$$\left.\begin{aligned} r_{50} &= 1.9t^{0.4}\dot{m}^{0.47} \\ \\ r_1 &= 2.8t^{0.38}\dot{m}^{0.47} \end{aligned}\right\} \begin{aligned} &1<\dot{m}<3000; && [16.39.17] \\ &10<t<300; \\ &\quad r>W && [16.39.18] \end{aligned}$$

where r is the distance from the axis of the flame for a given lethality (m).

16.40 Notation

Ar	Archimedes number
Bi	Biot number
Fo	Fourier number
Fr	Froude number
Le	Lewis number
Nu	Nusselt number
Re	Reynolds number
Pe	Peclet number
Pr	Prandtl number
g	acceleration due to gravity
P	absolute pressure
R	universal gas constant
t	time
T	absolute temperature
ρ	density
σ	Stefan–Boltzmann constant

Subscript

max	maximum

Section 16.2

Subsections 16.2.1–16.2.7

A	area of flame front cone; constant (Equation 16.2.12)
A'	area defined by Equation 16.2.9
B	constant
E	apparent activation energy
h	height of flame front cone
ΔH_c	net heat of combustion (kcal/mol)
k_1, k_2	constants
l	slant height of flame front cone
L	lower flammability limit (%v/v)
n	index
r	radius of flame front cone
S_u	burning velocity
t	temperature (°C)
u	velocity of gas
U	upper flammability limit (%v/v)
V	volumetric flow of gas
y	concentration of fuel component i (mole fraction)
α	half-angle of apex of flame front cone
τ	time delay before ignition

Subscripts

i	fuel component i
t	at temperature t
25	at 25°C

Subsection 16.2.8

a_i	constant for component i
b_i	constant for component i
c_i	constant for component i
d_i	constant for component i
c_{pi}	specific heat at constant pressure of component i
c_{pm}	mean specific heat over range specified
c_{pmp}	mean specific heat of products
C_{pmr}	mean specific heat of reactants
ΔH_c	heat of combustion
ΔH_1	enthalpy change between states 0 and 1
ΔH_2	enthalpy change between states 1 and 2
n	number of moles per mole of fuel
p	number of products
r	number of reactants

Subscripts

i	component i
o	standard state
p	products
r	reactants
1, 2	initial, final state

Subsection 16.2.9

D_o	quenching diameter
$D_{\parallel}$	critical slot width

Section 16.3

Subsection 16.3.3

g	boundry velocity gradient
r	diameter of tube
V	volumetric flow gas

Subscripts

B	blow-off
F	flashback

Subsection 16.3.4

Equation 16.3.2

d	diameter of pipe (m)
D	diffusion coefficient (m^2/s)
L	flame length (m)
u	fuel velocity (m/s)

Equation 16.3.3–16.3.5

C_t	concentration of fuel in stoichiometric mixture (mold fraction)
D	diameter of pipe (m)
L	flame length (m)
M_n	molecular weight of fuel
M_s	molecular weight of surrounding fluid (normally air)
T_f	absolute adiabatic flame temperature (K)
T_n	absolute temperature of fuel in pipe (K)
W	diamter at top of flame (m)
x	axial distance (m)
Z	flame diameter (m)
α_t	ratio of number of mole of unreacted and reacted gas in stoichiometric mixture

Subsection 16.3.5

c_p	specific heat of gas at constant pressure
g_B	critical velocity gradient for blow-off
k	constant
K	Karlovitz number

S_u	burning velocity
T_u	absolute temperature of unburned gas
T_1	absolute temperature defined by Figure 16.17
U	flow line velocity
x, y	coordinates defined by Figure 16.17
η_o	width of wave

Equations 16.3.11–16.3.13

d	diameter of sphere
η_o	thickness of unburnt outer shell

Subscripts

b	burnt
u	unburnt

Subsection 16.3.5

A	pre-exponential factor
c	specific heat of reading mass
E	activation energy
k	thermal conductivity
m	number defining geometry of reaction volume
Q	heat released per unit volume
Q'	heat of reaction per unit mass
r	semi-thickness or radius of reacting volume
x, y, z	distances in x, y, z directions
δ	dimensionless parameter defined by Equation 16.3.20
η	dimensionless parameter defined by Equation 16.3.18
ζ	dimensionless parameter defined by Equation 16.3.21
τ	dimensionless parameter defined by Equation 16.3.22

Subscript

o	initial

Subsection 16.3.9

c_p	specific heat of gas at constant pressure
S	burning velocity

Equations 16.3.27–16.3.29

E	apparent activation energy
k_1, k_2	constants
p	pressure
r	radius of vessel
τ	ignition time delay

Equations 16.3.30 and 16.3.31

d	critical diameter
h	excess enthalpy
H	minimum ignition energy
K	constant
T_f	absolute adiabatic flame temperature
T_o	absolute temperature of unhurried gas mixture ahead of the flame front
ρ	density of gas mixture

Equations 16.3.32–16.3.34

d_c	width of spark kernel
k	thermal conductivity of gas
l	characteristic flame dimension
α	thermal diffusivity of gas
δ	width of flame zone
ρ	density of gas

Subscripts

L	laminar
T	turbulent

Equations 16.3.35 and 16.3.36

A	constant (Equation 16.3.25)
A, B	constant (Equation 16.3.36)
E	minimum ignition energy
t	excitation time
α	index
β	index

Subsection 16.3.10

Equation 16.3.37

g	acceleration due to gravity (cm/s^2)
r	radius of tube
v_o	velocity of bubble (cm/s)

Equations 16.3.38–16.3.48 and 16.3.50–16.3.52

B	constant
m, n	indices
S_t	average velocity of displacement of turbulent wave
S_u	burning velocity
u'	axial component of turbulence
v'	radial component of turbulence
U	average velocity
y	mol fraction
α_i	ratio of mass of fuel component i + corresponding amount of oxidant to total mass of fuel + oxidant
ϕ_1, ϕ_2	functions of turbulence

Equation 16.3.40

S_u	burning velocity (cm/s)
T_u	absolute temperature of unburned gas (K)

Subscripts

i	component i
L	laminar
m	mixture
T	turbulent

Equation 16.3.49

d	burner diameter (cm)
u_n	laminar burning velocity (cm/s)
u_t	turbulent burning velocity (cm/s)

Equations 16.3.53–16.3.62

A	constant
c_p	specific heat of gas
D	diffusion coefficient of deficient reactant
k	thermal conductivity of gas
K	Karlovitz flame stretch factor
L	integral length scale of turbulence
n	index
R_L	turbulent Reynolds number
R_λ	unburnt gas Reynolds number
u'	r.m.s. turbulent velocity

u_l	laminar burning velocity
u_t	turbulent burning velocity
u_k'	effective r.m.s. turbulent velocity acting on Flame
U	average velocity
λ	Taylor miscoscale
v	kinematic viscosity

Section 16.3.11

A	constant
c	specific heat of unburned gas
d	quenching diameter
d_o	quenching diameter
d_p	depth of penetration of quenching
d_q	quenching distance
$d_{\parallel}$	critical slot width
f	geometrical factor
g_F	critical boundary velocity for flashback
k	thermal conductivity of gas
k_1-k_3	constants
L	gap length
S_L	laminar burning velocity
S_u	burning velocity
T_f	absolute flame temperature
T_i	absolute ignition temperature
T_o	absolute temperature of unburned gas
u'	r.m.s. turbulent velocity
x	half-width of slot
α	thermal diffusivity

Subscript

u	unburned

Subsection 16.3.12

c	constant
k	constant
m, n	indices
P_{cf}	absolute final pressure for cool flame
ΔP_{cf}	pressure rise for cool flame
P_o	initial pressure
ΔT_{cf}	temperature rise for cool flame
τ	ignition delay

Section 16.4

Subsection 16.4.2

d_L	diameter of droplet
K	burning constant
$\dot{m}_F$	mass burning rate of droplet
ρ_L	density of liquid

Subsection 16.4.3

C_f	flame front volumetric concentration
C_v	volumetric concentration
V_a	downward velocity of air
V_f	upward velocity of flame through suspension
V_s	sedimentation velocity of drops relative to air

Subsections 16.4.4 and 16.4.5

B	Spalding mass transfer number
c_p	specific heat of fuel
c_{pa}	specific heat of air
c_{pg}	specific heat of gas
C_1	ratio of surface mean area to Sauter mean diameter
C_3	ratio of volume mean diameter to Sauter mean diameter
d_q	quenching diameter
D_{32}	Sauter mean diameter
E_{min}	minimum ignition energy
f	swelling factor of fuel
H	heat of combustion
k	thermal conductivity of fuel
L	latent heat of vaporization
q	mass ratio of fuel to air
S_g	laminar burning velocity of gases liberated from particles
S_u	laminar burning velocity
ΔT	temperature difference
α	thermal diffusivity of particle
α_g	thermal diffusivity of gases
δ_r	thickness of reaction zone
ϵ	emissivity of particle
ρ	density
ϕ	equivalence ratio

Subscripts

b	boiling point of fuel
f	fuel
g	gas
p	fuel
pr	pre-reaction zone
r	reaction zone
s	surface of fuel
st	stoichiometric

