absolute original pressure, p_o is the absolute pressure at the surface, T is the absolute temperature of the volume of air and θ is the potential temperature of this air.

Taking logarithms of Equation 15.12.32 and differentiating with respect to z:

$$\frac{1}{\theta}\frac{\mathrm{d}\theta}{\mathrm{d}z} = \frac{1}{T}\frac{\mathrm{d}T}{\mathrm{d}z} - \frac{\gamma-1}{\gamma}\,\frac{1}{p}\,\frac{\mathrm{d}p}{\mathrm{d}z} \qquad [15.12.33]$$

and noting that

$$\mathrm{d}p = g\rho(-\mathrm{d}z) \qquad [15.12.34]$$

and

$$\rho = \frac{p}{RT} \qquad [15.12.35]$$

where g is the acceleration due to gravity, R is the universal gas constant and γ is the ratio of the specific heats of air, the following relation is obtained:

$$\frac{1}{\theta}\frac{\mathrm{d}\theta}{\mathrm{d}z} = \frac{1}{T}\left(\frac{\mathrm{d}T}{\mathrm{d}z} + \Gamma\right) \qquad [15.12.36]$$

with

$$\Gamma = \frac{\gamma - 1}{\gamma}\frac{g}{R} \qquad [15.12.37]$$

The term $(\mathrm{d}T/\mathrm{d}z + \Gamma)$ is the difference between the actual temperature gradient and the dry adiabatic lapse rate. Under adiabatic conditions it is zero, so that $\mathrm{d}T/\mathrm{d}z = -\Gamma$.

At the surface the potential temperature θ and the absolute temperature T are equal by definition, so that Equation 15.12.36 becomes

$$\frac{\mathrm{d}\theta}{\mathrm{d}z} = \frac{\mathrm{d}T}{\mathrm{d}z} + \Gamma \qquad [15.12.38]$$

The relation between the vertical temperature gradient and the stability condition is described below.

15.12.14 Vertical heat flux and the Bowen ratio

Another feature that affects turbulence is buoyancy effects associated with the vertical heat flux. As already mentioned, in neutral conditions this heat flux is negligible, but in unstable and stable conditions it is significant. The vertical heat flux consists of a sensible heat flux and a latent heat flux. The ratio of the vertical sensible heat flux to the vertical latent heat flux is given by the Bowen ratio Bo:

$$\mathrm{Bo} = \frac{H}{L_e E} \qquad [15.12.39]$$

where H is the sensible heat flux into the air, E is the evaporation rate and L_e is the latent heat of evaporation. Over land, the latent heat flux is usually small compared to the sensible heat flux.

There are several empirical methods of estimating the vertical heat flux H (e.g. Holtslag and van Ulden, 1983). For the United Kingdom, the following equation is given by Clarke (1979, NRPB R91):

$$H = 0.4(S - 100) \qquad [15.12.40]$$

where H is the vertical heat flux (W/m^2) and S the incoming solar radiation (W/m^2).

The incoming solar radiation (ISR) may be estimated from Figure 15.37. Figure 15.37(a) gives the value of the ISR for a cloudless day as a function of time of day and month. For cloudy conditions this value is multiplied by the correction factor given in Figure 15.37(b).

15.12.15 Stability conditions

As stated earlier, stability has traditionally been described primarily in terms of the vertical temperature gradient. The theoretical adiabatic condition and some of the other conditions that occur in practice are illustrated in Figure 15.38. Curve 1 shows the dry adiabatic condition. Curve 2 shows a superadiabatic condition which can result from strong sunlight, or insolation, or from passage of cold air over a warm surface and which promotes convection and favours instability. Curve 3 shows a neutral condition which is associated with overcast skies and moderate to strong wind speeds and which is neutral with respect to stability. Curve 4 shows a subadiabatic condition that favours stability. Curve 5 shows an isothermal condition that favours stability strongly. Curve 6 shows an inversion condition that suppresses convection and is most favourable to stability.

There are several different types of inversion condition. One is surface inversion, as shown by Curve 6 in Figure 15.38. This tends to occur at night with clear skies and light winds when the ground and the air near to it lose heat by radiation. The condition is therefore also referred to as radiation inversion.

Another type of inversion is elevated inversion, as illustrated in Figure 15.39.

There are a number of causes for such inversions. One is subsidence of air from greater heights, which results in compression and hence warming. Another is a sea breeze, which may introduce a layer of cold air beneath a warm air mass. A third is a meteorological front, which also constitutes a boundary between cold air below and warm air above.

An inversion layer inhibits vertical motion. Surface inversion suppresses upward dispersion of a gas release at ground level and also downward dispersion of a release at elevated level. Elevated inversion acts as a 'lid', inhibiting further upwards dispersion. There is a virtually permanent inversion lid on the atmosphere at a height of about 10,000 m.

If in any layer the rate of change of temperature with height is negative, that layer is effectively a 'mixing layer' There is diurnal variation of stability within the lowest few hundred metres above the ground. The rate of change of temperature with height tends to be negative by day and positive by night giving, respectively, a lapse and an inversion condition. The latter is a surface inversion. Figure 15.40(a) illustrates a typical diurnal variation. An elevated inversion, however, can last for days or even weeks on end.

There are several special features that can affect stability. These include (1) semi-permanent pressure areas, (2) sea–land locations and (3) urban areas. Some areas are subject to a relatively fixed high or low pressure system. The United Kingdom, for example, is often under the influence of the Icelandic semi-permanent low pressure area, with cloudy weather and near neutral stability. Stability in coastal locations is strongly influenced by sea–land interactions. One effect may be the complete suppression of surface inversion during winter due to relatively warm sea breezes, as illustrated in Figure 15.40(b). Urban areas affect stability in various ways. One major aspect is the 'heat island' effect, which prevents the development of surface inversion at night.

15.12.16 Stack plume regimes

The effect of stability conditions on dispersion has been studied extensively and is most readily illustrated in relation to the behaviour of the plume from an elevated source such as a factory chimney. Some of the principal types of plume behaviour are shown in Figure 15.41.

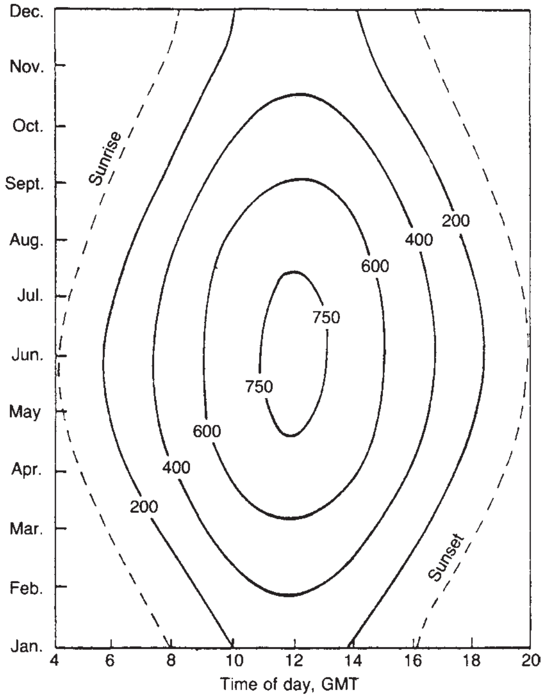
15.12.17 Stability criteria

A simple stability parameter, the environmental stability s, may be defined:

$$s = \frac{g}{T}\left(\frac{\mathrm{d}T}{\mathrm{d}z} + \Gamma\right) \qquad [15.12.41a]$$

$$= \frac{g}{\theta}\left(\frac{\mathrm{d}\theta}{\mathrm{d}z}\right) \qquad [15.12.41b]$$

This parameter is proportional to the rate at which the generation of turbulence is suppressed.



(a)

Cloud amount (eighths)	Multiply ISR by
0	1.07
1	0.89
2	0.81
3	0.76
4	0.72
5	0.67
6	0.59
7	0.45
8	0.23

(b)

Figure 15.37 *Incoming solar radiation (ISR) at Cambridge (after Clarke, 1979 NRPB R91; reproduced by permission): (a) ISR on a cloudless day (W/m^2); (b) correction factor by which ISR for cloudless day is multiplied to allow for cloudy conditions*

15.12.18 Richardson number

The rate at which mechanical turbulence is generated by wind shear is proportional to $(\mathrm{d}u/\mathrm{d}z)^2$. A criterion for the stability of the atmosphere that is effectively the ratio of the rates of suppression and generation of turbulence, as just described, was proposed by L.F. Richardson (1920, 1925) and is known as the Richardson number.

There are several forms of the Richardson number. The gradient Richardson number Ri is defined as

$$\mathrm{Ri} = \frac{g}{T}\left[\frac{\mathrm{d}T/\mathrm{d}z + \Gamma}{(\mathrm{d}u/\mathrm{d}z)^2}\right] \qquad [15.12.42a]$$

$$= \frac{g}{\theta}\left[\frac{\mathrm{d}\theta/\mathrm{d}z}{(\mathrm{d}u/\mathrm{d}z)^2}\right] \qquad [15.12.42b]$$

The bulk Richardson number $\mathrm{Ri_B}$ is defined as

$$\mathrm{Ri_B} = \frac{g}{T}\frac{\Delta\theta/\Delta z}{u^2}z^2 \qquad [15.12.43]$$

This form of the Richardson number is convenient for use where the value is determined experimentally from measurements made at two heights. The value of z is usually taken as the geometric mean of these heights and the value of u as that at the upper level. The flux Richardson number $\mathrm{Ri_F}$ is defined as

$$\mathrm{Ri_F} = -\frac{gH}{Tc_\mathrm{p}\tau(\mathrm{d}u/\mathrm{d}z)} \qquad [15.12.44]$$

where c_p is the specific heat of air, H is the vertical heat flux and τ is the Reynolds stress.

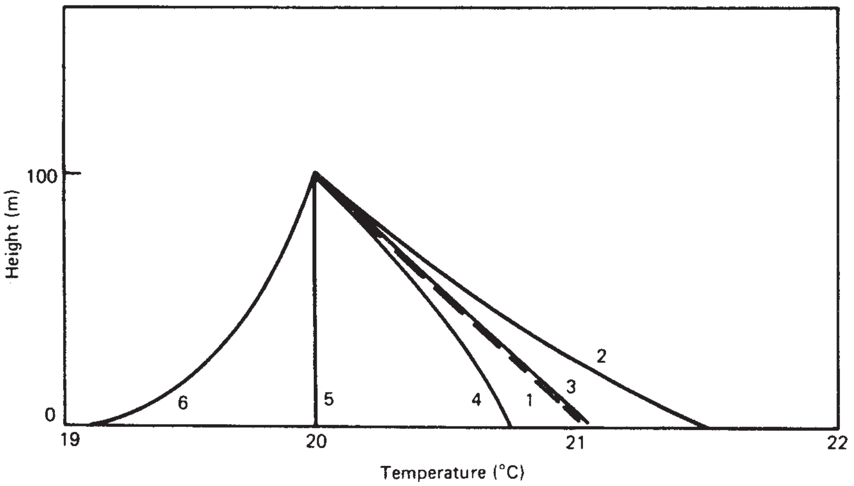


Figure 15.38 Vertical temperature profiles and lapse rates (American Society of Mechanical Engineers, 1973/2; reproduced by permission): (1) dry adiabatic condition; (2) super-adiabatic condition; (3) neutral condition; (4) subadiabatic condition; (5) isothermal condition; (6) inversion condition

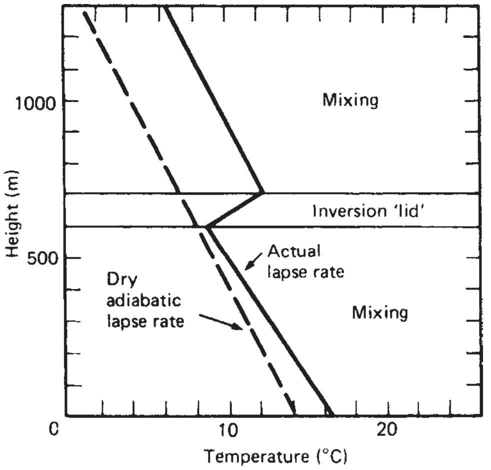

Figure 15.39 Elevated inversion (American Society of Mechanical Engineers, 1973/2; reproduced by permission)

A modified Richardson number $\mathrm{Ri}_{\mathrm{mod}}$ which is also used is

$$\mathrm{Ri}_{\mathrm{mod}} = g\frac{\Delta\rho}{\rho_{\mathrm{a}}}\frac{l}{u^2} \qquad [15.12.45]$$

where l is the mixing length and $\Delta\rho$ is the density difference between the cloud and the air.

The Richardson number Ri is the ratio of the buoyancy to the turbulent stress and is a criterion of similarity for turbulent motion. In his original treatment, Richardson suggested that there is a critical value $\mathrm{Ri}_{\mathrm{cr}}$ at which motion becomes turbulent and postulated that this value is unity. Then for $\mathrm{Ri} < 1$ motion is laminar and for $\mathrm{Ri} > 1$ it is turbulent.

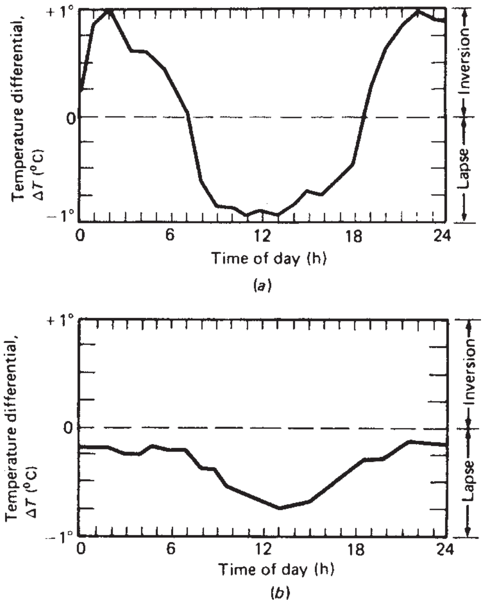

Figure 15.40 Diurnal variation of vertical temperature profile (American Society of Mechanical Engineers, 19731/2; reproduced by permission): (a) open country site all year; (b) coastal site in winter

Subsequent work indicates other values for the critical Richardson number. Obukhov (1971) quotes various values derived from theory including 1/2 (Prandtl), 1/4 (Taylor) and 1/24 (Tollmien) as well as an experimental value of 1/11 (Sverdrup).

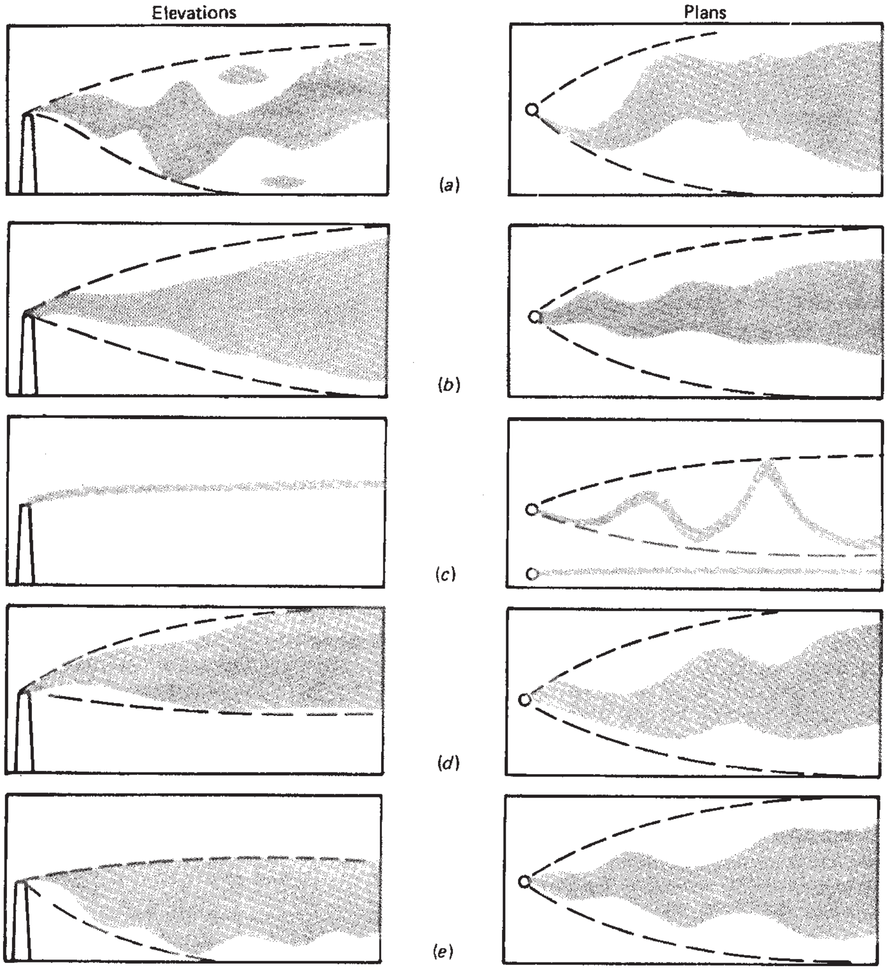

Figure 15.41 *Plume behaviour as a function of atmospheric stability conditions: (a) unstable ('looping'); (b) neutral ('coning'); (c) stable above and below source; surface inversion ('fanning'); (d) stable below source only: surface inversion ('lofting'); (e) stable above source only – elevated inversion ('fumigation')*

Since mechanical turbulence decreases quite rapidly with increase in height, the Richardson number is a function of height.

15.12.19 Monin–Obukhov length

The stability criteria just described take no account of two parameters that are now known to be important determinants of similarity in the surface layer. These are the vertical heat flux H and the friction velocity u_*.

These parameters are taken into account in another criterion of stability that is now increasingly used. This is the Monin–Obukhov length scale L (Monin and Obukhov, 1954; Obukhov, 1971), which is defined as

$$L = -\frac{u_*^3 c_p \rho T}{kgH} \qquad [15.12.46]$$

This parameter has the dimensions of length. It may be regarded as a measure of the depth of the mechanically mixed layer near the surface.

The Monin–Obukhov length L is negative for unstable and positive for stable conditions and infinite for adiabatic conditions. A dimensionless parameter, the Monin–Obukhov parameter ζ is obtained by taking the ratio of the height ζ to the Monin–Obukhov length L:

$$\zeta = z/L \qquad [15.12.47]$$

The Monin–Obukhov parameter is thus directly proportional to the height. Thus both the Richardson number and the Monin–Obukhov parameter are functions of the height.

The Richardson numbers and the Monin–Obukhov length and parameter are related, but the relations depend on stability conditions. Colder (1972) gives the following relations. For unstable conditions the Pandolfo–Businger hypothesis gives a good approximation:

$$\frac{z}{L} = \mathrm{Ri} \qquad [15.12.48a]$$

For stable conditions use may be made of the empirical relation given by McVehil (1964):

$$\frac{z}{L} = \frac{\text{Ri}}{1 - \beta\text{Ri}} \qquad [15.12.48b]$$

Values of the constant β are reviewed by Colder who uses $\beta = 7$.

The relation between the Richardson number and the Monin–Obukhov parameter may also be written in alternative form as given by Tagliazucca and Nanni (1983). For unstable conditions

$$\text{Ri} = \frac{z}{L} \qquad [15.12.49a]$$

$$= \frac{z/L}{1 + \gamma z/L} \qquad [15.12.49b]$$

where γ is a constant.

The following empirical relation for the Monin–Obukhov length has been obtained by Venkatram (1980b):

$$L = 1100u_*^2 \qquad [15.12.50]$$

15.12.20 Other stability criteria

Another stability parameter is the Kazanski–Monin parameter μ (Kazanski and Monin, 1960). This is defined as

$$\mu = \frac{ku_*}{fL} \qquad [15.12.51a]$$

$$= \frac{h'}{L} \qquad [15.12.51b]$$

where f is the Coriolis parameter and h' is the scale height of the neutral ABL. This parameter is also sometimes denoted by the symbol S.

A further stability criterion that is sometimes used is the non-dimensional windshear S:

$$S = \frac{kz}{u_*}\frac{\mathrm{d}u}{\mathrm{d}z} \qquad [15.12.52]$$

The condition $S = 1$ corresponds to the law of the wall as given in Equation 15.12.15.

15.12.21 Stability classification

The stability conditions have a strong influence on dispersion. The principal dispersion relations contain parameters that are functions of these conditions. Stability is a complex phenomenon, however, and its characterization is a difficult problem. There is a large literature dealing with approaches to turbulence typing or stability classification. Accounts are given by Pasquill (1962a), Gifford (1976b) and Sedefian and Bennett (1980).

A simple set of stability categories is:

(1) unstable conditions – lapse conditions;
(2) neutral conditions;
(3) stable conditions – including inversion conditions.

These categories are used to define the diffusion parameters in the Sutton equations, as described below.

A stability classification based on insolation and wind speed has been given by Pasquill (1961, 1962a) and is shown in Table 15.14. Night refers to the period from 1 h before sunset to 1 h after sunrise. Strong insolation corresponds to sunny, midday conditions in midsummer England and slight insolation to similar conditions in midwinter. If during day or night, there are overcast conditions then, regardless of wind speed, category D should be assumed.

Stability conditions in terms of the Pasquill stability categories are approximately:

A	Unstable conditions
D	Neutral conditions
F	Stable conditions

The frequency of the different Pasquill stability categories in Great Britain is shown in Table 15.15. The contours on the map given in Figure 15.42 show the percentage of time during which the neutral category D prevails.

The Pasquill stability categories are used to define the dispersion coefficients in the Pasquill–Gifford equations and the parameters in the Pasquill equations, as described below.

An additional stability category G is used by some workers (e.g. Bryant, 1964 UKAEA AHSB(RP) R42).

Relations between the Pasquill stability categories and the two main stability criteria, the Richardson number Ri and the Obukhov length L have been given by Pasquill and Smith (1971) and are shown in Table 15.16.

There are a number of other stability classifications schemes. A review of these has been given by Gifford (1976b). Some of schemes are shown in Table 15.17.

The scheme of Brookhaven National Laboratory (BNL) (Singer and Smith, 1966) is based on the fluctuations of the horizontal wind direction trace recorded over a 1 hour period. The categories are

A	Fluctuations >90° peak to peak,
B2	Fluctuations 40–90°,
B1	Fluctuations 15–45°,
C	Fluctuations >15° distinguished by unbroken solid core of trace,
D	Trace approximates a line, short-term fluctuations <15°.

Typical wind direction traces illustrating these wind gustiness categories given by Singer and Smith are shown in Figure 15.43.

The BNL scheme makes it possible to classify turbulence using relatively simple wind direction measurements and to relate the stability categories to experimental dispersion data obtained at a site. Strictly the categories are site specific and those published for BNL apply to the BNL site. The relations between the BNL categories and the wind speed and temperature gradient is shown in Table 15.18.

The scheme proposed by D.B. Turner (1961, 1964) is a version of Pasquill's scheme in which the insolation is according to the amount and height of cloud cover and the solar elevation angle.

The scheme developed by Klug (1969) is similar to that of Pasquill, but differs in that the categories are defined using more detailed rules for cloud cover, wind speed, time of day and season.

The scheme of Cramer (1957, 1959b) is based on correlation of stability with the azimuth σ_{A} and the elevation angle σ_{E}. Cramer's turbulence categories are shown in Table 15.19.

Surface wind speed at 10 m *height* (mile/h)	*Frequency of stability category* (%)						
	A	*B*	*C*	*D*	*E*	*F*	*G*
16	0	4	11	80	3	2	0
14.5	0	4	13	75	4	3	1
13	0	4	14	70	5	5	2
11.5	1	5	15	65	6	6	2
10	1	6	17	60	7	7	2
9	2	7	19	55	7	7	3
8	2	9	21	50	6	8	4

The Tennessee Valley Authority (TVA) scheme, described by Carpenter *et al.* (1971) is concerned with stability classification for buoyant plumes from tall chimneys. It is based on lapse rate $\Delta\theta/\Delta z$. The TVA stability categories are given in Table 15.20.

Relationships between some of these stability classification, or turbulence typing, schemes have been given by Gifford and are shown in Table 15.21.

The Pasquill scheme has been modified by F.B. Smith (1973) so that the stability is described in terms of a continuous index P rather than by discrete categories. The P value is a function of the wind speed, the upward heat flux and the incoming solar radiation, and also of the roughness length. P values of 0.5–6.5 correspond to the Pasquill categories A–G as follows:

	P
A	0.5
B	1.5
C	2.5
D	3.6
E	4.5
F	5.5
G	6.5

The graph given by Smith for the determination of the P value is shown in Figure 15.44.

There are a number of other stability classification schemes based on relations between the Pasquill stability categories and particular parameters. A review of several such schemes has been given by Sedefian and Bennett (1980), as shown in Table 15.22. The authors also analysed dispersion data and derived relations for the P value in some of the schemes.

In the σ_θ, or sigma theta, method the stability category is taken as a function of the wind direction standard deviation σ_θ. This method is one of two that has been recommended by the Nuclear Regulatory Commission and is widely used.

Sedefian and Bennett give the following relation involving σ_θ:

$$\sigma_\theta(z_2) = \sigma_\theta(z_1)(z_2/z_1)^{P_\theta} \qquad [15.12.53]$$

where P_θ is an index and where the heights z_1 and z_2 are 10 and 50 m, respectively. The values of P_θ corresponding to Pasquill categories A–F are −0.06, −0.15, −0.17, −0.23, −0.38 and −0.53, respectively.

The temperature difference ΔT method is the other method recommended by the NRC.

The wind speed ratio U_R is a parameter devised by Sedefian and Bennett and is the ratio of the wind speeds at 50 and 10 m height. The authors give the following relation involving U_R

$$U_R = (z_2/z_1)^{P_u} \qquad [15.12.54]$$

where P_u is an index and U_R is the wind speed ratio and where the heights z_1 and z_2 are 10 and 50 m, respectively. The values of P_u are related to the Pasquill stability categories.

[a] After Golder (1972).

Pasquill related his stability categories to the lateral spread of the wind θ. The relations are given in Table 15.24.

There have been a number of studies in which stability classification schemes have been compared with

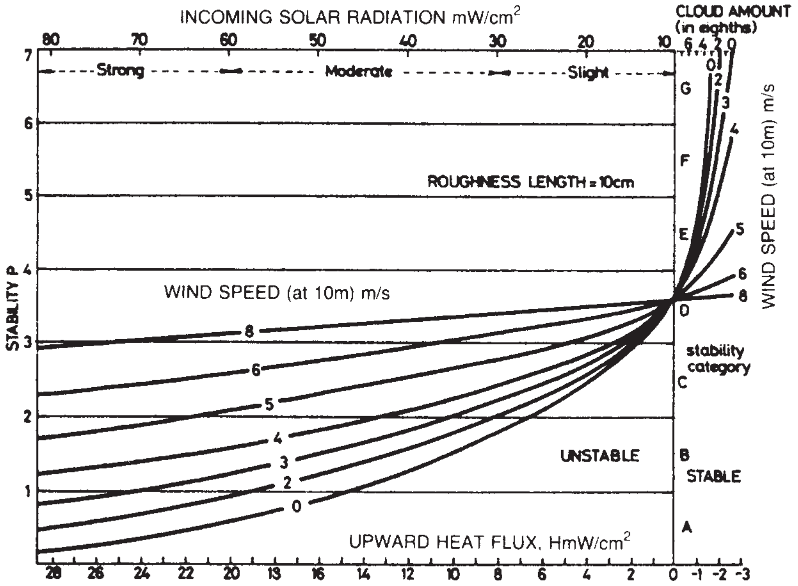

Figure 15.44 *Stability parameter, or P value (after F.B. Smith, 1973; Clarke, 1979 NRPB R91; reproduced by permission)*

Table 15.22 *Some schemes for assigning Pasquill stability categories (after Sedefian and Bennett, 1980)*

Scheme	*Comment*
Wind direction standard deviation σ_θ	One of two methods given in NRC *Guide* 1.23
Temperature difference, ΔT	Other method given in NRC *Guide* 1.23
Richardson number, Ri	Authors' own method,utilizing relations given by Golder (1972) between Pasquill categories and Monin–Obukhovlength L and roughness length z_o
Bulk Richardson number, $\mathrm{Ri_B}$	Authors' own method
Wind speed ratio U_R	Authors' own method, based on ratio of wind speed sat heights of 10 and 50 m
Stability array (STAR)	Author's own method, based on wind speed at 10 m, solar altitude and cloud cover

experimental measurements, including those done by Sedefian and Bennett (1980) and A.E. Mitchell (1982).

An alternative approach to stability is to treat it as primarily a function of the Obukhov length L and the roughness length z_o. Colder (1972) has developed relationships between the Pasquill stability categories and these two parameters. Figure 15.45 shows these relations. Colder also concluded that the most appropriate conversion between the Pasquill and Turner categories is A to 1, B to 2, C to 3, D to 4, E to 6 and F to 7.

Relations between the Turner stability categories and the Monin–Obukhov length, inferred from the work of Colder (1972) have been given by Ning and Yap (1986). These are given in Table 15.25.

Another stability classification scheme is that of Holtslag and van Ulden (1983). This is based on the sensible heat flux.

The stability classifications just described were developed for use over land. They do not necessarily hold over water.

A stability classification scheme for use over water has been developed at the Naval Postgraduate School (NFS), Monterey, by Schacher, Fairall and Zannetti (1982).

Following Colder, stability is treated as primarily a function of the Monin–Obukhov length and the roughness length. The Monin–Obukhov length is determined from air-sea temperature difference, wind speed and relative humidity. Figure 15.46, given by Skupniewicz and Schacher (1986), illustrates the classification for 50% relative humidity. A somewhat similar scheme has been given by Hasse and Weber (1985). In that stability is characterized by the Monin–Obukhov length, the derivation and use of this parameter may be regarded as a stability classification 'scheme'.

The selection of a stability classification method scheme for gas dispersion modelling is exemplified by the set of schemes used in the DRIFT dense gas dispersion model described in Section 15.35. The model can accommodate three schemes. One is the use of the Monin–Obukhov length, valid for all locations and all times. The others are the Pasquill scheme, used for day on land, and the Holtslag and van Ulden scheme, used for neutral or unstable conditions for day on land.

Table 15.23 *Relations between Pasquill stability categories and parameters of some typing schemes (after Sedfian and Bennett, 1980)(Courtesy of Pergamon Press)*

Pasquill stability	σ_θ (10 and 50 m) (°)	σ_θ (50 m)^a (°)	$\Delta T/\Delta z$ (°C/100 m)	Ri^b	$\mathrm{Ri_B}^b$	$U_R{}^b$

Table 15.24 *Relations between Pasquill stability categories and lateral spread of wind*

Pasquill stability category	*Lateral spread* θ (deg)	
	$d = 0.1$ km	$d = 100$ km
A	60	(20)
B	45	(20)
C	30	10
D	20	10
E	(15)	(5)
F	(10)	(5)

The stability category is the other main piece of information which is required, in addition to the wind characteristics, for the estimation of dispersion at a given location.

15.12.22 Flux–gradient relations

In the surface layer it is assumed that stress does not vary with height. Similar arguments based on the work of Monin and Obukhov lead to the conclusion that for any transferable property S the relation between vertical flux and vertical gradient is determined by the following parameters: z, ρ, g/T, τ/ρ, and $H/c_p\rho$.

The flux–gradient relations may be expressed in the form:

$$\frac{dS}{dz} = \frac{S_*}{kz}\phi_s\left(\frac{z}{L}\right) \qquad [15.12.55]$$

where S is the mean quantity of the property per unit mass of air, S_* is a scale parameter with the same dimensions as S, ϕ is a similarity factor, and the subscript s denotes the property specified.

The scale parameter S_* is defined by the relation to the vertical flux F_s:

$$S_* = \frac{F_s}{\rho u_*} \qquad [15.12.56]$$

The vertical flux is given by the relation:

$$F_s = -\rho K_s \frac{dS}{dz} \qquad [15.12.57]$$

where K is a turbulent exchange coefficient.

For momentum, heat and water vapour the flux relations are:

$$\tau = \rho K_M \frac{du}{dz} \qquad [15.12.58]$$

$$H = -\rho c_p K_H \frac{d\theta}{dz} \qquad [15.12.59]$$

$$E = -\rho L_W K_W \frac{dq}{dz} \qquad [15.12.60]$$

where c_p is the specific heat of air, E is the vertical flux of water vapour, H is the vertical heat flux, L_W is the latent heat of water vapour, q is the specific humidity, or

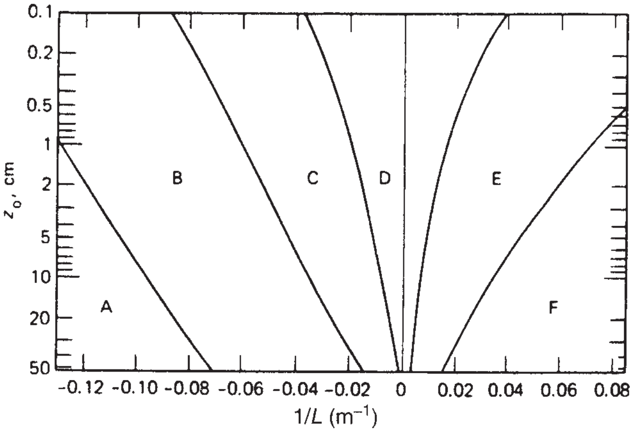

***Figure 15.45** Relations between Pasquill stability categories and Monin–Obukhov length and surface roughness (Golder, 1972) (Courtesy of Kluwer Academic Publishers)*

***Table 15.25** Relations between Turner stability categories and Monin–Obukhov length (after Ning and Yap, 1986) (Courtesy of Pergamon Press)*

Turner stability category[a]	$1/L$ (m^{-1})
A	$1/L \leq -0.087$
B	$-0.087 \leq 1/L < -0.028$
C	$-0.028 \leq 1/L < -0.005$
D	$-0.005 \leq 1/L$

[a] D.B. Turner (1964) denoted his stability categories 1–7.

Ning and Yap state that the Turner stability categories A–D are derived from the work of Golder (1972) for a roughness length z_o of 20 cm on land, and the Holtslag and van Ulden scheme, used for neutral or unstable conditions for day on land.

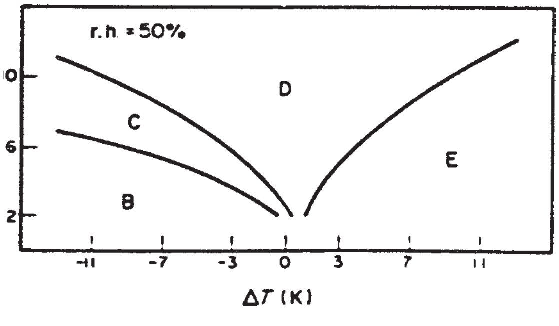

***Figure 15.46** Illustration of the NPS stability classification scheme over water (Skupniewicz and Schacher, 1986) (Courtesy of Pergamon Press)*

concentration of water vapour, u is the wind velocity, θ is the potential temperature, ρ is the density of air, and the subscripts H, M and W denote heat, mass and water vapour, respectively.

The corresponding equations for the turbulent exchange coefficients are then

$$K_{\mathrm{M}} = \frac{\tau}{\rho \mathrm{d}u/\mathrm{d}z} \qquad [15.12.61]$$

$$K_{\mathrm{H}} = -\frac{H}{\rho c_{\mathrm{p}} \mathrm{d}\theta/\mathrm{d}z} \qquad [15.12.62]$$

$$K_{\mathrm{W}} = -\frac{E}{\rho L_{\mathrm{W}} \mathrm{d}q/\mathrm{d}z} \qquad [15.12.63]$$

Then, applying Equations 15.12.56 and 15.12.57 to momentum and noting that for this case

$$S = u \qquad [15.12.64]$$

and

$$F_s = -\rho u_*^2 \qquad [15.12.65]$$

gives

$$\frac{\mathrm{d}u}{\mathrm{d}z} = \frac{u_*}{kz}\phi_{\mathrm{M}} \qquad [15.12.66]$$

Similarly, the gradient relations for heat and water vapour are:

$$\frac{\mathrm{d}\theta}{\mathrm{d}z} = -\frac{H}{\rho c_{\mathrm{p}} k u_* z}\phi_{\mathrm{H}} \qquad [15.12.67]$$

$$\frac{\mathrm{d}q}{\mathrm{d}z} = -\frac{E}{\rho L_{\mathrm{W}} k u_* z}\phi_{\mathrm{W}} \qquad [15.12.68]$$

The relations for the turbulent exchange coefficients become:

$$K_{\mathrm{M}} = k u_* z/\phi_{\mathrm{M}} \qquad [15.12.69]$$

$$K_{\mathrm{H}} = k u_* z/\phi_{\mathrm{H}} \qquad [15.12.70]$$

$$K_{\mathrm{W}} = k u_* z/\phi_{\mathrm{W}} \qquad [15.12.71]$$

Also from the definitions of the Richardson number Ri and the Monin–Obukhov parameter z/L, as given by Equations 15.12.42b and 15.12.46, and from Equations 15.12.66 and 15.12.67

$$\mathrm{Ri} = \frac{z}{L}\frac{\phi_{\mathrm{H}}}{\phi_{\mathrm{M}}^2} \qquad [15.12.72]$$

15.12.23 Universal functions

Monin and Obukhov expanded the function $\phi_{\mathrm{M}}(z/L)$ as the power series

$$\phi_{\mathrm{M}} = 1 + \alpha_1\left(\frac{z}{L}\right) + \alpha_2\left(\frac{z}{L}\right)^2 + \cdots \qquad [15.12.73]$$

where α_1 and α_2 are coefficients. They truncated the series after the first term in (z/L) to give

$$\phi_{\mathrm{M}} = 1 + \alpha\left(\frac{z}{L}\right) \qquad [15.12.74]$$

where α $(=\alpha_1)$ is the Monin–Obukhov coefficient. This coefficient is to be determined empirically.

An alternative relation for ϕ_{M} is the exponential relation proposed by Swinbank (1964):

$$\phi_{\mathrm{M}} = \left[1 - \exp(z/L)\right]^{-1} \qquad [15.12.75]$$

Relations for the universal functions have been derived by a number of authors and have been reviewed by Dyer (1974). Some of these relations are given in Table 15.26. Obukhov (1971) has defined an alternative universal function by the relation

$$K_{\mathrm{M}} = K_{\mathrm{Mo}}\phi(\mathrm{Ri}) \qquad [15.12.76]$$

where K_{Mo} is the adiabatic value of K_{M}. He gives the following relations for ϕ (Ri):

$$\phi(\mathrm{Ri}) = 1 \qquad \mathrm{Ri} = 0 \qquad [15.12.77a]$$

$$= \left(1 - \frac{\mathrm{Ri}}{\mathrm{Ri}_{\mathrm{cr}}}\right)^{1/2} \qquad \mathrm{Ri} < \mathrm{Ri}_{\mathrm{cr}} \qquad [15.12.77b]$$

$$= 0 \qquad \mathrm{Ri} > \mathrm{Ri}_{\mathrm{cr}} \qquad [15.12.77c]$$

where the subscript cr denotes critical.