Section 16.6

a	volume coefficicint of expansion
A	pre-exponential term
B	constant (Equations 16.6.31–16.6.33 only); dimensionless parameter (Equations 16.6.86–16.6.90 only)
c	specific heat of material
c_1-c_3	roots, solutions of equations
C	concentration of oxygen
C_o	concentration of oxygen in air
C_1, C_2	constants
d	diameter of sphere
D	constant
D_p	diffusion coefficient in pores
E	activation energy
F	constant
G	constant
h	surface heat transfer coefficient
h_c	convection heat transfer coefficient
h_r	radiation heat transfer coefficient
j	shape index, or factor (=0 for slab; =1 for cylinder; =2 for sphere)
k	thermal conductivity
M	parameter defined by Equation 16.6.108
n	index
P	parameter defined by Equation 16.6.109
q	heat transferred by radiation
Q	heat released by reaction per unit volume
$Q(T_a)$	modified heat released by reaction per unit volume

Q'	heat released by reaction per unit mass
Q''	modified heat released by reaction per unit volume
Q^*	modified heat released by reaction per unit mass
r	radial distance, half-width
r_1	inner radius of cylinder
r_2	outer radius of cylinder
R	gas constant
R_o	average radius
S	surface area
t	time
T	temperature
ΔT	temperature difference
V	volume
x	horizontal distance
z	dimensionless distance
α	Biot number
β	effective heat transfer coefficient
δ	dimesionless ignition parameter
δ_c	critical ignition parameter
δ^*	modified critical ignition parameter
ϵ	dimensionless parameter
ϵ_1	emissivity of surface
ϵ_2	emissivity of surroundings
θ	dimensionless temperature difference
ν	kinematic viscosity
ρ	density of material
τ	dimensionless time
ξ	dimensionless parameter defined by Equation 16.6.78
χ	dimensionless parameter defind by Equation 16.6.93
ϕ	fractional conversion
ϕ^*	small fractional conversion necessary to initiate autocatalytic reaction
ψ	fractional temperature defined by Equation 16.6.100
$\psi(C)$	concentration function defined by Equation 16.6.80
ψ'	derivative of ψ with respect to τ
ω	dimensionless concentration

Subscripts

a	ambient
c	critical value
cb	critical value for cube
f	fluid
i	induction, initial value
im	initial value for medium
o	centre
p	hot face
s	surface
sb	critical value for slab

Section 16.7

a	radius of sphere (m); half distance between axes of two parallel cylinders (m) (Equation 16.7.53 only); length of tank (m) (Equations 16.7.184–16.7.187, 16.7.190 and 16.7.191 only)
A	area (m^2)
A_n	parameter defined by Equation 16.7.185
A_p	cross-sectional area of pipe (m^2)
b	radius of sphere (m); width of tank (m) (Equations 16.7.184–16.7.187, 16.7.190 and 16.7.191 only)
B	parameter defined by Equation 16.7.65; parameter defined by Equation 16.7.185
c	concentration of ions (kmol/m^3); height of tank (m) (Equations 16.7.184–16.7.187 only)
c	constant
c_o	concentration of ions in the bulk fluid (kmol/m^3)
c_s	concentration of ions at the pipe wall (kmol/m^3)
c^*	charging tendency (As/m^2)
C	capacitance (F)
d	diameter (m)
d_d	diameter of droplet, particle (m)
d_p	diameter of pipe (m)
D	displacement (C/m^2)
D_m	molecular diffusion coefficient (m^2/s)
e	charge on proton (C) (=1.6 × 10^{-19})
E	field strength (V/m)
E_b	breakdown field strength (V/m)
E_e	field strength for onset of incendive discharge (V/m)
E_i	field strength at surface of inner cylinder (V/m)
E_{mf}	maximum field strength with tank full of liquid (V/m)
E_{mh}	maximum field strength with tank half full of liquid (V/m)
E_o	field strength at surface of outer cylinder (V/m)
E_v	field strength in vapour space of tank (V/m)
E_z	field strength at distance z below roof of tank (V/m)
E_γ	field strength at fraction γ of tank height (V/m)
f	friction factor
f	fraction of charge unrelaxed (Equations 16.7.161–16.7.162 only)
F	Faraday's constant (C/kmol) (=9.65 × 10^7)
F_c	field applied in contact between surfaces (N)
F_e	force (VAs/m)
g	acceleration due to gravity (m/s^2)
G	parameter defined by Equation 16.7.142; conductance (S) (Equation [16.7.3] only)
h	height of liquid in tank (m)
h_1	height of liquid in tank (m)
h_v	height of vapour in tank (m)
H	height of tank (m)
I	current (A)
I_i	current at inlet of pipe (A)
I_{lk}	leakage current (A)
I_o	current at outlet of pipe, at inlet of tank (A)
I_∞	streaming current in infinitely long pipe (A)
j	charge flux (A/m^2)
J	current density (A/m^2)
k	Boltzmann constant (J/K) (=1.38 × 10^{-23}); constant (Equation 16.7.221 only)
l	length (m)
L	length of tank (m)
m	mass (kg)
n	number of ions per unit volume (ions/ m^3)
n_d	number of droplets per unit volume (droplets/m^3)
n_t	transference number
N	Avogadro's constant (molecules/kmol) (=6.02 × 10^{26})
p	height of vapour space (m)
P	pressure (N/m^2)
ΔP	pressure drop (N/m^2)
q	charge (C)
q'	charge (on second body) (C)

q_o	charge in equilibrium with initial voltage (C) (charging); initial charge (C) (discharging)
Q	volumetric flow (m^3/s)
r	radial distance (m); (with subscript) radius (m)
r_c	radius of cylinder (m)
r_i	radius of inner cylinder (m)
r_o	radius of outer cylinder (m)
r_p	radius of pipe (m)
R	universal gas constant (VC/mol K)
R	resistance (Ω); gas constant (Equations 16.7.103–16.7.106 and 16.7.133–16.7.136 only)
R_p	resistance of liquid in pipe (Ω)
s	space charge density (C/m^3)
s_m	mass charge density (C/kg)
s_{mf}	space charge density with tank half full of liquid (C/m^3)
s_{ms}	space charge density with tank full of mist (C/m^3)
s_o	space charge density of liquid entering tank (C/m^3); initial space charge density (Equation 16.6.202 only) (C/m^3)
s_t	space charge density of liquid in tank (C/m^3)
S	surface area (m^2)
t	time (s)
$t_{1/2}$	half-life (s)
T	absolute temperature (K)
u	liquid velocity (m/s); ionic mobility (m^2/V s) (Equations 16.7.85–16.7.113)
u_{st}	Stokes' velocity (m/s)
v	ionic velocity (m/s)
V	potential difference, potential above earth, voltage (V)
V_{cn}	volume of containment (m^3)
V_d	potential difference across double layer (V)
V_e	volume of charge cloud (m^3)
V_o	initial voltage (V)
V_s	streaming potential (V)
V_{set}	settling potential gradient (V/m)
V_{ves}	volume of vessel (m^3)
w	fraction of height of tank filled with liquid
W	energy, work (J)
x	distance (m); half-distance between parallel plates (m) (Equation 16.7.56 only)
x, y, z	spatial coordinates (m)
X	volume fraction of dispersed phase (v/v)
Y	parameter defined by Equation 16.7.148
z	number of elementary charges per particle
α	shape parameter defined by Equation 16.7.186; parameter defined by Equation 16.7.169
β	shape parameter defined by Equation 16.7.152; parameter defined by Equation 16.7.187; parameter defined by Equation 16.7.191
γ	surface tension (N/m); fraction of tank height at which field strength is measured (Equation 16.7.184 only)
δ	thickness of double layer (m)
δ_m	thickness of diffusion layer (m)
ϵ	relative permittivity, dielectric constant
ϵ_a	absolute permittivity (F/m)
ϵ_{ar}	relative permittivity of air
ϵ_o	permittivity of free space (F/m) (=8.85×10^{-12})
η	viscosity (kg/m s)
ζ	zeta potential (V)
κ	conductivity (S/m = Ω^{-1} m^{-1})
κ_e	effective conductivity (S/m)
κ_r	rest conductivity (S/m)
λ	parameter defined by Equation 16.7.160
ν	kinematic viscosity (m^2/s)
ρ	volume resistivity, resistivity (Ω m)
ρ_e	effective density of dust cloud or settled powder (kg/m^3)
ρ_l	density of liquid (kg/m^3)
ρ_s	density of particle material (kg/m^3)
$\Delta\rho$	density difference between droplet and continuous liquid phase (kg/m^3)
σ	surface charge density (C/m^3)
τ	relaxation time, relaxation time constant (s)
τ_o	initial relaxation time (s)
τ_s	shear stress (N/m^2)
τ_{so}	shear stress at wall (N/m^2)
ϕ	potential (V)
ψ	Euler's constant (=0.577)

Subscripts

d	droplet, particle
fp	fill pipe
l	liquid
lk	leakage
ms	mist
p	pipe
t	tank
v	vapour
ves	vessel
∞	infinitely long pipe

Units

Units in this section are SI, as given above,
with the following exceptions:
Equations 16.7.123–16.7.150, 16.7.152,
16.7.154–16.7.156: cgs units
Subsections 16.7.34 and 16.7.36: units defined locally
For resistivity
ohm^{-1} = Ω^{-1} = mho = S
Units of surface resistivity: Ω
Units of volume resistivity: Ω m
cu = conductivity units (pS/m)

Section 16.10

P	probability of ignition
P_a	probability of ignition by event itself
P_b	probability of ignition by a specific ignition source
$P_{b,i}$	probability of ignition by a ignition source i
$P_{b,i,1}$	probability that ignition source i is present
$P_{b,i,2}$	probability that flammable region of gas cloud reaches ignition source i
$P_{b,i,3}$	probability that ignition source i if active is able to ignite gas
$P_{b,i,4}$	probability that ignition source i is active
P_c	probability of ignition by a background ignition source
r	distance
θ	direction
θ_s	semi-angle of sector
μ	density of ignition source

Subscript

i	*i*th ignition source

Section 16.11

B	rate of penetration of burning into fuel bed
C	mass of air required for complete combustion of unit mass of fuel
d	depth of fuel bed consumed by fire
D	duct diameter
f	fraction of surface covered by lining
L	length of flame zone
L^*	dimensionless parameter defined by Equation 16.11.1
V	velocity of advance of leading edge of flame
V^*	dimensionless parameter defined by Equation 16.11.2
V_A	velocity of air
ρ_A	density of air
ρ_f	density of fuel bed

Section 16.13

A	area
A	constant in Equation 16.13.59
A_i	constant in Equation 16.13.55a
B	radiosity
c	velocity of sound
c_o	velocity of sound in vacuum
C_c	correction factor for emissivity of carbon dioxide
C_w	correction factor for emissivity of water vapour
e	emissive power
F_A	angle factor
F_{A_1-A2}	angle factor between surface A_1 and surface A_2
F_o	interchange factor
F_ϵ	emissivity factor
h	Planck's constant
H	incident radiation
i	intensity of radiation
I	intensity of radiation
I_o	intensity of radiation at surface of source
J_T	thermal radiation flux (unattenuated)
k	Boltzmann constant
k_i	constant in Equation 16.13.55
k_1, k_2	constants in Equation 16.13.52
L	mean path length
n	refractive index
P_{CO_2}	partial pressure of carbon dioxide
P_{H_2O}	partial pressure of water vapour
r	distance
R	radiant heat factor
V	visual range
w	concentration of water in atmosphere (pr mm) (pr = precipitative water; see text)
w_i	concentration of water in atmosphere which causes absorption in window *i* to go from weak band to strong band absorption (pr mm)
x	path length in flame
X	path length outside flame
α	absorptivity
β	extinction coefficient
β_i	constant in Equation 16.13.55b
γ	scattering coefficient
ϵ_{CO_2}	emissivity of carbon dioxide
ϵ_{H_2O}	emissivity of water vapour
$\Delta\epsilon$	emissivity correction
Φ	radiant heat flux
θ	angle
κ	absorption coefficient
λ	wavelength
v	wave frequency
ρ	reflectivity
τ	transmissivity
τ_{ai}	transmissivity based on absorption in window *i*
τ_{si}	transmissivity based on scattering in window *i*
τ_{Ti}	total transmissivity in window *i*
ω	solid angle

Subscripts

b	black body
i, j	for surfaces *i, j*
s	source
t	target
λ	for wavelength λ
v	for wave frequency v

Section 16.14

Subsection 16.14.5

A_r	area of radiation of hot gas layer (m^2)
c_p	specific heat of hot gas layer (J/kg K)
I_r	effective thermal radiation intensity (W/m^2)
k	parameter defined by Equation 16.14.9
k_l	concentration at lower explosive limit (kg/m^3)
k_u	concentration at upper explosive limit (kg/m^3)
m	total mass of vapour released
q	heat loss by radiation (W)
r_l	parameter of cloud at lower explosive limit
r_u	parameter of cloud at lower explosive limit
t	time (s)
t_{eff}	effective duration of fire (s)
$t_{1/2}$	half-life of fire (s)
T_a	absolute temperature of environment (K)
T_g	absolute temperature of hot gas (K)
V_r	volume of hot gas layer (m^3)
x, y, z	distance in downwind, crosswind, vertical directions (m)
β	parameter defined by Equation 16.14.13
ϵ_a	emissivity of environment
ϵ_g	emissivity of hot gas
ρ	density of hot gas layer (kg/m^3)
σ	Stefan–Boltzmann constant ($W/m^2 K^4$)
$\sigma_x, \sigma_y, \sigma_z$	dispersion coefficients in downwind, crosswind, vertical directions (m)

Subscript

i	initial

Subsections 16.14.6 and 16.14.7

D	cloud depth (m)
H	visible flame height (m)
r	stoichiometric air–fuel mass ratio
S	flame speed (m/s)
U_w	wind speed (m/s)

w	parameter
W	width of pool fire
α	constant pressure expansion ratio for stoichiometric combustion
ρ_a	density of air (kg/m^3)
ρ_o	density of fuel–air mixture (kg/m^3)
ϕ	Volumetric concentration of fuel (v/v)

Subscript

st	stoichiometric

Section 16.15

Subsections 16.15.5–16.15.9

D	diameter of fireball (m)
f	fraction of fuel released entering fireball
k_1, k_2	constants
M	mass of fuel (kg)
M_r	mass of liquid released (kg)
n_1, n_2	indices
t_a	duration of combustion in system dominated by initial momentum effects (s)
t_b	duration of combustion in system dominated by buoyancy effects (s)
t_c	duration of combustion in system dominated by deflagration effects (s)
t_d	duration time of fireball (s)
t_e	time at which lift-off occurs (s)
ϕ	fraction of liquid vaporized

Equation 16.15.9a

d	persistence time (s)
W	mass of propellant (lb)

Equation 16.15.15

P	absoluter pressure at moment of release (Mpa)

Equation 16.15.16

E	surface emissive power (kW/m^2)
P	absolute pressure (MPa)

Subsections 16.15.11–16.15.13

E	surface emissive power
F	view factor
h	height of center of fireball
ΔH_c	heat of combustion (kJ/kg)
I	heat received by target
l	distance between center of fireball and target
Q	heat release rate (kW)
Q_r	heat rediated
r	radius of fireball
x	distance from point directly beneath centre of fireball and target, or ground distance
α	absorptivity of target
τ	atmospheric transmissivity
θ, ϕ	angles defined in Figure 16.87

Subsection 16.15.15

F_B	buoyancy force (N/m^2)
F_R	fluid resistance force (N/m^2)
g	acceleration due to gravity (m/s^2)
r	radius of fireball (m)
t	time (s)
t_b	burnout time
ρ	density of fireball (kg/m^3)

Equations 16.15.33–16.15.40

r	radius of fireball (ft)
r_b	radius of fireball at burnout (ft)
R	rate of addition of propellant (lb/s)
t	times (s)
W	mass of fireball (lb)
W_b	mass of propellant, and fireball, at burnout (lb)
ρ_b	density of fireball at burnout (lb/ft^3)

Subscript

b	burnout

Subsection 16.15.16

D	diameter of fireball (m)
M	mass of fuel (kg)
r	radius of fireball (m)
t_b	duration time of fireball (s)
W_b	mass of fireball, including air, at burnout (kg)
W_f	mass of fuel (kg)

Subsection 16.15.17

r	radius of cloud
t	time
V_f	volume of initial cloud of fuel
z	height of center of cloud
β	entrainment coefficient
ρ_a	density of air
ϕ	equivalence ratio

Subscripts

p	products
r	reactants

Subsection 16.15.18

M	mass of fuel
t_b	burning time
v_o	mean release velocity
ρ_a	density of air

Subsection 16.15.19

c	specific heat (kJ/kg °C)
D	diameter of fireball (m)
f	flash fraction
F_r	fraction of heat radiated, heat radiation factor
g	acceleration due to gravity (m/s^2)
H	enthalpy of fireball (kJ)
ΔH_c	heat of combustion (kJ/kg)
I	heat radiation intensity received by target (kW/m^2)
l	distance from centre of fireball to target (m)
M	mass of fuel released (kg)
M_a	mass of air in fireball (kg)
M_f	mass of fuel in fireball (kg)
N	parameter governing transition from control by momentum to control by gravity slumping
P	vapour pressure (MPa)
Q	heat of combustion (kJ/kg)

Q_r	heat radiation rate (kW)
r	radius of cloud (m)
R	stoichiometric value of M_a/M_f
t	time (s)
t'	time for cloud to fall below lower flammability limit (s)
t_d	duration time of fireball (s)
t_e	lift-off time (s)
t_g	time to transition from control by momentum to control by gravity slumping (s)
T_f	absolute mean temperature of fireball (K)
T_o	absolute temperature of initial reactants (K)
V	volume of cloud (m^3)
α	momentum per unit mass (m/s)
η	thermal efficiency
$\Delta\rho$	density difference between vapour and air (kg/m^3)
ρ_a	density of air (kg/m^3)
ρ_f	density of products at temperature T_f (kg/m^3)
ρ_o	density of products at temperature T_o (kg/m^3).
ρ_v	density of vapour (kg/m^3)