Equation 15.12.77a follows from the definition of ϕ (Ri) and from the fact that for adiabatic conditions $\mathrm{Ri} = 0$, and Equation 15.12.77c follows from the fact that turbulence is suppressed for $\mathrm{Ri} > \mathrm{Ri}_{\mathrm{cr}}$.

As already described, the Monin–Obukhov form of the universal function ϕ_{M} gives for the wind velocity gradient Equation 15.12.24, which on integration yields Equation 15.12.25 or, for $z \gg z_{\mathrm{o}}$, Equation 15.12.26.

15.12.24 Turbulent exchange coefficients

The turbulent exchange coefficients are:

K_{M}	Turbulent exchange coefficient for momentum; eddy viscosity.
K_{H}	Turbulent exchange coefficient for heat; eddy thermal diffusivity.
K_{W}	Turbulent exchange coefficient for water vapour; eddy diffusivity.

These coefficients are defined by Equations 15.12.58–15.12.60, respectively. It was assumed in early work by Schmidt (1925) that

$$K_{\mathrm{M}} = K_{\mathrm{H}} = K_{\mathrm{W}} \qquad [15.12.78]$$

The identity of the three exchange coefficients is still a common assumption for neutral conditions. According to Dyer (1974), however, there is evidence that for such conditions the ratio $K_{\mathrm{H}}/K_{\mathrm{M}}$ is equal to 1.35.

From Equations 15.12.69–15.12.71, the ratio of the exchange coefficients may be expressed in terms of the ratios of the universal functions ϕ_{M}, ϕ_{H} and ϕ_{W}. For neutral conditions the latter approach unity. For other conditions the ratios $K_{\mathrm{H}}/K_{\mathrm{M}}$ and $K_{\mathrm{W}}/K_{\mathrm{M}}$ will be unity only if the asymptotic approach to unity of the ϕ_{H} and ϕ_{W} is identical with that of ϕ_{M}. For unstable conditions there is evidence that this is not so.

The identity of the exchange coefficients for mass and heat transfer implies, from Equations 15.12.58 and 15.12.59,

$$\frac{H}{C_{\mathrm{p}}\tau} = -\frac{\mathrm{d}\theta/\mathrm{d}z}{\mathrm{d}u/\mathrm{d}z} \qquad [15.12.79]$$

Equation 15.12.79 is a form of the Reynolds analogy.

Table 15.26 *Some forms of the universal functions (after Dyer, 1974) (Courtesy of Kluwer Academic Publishers)*

15.12.25 Wind direction fluctuations

Wind direction fluctuations may be defined in terms of the standard deviation of the horizontal direction and inclination of the wind:

σ_θ Standard deviation of the horizontal direction of the wind.
σ_ϕ Standard deviation of the inclination to the horizontal of the wind.

Alternative notation for these quantities is for σ_θ the standard deviation of the azimuth σ_A and for σ_ϕ the standard deviation of the elevation σ_E. Distributions of the standard deviations σ_θ and σ_ϕ by Pasquill stability category have been given by Luna and Church (1972) and are shown in Figure 15.47.

As described above, the concentration measured in a plume varies with the sampling time. Similarly, the value measured for σ_θ varies with sampling time. Slade (1968) suggests that a correction for sampling time may be made using the following approximate relation:

$$\frac{\sigma_\theta}{\sigma_{\theta \mathrm{r}}} = \left(\frac{t}{t_\mathrm{r}}\right)^p \qquad [15.12.80]$$

where t is the sampling period which yields σ_θ, p is an index and subscript r denotes the reference value. The value of p is of the order of 0.2.

The standard deviations σ_θ and σ_ϕ are used in the Pasquill model for passive gas dispersion.

15.12.26 Wind velocity fluctuations

The wind velocities u, v and w in the downwind, crosswind and vertical directions respectively, may be written as the sum of a mean velocity and a velocity fluctuation:

$$u = \bar{u} + u' \qquad [15.12.81a]$$

$$v = \bar{v} + v' \qquad [15.12.81b]$$

$$w = \bar{w} + w' \qquad [15.12.81c]$$

where $\bar{u}$, $\bar{v}$ and $\bar{w}$ are the mean values and u' v' and w' the fluctuations of u, v and w, respectively.

Wind velocity fluctuations may be defined in terms of the standard deviations σ_u, σ_v and σ_w of the velocities as follows:

$$\sigma_u = \left(\overline{u'^2}\right)^{1/2} \qquad [15.12.82a]$$

$$\sigma_v = \left(\overline{v'^2}\right)^{1/2} \qquad [15.12.82b]$$

$$\sigma_w = \left(\overline{w'^2}\right)^{1/2} \qquad [15.12.82c]$$

where $\overline{u^2}$, $\overline{v^2}$ and $\overline{w^2}$ are the variances of u, v and w, respectively.

Relationships for σ_u, σ_v and σ_w derived from the work of Wyngaard, Cote and Rao (1974) and Wyngard (1975) have been given by S.R. Hanna, Briggs and Hosker (1982). For σ_u:

$$\frac{\sigma_u}{u_*} = \left(12 - 0.5\frac{z_\mathrm{i}}{L}\right)^{1/3} \quad \text{unstable} \qquad [15.12.83]$$

$$= 2.0 \exp\left(-3\frac{fz}{u_*}\right) \quad \text{neutral} \qquad [15.12.84]$$

$$= 2.0\left(1 - \frac{z}{z_\mathrm{i}}\right) \quad \text{stable} \qquad [15.12.85]$$

where f is the Coriolis parameter, L is the Monin–Obukhov length and z_i is the mixed layer height. The authors also give relationships for σ_v and σ_w.

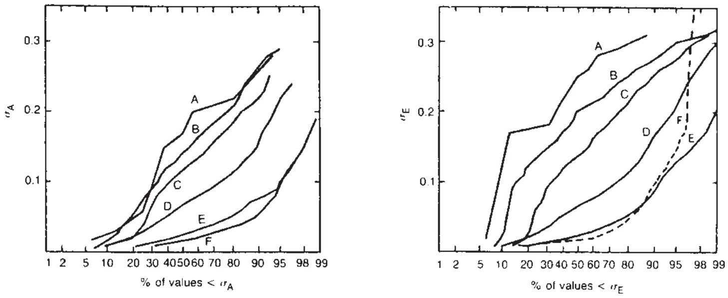
15.12.27 Turbulence intensity

Intensities of turbulence are defined as:

$$i_y = \left(\overline{v'^2}\right)^{1/2} / \bar{u} \qquad [15.12.86a]$$

$$i_z = \left(\overline{w'^2}\right)^{1/2} / \bar{u} \qquad [15.12.86b]$$

where i_y and i_z are the intensities of the lateral and vertical components of turbulence, respectively.



(a) (b)

Figure 15.47 *Standard deviations of wind direction fluctuations (Luna and Church, 1972): (a) distribution of σ_A by stability class; (b) distribution of σ_A by stability class. A–F, Pasquill stability categories. Reproduced by permission*

The root-mean-square turbulent velocities are related to the friction velocity:

$$\left(\overline{v'^2}\right)^{1/2} = 2.2u_* \qquad [15.12.87a]$$

$$\left(\overline{w'^2}\right)^{1/2} = 1.25u_* \qquad [15.12.87b]$$

For neutral conditions, combining Equations 15.12.86, 15.12.87 and 15.12.20:

$$i_y = \frac{0.88}{\ln(z/z_o)} \qquad [15.12.88a]$$

$$i_z = \frac{0.5}{\ln(z/z_o)} \qquad [15.12.88b]$$

Also, combining Equations 15.12.82 and 15.12.86:

$$i_y = \sigma_v/\bar{u} \qquad [15.12.89a]$$

$$i_z = \sigma_w/\bar{u} \qquad [15.12.89b]$$

15.12.28 Eddy dissipation rate

The eddy dissipation rate t is the rate at which on the small scale turbulence is dissipated into heat. In the surface layer:

$$\epsilon = \frac{u_*^3}{kz}(\phi_{\mathrm{M}} - z/L) \qquad [15.12.90]$$

For neutral conditions:

$$\epsilon = \frac{u_*^3}{kz} \qquad [15.12.91]$$

15.12.29 Lagrangian turbulence

Turbulence may be measured at a fixed point or by reference to a particle moving through the turbulent field. The types of turbulence measured in these two different ways are known as Eulerian and Lagrangian turbulence, respectively. The dispersion of a gas in air is a Lagrangian process, but it is generally observed by Eulerian measurements.

The difference between the two types of turbulence may be illustrated by the following simplified argument. Consider a wind speed u carrying a circular eddy radius r and tangential velocity ω. The Eulerian time scale t_{E} is the time for the eddy to pass a fixed point:

$$t_{\mathrm{E}} = 2r/u \qquad [15.12.92]$$

The Lagrangian time scale t_{L}, is the time for a particle on the circumference of the eddy to travel once round the eddy:

$$t_{\mathrm{L}} = 2\pi r/\omega \qquad [15.12.93]$$

The ratio β of the Lagrangian to the Eulerian time scale is then

$$\beta = \frac{t_{\mathrm{L}}}{t_{\mathrm{E}}} \qquad [15.12.94a]$$

$$= \frac{\pi}{\omega/u} \qquad [15.12.94b]$$

$$= \frac{\pi}{i} \qquad [15.12.94c]$$

with

$$i = \omega/u \qquad [15.12.95]$$

where i is the intensity of turbulence.

The ratio β decreases as the intensity of turbulence increases. Reid (1979) gives the relation

$$\beta = 0.5/i \qquad [15.12.96]$$

This suggests that, although the form of Equation 15.12.93 derived from the crude model is correct, the equation overestimates β. An average value given by Pasquill (1974) for β is 4.

A study of the time scales over water is described by Sethuraman, Meyers and Brown (1976).

15.12.30 Autocorrelation function

If in a field of homogenous turbulence measurements are made at two points of the instantaneous components of velocity u'_1 and u'_2 and, if the position of the second point is moved while that of the first is kept fixed, a correlation coefficient $R(x)$ may be defined as

$$R(x) = \overline{u'_1 u'_2}/\overline{u'^2} \qquad [15.12.97]$$

For eddy sizes which are large compared with the distance x this correlation coefficient is high, and vice versa.

The correlation coefficient may also be expressed in terms of time. This time correlation coefficient $R(\tau)$, which is also known as the autocorrelation coefficient, is defined as

$$R(\tau) = \overline{u(t)u(t+\tau)}/\overline{u^2} \qquad [15.12.98]$$

The two correlation coefficients are identical:

$$R(\tau) = R(x) \qquad [15.12.99]$$

with $x = u\tau$.

Properties of the autocorrelation coefficient are:

$$R(\tau) = 1 \quad \tau = 0 \qquad [15.12.100a]$$

$$= 0 \quad \tau \to \infty \qquad [15.12.100b]$$

The form of the autocorrelation coefficient is not fully understood. One model commonly used is the Markov model for which

$$R(\tau) = \exp(-\tau/t_{\mathrm{L}}) \qquad [15.12.101]$$

15.12.31 Taylor's theorem

A relation between the autocorrelation function and the dispersion parameters has been derived by G.I. Taylor (1921). The displacement x of a particle is related to its velocity u as follows:

$$x(t) = \int_0^t u(t')\,\mathrm{d}t' \qquad [15.12.102]$$

Then

$$\frac{\mathrm{d}\left[x^2(t)\right]}{\mathrm{d}t} = 2x\frac{\mathrm{d}x}{\mathrm{d}t} \qquad [15.12.103a]$$

$$= 2\int_0^t u(t)u(t')\,\mathrm{d}t' \qquad [15.12.103b]$$

Substituting the autocorrelation coefficient from Equation 15.12.98 in Equation 15.12.103 yields

$$\frac{d\overline{x^2}}{dt} = 2\overline{u^2}\int_0^t R(\tau)\,d\tau \qquad [15.12.104]$$

But it can be shown that

$$\sigma_x^2 = \overline{x^2} \qquad [15.12.105]$$

Hence

$$\frac{d\sigma_x^2}{dt} = 2\overline{u^2}\int_0^t R(\tau)\,d\tau \qquad [15.12.106]$$

and

$$\sigma_x^2 = 2\overline{u^2}\int_0^t\int_0^{t'} R(\tau)\,d\tau\,dt' \qquad [15.12.107]$$

Equation 15.12.107 is Taylor's theorem.

If a form of the autocorrelation coefficient is assumed, such as that given in Equation 15.12.101, it is possible to derive from Equation 15.12.107 an expression for the dispersion coefficient. The application of Taylor's theorem for this purpose is described below.

15.12.32 Mixed layer scaling

Much of the foregoing treatment has been concerned with the properties of, and similarity within, the surface stress layer. In mixed layer scaling, similarity is extended to the whole boundary layer.

The initial treatment by Deardorff (1970) was for the convective boundary layer, in other words, for the planetary boundary layer in convective, or unstable, conditions, and is also termed convective layer, or convective velocity, scaling.

Scaling has also been extended by other workers such as Caughey, Wyngaard and Kaimal (1979) to stable conditions and for this the term 'mixed layer scaling' is perhaps more appropriate. A parameter widely used in mixed layer scaling is

$$X = \frac{w_* x}{u z_i} \qquad [15.12.108]$$

where w_* is the convective velocity and z_i the mixed layer height.

15.12.33 Mixed layer height

Over land the mixed layer has a height of some 1000–2000 m by day but about an order of magnitude less by night. Over sea the diurnal variation is much less. By day the mixed layer height is usually set by an inversion layer capping the well mixed layer above the ground surface. By night, when there is some degree of inversion at all levels, the height of the mixed height may be taken as that at which surface induced mechanical turbulence dies out. Extensive data on the mixed layer height in the United States have been published by Holzworth (1972).

The mixed layer height z_i has been investigated by Zilitinkevich (1972a), who gives the following relations:

$$z_i = \frac{k u_*}{f} \quad \text{neutral conditions} \qquad [15.12.109a]$$

$$= c\left(\frac{u_* L}{f}\right)^{1/2} \quad \text{stable conditions} \qquad [15.12.109b]$$

where c is a constant. Values of the constant c are quoted by Venkatram and Paine (1985) as varying between 0.4 and 0.7.

Another correlation, applicable to stable conditions at night in high wind, is that of Venkatram and Paine (1985):

$$z_i = 2300 u_*^{3/2} \qquad [15.12.110]$$

They state that the constant, given here as 2300, tends to be site specific and quote a value of 1300 at another site.

15.12.34 Convective velocity scale

The convective velocity, or velocity scale, w_* is defined as

$$w_* = \frac{g Q_o z_i}{T_o} \qquad [15.12.111]$$

where Q_o is the surface heat flux and T_o is the absolute average temperature of the mixed layer.

The convective velocity w_* may be estimated from correlations for the quantity σ_w/w_*, together with correlations for σ_w or, more directly, from correlations for w_* itself. A correlation of the first type has been given by Irwin (1979a) and is shown in Figure 15.48. Correlations for σ_w have been discussed above.

Direct relations for w_* have been given by Venkatram (1978) in terms of the maximum surface heat flux Q_m and the maximum mixed layer height z_{im} as follows:

$$w_* = A Q_m^{1/2} \qquad [15.12.112]$$

with

$$Q_m = Q_o \sin(\pi t/2\tau) \qquad [15.12.113]$$

And

$$w_* = B z_{im} \qquad [15.12.114]$$

where τ is the time after sunrise when Q_o is a maximum, and A and B are constants. The values of the constants are $A = 4.74$ and $B = 1.12 \times 10^{-3}$.

15.12.35 Density effects

In some conditions the density of the air may be assumed to be a function of temperature and humidity, but not of pressure. This is the Boussinesq approximation. Then the buoyancy of the air, which is a function of the ratio of the density difference to the mean density, may be assumed to be a function of the ratio of the temperature difference to the mean absolute temperature. The Boussinesq approximation is generally valid when the ratio of the density difference to the mean density is 0.1 or less.

15.12.36 Meteorological variables

The meteorological variables of particular interest here in respect of gas dispersion are (1) wind speed and (2) stability category. Other variables that are of interest in hazard assessment generally include: (1) minimum temperature, (2) maximum temperature, (3) maximum wind speed and (4) maximum rainfall. The behaviour of the variable may be expressed in terms of the values averaged over a fixed period such as an hour, day, month or year.

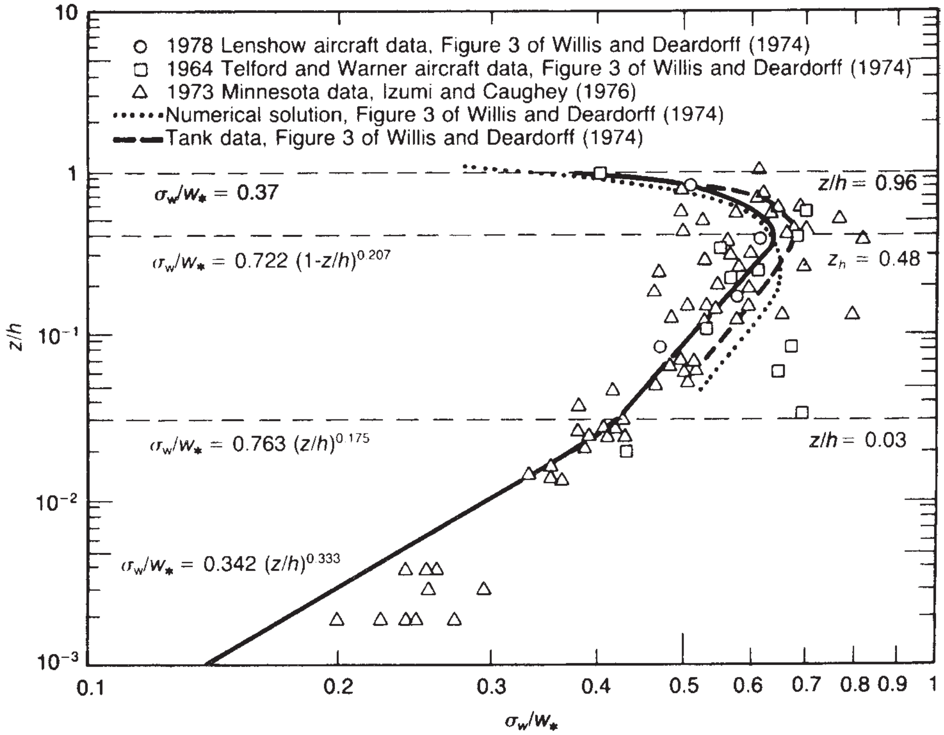


Figure 15.48 *Relation between the standard deviations of the vertical velocity fluctuations σ_w and the convective velocity w_* for fully convective conditions (Irwin, 1979a; reproduced by permission)*

15.12.37 Meteorology of the United Kingdom

Information on the meteorological characteristics of the United Kingdom is available from the Meteorological Office. A simple introduction is given in *Climate of the British Isles* (Meteorological Office, 1994), which contains a number of maps of wind speed, minimum temperature, maximum temperature, rainfall and snowfall. An account of British meteorology with particular reference to the hazards that it poses is given in *Environmental Hazards in the British Isles* (Perry, 1981).

15.13 Topography

In dispersion work the ground surface that may be regarded as the base case is flat grassland such as that on Salisbury Plain, where much of the early work on dispersion was done. Terrain may differ from this base case in a number of ways, particularly in respect of:

(1) surface roughness;
(2) urban areas;
(3) coastal zones and sea;
(4) complex terrain;
(5) buildings and obstructions.

General aspects of such terrain are considered briefly in this section. Models for dispersion over such terrain are treated in Section 15.14 and the corresponding dispersion parameters in Section 15.16.

15.13.1 Surface roughness

There is a wide range of surface roughness that is of interest in dispersion work. At one extreme ice has a very low value of the roughness length, while trees or urban areas have a very high value. There are also considerable differences in the roughness length of fields. For example, that for short grass is much lower than for wheat. The surface roughness of sea is affected by the wave motion and requires special treatment.

15.13.2 Urban areas

Accounts of dispersion over urban areas have been given by Gifford (1976a,b) and by S.R. Hanna (1976). An urban area acts as a heat island. It also constitutes terrain with a high surface roughness. Over an urban area the principal meteorological features such as wind speed, air and surface temperatures, mixing height and stability, are different from those over rural terrain.

Stable air from the surrounding rural area is modified as it approaches an urban area. Stability near a city tends to be nearly neutral, however stable the rural area may be. Hence the more stable conditions associated with Pasquill categories F and G tend not to occur. An urban area also tends to give increased turbulence. Measurements by Bowne, Ball and Anderson (1968) at Fort Wayne showed that the intensity of turbulence was some 40% above that of the surrounding area.

15.13.3 Coastal areas and water

Dispersion over coastal areas and water has been described by Gifford (1976a,b) and Lyons (1976). Water in this context includes both sea and lakes, but unless otherwise stated reference here is to sea. Much of the experimental work described by Lyons, however, relates to the Great Lakes, which constitute a feature well suited to the study of coastal area dispersion.

Conditions at the coastline may exhibit extreme variations of wind pattern, temperature and humidity. In fact radical changes of stability and turbulence are the rule. Dispersion under such conditions is much more complex than over flat rural terrain and Lyons places some emphasis on what is not known as well as what is.

In general, turbulence, and hence dispersion, is often less over sea than over land. In particular, this is so when warm air is advected over colder water. On the other hand, when colder, or drier air, is advected over warmer water, strong turbulence can occur. Lyons distinguishes three situations:

(1) dispersion over water;
(2) dispersion over the coastline
    (a) with gradient wind,
    (b) with sea breeze.

The surface of the sea tends to be more uniform than that of land, but sharp differences of water temperature and the sudden discontinuity at the coastline introduce complications not met on a land mass.

For dispersion over water, in unstable and neutral conditions, with a flow of cold air over warmer water, intensity of turbulence is high. Water spouts and steam devils, may occur. In stable conditions, with a flow of warm air over colder water, intense inversion can occur. Conditions in which conduction of heat from the air to the water below is a dominant influence on the over-water air temperature are termed by Lyons 'conduction inversions'.

For dispersion in a gradient onshore flow, without a sea breeze, the low level flow crossing the coastline reacts to the changes in surface roughness, temperature and evaporation. This creates internal boundary layers for momentum, heat and water vapour that do not necessarily coincide.

Two conditions are of particular interest: plume trapping and fumigation. As described above, plume trapping occurs when a plume is trapped beneath an elevated inversion, while fumigation is of several types, that of interest here being coastline fumigation in which cold sea air is heated rapidly by the ground.

Sometimes a sea breeze blows onshore at low level while the gradient wind above blows in the opposite direction. This condition tends to occur in very light gradient winds, strong insolation and daytime air temperatures greater than the sea surface temperature. The condition, known as a 'sea breeze', is therefore something different from a simple onshore wind. The sea breeze inflow layer has a depth of some 100–1000 m, typically 500 m, and the peak wind speed is about 7 m/s.

Dispersion in a sea breeze is often regarded as the least favourable condition for dispersion of pollutants from a source near the coastline, in that the breeze will tend to blow these back on shore. In practice, along shore air movements, wind shear and other effects can cause appreciable dispersion. The effects of sea breeze tend to be varied.

Over the sea, most of the meteorological parameters, and their diurnal variation, tend to differ from those over land. The stability categories required to classify stability are different, as are the roughness length and friction velocity, and the mixed layer height.

15.13.4 Complex terrain

An account of dispersion over complex terrain has been given by Egan (1976) and Gifford (1976a,b). Urban and industrial development often occurs at sites that have some special geographical feature, such as along rivers, in valleys, or at the base of mountains beside a lake or the sea or at the end of a plain. Thus complex terrain is likely to be encountered quite frequently. The type of terrain principally discussed by Egan is mountainous areas.

In complex terrain there are a number of effects that tend to increase dispersion. One is wind shear due to the variation of wind speed and wind direction with height. Another is distortion of the plume.

There are significant distortions of flow in complex terrain. Flow separation, which occurs when the streamlines no longer follow the shape of an obstacle, may take place. Separation tends to be less severe for flow around an isolated three-dimensional object such as a hill than for flow normal to an object that is effectively two-dimensional such as a ridge. Separation is more pronounced for unstable or neutral conditions than for stable conditions, which tend to suppress it.

The difference between complex and level terrain in respect of stability is most marked for stable conditions. Stable stratification is liable to produce shearing motions and thus to promote turbulence. The effect of the terrain is less pronounced for unstable and neutral conditions.

Air flow in stable stratified conditions has been the subject of considerable work, since the phenomenon constitutes a hazard to aircraft, but this work tends to concentrate on the two-dimensional aspects, and there is less work available on three-dimensional stratified flow.

In valleys there tend to be local variations of wind direction and velocity. Typically there are upslope winds during the day and downslope winds at night. Two issues in air pollution in complex terrain are the impingement of a plume from an elevated source on the ground and episodes of high pollution in stagnant regions.

15.13.5 Buildings and obstructions

Dispersion at buildings and other obstructions has been described by Halitsky (1968), Gifford (1976a,b) and S.R. Hanna, Briggs and Hosker (1982). The presence of buildings or other obstructions in the path of the gas cloud has a marked influence on its flow and dispersion. Buildings act as obstacles to the flow of gas. They also give rise to flow distortions with local pressure and velocity fluctuations.

In considering the effect of a building in the near field, therefore, there is a distinction to be made between its influence on a release from a source some distance upwind and its influence on one from a source at a point near the building such as on its roof or in its lee. In the far field the influence of a number of buildings may often be treated in terms of their effect on the surface roughness.

Diagrams and photographs showing the flow patterns around buildings have been given by a number of authors, including Halitsky (1968), Hosker (1979) and D.J. Wilson (1979a). The flow pattern for conditions where the wind is perpendicular to the upwind face of a rectangular building are shown in Figure 15.49. This shows several important features. There is a roof cavity at the front edge of the building. Above this cavity, starting at about its maximum height, is a high turbulence layer boundary and a roof wake boundary. In the lee of the building there is a wake cavity.

15.14 Dispersion Modelling

There are a number of different approaches to the modelling of dispersion. These include:

(1) gradient transfer models;
(2) statistical models;
(3) similarity models;
(4) top hat, box and slab models.

These are now described in turn.

15.14.1 Diffusion equation

The fundamental equation for diffusion of a gas, in rectangular coordinates, is

$$\frac{\mathrm{d}\chi}{\mathrm{d}t} + u\frac{\mathrm{d}\chi}{\mathrm{d}x} + v\frac{\mathrm{d}\chi}{\mathrm{d}y} + w\frac{\mathrm{d}\chi}{\mathrm{d}z} = K_x\frac{\mathrm{d}^2\chi}{\mathrm{d}x^2} + K_y\frac{\mathrm{d}^2\chi}{\mathrm{d}y^2} + K_z\frac{\mathrm{d}^2\chi}{\mathrm{d}z^2} \qquad [15.14.1]$$

where x, y, z are the rectangular coordinates (m), K_x, K_y, K_z are the diffusion coefficients in the x, y, z directions (m^2/s), t is the time (s), u, v, w are the mean wind speeds in the x, y, z directions (m/s) and χ is the concentration (kg/m^3). The coordinate system is shown in Figure 15.50(a).

If the wind speed in the y and z directions is zero ($v = w = 0$) and the diffusion coefficients are the same in each direction ($K_x = K_y = K_z = K$), Equation 15.14.1 becomes

$$\frac{\mathrm{d}\chi}{\mathrm{d}t} + u\frac{\mathrm{d}\chi}{\mathrm{d}x} = K\left(\frac{\mathrm{d}^2\chi}{\mathrm{d}x^2} + \frac{\mathrm{d}^2\chi}{\mathrm{d}y^2} + \frac{\mathrm{d}^2\chi}{\mathrm{d}z^2}\right) \qquad [15.14.2]$$

where x, y, z are the distances in the downwind, crosswind and vertical directions (m) and K is the diffusion coefficient (m^2/s).

If the wind speed in the x direction is also zero ($u = 0$), Equation 15.14.2 reduces to

$$\frac{\mathrm{d}\chi}{\mathrm{d}t} = K\left(\frac{\mathrm{d}^2\chi}{\mathrm{d}x^2} + \frac{\mathrm{d}^2\chi}{\mathrm{d}y^2} + \frac{\mathrm{d}^2\chi}{\mathrm{d}z^2}\right) \qquad [15.14.3]$$

The corresponding equation for a symmetrical spherical system is

$$\frac{\mathrm{d}\chi}{\mathrm{d}t} = \frac{K}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}\chi}{\mathrm{d}r}\right) \qquad [15.14.4]$$

with

$$r^2 = x^2 + y^2 + z^2 \qquad [15.14.5]$$

where r is the radial coordinate (m).

Analytical solutions of the above equations with a constant value of the diffusion coefficient K have been given by O.F.T. Roberts (1923) as described below.

15.14.2 Gradient transfer models

Gradient transfer models, or K models, are solutions of the diffusion equation. Although the assumption of a constant diffusion, or turbulent exchange, coefficient was made in the early work, it is known that this is an oversimplification that

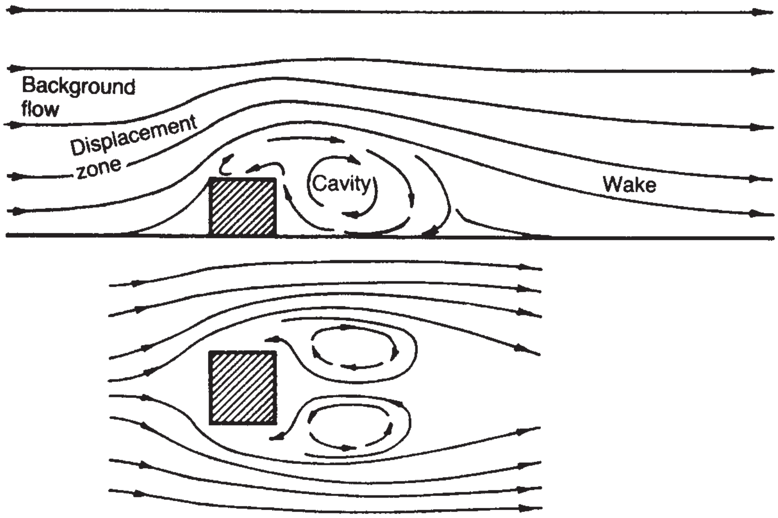

Figure 15.49 *Simplified flow pattern around a sharp-edged building (Pasquill and Smith, 1983; after Halitsky, 1968; reproduced by permission)*

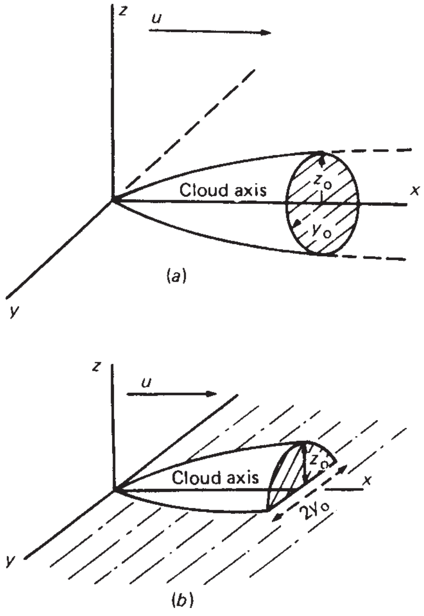

***Figure 15.50** Coordinates for dispersion equations: (a) elevated source; (b) ground level source*

yields unsatisfactory results. The approach now adopted is to solve the diffusion equation using relationships for the variation of the individual exchange coefficients K_x, K_y and K_z and for the wind speed u. If the form of these relations is amenable, an analytical solution may be obtained, but usually it is necessary to resort to numerical solution.

15.14.3 Statistical models

Analytical solution of the diffusion equation with a constant exchange coefficient K shows that the concentration profiles obtained for releases such as plumes and puffs are Gaussian in form and may therefore be characterized by standard deviations for dispersion, or dispersion coefficients, σ_x, σ_y and σ_z.

The statistical properties of turbulence may be described in terms of quantities such as the Lagrangian time scale and the autocorrelation function. Moreover, using Taylor's theorem the autocorrelation function may be related to the standard deviations of the wind velocity fluctuations, which in turn may be related to the standard deviations for dispersion.

In the model developed by O.G. Sutton (1953) the diffusion parameter C is related to the dispersion coefficients, while in the Pasquill–Gifford model these dispersion coefficients are used directly. These models therefore possess a statistical basis.

15.14.4 Similarity models

Another approach is the use of dimensional analysis to derive similarity, or self-similar, models. Typically, the basis of a similarity model is an equation, derived from dimensional analysis, for the rate of growth of some characteristic dimension of the cloud, such as the height of a plume. This part of the model, however, gives no information about the concentration distribution within the cloud; for this, additional relations are required, which tend to have an empirical basis.

Similarity models are used particularly for buoyant plumes and momentum jets, but such models also exist for plumes and puffs. The similarity approach is also used to obtain relationships for the dispersion coefficients used in the Gaussian models.

15.14.5 Similarity criteria

There are a number of dimensionless groups which constitute criteria of similarity and which are particularly relevant in dispersion work.

The Reynolds number Re is defined as

$$\mathrm{Re} = \frac{ul\rho}{\mu} \qquad [15.14.6a]$$

$$= \frac{ul}{\nu} \qquad [15.14.6b]$$

where l is a characteristic dimension, u is the velocity of the fluid, μ its viscosity, ν its kinematic viscosity and ρ its density. The Reynolds number is the ratio of the inertial forces to the viscous forces and is a criterion for similarity of flow regime. The Peclet number Pe is

$$\mathrm{Pe} = \frac{ul}{D} \qquad [15.14.7]$$

where D is the diffusion coefficient, or diffusivity.

The Peclet number characterizes the ratio of the inertial forces to the diffusivity and is a criterion for the relative importance in mass transfer of bulk transport and diffusive transport.

The Schmidt number Sc is

$$\mathrm{Sc} = \frac{\mu/\rho}{D} = \frac{\mu}{\rho D} \qquad [15.14.8a]$$

$$= \frac{\nu}{D} \qquad [15.14.8b]$$

It is thus the ratio of the Peclet and Reynolds numbers

$$\mathrm{Sc} = \mathrm{Pe}/\mathrm{Re} \qquad [15.14.9]$$

The Schmidt number is the ratio of the kinematic viscosity to the diffusivity and is a criterion for similarity of mass transfer. The Prandtl number Pr is

$$\mathrm{Pr} = \frac{\mu/\rho}{k/c_p\rho} = \frac{c_p\mu}{k} \qquad [15.14.10]$$

where c_p is the specific heat of the fluid and k its thermal conductivity. The Prandtl number is the ratio of the kinematic viscosity to the thermal diffusivity and is a criterion of similarity for heat transfer, corresponding to the Schmidt number for mass transfer.

The Froude number Fr is

$$\mathrm{Fr} = \frac{u}{(gl)^{1/2}} \qquad [15.14.11]$$

It is the ratio of the inertial force to the gravitational force and is a criterion of similarity where buoyancy is significant.

15.14.6 Top hat, box and slab models

Another family of models is that comprising the models referred to as top hat, box and slab models.

A top hat model has an essentially flat top, although vertical mixing takes place at the top surface. The cloud can therefore be considered to have a defined height.

In a box model the cloud is treated as a vertical cylinder that at a given instant has a uniform concentration throughout. A source cloud is defined, which may or may not contain some initial entrained air, and the subsequent development of the cloud is described in terms of its advection and of the entrainment of air into it. In a slab model the concentration in the cloud is a function of distance. However, the terms 'box' and 'slab' are not invariably used in this way. A model in which the concentration in the cloud varies with distance is sometimes called a box model.

The principal application of box and slab models in hazard assessment is to the dispersion of dense gases. Such box models are usually solved numerically, although some analytical solutions have been obtained.

The term 'box model' is also applied to models of passive gas dispersion in a defined zone such as an urban area. The zone is modelled as a perfectly mixed box in which the concentration is uniform. This use of the term appears to antedate its application to dense gas dispersion.

The box model has also served as a starting point for the development of models in which the concentration profile is based on similarity.

15.14.7 Physical modelling

Complex situations that are not readily handled by the various types of model described may be investigated by physical modelling using wind tunnels or water flumes. In such a study it is necessary to establish similarity of conditions. This means that the relevant dimensionless similarity criteria should ideally have identical values in the scenario investigated and in the tunnel experiments. Since in some cases several such groups may be involved, it may not be possible to achieve complete identity of all the groups.

15.15 Passive Dispersion

The dispersion of gases with neutral buoyancy, or passive dispersion, has been the subject of a very large volume of work. Some of the early work was oriented to gas warfare, but latterly air pollution has been the principal concern.

Neutral buoyancy is commonly due to the low concentration of the contaminant gas released, although it may also occur if the density of the gas is close to that of air. The neutral buoyancy condition may be negated if the gas release causes a large change in the temperature of the resultant cloud.

Hazard assessment utilizes, but has not greatly contributed to, work on neutral density gas dispersion. Most of the work has therefore been concerned with dispersion of continuous releases from an elevated point source, as represented by an industrial chimney stack. The two other main types of release studied that are of industrial relevance are continuous and instantaneous point source releases at ground level. There is some work on continuous line sources at ground level, relevant to gas warfare, but also to industrial area releases.

Early work on the subject includes that of G.I. Taylor (1915) and O.F.T. Roberts (1923). The models that are most widely used, however, are those of O.G. Sutton (1953) and of Pasquill (1961, 1962a) and the Pasquill–Gifford model (Pasquill, 1961; Gifford, 1961).

In this section an account is given of experimental studies and empirical features of passive dispersion. Section 15.16 describes passive dispersion models and Sections 15.17–15.19 describe dispersion over particular surfaces, dispersion in particular conditions and dispersion parameters, respectively.

15.15.1 Experimental studies

Passive gas dispersion has been the subject of a large volume of experimental work. Accounts of this work include those by Islitzer and Slade (1968), Slade (1968), Colder (1972), Gifford (1976a,b) and A.E. Mitchell (1982). Some experimental studies of such dispersion are listed in Table 15.27. More detailed listings are given by Islitzer and Slade (1968).

Work on passive gas dispersion on Salisbury Plain at Porton Down established what may be regarded as a base case for terrain. The terrain at Porton is open country with some clumps of trees. The work at Porton provides the experimental background for the work of O.G. Sutton (1953) and Pasquill (1962a).