Subsection 16.15.20

D_{FB}	duration time of fireball (s)
E_T	heat released (J)
F_R	fraction of heat radiated
H	heat of combustion (J/kg)
I_T	unattenuated thermal radiation at radius of target (W/m^2)
I_{TA}	thermal radiation at radius of target, taking account of atmospheric attenuation (W/m^2)
M	mass of fuel in fireball (te)
M_s	mass of fuel in vessel (te)
P_D	radiative power density (W/m^3)
P_{FB}	radiative power (W)
R_{FB}	radius of fireball (m)
R_T	distance from centre of fireball to target (m)
T_e	effective absolute fireball temperature (K)
V_{FB}	volume of fireball (m^3)
X	parameter
σ	Stefan–Boltzmann constant (W/m^2 K^4)
τ	atmospheric transmissivity
ϕ	theoretical adiabatic flash fraction

Section 16.16

Subsections 16.16.4 and 16.16.5

D	diameter of fireball (m)
M	mass of chemicals (kg)
t_d	duration time of fireball (s)

Subsection 16.16.6

d	diameter of fireball (ft)
D	diameter of fireball (m)
M	mass of material (fuel + oxidizer) in fireball (kg)
t_d	duration time of fireball (s)
W	mass of material (fuel + oxidizer) in fireball (lb)

Subsection 16.16.7

d	diameter of fireball (ft)
D	diameter of fireball (m)
M	mass of explosive (kg)
t_d	duration time of fireball (s)
W	mass of explosive (lb)

Subsection 16.16.9

D	diameter of fireball (m)
M	mass of explosive (kg)
t_c	time to complete combustion (s)
t_d	duration time of fireball (s)
t_s	time for transition from hemispherical to spherical shape (s)
T_f	absolute temperature of fireball at termination
ϕ	parameter defined by Equation 16.16.21

Section 16.17

Subsection 16.17.4

d	pan diameter
u	velocity
v	liquid burning velocity
μ	viscosity
ρ	density

Subscripts

g	gas
l	liquid

Subsection 16.17.5

c_p	specific heat of air (kJ/kg)
D	flame diameter (m)
D'	elongated flame base (m)
D_w	maximum pool dimension in direction of wind (m)
g	acceleration due to gravity (m/s^2)
ΔH_c	heat of combustion of fuel (kJ/kg)
L	flame height (m)
m	mass burning rate (kg/m^2 s)
N	dimensionless parameter defined by Equation [16.17.4]
Q	total heat release rate (kW)
r_s	stoichiometric mass air to volatiles ratio
T_o	absolute temperature of ambient air (K)
u	wind speed (m/s)
u^*	dimensionless wind speed
u_c	characteristic wind speed (m/s)
u_{10}	wind speed at height of 10 m (m/s)
u_{10}^*	dimensionless wind speed at height of 10 m
α, β, γ	number of carbon, hydrogen, oxygen atoms in fuel molecule
θ	angle of tilt from vertical (rad)
μ_a	viscosity of air (kg/m s)
ρ_a	density of ambient air (kg/m^3)
ρ_g	density of fuel vapour at normal boiling point (kg/m^3)

Equations 16.17.5 and 16.17.6

A	constant
u	vapour velocity (m/s)
ρ	density of vapour (kg/m^3)
$\Delta\rho$	density difference between vapour and air (kg/m^3)

Subsection 16.17.6

d	pool diameter
F	view factor
k	extinction coefficient

q	heat transferred from flame to pool
q_c	heat transferred from flame to pool by conduction
q_r	heat transferred from flame to pool by radiation
q_{rim}	heat transferred from flame to pool by pan rim
T_b	absolute temperature of burning liquid surface
T_r	absolute temperature of flame
U	heat transfer coefficient

Equations 16.17.27 and 16.17.28

ΔH_c	net heat of combustion (kJ/kmol)
ΔH_v	latent heat of vaporization (kJ/kmol)
k_1, k_2	constants
v	liquid burning rate (cm/min)
v_∞	liquid burning rate for pool of infinite diameter (cm/min)

Equations 16.17.29 and 16.17.30

m	mass burning rate (kg/m^2 s)
m_∞	mass liquid burning rate for pool of infinite diameter (kg/m^2 s)
ϵ	flame emissivity
ρ_l	density of liquid (kg/m^3)

Equations 16.17.31–16.17.39

Δh_g	total heat of gasification (kJ/kg)
k	absorption–extinction coefficient
k_3	constant
L_m	mean beam length
m	mass burning rate (kg/m^2 s)
m_∞	mass liquid burning rate for pool of infinite diameter (kg/m^2 s)
T_f	absolute temperature of effective equivalent gray gas (K)
β	mean beam length corrector
ϵ	flame emissivity

Subsection 16.17.8

Equation 16.17.40

d	diameter of fire (ft)
k_4	constant
q	heat flux from surface (BTU/ft^2 h)
q_∞	heat flux from surface of 'large' fire (BTU/ft^2 h)

Equation 16.17.41

E	surface emissive power (kW/m^2)
T_f	absolute temperature of flame (K)
ϵ	emissivity of flame

Subsection 16.17.9

A, B	parameters defined by Equations 16.17.46c and 16.17.46d, respectively
$A_1 - A_4$	parameters defined by Equations 16.17.51d, 16.17.51f, 16.17.51h and 16.17.51i, respectively
B_1	parameter defined by Equation 16.17.51e
E	surface emissive power (kW/m^2)
$f(v)$	parameter defined by Equation 16.17.51g
F	view factor
h	height of tank
I	heat radiation incident on target (kW/m^2)
l, l'	distances defined by Figures 16.94.95 and 97
l_s	slant distance between heat source and target
L	parameter defined by Equations 16.17.46a, 16.17.48b, 16.17.51a, 16.17.58b
Q_r	heat radiation rate (kW)
r	radius of surface (m)
R	parameter defined by Equations 16.17.44a and 16.17.56a
x	ground distance between source and target (m)
X	parameter defined by Equations 16.17.46b, 16.17.48c and 16.17.51b

α	absorptivity
β	angle of target surface to horizontal
θ	angle of tilt of cylinder
τ	atmospheric transmissivity
ϕ	parameter defined by Equation 16.17.51c

Subscripts

h	horizontal surface
m	maximum
v	vertical surface

Subsection 16.17.13

D	diameter of cylinder
F	view factor
h	height of flame (m)
Δh_c	heat of combustion (kJ/kg)
H	dimensionless flame height
k	extinction coefficient
l	distance from centre of flame to target (m)
L	dimensionless distance to target
m	mass burning rate (kg/m^2 s)
P	radiative power (kW)
q_i	thermal radiation incident on target (kW/m^2)
T_f	absolute temperature of flame (K)
β	mean beam length corrector
ϵ_f	emissivity of flame
χ_r	fraction of heat radiated

Subscript

∞	pool of infinite diameter

Subsection 16.17.15

Fr'	modified Froude number
g	acceleration due to gravity (m/s^2)
H	length of flame (m)
u_w	wind speed (m/s)
W	width of trench (m)
W'	extended width of flame base (m)
θ	angle of tilt of flame (°)

Section 16.18

Subsections 16.18.2–16.18.4

C_L	lower explosive limit (v/v)
$\bar{C}_L$	modified lower explosive limit (v/v)
d	flare diameter (m)
D	distance from centre of flame to target (m)
F_r	fraction of heat radiated
I	heat radiation intensity incident on target (kW/m^2)
k	ratio of specific heats of gas
K	allowable heat radiation incident on target (kW/m^2)

M	molecular weight of gas
P	pressure just inside flare tip (kPa)
Q	net heat release rate (kW)
r	radius from centre of flame (m)
R	parameter defined by Equation 16.18.10
T	absolute temperature of gas (K)
u_j	exit velocity of gas at flare tip (m/s)
u_s	velocity of sound (m/s)
u_∞	wind velocity (m/s)
V	volumetric flow of gas (m^3/s)
W	mass flow of gas (kg/s)
$\Sigma\Delta x$	horizontal deviation of flame (m)
x_c	horizontal distance from flare tip to centre of flame (m)
$\Sigma\Delta y$	vertical deviation of flame (m)
y_c	vertical distance from flare tip to center of flame (m)
τ	atmospheric transmissivity

Subscript

j	flare tip

Subsection 16.18.6

A	surface area of flame (m^2)
b	lift-off distance of flame frustrum (m)
C	parameter defined by Equation 16.18.30
d_j	diameter of virtual source (m)
d_o	throat diameter of imagined flow nozzle (m)
D_s	effective diameter of source (m)
E	surface emissive power (kW/m^2)
F	view factor
F_r	fraction of heat radiated
g	acceleration due to gravity (m/s^2)
I	heat radiation incident on target (kW/m^3)
K	parameter defined by Equation 16.18.25
L_B	length of flame (m)
L_{Bo}	length of flame in still air (m)
$\dot{m}$	mass flow of gas (kg/s)
M	molecular weight
M_k	kilogram molecular weight of gas (kg/mol)
P_o	atmospheric pressure (N/m^2)
Q	neat heat release rate (kW)
R	velocity ratio
R_c	gas constant (J/mol K)
R_L	length of flame frustrum (m)
T	absolute temperature (K)
T_j	absolute temperature of gas in expanded jet (K)
W	mass fraction of fuel in stoichiometric mixture with air
W_1	width of base of flame frustrum (m)
W_2	width of top of flame frustrum (m)
u	gas velocity (m/s)
u_j	velocity of gas in expanded jet (m/s)
v	wind velocity (m/s)
α	angle between hole axis and flame axis (°)
α_b	angle between hole axis and line joining tip of flame to centre of hole plane (°)
β	parameter defined by Equation 16.18.19
γ	ratio of gas specific heats
θ_j	angle of flame to horizontal (°)
θ_{jv}	angle between hole axis and wind vector in plane containing hole axis, flame axis and wind vector (°)
ρ_a	density of air (kg/m^3)
$\rho_g{}^o$	density of gas at standard conditions (kg/m^3)
ρ_j	density of gas in expanded jet (kg/m^3)
ξ	Richardson number based on flame length in still air
τ	atmospheric transmissivity
Ψ	parameter defined by Equation 16.18.17

Subscripts

a	air
j	expanded jet
p	mean product value
l	adiabatic combustion conditions

Subsection 16.18.7

A	total surface area of flame (m^2)
b	lift-off distance (m)
$c(\xi)$	parameter defined by Equation 16.18.49
d_j	diameter of expanded jet (m)
D_s	effective source diameter (m)
$f(\xi)$	diameter defined by Equation 16.18.45
F	view factor
$F_{s\infty}$	fraction of heat radiated for flames which emit black body radiation
g	acceleration due to gravity (m/s^2)
G	initial momentum flux of expanded jet (N)
$h(\xi)$	parameter defined by Equation 16.18.48
k	gray gas absorption coefficient (m^{-1})
L	characteristic length (m) (Equation 16.18.38); length representing emitting path length (Equation 16.18.55)
Lb_{xy}	parameter defined by Equation 16.18.51
L_{bo}	length of vertical flame in still air (m)
q	heat radiation incident on target (kW/m^2)
Q	net heat release rate (kW)
$r(\xi)$	parameter defined by Equation 16.18.46
S	surface emissive power (kW/m^2)
S_∞	black body surface emissive power (kW/m^2)
u_a	wind speed in release direction (m/s)
u_j	velocity of expanded jet (m/s)
w_a	wind speed perpendicular to release (m/s)
W	mass fraction of fuel in stoichiometric mixture with air
W_1	maximum diameter of flame (m)
W_2	minimum diameter of flame (m)
x, y, z	distances in release, vertical, crosswind directions (m)
X, Y, Z	x, y, z positions of flame
ρ_a	density of air (kg/m^3)
ρ_j	density of expanded jet (kg/m^3)
τ	atmospheric transmissivity
ξ	Richardson number
Ψ	parameter defined by Equation 16.18.40
Ω_x, Ω_y	parameters defined by Equations 16.18.42 and 16.18.43

Subscripts

a	air
en	end of flame
j	expanded jet
sd	side of flame

Section 16.19

Subsection 16.19.2

l_i	impingement distance (m)
m	mass flow (kg/s)

Subsection 16.19.6

D_{max}	maximum cone diameter (m)
F_x, F_y, F_z	view factors defined by Equations 16.19.3, 16.19.4 and 16.19.6
h	height of vent orifice (m)
h_1	distance from ground to bottom of flame radiator (m)
h_2	distance from ground to top of flame radiator (m)
I	radiant heat flux (W/m^2)
l	length of flame (m)
r	radius of flame at tip (M)
T	absolute temperature of flame (K)
x, y	distances defined in Figure 16.106 (m)
ϵ	emissivity of flame

Subsection 16.19.7

A, B, C	constants
d	diameter of orifice (m)
D	diameter of flame (m)
F	fraction of heat radiated
g	acceleration due to gravity (m/s^2)
h	lift-off height (m)
H	height of flame (m)
H^*	flame radiation height (m)
m	index
Q	heat release rate (MW)
u	gas velocity at nozzle exit (m/s)

Subsection 16.19.9

D_j	diameter of jet (m)
ΔH_c	heat of combustion (J/kg)
L	length of flame (m)
$\dot{m}$	mass flow (kg/s)
R_s	radius of flame at distance s (m)
s	distance along centre line (m)
u_j	velocity of jet (m/s)
u_w	wind velocity (m/s)
x, z	distances in horizontal, vertical directions (m)

Subsection 16.19.10

F	fraction of heat radiated
ΔH_c	heat of combustion (kJ/kg)
$\dot{m}$	mass flow (kg/s)
q	heat radiation incident on target (kW/m^2)
x	distance from source to target (m)
τ	atmospheric transmissivity

Subsection 16.19.11

L	flame length (m)
q	fuel flow (kg/s)

Subsection 16.19.2

L	length of flame (m)
$\dot{m}$	mass flow (kg/s)
W	half-width of flame at tip (m)

Subsection 16.19.13

f	fraction of heat radiated
F	flame length (m)
H_c	heat of combustion (J/kg)
m	mass flow (kg/s)
q	heat radiation incident on target (kW/m^2)
x	distance between source and target (m)
τ	atmospheric transmissivity

Subsection 16.19.14

As Subsection 16.18.6 plus

b	modified lift-off distance
D_j	jet diameter (m)
D_s	effective source diameter (m)
L	flame length (m)
ρ_a	density of air (kg/m^3)
ρ_j	initial density at jet (kg/m^3)
ρ_v	density of vapour (kg/m^3)

Subsection 16.19.16

F	view factor
h	height of jet above ground including any lift-off
L	visible length of flame
r_f	radius of flame at height z
x	distance between axis of jet and target
z	height of flame differential element
α	half-angle of flame
ψ	angular position of flame differential element

Equations 16.19.31 and 16.19.32

As Subsection 16.18.6 plus

D_c	diameter of cylinder equivalent to flame
L	length of cylinder equivalent to flame
L_{BV}	height of centre of flame tip above level of jet exit
α_B	angle between vertical and line joining jet exit and centre of flame tip
θ	angle between vertical and flame axis

Subsection 16.19.18

A	area of ventilation opening (m^2)
H	height of ventilation opening (m)

Section 16.20

Subsection 16.20.1

A	wetted surface area
k	constant
n	index
Q	heat absorbed

Equations 16.20.2–16.20.8

A	wetted surface area (ft^2)
q	heat absorbed per unit area (BTU/ft^2 h)
Q	heat absorbed (BTU/h)

Subsection 16.20.4

c	specific heat of wall metal
d	thickness of wall metal
F	parameter (see text)
Q	heat absorbed per unit area
t	time
T_A	asymptotic value of T_1
T_o	absolute initial wall temperature
T_1	absolute wall temperature at time t
ϵ	emissivity of external surface of wall
ρ	density of wall metal
σ	Stefan–Boltzmann constant

Equations 16.20.12 and 16.20.13

A	parameter defined by Equation 16.20.13
K	ratio of outside to inside diameter of wall
P_b	burst pressure
T	wall temperature (°C)
σ_u	ultimate tensile strength or wall metal
σ_y	yield strength of wall metal

Section 16.21

Subsection 16.21.3

I	thermal radiation intensity (cal/cm^2 s)
k	thermal conductivity of wood (cal/cm^2 s (°C/cm))
t_i	ignition time (s)
α	thermal diffusivity (cm^2/s)
ρ	density of wood (g/cm^2)

Equations 16.21.1–16.21.4

A	parameter defined by Equation 16.21.2 (cal^2/cm^4 (°C)^2)
B	parameter defined by Equation 16.21.4 (cal^2/cm^4 (°C)^2)
I_p	minimum thermal radiation intensity for piloted ignition (cal/cm^2 s)
I_s	minimum thermal radiation intensity for spontaneous ignition (cal/cm^2 s)
s	specific heat of wood (cal/g °C)

Equations 16.21.5–6.21.18

c	specific heat of wood (cal/g °C)
h	heat transfer coefficient for convection (cal/cm^2 s °C)
I_o	minimum thermal radiation intensity (cal/cm^2 s)
L	linear dimension (cm)
t	time (s)
T_o	absolute initial temperature (K)
T_s	absolute surface temperature for ignition (K)
T_∞	absolute surface temperature for ignition at infinite time (K)
β	cooling modulus
γ	energy modulus
θ_s	absolute surface temperature difference for ignition (°C)
θ_∞	absolute surface temperature difference for ignition at infinite time (°C)

Equations 16.21.19 and 16.21.20

k_1	constant
L	thickness of slab (cm)
n_1–n_3	indices

Subsection 16.21.4

c	specific heat of material
ΔH	enthalpy change per unit mass in raising material to its firepoint
k	thermal conductivity of material
L	'heating length'
$\dot{q}$	rate of heat transfer across surface
V	rate of flame spread
α	thermal diffusivity of material
ρ	density of material
τ	thickness
τ_{cr}	critical thickness

Section 16.22

Subsection 16.22.5

c	specific heat of skin
k	thermal conductivity of skin
Q	net heat absorbed
T_o	initial temperature of skin
T_s	surface temperature of skin
ρ	density of skin