An important set of experiments carried out on this terrain are those used by Pasquill to derive parameters in his dispersion models. In this work there was a continuous release from a point source at ground level, the distance to which concentration measurements were made was 800 m and the sampling period was 10 min.

15.15.2 Empirical features

Experiments on passive gas dispersion indicate several important empirical features. The fundamental features have been described by O.G. Sutton (1953).

One of the most important features is that, for both continuous and instantaneous releases from a point source at ground level, the concentration profiles are Gaussian. Another basic feature is that for both types of release the spread of the measured concentration increases as the sampling period increases. It is observed that the plume from a continuous point source release tends to meander and that the dispersion due to turbulence is augmented by that due to this meandering.

The concentration downwind of a continuous or instantaneous point source at ground level is found to vary according to the strength of the source, provided that the latter does not itself cause appreciable convection. For a continuous point source the concentration is also inversely proportional to the mean wind speed.

The concentration on the centre line of a continuous point source is

$$\chi \propto x^{-1.76} \qquad [15.15.1]$$

and that on the centre plane of a continuous infinite line crosswind source is

$$\chi \propto x^{-1.09} \qquad [15.15.2]$$

This information on the variation of concentration with distance has played an important role in guiding the development of dispersion models.

Table 15.27 *Some experimental studies of passive gas dispersion*

Location	*Experiment*	*Reference*
A Continuous elevated sources[a]		
Porton Down	Porton	J.S. Hay and Pasquill (1957)
Idaho Falls, ID	National Reactor Testing Station (NRTS)	Islitzer (1961)
Richland, WA	Hanford	Hilst and Simpson (1958); Nickola (1977)
Harwell	Harwell (BEPO)	Stewart *et al.* (1954)
Long Island, NY	Brookhaven National Laboratory (BNL)	Gartrell *et al.* (1964); Carpenter *et al.* (1971)
Tennessee Valley, TN	Tennessee Valley Authority (TVA)	
B Continuous ground level releases[a]		
Porton Down	Porton	J.S. Hay and Pasquill (1959)
Cardington	Cardington	Pasquill (1962)
O'Neill, NE	Prairie Grass	Cramer (1957); Lettau and Davidson (1957); Barad (1958); Islitzer and Slade (1964)
Round Hill	Round Hill	Islitzer and Slade (1964)
Richland, WA	Green Glow	Barad and Fuquay (1962); Fuquay, Simpson and Hinds (1964)
Cape Kennedy, FL	Ocean Breeze	Haugen and Fuquay (1963); Haugen and Taylor (1963)
Vandenberg AFB, CA	Dry Gulch	Haugen and Fuquay (1963); Haugen and Taylor (1963)
Idaho Falls, ID	NRTS	Islitzer and Dumbault (1963)
C Instantaneous ground level releases[b]		
Porton Downs	Porton	F.B. Smith and Hay (1961)
Edwards AFB, CA	Sand Storm	J.H. Taylor (1965)
Agesta and Studsvik, Sweden		Högström (1964)
Dugway Proving Grounds, Utah	Dugway	Cramer *et al.* (1964)
Point Arguello, CA	Naval Missile Facility (NMF)	T.B. Smith *et al.* (1964)
Idaho Falls, ID	NRTS	Islitzer and Markee (1964)
Dallas, TX	Cedar Hill	McCready, Smith and Wolf (1961)
D Releases in urban areas		
Worcester, MA		Yersel, Goble and Morrill (1983)
St Louis, MO		McElroy and Pooler (1968)
E Releases over water		
Cameron, LA		Dabberdt *et al.* (1982)
Pismo Beach, CA		Dabberdt *et al.* (1982)

[a] Many of these experiments are also described by Slade (1968).
[b] These releases are more accurately described as 'quasi-instantaneous'.

15.16 Passive Dispersion: Models

Some principal models for passive dispersion are:

(1) Roberts model;
(2) Sutton model;
(3) Pasquill model;
(4) Pasquill–Gifford model.

An account is now given of each of these models in turn.

15.16.1 Roberts model

The fundamental diffusion equation has been given in Section 15.14. Solutions of this equation have been given by O.F.T. Roberts (1923), who analysed the behaviour of smoke from various types of release. The following treatment is based on Roberts' work and on modifications of it derived by O.G. Sutton (1953).

For dispersion from an instantaneous point source under windless conditions Equation 15.14.4 is applicable. The relevant boundary conditions are:

$$\chi \to 0 \quad \text{as} \quad t \to 0, \quad r > 0 \qquad [15.16.1a]$$

$$\chi \to 0 \qquad t \to \infty \qquad [15.16.1b]$$

The continuity condition is

$$\int_{-\infty}^{\infty} \iint \chi \, \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}z = Q^* \qquad [15.16.2]$$

where Q^* is the mass released instantaneously (kg). The solution of Equation 15.14.4 is then

$$\chi(r,t) = \frac{Q^*}{8(\pi K t)^{3/2}} \exp\left(-\frac{r^2}{4Kt}\right) \qquad [15.16.3a]$$

$$\chi(x,y,z,t) = \frac{Q^*}{8(\pi K t)^{3/2}} \exp\left[-\frac{(x^2+y^2+z^2)}{4Kt}\right] \qquad [15.16.3b]$$

Equation 15.16.3b may also be applied to an instantaneous point source with a wind speed in the x direction by measuring the coordinates from an origin moving with the cloud at the mean wind speed.

For dispersion from a continuous point source under windless conditions, Equations 15.16.3, with Equation 15.14.5, may be integrated with respect to time to give

$$\chi(r,t) = \frac{Q}{(4\pi K r)} \operatorname{erfc}\left[\frac{r}{2(Kt)^{1/2}}\right] \qquad [15.16.4a]$$

$$\chi(x,y,z,t) = \frac{Q}{4\pi K(x^2+y^2+z^2)^{1/2}} \operatorname{erfc}\left[\frac{(x^2+y^2+z^2)^{1/2}}{2(Kt)^{1/2}}\right] \qquad [15.16.4b]$$

where Q is the continuous mass rate of release (kg/s). At steady state, Equation 15.16.4 becomes

$$\chi(r) = \frac{Q}{4\pi K r} \qquad [15.16.5a]$$

$$\chi(x,y,z) = \frac{Q}{4\pi K(x^2+y^2+z^2)^{1/2}} \qquad [15.16.5b]$$

Equation 15.16.5b may be applied to a continuous point source with a wind speed u in the x direction by a transformation of coordinates. This gives

$$\chi(x,y,z) = \frac{Q}{4\pi K(x^2+y^2+z^2)^{1/2}} \times \exp\left\{-\frac{u}{2K}\left[(x^2+y^2+z^2)^{1/2} - x\right]\right\} \qquad [15.16.6]$$

If the concentrations considered are those not too far from the x axis so that

$$\frac{y^2+x^2}{x^2} \ll 1 \qquad [15.16.7]$$

then for all but the lightest winds Equation 15.16.6 becomes

$$\chi(x,y,z) = \frac{Q}{4\pi K x} \exp\left[-\frac{u}{4Kx}(y^2+z^2)\right] \qquad [15.16.8]$$

For dispersion from a continuous infinite line source at right angles to the wind direction, Equation 15.16.6 can be modified and integrated in the y direction to give

$$\chi(x,z) = \frac{Q'}{2\pi K} \exp\left(\frac{ux}{2K}\right) K_o\left[\frac{u(x^2+z^2)^{1/2}}{2K}\right] \qquad [15.16.9]$$

where Q' is the continuous mass rate of release per unit length (kg/ms). K_o is the modified Bessel function of the second kind. Provided the term $u(x^2+z^2)^{1/2}/2K$ is sufficiently large, Equation 15.16.9 may be approximated by

$$\chi(x,z) = \frac{Q'}{(2\pi K x)^{1/2}} \exp\left(-\frac{uz^2}{4Kx}\right) \qquad [15.16.10]$$

For the case where dispersion is anisotropic the equations are as follows. For an instantaneous point source:

$$\chi(x,y,z,t) = \frac{Q'}{8(\pi t)^{3/2}(K_x K_y K_z)^{1/2}} \times \exp\left[-\frac{1}{4t}\left(\frac{x^2}{K_x} + \frac{y^2}{K_y} + \frac{z^2}{K_z}\right)\right] \qquad [15.16.11]$$

For a continuous point source

$$\chi(x,y,z) = \frac{Q}{4\pi x(K_x K_y)^{1/2}} \exp\left[-\frac{u}{4x}\left(\frac{y^2}{K_y} + \frac{z^2}{K_z}\right)\right] \qquad [15.16.12]$$

For a continuous infinite line crosswind source:

$$\chi(x,z) = \frac{Q'}{(2\pi x K_z x)^{1/2}} \exp\left(-\frac{uz^2}{4K_z x}\right) \qquad [15.16.13]$$

The equations derived so far apply to an elevated source dispersion which is unaffected by the ground. If the source is on the surface, the ground forms an impervious boundary. The coordinate system is shown in Figure 15.50(b). The effect of the ground is to double the concentration. Thus Equations 15.16.11–15.16.13 become: for an instantaneous point source

$$\chi(x,y,z,t) = \frac{Q^*}{4(\pi t)^{3/2}(K_x K_y K_z)^{1/2}} \times \exp\left[-\frac{1}{4t}\left(\frac{x^2}{K_x} + \frac{y^2}{K_y} + \frac{z^2}{K_z}\right)\right] \qquad [15.16.14]$$

for a continuous point source

$$\chi(x,y,z) = \frac{Q}{2\pi x(K_y K_z)^{1/2}} \exp\left[-\frac{u}{4x}\left(\frac{y^2}{K_y} + \frac{z^2}{K_z}\right)\right] \qquad [15.16.15]$$

and for a continuous infinite line crosswind source

$$\chi(x,\, z) = \frac{2Q'}{(2\pi x K_z x)^{1/2}} \exp\left(-\frac{uz^2}{4K_z x}\right) \qquad [15.16.16]$$

An intermediate situation occurs where the ground forms an impervious barrier to the material from an elevated source such as a chimney or high vent. For this case it can be shown that for a continuous elevated point source

$$\chi(x,y,z) = \frac{Q}{4\pi Kx}\exp\left(-\frac{uy^2}{4Kx}\right) \times \Bigl\{\exp\Bigl[-\frac{u}{4Kx}(z-h)^2+\exp\Bigl[-\frac{u}{4Kx}(z+h)^2\Bigr]\Bigr\} \quad [15.16.17]$$

where h is the height of the source (m). Equation 15.16.17 reduces to Equation 15.16.15 if h is set equal to zero.

The equations for continuous sources are steady-state equations and therefore apply only to fully established plumes. The concentrations given by the equations are applicable only if the duration of the release t is equal to or greater than the ratio of the distance x at the location of interest to the wind speed u ($t \geq x/u$).

Equations 15.16.14–15.16.17 give the concentrations at all distances from the source. For practical purposes it is convenient to define some boundaries for the cloud. The convention adopted is to take the cloud boundaries y_o and z_o as a fixed proportion, usually one-tenth, of the maximum concentration at distance x. If y_o and z_o are the semi-lateral and semi-vertical dimensions of the cloud, as shown in Figure 15.50, then from Equation 15.16.15, for a continuous point source

$$y_o = \left(\frac{4}{u}K_y x \ln 10\right)^{1/2} \quad [15.16.18]$$

$$z_o = \left(\frac{4}{u}K_z x \ln 10\right)^{1/2} \quad [15.16.19]$$

Hence

$$y_o \propto z_o \propto x^{1/2} \quad [15.16.20]$$

The ground level concentration on the centre line ($y = z = 0$) of a continuous point source is given by Equation 15.16.15 as

$$\chi(x) = \frac{Q}{2\pi x(K_x K_y)^{1/2}} \quad [15.16.21]$$

and that on the centre plane ($z = 0$) of a continuous infinite line crosswind source is given by Equation 15.16.16 as

$$\chi(x) = \frac{2Q'}{(2\pi K_z x)^{1/2}} \quad [15.16.22]$$

The visible outline of the cloud is not determined as simply, but depends on the theory of opacity.

An important implication of Equations 15.16.15 and 15.16.16 is that for Equation 15.16.15 at a fixed distance x from the source the concentration distribution in both the crosswind and the vertical directions is a Gaussian, or normal, distribution. Similarly, Equation 15.16.16 gives a concentration distribution that is Gaussian in the vertical direction. This feature is important in the further development of dispersion equations, as described below.

It can also be seen from Equations 15.16.15 and 15.16.16 that the ground level concentration downwind along the centre line, or axis, of a continuous point source ($y = z = 0$), is

$$\chi \propto x^{-1} \quad [15.16.23]$$

and that the ground level concentration downwind over the centre plane of a continuous infinite line crosswind source is

$$\chi \propto x^{-1/2} \quad [15.16.24]$$

Comparison of relations 15.16.23 and 15.16.24 with the relations 15.15.1 and 15.15.2 obtained by experiment shows that this model is unsatisfactory.

Thus, it is not appropriate to model dispersion in the atmosphere using the constant Fickian diffusion coefficient K. Nevertheless, the equations given form the basis for most subsequent developments in work on passive dispersion.

15.16.2 Sutton model

The failure of the simple Fickian diffusion model has prompted the search for more realistic models of dispersion. The first model considered here is that of O.G. Sutton (1953).

The basic equation derived by Sutton for an instantaneous point source at ground level is

$$\chi(x,y,z,t) = \frac{2Q^*}{\pi^{3/2}C_x C_y C_z (ut)^{3/2(2-n)}} \times \exp\left[-(ut)^{n-2}\left(\frac{x^2}{C_x^2}+\frac{y^2}{C_y^2}+\frac{z^2}{C_z^2}\right)\right] \quad [15.16.25]$$

where C_x, C_y, C_z are diffusion parameters in the downwind, crosswind and vertical (x, y, z) directions ($\mathrm{m}^{\frac{1}{2}n}$), n is the diffusion index, and the coordinates x, y, z are measured from an origin moving with the cloud at the mean wind speed u.

Equation 15.16.25 is related to Equation 15.16.14 in the Roberts model and becomes identical with it by putting

$$n = 1 \quad [15.16.26a]$$

$$C^2 = \frac{4K}{u} \quad [15.16.26b]$$

The equation for a continuous point source at ground level is

$$\chi(x,y,z) = \frac{2Q}{\pi C_y C_z u x^{2-n}}\exp\left[-x^{n-2}\left(\frac{y^2}{C_y^2}+\frac{z^2}{C_z^2}\right)\right] \quad [15.16.27]$$

and that for a continuous infinite line crosswind source at ground level is

$$\chi(x,y,z) = \frac{2Q'}{\pi C_z u x^{1/2(2-n)}} \times \exp\left[-x^{n-2}\left(\frac{y^2}{C_z^2}\right)\right] \quad [15.16.28]$$

The equation for a continuous elevated point source is

$$\chi(x,y,z) = \frac{Q}{\pi C_y C_z u x^{(2-n)}}\exp\left(-x^{n-2}\frac{y^2}{C_y^2}\right) \times \left\{\exp\left[-x^{n-2}\frac{(z-H)^2}{C_z^2}+\exp\left[-x^{n-2}\frac{(z+H)^{1/2}}{C_z^2}\right]\right]\right\} \quad [15.16.29]$$

where H is the height of the source (m).

As mentioned above, the concentrations given by the equations for continuous sources are applicable only if the duration t of the release is equal to or greater than the ratio of the distance x to the wind speed u ($t \geq x/u$).

Equations 15.16.27–15.16.29 correspond to Equations 15.16.15–15.16.17 in the Roberts model. Equations 15.16.25 and 15.16.27–15.16.29 are frequently written with the assumption of isotropic conditions, for which the diffusion parameters are

$$C_x = C_y = C_z = C \qquad [15.16.30]$$

The index n and the generalized diffusion parameter C are meteorological constants. Values of these constants have been discussed in detail by O.G. Sutton (1947, 1953). The index n is a function of the stability conditions. The limiting values of n are zero and unity under conditions of very high and very low turbulence, respectively. In average conditions n has a value of approximately 1/4. The value of the generalized diffusion parameter C is a function of the height above ground and of the stability conditions. Values of these parameters given by Sutton are shown in Table 15.28. Further values are given in Section 15.28.

15.16.3 Pasquill model

Another general system of dispersion equations has been derived by Pasquill (1961, 1962a, 1965) and is generally referred to as the Pasquill model. The basis of the system is a modification of Equation 15.16.29 for a continuous point source at ground level:

$$C_o = \frac{2.8 \times 10^{-3} Q}{u d h \theta} \qquad [15.16.31]$$

where C_o is the ground level concentration on the axis of the plume (units/m^3), d is the distance in the downwind direction (km), h is the vertical spread (m), Q is the mass rate of release (units/min), u is the mean wind speed (m/s) and θ is the lateral spread (degrees).

Equation 15.16.31 is based on Equation 15.16.29, generalized to allow for relatively slow changes of wind direction. The lateral spread θ and the vertical spread h define an envelope at the edge of which concentrations are one-tenth of the axial or ground level values, respectively, that is, the envelope of the cloud defined by the usual convention.

Equation 15.16.31 is for a continuous source and hence, as mentioned above, the concentrations given are applicable only if the duration of the release is equal to or greater than the ratio of the distance to the wind speed u ($t > d \times 10^3/u$).

Table 15.28 *Meteorological parameters for Sutton model*[a] *(after O.G. Sutton, 1947)*

Source height (m)	n	C_y (m$^{1/8}$)		C_y (m$^{1/8}$)
0	0.25	0.21		0.12
10	0.25	0.21		0.12
25	0.25		0.12	
30	0.25		0.10	
75	0.25		0.09	
100	0.25		0.07	

[a] Values are for small lapse rate and wind speed of 5 m/s.

For the lateral spread θ used in Equation 15.16.31, Pasquill recommends that if suitable data are available the following relations should be used:

$$\theta = 4.3\sigma_\theta \qquad [15.16.32]$$

with

$$\sigma_\theta \approx \sigma_y / x \qquad [15.16.33]$$

where x is the downwind distance (m), σ_y is the standard deviation of concentration in the crosswind direction (m) and σ_θ is the standard deviation of wind direction (degrees).

If such data are not available, he suggests that approximate estimates of θ for a long release, lasting 1 h or more, may be made from wind direction traces using the following rules:

$d =$ 0.1 km
$\theta =$ difference between maximum and minimum trace over period of release
$d =$ 100 km
$\theta =$ difference between maximum and minimum '15-min averages' of wind direction

For a short release, lasting a few minutes, Pasquill gives the estimates of θ shown in Table 15.29.

The vertical spread used in Equation 15.16.31 increases with distance d at a rate that depends on the extent of vertical mixing. If, however, vertical convection is suppressed by an isothermal or inversion layer, the height of this layer sets a limit to h. Ultimately, the concentration between the ground and the layer becomes uniform.

For the vertical spread h, Pasquill recommends that if suitable data are available the following relation be used:

$$h = 2150 d \sigma_\phi \qquad [15.16.34]$$

where σ_ϕ is the standard deviation of the wind inclination (rad) and ϕ is the wind inclination (rad).

If such data are not available, he suggests that tentative estimates of h be made using the graph shown in Figure 15.51. These estimates are applicable only to open country. The curves given in the graph are fitted by the approximate equations given in Table 15.29. The limits of the equations are as shown in the table.

In the stable conditions of a clear night with very light winds (<2 m/s), and thus under conditions conducive to sharp ground frost or heavy dew, the vertical spread h may be even less than that given for stability category F.

In unstable conditions, the vertical spread h may be estimated by the methods just described only until it reaches a value h' equal to the estimated vertical extent of convection which will occur at some distance d'. Under these conditions at the distance d' there is a concentration profile with a limiting vertical spread h'. For approximate work it may be assumed that over a further interval d', and therefore at a distance $2d'$, a uniform concentration develops. Thus for distances greater than $2d'$ the vertical spread h used in Equation 15.16.31 may be taken as $2h'$.

The wind speed u and the wind direction used in Equation 15.16.31 at distances 0.1 and 1 km are the usual

***Table 15.29** Meteorological parameters for Pasquill model (after Pasquill, 1961)*

A Lateral spread for a short release, θ

Pasquill stability category	*Lateral spread θ* (deg)	
	$d = 0.1$ km	$d = 100$ km
A	60	(20)
B	45	(20)
C	30	10
D	20	10
E	(15)	(5)
F	(10)	(5)

B Vertical spread, h

Pasquill's values, shown in Figure 15.51, are fitted by the following approximate equations:

A	$\log_{10} h = 2.95 + 2.19 \log_{10} d + 0.723(\log_{10} d)^2$	$0.1 < d < 2$
B	$\log_{10} h = 2.36 + 1.05 \log_{10} d + 0.067(\log_{10} d)^2$	$0.1 < \mathrm{d} < 10$
C	$\log_{10} h = 2.14 + 0.919 \log_{10} d - 0.017(\log_{10} d)^2$	$0.1 < d < 30$
D1	$\log_{10} h = 1.85 + 0.835 \log_{10} d - 0.0097(\log_{10} d)^2$	$0.1 < d < 100$
D2	$\log_{10} h = 1.83 + 0.754 \log_{10} d - 0.087(\log_{10} d)^2$	$0.1 < d < 100$
E	$\log_{10} h = 1.66 + 0.670 \log_{10} d - 0.100(\log_{10} d)^2$	$0.1 < d < 100$
F	$\log_{10} h = 1.48 + 0.656 \log_{10} d - 0.122(\log_{10} d)^2$	$0.1 < d < 100$

surface values. At distances of 10 and 100 km, the wind speed and direction used are the averages of the surface and geostrophic values, but in addition the latter is backed (i.e. moved anticlockwise) by 10°.

For an elevated source, Equation 15.16.31 is modified by the stack correction factor F_1 to give

$$C_c = \frac{2.8 \times 10^{-3} \times QF_1}{udh\theta} \qquad [15.16.35]$$

with

$$F_1 = \exp\left[-2.303\left(\frac{H}{h}\right)^2\right] \qquad [15.16.36]$$

where C_c is the ground level concentration on the axis of the plume for the elevated source (units/m^3), and H is the height of the stack (m).

Equations 15.16.31 and 15.16.35 give the concentration on the axis of the plume. Other concentrations may be calculated by multiplying the values given by these equations by the off-axis correction factor F_2:

$$F_2 = \exp\left[-2.303\left(\frac{2\alpha}{\theta}\right)^2\right] \qquad [15.16.37]$$

where α is the deviation from the axis (degrees). Thus Equation 15.16.31 becomes

$$C = \frac{2.8 \times 10^{-3} QF_1F_2}{udh\theta} \qquad [15.16.38]$$

where C is the ground level concentration (units/m^3).

The parameters θ and h are functions of distance and should be determined for the distance d at which the concentration C_o or C_c is to be calculated. It is convenient to tabulate and plot base values of C_o or C_c at distances d of 0.1, 1, 10 and 100 km and to obtain other values by interpolation. lines of equal concentration, or isopleths, may be calculated from Equation 15.16.38 by fixing the concentration C and determining the corresponding distance d and deviation α.

As an illustration of the application of the method the example described by Pasquill (1961, 1962a) is given. The problem is the determination of the ground level concentration for a prolonged release from continuous point sources (1) at ground level and (2) above ground level. A statement of the problem is given in Section A of Table 15.30. The results of the calculations for the solution of the problem are shown in Section B of the table and in Figures 15.52 and 15.53.

It may be noted that, although Equation 15.16.31 is for a continuous point source, so that the concentration given is applicable only if the duration t is equal to or greater than the ratio of the distance to the wind speed ($t \geq d \times 10^3/u$), it nevertheless gives the correct value of the total dosage for the total mass released, and may therefore be used to calculate dosage for a nearly instantaneous point source.

Graphical solutions of the Pasquill model have been presented by Bryant (1964 UKAEA AHSB(RP) R42).

15.16.4 Pasquill–Gifford model

An alternative form of the Sutton equations has been presented by Pasquill (1961, 1962a) and values of the dispersion coefficients used in this model have been obtained by Gifford (1961). This alternative form is often referred to as the Pasquill–Gifford model, as described below.

In this formulation, use is made of the relations given by O.G. Sutton (1953, p. 286):

$$\sigma_x^2 = \frac{C^2}{2}(ut)^{2-n} \qquad [15.16.39]$$

Similar expressions apply for σ_y and σ_z where σ_x, σ_y and σ_z are the standard deviations, or dispersion coefficients, in

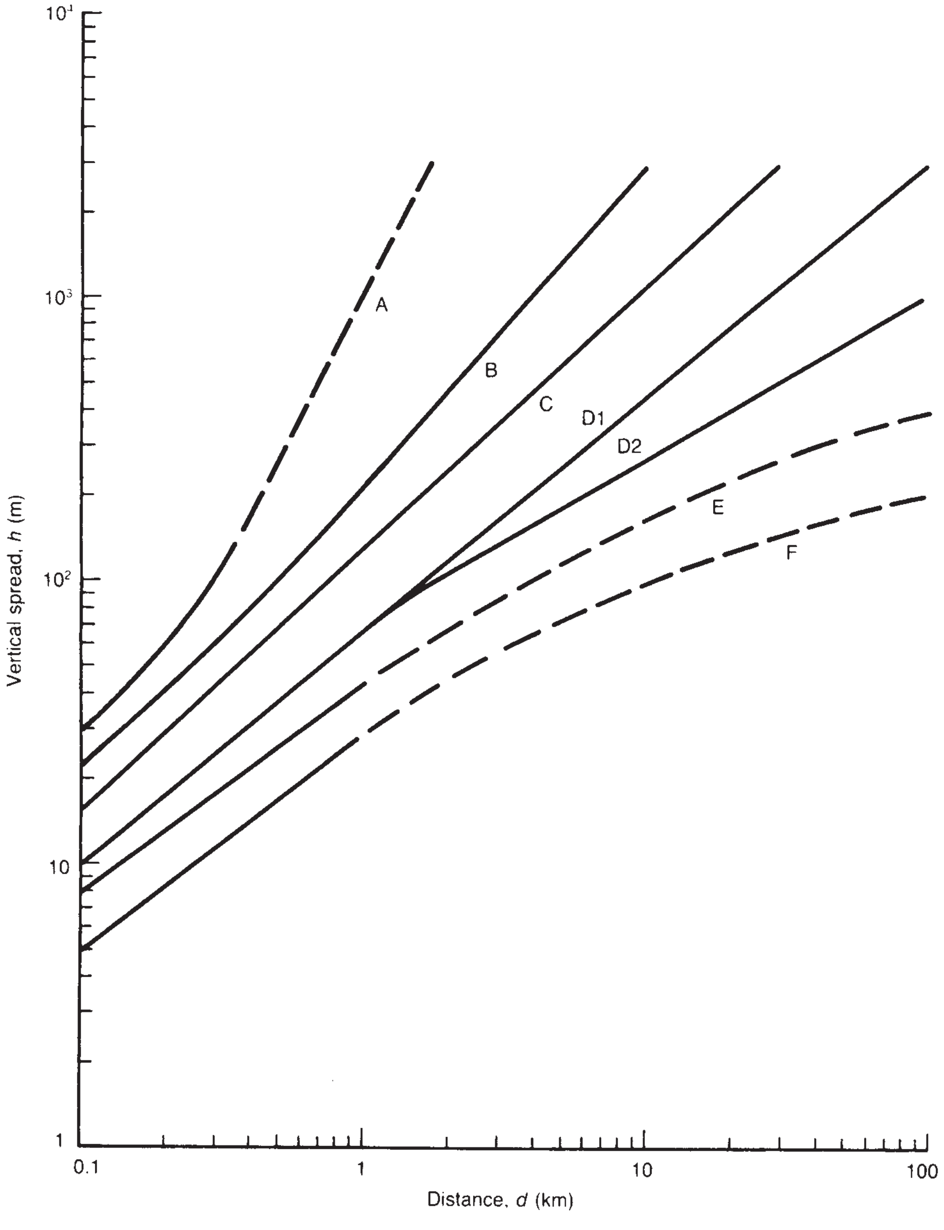

Figure 15.51 *Vertical spread h for Pasquill equation (Pasquill, 1961) (Courtesy of HM Stationery Office)*

the downwind, crosswind and vertical (x, y, z) directions (m).

The equation for an instantaneous point source at ground level then becomes

$$\chi(x,y,z,t) = \frac{2Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z} \times \exp\left[-\frac{1}{2}\left(\frac{x^2}{\sigma_x^2}+\frac{y^2}{\sigma_y^2}+\frac{z^2}{\sigma_z^2}\right)\right] \qquad [15.16.40a]$$

where the coordinates x, y, z are measured from an origin moving with the cloud at the mean wind speed u. Alternatively, if the coordinates are measured from the point of release

$$\chi(x,y,z,t) = \frac{2Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z} \times \exp\left\{-\frac{1}{2}\left[\frac{(x-ut)^2}{\sigma_x^2}+\frac{y^2}{\sigma_y^2}+\frac{z^2}{\sigma_z^2}\right]\right\} \qquad [15.16.40b]$$

Table 15.30 *Illustrative example of the application of the Pasquill equation for a prolonged release from continuous point sources at and above ground level (after Pasquill, 1961)*

A Problem

Effective height of elevated source H	100 m
Stability category	B–C
Surface wind speed	4 m/s
Surface wind direction	275°
Geostrophic wind direction	8 m/s
Geostrophic wind speed	325°
Vertical extent of convection	1000 m
Source strength	1 unit/min

B Solution

Distance at which vertical spread h equals vertical extent of convection h'				5.5 km			
1 Ground level source							
Distance d, km		0.1	1		10		100
Effective wind speed u, m/s		4	4		6		6
Effective wind direction, deg		275	275		290		290
Lateral spread θ[a], deg		120	93		67		40
Effective vertical spread h, m		20	170		2000		2000
Concentration along axis C_0, units/m^3		2.9×10^{-6}	4.4×10^{-8}		3.5×10^{-10}		5.8×10^{-11}
2 Elevated source							
Arbitrary values of h/H	1/2	2/3	4/5	1	1½	2	4
Corresponding values of:							
Effective vertical Spread h, m	50	67	80	100	150	200	400
Distance d, km	0.28	0.37	0.46	0.59	0.86	1.15	2.20
Concentration along axis C_0, $\times 10^{-10}$ units/m^3	4600	2700	1800	1200	580	330	82
Stack correction factor F_1	10^{-4}	5.6×10^{-3}	0.027	0.10	0.36	0.56	0.87
Corrected concentration C_c, $\times 10^{-10}$ units/m^3	0.46	15	49	120	210	185	71

[a] These values are obtained from wind direction traces.

The equation for a continuous point source at ground level becomes

$$\chi(x,y,z) = \frac{Q}{\pi\sigma_y\sigma_z u} \times \exp\left[-\frac{1}{2}\left(\frac{y^2}{\sigma_y^2}+\frac{z^2}{\sigma_z^2}\right)\right] \qquad [15.16.41]$$

The equation for a continuous infinite line crosswind source at ground level becomes

$$\chi(x,z) = \frac{2Q'}{(2\pi)^{1/2}\sigma_z u} \times \exp\left(-\frac{1}{2}\frac{z^2}{\sigma_z^2}\right) \qquad [15.16.42]$$

The equation for a continuous elevated point source becomes

$$\chi(x,y,z) = \frac{Q}{2\pi\sigma_y\sigma_z u}\exp\left(-\frac{y^2}{2\sigma_y^2}\right) \times \left\{\exp\left[-\frac{(z-h)^2}{2\sigma_z^2}\right] + \exp\left[-\frac{(z+h)^2}{2\sigma_z^2}\right]\right\} \qquad [15.16.43]$$

As mentioned above, the concentrations given by the equations for continuous sources are applicable only if the duration t of the release is equal to or greater than the ratio of the distance x to the wind speed u ($t \geq x/u$). Equations 15.16.40–15.16.43 correspond to Equations 15.16.25 and 15.16.27–15.16.29, respectively. As stated above, Equations 15.16.40–15.16.43 are often referred to as the Pasquill–Gifford model. Pasquill (1962a, p. 190) himself states that an equation of the particular form of Equation 15.16.40a appears to have been first given by Frenkiel (1952), but that Equations 15.16.41 and 15.16.42 are implicit in the equations given by O.G. Sutton (1947). D.B. Turner (1970, p. 3) states that values of the dispersion coefficient σ have been obtained by Cramer and co-workers (Cramer, Record and Vaughan, 1958; Cramer, 1959a,b) and by Gifford (1961), the tetter's values for continuous releases being converted from Pasquill's values of angular spread and height for similar releases, which were described above. It is the latter that are recommended for use by D.B. Turner (1970, p. 3).

Again the dispersion coefficients σ_x, σ_y and σ_z are meteorological constants. Different values are used for

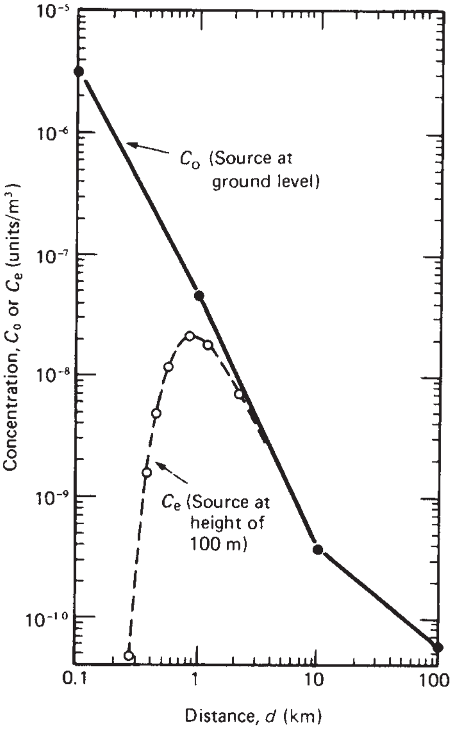

Figure 15.52 Illustrative example of Pasquill equation: ground level concentrations along axis for a prolonged release from continuous point sources at and above ground level (Pasquill, 1961) (Courtesy of HM Stationery Office)

Equations 15.16.40 for an instantaneous point source and for Equations 15.16.41–15.16.43 for a continuous source. The values of the dispersion coefficients σ_y and σ_z for a continuous point source have been discussed in detail by D.B. Turner (1970, p. 7). The values given by the latter, which are based on the work of Gifford (1961), are shown in Figures 15.54(a) and (b). These estimates are applicable only to open country. The curves in the graph are fitted by the approximate equations given in Table 15.31, Section A. The limits of the equations are as shown in the table.

The values given for the dispersion coefficients are best estimates (D.B. Turner, 1970, p. 7). In unstable and in stable conditions several-fold errors may occur in the estimate of σ_z. There are some circumstances, however, when the estimate of σ_z may be expected to be within a factor of 2. These are (1) for all stability conditions up to a few hundred metres, (2) for neutral or moderately stable conditions at distances up to a few kilometres and (3) for unstable conditions in the lower 1000 m of the atmosphere with a marked inversion above at distances up to 10 km or more. The uncertainty in the estimation of σ_y is, in general, less than that in the estimation of σ_z. Equations 15.16.41 and 15.16.43 are applicable only for time periods up to about 10 min. For time periods exceeding 10 min the concentration downwind of the source is somewhat less, due to alteration of the wind direction. This effect can be taken into account for time periods of between 10 min and 2 h using the following approximate relation suggested by D.B. Turner (1970, p. 38):

$$\chi \propto t^{-0.17} \qquad [15.16.44]$$

The concentration from a continuous point source at ground level or at an elevation obtained from Equations

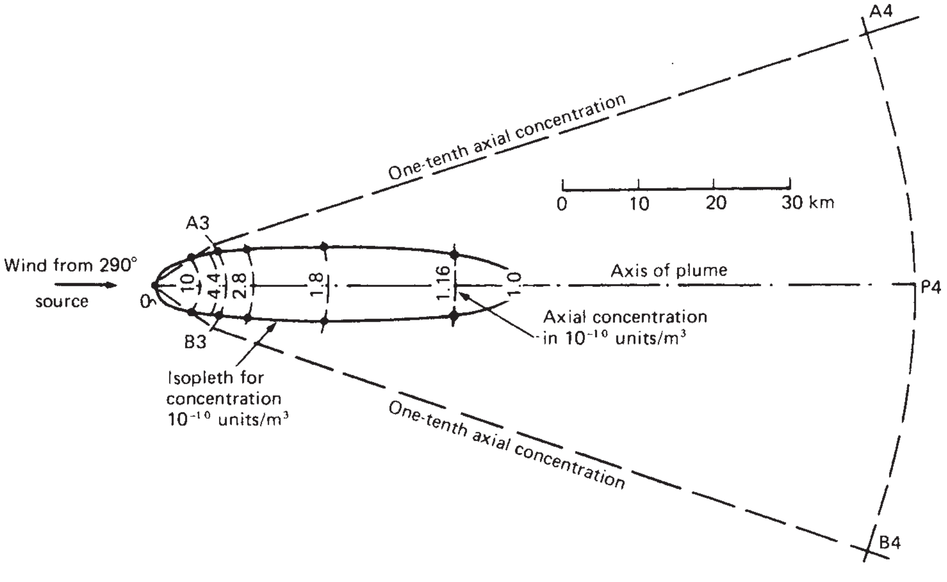

Figure 15.53 Illustrative example of Pasquill equation: ground level concentration profile for a prolonged release from a continuous point source at ground level (Pasquill, 1961; reproduced by permission of HM Stationery Office)

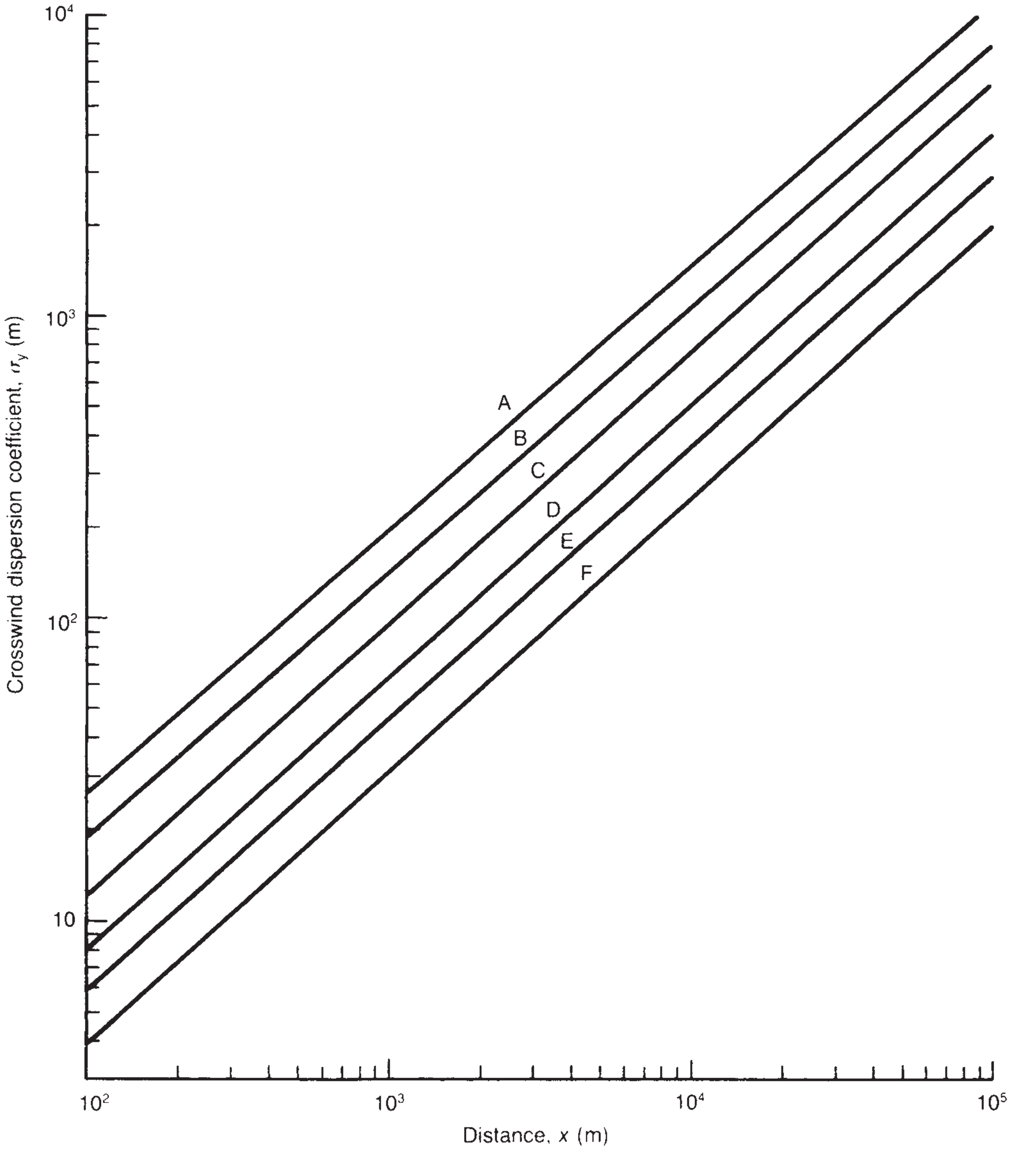

Figure 15.54(a) *Meteorological parameters for Pasquill–Gifford equations for continuous source: crosswind dispersion coefficient σ_y (D.B. Turner, 1970). A–F refer to Pasquill stability categories.*

15.16.41 and 15.16.43, respectively, is often plotted as xu/Q vs distance x.

The values of the dispersion coefficients σ_x, σ_y and σ_z for an instantaneous point source, which differ from those for continuous sources, are discussed by Slade (1968). The values of σ_y and σ_z given by the latter are shown in Table 15.31, Section B. It is normally assumed that σ_x is equal to σ_y.

15.16.5 Effect of sampling period

As described above, if the concentration in a plume is sampled virtually instantaneously, the concentration distribution has a relatively narrow spread, while if the sample is taken over a longer time period, the distribution has a wider spread. D.B. Turner (1970) quotes the following estimates by Meade of the effect of sampling period t on the concentration χ at ground level expressed as the ratio χ/χ_3, where χ_3 is the concentration for a sampling period of 3 min.

t	χ/χ_3
3 min	1.00
15 min	0.82
1 h	0.61
3 h	0.51
24 h	0.36

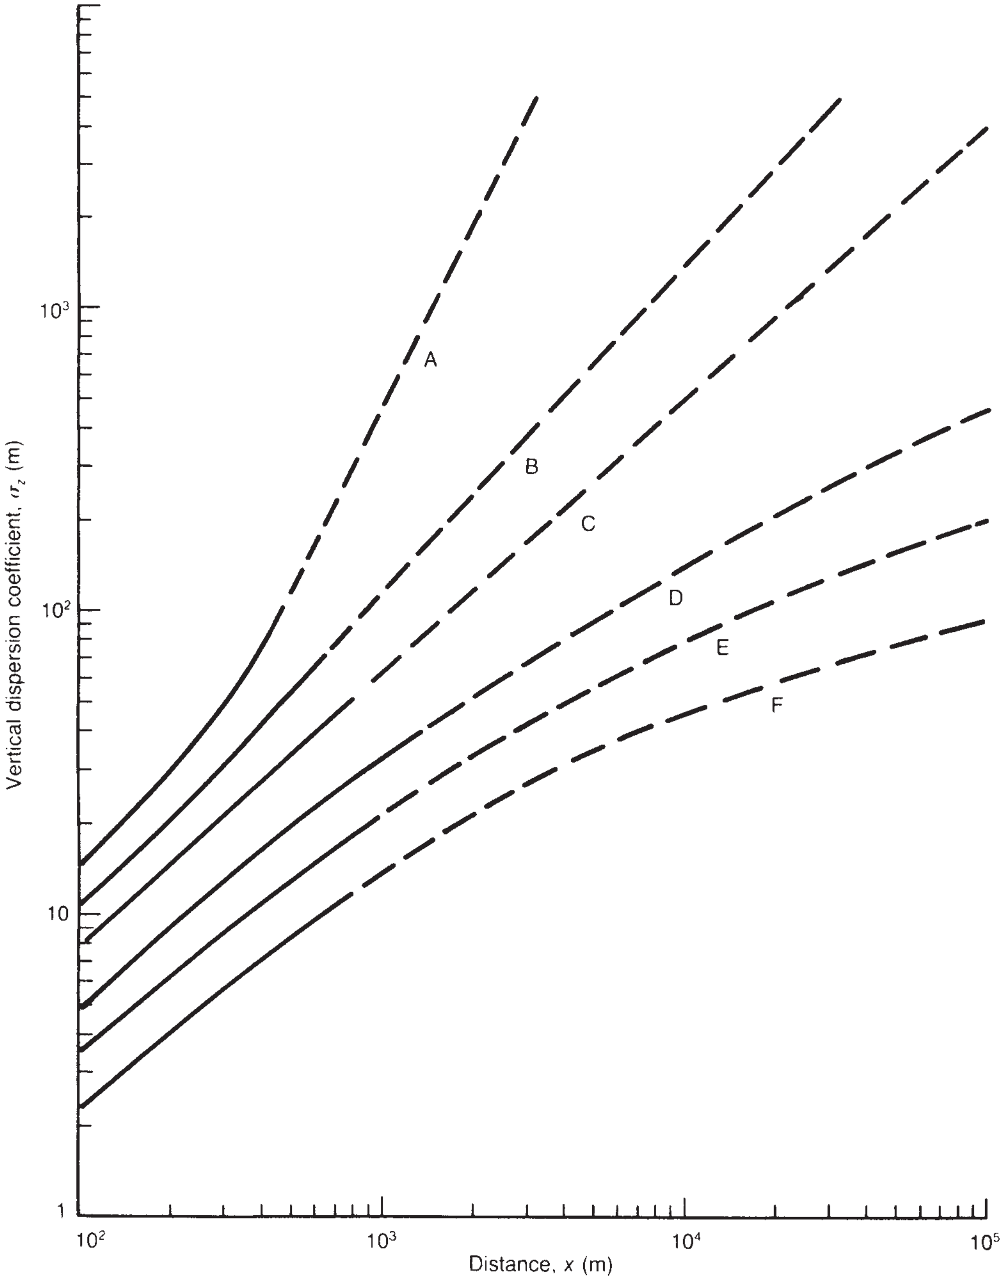

Figure 15.54(b) *Meteorological parameters for Pasquill–Gifford equations for continuous source: vertical dispersion coefficient σ_ζ (D.B. Turner, 1970). A–F refer to Pasquill stability categories*

He suggests that the variation of concentration with sampling period may be taken into account using the following approximate relation:

$$\frac{\chi}{\chi_r} = \left(\frac{t_\mathrm{r}}{t}\right)^p \quad [15.16.45]$$

where t is the sampling period which yields concentration χ, p is an index and subscript r denotes the reference value. Equation 15.16.45 is intended for use for sampling periods up to 2 h using a typical reference sampling period of 10 min. The value of index p is between 0.17 and 0.2.

Table 15.31 Meteorological parameters for the Pasquill–Gifford model

A values of σ_v and σ_z for continuous sources given by Turner (1970) are shown in Figure 15.54. Turner's values are fitted by following approximate equations:

Pasquill stability category	*Dispersion Coefficient*		
	σ_y	σ_z (m)	
A	$\sigma_y = 0.493x^{0.88}$	$\sigma_z = 0.087x^{1.10}$	$100 < x < 300$
		$\log_{10}\sigma_z = -1.67 + 0.902\log_{10}x + 0.181(\log_{10}x)^2$	$300 < x < 3000$
B	$\sigma_y = 0.337x^{0.88}$	$\sigma_z = 0.0135x^{0.95}$	$100 < x < 500$
		$\log_{10}\sigma_z = -1.25 + 1.09\log_{10}x + 0.0018(\log_{10}x)^2$	$500 < x < 2 \times 10^4$
C	$\sigma_y = 0.195x^{0.90}$	$\sigma_z = 0.112x^{0.91}$	$100 < x < 10^5$

		$\log_{10}\sigma_z = 1.91 - 1.37\log_{10}x - 0.119(\log_{10}x)^2$	$500 < x < 10^5$

B Values of σ_y and σ_z for instantaneous sources given by Slade (1968)

Stability condition	$x = 100$ m		$x = 400$ m		*Approximate equation*	
	σ_y (m)	σ_z (m)	σ_y (m)	σ_z (m)		
Unstable	10	15	300	220	$\sigma_y = 0.14x^{0.92}$	$\sigma_z = 0.53x^{0.73}$
Neutral	4	3.8	120	50	$\sigma_y = 0.06x^{0.92}$	$\sigma_z = 0.15x^{0.70}$
Very stable	1.3	0.75	35	7	$\sigma_x = 0.024x^{0.89}$	$\sigma_z = 0.05x^{0.61}$

15.16.6 Plume model characteristics

The Sutton equations for instantaneous and continuous point sources are models of the behaviour of a 'puff' and a 'plume' of gas, respectively. The equations are convenient in form for the calculation of various derived quantities and have been used extensively. Some important characteristics in the plume model of dispersion from a ground level source are (1) the concentration on the axis of the plume and (2) the dimensions of the plume. Again, these quantities are mainly of interest at ground level.

Applying the Sutton model, for a continuous point source at ground level use is made of Equation 15.16.27 with Equation 15.16.30. If the concentration considered is that at ground level $z = 0$, then

$$\chi(x, y, 0) = \frac{2Q}{\pi C^2 u x^{2-n}} \exp\left(-x^{n-2}\frac{y^2}{C^2}\right) \qquad [15.16.46]$$

For the ground level concentration χ_{cl} on the axis $y = 0$

$$\chi_{\mathrm{cl}} = \chi(x, 0, 0) = \frac{2Q}{\pi C^2 u x^{2-n}} \qquad [15.16.47]$$

For $n = 0.25$ and $C = 0.14$

$$\chi_{\mathrm{cl}} = \frac{32Q}{u x^{1.75}} \qquad [15.16.48]$$

The cloud boundary concentration χ_{cb} may be defined as either one-tenth of the axial concentration χ_{cl} or as the extinction concentration χ_{ex}. For the dimensions of the cloud at ground level the coordinates (x, y) of a point of concentration χ_{cb} are obtained from Equation 15.16.46.

The plume model for dispersion from an elevated source is also relevant. In this case two important characteristics are (1) the maximum concentration on the axis at ground level and (2) the distance at which the maximum ground level concentration occurs.

For a continuous elevated point source, use is made of Equation 15.16.29 with Equation 15.16.30. If the concentration considered is that at ground level on the axis $y = 0$ and $z = 0$, then

$$\chi_{\mathrm{cl}} = \chi(x, 0, 0) = \frac{2Q}{\pi C^2 u x^{2-n}} \exp\left(-x^{n-2}\frac{H^2}{C^2}\right) \qquad [15.16.49]$$

For the maximum ground level concentration χ_{mgl} on the axis the appropriate equation may be shown to be

$$x_{\mathrm{mgl}} = \frac{2Q}{e\pi u H^2}\frac{C_z}{C_y} \qquad [15.16.50]$$

where e is the base of natural logarithms.

The distance χ_{mgl} at which the maximum ground level concentration χ_{mgl} occurs may be shown to be given by the equation

$$\chi_{\mathrm{mgl}} = \left(\frac{H}{C_z}\right)^{2/(2-n)} \qquad [15.16.51]$$

The corresponding equations based on the Pasquill–Gifford model are as follows. For a continuous point source at ground level use is made of Equation 15.16.41. If the concentration considered is that at ground level $z = 0$, then

$$\chi(x,y,0) = \frac{Q}{\pi\sigma_y\sigma_z u}\exp\left(-\frac{1}{2}\frac{y^2}{\sigma_y^2}\right) \qquad [15.16.52]$$

For the ground level concentration on the axis

$$\chi_{\mathrm{cl}} = \frac{Q}{\pi\sigma_y\sigma_z u} \qquad [15.16.53]$$

For the dimensions of the cloud at ground level, the coordinates (x, y) of a point of concentration χ_{cb} are obtained from Equation 15.16.52.

For a continuous elevated source use is made of Equation 15.16.43. If the concentration considered is that at ground level on the axis $y = z = 0$, then

$$x_{\mathrm{cl}} = \frac{Q}{\pi\sigma_y\sigma_z u}\exp\left(-\frac{1}{2}\frac{h^2}{\sigma_z^2}\right) \qquad [15.16.54]$$

For the maximum ground level concentration χ_{mgl} on the axis the appropriate equation may be shown to be

$$\chi_{\mathrm{mgl}} = \frac{2Q}{e\pi u h^2}\frac{\sigma_z}{\sigma_y} \qquad [15.16.55]$$

The distance at which the maximum ground level concentration occurs may be shown to be the point at which

$$\sigma_z = \frac{h}{2^{1/2}} \qquad [15.16.56]$$

15.16.7 Puff model characteristics

Some important quantities in the puff model of dispersion from a ground level source are (1) the concentration at the centre of the cloud, (2) the dimensions of the cloud, (3) the maximum distance travelled and (4) the total integrated dosage given by the cloud. These quantities are mainly of interest at ground level.

Applying the Sutton model, for an instantaneous point source at ground level use is made of Equation 15.16.25 with Equation 15.16.30. If the concentration considered is that at ground level $z = 0$, then

$$\chi(x,y,0,t) = \frac{2Q^*}{\pi^{3/2}C^3(ut)^{3/2(2-x)}} \times \exp\left[-(ut)^{x-2}\left(\frac{x^2}{C^2}+\frac{y^2}{C^2}\right)\right] \qquad [15.16.57]$$

For the ground level concentration χ_{cc} at the centre of the cloud $x = y = 0$

$$\chi_{\mathrm{cc}} = \chi(0,0,0,t) = \frac{2Q^*}{\pi^{3/2}C^3(ut)^{3/2(2-n)}} \qquad [15.16.58]$$

For $n = 0.25$ and $C = 0.14$

$$\chi_{\mathrm{cc}} = \frac{131Q^*}{(ut)^{2.62}} \qquad [15.16.59]$$

For the other quantities mentioned it is necessary to define the cloud. If the definition used is the convention that the concentration χ_{cb} at the cloud boundary is one-tenth of that at the centre, then

$$\frac{\chi_{\mathrm{cb}}}{x_{\mathrm{cc}}} = 0.1 \qquad [15.16.60]$$

Alternatively, the cloud boundary concentration may be defined as some extinction value χ_{ex} at which the concentration is no longer of interest:

$$\chi_{\mathrm{cb}} = \chi_{\mathrm{ex}} \qquad [15.16.61]$$

A typical extinction concentration is the lower flammability limit for a flammable gas.

For the dimensions of the cloud at ground level the cloud radius x is determined by calculating χ_{cc} from Equation 15.16.58, χ_{cb} from Equation 15.16.60 or 15.16.61 and χ from Equation 15.16.57, setting $\chi = \chi_{\mathrm{cb}}$.

For the maximum distance travelled by the cloud the group ut is calculated from Equation 15.16.58 with χ_{cc} set equal to χ_{ex}.

The corresponding equations based on the Pasquill–Gifford model are as follows. For an instantaneous point source at ground level use is made of Equation 15.16.40. If the concentration considered is that at ground level $z = 0$, then

$$\chi(x,y,0,t) = \frac{2Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z} \times \exp\left[-\frac{1}{2}\left(\frac{x^2}{\sigma_x^2}+\frac{y^2}{\sigma_y^2}\right)\right] \qquad [15.16.62]$$

For the ground level concentration χ_{cc} at the centre of the cloud $x = y = 0$

$$\chi_{\mathrm{cc}} = \frac{2Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z} \qquad [15.16.63]$$

For the dimensions of the cloud at ground level the cloud radius x is determined by calculating χ_{cc} from Equation 15.16.63, χ_{cb} from Equation 15.16.60 or 15.16.61 and χ from Equation 15.16.62, setting $\chi = \chi_{\mathrm{cb}}$.

For the maximum distance travelled by the cloud use is made of Equation 15.16.63 with χ_{cc} set equal to χ_{ex}.

15.16.8 Dosage and dosement

The total integrated dosage D_{tid}, or more simply the dosage D, is

$$D = \int_0^\infty \chi \,\mathrm{d}t \qquad [15.16.64]$$

In the Sutton model for a puff release, the dosage at ground level on the axis may be obtained by integrating Equation 15.16.57 to obtain

$$D(x,0,0) = \frac{2Q^*}{\pi C^2 u(ut)^{2-n}} \qquad [15.16.65]$$

In the Pasquill–Gifford model for a puff release, the dosage D at ground level and at ground level on the axis, the appropriate equations may be shown to be, respectively,

$$D(x,y,0) = \frac{Q^*}{\pi\sigma_y\sigma_z u}\exp\left(-\frac{1}{2}\frac{y^2}{\sigma_y^2}\right) \qquad [15.16.66a]$$

and

$$D(x,0,0) = \frac{Q^*}{\pi\sigma_y\sigma_z u} \qquad [15.16.66b]$$

For some materials it is necessary to work in terms not of the dosage D as defined by Equation 15.16.64 but of a load, or dosement, defined as

$$L = \int_0^\infty \chi^n \mathrm{d}t \qquad [15.16.67]$$

where n is an index.

For the Pasquill–Gifford model it has been shown by Tsao and Perry (1979) that for a puff release the dosement at ground level is

$$L = \left[\frac{2Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z}\frac{\pi^{1/2}}{(2\pi)^{1/2}}\right]^n \frac{\sigma_x}{u}\left[1+\mathrm{erf}\left(\frac{n^{1/2}x}{2^{1/2}\sigma_x}\right)\right] \times \exp\left(-n\frac{y^2}{2\sigma_y^2}\right) \qquad [15.16.68]$$

For a plume release the load, or dosement, is obtained from the steady-state concentration and the period of exposure to that concentration.

15.16.9 Virtual sources

In the models just described, it is assumed that the sources are point sources, instantaneous or continuous. If the source is of finite size, it may be necessary to allow for this using the virtual source method. An account of the method has been given by Mecklenburgh (1985).

The need to allow for finite source size may occur, for example, as the result of the instantaneous flashing off of vapour at the source to form a relatively large cloud. A change of surface roughness, and hence of the dispersion parameter, may also require the use of the virtual source method.

Mecklenburgh treats the determination of the ground level concentration at the centre of the cloud formed from an instantaneous release. For this he utilizes Equation 15.16.63 rewritten in the form

$$\sigma_x\sigma_y\sigma_z = \frac{2V}{(2\pi)^{3/2}C} \qquad [15.16.69]$$

where C is the volumetric concentration (v/v) and V is the volume of gas released (m^3), together with the following relationships for the dispersion parameters:

On site:

$\sigma_x = 0.13x$; $\sigma_y = 0.064x^{0.905}$; $\sigma_z = 0.395x^{0.701}$;

$(\sigma_y\sigma_z)^{1/2} = 0.159x^{0.803}$; $(\sigma_x\sigma_y\sigma_z)^{1/3} = 0.149x^{0.869}$

Off site:

$\sigma_x = 0.13x$; $\sigma_y = 0.064x^{0.905}$; $\sigma_z = 0.200x^{0.760}$;

$(\sigma_y\sigma_z)^{1/2} = 0.113x^{0.833}$; $(\sigma_x\sigma_y\sigma_z)^{1/3} = 0.118x^{0.888}$

The equations are for Pasquill stability category D and a surface roughness of 0.1 on site and 1.0 (urban) off site. The method involves the repeated use of Equation 15.16.69, sometimes to determine the group $\sigma_x\sigma_y\sigma_z$ from C and sometimes vice versa.

Consider as an illustration the example given by Mecklenburgh, which is the determination of (1) the concentration of gas at the works boundary and (2) the distance to the lower flammability limit for a release of 8240 m^3 of gas from a point where the distance in the downwind direction between that point and the works boundary is 100 m.

The release gives a cloud of finite size. Equation 15.16.69 is strictly applicable to an instantaneous point source. In order to allow for the finite size of the cloud, the release is assumed to originate from a point source VS1 located at a virtual distance v_1 upwind of the actual release point. Then

$$x_{v1} = v_1 + x_\mathrm{s} \qquad [15.16.70]$$

where v_1 is the distance between the virtual and actual sources (m), x_s is the distance between the actual source and the point of interest (m) and $x_{\mathrm{v}1}$ is the distance between the virtual source and the point of interest (m). These distances are shown in Figure 15.55(a). The concentration of the cloud at the actual source is taken as pure gas so that $C = 1$ v/v.

Then Equation 15.16.69 with $V = 8240$ m^3 and $C = 1$ v/v yields $(\sigma_x\sigma_y\sigma_z) = 1046$ m^3. The on-site equations for the σ values (with x in these relations equal to v_1) give $v_1 = 129$ m. The virtual source VS1 is thus 129 m upwind of the actual source.

For the concentration at the works boundary, the distance $x_{\mathrm{v}1}$ between the virtual source and the boundary is given by Equation 15.16.70 with $x_\mathrm{s} = \mathrm{x_b}$, so that

$$x_{v1} = v_1 + x_\mathrm{b} \qquad [15.16.71]$$

where x_b is the distance between the actual source and the boundary (m). Using the on-site σ equations (with $x = x_{\mathrm{v}1}$) yields $(\sigma_x\sigma_y\sigma_z) = 4696\mathrm{m}^3$. Then from Equation 15.16.69 at the boundary $C = 0.223$ v/v.

Across the boundary the surface roughness changes and it is necessary to utilize a second virtual source VS2, determining its distance upwind from conditions at the works boundary. Utilizing again $C = 0.223$ v/v, and hence $(\sigma_x\sigma_y\sigma_z) = 4696\mathrm{m}^3$, but this time using the off-site σ equations (with $x = x_{v2}$), gives $x_{v2} = 365$ m. At the boundary

$$x_{v2} = v_2 + x_\mathrm{b} \qquad [15.16.72]$$

where v_2 is the distance between the virtual and actual sources (m). Then, from Equation 15.16.72, $v_2 = 365$ $100 = 265$ m.

For the distance to the lower flammability limit, the distances are shown in Figure 15.55(b). Setting $C = 0.0355$ v/v in Equation 15.16.69 yields $(\sigma_x\sigma_y\sigma_z) = 29{,}475$ m^3. Using the off-site σ equations (with $x = x_{v2}$) gives $x_{v2} = 528$ m. But

$$x_{v2} = v_2 + (x_\mathrm{s} - x_\mathrm{b}) \qquad [15.16.73]$$

Hence $x_\mathrm{s} = 528 - (265 - 100) = 363$ m.

15.16.10 *K*-theory models

An alternative approach to that given in the Sutton, Pasquill and Pasquill–Gifford models is the direct solution of the fundamental diffusion equation in which the dispersion is characterized by the parameter K. As mentioned

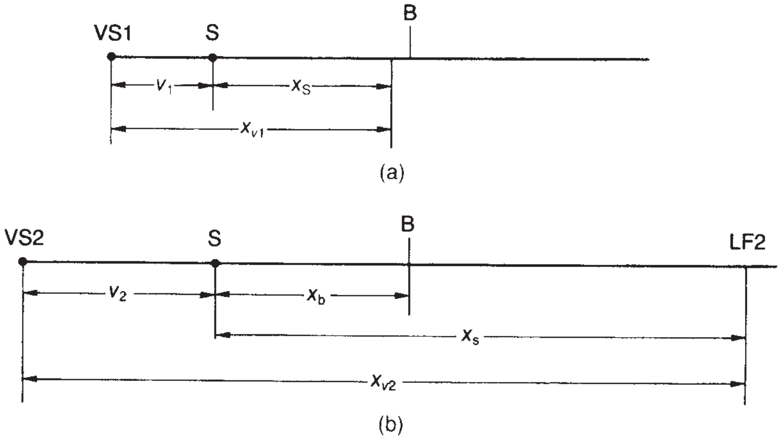

Figure 15.55 *Virtual source method: (a) use of virtual source to allow for finite size of initial cloud; and (b) use of virtual source to allow for change in surface roughness*

above, early work on this, in which K was assumed to be a constant, such as that of Roberts, gave unsatisfactory results, but more modern models, which take into account the variation of K, have been more successful and find use alongside the models already described.

Accounts of such gradient transfer, or K-theory, models are given by S.R. Hanna, Briggs and Hosker (1982), by Runca (1982) and Gryning, van Ulden and Larsen (1983). These if-theory models may be solved analytically, if correlations of a suitable form are available for K. Alternatively, they may be solved numerically.

For analytical solutions the profiles of the wind velocity u and of the parameter K may be expressed as power functions of the height z.

$$u = u_r\left(\frac{z}{z_r}\right)^m \qquad [15.16.74]$$

$$K = K_r\left(\frac{z}{z_r}\right)^n \qquad [15.16.75]$$

where m and n are indices and r denotes the reference value.

A further discussion of values of the parameter K is given in Section 15.24. Various analytical solutions for K-theory models are given by S.R. Hanna, Briggs and Hosker (1982).

Numerical solution of K-theory models tends to involve severe problems both of numerical inaccuracy and numerical instability. The effect of the former is to give a spurious diffusion which arises solely from the numerical method of solution. The effect of the latter is to require very small step lengths and hence very long computation times.

15.16.11 Criterion for type of release

The dispersion situations that occur in practice often correspond not to the puff or the plume model but to the intermediate case. The usual method of dealing with this problem is to calculate dispersion using both models and to take the worst case.

The alternative approach is to select the model on the basis of a suitable criterion. A criterion for deciding whether to use the puff or the plume model, as given by the respective Pasquill–Gifford equations, has been suggested by Eisenberg, Lynch and Breeding (1975). The puff model is preferable if the diffusion in the downwind, or x, direction is large relative to the length of the plume. A measure of diffusion in the downwind direction is the dispersion coefficient σ_x, where this is evaluated using the puff data, and a measure of the length of the plume is ut_e, where u is the wind speed and t_e is the time taken for total discharge or evaporation of the gas. The coefficient σ_x is evaluated using the puff data at $ut_e/2$. The authors suggest the following criteria:

$ut_e < 2\sigma_x$	Use puff model
$ut_e > 5\sigma_x$	Use plume model
$2\sigma_x < ut_e < 5\sigma_x$	Neither model entirely appropriate

In addition, the plume model is undefined for zero wind speeds, is inaccurate for low wind speeds and is therefore not recommended for use at wind speeds of less than 2 m/s. Further criteria for model selection are given in relation to some of the model systems described below.

15.17 Passive Dispersion: Dispersion over Particular Surfaces

15.17.1 Dispersion over urban areas

Accounts of dispersion over and in urban areas have been given by Gifford (1972, 1976a,b), S.R. Hanna (1976) and S.R. Hanna, Briggs and Hosker (1982). There are two rather different types of model that are used to describe the concentration of pollutant in an urban area. The first type is concerned with the overall concentration of the pollutant in the urban atmosphere as required for pollution studies. The second describes the dispersion and gives concentration profiles.

Models used for dispersion over and within an urban area include the Pasquill–Gifford model and K models. D.B. Turner (1964) carried out a study to validate the use of the Pasquill–Gifford model over and within a city, and various other workers have carried out studies to determine the parameters of this model in the urban situation.

Models used for pollution studies include rollback models, statistical correlations and box models. In a rollback model it is assumed that the concentration is proportional

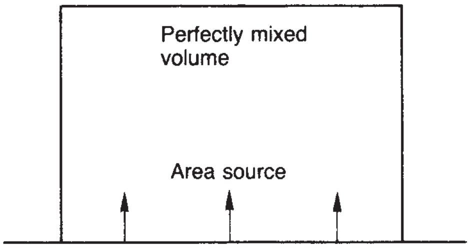

Figure 15.56 Box model for dispersion over an urban area

to the strength of the emission source(s). A rollback model therefore focuses attention on the level of emissions. Statistical correlations are used to relate concentrations to meteorological variables such as solar radiation, wind speed and temperature.

In a box model the urban area is treated as a box as shown in Figure 15.56. The basic equation is

$$\Delta x z_i \frac{\mathrm{d}\chi}{\mathrm{d}t} = \Delta x Q_\mathrm{a} + u z_i(\chi_\mathrm{b} - \chi) + \Delta x \frac{\mathrm{d}z_i}{\mathrm{d}t}(\chi_\mathrm{a} - \chi) \qquad [15.17.1]$$

where Q_a is the mass rate of release per unit area, Δx is an incremental length, z_i is the mixed layer height, χ is the concentration, χ_a is the concentration above the mixed layer height and χ_b is the concentration upwind of the city, or background concentration.

With zero background concentration and at steady state, Equation 15.17.1 becomes

$$\chi = \frac{\Delta x Q_\mathrm{a}}{z_i u} \qquad [15.17.2]$$

In some versions of the box model it is assumed that the pollutant is mixed not to the mixed layer height z_i, but to some other height. A correlation for this height is given by S.R. Hanna (1976).

Dispersion coefficients for use in the Pasquill–Gifford model in urban areas are discussed in Section 15.19.

15.17.2 Dispersion over coastal areas and water

An account of the meteorology relevant to coast and sea is given in *Physics of the Marine Atmosphere* (Roll, 1965). The modelling of dispersion over coastal areas and water has been described by Gifford (1976a,b) and by Lyons (1976).

Dispersion over coastal areas and water is most often modelled using the Pasquill–Gifford method. It is pointed out by Lyons that this involves use of the model outside the range of conditions for which it was developed, which were flat rural terrain. Moreover, a further weakness is that the assumption of a steady state is less valid in the more variable wind conditions characteristic of coastal areas. Nevertheless, this is the model that is most widely used. Dispersion coefficients for this model are described in Section 15.19.

Several other models are described by Lyons. These include a model for conduction inversion and one for shoreline fumigation based on a modification of the nocturnal inversion breakup model of Turner.

15.17.3 Dispersion over complex terrain

A description of the modelling of dispersion over complex terrain has been given by Egan (1976).

A model which has been used for complex terrain is the model of Environmental Research and Technology Inc. (ERT) which is based on the Pasquill–Gifford equation for a release from an elevated continuous point source as given in Equation 15.16.43. The effective stack height h_o is taken as usual as the sum of the actual stack height h and the plume rise Δh. Then an effective plume height, essentially the height of the centre line of the plume, is defined as follows. For a receptor on a hill, the height h_1 of which is lower than the effective stack height h_0, the effective plume height h_p is taken as

$$h_\mathrm{p} = h_0 - h_1/2 \quad h_1 < h_0 \qquad [15.17.3a]$$

whilst for a receptor on a hill height h_2, which is higher than h_0, the expression used for h_p is

$$h_\mathrm{p} = h_0/2 \quad h_2 < h_0 \qquad [15.17.3b]$$

The model has been used for unstable, neutral and stable conditions. For a hill higher than the effective stack height this model is the so-called 'half-height' model.

Flow in complex terrain may be modelled using potential flow theory. Standard cases in potential flow are treated by Lamb (1932) and Milne-Thomson (1938). Two cases relevant to complex terrain are the half circular cylindrical ridge and the hemispherical hill. Potential flow theory may be extended to include diffusion.

Thus the Pasquill–Gifford equation giving the ground level centre line concentration from an elevated point source may be modified to give

$$\chi = \frac{Q}{(\pi\sigma_y\sigma_x z_u)_\mathrm{f}(D_y D_z)} \exp\left[-\frac{(\eta h_0)^2}{2\sigma_{z\mathrm{f}}^2 \zeta^2 D_z^2}\right] \qquad [15.17.4]$$

with

$$D_y = \sigma_y/\sigma_{y\mathrm{f}} \qquad [15.17.5a]$$

$$D_z = \sigma_y/\sigma_{z\mathrm{f}} \qquad [15.17.5b]$$

$$\eta = (h_\mathrm{p} - z)/h_0 \qquad [15.17.6]$$

$$\zeta = (\mathrm{d}\psi/\mathrm{d}h_\mathrm{p})_\mathrm{o}/(\mathrm{d}\psi/\mathrm{d}h_\mathrm{p}) \qquad [15.17.7]$$

where h_p is the local height of the plume, z is the local height of the terrain, ψ is the stream function and subscripts f and o denote flat terrain and effective source height, respectively, ζ is the ratio of the average vertical gradient of the stream function at the effective source height to the gradient at the plume centre line over the surface.

For flat terrain, D_y, D_z, η and ζ are all unity. For two-dimensional flow, as over a ridge, it can be shown that near the surface η and ζ are approximately equal and, assuming that D_y and D_z are also equal to unity, Equation 15.17.4 reduces to Equation 15.16.43. For three-dimensional flow, as over a hill, the parameters η and ζ have the values

$$\eta = h_0/3a \qquad [15.17.8]$$

$$\zeta = 2h_0/3a \qquad [15.17.9]$$

where a is the radius of the hill. Then, again assuming that D_y and D_z are unity, Equation 15.17.4 becomes

$$\chi = \frac{Q}{(\pi\sigma_y\sigma_z u)_\mathrm{f}} \exp\left[-\frac{(h_0/2)^2}{2\sigma_{z\mathrm{f}}^2}\right] \qquad [15.17.10]$$

Comparing Equation 15.17.10 with Equation 15.16.43 it can be seen that the effect of the hill is to give an equivalent source height h_e half the effective source height h_o. Thus Equation 15.17.10 is another form of the 'half-height' equation for complex terrain.

Another approach is physical modelling using wind and water tunnels. As described above, Egan discusses the requirements of similarity in such work. He gives several examples of tunnel studies for complex terrain.

15.17.4 Dispersion at buildings and obstacles

Accounts of models available for dispersion at buildings and obstacles are given by Halitsky (1968), Gifford (1976a,b), Vincent (1977), S.R. Hanna, Briggs and Hosker (1982) and Fackrell (1984a). A review of the aerodynamics of flow around buildings has been given by J.C.R. Hunt (1971).

Treatments of the effect of a building on release from an upwind source are mainly concerned with the case of an elevated source. A rule-of-thumb applicable to this situation is that the plume will rise over the building if the distance from the source to the building is greater than $2h$, where h is the height of the building, and if the height h_s of the source exceeds two-thirds that of the building ($h_s > 2h/3$).

The overall effect of the building is to enhance the dispersion of the plume. D.J. Wilson and Netterville (1978) found that the main effect is to increase the mixing between the roof and ground levels. Around the building itself aerodynamic effects may give high local concentrations.

For groups of buildings or buildings of less regular shape, the flow patterns tend to be complex. It has been shown by Cagnetti (1975) for a reactor site that dispersion may vary markedly for relatively small changes in wind direction. Dispersion from sources close to a building has been modelled more extensively, since this is relevant to the siting of vents and stacks.

Rules for the siting of roof stacks for the case of wind impinging perpendicularly on the face of a rectangular building, as shown in Figure 15.57, have been derived by D.J. Wilson (1979a). For a building with height h, crosswind width w and alongwind length l, he defines a scaling factor R such that

$$R = D_s^{0.67} D_l^{0.33} \qquad [15.17.11]$$

where D_s is the smaller dimension of the height h and the width w, and D_l is the larger of these two. He gives the following correlations for the roof cavity length l_c and height h_c:

$$l_c = 0.9R \qquad [15.17.12]$$

$$h_c = 0.22R \qquad [15.17.13]$$

The upper boundary Z_{II} of the high turbulence layer, which starts near the maximum roof cavity height, is given as

$$\frac{Z_{II}}{R} = 0.27 - 0.1\frac{x}{R} \qquad [15.17.14]$$

and that of the roof wake Z_{III} as

$$\frac{Z_{III}}{R} = 0.28\left(\frac{x}{R}\right)^{1/3} \qquad [15.17.15]$$

where x is the downwind distance.

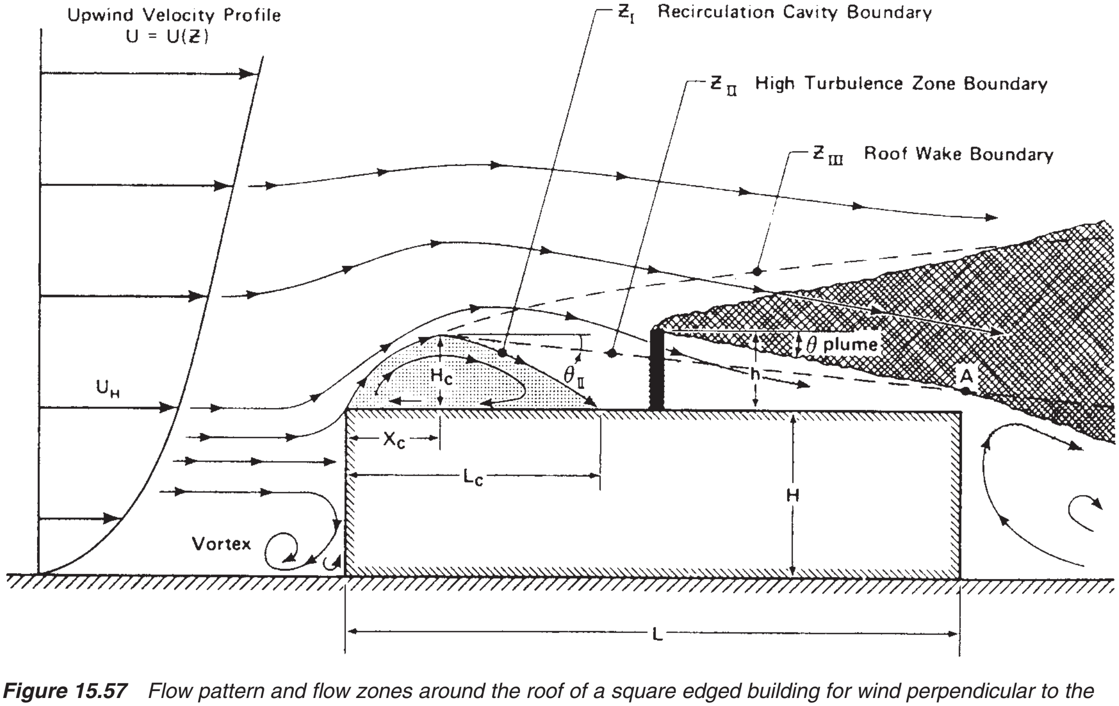

Figure 15.57 *Flow pattern and flow zones around the roof of a square edged building for wind perpendicular to the upwind face (D.J. Wilson, 1979a) H, H_c, L, L_c in the figure are denoted in the text by h, h_c, l, l_c (Courtesy of the American Society of Heating, Refrigerating and Air Conditioning Engineers)*

Wilson suggests that for a roof-mounted stack there is little risk of high pollutant concentrations on the roof if plume clears the boundary of the high turbulence zone and virtually no risk if it clears the roof wake boundary.