Subsection 16.22.6

Equation 16.22.2

I	thermal radiation intensity (W/m^2)
n	index
t	time (s)

Equations 16.22.3 and 16.22.4

D	thermal dose (kJ/m^2)
I	thermal radiation intensity (kW/m^2)
L	thermal load ((s kW/m^2)$^{4/3}$)
L'	thermal load ([s (W/m^2)$^{4/3}$]/10^4)
t	exposure time (s)

Equation 16.22.5

I	thermal radiation intensity (W/m^2)
L'	thermal load ([s (W/m^2)$^{4/3}$]/10^4)
t	exposure time (s)

Subsection 16.22.13

Equation 16.22.6

I	thermal radiation intensity (W/m^2)
n	index
t	time (s)

Equation 16.22.7

a	absorptivity of fabric
C	specific heat of fabric (J/g °C)
S	density of fabric (g/cm^2)
t_p	time to piloted ignition (s)
T_o	initial temperature of fabric (°C)
T_p	piloted ignition temperature (°C)
W	incident heat radiation (W/cm^2)

Equation 16.22.8

D_s	clothing ignition load (s (kW/m^2)^2)
I	thermal radiation intensity (kW/m^2)
t	time (s)

Subsections 16.22.15 and 16.22.17

I	thermal radiation intensity (W/m^2)
t	time of exposure (s)
Y	probit

Subsection 16.22.18

L'	thermal load ([s ([W/m^2)$^{4/3}$]/10^4)
P_m	mortality
P_{ma}	average mortality
Y	probit

δ	burn depth (m)
δ_a	burn depth corresponding to average mortality (mm)

Subscripts

a	average
l	upper
u	lower
1	first coefficient
2	second coefficient

Section 16.26

D	mass median drop size (mm)
k_1	constant
n_1, n_2	indices
R	rate of water application (l/m^2 s)
R_c	critical rate of water application (l/min)
t	time to extinguish fire (s)
ΔT	difference between water temperature and liquid fire point (°C)

Section 16.27

A	surface area of droplet (m^2)
B	mass transfer number
c	absorption coefficient
C_d	drag coefficient
D	droplet diameter (m)
g	acceleration due to gravity (m/s^2)
G	liquid mass flux (kg/m^2 s)
h_d	surface enthalpy of droplet (J/kg)
h_s	free stream enthalpy (J/kg)
L	latent heat of evaporation of droplet (J/kg)
m_d	mass of droplet (kg)
M_r	rate of evaporation loss due to thermal radiation (kg/s)
Q	heat flux droplets (W/m^2) (Equation 16.27.8); heat flux between water and surface (W/m^2) (Equation 16.27.9)
t	time (s)
δt	time of exposure of droplet (s)
U	gas velocity (m/s)
v	droplet velocity (m/s)
ν	gas kinematic viscosity (m^2/s)
ρ_g	gas density (kg/m^3)

Section 16.36

t	time (min)
T	temperature (°C)

Subsection 16.36.4

A_T	total surface area of walls and ceilings, excluding ventilation openings (m^2)
A_W	area of ventilation openings, including doors and windows (m^2)
k_f	constant
M_f	total mass of combustible material (kg of wood equivalent)
$\dot{m}$	mass burning rate (kg/min)
t_f	effective fire resistance time (min)

Subsection 16.36.11

Equations 16.36.3–16.36.4

A_W	area of ventilation opening (m^2)
H	height of ventilation opening (m)
ΔH_c	heat of combustion (kJ/kg)
k_v	constant (kg/$m^{3/2}$ s)
$\dot{m}$	mass burning rate (kg/s)
$\dot{q}$	heat release rate (kW)

Equations 16.36.5–16.36.8

A_T	total area of enclosure, excluding ventilation openings (m^2)
A_W	area of ventilation openings (m^2)
h	height of opening (m)
L	mass of fuel (kg)
$\dot{q}_{fo}$	heat release rate at flashover (kW)
T_o	ambient temperature (°C)
T_u	upper limit air temperature (°C)
η	ventilation parameter ($m^{-1/2}$)
τ	fire load parameter (kg/m^2)

Subsection 16.36.12

A_f	surface area of fuel (m^2)
I	thermal radiation intensity (kW/m^2)
L_v	heat of gasification of volatiles (kJ/kg)
$\dot{m}$	mass burning rate (kg/s)
T^*	constant
T_o	absolute ambient temperature (K)
T_u	absolute upper gas temperature (K)
$\theta_1 - \theta_5$	modification factors (see text)

Subsection 16.36.13

B	width of window (m)
H	height of window (m)
$\dot{m}$	mass burning rate (kg/s)
n	shape factor defined by Equation 16.36.13
x	horizontal reach of flame (m)
z	height of flame above top of window (m)

Section 16.39

L	length of flame (m)
$\dot{m}$	mass release flow (kg/s)
M	mass of LPG (te)
r	distance of specified lethality (m)
t	exposure time (s)
t_d	duration time (s)
W	half-width of flame at flame tip (m)

Subscripts

1	1% lethality
50	50% lethality

LEES' LOSS PREVENTION IN THE PROCESS INDUSTRIES

VOLUME 2

Hazard Identification, Assessment and Control

THIRD EDITION

Edited by
SAM MANNAN

Lee's Loss Prevention in the Process Industries

Volume 2

This book is dedicated to

Herbert Douglas Lees (1860–1944), gas engineer;
Frank Priestman Lees (1890–1916), gas engineer;
Herbert Douglas Lees (1897–1955), gas engineer;
David John Lees (1936–), agricultural engineer;
Frank Lyman MacCallum (1893–1955), mining engineer and missionary;
Vivien Clare Lees (1960–), plastic and hand surgeon;
Harry Douglas Lees (1962–), restaurateur
and their families

'They do not preach that their God will rouse them a little before
the nuts work loose.
They do not teach that His Pity allows them to drop their job when
they dam'-well choose.
As in the thronged and the lighted ways, so in the dark and the
desert they stand,
Wary and watchful all their days that their brethren's days may be
long in the land.'

Rudyard Kipling (The Sons of Martha, 1907)

Wo einer kommt and saget an,
Er hat es allen recht getan,
So bitten wir diesen lieben Herrn,
Er wöll uns solche Kunste auch lehrn

(Whoever is able to say to us
'I have done everything right',
We beg that honest gentleman
To show us how it is done)

Inscription over the 'Zwischenbau' adjoining the Rathaus in Brandenburg-on-the-Haven
(quoted by Prince B.H.M. von Bulow in *Memoirs*, 1932)

If the honeye that the bees gather out of so manye floure of herbes . . . that are growing in other mennis medowes . . . may justly be called the bees' honeye . . . so maye I call it that I have . . . gathered of manye good autores . . . my booke.

William Turner (quoted by A. Scott-James in *The Language of the Garden: A Personal Anthology*)

Preface to Third Edition

The first edition of this book appeared in 1980, at the end of a decade of rapid growth and development in loss prevention. In the preface to the second edition, Frank P. Lees wrote, "After another decade and a half the subject is more mature, although development continues apace. In preparing this second edition it has been even more difficult than before to decide what to put in and what to leave out." Frank Lees' statement in 1996 rings even truer today, another eight years later in 2004. Industrial advances and technology changes coupled with recent events have made it essential to focus on new topics while keeping a complete grasp of all of older technologies and learnings as well. Safety programs today must also consider issues such as chemical reactivity hazards, safety instrumented systems, and layer of protection analysis. In the post 9-11 world, process safety and loss prevention must also include consideration of issues related to chemical security and resilient engineering systems.

The history of safety regulations in the United States can be traced back to the year before the beginning of the twentieth century. The River and Harbor Act, the first known federal legislation relevant to safety was promulgated in 1899. Since then, the total number of legislations has steadily increased. In addition to the federal government, local entities such as the state, county, and cities have also promulgated regulations and ordnances, which impose safety requirements on process facilities. Varying degrees of similar legislative action has also occurred in the rest of the world. These legislation were all promulgated in response to some event, demographic changes, as well as changes in the industry. Also, as our understanding of the hazards associated with industrial processes developed, procedures and practices were put in place to limit or eliminate the damage. Government programs and industry initiatives spurred improvements in the science and technology needed for the recognition of hazards and associated risks.

Management systems have been put in place to implement regulations and industry practices. Government regulations will continue to be a significant driver for safety programs. As such, one of the main objectives of these management systems is to ensure compliance. However, it is also quite clear that profitability is directly related to safety and loss prevention. Thus the management systems for safety are intricately tied into the operational management.

The industrial revolution brought prosperity and along with it the use of hazardous processes and complex technologies. Growing economies and global competition has led to more complex processes involving the use of hazardous chemicals, exotic chemistry, and extreme operating conditions. As a result, a fundamental understanding of the hazards and associated risks is essential. Process safety and risk management requires the application of the basic sciences and a systematic approach. Recent advances, such as overpressure protection alternatives and reactive chemistry allow safer design and operation of processes.

In the multiple barriers concept, plants are designed with several layers so that an incident would require the failure of several systems. Another novel approach to process safety and risk management is to consider various actions in a descending hierarchical order. Inherently safer design consideration should be first in the hierarchy followed by prevention systems, mitigation, and response. The success of these systems is dependent on the fundamental understanding of the process and the associated hazards. Chronic as well as catastrophic consequences resulting from toxic and flammable substances can be reduced and/or eliminated through appropriate design and operating practices.