Concentrations arising from vents on roofs have been studied in wind tunnel investigations as described by Halitsky (1963, 1968) and D.J. Wilson (1976). Results of such studies are plotted in terms of the dimensionless concentration K defined as

$$K = \frac{\chi A u}{Q} \qquad [15.17.16]$$

where A is a characteristic area, Q is the mass rate of release and u is the wind speed. A typical characteristic area is wh.

Wilson gives the following correlation for the maximum value of the concentration $\chi(x)$ from a roof vent:

$$\frac{\chi(x)}{\chi(0)} = 9.1 \frac{w_o A_v}{u x^2} \qquad [15.17.17]$$

where A_v is the vent area, u is the wind speed, w_o is the effluent velocity, x is the downwind distance, and $\chi(0)$ is the effluent concentration.

For a roof stack, a widely used rule-of-thumb is the '2½' rule that to avoid downwash problems the stack height should be 2½ times the building height. This height will cause the plume to clear the wake cavity.

Another model is that of G.A. Briggs (1974), which applies to a stack located upwind of the building. For such a stack of height h the effective stack height h' is taken as

$$h' = h - h_d \qquad [15.17.18a]$$

with

$$h_d = 2\left(\frac{w_o}{u} - 1.5\right) D_s \qquad [15.17.18b]$$

where D_s is the diameter of the stack outlet, h_d is the downwash, or initial fall in the plume, and w_o is the efflux velocity from the stack. The equation reflects the fact that downwash does not occur if the efflux velocity is maintained above a critical level, generally taken as $w_o/u = 1.5$. The plume is out of the building wake if $h' > (h + 1.5D_s)$. If this condition does not apply, the plume is to some degree affected by the building and if $h_o < 0.5D_s$, it is assumed to be trapped by the wake cavity. Then

$$h_0 = h' \qquad h' > (h + 1.5D_s) \qquad [15.17.19a]$$

$$= 2h' - (h + 1.5D_s) \qquad h' < (h + 1.5D_s) \qquad [15.17.19b]$$

$$= h' - 1.5D_s \qquad h' < h \qquad [15.17.19c]$$

If the plume is trapped it may be treated as a ground level source with initial area D_s^2.

If a plume is entrained into the wake cavity ($h_0 < 0.5D_s$), the dimensionless concentration tends to lie in the range 0.2–2. Given that the plume is entrained into the wake cavity, the precise height of the stack makes little difference to the ground concentrations. There is, however, one particular case where stack height can have a marked effect. If the stack height is about the same height as the wake cavity, the effluent may be carried directly to the ground along the boundary of the cavity.

There have been a number of treatments of the wake cavity in the lee of the building. These include studies of the characteristics of the wake cavity itself and of the concentrations resulting from a release within the cavity. The wake cavity approximates a perfectly mixed zone with the concentration being nearly the same throughout.

A review of models for building-influenced dispersion has been given by Fackrell (1984a). These include: the model of Gifford (1960a), described below; the models of D.B. Turner (1970) and Barker (1982), which involve the use of a virtual source; and those of Ferrara and Cagnetti (1980) and Huber and Snyder (1976), which involve modification of the dispersion coefficients. Both the models that use a virtual source and those that use modified dispersion coefficients correlate the parameters in terms of the building width w and height h.

For the wake cavity itself, Hosker (1979, 1980) has developed the following correlations for the length x_r:

$$\frac{x_r}{h} = \frac{A(w/h)}{1 + B(w/h)} \qquad [15.17.20]$$

with

$$A = -2.0 + 3.7(l/h)^{-1/3} \qquad l/h < 1 \qquad [15.17.21a]$$

$$= 1.75 \qquad l/h > 1 \qquad [15.17.21b]$$

$$B = -0.15 + 0.305(l/h)^{-1/3} \qquad l/h < 1 \qquad [15.17.22a]$$

$$= 0.25 \qquad l/h > 1 \qquad [15.17.22b]$$

As far as concerns the width y_r and height z_r of the cavity, these rarely exceed the building width w and height h, respectively.

For a plume from a source in the wake cavity, the following treatment by Gifford (1960a, 1976a,b) is widely quoted. Following an approach by Fuquay, an atmospheric dilution factor D_A is defined as

$$D_A = Q/\chi \qquad [15.17.23a]$$

$$= \pi \sigma_y \sigma_z u \qquad [15.17.23b]$$

where Q is the mass rate of release, u is the wind speed, and σ_y and σ_z are the downwind and crosswind dispersion coefficients, respectively. But a building dilution factor D_B can be defined as

$$D_B = cAu \qquad [15.17.24]$$

where A is the cross-sectional area of the building normal to the wind ($= wh$) and c is a constant. The total dilution factor D_{tot} is

$$D_{tot} = D_A + D_B \qquad [15.17.25a]$$

$$= (\pi \sigma_y \sigma_z + cA)u \qquad [15.17.25b]$$

$$= Q/\chi \qquad [15.17.25c]$$

Hence

$$\chi = \frac{Q}{(\pi \sigma_y \sigma_z + cA)u} \qquad [15.17.26]$$

Gifford (1960a) has estimated that the value of c lies in the range 0.5–2. He states (Gifford, 1976b) that this estimate, though widely quoted, was purely intuitive and that there are other studies that support a value of about 0.5.

There is evidence that the dispersion coefficients σ_y and σ_z applicable in Equation 15.17.26 differ somewhat from the regular values. The latter tend to give downwind concentrations that vary with distance to a power lying between −1.3 and −1.6, depending on the stability condition. Laboratory studies by Meroney and Yang (1971) and Huber and Snyder (1976) have found this power to be close to −0.8 to a distance of 50 h, although field studies such as those by Dickson, Start and Markee (1969) have given the power as about −1.3.

Gifford (1976b) draws attention to other conditions in which dispersion deviates from that predicted by Equation 15.17.26.

Barry (1964) has reviewed published expressions for the concentration given by pollutants in the lee of a rectangular block of square cross-section (alongwind length = height = S) and found them to be of the general form

$$\bar{C} = k\left(\frac{Q}{S^2u}\right) \qquad [15.17.27]$$

where $\bar{C}$ is the mean concentration, Q is the source strength, u is the main stream air velocity and k is a constant. The value of the constant k is in the range 0.5–20.

Vincent (1977) has described wind tunnel work on the dispersion of pollutant near buildings, and particularly in building wakes. He uses dimensional analysis to derive the principal parameters governing flow around a rectangular block. These are X/S and

$$H = \frac{ut_{\mathrm{d}}}{S} \qquad [15.17.28]$$

$$\Lambda = \frac{l_{\mathrm{f}}k_{\mathrm{f}}^{1/2}}{Su} \qquad [15.17.29]$$

where k_{f} is the characteristic energy of free stream turbulence, l_{f} is the characteristic length scale of free stream turbulence, t_{d} is the mean residence time of the scalar entities in the wake bubble, X is the length of the wake 'bubble' and Λ is a free stream turbulence parameter. Vincent gives results of wind tunnel work correlating H and X/S against Λ.

For a pollutant source wholly contained within the bubble he derives the relation

$$\bar{C} \approx \frac{QSH}{Vu} \qquad [15.17.30]$$

But

$$V \approx \left(\frac{X}{S}\right)S^3 \qquad [15.17.31]$$

where V is the volume of the wake bubble. Then from Equations 15.17.30 and 15.17.31

$$\bar{C} \approx \left(\frac{Q}{S^2u}\right)\left(\frac{H}{X/S}\right) \qquad [15.17.32]$$

Vincent points out that Equation 15.17.32 gives for k in Equation 15.17.27 the explicit expression $H/(X/S)$.

Fackrell (1984b) has derived a model for a building wake and for the concentration in this wake and has used wind tunnel experiments to obtain values of the parameters involved. For flow out of the wake

$$F = \alpha S u_{\mathrm{h}} C_{\mathrm{w}} \qquad [15.17.33]$$

where C_{w} is the average concentration in the near-wake region, F is the flow out of the wake, S is the surface area of the near-wake region, u_{h} is the wind speed at the building height in undisturbed flow, and α is a flux constant. If there is a source of strength Q in the wake

$$F = Q \qquad [15.17.34]$$

so that from Equations 15.17.33 and 15.17.34

$$Q = \alpha S u_{\mathrm{h}} C_{\mathrm{w}} \qquad [15.17.35]$$

The residence time in the wake is

$$t_{\mathrm{r}} = \frac{V}{\alpha S u_{\mathrm{h}}} \qquad [15.17.36]$$

where t_{r} is the residence time in the near-wake region and V is the volume of the near-wake region.

Fackrell defines the following dimensionless quantities for the recirculation, or near-wake, region:

$$\beta = \frac{AL_{\mathrm{r}}}{V} \qquad [15.17.37]$$

$$\lambda_{\mathrm{r}} = L_{\mathrm{r}}/h \qquad [15.17.38]$$

$$\tau_{\mathrm{r}} = \frac{u_{\mathrm{h}}t_{\mathrm{r}}}{h} \qquad [15.17.39]$$

$$\chi_{\mathrm{w}} = \frac{C_{\mathrm{w}}u_{\mathrm{h}}A}{Q} \qquad [15.17.40]$$

where A is the frontal area of the building, h is the height of the building, L_{r} is the length of the recirculation region, β is the wake shape parameter, λ_{r} is the dimensionless length of the recirculation region, τ_{r} is the dimensionless residence time in the recirculation region and χ_{w} is the dimensionless average concentration in the near-wake region.

Then from Equations 15.17.35–15.17.40

$$\chi_{\mathrm{w}} = \frac{A}{\alpha S} \qquad [15.17.41]$$

$$= \beta\frac{\tau_{\mathrm{r}}}{\lambda_{\mathrm{r}}} \qquad [15.17.42]$$

Fackrell reviews the correlations available for λ_{r} and τ_{r}. He modifies Equation 15.17.20 of Hosker to give

$$\lambda_{\mathrm{r}} = \frac{1.8(b/h)}{\left[(l/h)^{0.3}\right][1+0.24(b/h)]} \qquad 0.3 \le \frac{l}{h} \le 3 \qquad [15.17.43]$$

where b is the crosswind breadth of the building. He also obtains

$$\tau_{\mathrm{r}} = \frac{11(b/h)^{1.5}}{\left[1+0.6(b/h)^{1.5}\right]} \qquad [15.17.44]$$

15.18 Passive Dispersion: Dispersion in Particular Conditions

The other type of special situation is determined not by the terrain but by the meteorological conditions. Two such situations are considered here:

(1) dispersion in calm conditions;
(2) dispersion in a uniformly mixed layer.

15.18.1 Dispersion in calm conditions

For a small proportion of the time, calm, near windless, conditions prevail. These occur typically on clear nights with frost or heavy dew.

Conditions that are usually classified as Pasquill category F apply in the United Kingdom for some 20% of the time. Included in these are the periods of calm. Beattie (1963 UKAEA AHSB(S) R64) found that the proportion of time for which such conditions apply is about 5–8%. Pasquill actually excluded such conditions from his original categories because dispersion then tends to be irregular.

Beattie has classified such conditions as category G, but does not give the associated dispersion coefficients. It is natural to assume that dispersion is less in G than in F conditions. This assumption is made, for example, in NRC *Regulatory Guide* 1.21. However, there is evidence to show that under G conditions dispersion is ill-defined. Work on such conditions by Sagendorf (1975) has shown that a plume is subject to considerable meander, while work by van der Hoven (1976) has indicated values of dispersion coefficients which correspond to those found across the whole range from A to F conditions.

15.18.2 Dispersion in a uniformly mixed layer

Another meteorological condition that requires special treatment is that of limited mixing fumigation, where there is an elevated inversion which acts as a 'lid'. There is then a well mixed layer of height H in which, beyond a certain distance, the concentration is uniform. For this condition Gifford (1976a) gives the relation

$$\chi = \frac{Q}{(2\pi)^{1/2}\sigma_y u H} \qquad [15.18.1]$$

where, in this case, H is the height of the 'lid', Q is the mass rate of release, u is the wind speed, σ_y is the crosswind dispersion coefficient and χ is the concentration.

15.19 Passive Dispersion: Dispersion Parameters

The dispersion models described contain parameters that are functions of the meteorological variables and of the distance from the source. The Sutton model contains the diffusion parameter C, the Pasquill model the parameters θ and h, and the Pasquill–Gifford models the dispersion coefficient σ. The values of, and correlations for, these parameters proposed by the authors of the models were given in the overall account of these models in Section 15.16. There is, in addition, a considerable literature on these parameters, especially the Pasquill–Gifford dispersion coefficients, ranging from fundamental relations to empirical correlations, which is now described.

In the estimation of dispersion parameters a crucial aspect is the definition of the stability condition. It is argued by Atwater and Londergan (1985) that the representation of stability is of more importance than the correlation of dispersion coefficients with stability. In some cases, there are differences of two or more stability classes between the class based on the meteorology and that inferred from the observed dispersion coefficients and between that inferred from the horizontal dispersion coefficient and that inferred from the vertical dispersion coefficient. The discussion of dispersion parameters is confined initially to those for a plume. Those for a puff are considered in Section 15.19.12.

15.19.1 Fundamental relations

The relations between the turbulent exchange coefficient K, the Sutton diffusion parameter C, the Pasquill parameters θ and h, and the Pasquill–Gifford dispersion coefficient σ may be summarized as follows.

As described above, the condition for the reduction of the Sutton model to the K-model is

$$n = 1 \qquad [15.19.1]$$

$$C_x^2 = \frac{4K_x}{u} \qquad [15.19.2]$$

Similar equations apply relating σ_y to c_y, and σ_z to c_z.

The relation between the Pasquill–Gifford dispersion coefficients and the Sutton diffusion parameters is

$$\sigma_x = \frac{1}{2}C_x^2(ut)^{2-n} \qquad [15.19.3]$$

Similar equations apply relating σ_y to C_y and σ_z to C_z.

The relation between the Pasquill–Gifford dispersion coefficients and the turbulent exchange coefficients is

$$\sigma_x^2 = 2K_x t \qquad [15.19.4]$$

Similar equations apply relating σ_y to $K_{\hat{y}}$ and σ_z to K_z.

The Pasquill parameters are related to the Pasquill–Gifford dispersion coefficients as follows:

$$\sigma_y = \sigma_\theta x \qquad [15.19.5]$$

with

$$\sigma_\theta = \frac{\theta}{4.3} \qquad [15.19.6]$$

and

$$\sigma_z = \frac{h}{2.15} \qquad [15.19.7]$$

The constants 4.3 and 2.15 in Equations 15.19.6 and 15.19.7 are the values derived from the Gaussian distribution corresponding to the cloud boundary as defined by convention.

The physical meaning of the dispersion coefficient may be interpreted as follows. For diffusion through a vertical plane in the x direction, the dispersion variance σ_x^2 is the second moment of the concentration with respect to distance x, normalized with respect to concentration:

$$\sigma_x^2 = \frac{\int_{-\infty}^{\infty}\chi^{x^2}\,\mathrm{d}x}{\int_{-\infty}^{\infty}\chi\,\mathrm{d}x} \qquad [15.19.8]$$

Similar expressions apply to σ_y and σ_z.

Following Csanady (1973), consider the one-dimensional diffusion of a mass Q^*_{ps} of material (kg/m^2) initially concentrated in a thin sheet at $x = 0$, in an instantaneous plane source. Then the diffusion is given by the relationship

$$\frac{\partial\chi}{\partial t} = K_x \frac{\partial^2\chi}{\partial x^2} \qquad [15.19.9a]$$

The mass released is

$$Q^*_{\mathrm{ps}} = \int_{-\infty}^{\infty} \chi \mathrm{d}x \qquad [15.19.9b]$$

and the solution is

$$\chi = \frac{Q^*_{\mathrm{ps}}}{2(\pi K_x t)^{1/2}} \exp\left(\frac{-x^2}{4K_x t}\right) \qquad [15.19.9c]$$

Furthermore, it may be shown that

$$Q^*_{\mathrm{ps}} = \frac{1}{2K_x t}\int_{-\infty}^{\infty} \chi x^2 \mathrm{d}x \qquad [15.19.10]$$

Hence from Equations 15.19.8, 15.19.9b and 15.19.10

$$\sigma_x = (2K_x t)^{1/2} \qquad [15.19.11]$$

Moving on, if the exponential form of the autocorrelation coefficient $R(\tau)$ given in Equation 15.12.101 is used in Taylor's theorem as given in Equation 15.12.107, the solution obtained is

$$\sigma_x^2 = 2\sigma_u^2 t_{\mathrm{L}}^2 \left[\frac{t}{t_{\mathrm{L}}} - 1 + \exp\left(-\frac{t}{t_{\mathrm{L}}}\right)\right] \qquad [15.19.12]$$

where t_{L} is the Lagrangian time scale.

Then for a short time t ($t \to 0$)

$$\sigma_x \propto t \qquad [15.19.13a]$$

while for a long time ($t \to \infty$)

$$\sigma_x \propto t^{1/2} \qquad [15.19.13b]$$

Since the distance x is proportional to the time t ($x = ut$), at short times

$$\sigma_x \propto x \qquad [15.19.14]$$

Similar relations apply for σ_y and σ_z.

The dispersion coefficients may be related to the standard deviations of the wind velocity (σ_{v}, α_{w}) as follows:

$$\sigma_y = \sigma_{\mathrm{v}} t f_1(t/T_y) \qquad [15.19.15a]$$

$$\sigma_z = \sigma_{\mathrm{w}} t f_2(t/T_z) \qquad [15.19.15b]$$

where f_1 and f_2 are universal functions and T_y and T_z are the time scales (s) for lateral and vertical dispersion, respectively. But

$$\sigma_{\mathrm{v}} t \approx \sigma_\theta x \qquad [15.19.16a]$$

$$\sigma_{\mathrm{w}} t \approx \sigma_\phi x \qquad [15.19.16b]$$

Hence from Equations 15.19.15 and 15.19.16

$$\sigma_y = \sigma_\theta x f_1(t/T_y) \qquad [15.19.17a]$$

$$\sigma_z = \sigma_\phi x f_2(t/T_z) \qquad [15.19.17b]$$

The universal functions f_1 and f_2 may be derived from theoretical considerations or expressed as empirical correlations. Pasquill (1976a) has tabulated values of f_1, which is taken as independent of stability and source height and as a function of distance only. Irwin (1979a) has correlated these values as follows:

$$f_1 = \left(1 + 0.031x^{0.46}\right)^{-1} \quad x \le 10^4 \qquad [15.19.18a]$$

$$= 33x^{-1/2} \quad x > 10^4 \qquad [15.19.18b]$$

Correlations for both f_1 and f_2 have been given by Draxler (1976). He obtains for f_1 the relation

$$f_1 = \frac{1}{[1 + 0.9(t/T_{\mathrm{i}})]^{1/2}} \qquad [15.19.19]$$

where T_{i} is the dispersion time. He states that the function f_2 may be assumed equal to f_1 except for a ground level source in unstable conditions and an elevated source in stable conditions. For the former case it was difficult to obtain a correlation, but for a limited set of data

$$f_2 = \frac{0.3(t/T_{\mathrm{i}} - 0.4)^2}{0.16} + 0.7 \qquad [15.19.20a]$$

For the latter case he obtained

$$f_2 = \frac{1}{1 + 0.945(t/T_{\mathrm{i}})^{0.806}} \qquad [15.19.20b]$$

The dispersion time T_{i} is the time for f_1, or f_2, to become equal to 0.5. Draxler gives the following values for T_{i} (in seconds)

Source height	*Horizontal dispersion*		*Vertical dispersion*	
	Stable	*Unstable*	*Stable*	*Unstable*
Ground level	300	300	50	100
Elevated	1000	1000	100	500

A further discussion of these universal functions is given by Gryning *et al.* (1987).

15.19.2 Sutton diffusion parameters

Sutton's original values for the diffusion parameters C_y and C_z have been given in Section 15.16. Values have also been given by other workers as shown in Table 15.32.

15.19.3 Pasquill cloud parameters

Pasquill's original values for the cloud parameters θ and h have been given in Section 15.16.

For a long release where wind direction traces are not available, Beattie (1963 UKAEA AHSB(S) R64) has suggested the use of the following values for θ:

$d = 0.1$ km, $\theta = 30°$
$d = 100$ km, $\theta = 15°$

Table 15.32 *Sutton diffusion parameters*

A Values given by N.G. Stewart, Gale and Crooks (1958)
Source height: 68 cm

Downwind distance (m)	*Stability condition*	C_y	C_z
150–1000	Unstable		0.27
	Neutral		0.22
	Stable		0.12
590–620	Unstable, neutral	0.46	
880–1050	Unstable, neutral	0.28	
1200	Unstable, neutral	0.33	
2400–2800	Unstable, neutral	0.26	
6000–9700	Unstable, neutral	0.18	

B Values of Brookhaven National Laboratory (after Slade, 1968)[a]
Source height: Elevated and ground level sources

Wind gustiness Category	*n*	C_y	C_z
B2	0.15	0.48	0.50
B1	0.26	0.44	0.38
C	0.48	0.54	0.32
D	0.57	0.41	< 0.08

C Values of Barad and Fuquay (1962)

Stability condition	*Wind speed* (m/s)	*n*	C_y	C_z
Source height: elevated				
Unstable	1	0.20	0.30	0.30
	5		0.26	0.26
	10		0.24	0.24
Neutral	1	0.25	0.15	0.15
	5		0.12	0.12
	10		0.11	0.11
Source height: ground level				
Unstable	1	0.20	0.35	0.35
	5		0.30	0.30
	10		0.28	0.28
Neutral	1	0.25	0.21	0.17
	5		0.15	0.14
	10		0.14	0.13

D Values of V.J. Clancey (1974a)

Stability condition	*n*	*C*
Lapse	0.17	0.2
Neutral	0.25	0.14
Inversion	0.35	0.09

E Values of Long (1963)

Stability condition	*n*	C_y ($m^{n/2}$)	C_z ($m^{n/2}$)
Large lapse	1/5	0.37	0.21
Neutral	1/4	0.21	0.12
Moderate inversion	1/3	0.13	0.08
Large inversion	1/2	0.11	0.06

[a] A slightly different set of values are given by Gifford (1976b).

These values of θ are based on neutral weather conditions with Pasquill stability category D and relatively invariant wind direction, but are also applicable to stable weather conditions with Pasquill stability category F if the wind direction is variable. The values quoted are three times greater than those given by Pasquill for a short release in stability category F conditions, as shown in Table 15.29. The difference may be regarded as allowing for the variability of wind direction which tends to apply to this type of weather. If, however, the wind direction is invariant, then the lower values given in Table 15.29 for stability category F should be used.

15.19.4 Pasquill–Gifford dispersion coefficients

The dispersion coefficients most often used with the Pasquill–Gifford model are probably those of D.B. Turner (1970), as given in Section 15.16. There are, however, several other sets.

Correlations of the dispersion coefficients in terms of the Brookhaven National Laboratory (BNL) stability categories have been given by Singer and Smith (1966) as shown in Table 15.33 and in Figure 15.58.

Correlations have also been given by Carpenter *et al.* (1971) of the Tennessee Valley Authority (TVA) in terms of temperature gradient categories as shown in Figure 15.59.

BNL gustiness class	*Dispersion coefficient* (m)	
	σ_y	σ_z
B2	$0.40x^{0.91}$	$0.41x^{0.91}$
B1	$0.36x^{0.86}$	$0.33x^{0.86}$
C	$0.32x^{0.78}$	$0.22x^{0.78}$
D	$0.31x^{0.71}$	$0.06x^{0.71}$

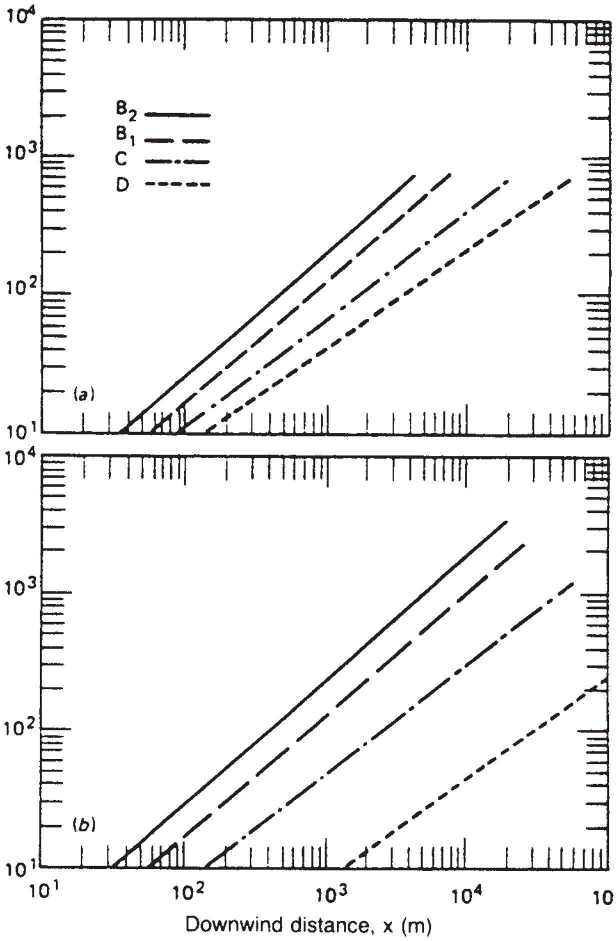

***Figure 15.58** Meteorological parameters for Pasquill–Gifford equations for continuous source: dispersion coefficients based on BNL scheme (Gifford, 1976b; after Singer and Smith, 1966) (Courtesy of Nuclear Safety)*

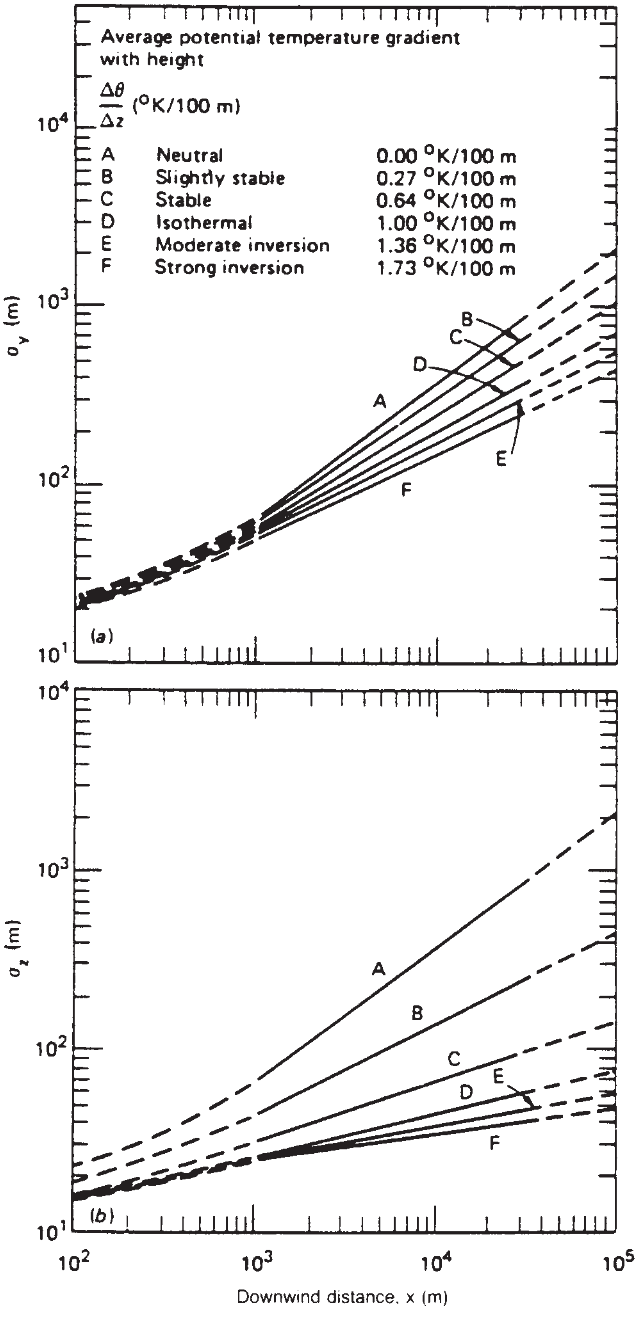

***Figure 15.59** Meteorological parameters for Pasquill–Gifford equations for continuous source: dispersion coefficients based on TVA scheme (Gifford, 1976b; after Carpenter et al., 1971 (Courtesy of Nuclear Safety)*

It can be seen from comparison of Figure 15.54 and Figures 15.58 and 15.59 that the correlations for the dispersion coefficients differ. An attempt to resolve these differences has been made by G.A. Briggs (1974). His work has been summarized by Gifford (1976b).

The Pasquill–Gifford curves are based on experiments on dispersion of non-buoyant gas over flat ground up to a downwind distance of 800 m. The BNL curves are for dispersion of a non-buoyant plume from an elevated stack (108 m) out to a distance of several kilometres with few measurements taken within 800 m. The TVA curves are for dispersion of a buoyant plume with stack heights of 75–250 m, and with effective stack heights at least twice these values, and to a distance of up to some tens of kilometres. The dispersion of this latter type of plume is a function more of buoyancy and entrainment effects than of atmospheric turbulence.

Briggs therefore proposed a set of interpolation formulae with properties conformable to these three sets of results. They would agree with the Pasquill–Gifford curves for downwind distances over the range 100–10,000 m except that for A and B stability classes and for σ_z 100, the σ_z curves would be based on the values given by the American Society of Mechanical Engineers (ASME) (1968/1), which reflect mainly BNL data. The BNL and TVA curves agree reasonably well with each other, except at short distances where the latter are influenced by buoyancy; they also agree reasonably well with the Pasquill–Gifford curves at about 10 km, except for the A and B conditions, as just described.

Briggs' formulae are shown in Table 15.34 and curves given by Hosker (1974b) based on these are shown in Figure 15.60. The formulae are applicable up to 10 km.

15.19.6 Pasquill–Gifford dispersion coefficients: NRPB scheme

A scheme for the estimation of the Pasquill–Gifford dispersion coefficients based on F.B. Smith's *P* stability classification and his correlation of the vertical coefficient σ_z and on allowance for plume meandering for the horizontal dispersion σ_y has been developed at the National Radiological Protection Board (NRPB), as described by Clarke (1979 NRPB R91).

Following F.B. Smith (1973), the vertical dispersion coefficient σ_z is a function of the distance, the *P* class and the roughness length z_o. The value of σ_z is obtained from Figures 15.61–15.63. Figure 15.61 gives σ_z as a function of distance for $P = 3.6$ and $z_o = 0.1$ m. Figure 15.62 gives the correction for other *P* values at the same value of z_o. Figure 15.63 gives the correction for other values of z_o for all *P* values.

D	$0.08x(1+0.0001x)^{-1/2}$	$0.06x(1+0.0015x)^{-1/2}$
E	$0.06x(1+0.0001x)^{-1/2}$	$0.03x(1+0.003x)^{-1}$
F	$0.04x(1+0.0001x)^{-1/2}$	$0.016x(1+0.0003x)^{-1}$

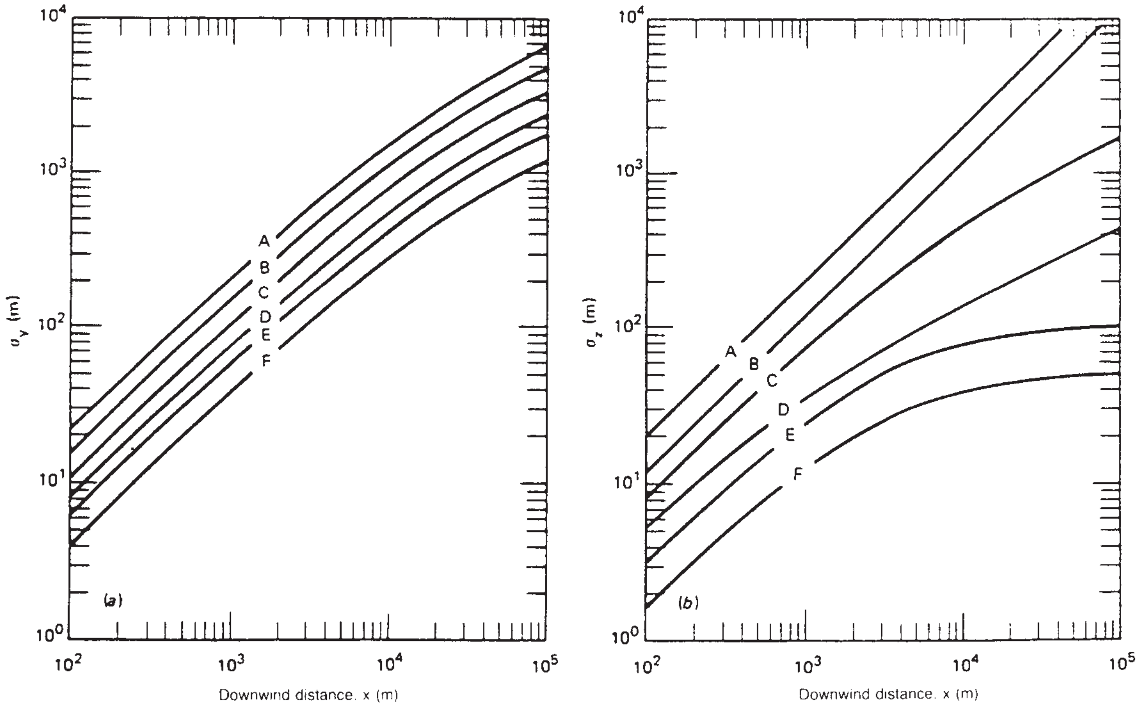

Figure 15.60 *Meteorological parameters for Pasquill–Gifford equations for continuous source: dispersion coefficients based on Briggs' interpolation formulae for open country (Gifford, 1976b; after Hosker, 1974b) (Courtesy of Nuclear Safety)*

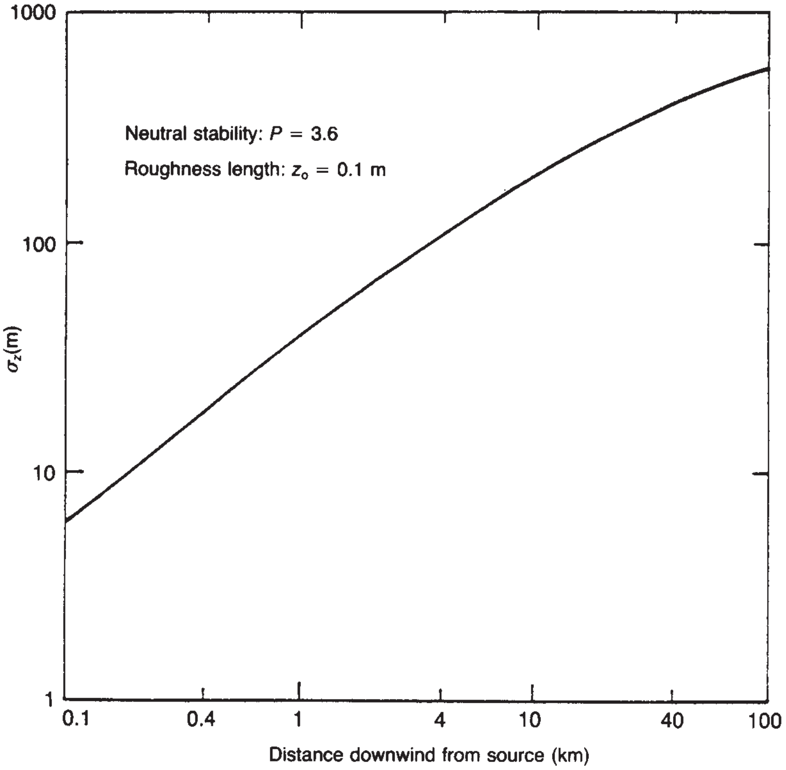

Figure 15.61 *Meteorological parameters for Pasquill–Gifford equations for continuous source: dispersion coefficients based on NRPB scheme (Clarke, 1979 NRPB R-91): vertical dispersion coefficient σ_z for stability parameter $P = 3.6$ and surface roughness $z_0 = 0,1$ m*

Formulae for σ_z for the discrete Pasquill classes, or P values, and for discrete values of z_0 have been given by Hosker (1974b). These are

$$\sigma_z = \frac{ax^b}{1 + cx^d} F(z_0, x) \qquad [15.19.21]$$

with

$$F(z_0, x) = \ln\left\{fx^g\left[1 + \left(hx^j\right)^{-1}\right]\right\} \qquad z_0 \geq 0.1 \qquad [15.19.22a]$$

$$= \ln\left[fx^g\left(1 + hx^j\right)^{-1}\right] \qquad z_0 < 0.1 \qquad [15.19.22b]$$

where $F(z_0, x)$ is the roughness length correction factor and a–j are constants or indices. Values of the constants and indices for use in Equations 15.19.21 and 15.19.22 are given in Table 15.35.

Figure 15.64 shows the values of σ_z given by Smith's scheme for roughness length $z_0 = 0.1$ m.

For the horizontal dispersion coefficient σ_y the regular Pasquill–Gifford values, which apply for very short releases, typically of 3 min duration, are used for releases of up to 30 min duration. For longer releases, account is taken of meandering using the relation

$$\sigma_y^2 = \sigma_{yt}^2 + \sigma_{yw}^2 \qquad [15.19.23]$$

where σ_{yt} is the turbulent diffusion (or 3 min) term and σ_{yw} is the term due to fluctuations in wind direction.

The values used for σ_{yt} are the regular Pasquill–Gifford values. For σ_{yw} two relations are given. If the standard deviation of the horizontal wind direction σ_θ is known, use is made of the equation

$$\sigma_{yw} = \sigma_\theta x \qquad [15.19.24a]$$

and if it is not, the equation used is

$$\sigma_{yw} = 0.065\left(\frac{7T}{u_{10}}\right)^{1/2} x \qquad [15.19.24b]$$

where T is the duration of the release (h), x is the downwind distance (m), u_{10} is the wind speed at 10 m height (m/s) and σ_θ is the horizontal standard deviation of the wind direction averaged over 3 min periods and sampled over the duration of the release (rad).

15.19.7 Pasquill–Gifford dispersion coefficients: other correlations

Various authors have given for the Pasquill–Gifford coefficients power law formulae of the form

$$\sigma_y = ax^b \qquad [15.19.25a]$$

$$\sigma_z = cx^d \qquad [15.19.25b]$$

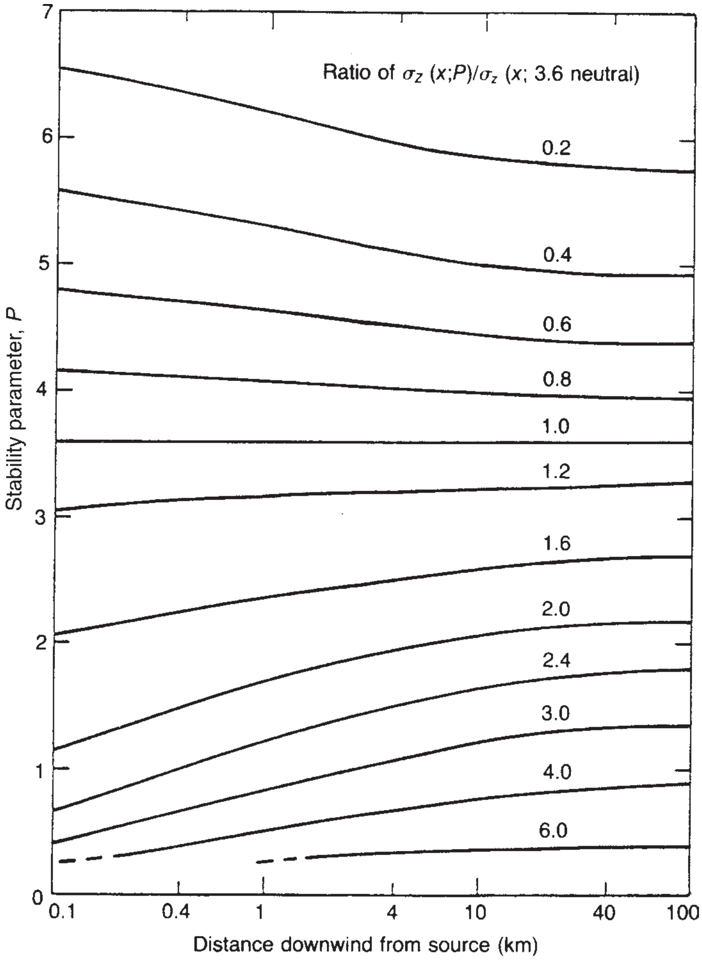

Figure 15.62 *Meteorological parameters for Pasquill–Gifford equations for continuous source: dispersion coefficients based on NRPB scheme (Clarke, 1979 NRPB R91): correction factor to vertical dispersion coefficient σ_z for stability parameter P*

Many of the Pasquill–Gifford curves given in Figures 15.54 and 15.58–15.60 clearly cannot be fitted over their whole range by such formulae, but provided they are used over the range of their validity such equations have their use in making it possible to obtain analytical solutions to dispersion problems.

R.W. McMullen (1975) has given the following formulae for both dispersion coefficients:

$$\sigma = \exp\left[a + b \ \ln x + c(\ln x)^2\right] \qquad [15.19.26]$$

where σ may be either σ_y or σ_z. The values of the constants a–c are given in Table 15.36.

15.19.8 Dispersion coefficients for urban areas

Work on dispersion coefficients for use in the Pasquill–Gifford model over and in urban areas has been described by a number of workers, including D.B. Turner (1964), Bowne, Ball and Anderson (1968), Bowne and Ball (1970) and Bowne (1974), McElroy and Pooler (1968), McElroy (1969) and Yersel, Goble and Morrill (1983). In general, dispersion over or within an urban area is greater than over a flat rural area. Mechanical turbulence is enhanced by the increase surface roughness and thermal turbulence by the heat island effect.

Summaries of experimental work on dispersion over urban areas have been given by Gifford (1972, 1976a,b). The experimental work of McElroy and Pooler (1968) over St Louis has provided dispersion data. These data have been used by Pasquill (1970) to compare dispersion over urban and rural terrains. Further data have been analysed by W.B. Johnson *et al.* (1971). On the basis of this work, G.A. Briggs (1974) has proposed relations for the dispersion coefficients. Table 15.37 gives information on the vertical dispersion coefficient σ_z and Table 15.38 gives

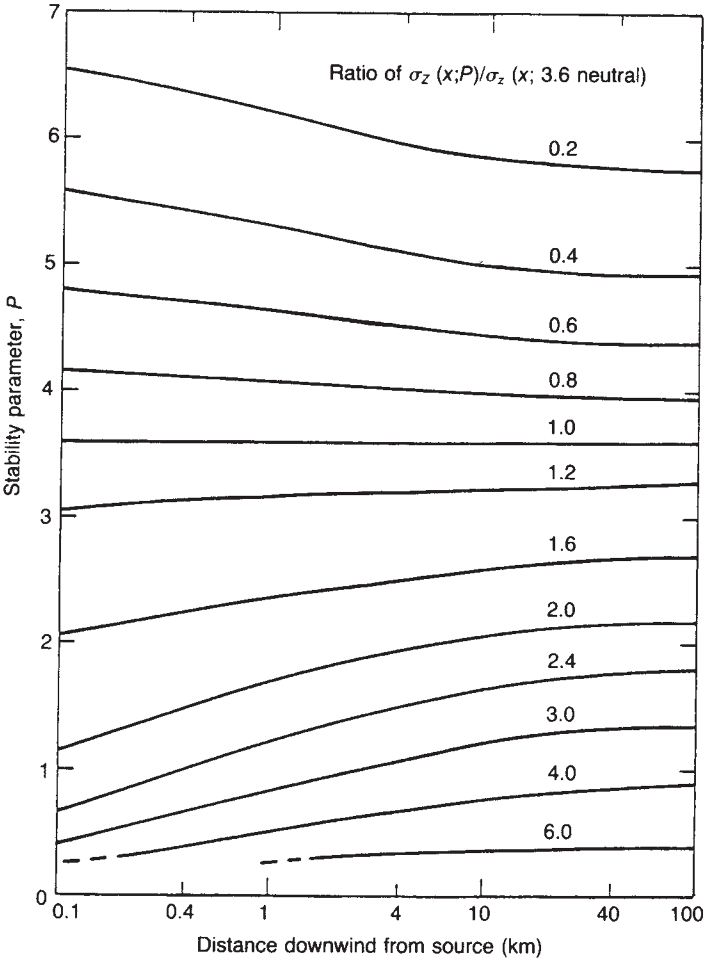

Figure 15.63 *Meteorological parameters for Pasquill–Gifford equations for continuous source: dispersion coefficients based on NRPB scheme (Clarke, 1979 NRPB R91): correction factor to vertical dispersion coefficient σ_z for surface roughness z_0*

the Briggs' formulae for both the horizontal and the vertical dispersion coefficients σ_y and σ_z. Figure 15.65 shows graphs obtained by Hosker from Briggs' equations.

Experimental work on dispersion over short distances within an urban area at Worcester, Massachusetts, has been conducted by Yersel, Goble and Morrill (1983). They carried out releases in a parking lot, with the nearest building 40 m away, and measured the concentration at distances up to 600 m. Their results for σ_y and σ_z are shown in Figure 15.66. For σ_y the values for stability class B are well described by the regular Pasquill–Gifford curves for class A, a shift of one class, while for classes C and D the values are best described by a shift of two classes. For σ_z, however, the data differ significantly in magnitude and slope and around 200 m are substantially higher than even the class A curve.

15.19.9 Dispersion coefficients for coastal areas and water

A number of authors have described work on dispersion coefficients for the Pasquill–Gifford model for coastal areas and water, including Kondo (1975), Gifford (1976a,b), Lyons (1976), S.R. Hanna, Paine and Schulman (1984), Hasse and Weber (1985), Larsen and Gryning (1986) and Skupniewicz and Schacher (1986). In general, dispersion over water tends to be less than over land but, as described above, this generalization needs heavy qualification.

The surface roughness of the sea may be characterized by a roughness length, but waves do not behave as simple roughness elements. This problem is discussed by Gifford (1976a,b).

In order to use the Pasquill–Gifford model it is necessary to define the stability classes. The Pasquill classes over land are not necessarily applicable without

Table 15.35 *Pasquill–Gifford dispersion coefficients: Hester's formulae (Hosker, 1974b) (Courtesy of International Atomic Energy Agency)*

A Vertical dispersion coefficient

Stability class	*a*	*b*	*c*	*d*
A	0.112	1.06	5.38×10^{-4}	0.815
B	0.130	0.950	6.52×10^{-4}	0.750
C	0.112	0.920	9.05×10^{-4}	0.718
D	0.098	0.889	1.35×10^{-3}	0.688
E	0.0609	0.895	1.96×10^{-3}	0.684
F	0.0638	0.783	1.36×10^{-3}	0.672

B Roughness length correction factor

Roughness length (m)	*f*	*g*	*h*	*i*
0.01	1.56	0.0480	6.25×10^{-4}	0.45
0.04	2.02	0.0269	7.76×10^{-4}	0.37
0.1	2.72	0	0	0
0.4	5.16	−0.098	18.6	−0.225
1.0	7.37	−0.0957	4.29×10^{3}	−0.60
4.0	11.7	−0.128	4.59×10^{4}	−0.78

modification over sea. The definition of suitable classes for use over sea was discussed in Section 15.12.

Empirical correlations for the Pasquill–Gifford dispersion coefficients for use over water have been given by Skupniewicz and Schacher (1986) in terms of the NFS stability classification. The relations are

$$\sigma_y = \sigma_y(R)\left(\frac{x}{R}\right)^{\alpha} \qquad [15.19.27a]$$

$$\sigma_z = \sigma_z(R)\left(\frac{x}{R}\right)^{\beta} \qquad [15.19.27b]$$

where $\sigma_y(R)$ and $\sigma_z(R)$ are the values of σ_y and σ_z at the reference distance R (= 100 m), and α and β are indices. Values of σ_y and σ_z at 100 m and of the indices α and β are given in Table 15.39.

These equations are empirical correlations. The data for σ_y exhibit considerable scatter. The authors state that stability classification can reasonably be used to characterize σ_z but not σ_y.

An alternative treatment for the estimation of dispersion coefficients for use over water based on the AMS Workshop scheme has been given by S.R. Hanna, Paine and Schulman (1984).

15.19.10 Dispersion coefficients for complex terrain

Dispersion coefficients for complex terrain are discussed by Egan (1976). In general, dispersion over complex terrain tends to give complex dispersion patterns. The overall effect is generally to increase dispersion, but, as described below, there are two features that may lead to local high concentrations.

There tends to be enhancement of both the dispersion coefficients, but the crosswind dispersion coefficient σ_y is enhanced more than is the vertical dispersion coefficient σ_z. This is often attributed mainly to plume meandering and splitting. For a ground level source the implication is that the ground level centre line concentration will be less than for flat terrain.

For an elevated source the situation is not quite so straightforward. The Pasquill–Gifford Equation 15.16.55 for the maximum ground level concentration for a release from an elevated continuous point source shows that, if there is an increase in the ratio σ_z/σ_y, this maximum concentration increases. Therefore, in principle, if σ_z increases and there is no compensating increase in σ_y, there will be an increase in the maximum ground level concentration and a decrease in the distance at which this occurs. The other feature that can give rise to a high local concentration is a stagnant pocket.

15.19.11 Effect of sampling period

As described above, if the concentration in a plume is sampled virtually instantaneously, the concentration distribution has a relatively narrow spread, while if the sample is taken over a longer time period the distribution has a wider spread. It follows that the dispersion coefficients are a function of the sampling period. The following relation has been proposed by Gifford (1976a) to take account of this variation:

$$\frac{\sigma_y}{\sigma_{yr}} = \left(\frac{t}{t_r}\right)^{p} \qquad [15.19.28]$$

where t is the sampling period which yields dispersion coefficient σ_y, p is an index, and subscript r denotes the reference value. The value of p is approximately 0.2 for sampling periods between 3 min and 1 h and in the range 0.25–0.3 for periods between 1 and 100 h.

Gifford states that similar considerations apply to σ_z, except that the effect of variations in σ_z should not extend beyond downwind distances of a few kilometres.

The regular Pasquill–Gifford curves correspond to a sampling period of about 10 min.

15.19.12 Puff dispersion coefficients

For a puff, the size of eddy that mainly influences dispersion lies within a limited range, approximately 1/3 to 3 times the size of the puff. A smaller eddy effects little dispersion, while a larger one moves the whole cloud.

Relations for a puff dispersion coefficient σ have been derived by Batchelor (1952) from similarity considerations. It can be shown that

$$\sigma^2 = \sigma_o^2 + c_1(\epsilon\sigma_o)^{2/3}t^2 \quad \text{short times} \qquad [15.19.29a]$$

$$= c_2\epsilon t^3 \quad \text{intermediate times} \qquad [15.19.29b]$$

$$= c_3 t \quad \text{long times} \qquad [15.19.29c]$$

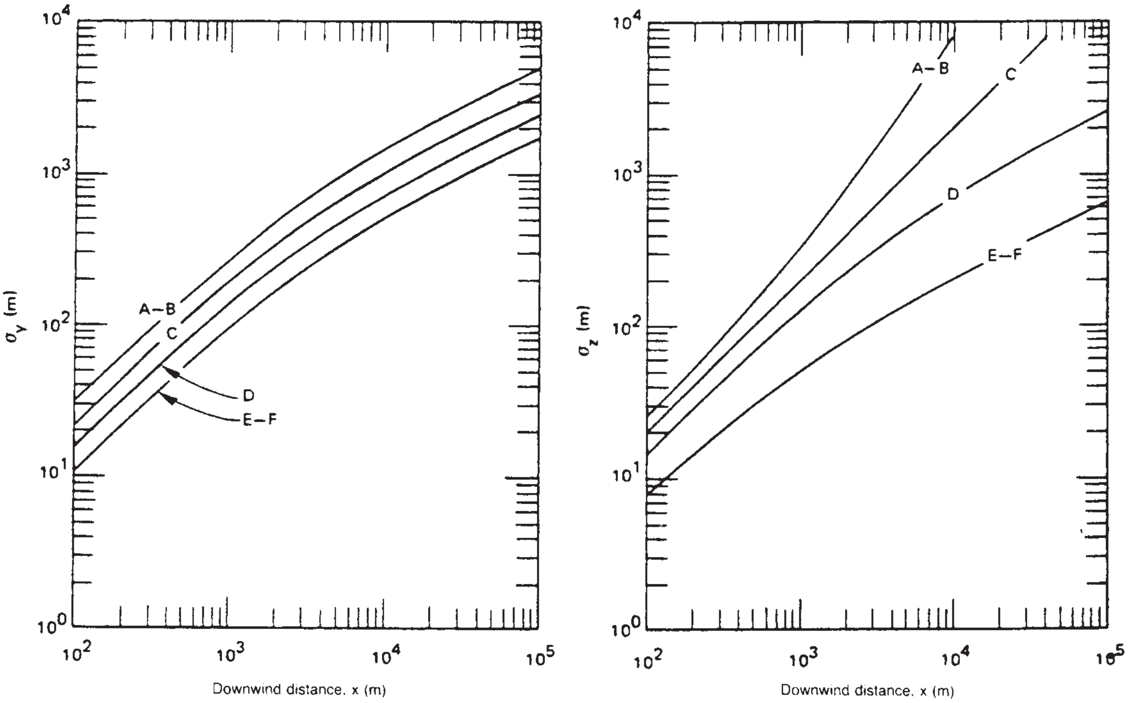

***Figure 15.65** Meteorological parameters for Pasquill–Gifford equations for continuous source: dispersion coefficients based on Briggs' interpolation formulae for urban areas (Gifford, 1976b; after Hosker, 1974b) (Courtesy of Nuclear Safety)*

[a] Over land values are those given by DTIC (1980).
[b] Insufficient data for verification.

where ε is the eddy dissipation rate, σ_0 is the initial size of the cloud, and c_1, c_2 and c_3 are constants.

The constant c_2 is generally found to lie in the range 0.5–2 and is often taken as unity.

Then, from Equation 15.19.29,

$$\sigma \propto t \quad \text{short times} \qquad [15.19.30]$$

$$\propto t^{3/2} \quad \text{intermediate times} \qquad [15.19.30b]$$

$$\propto t^{1/2} \quad \text{long times} \qquad [15.19.30c]$$

Also at long times

$$\sigma^2_{\text{puff}} \rightarrow \sigma^2_{\text{plume}} \quad t \rightarrow 0 \qquad [15.19.31]$$

Here short times may be interpreted as a few seconds and long times as greater than 10^4 s. Generally it is the intermediate times that are of most interest. The number of data sets available on which to base estimates of the puff dispersion is very much less than for plume dispersion. Work on puff dispersion coefficients has been described by Islitzer and Slade (1968), who give the (σ_y and σ_z values shown in Table 15.31.

A somewhat different variation of the puff dispersion coefficients with distance, or time, is suggested by the work of Gifford (1977). One of his plots showing experimental data on the relation between σ_y and t is given in Figure 15.67. For times up to about 10^4 s the data give a reasonably good fit to relation 15.19.30b for intermediate times.

A method of estimating the dispersion coefficients based on Equation 15.19.29 has been given by S.R. Hanna, Briggs and Hosker (1982). For σ_y, Equation 15.19.29b is used up to a travel time of 10^4 s, the eddy dissipation rate ϵ being initially determined locally and then, as σ_y approaches $0.3z_i$ where z_i is the mixed layer height, at a height midway in the boundary layer. At a travel time equal to 10^4 s, the constant c_3 in Equation 15.19.29c is evaluated by equating the values of σ_y obtained from Equations 15.19.29b and 15.19.29c, and thereafter Equation 15.19.29c is used with this value of c_3. For σ_z, a similar procedure is used, except that once σ_z attains a value of $0.3z_i$ that value is used for all times thereafter.

15.19.13 Turbulent exchange coefficients

The foregoing account of dispersion parameters has concentrated mainly on those for the Pasquill–Gifford model.

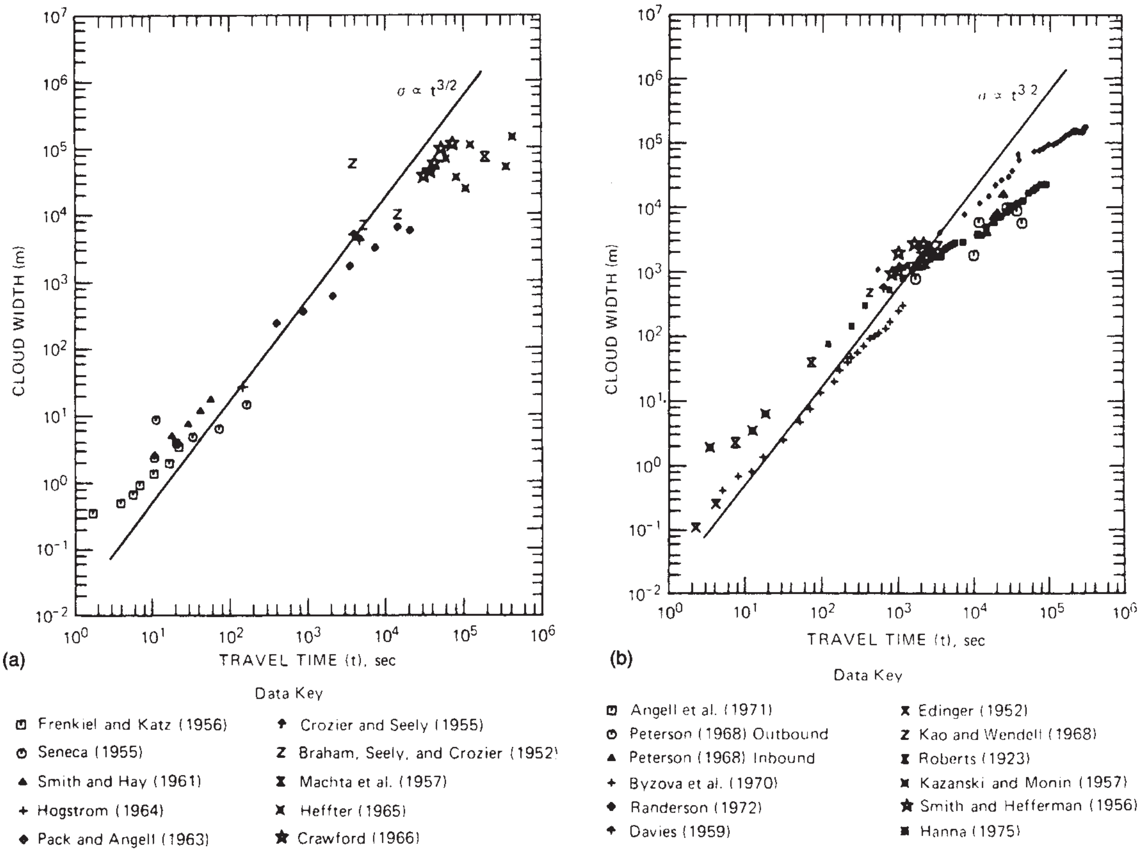

Figure 15.67 *Meteorological parameters for Pasquill–Gifford equations for instantaneous source: dispersion coefficient σ (Gifford, 1977): (a) selection of original data of Crawford (1966); (b) collection of subsequent data by Gifford. The references quoted are those given by Gifford and do not all appear in this text*

The turbulent exchange coefficients *K* used in *K*-theory models have been discussed in Section 15.12. Accounts of *K*-theory models commonly include a discussion of the estimation of the *K* values used in the models.

15.20 Dispersion of Jets and Plumes

The dispersion of material issuing as a leak from a plant is determined by its momentum and buoyancy. If momentum forces predominate, the fluid forms a jet, while if buoyancy forces predominate, it forms a plume. Such dispersion contrasts with the dispersion by atmospheric turbulence considered so far. However, once the momentum or buoyancy decay dispersion by atmospheric turbulence becomes the predominant factor for leaks also.

Emission situations were classified in Section 15.1. In respect of jets and plumes the following distinctions may be made:

(1) Fluid
  (a) gas,
  (b) liquid,
  (c) two-phase vapour–liquid mixture;
(2) Fluid momentum
  (a) low momentum,
  (b) high momentum;
(3) Fluid buoyancy
  (a) positive buoyancy,
  (b) neutral buoyancy,
  (c) negative buoyancy;
(4) Atmospheric conditions
  (a) low turbulence,
  (b) high turbulence.

If the momentum of the material issuing from an orifice on a plant is high, the dispersion in the initial phase at least is due to the momentum, and the emission is described as a momentum jet. If the momentum is low, either because the initial momentum is low or because it has decayed, the dispersion is due to buoyancy and atmospheric turbulence, and, if buoyancy is involved, the emission is described as a buoyant plume: the buoyancy may be positive or negative.

An account is now given of dispersion by momentum jets and buoyant plumes. Both types of emission are sometimes described as plumes, the jet being a forced plume. The forces in a buoyant plume are often of the same order as those in a momentum jet. Selected references on jets and plumes are given in Table 15.40. Some jet and plume dispersion situations are illustrated in Figure 15.68. The figure shows schematically instances of releases issuing as jets and becoming plumes as the influence of buoyancy takes over from that of momentum.

15.20.2 Gas jets

The behaviour of a circular, or conical, turbulent momentum gas jet has been studied by Ricou and Spalding (1961), Long (1963) and Cude (1974b).

Long summarizes the empirical features of such a jet. The characteristics that he enumerates include the following. The jet is conical and apparently diverges from a virtual point source upstream of the orifice; dilution occurs by turbulent mixing; the time–mean velocity and time–concentration profiles are similar after 10 diameters and are approximately Gaussian; the concentration profile is wider than the velocity profile; the jet entrains air, but conserves its momentum, so that the momentum flux at any plane normal to the axis is constant.

Models of a momentum jet have been given by Ricou and Spalding, Long and Cude. The following treatment is based on these models, particularly that of Long. A momentum

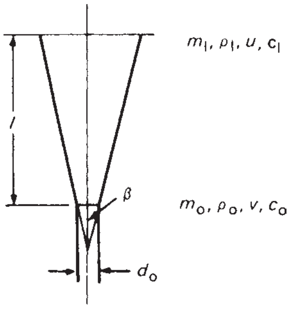

Figure 15.69 *Momentum jet*

jet is shown schematically in Figure 15.69. For such a jet the mass discharge flow is

$$m_\mathrm{o} = \frac{\pi}{4} d_\mathrm{o}^2 p_\mathrm{o} u_\mathrm{o} \qquad [15.20.1]$$

the mass balance is

$$m_x = \frac{\pi}{4}(2x \tan\beta) 2\rho_x u \qquad [15.20.2]$$

and the momentum balance is

$$\frac{m_x}{m_\mathrm{o}} = \frac{u_\mathrm{o}}{u} \qquad [15.20.3]$$

where d_o is the diameter of the outlet, m is the mass flow, u is the velocity of the gas, x is the axial distance from the outlet, β is the half-angle of the jet, ρ is the density of the gas and subscripts o and x denote the orifice and the mean value axial distance x, respectively. Then from Equations 15.20.1–15.20.3 the mass flow ratio is

$$\frac{m_x}{m_\mathrm{o}} = k_1 \frac{x}{d_\mathrm{o}} \left(\frac{\rho_x}{\rho_\mathrm{o}}\right)^{1/2} \qquad [15.20.4]$$

with

$$k_1 = 2\tan\beta \qquad [15.20.5]$$

In modelling a gas jet, it is necessary to distinguish for velocity u at distance x between the mean value (u_x), the value on the axis ($u_{x\mathrm{o}}$) and the value at radial distance r (u_{xr}). A similar notation is used for concentration c and density η From Equation 15.20.4 the velocity ratio is

$$\frac{u_x}{u_\mathrm{o}} = \frac{1}{k_1}\left(\frac{x}{d_\mathrm{o}}\right)^{-1}\left(\frac{\rho_x}{\rho_\mathrm{o}}\right)^{-1/2} \qquad [15.20.6]$$

The mean volumetric concentration is inversely proportional to the volumetric flow of the gas–air mixture and hence

$$\frac{c_x}{c_\mathrm{o}} = \frac{1}{k_1}\left(\frac{x}{d_\mathrm{o}}\right)^{-1}\left(\frac{\rho_x}{\rho_\mathrm{o}}\right)^{1/2} \qquad [15.20.7]$$

where c is the volumetric concentration. Long proposes for the constant k_1 the value of 0.32 obtained by Ricou and Spalding.

If a Gaussian radial concentration profile is assumed, Equation 15.20.7 may be rewritten as

$$\frac{c_{xr}}{c_\mathrm{o}} = k_2\left(\frac{x}{d_\mathrm{o}}\right)^{-1}\left(\frac{\rho_{x\mathrm{o}}}{\rho_\mathrm{o}}\right)^{1/2} \exp\left[-\left(\frac{k_3 r}{x}\right)^2\right] \qquad [15.20.8]$$

where k_2 and k_3 are constants.

From the work of a number of experimenters Long proposes for constants k_2 and k_3 values of 6 and 5, respectively. The density $\eta_{x\mathrm{o}}$ is not readily calculated, but it is frequently set equal to the density of air (e.g. Cude, 1974b). The point is discussed by Gugan (1976).

The length of the jet may be obtained by combining Equations 15.20.3 and 15.20.4 to give

$$\frac{x}{d_\mathrm{o}} = \frac{u_\mathrm{o}}{k_1 u_x}\left(\frac{\rho_x}{\rho_\mathrm{o}}\right)^{-1/2} \qquad [15.20.9]$$

The end of the jet is usually defined (e.g. Cude, 1974b) as the point at which the jet velocity u_x equals the wind speed w. Then

$$\frac{x_\mathrm{tr}}{d_\mathrm{o}} = \frac{u_\mathrm{o}}{k_1 w}\left(\frac{\rho_x}{\rho_\mathrm{o}}\right)^{-1/2} \qquad [15.20.10]$$

where x_tr is the length of the jet at the transition point and w is the wind speed. For the purpose of determining this transition in relatively still air, the wind speed is generally taken as 2 m/s.

As already mentioned, the axial gas concentration $c_{x\mathrm{o}}$ is found to be twice the mean gas concentration c_x:

$$c_{x\mathrm{o}} = 2c_x \qquad [15.20.11]$$

The minimum discharge velocity of the jet to obtain a safe value c_s of the concentration $c_{x\mathrm{o}}$ may be obtained by combining Equations 15.20.7, 15.20.9 and 15.20.11 and so that

$$\frac{u_\mathrm{o}}{u} = \frac{2c_\mathrm{o}\rho_{x\mathrm{o}}}{c_{x\mathrm{o}}\rho_\mathrm{o}} \qquad [15.20.12]$$

The behaviour of the momentum jet was studied experimentally by Ricou and Spalding (1961). In addition to air, they also used hydrogen, propane and carbon dioxide. As already mentioned, they obtained for the constant k_1 the value of 0.32. They verified Equation 15.20.4 up to 418 diameters. These authors also discuss the ratio of the widths of the concentration and velocity profiles and make the assumption that this has a value of 1.17.

In their theoretical analysis they point out that another feature of the momentum jet is that at high Reynolds number and uniform fluid density and at a distance along the axis that is large compared with the outlet diameter the mass flow m of entrained air is proportional to the axial distance x. They give the relations

$$\frac{\mathrm{d}m}{\mathrm{d}x} = k(M\rho_\mathrm{a})^{1/2} \qquad [15.20.13a]$$

$$\frac{m}{x} = k(M\rho_\mathrm{a})^{1/2} \qquad [15.20.13b]$$

with

$$M = M_o = \frac{\pi}{4} d_o^2 \rho_o u_o^2 \qquad [15.20.14]$$

where M is momentum flux and k is a constant. They give for k a value of 0.282.

For work on jets, Mecklenburgh (1985) introduces the air/fuel mass ratio θ. For this ratio

$$\theta = \left(\frac{1}{c_x} - 1\right)\frac{\rho_a}{\rho_x} \qquad [15.20.15]$$

$$u = \frac{u_o}{1+\theta} \qquad [15.20.16]$$

A set of equations for velocity ratio u_{xo}/u_o and the concentration ratio c_{xo}/c_o for circular and planar jets has been given by C.J. Chen and Rodi (1980). These are, for a circular jet

$$\frac{u_{xo}}{u_o} = 6.2\left(\frac{x}{d_o}\right)^{-1}\left(\frac{\rho_o}{\rho_a}\right)^{1/2} \qquad [15.20.17]$$

$$\frac{c_{xo}}{c_o} = 5\left(\frac{x}{d_o}\right)^{-1}\left(\frac{\rho_o}{\rho_a}\right)^{1/2} \qquad [15.20.18]$$

and for a planar jet

$$\frac{u_{cl}}{u_o} = 2.4\left(\frac{x}{d}\right)^{-1/2}\left(\frac{\rho_o}{\rho_a}\right)^{1/2} \qquad [15.20.19]$$

$$\frac{c_{cl}}{c_o} = 2\left(\frac{x}{d}\right)^{-1/2}\left(\frac{\rho_o}{\rho_a}\right)^{-1/2} \qquad [15.20.20]$$

where d is the width of the slot and the subscript cl denotes the centre line.

A set of equations for the velocity ratio u_m/u_o only for circular, planar and radial jets for air has been given by Rajaratnam (1976). These are, for a circular jet

$$\frac{u_m}{u_o} = 6.3\left(\frac{x}{d_o}\right)^{-1} \qquad [15.20.21]$$

for a planar jet

$$\frac{u_m}{u_o} = 3.5\left(\frac{x}{b_o}\right)^{-1} \qquad [15.20.22]$$

and for a radial jet

$$\frac{u_m}{u_o} = 3.5\frac{r_p}{b_o}\left(\frac{r}{b_o}\right)^{-1} \qquad [15.20.23]$$

where b_o is the half-width of the slot (for a planar or radial jet), r is the radial distance, r_p is the radius of the pipe or flange in which the outlet exists and the subscript m denotes the centre line, and hence the maximum.

Hess, Leuckel and Stoeckl (1973) have given relations for both subsonic and sonic gas jets. For the subsonic flow the condition is

$$\frac{P_v}{P_a} < \left(\frac{\gamma+1}{2}\right)^{\gamma/(\gamma+1)} \qquad [15.20.24]$$

At the exit plane after isentropic expansion

$$P_E = P_a \qquad [15.20.25]$$

$$T_E = T_v\left(\frac{P_a}{P_v}\right)^{(\gamma-1)/\gamma} \qquad [15.20.26]$$

$$\rho_E = \rho_v\left(\frac{P_a}{P_v}\right)^{1/\gamma} \qquad [15.20.27]$$

$$u_E = \left\{\frac{2\gamma}{\gamma-1}RT_v\left[1-\left(\frac{P_a}{P_v}\right)^{(\gamma-1)/\gamma}\right]\right\} \qquad [15.20.28]$$

where P is the absolute pressure, R is the universal gas constant, T is the absolute temperature, γ is the ratio of the gas specific heats, and subscripts a, E and v denote atmospheric conditions, exit conditions and vessel conditions, respectively.

Some illustrative calculations on momentum jets have been given by Cude (1974b), Gugan (1976) and Mecklenburgh (1985).

15.20.3 Gas jets: sonic jets

The models just given apply to a gas jet with subsonic flow. A different treatment is necessary for sonic flow conditions. Models for underexpanded sonic jets have been reviewed by Ramskill (1985 SRD R302). The structure of an underexpanded sonic jet is shown in Figure 15.70.

As already mentioned, Hess, Leuckel and Stoeckl (1973) have also given a treatment for circular jets with sonic flow. For sonic flow the condition is

$$\frac{P_v}{P_a} \geq \left(\frac{\gamma+1}{2}\right)^{\gamma/(\gamma-1)} \qquad [15.20.29]$$

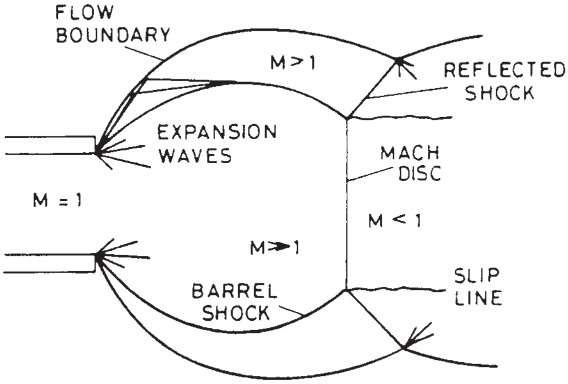

Figure 15.70 Underexpanded momentum jet (Ewan and Moodie, 1986). M, Mach number (Reproduced by permission of Gordon and Breach Science Publishers, ©)

At the exit plane, after isentropic expansion $P_E > P_a$, and the conditions are:

$$P_E = P_v\left(\frac{2}{\gamma+1}\right)^{\gamma/(\gamma-1)} \quad [15.20.30]$$

$$T_E = T_v\left(\frac{2}{\gamma+1}\right) \quad [15.20.31]$$

$$\rho_E = \rho_v\left(\frac{2}{\gamma+1}\right)^{\gamma/(\gamma-1)} \quad [15.20.32]$$

$$u_E = \left(\frac{2\gamma}{\gamma+1}RT_v\right)^{1/2} \quad [15.20.33]$$

At the shock plane downstream of the exit, Hess, Leuckel and Stoeckl define an equivalent diameter:

$$D_s = \frac{2M_s}{(\pi\rho_s M_s u_s)^{1/2}} \quad [15.20.34]$$

where D is the diameter, M is the mass flow and subscript s denotes the shock plane.

It has been shown by Ramskill that the equivalent diameter may also be expressed as

$$D_s = D_N\left[\left(\frac{P_v}{P_a}\right)^{(\gamma-1)/\gamma}\right]^{1/2} \quad [15.20.35]$$

where subscript N denotes the nozzle.

The term 'equivalent diameter' is generally used in work on underexpanded jets and is used here also. It should not be confused with the equivalent diameter used to relate non-circular to circular orifices and ducts.

For the velocity at this plane it is assumed that all the excess pressure goes to increase the momentum of the jet:

$$u_s = u_E + \frac{P_E - P_a}{\rho_E u_E} \quad [15.20.36]$$

Also

$$\rho_s = \frac{\rho_E u_E D_N^2}{u_s D_s^2} \quad [15.20.37]$$

Another model based on the apparent diameter is that given in the TNO *Yellow Book* (1979). The equations of this model are as follows. In the model use is made of gas densities normalized with respect to the density of air, these densities being denoted by a prime. The radial velocity and concentration are expressed as

$$\frac{u_{xy}}{u_m} = \exp(-b_1 b_3^2) \quad [15.20.38]$$

$$\frac{j_{xy}}{j_m} = \exp(-b_2 b_3^2) \quad [15.20.39]$$

with

$$b_3 = y/x'' \quad [15.20.40]$$

$$x'' = x + x' \quad [15.20.41]$$

where j is the volumetric concentration of the gas, u is the velocity of the gas, x is the axial distance from the outlet, x' is the distance between the virtual source and the outlet, y is the radial distance, b_1 and b_2 are constants, b_3 is defined by Equation 15.20.40 and subscript m denotes the centre line, and hence maximum, and subscript xy denotes point (x, y).

The following relations are given for the constants b_1 and b_2

$$b_1 = 50.5 + 48.2\rho'_{ga} - 9.95(\rho'_{ga})^2 \quad [15.20.42]$$

$$b_2 = 23 + 41\rho'_{ga} \quad [15.20.43]$$

where ρ'_{ga} is the normalized density of the gas at atmospheric conditions.