Managing safety is no easy task, but it makes bottom-line sense. There is a direct payoff in savings on a company workers' compensation insurance, whose premiums are partly based on the number of claims paid for job injuries. The indirect benefits are far larger, for safe plants tend to be well run in general and more productive. The recipe for safety is remarkably consistent from industry to industry. It starts with sustained support of top management followed by implementation of appropriate programs and practices that institutionalize safety as a culture as compared to add-on procedures. The ingraining of safety as second nature in day-to-day activities requires a paradigm shift and can only be accomplished when safety is viewed as an integral and comprehensive part of any activity as compared to being a stand-alone or add-on activity.

This third edition of ***Loss Prevention in the Process Industries*** represents a combination of appropriate revisions of the essential compilations put together by Frank P. Lees, along with several new chapters and additions on new areas that deserve attention and discussion. The third edition includes five new chapters and three new appendices. The five new chapters address incident investigation, inherently safer design, reactive chemicals, safety instrumented systems, and chemical security. The three new appendices address process safety management regulation in the United States, risk management program regulation in the United States, and incident databases.

The chapter on incident investigation provides a summary of incident investigation procedures that can be used not only to determine causes of incidents but also provides a primer on capturing and integrating lessons learned from incident investigations into design, operations, maintenance, and response programs. Chemical process incidents can be accompanied by significant consequences, both in terms of human life and in financial impact. Many major chemical process incidents are the result of a complex scenario involving simultaneous failures of multiple safeguards. A robust system for incident investigation is usually necessary to determine and understand the causes, as well as implement measures to prevent a repeat event. This chapter is intended to provide an overview of incident investigation by addressing major concepts, principles, and characteristics of effective incident investigations of chemical process events. The focus is on incidents pertaining to chemical processes and their associated hazards, and the associated investigation techniques appropriate for complex systems and scenarios. This chapter is based on

best practices for incident investigation, and those common concepts (i.e., tools, techniques, definitions) included in root cause investigation methodologies currently in the public domain in use in the process industry. It is not the intention to provide a stand-alone investigation methodology/guideline, nor address internal or proprietary investigation methodologies.

The chapter on inherently safer design addresses options and issues that can be considered with regard to the design and operation of plants. Inherently safer design is a philosophy that focuses on elimination of hazards or reduction of the magnitude of hazards rather than the control of hazards. Many of the concepts of inherently safer design have been applied by engineers in a wide variety of technologies for many years, without recognizing the common approach. In the late 1970s, in the wake of many large incidents in the chemical industry, Trevor Kletz recognized the common philosophies of hazard elimination and hazard reduction, gave the philosophy the name "inherently safer design," and developed a specific set of approaches to help engineers in the chemical process industries to design inherently safer processes and plants. Trevor realized that increased expectations for safety, from companies, regulatory bodies, and society in general, combined with the increased potential damage from incidents in the larger plants being built to meet increased demand and global markets, resulted in increased complexity and cost for the safety systems required to satisfy these demands. Furthermore, while hazard control systems can be made highly reliable, they can never be perfect and will always have some failure probability. While this probability can be made very small, there is always some chance that all safety systems will fail simultaneously and the result would be a large incident. Also, the hazard management systems require ongoing maintenance, as well as management and operator training, for the life of the plant. This results in ongoing costs, and the potential for future deterioration of the safety systems. Deteriorated systems will have reduced reliability, increasing the potential for a catastrophic accident. Trevor Kletz suggested that in many cases, a simpler, cheaper, and safer plant could be designed by focusing on the basic technology, eliminating or significantly reducing hazards, and therefore the need to manage them.

The chapter on reactive chemicals provides an overview of this critical issue and provides guidance on management systems as well as experimental and theoretical methods for analyses of chemical reactivity hazards. Serious incidents arising from uncontrolled reactivity have taken place since the inception of the chemical industry. The human toll of such incidents has been staggering. In recent decades, greater recognition and resources have been directed toward preventing and mitigating such occurrences. A number of incidents have been so severe as to prompt regulatory initiatives to force better management of reactivity. It is prudent for any company, organization, or other group to scrutinize the chemicals being handled and implement measures to limit the risk of a major reactive hazards event. A sampling of incidents that have substantially heightened concerns regarding reactive hazards in the general public, in governmental agencies, and in industry includes:

- The 1976 ICMESA incident in Seveso, Italy in which an uncontrolled chemical reaction generated pressure resulting in relief venting of a highly toxic dioxane into the neighboring villages and countryside.
- The 1984 Union Carbide incident in Bhopal, India in which methyl isocyanate was contacted with water, generating highly toxic cyanide gas and leading to thousands of fatalities.
- The 1994 Napp Technology incident in Lodi, New Jersey in which an uncontrolled reaction involving gold ore processing led to the deaths of five firefighters.
- The 1999 Concept Sciences incident in Allentown, Pennsylvania in which an explosion arising from a process concentrating hydroxylamine resulted in five fatalities. Another event involving purified hydroxylamine took place in a Nissin Chemical plant in Gunma Prefecture, Japan in 2000 and led to four fatalities.
- The 2001 TotalFinaElf incident in Toulouse, France in which ammonium nitrate being processed for nitrogen fertilizers exploded leading to 30 fatalities.

These events, as well as numerous others, have influenced the perception and approach to reactive hazards.

The chapter on safety instrumented systems addresses systems and procedures that need to be in place with regard to this area of safety and instrumentation. In many processes, technical or manufacturing issues limit the engineer's capability to design an inherently safer process. Further, there is generally a point where the required capital investment is disproportional to the additional risk reduction provided by the process modification. In other words, the derived safety benefit is too low relative to the economic investment. When this occurs, protection layers or safeguards must be provided to prevent or mitigate the process risk. A Safety Instrumented System (SIS) is a protection layer, which shuts down the plant, or part of it, if a hazardous condition is detected. Throughout the years, SIS have also been known as Emergency Shutdown Systems (ESD, ESS), Safety Shutdown Systems (SSD), Safety Interlock Systems (SIS), Safety Critical Systems (SCS), Safety Protection Systems (SPS), Protective Instrumented Systems (PIS), interlocks, and trip systems. Regardless of what the SIS may be called, the essential characteristic of the SIS is that it is composed of instruments, which detect that process variables are exceeding preset limits, a logic solver, which processes this information and makes decisions, and final control elements, which take necessary action on the process to achieve a safe state.

The chapter on chemical security deals with this new and critical element of the management of a process facility following the events of September 11, 2001. Security management is required for protecting the assets (including employees) of the facility, maintaining the ongoing integrity of the operation, and preserving value of the investment. Process security and process safety have many parallels and make use of many common programs and systems for achieving their ends. Process security requires a management systems approach to develop a comprehensive security program, which shares many common elements to process safety management.

The new appendix on process safety management regulation in the United States provides a summary of this regulatory requirement. The fourteen elements of the OSHA Process Safety Management (PSM) regulation (*29 CFR 1910.119*) were published in the U.S. Federal Register on February 24, 1992. The objective of the regulation is to

prevent or minimize the consequences of catastrophic releases of toxic, reactive, flammable, or explosive chemicals. The regulation requires a comprehensive management program: a holistic approach that integrates technologies, procedures, and management practices. The process safety management regulation applies to processes that involve certain specified chemicals at or above threshold quantities, processes that involve flammable liquids or gases on-site in one location, in quantities of 10,000 pounds or more (subject to few exceptions), and processes that involve the manufacture of explosives and pyrotechnics. Hydrocarbon fuels, which may be excluded if used solely as a fuel, are included if the fuel is part of a process covered by this regulation. In addition, the regulation does not apply to retail facilities, oil or gas well drilling or servicing operations, or normally unoccupied remote facilities.

The new appendix on risk management program regulation in the United States provides a summary of this regulatory requirement administered by the U.S. Environmental Protection Agency. In 1996, EPA promulgated the regulation for ***Risk Management Programs for Chemical Accident Release Prevention*** (40 CFR 68). This federal regulation was mandated by section 112(r) of the Clean Air Act Amendments of 1990. The regulation requires regulated facilities to develop and implement appropriate risk management programs to minimize the frequency and severity of chemical plant accidents. In keeping with regulatory trends, EPA required a performance-based approach towards compliance with the risk management program regulation. The EPA regulation also requires regulated facilities to develop a Risk Management Plan (RMP). The RMP includes a description of the hazard assessment, prevention program, and the emergency response program. Facilities submit the RMP to the EPA and subsequently is made available to governmental agencies, the state emergency response commission, the local emergency planning committees, and communicated to the public.