The equivalent diameter d_{eq} is defined as

$$d_{eq} = d_o\left(\frac{\rho'_{go}}{\rho'_{oeq}}\right)^{1/2} \quad [15.20.44]$$

where ρ'_{go} is the normalized density of the gas at the outlet and ρ'_{oeq} is the normalized density of the gas at the equivalent diameter. The velocity ratio is

$$\frac{u_m}{u_o} = \frac{b_1}{4}\left(\frac{d_{eq}}{x''}\right)^2\left[0.32\frac{x}{d_{eq}}\frac{\rho'_{ga}}{\left(\rho'_{oeq}\right)^{1/2}} + 1 - \rho'_{ga}\right]\frac{\rho'_{oeq}}{\rho'_{ga}} \quad [15.20.45]$$

and the concentration ratio is

$$\frac{j_m}{j_o} = \frac{(b_1 + b_2)/b_1}{0.32\ (x/d_{eq})(\rho'_{ga}/\rho'_{oeq}) + 1 - \rho'_{ga}} \quad [15.20.46]$$

Ewan and Moodie (1986) have given a treatment of underexpanded sonic jets based on the work of Kleinstein (1964). For fully expanded supersonic jets Kleinstein obtained the relation

$$\frac{u_m}{u_n} = 1 - \exp\left[\frac{1}{k(\rho_a/\rho_e)^{1/2}(z/r_n) - x_c}\right] \quad [15.20.47]$$

where k is a compressible eddy coefficient, r_n is the equivalent radius, u is the velocity of the gas, x_c is a dimensionless core length, z is the distance along the axis from the outlet and subscripts e, m and n denote the exit, the maximum and the nozzle, respectively.

They also quote the following equation given by Warren (1957) and based on a different analysis for the radial variation of velocity in fully developed flow

$$\frac{u}{u_m} = \exp\left\{-\ln\left[2\left(\frac{r}{r_{0.5}}\right)^2\right]\right\} \quad [15.20.48]$$

where $r_{0.5}$ is the radius at which the velocity is half the centre line value.

Ewan and Moodie have adapted the Kleinstein model to an underexpanded jet by introducing the equivalent diameter. For the expansion

$$N = \frac{P_{\mathrm{v}}}{P_{\mathrm{a}}} \qquad [15.20.49]$$

$$P_{\mathrm{e}} = P_{\mathrm{v}}\left(\frac{2}{\gamma + 1}\right)^{\gamma/(\gamma-1)} \qquad [15.20.50]$$

$$\rho_{\mathrm{e}} = \rho_{\mathrm{v}}\left(\frac{2}{\gamma + 1}\right)^{1/(\gamma-1)} \qquad [15.20.51]$$

$$\rho_{\mathrm{eq}} = \rho_{\mathrm{e}}\left(\frac{P_{\mathrm{a}}}{P_{\mathrm{e}}}\right) \qquad [15.20.52]$$

where N is the ratio of the vessel pressure to atmospheric pressure and subscripts eq and v denote equivalent and vessel, respectively. Equivalent conditions are based on the sonic jet at ambient pressure, nozzle exit temperature and nozzle mass flow. They obtain for the velocity ratio

$$\frac{u_{\mathrm{m}}}{u_{\mathrm{n}}} = 1 - \exp\left[\frac{1}{k\left(\rho_{\mathrm{a}}/\rho_{\mathrm{eq}}\right)^{1/2}(z^*/r_{\mathrm{eq}}) - x_{\mathrm{c}}}\right] \qquad [15.20.53]$$

with

$$k = 0.08(1 - 0.16\,\mathrm{Ma}) \qquad [15.20.54]$$

$$z^* = z - 2z_{\mathrm{b}} \qquad [15.20.55]$$

$$z_{\mathrm{b}} = 0.77\,d_{\mathrm{n}} + 0.068\,d_{\mathrm{n}}^{1.35}N \qquad [15.20.56]$$

where d is the diameter, Ma is the Mach number, z_{b}, is the barrel length and z^* is the modified axial distance. The unit of length in Equations 15.20.55 and 15.20.56 is millimetres.

The equivalent diameter d_{eq} is derived as follows. For continuity

$$\rho_{\mathrm{e}}u_{\mathrm{n}}A_{\mathrm{e}} = \rho_{\mathrm{eq}}u_{\mathrm{eq}}A_{\mathrm{eq}} \qquad [15.20.57]$$

where A is the cross-sectional area of flow. But

$$\rho u = \frac{Pu}{RT} \qquad [15.20.58a]$$

$$= \frac{Pu}{(\gamma RT)^{1/2}}\left(\frac{\gamma}{RT}\right)^{1/2} \qquad [15.20.58b]$$

$$= P\,\mathrm{Ma}\left(\frac{\gamma}{R}\right)^{1/2}\frac{1}{T^{1/2}} \qquad [15.20.58c]$$

Then from Equation 15.20.57

$$\frac{\rho_{\mathrm{e}}u_{\mathrm{n}}}{\rho_{\mathrm{eq}}u_{\mathrm{eq}}} = \frac{A_{\mathrm{eq}}}{A_{\mathrm{e}}} = \frac{P_{\mathrm{e}}}{P_{\mathrm{a}}} \qquad [15.20.59]$$

Hence

$$d_{\mathrm{eq}} = d_{\mathrm{n}}\left(\frac{P_{\mathrm{e}}}{P_{\mathrm{a}}}\right)^{1/2} \qquad [15.20.60]$$

In calculating the equivalent diameter the authors apply to the flow a discharge coefficient C_{D} so that Equation 15.20.60 becomes

$$d_{\mathrm{eq}} = d_{\mathrm{n}}\left(\frac{C_{\mathrm{D}}P_{\mathrm{e}}}{P_{\mathrm{a}}}\right)^{1/2} \qquad [15.20.61]$$

They quote the value of C_{D} of 0.85 assumed by Birch *et al.* (1984). For the concentration ratio they obtain

$$\frac{m_{\mathrm{cl}}}{m_{\mathrm{e}}} = 1 - \exp\left[\frac{1}{k'\left(\rho_{\mathrm{a}}/\rho_{\mathrm{eq}}\right)^{1/2}(z^*/r_{\mathrm{eq}}) - x_{\mathrm{c}}}\right] \qquad [15.20.62]$$

where k' is another eddy viscosity coefficient and m is the mass fraction. The constant k' has the value 0.104.

15.20.4 Liquid jets

It is also necessary to consider liquid jets. The 'throw' of a liquid jet can be quite large. Such a jet may reach beyond the limit of the area classification zone or may jump over a bund.

The simplest treatment of a liquid jet is based on the assumption that the jet suffers no drag and does not disintegrate. For a jet at ground level, as shown in Figure 15.71(a) the motion in the horizontal direction is given by

$$\frac{\mathrm{d}x}{\mathrm{d}t} = u\cos\alpha \qquad [15.20.63]$$

where t is time, u is the horizontal velocity of the liquid, x is the horizontal distance and α is the angle between the jet and the horizontal. At $t = 0$, $x = 0$ and hence

$$x = ut\cos\alpha \qquad [15.20.64]$$

For motion in the vertical direction

$$\frac{\mathrm{d}^2z}{\mathrm{d}t^2} = -g \qquad [15.20.65]$$

Integrating Equation 15.20.65 gives

$$\frac{\mathrm{d}z}{\mathrm{d}t} = -gt + c \qquad [15.20.66]$$

where g is the acceleration due to gravity, z is the vertical distance and c is a constant of integration. At $t = 0$, $\mathrm{d}z/\mathrm{d}t = u\sin\alpha$ and hence

$$\frac{\mathrm{d}z}{\mathrm{d}t} = u\sin\alpha - gt \qquad [15.20.67]$$

At $t = 0$, $z = 0$ and hence

$$z = ut\sin\alpha - \frac{1}{2}gt^2 \qquad [15.20.68]$$

The jet returns to the ground at $t = t$, $z = 0$ and hence

$$t = \frac{2u\sin\alpha}{g} \qquad [15.20.69]$$

Then from Equations 15.20.64 and 15.20.69 the horizontal distance travelled is

$$x = \frac{u^2\sin^2\alpha}{g} \qquad [15.20.70]$$

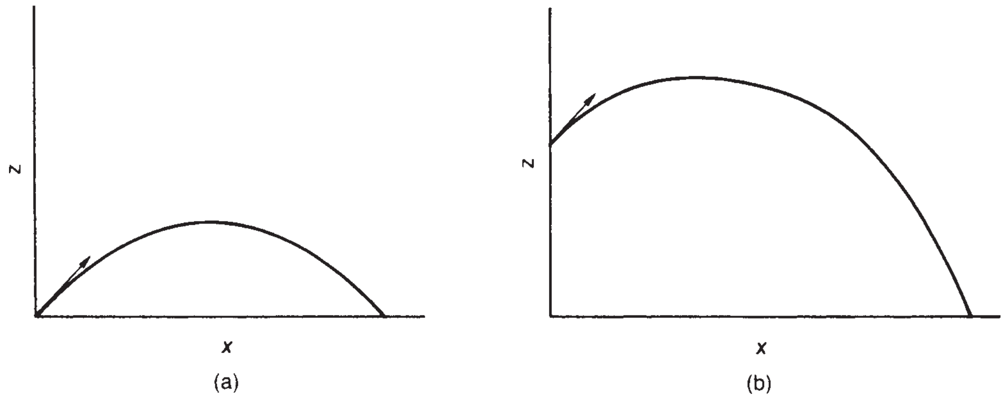

Figure 15.71 *Travel range of a liquid jet, neglecting air resistance and break up: (a) jet from ground level source; (b) jet from elevated source*

The maximum distance of travel $x_{\max}$ occurs at $\alpha = 45°$ and is

$$x_{\max} = \frac{u^2}{g} \qquad [15.20.71]$$

where the subscript max denotes maximum.

For an elevated jet, as shown in Figure 15.71(b), the jet returns to the ground at $t = t$, $z = -l$ and, following the same approach, it may be shown that

$$x = \frac{u^2}{g}\left\{\frac{\sin 2\alpha}{2} + \left[\left(\frac{\sin 2\alpha}{2}\right)^2 + \frac{2\,lg\cos 2\alpha}{u^2}\right]^{1/2}\right\} \qquad [15.20.72]$$

where l is the height above the ground of the outlet and z is the vertical distance above the outlet. Equation 15.20.72 reduces to Equation 15.20.70 for $l = 0$.

For a horizontal elevated jet the following simple treatment is applicable.

$$x = ut \qquad [15.20.73]$$

$$l = \frac{1}{2}gt^2 \qquad [15.20.74]$$

From Equations 15.20.73 and [15.20.74]

$$x = u\left(\frac{2l}{g}\right)^{1/2} \qquad [15.20.75]$$

Equation 15.20.72 reduces to Equation 15.20.75 for $\alpha = 0$.

In practice, the travel distance of the liquid jet will be less than that predicted by the expressions just given, because the jet is subject to air resistance and to disintegration. It is often assumed that the actual travel distance is halved by these factors.

A treatment that takes air resistance into account is as follows. It is assumed that the resistance is proportional to the velocity. Then for motion in the horizontal direction

$$\frac{d^2x}{dt^2} = -k\frac{dx}{dt} \qquad [15.20.76]$$

Following the same approach as previously, it can be shown

$$x = \frac{u\cos\alpha}{k}[1 - \exp(-kt)] \qquad [15.20.77]$$

with

$$t = \frac{(ku\sin\alpha + g)[1 - \exp(-kt)]}{kg} \qquad [15.20.78]$$

where k is a constant representing air resistance.

The disintegration of a liquid jet under air resistance has been studied by a number of workers including Rayleigh (1932), van de Sande and Smith (1976) and Engh and Larsen (1979). The following treatment is based on the work of the latter.

The disintegration of a jet is determined by the Weber number We, which gives the ratio of the momentum to the surface tension forces. The Weber number is

$$\mathrm{We} = \frac{\rho u^2 d}{2\sigma} \qquad [15.20.79]$$

where d is the diameter of the jet, u is the velocity of the jet and σ is the surface tension.

The propagation of a disturbance in a liquid jet leading to its break up was studied by Lord Raleigh. In his model the amplitude δ of a surface disturbance of initial amplitude δ_o increases exponentially with time t:

$$\delta = \delta_o \exp(\alpha t) \qquad [15.20.80]$$

where α is a constant. When the amplitude δ of the disturbance is equal to the jet radius a, disintegration into drops begins. Drops are therefore formed at time

$$t = \ln(a/\delta_o)/\alpha \qquad [15.20.81]$$

Then the break-up length Z is

$$Z = ut \qquad [15.20.82]$$

$$= u\ln(a/\delta_o)/\alpha \qquad [15.20.83]$$

From this starting point Engh and Larsen derive the following expression for break-up length:

$$\frac{Z}{d} = 1.03\ln(a/\delta_o)(2\mathrm{We})^{1/2} \quad [15.20.84]$$

For an inviscid jet it has been found that

$$\ln(a/\delta_o) \approx 12 \quad [15.20.85a]$$

Other values of the term $\ln(a/\delta_o)$ have been given by various workers.

Engh and Larsen conducted experiments on water and molten steel. They state that the term $\ln(a/\delta_o)$ decreases with increasing length/diameter (l/d) ratio of the nozzle, tending for $l/d \geq 13$ to a value

$$\ln(a/\delta_o) \approx 4 \quad [15.20.85b]$$

They also state that for water their results give

$$\frac{z}{d} \approx 100 \quad [15.20.86]$$

The relations for jet travel and for jet disintegration depend on different parameters, but for many cases of practical interest the jet will start to disintegrate within a short distance of the orifice.

15.20.5 Two-phase jets

Work on two-phase jets includes that by R. Brown and York (1962), Bushnell and Gooderum (1968), Hetsroni and Sokolov (1971), Gyarmathy (1976), Suzuki *et al.* (1978), Melville and Bray (1979a,b), Koestel, Gido and Lamkin (1980), and Tomasko, Weigand and Thompson (1981a,b). A review has been given by Appleton (1984 SRD R303). Two-phase jets may be classified as non-flashing or flashing.

A liquid jet in air tends to disintegrate. Break up may occur due either to air resistance or to vapour bubble formation. The break up of a non-flashing jet due to air resistance was considered in the previous section.

A two-phase non-flashing jet consists of a gas flow with entrained droplets. Characteristics of interest are: for the gas phase, the centre line and the radial velocities; and for the liquid phase, the radial mass flux of the droplets. Relations for these may be found in the work of Hetsroni and Sokolov (1971) and Melville and Bray (1979a,b).

It is two-phase flashing jets, however, which are of prime interest here. An account of such jets is given in Section 15.21.

15.20.6 Plumes

The principal types of jet and plume that occur are illustrated in Figure 15.72. Figure 15.72(a) shows a non-buoyant jet, or pure jet, or simply a jet. Figure 15.72(b) shows a pure plume with no momentum. This figure, therefore, shows as the source not a discharge orifice, but a heated surface. Figure 15.72(c) shows a buoyant plume, with some initial momentum, or forced plume. Figure 15.72(d) shows a negatively buoyant plume.

Accounts of plumes are given in *Plume Rise* (G.A. Briggs, 1969), *Vertical Turbulent Buoyant Jets* (C.J. Chen and Rodi, 1980) and *Handbook on Atmospheric Diffusion* (S.R. Hanna, Briggs and Hosker, 1982). Work on plumes includes that by O.G. Sutton (1950), Yih (1951), Rouse, Yih and Humphreys (1952), B.R. Morton (1959, 1961), Long (1963), Schmidt (1965), J.S. Turner (1966), G.A. Briggs (1965, 1968, 1976), Ooms (1972), Cude (1974a,b), Ooms, Mahieu and Zelis (1974), Davidson and Slawson (1982) and Frick (1984).

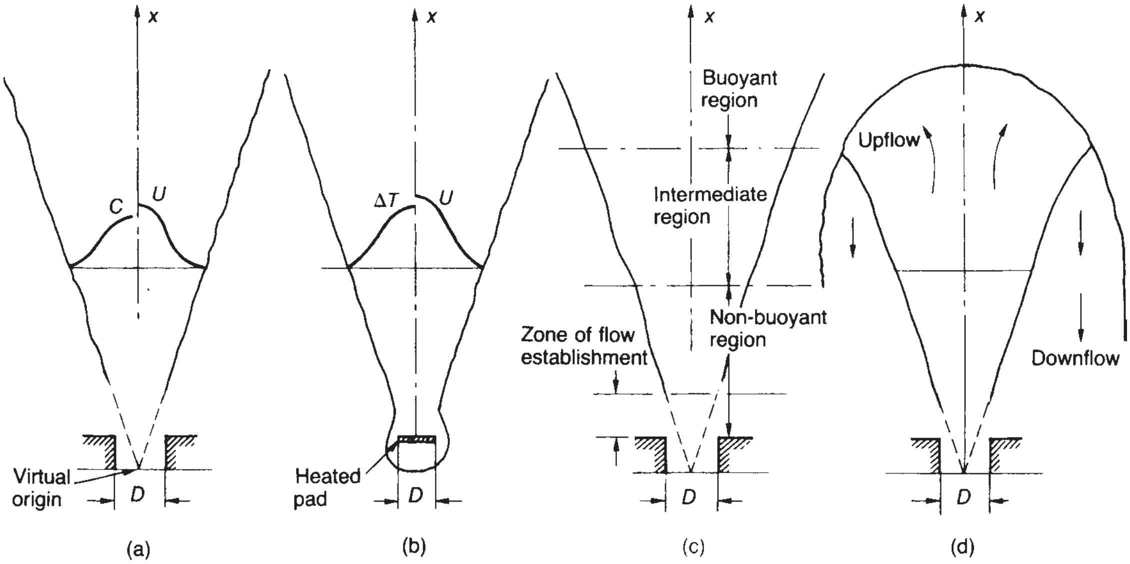

Figure 15.72 Principal types of jet and plume (after C.J. Chen and Rodi, 1980): (a) pure, non-buoyant jet; (b) pure plume; (c) buoyant jet (forced plume); (d) negatively buoyant jet

Most models of plumes deal with the case of an initial jet in which the momentum decays so that the emission undergoes transition to a buoyant plume. Much of the work on plumes relates to elevated emissions from stacks and is concerned primarily with pollution rather than with hazards. Fundamental quantities in models of dispersion of forced and buoyant plumes are the momentum and buoyancy fluxes.

The momentum flux at the outlet orifice is

$$M_o = \pi r_o^2 \rho_o u_o^2 \qquad [15.20.87]$$

where M is the momentum flux, r_o the radius of the outlet, u is the velocity of the gas, ρ is the density and subscript o denotes the outlet. The buoyancy flux at the outlet is

$$F_o = \pi r_o^2 g(\rho_a - \rho_o)u_o \qquad [15.20.88]$$

where F is the buoyancy flux and subscript a denotes air.

Use is frequently made of momentum and buoyancy fluxes which are normalized with respect to density, for example,

$$M_o = \pi r_o^2 \frac{\rho_o}{\rho_a} u_o^2 \qquad [15.20.89]$$

$$F_o = \pi r_o^2 g \frac{\rho_a - \rho_o}{\rho_a} u_o \qquad [15.20.90]$$

This then gives for momentum and buoyancy the SI units m^4/s^2 and m^4/s^3, respectively. In addition, π is sometimes omitted from the definitions of momentum and buoyancy.

In expressions for buoyancy flux, use is sometimes made of the relation

$$\frac{\rho_a - \rho}{\rho_r} = \beta(T - T_a) \qquad [15.20.91]$$

where β is the coefficient of cubical expansion ($\approx 1/T_r$) and subscript r denotes the reference.

The measure of the ratio of the momentum forces to the buoyancy forces is given by the Froude number Fr. The Froude number is defined as

$$\mathrm{Fr} = \frac{u}{(gl)^{1/2}} \qquad [15.20.92]$$

where l is a characteristic length.

In the context of plumes, the Froude number is more usually defined as

$$\mathrm{Fr} = \frac{u}{(gd_o(\rho_a - \rho_o/\rho_a))^{1/2}} \qquad [15.20.93]$$

where d_o is the diameter of the outlet.

Use is also sometimes made of the following Froude group (e.g. C.J. Chen and Rodi, 1980):

$$\mathrm{Fr} = \frac{u^3}{gd_o((\rho_a - \rho_o)/\rho_a)} \qquad [15.20.94]$$

In some definitions of the Froude number the divisor of the term $\rho_a - \rho_o$ is ρ_o rather than ρ_a. The Froude number is a criterion for the transition from momentum control to buoyancy control.

Some principal characteristics of a plume have been described by Long (1963). He summarizes the empirical features of a buoyant plume as follows. Under turbulent conditions the plume is conical and apparently diverges from an equivalent point source, the position of the point source depending on the point of transition from laminary to turbulent flow; the time–mean velocity and time–concentration profiles are similar and are approximately Gaussian.

Under adiabatic conditions buoyancy is conserved within the plume and the buoyancy flux remains constant with distance. The momentum flux therefore increases with distance. For the distance within which turbulence sets in for a pure plume Long gives the following relation based on the work of Yih (1951) on plumes from cigarettes:

$$x_{lt} = \left(\frac{\mu^3}{\rho_a^2 Q \Delta\rho_o g}\right)^{1/2} \times 10^5 \qquad [15.20.95]$$

where Q is the volumetric flow, x_{lt} is the distance for transition from laminar to turbulent flow, μ is the viscosity and Δ is the density difference. For most plumes of practical interest this transition distance is very short.

For the concentration ratio and radial distribution of a plume, Long gives:

$$\frac{c_{xr}}{c_o} = k_4 \left(\frac{Q^2 \rho_a}{\Delta\rho_o g x^5}\right)^{1/3} \exp\left[\left(\frac{k_5 r}{x}\right)^2\right] \qquad [15.20.96]$$

where c is the volumetric concentration, r is the radial distance, k_4 and k_5 are constants, and subscript xr denotes at the axial distance x and radial distance r.

Long suggests that, from the work of Yih, the time mean values of the constants k_4 and k_5 may be taken as 11 and 8.4, respectively.

For a forced plume with both momentum and buoyancy, Long proposes as the criterion of transition from momentum to buoyancy control the following modified Froude number:

$$\mathrm{Fr} = \frac{\rho_o^{3/2} u_o^2}{\rho_a^{1/2} \Delta\rho_o g d_o} \qquad [15.20.97]$$

He obtains an approximate value for the transition point by equating Equations 15.20.8 and 15.20.9. Then the transition point occurs at 2.4$\mathrm{Fr}^{1/2}$ diameters from the source. This criterion is confirmed by the work of Ricou and Spalding (1961) in that the point of equal entrainment in the jet and plume regimes occurs at 2.3 $\mathrm{Fr}^{1/2}$ diameters. The jet persists at least to 0.5 $\mathrm{Fr}^{1/2}$ diameters and the plume is fully developed beyond 3 $\mathrm{Fr}^{1/2}$ diameters.

With the exception of last point, the treatment just given applies to a pure plume in a still atmosphere. In many practical applications the case to be considered is more complex. The emission may have both momentum and buoyancy, starting off as a jet and undergoing transition to a plume. The plume may be affected by the various weather conditions. In addition, the plume may have heavy gas characteristics requiring special treatment.

15.20.7 Plumes in atmospheric turbulence

A different situation occurs where a higher wind speed results in atmospheric turbulence. If conditions are such that the discharge momentum and buoyancy effects are negligible relative to atmospheric turbulent diffusion, the dispersion may be estimated using the methods described in Section 15.10 such as the Sutton and Pasquill–Gifford models.

Using the Sutton model, Long (1963) gives the following equations for an elevated vent, derived from Equation 15.16.2(c) The full equation is

$$\chi(x,y,z) = \frac{Q}{\pi C_y C_z u x^{2-n}} \exp\left(-\frac{y^2}{C_y^2 x^{2-n}}\right) \times \left[\exp\left(-\frac{z^2}{C_z^2 x^{2-n}}\right) + \exp\left(-\frac{(z+2h)}{C_z^2 x^{2-n}}\right)^2\right] \qquad [15.20.98a]$$

and that for the axial concentration at ground level ($y = z = 0$)

$$\chi(x,0,0) = \frac{Q}{\pi C_y C_z u x^{2-n}}\left[1 + \exp\left(\frac{4h^2}{C_z^2 x^{2-n}}\right)\right] \qquad [15.20.98b]$$

where x, y and z are the downwind, crosswind and vertical distances, C is the diffusion parameter, h is the height of the outlet, Q is the volumetric flow from the outlet, u is the wind speed, χ is the concentration, n is the diffusion index and subscripts x and y denote downwind and crosswind, respectively. The origin of the coordinates in Equation 15.20.98, but in this equation only, is the outlet of the vent. The maximum ground level concentration χ_{mgl} is

$$\chi_{\text{mgl}} = 0.234\frac{Q}{uh^2}\frac{C_z}{C_y} \qquad [15.20.99]$$

The distance χ_{mgl} from the source at which the maximum ground level concentration occurs is

$$\chi_{\text{mgl}} = \left(\frac{h^2}{C_z^2}\right)^{1/(2-n)} \qquad [15.20.100]$$

Values of the index n and of the generalized diffusion parameters C_y and C_z for the first 10 m above ground are given by Long as follows:

Stability condition	n	C_y ($\text{m}^{n/2}$)	C_z ($\text{m}^{n/2}$)
Large lapse rate	1/5	0.37	0.21
Neutral condition	1/4	0.21	0.12
Moderate inversion	1/3	0.13	0.08
Large inversion	1/2	0.11	0.06

The Sutton equation (15.20.98) was not originally intended for use over the very short distances involved in vent calculations, and its use demands some justification. This point has been discussed by Long, who concludes that the use of the equation is justified. A further discussion of this aspect is given in Section 15.48.

15.20.8 Plumes with negative buoyancy

In many practical situations the emission of interest is that of a dense gas. Plumes with negative buoyancy are therefore of particular interest. A study of a plume with negative buoyancy has been made by J.S. Turner (1966). He carried out experiments in which a dense liquid was injected into a less dense one. The flow pattern obtained is illustrated in Figure 15.72(d).

For this case Turner obtained the following expression for maximum plume rise z_{max}:

$$z_{\text{max}} = C\frac{M^{3/4}}{F^{1/2}} \qquad [15.20.101]$$

with

$$F = \pi r_o^2 g\left(\frac{\rho_o - \rho_1}{\rho_1}\right)u_o \qquad [15.20.102]$$

$$M = \pi r_o^2 u_o^2 \qquad [15.20.103]$$

where F is the buoyancy flux, M is the momentum flux, u_o is the outlet velocity of the gas, ρ_o is the density of the outlet gas, ρ_1 is the density of ambient fluid and C is a constant. Turner gives the value of the constant C as 1.85.

15.20.9 Cude model

A model for jets and plumes has been given by Cude (1974b). The Cude model distinguishes between a jet, a buoyant plume, a negatively buoyant plume and a buoyant plume at low wind speed.

Plume in still air

A treatment of the rise or fall of a buoyant plume in low wind speed conditions has been given by Bosanquet (Bosanquet 1935, 1957; Bosanquet and Pearson, 1936). In the simplified form given by Cude, the rise or fall of the plume is

$$i = -wAF_1(x_1) \qquad [15.20.104]$$

with

$$A = 9.42\frac{gN}{w^4}\frac{\rho_g - \rho_a}{\rho_a} \qquad [15.20.105]$$

$$x_1 = t_1/A \qquad [15.20.106]$$

where A is a time parameter, $F_1(x_1)$ is a function that expresses the change in density of the plume as a result of dilution by air, i is the rise or fall of the plume at a distance wt_1 from the source, N is the volumetric flow from the outlet, t_1 is an arbitrarily chosen time interval, w is the wind speed and ρ_g is the density of the gas at the outlet. The time t_1 is taken by Cude as 100 s.

If the gas density is greater than that of air, the plume falls and i has a negative numerical value, while if the gas density is less than that of air the plume rises and i has a positive value.

The function $F_1(x_1)$ is a complicated one. Some values are

x_1	F_1	x_1	F_1
$<10^{-3}$	$1.0543x_1^{0.75}$	10	2.33
10^{-3}	0.0059	10^2	4.50
10^{-2}	0.0323	10^3	6.79
10^{-1}	0.170	10^4	9.09
1	0.767	$>10^4$	$= \ln x_1 - 0.12$

Plume in atmospheric turbulence

For conditions of atmospheric turbulence with higher wind speeds Cude gives the following equations. For the axial concentration p_a from an elevated source

$$p_a = \frac{5.82J}{wx^{1.75}} \qquad [15.20.107]$$

for the maximum ground level concentration p_{mgl}

$$p_{mgl} = \frac{0.234J}{w(H+l)^2} \qquad [15.20.108]$$

and for the distance x_{mgl} at which the maximum ground level concentration occurs

$$x_{mgl} = 5.3(H+l)^{1.14} \qquad [15.20.109]$$

where H is the height of the outlet (m), J is the volumetric flow from the outlet referred to the ambient temperature (m^3/s), l is the height of the jet (and of the horizontal axis of the plume above the outlet) (m), p_a is the concentration of gas along the axis at a distance x (mole fraction), p_{mgl} is the maximum ground level concentration of the gas (mole fraction), w is the wind speed (m/s), x is the downwind distance (m) and x_{mgl} is the distance at which the maximum ground level concentration occurs (m).

Momentum jet

For a momentum jet the model given by Cude is that already described in Equations 15.20.1–15.20. The height of the jet at which transition occurs is calculated as follows. It is assumed that at the transition point the mass flow of the gas–air mixture m_l can be approximated by the mass flow of air m_a

$$m_l \approx m_a \qquad [15.20.110]$$

and that the velocity of the jet u is equal to that of the wind w

$$u \approx w \qquad [15.20.111]$$

Then for still air, substituting in Equation 15.20.4 for d_o from Equation 15.20.1 and for m_l from Equation 15.20.110

$$\frac{m_a}{l} = k_1 k_6 (m_o v)^{1/2} \qquad [15.20.112a]$$

$$= k_1 k_6 \psi^{1/2} \qquad [15.20.112b]$$

with

$$k_6 = \left(\frac{\pi p_l}{4}\right)^{1/2} \qquad [15.20.113]$$

$$\psi = m_o v \qquad [15.20.114]$$

where m_o is the mass flow at the outlet, v is the velocity of the gas at the outlet, ψ is the momentum flux in the still air, ρ_l is the density of the jet at distance l, and k_6 is a constant.

Forced plume in wind

For a momentum jet that undergoes transition to a plume in a wind, Cude gives the following treatment. The situation is illustrated in Figure 15.73. The transition from momentum to buoyancy control is obtained as follows. For windy

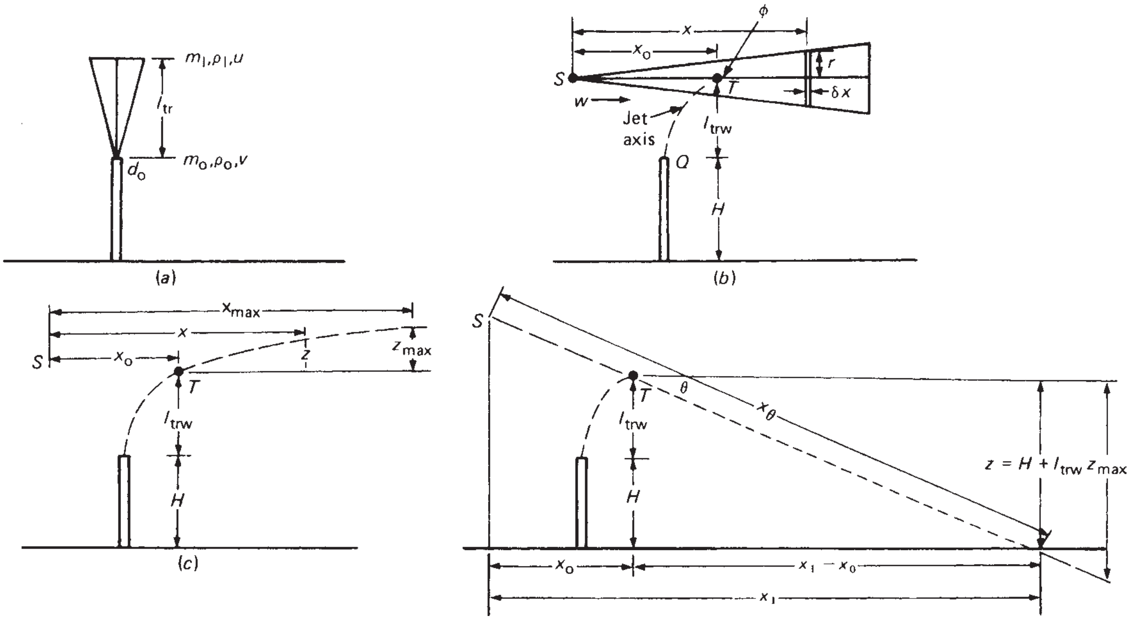

Figure 15.73 *Cude model of dispersion as jet and plumes from a stack (after Cude, 1977): (a) turbulent momentum jet; (b) and (c) buoyant plumes; (d) negatively buoyant plume with steep descent*

conditions the momentum flux is a vector quantity. In this treatment it is assumed that

$$\psi_{\mathrm{w}} = \left[(m_{\mathrm{o}}v)^2 + (m_{\mathrm{a}}w)^2\right]^{1/2} \quad [15.20.115]$$

where ψ_{w} is momentum flux in windy conditions. But from Equations 15.20.3, 15.20.110 and 15.20.111

$$\frac{m_{\mathrm{o}}v}{m_{\mathrm{a}}w} = 1 \quad [15.20.116]$$

Hence from Equations 15.20.114–15.20.116

$$\psi_w = 2^{1/2}\psi \quad [15.20.117]$$

Then, since from Equation 15.20.112b the length of the jet is inversely proportional to the root of the momentum flux, the transition heights of the jet in still air conditions l_{tr} and in windy conditions l_{trw} are related as follows:

$$l_{\mathrm{trw}} = \frac{l_{\mathrm{tr}}}{2^{1/4}} = \frac{l_{\mathrm{tr}}}{1.2} \quad [15.20.118]$$

The following relation is given by Cude for the horizontal displacement of the transition point x_{trw}:

$$x_{\mathrm{trw}} \approx 0.5\, l_{\mathrm{trw}} \quad [15.20.119]$$

The height reached by the plume from the transition point is calculated as follows. It is assumed that, as shown in Figure 15.73(b), there is a virtual source for the plume at point S that is a distance x_{o} upwind from the transition point T. This assumption allows for the mixing effect of the jet. The distance x_{o} is that which would be necessary to achieve the same concentration at the transition point if the mixing were done by the wind. Then, consider the element δx in Figure 15.73(b):

Volume of element $= \pi r^2 \delta x$

Volume of pure gas in element $= Q\delta x/w$

Volume of air in element $= \pi r^2 \delta x - Q\delta x/w$

Mass of pure gas in element $= Q\rho_{\mathrm{o}}\delta x/w$

Mass of air in element $= \pi r^2 \rho_{\mathrm{a}}\delta x - Q\rho_{\mathrm{a}}\delta x/w$

Mass of air displaced by element $= \pi r^2 \rho_{\mathrm{a}}\delta x$

$$\begin{aligned}\text{Buoyancy force on element} &= g[\pi r^2\rho_{\mathrm{a}}\delta x - (\pi r^2\rho_{\mathrm{a}}\delta x \\ &\quad - Q\rho_{\mathrm{a}}\delta x/w) - Q\rho_{\mathrm{o}}\delta x/w] \\ &= \frac{gQ\delta x}{w}(\rho_{\mathrm{a}} - \rho_{\mathrm{o}})\end{aligned}$$

where Q is the volumetric flow of the gas at the outlet, r is the radius of the plume and x is the downwind distance from the virtual source.

The rising plume experiences a resistance due to the shear stress in the air adjacent to it. Equating the buoyancy force and the shear stress

$$\frac{gQ\delta x}{w}(\rho_{\mathrm{a}} - \rho_{\mathrm{o}}) = 2\pi r\delta x u_{\mathrm{b}}^2 \rho_{\mathrm{a}} D_{\mathrm{c}} \quad [15.20.120]$$

where D_{c} is the drag coefficient and u_{b} is the buoyancy, or upward, velocity of the plume.

But

$$r = x\tan\phi \quad [15.20.121]$$

where ϕ is the angle between the axis and the edge of the plume, or half-angle of plume. Hence Equation 15.20.120 can be rearranged to give

$$u_{\mathrm{b}} = k_7 x^{-1/2} \quad [15.20.122]$$

with

$$k_7 = \left(\frac{gQ}{2\pi D_{\mathrm{c}} w\tan\phi}\,\frac{\rho_{\mathrm{a}} - \rho_{\mathrm{o}}}{\rho_{\mathrm{a}}}\right)^{1/2} \quad [15.20.123]$$

The half-angle of a plume from a stack is generally 5° or 6° so that $\tan\phi \approx 1$. The drag coefficient D_{c} is estimated by Cude from the work of Bodurtha, Palmer and Walsh (1973) as 0.4.

The treatments given by Cude for rising and for falling plumes are slightly different. The condition for a rising plume is $\rho_{\mathrm{o}} < \rho_{\mathrm{a}}$. The treatment for a rising plume shown in Figure 15.73(c) is as follows. The rise of the plume is given by

$$\mathrm{d}z = \frac{u_{\mathrm{b}}\mathrm{d}x}{w} \quad [15.20.124a]$$

$$= \frac{k_7 x^{-1}\mathrm{d}x}{w} \quad [15.20.124b]$$

where z is the vertical distance above the transition point. Integrating Equation 15.20.124 with the boundary conditions

$z = 0, \quad x = x_{\mathrm{o}}$

gives

$$z = \frac{2k_7}{w}\left(x^{1/2} - x_{\mathrm{o}}^{1/2}\right) \quad [15.20.125]$$

The maximum rise $z_{\max}$ of a plume occurs at a distance $x_{\max}$ where

$$x_{\max} = k_8 w + x_{\mathrm{o}} \quad [15.20.126]$$

where k_8 is a constant. The value of the constant k_8 may be obtained from the observation that a plume generally reaches its maximum rise after 200 s so that $k_8 = 200$. Then from Equation 15.20.125

$$z_{\max} = \frac{2k_7}{w}\left(x_{\max}^{1/2} - x_{\mathrm{o}}^{1/2}\right) \quad [15.20.127]$$

The distance x_{o} is obtained from Equation 15.20.107:

$$x_{\mathrm{o}} = \left(\frac{5.82J}{wp_{\mathrm{a}}}\right)^{1/1.75} \quad [15.20.128]$$

The concentration p_{a} is, in this case, the concentration on the axis at the transition point and, assuming that the axial concentration is twice the mean concentration in the jet,

$$p_{\mathrm{a}} = \frac{2M_{\mathrm{a}}m_{\mathrm{o}}}{Mm_{\mathrm{a}}} \quad [15.20.129]$$

$$= \frac{2M_{\mathrm{a}}\omega}{Mv} \quad [15.20.130]$$

where M is the molecular weight of the gas and M_a is the molecular weight of the air.

The total effective height h_{pl} reached by the plume is thus

$$h_{pl} = H + l_{trw} + z_{max} \qquad [15.20.131]$$

The maximum ground level concentration p_{mgl} is calculated from an equation similar to Equation 15.20.108, using the total effective height of the plume:

$$p_{mgl} = \frac{0.234J}{wh_{pl}^2} \qquad [15.20.132]$$

and the distance x_{mgl} at which the maximum ground level concentration occurs is calculated from an equation similar to Equation 15.20.109:

$$x_{mgl} = 5.3h_{pl}^{1.14} \qquad [15.20.133]$$

The treatment for a falling plume, which is an approximate one, is as follows. The condition for a falling plume is $\rho_o > \rho_a$. As before, calculations are made of the distances z and z_{max}, but in this case the quantities denote vertical distances below the transition point. In calculating k_7, the term $[(\rho_a - \rho_o)/\rho_a]$ is replaced by the term $[(\rho_o - \rho_a)/\rho_a]$.

For a falling plume there are two situations that can arise. If conditions are favourable

$$z_{max} < (H + l_{trw}) \qquad [15.20.134]$$

The plume tends to become horizontal as it approaches the ground. In this case the method is to determine the total effective height h_{pl} from Equation 15.20.131 but with the modification that the term z_{max} is subtracted not added. The maximum ground level concentration z_{max} is then calculated as before from Equation 15.20.132.

It should be noted that Equation 15.20.132, which is approximate, gives very large values for p_{mgl} for very small values of h_{pl} and is not valid for such values. A check may be made by substituting x_{max} instead of x_o into Equation 15.20.128 and calculating p_a. If $p_a < p_{mgl}$, the value of p_{mgl} is rejected and the value of p_a is accepted in its place.

If conditions are unfavourable

$$z_{max} > (H + l_{trw}) \qquad [15.20.135]$$

The plume approaches the ground at an angle. The maximum ground level concentration is the axial concentration in the plume when it reaches ground level. The situation is shown in Figure 15.73(d). In this case the method is to make the substitution

$$z = (H + l_{trw}) \qquad [15.20.136]$$

The distance x_1 from the virtual source at which the plume axis reaches the ground is then calculated from Equation 15.20.125, using Equation 15.20.13. Then from the geometry of Figure 15.73(d)

$$\tan\theta = \frac{H + l_{trw}}{x_1 - x_o} \qquad [15.20.137]$$

where θ is angle between axis of plume and horizontal. The horizontal component of the plume velocity is w and the vertical component is $w\tan\theta$. The resultant velocity u_θ is

$$u_\theta = w\left(1 + \tan^2\theta\right)^{1/2} \qquad [15.20.138]$$

The distance x_θ from the virtual source S to the point where the plume reaches the ground measured along the axis of the plume is

$$x_\theta = \frac{x_1}{\cos\theta} = x_1\left(1 + \tan^2\theta\right)^{1/2} \qquad [15.20.139]$$

The maximum ground level concentration p_{mgl} may be estimated by substituting u_θ and x_θ for w and x_o in Equation 15.20.128. The distance x_{mgl} at which the maximum ground level concentration is reached is

$$x_{mgl} = x_1 - x_o \qquad [15.20.140]$$

Cude has compared his method with that of Bosanquet and with experimental data on plume paths given by N.G. Stewart *et al.* (1954) and quoted by Pasquill (1962a, p. 221). It predicts a plume rise approximately twice that of Bosanquets method and apparently more in accordance with the experimental data of Stewart *et al.* It gives a maximum ground level concentration which is approximately half that obtained by Bosanquets method, although Cude emphasizes that this difference is well within the range of variations which arise as a result of different atmospheric conditions. The method is applicable where the density difference between the plume and the air is zero, a condition where Bosanquets method is unreliable.

15.20.10 Briggs models

A model for jet and plumes and, in particular, for plume rise has been given by G.A. Briggs (1965, 1968, 1969, 1976), and S.R. Hanna, Briggs and Hosker (1982). The Briggs model distinguishes between a plume dominated by momentum and a plume dominated by buoyancy; between a vertical plume and a bent-over plume; and between a plume near the source and a plume in the three main stability conditions (stable, near neutral and convective, or unstable). The plume scenarios described in Briggs' models are illustrated in Figure 15.74.

In these models, the prime concern is with stack gases that have a temperature much greater than that of air but a molecular weight that does not differ greatly from that of air. For such gases Briggs defines the momentum flux as

$$M = wV \qquad [15.20.141]$$

and the buoyancy flux as

$$F = g\frac{(T_p - T_{en})}{T_p}V \qquad [15.20.142]$$

where F is the buoyancy flux, M is the momentum flux, V is the volumetric flow, w is the velocity in the vertical direction and the subscripts en and p denote environment and plume, respectively. The volumetric flow V is defined as

$$V = wr^2 \quad \text{Vertical plume} \qquad [15.20.143a]$$

$$V = ur^2 \quad \text{Bent-over plume} \qquad [15.20.143b]$$

where r is the radius and u is the wind speed.

Thus, in definition 15.20.143 Briggs omits the term π and in definitions 15.20.141 and 15.20.142 the term πr^2.

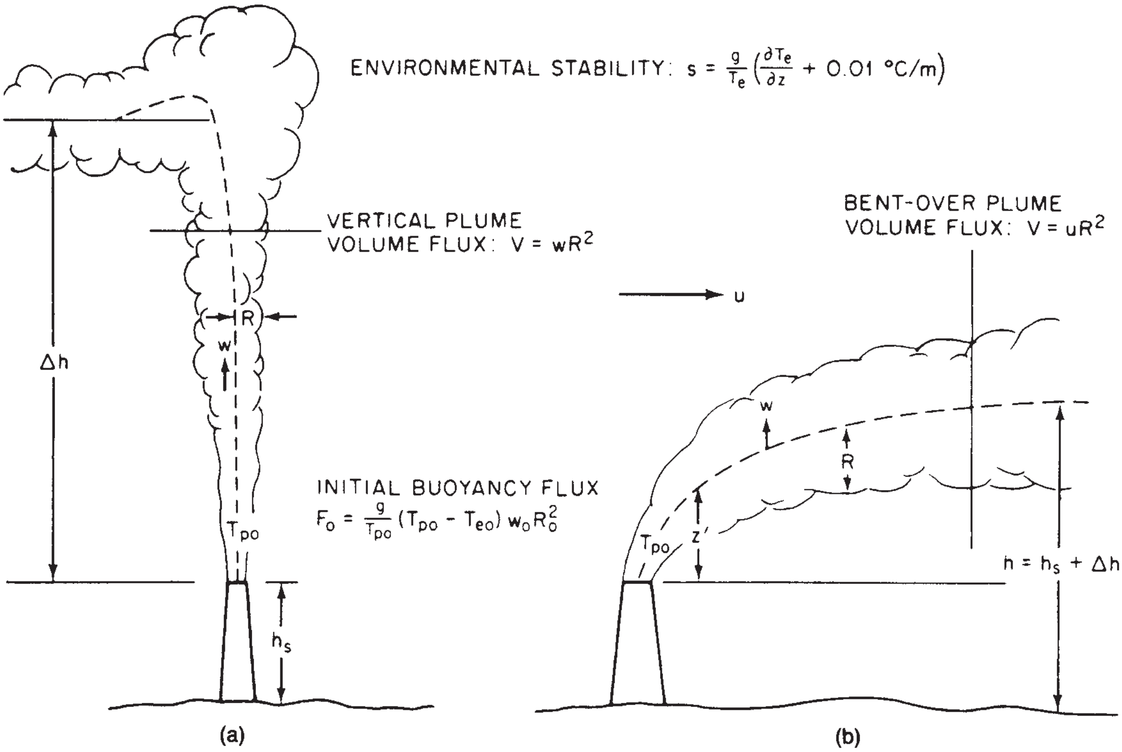

Figure 15.74 Briggs model of dispersion of plumes from a stack (S.R. Hanna, Briggs and Hosker, 1982): (a) vertical plume; and (b) bent-over plume h and R in the figure are denoted in the text by h_e and r, respectively

He adopts a similar approach to the definition of other quantities.

The initial momentum flux is

$$M_o = w_o V_o \qquad [15.20.144]$$

and the initial buoyancy flux is

$$F_o = g\left(\frac{T_{po} - T_{eo}}{T_{po}}\right) V_o \qquad [15.20.145a]$$

$$F_o = g\left(1 - \frac{T_{eo}}{T_{po}}\right) V_o \qquad [15.20.145b]$$

where subscripts eo, o and po denote the initial environment, the outlet and the initial plume, respectively.

If the molecular weight of the gas emitted differs significantly from that of air, the initial momentum and buoyancy may be modified as follows:

$$M_o = \frac{\rho_o}{\rho_a} w_o V_o \qquad [15.20.146]$$

$$F_o = g\left(1 - \frac{T_{eo} m_p}{T_{po} m_o}\right) V_o \qquad [15.20.147]$$

where m is the molecular weight.

The basis of the Briggs model is the equations for conservation of momentum and of buoyancy, together with additional relations required for the solution, or closure, of the equations. The closure relation is the Taylor entrainment assumption.

The basic equations are as follows. For conservation of momentum

$$\frac{dM}{dz} = \frac{F}{w} \quad \text{Vertical plume, bent-over plume} \qquad [15.20.148]$$

For conservation of buoyancy

$$\frac{dF}{dz} = -sV \quad \text{Vertical} \qquad [15.20.149a]$$

$$\frac{dF}{dz} = -\frac{sV}{S} \quad \text{Bent-over plume} \qquad [15.20.149b]$$

with

$$s = \frac{g}{T_e}\left(\frac{dT_e}{dz} + \Gamma\right) \qquad [15.20.150]$$

where s is the environmental stability, S is the ratio of the effective area influenced by the plume momentum to the cross-sectional area of the so-called thermal plume, T_e is the absolute temperature of the environment, z is the vertical distance above the outlet and Γ is the dry adiabatic lapse rate. The value of S is found to be 2.3. For closure

$$\frac{\mathrm{d}V}{\mathrm{d}z} = 2r\alpha w \quad \text{Vertical plume} \qquad [15.20.151a]$$

$$\frac{\mathrm{d}V}{\mathrm{d}z} = 2r\beta w \quad \text{Bent-over plume} \qquad [15.20.151b]$$

where α and β are constants.

The velocities are

$$w = \frac{\mathrm{d}z}{\mathrm{d}t} \qquad [15.20.152]$$

$$u = \frac{\mathrm{d}x}{\mathrm{d}t} \qquad [15.20.153]$$

An alternative form of the equation for conservation of momentum, utilizing Equations 15.20.141 and 15.20.152, is

$$\frac{\mathrm{d}(wV)}{\mathrm{d}t} = F \qquad [15.20.154]$$

The derivation of the model equations is largely based on solutions of Equation 15.20.154 for the various conditions.

Plume near source: vertical plume

At the source there is a momentum-dominated plume, or jet. Then, taking the buoyancy as zero, or setting $F = 0$, gives

$$wV = \text{constant} \qquad [15.20.155a]$$

Hence

$$(wV)^{1/2} = \text{constant} \qquad [15.20.155b]$$

Then from Equation 15.20.143a

$$(wV)^{1/2} = wr \qquad [15.20.156a]$$

$$= w_o r_o \qquad [15.20.156b]$$

But for a jet

$$r = \beta z \qquad [15.20.157]$$

The constant β has the value 0.16 for the jet phase. Then

$$wz \propto w_o r_o \qquad [15.20.158]$$

From the work of Pai, the centre line velocity w_{cl} of a jet is

$$w_{cl} = 13\frac{w_o r_o}{z} \qquad [15.20.159]$$

But the mean velocity is about half the centre line velocity and hence

$$w = 6.25\frac{w_o r_o}{z} \qquad [15.20.160a]$$

$$= 6.25\frac{M^{1/2}}{z} \qquad [15.20.160b]$$

Transition from momentum to buoyancy control occurs at time

$$t = \frac{M}{F_o} \qquad [15.20.161]$$

Typically, the time to transition is less than 10 s.

After transition there is a buoyancy dominated plume, or buoyant plume. For this

$$w = 2.3\frac{F_o^{1/2}}{z} \qquad [15.20.162]$$

The radius r is again given by Equation 15.20.157, but the constant β has a value of 0.15 for the plume phase.

Plume near source: bent-over plume

Near the source, setting F = constant in Equation 15.20.154 gives on integrating

$$wV = M_o + F_o t \qquad [15.20.163]$$

But for a bent-over plume

$$r = \beta z \qquad [15.20.164]$$

Then from Equations 15.20.143b, 15.20.152, 15.20.163 and 15.20.164

$$u(\beta z)^2\frac{\mathrm{d}z}{\mathrm{d}t} = M_o + F_o t \qquad [15.20.165]$$

$$\int_0^z z^2\,\mathrm{d}z = \int_0^t \left(\frac{M_o}{\beta^2 u} + \frac{F_o t}{\beta^2 u}\right)\mathrm{d}t \qquad [15.20.166]$$

$$z = \left(\frac{3M_o t}{\beta^2 u} + \frac{3F_o t^2}{2\beta^2 u}\right)^{1/3} \qquad [15.20.167]$$

Alternatively, since

$$u = x/t \qquad [15.20.168]$$

Equation 15.20.167 can be written as

$$z = \left(\frac{3M_o x}{\beta^2 u^2} + \frac{3F_o x^2}{2\beta^2 u^3}\right)^{1/3} \qquad [15.20.169]$$

For the momentum-dominated plume, setting $F_o = 0$, gives

$$z = \left(\frac{3M_o t}{\beta^2 u}\right)^{1/3} \qquad [15.20.170]$$

or from Equation 15.20.168

$$z = \left(\frac{3M_o x}{\beta^2 u^2}\right)^{1/3} \qquad [15.20.171]$$

Equation 15.20.171 is the 1/3 law for a bent-over momentum plume.

For the buoyancy-dominated plume, setting $M_o = 0$, gives

$$z = \left(\frac{3F_o t^2}{2\beta^2 u}\right)^{1/3} \qquad [15.20.172]$$

and

$$z = \left(\frac{3}{2}\frac{F_o x^2}{\beta^2 u^3}\right)^{1/3} \qquad [15.20.173]$$

But for a buoyant plume the constant β has the value 0.6. Substituting in Equation 15.20.173 gives

$$z = C_1 \frac{F_o^{1/3}}{u} x^{2/3} \qquad [15.20.174]$$

with

$$C_1 = 1.6 \qquad [15.20.175]$$

where C_1 is a constant. Equation 15.20.174 is the 2/3 law for a bent-over buoyant plume. A table of values of the constant C_1 is given by G.A. Briggs (1976). His preferred value is 1.6.

Plume rise in stable conditions

In stable conditions the environmental stability s is constant. Then from Equations 15.20.148, 15.20.149 and 15.20.152

$$\frac{d^2M}{dt^2} = -sM \qquad [15.20.176]$$

This is the equation of a harmonic oscillator.

Briggs introduces a correction to the environmental stability s to allow for the effective vertical momentum flux M_{eff} and defines a modified stability s' such that

$$\begin{aligned} s' &= s \qquad \text{Vertical plume} \qquad [15.20.177a] \\ &= \frac{M}{M_{\mathrm{eff}}} s \quad \text{Bent-over plume} \end{aligned}$$

The ratio M/M_{eff} has the value 2.3. Then from Equations 15.20.141 and 15.20.176, and using s' rather than s,

$$\frac{d^2(wV)}{dt^2} = s' wV \qquad [15.20.178]$$

Integrating Equation 15.20.178 with the initial conditions

$t = 0; \quad d(wV)/dt = F_o; \quad wV = M_o$

gives

$$wV = M_o \cos(w't) + \frac{F_o}{w'} \sin(w't) \qquad [15.20.179]$$

with

$$w' = s'^{1/2} \qquad [15.20.180]$$

In Briggs' model use is made of several plume heights. One is the maximum rise $z_{\max}$. Another is the 'equilibrium' height z_{eq}, defined as the point at which $F = 0$. A third is the 'falling back' height z_{fb} defined as the height where the plume at maximum rise would be in equilibrium if no further mixing were to take place. Both z_{eq} and z_{fb} are fractions of $z_{\max}$, as described below.

Plume rise in stable conditions: vertical plume

For the momentum plume, G.A. Briggs (1976) gives

$$z_{\max} \approx 4\left(\frac{M_o}{s}\right)^{1/2} \qquad [15.20.181]$$

and also

$$z_{\mathrm{eq}} = 0.77 z_{\max} \qquad [15.20.182a]$$

$$z_{\mathrm{fb}} = 0.8 z_{\max} \qquad [15.20.182b]$$

S.R. Hanna, Briggs and Hosker (1982) also give

$$z_{\mathrm{eq}} = 2.44\left(\frac{M_o}{s}\right)^{1/4} \qquad [15.20.183]$$

For the buoyant plume G.A. Briggs (1976) gives

$$z_{\max} = 5\frac{F_o^{1/4}}{s^{3/8}} \qquad [15.20.184]$$

S.R. Hanna, Briggs and Hosker (1982) also give

$$z_{\mathrm{eq}} = 5.3\frac{F_o^{1/4}}{s_o^{3/8}} - 6r_o \qquad [15.20.185]$$

The last term in Equation 15.20.185 is a correction to allow for the virtual source.

Plume rise in stable conditions: bent-over plume

For the buoyant plume, Equation 15.20.178 may be reformulated using Equations 15.20.143, 15.20.152 and 15.20.157. Then integrating the equation and taking the maximum value of z gives

$$z_{\max} = \left(\frac{3F_o}{\beta^2 u s'}\right)^{1/3} \left\{1 + \left[1 + \left(\frac{w' M_o}{F_o}\right)^2\right]^{1/2}\right\}^{1/3} \qquad [15.20.186]$$

But for $F_o \gg (M_o/w')$ Equation 15.20.186 reduces to

$$z_{\max} = \left(\frac{6F_o}{\beta^2 u s'}\right)^{1/3} \qquad [15.20.187]$$

Taking the constant β as 0.6 in Equation 15.20.187 gives

$$z_{\max} = 2.6\left(\frac{F_o}{us'}\right)^{1/3} \qquad [15.20.188]$$

Also

$$z_{\mathrm{eq}} = 0.79 z_{\max} \qquad [15.20.189a]$$

$$z_{\mathrm{fb}} = 0.83 z_{\max} \qquad [15.20.189b]$$

G.A. Briggs (1976) also gives the following equation for plume rise Δh:

$$\Delta h = C_2\left(\frac{F_o}{us}\right)^{1/3} \qquad [15.20.190]$$

where C_2 is a constant. Values of the constant C_2 are tabulated by Briggs (1976). His preferred value is 2.6.

Plume rise limited by atmospheric turbulence

For conditions other than stable conditions, Briggs' treatment utilizes a 'break-up' model in which it is assumed that the plume rise terminates when the internal plume eddy dissipation rate equals the ambient eddy dissipation rate ϵ Then

$$\frac{\eta w^3}{z} = \epsilon \qquad [15.20.191]$$

where η is a constant. The constant η has the value 1.5. The term on the left-hand side of Equation 15.20.191 is the internal plume eddy dissipation rate. For a stack, the effective stack height (ESH) is

$$h_e = h_s + \Delta h \qquad [15.20.192]$$

where Δh is the plume rise above the stack outlet, h_e is the ESH and h_s is the actual stack height.

The plumes considered are momentum and buoyant plumes, both bent over.

Near neutral conditions

In near neutral conditions the ambient eddy dissipation rate is

$$\epsilon = \frac{u_*^3}{kh_e} \qquad [15.20.193]$$

where u_* is the friction velocity and k is von Karman's constant. The constant k has a value of 0.4.

Near neutral conditions: momentum plume

For a momentum plume for which the first phase of rise is given by Equation 15.20.171

$$\Delta h = \left(\frac{M_o}{\beta^2 u}\right)^{3/7}\left(\frac{\eta}{\epsilon}\right)^{1/7} \qquad [15.20.194]$$

From Equations 15.20.192 and [15.20.193]

$$\Delta h = \left(\frac{M_o}{\beta^2 u u_*}\right)^{3/7}(\eta k)^{1/7}\left(1+\frac{h_s}{\Delta h}\right)^{1/7}\Delta h^{1/7} \qquad [15.20.195]$$

and hence

$$\Delta h = \frac{(\eta k)^{1/6}}{\beta}\left(\frac{u}{u_*}\right)^{1/2}\left(\frac{M_o}{u^2}\right)^{1/2}\left(1+\frac{h_s}{\Delta h}\right)^{1/6} \qquad [15.20.196]$$

Assuming $\Delta h \gg h_s$ so that the last term of Equation 15.20.196 can be neglected and substituting for η and k values of 1.5 and 0.4, respectively, gives

$$\Delta h = \frac{0.9}{\beta}\left(\frac{u}{u^*}\right)^{1/2}\frac{M_o^{1/2}}{u} \qquad [15.20.197]$$

From Equations 15.20.141, 15.20.143a and 15.20.197, taking the constant β as 0.6 and the ratio u/u_* as 15,

$$\Delta h = 2.9\frac{w_o d_o}{u} \qquad [15.20.198]$$

where d_o is the diameter of the source.

G.A. Briggs (1982) also gives

$$\Delta h = 3d_o\left(\frac{w_o}{u} - 1\right) \qquad [15.20.199]$$

The additional term is evidently a virtual source correction.

Near neutral conditions: buoyant plume

For a buoyant plume for which the first phase of rise is given by Equation 15.20.173]

$$\Delta h = \left(\frac{2F_o}{3\beta^2 u}\right)^{3/5}\left(\frac{\eta}{\epsilon}\right)^{2/5} \qquad [15.20.200]$$

Proceeding as before, it can be shown that

$$\Delta h = \frac{2}{3\beta^2}(\eta k)^{2/3}\left(\frac{F_o}{uu_*^2}\right)\left(1+\frac{h_s}{\Delta h}\right)^{2/3} \qquad [15.20.201]$$

Neglecting the last term of Equation 15.20.201 and taking for the constants β, η and k values of 0.6, 1.5 and 0.4, respectively, gives

$$\Delta h = 1.3\left(\frac{F_o}{uu_*^2}\right) \qquad [15.20.202]$$

Briggs also gives as an approximation for Equation 15.20.201 the following equation:

$$\Delta h = 1.54\left(\frac{F_o}{uu_*^2}\right)^{2/3} h_s^{1/3} \qquad [15.20.203]$$

Convective conditions

For convective, or unstable, conditions Equation 15.20.193 does not apply. Instead, the relation used is

$$\epsilon = 0.25H \qquad [15.20.204]$$

where H is surface buoyancy flux. The resultant equation for plume rise is

$$\Delta h = 3\left(\frac{F_o}{u}\right)^{3/5} H^{-2/5} \qquad [15.20.205]$$

but this equation is to be regarded as tentative.

Ground level concentration

Once the plume rise Δh and hence the ESH h_e have been obtained, the maximum ground level concentration χ_{mgl} may be found in the usual way, using Equation 15.16.55, which may be written in the form

$$\chi_{mgl} = \frac{2Q}{e\pi u h_e^2}\frac{\sigma_z}{\sigma_y} \qquad [15.20.206a]$$

or

$$\chi_{mgl} = 0.234\frac{Q}{uh_e^2}\frac{\sigma_z}{\sigma_y} \qquad [15.20.206b]$$

where e is the base of natural logarithms, Q is the mass rate of release and σ_y and σ_z are the longitudinal and vertical dispersion coefficients, respectively.

The maximum ground level concentration χ_{mgl} is low both at low and at high wind speeds, because in the first case the plume rise is high and in the second dilution is high. It therefore passes through a maximum value $\chi_{\max}$ at some critical wind speed u_{c}.

A minimum value of the term uh_{e}^2 is obtained from Equation 15.20.201 when $\Delta h = h_{\mathrm{s}}/3$. The following relations can then be derived:

$$u_{\mathrm{c}} = 2.15\left(\frac{u}{u_*}\right)^{2/3}\left(\frac{F_{\mathrm{o}}}{h_{\mathrm{s}}}\right)^{1/3} \qquad [15.20.207]$$

$$u_{\mathrm{c}}h_{\mathrm{e}}^2 = 3.8\left(\frac{u}{u_*}\right)^{2/3} F_{\mathrm{o}}^{1/3}h_{\mathrm{s}}^{5/3} \qquad [15.20.208]$$

15.20.11 Jet transients

The jet and plume models described apply to steady-state conditions. The steady state is preceded and followed by transients that are much less well defined. In particular, the decay can result in a plume with a relatively low momentum. A study of gas jet transients has been described by Landis, Linney and Hanley (1994).

15.21 Dispersion of Two-phase Flashing Jets

The type of jet considered here is the jet resulting from a release of superheated liquid at high pressure, with choked liquid or two-phase flow. Such a jet may be divided into a number of zones, as shown in Figure 15.75. One common division is into two zones, a depressurization zone and an entrainment zone. In the depressurization zone, which is some two orifice diameters in length, the pressure falls essentially to atmospheric pressure, but there is little air entrainment. This occurs in the entrainment zone.

A modification of this scheme is to introduce between the depressurization and entrainment zone an intermediate zone in which deposition of liquid droplets, or rainout, is completed but negligible entrainment of air occurs. This is referred to here as the deposition zone.

The jet is commonly considered to end at the point where the jet velocity has fallen to a minimum value or to the wind speed, whichever is higher.

15.21.1 Disintegration of jets

Two-phase jets in general were considered in Section 15.2. The two-phase jets of main interest here are those of superheated liquids, which give flashing jets. A review of such jets has been given by Appleton (1984 SRD R303).

The break-up of a flashing jet will, in general, be due both to air resistance and vapour bubble formation. Appleton states that for most situations of interest in the process industries the latter will usually be the more important effect.

Work by Bushnell and Gooderum (1968) has shown that there is a critical degree of superheat above that the jet will disintegrate due to vapour bubble formation. They define a shattering temperature as follows:

$$\frac{T_{\mathrm{sh}} - T_{\mathrm{sat}}}{T_{\mathrm{sh}}} = \epsilon \qquad [15.21.1a]$$

Hence

$$T_{\mathrm{sh}} = \frac{T_{\mathrm{sat}}}{1-\epsilon} \qquad [15.21.1b]$$

where ϵ is a constant and subscripts sat and sh denote saturation and shattering, respectively. They give for the value of the constant ϵ the range 0.07–0.1.

Below the shattering temperature the jet remains well formed, while above it the jet shatters. In their work break-up did not appear to be affected by outlet diameter or liquid velocity. In the work of R. Brown and York (1962), however, for experiments where the Weber number was high, shattering occurred at lower values of the superheat. Mention should also be made of work by Suzuki *et al.* (1978), which has shown that, even when the jet conditions are held constant, large variations can occur in break-up length and pattern.

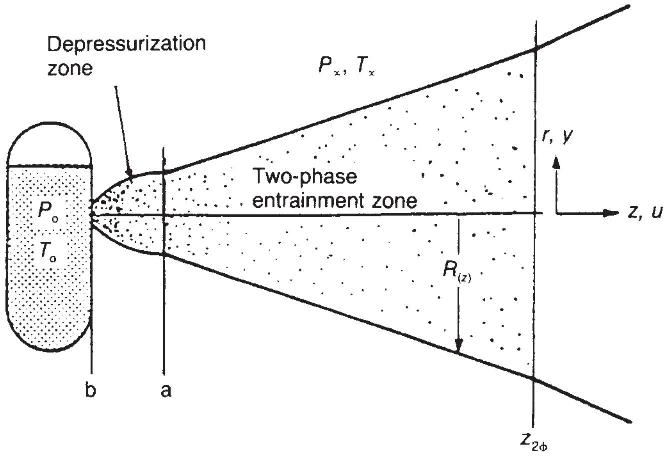

Figure 15.75 *Two-phase momentum jet (Fauske and Epstein, 1988). Subscript 2ϕ in the figure is denoted in the text by subscript tp.*

For a two-phase flashing jet the characteristics of interest are similar, but in this case the mass flow of droplets increases along the axis, so that in addition information is required on the production rate of droplets and on droplet size.

For droplet size relations for minimum and for maximum droplet size have been given by Koestel, Gido and Lamkin (1980) and by Gyarmathy (1976), respectively. Appleton has compared theoretical estimates from the methods of these authors with values obtained by Brown and York as follows:

Brown and York:	
Smooth orifice	34.7 μm
Rough orifice	54.5 μm
Koestel *et al.* (for minimum size)	19 μm
Gyarmathy (for maximum size)	31 μm

Quantitative treatment of the production rate of droplets is sparse. In Brown and York's experiments there was initial flashing and jet expansion some 0.15 m downstream from the outlet and there was then rapid evaporation of the droplets, so that by 1.2–1.5 m downstream practically all the liquid phase had disappeared.

15.21.2 Wheatley model

A model for a two-phase jet of liquefied ammonia has been given by Wheatley (1986, 1987 SRD R410). The model deals with: jet disintegration; gravitational settling of liquid droplets, or rainout; entrainment of air; and thermodynamics of mixing ammonia and moist air. It is not concerned with the effect on the jet of gravity or wind speed.

Wheatley's treatment of jet disintegration and rainout was considered in Section 15.1. The account given here is confined to his model for air entrainment. The situation that he considers is that in which the aerosol particles are sufficiently small for motion in the jet to be taken as homogeneous.

The basic relations of the model are

$$G_d = AuC \qquad [15.21.2]$$

$$G_d u_d = Au^2\rho \qquad [15.21.3]$$

and

$$G = G_d + G_a \qquad [15.21.4]$$

$$G = Au\rho \qquad [15.21.5]$$

Furthermore, from Equations 15.21.3 and 15.21.5

$$G_d u_d = Gu \qquad [15.21.6]$$

where A is the cross-sectional area of the jet, C is the concentration (mass per unit volume), G is the mass flow in the jet, u is the velocity of the jet, ρ is the density of the jet and subscripts a and d denote air and the end of deposition zone, respectively.

The relation for the growth of the jet due to air entrainment is

$$\frac{dG_a}{dz} = 2\pi Ru\rho_a f(\rho/\rho_a) \qquad [15.21.7]$$

where R is the radius of the jet and z is the distance downstream of the source. Here $f(\rho/\rho_a)$ is a function yet to be defined.

Wheatley considers two models of air entrainment. The first is that of Ricou and Spalding (1961). These workers give for an isothermal gas jet over a limited range of initial densities

$$\frac{dG_a}{dz} = \pi^{1/2}\tan\beta_\infty \rho_a^{1/2} u^{1/2} G^{1/2} \qquad [15.21.8]$$

where β_∞ is the asymptotic half-angle of the jet.

It is found empirically that $\beta_\infty = 9.1°$ and hence tan $\beta_\infty = 0.15$. An entrainment coefficient $\propto$ is sometimes defined as

$$\alpha = 1/2\tan\beta_\infty \qquad [15.21.9]$$

Comparison of Equations 15.21.7 and 15.21.8 implies

$$f(\rho/\rho_a) = 1/2(\rho/\rho_a)^{1/2}\tan\beta_\infty \qquad [15.21.10]$$

This equation indicates that entrainment is affected by the density of the jet.

A density effect is indicated in the following equation obtained for isothermal gas jets:

$$\tan\beta = 1/2\left(\frac{\rho_a}{\rho} + 1\right)\left(\frac{\rho}{\rho_a}\right)^{1/2}\tan\beta_\infty \qquad [15.21.11]$$

Wheatley quotes experimental work to the effect that, where the density ratio ρ/ρ_a is appreciably greater than unity, β can be smaller than β_∞ by a factor of about 2, which is not consistent with Equation 15.21.1. He notes that in the work of Ricou and Spalding the density ratio ρ/ρ_a was at most about 1.05 and concludes that Equation 15.21.8 is not valid where ρ differs significantly from ρ_a.

Work by B.R. Morton, Taylor and Turner (1956) has shown that f is independent of ρ/ρ_a. Thus, Equation 15.21.10 becomes

$$f(\rho/\rho_a) = 1/2\tan\beta_\infty \qquad [15.21.12]$$

and Equation 15.21.11 becomes

$$\tan\beta = 1/2(\rho_a/\rho + 1)\tan\beta_\infty \qquad [15.21.13]$$

This equation gives the decrease of β with increasing ρ found experimentally.

Wheatley concludes that the treatment of Morton, Taylor and Turner should be used in preference to that of Ricou and Spalding. This model forms the basis of the computer code TRAUMA developed by Wheatley (1987 SRD R393, SRD R394). The code was developed initially for ammonia but was subsequently generalized to handle other liquefied gases.

15.21.3 Webber and Kukkonen model

A generalized model of a two-phase jet has been given by Webber and Kukkonen (1990). The model is intended as an exploration of basic principles. Most attempts to model two-phase jets have been partial ones, concentrating on particular aspects and neglecting others. The aim of the work was to determine which are the important phenomena and hence how comprehensive a realistic model needs to be.

In this model the depressurization zone is ignored. For the entrainment zone the basic relations are:

$$\frac{\mathrm{d}(CuA)}{\mathrm{d}x}) = 0 \qquad [15.21.14]$$

$$\frac{\mathrm{d}(\phi uA)}{\mathrm{d}x} = 2\pi R u_{\mathrm{E}} \qquad [15.21.15]$$

$$\frac{\mathrm{d}(\phi u^2 A)}{\mathrm{d}x} = 0 \qquad [15.21.16]$$

with

$$A = \pi R^2 \qquad [15.21.17]$$

where A is the cross-sectional area of the jet, C is the concentration of the contaminant, R is the radius of the jet, u is the velocity of the jet, u_{E} is the entrainment velocity, x is the downstream distance and ϕ is the ratio of the densities of the jet and air.

For the density of the jet, two cases (A and B) are considered. For Case A the density of the jet is the same as that of the ambient air

$$\phi = 1 \qquad [15.21.18]$$

For Case B the jet is an isothermal mixture of contaminant and air:

$$\phi = 1 + C \qquad [15.21.19]$$

Two entrainment models are considered. These are the models of B.R. Morton, Taylor and Turner (1956) and Ricou and Spalding (1961), as treated by Wheatley. The authors state these models in the form

$$u_{\mathrm{E}} = \alpha u \qquad [15.21.20]$$

and

$$u_{\mathrm{E}} = \alpha \phi^{1/2} u \qquad [15.21.21]$$

where α is an entrainment coefficient. These two entrainment models are identical for Case A, but not for Case B.

For Case A of a jet of ambient density, the solution of Equations 15.21.14–15.21.16 with incorporation of either entrainment model is

$$R = 2\alpha x \qquad [15.21.22]$$

$$u = UL(2\alpha x) \qquad [15.21.23]$$

$$C = L/(2\alpha x) \qquad [15.21.24]$$

where L and U are length and velocity scales determined by conditions at the source, and x is the downstream distance.

The solution for Case B of a dense jet before incorporation of the entrainment model is

$$(\phi - 1)uA = B \qquad [15.21.25]$$

$$\phi u^2 A = f \qquad [15.21.26]$$

where B and f are the buoyancy and momentum flux, respectively. The quantities L and U are defined as

$$L = \left(\frac{B^2}{\pi f}\right)^{1/2} \qquad [15.21.27]$$

$$U = f/B \qquad [15.21.28]$$

With incorporation of the first entrainment model, Equation 15.21.20, Equations 15.21.25 and 15.21.26 yield for Case

$$R = L(q/p) \qquad [15.21.29]$$

$$1 - \phi = 1/q^2 \qquad [15.21.30]$$

$$\phi = 1/(pq)^2 \qquad [15.21.31]$$

with

$$p^2 = u/U \qquad [15.21.32]$$

$$q^2 = Au/\left(\pi L^2 U\right) \qquad [15.21.33]$$

$$p^2 = \left(1 + q^2\right)^{-1} \qquad [15.21.34]$$

$$q\left(1 + q^2\right)^{1/2} + \ln\left[q + \left(1 + q^2\right)^{1/2}\right] = 2\alpha x/L \qquad [15.21.35]$$

where p and q are dimensionless variables.

For the Case B Equations 15.21.25 and 15.21.26 with the second entrainment model, Equation 15.21.21, the result is

$$R = 2\alpha x[1 + L/(2\alpha x)]^{1/2} \qquad [15.21.36]$$

$$u = U[L/(2\alpha x)][1 + L/(2\alpha x)]^{-1} \qquad [15.21.37]$$

$$\phi = 1 + L/(2\alpha x) \qquad [15.21.38]$$

For a two-phase jet that is not dense initially, L is rather smaller than R, and U is larger than u at the end of the depressurization zone. For an initially dense jet, L can be somewhat larger than R, whilst U approximates to u at the end of the zone.

The authors then develop the model to treat the effects of gravity, wind speed and liquid deposition. They give illustrative estimates from this model, utilizing the TRAUMA code to determine the conditions at the end of the deposition zone.

15.21.4 Fauske and Epstein model

Fauske and Epstein (1988) have described a more specific two-phase jet model, shown in Figure 15.75. They point out that, although in laboratory work the shattering temperature exceeds the saturation temperature, in practice due to factors such as vaporization upstream, roughness of the hole and air resistance, the extent of superheat without disintegration is very small. They take it as established that a superheated liquid released to the atmosphere disintegrates into droplets in the size range 10–100 μm, citing the work of Bushnell and Gooderum just described.

The basic relations of the model for the depressurization zone are:

$$u_a = u_b + \frac{P_b - P_a}{u_b \rho_b} \qquad [15.21.39]$$

$$A_a = \frac{A_b u_b \rho_b}{u_a \rho_a} \qquad [15.21.40]$$

$$\rho_a = \frac{1}{x_a/\rho_g + (1 - x_a)/\rho_f} \qquad [15.21.41]$$

$$h_o = h_f + x_a h_{fg} \qquad [15.21.42]$$

where A is the cross-sectional area of the jet, h is the specific enthalpy of the jet, P is the pressure in the jet, u is the velocity of the jet, x is the vapour fraction, or quality, ρ is the density of the jet, subscript b denotes at the orifice, or break, and subscript a denotes the end of the depressurization zone. Subscripts f, fg, g and o denote the liquid, liquid-vapour transition, the vapour and stagnation conditions, respectively. The densities and specific enthalpies at the end of the zone are evaluated at atmospheric pressure.

For the entrainment zone the entrainment relation used is that of Ricou and Spalding (1961):

$$e \propto u\left(\frac{\rho}{\rho_\infty}\right)^{1/2} \qquad [15.21.43a]$$

$$= E_o \rho_\infty u \left(\frac{\rho}{\rho_\infty}\right)^{1/2} \qquad [15.21.43b]$$

where e is the entrainment rate, E_o is the entrainment coefficient and the subscript ∞ denotes atmospheric conditions.

The relations for the conditions at the entrainment zone are:

$$\frac{u}{u_a} = \frac{h - h_\infty}{h_o - h_\infty} \qquad [15.21.44a]$$

$$= \frac{R_a}{R}\frac{\rho_a}{\rho} \qquad [15.21.44b]$$

$$= \left[1 + 2E_o\left(\frac{\rho_\infty}{\rho_a}\right)^{1/2}\frac{z}{R_a}\right]^{-1} \qquad [15.21.44c]$$