The new appendix on incident databases addresses compilations of incident databases that can used for improving safety programs, developing trends, performance measures, and metrics. Incident prevention and mitigation of consequences is the focus of a number of industry programs regulatory initiatives. As part of these programs and regulations, accident history data are often collected. There are two basic types of information. One is a database consisting of standardized fields of data usually for a large number of incidents. The second are more detailed reports of individual incidents. Analysis of these incident history databases can provide insight into incident prevention needs. While the analysis and conclusions obtained from the incident database are often limited by the shortcomings of the databases themselves, the fact remains that incident history databases are very useful and can be a powerful tool in focusing risk reduction efforts. The conclusions can be used to identify systematically the greatest risks to allow prioritization of efforts to improve process safety. At the plant level this might entail identifying certain processes, types of equipment, chemicals, operations and other factors most commonly associated with incidents. Databases that cover a very large number of facilities are likely to reveal trends and patterns that no one company or facility could determine from their own experience. Statistical knowledge of the likelihood of the release of certain types of chemicals could help emergency responders, state emergency response commissions, and local emergency planning committees determine the most likely and most serious chemical releases in their areas and plan appropriate chemical accident responses. Incident databases may also help identify technologies and practices to prevent chemical accidents, or the need to develop them. For example, the data could indicate that inspection and preventive maintenance of equipment and instruments should become more thorough or more frequent.

Preface to Second Edition

The first edition of this book appeared in 1980, at the end of a decade of rapid growth and development in loss prevention. After another decade and a half the subject is more mature, although development continues apace. In preparing this second edition it has been even more difficult than before to decide what to put in and what to leave out.

The importance of loss prevention has been underlined by a number of disasters. Those at San Carlos, Mexico City, Bhopal and Pasadena are perhaps the best known, but there have been several others with death tolls exceeding 100. There have also been major incidents in related areas, such as those on the Piper Alpha oil platform and at the nuclear power stations at Three Mile Island and Chernobyl.

Apart from the human tragedy, it has become clear that a major accident can seriously damage even a large international company and may even threaten its existence, rendering it liable to severe damages and vulnerable to takeover.

Accidents in the process industries have given impetus to the creation of regulatory controls. In the UK the Advisory Committee on Major Hazards made its third and final report in 1983. At the same time the European Community was developing its own controls which appeared as the EC Directive on Major Accident Hazards. The resulting UK legislation is the NIHHS Regulations 1982 and the CIMAH Regulations 1984. Other members of the EC have brought in their own legislation to implement the Directive. There have been corresponding developments in planning controls.

An important tool for decision-making on hazards is hazard assessment. The application of quantitative methods has played a crucial role in the development of loss prevention, but there has been lively debate on the proper application of such assessment, and particularly on the estimation and evaluation of the risk to the public.

Hazard assessment involves the assessment both of the frequency and of the consequences of hazardous events. In frequency estimation progress has been made in the collection of data and creation of data banks and in fault tree synthesis and analysis, including computer aids. In consequence assessment there has been a high level of activity in developing physical models for emission, vaporization and gas dispersion, particularly dense gas dispersion; for pool fires, fireballs, jet flames and engulfing fires; for vapour cloud explosions; and for boiling liquid expanding vapour explosions (BLEVEs). Work has also been done on injury models for thermal radiation, explosion overpressure and toxic concentration, on models of the density and other characteristics of the exposed population, and on shelter and escape.

Some of these topics require experimental work on a large scale and involving international cooperation. Large scale tests have been carried out at several sites on dense gas dispersion and on vapour cloud fires and explosions. Another major cooperative research programme has been that of DIERS on venting of chemical reactors.

The basic approach developed for fixed installations on shore has also been increasingly applied in other fields. For transport in the UK the *Transport Hazards Report* of the Advisory Committee on Dangerous Substances represents an important landmark. Another application is in the offshore oil and gas industry, for which the report on the Piper Alpha disaster, the *Cullen Report*, constitutes a watershed.

As elsewhere in engineering, computers are in widespread use in the design of process plants, where computer aided design (CAD) covers physical properties, flowsheeting, piping and instrument diagrams, unit operations and plant layout. There is increasing use of computers for failure data retrieval and analysis, reliability and availability studies, fault tree synthesis and analysis and consequence modelling, while more elusive safety expertise is being captured by computer-based expert systems.

The subject of this book is the process industries, but the process aspects of related industries, notably nuclear power and oil and gas platforms are briefly touched on. The process industries themselves are continually changing. In the last decade one of the main changes has been increased emphasis on products such as pharmaceuticals and agrochemicals made by batch processes, which have their own particular hazards.

All this knowledge is of little use unless it reaches the right people. The institutions which educate the engineers who will be responsible for the design and operation of plants handling hazardous materials have a duty to make their students aware of the hazards and at least to make a start in gaining competence in handling them.

I would like again to thank for their encouragement the heads of the Department of Chemical Engineering at Loughborough, Professors D.C. Freshwater, B.W. Brooks and M. Streat; our Industrial Professors T.A. Kletz and H.A. Duxbury and Visiting Professor S.M. Richardson; my colleagues, past and present, in the Plant Engineering Group, Mr R.J. Aird, Dr P.K. Andow, Dr M.L. Ang, Dr P.W.H. Chung, Dr D.W. Edwards, Dr P. Rice and Dr A.G. Rushton – I owe a particular debt to the latter; the members of the ACMH, chaired by Professor B.H. Harvey; the sometime directors of Technica Ltd, Dr D.H. Slater, Mr P. Charsley, Dr P.J. Comer, Dr R.A. Cox, Mr T. Gjerstad, Dr M.A.F. Pyman, Mr C.G. Ramsay, Mr M.A. Seaman and Dr R. Whitehouse; the members of the IChemE Loss Prevention Panel; the IChemE's former Loss Prevention Officer, Mr B.M. Hancock; the members of the IChemE Loss Prevention Study Group and of the Register of Safety Professionals; the editorial staff of the IChemE, in particular Mr B. Brammer; numerous members of the Health and Safety Executive, especially Dr A.C. Barrell, Mr J. Barton, Dr D.A. Carter, Mr K. Cassidy, Mr P.J. Crossthwaite, Dr N.W. Hurst, Dr S.F. Jagger, Dr J. McQuaid, Dr K. Moodie, Dr C. Nussey, Dr R.P. Pape, Dr A.F. Roberts and Dr N.F. Scilly; workers at the Safety and Reliability Directorate, particularly Dr A.T.D. Butland, Mr I. Hymes, Dr D.W. Phillips and Dr D.M. Webber; staff at Shell Thornton Research Centre, including Dr D.C. Bull and Dr A.C. Chamberlain; staff at British Gas, including Dr J.D. Andrews, Dr M.J. Harris, Mr H. Hopkins, Dr J.M. Morgan and Dr D.J. Smith; staff at the Ministry of

Defence, Explosives Storage and Transport Committee, including Mr M.A. Gould, Mr J. Henderson and Mr P. Stone; and colleagues who have taught on post-experience courses at Loughborough, in particular Dr C.D. Jones, Dr D.J. Lewis and Mr J. Madden; BP International and Mr R. Malpas for allowing me to spend a period of study leave with the company in 1985–86 and Mr F.D.H. Moysen, Mr G. Hately, Mr M. Hough, Mr R. Fearon and others in the Central Safety Group and in Engineering Department; the Honourable Lord Cullen, my fellow Technical Assessors on the Piper Alpha Inquiry, Mr B. Appleton and Mr G.M. Ford and the Cremer and Warner team at the inquiry, in particular Mr G. Kenney and Mr R. Sylvester-Evans; other professional colleagues Dr L.J. Bellamy, Professor B.A. Buffham, Dr D.A. Crowl, Mr T.J. Gilbert, Mr D.O. Hagon, Dr D.J. Hall, Mr K.M. Hill, Professor T.M. Husband, Mr M. Kneale, Dr V.C. Marshall, Dr M.L. Preston, Dr J. Rasmussen, Dr J.R. Roach, Dr J.R. Taylor, Dr V.M. Trbojevic, Mr H.M. Tweeddale, Dr G.L. Wells and Dr A.J. Wilday; my research colleagues Dr C.P. Murphy, Mrs J.I. Petts, Dr D.J. Sherwin, Mr R.M.J. Withers and Dr H. Zerkani; my research students Mr M. Aldersey, Mr D.C. Arulanantham, Dr A. Bunn, Dr M.A. Cox, Dr P.A. Davies, Dr S.M. Gilbert, Mr P. Heino, Dr A. Hunt, Dr B.E. Kelly, Dr G.P.S. Marrs, Dr J.S. Mullhi, Dr J.C. Parmar, Mr B. Poblete, Dr A. Shafaghi and Dr A.J. Trenchard as well as colleagues' research students Mr E.J. Broomfield, Mr R. Goodwin, Mr M.J. Jefferson, Dr F.D. Larkin, Mr S.A. McCoy, Dr K. Plamping, Mr J. Soutter, Dr P. Thorpe and Mr S.J. Wakeman; the office staff of the Department, Mrs E.M. Barradell, Mr D.M. Blake, Miss H.J. Bryers and Miss Y. Kosar; the staff of the University Library, in particular Miss S.F. Pilkington; and my wife Elizabeth, whose contribution has been many-faceted and in scale with this book.

FRANK P. LEES
Loughborough,
1994

Preface to First Edition

Within the past ten or fifteen years the chemical and petroleum industries have undergone considerable changes. Process conditions such as pressure and temperature have become more severe. The concentration of stored energy has increased. Plants have grown in size and are often single-stream. Storage has been reduced and interlinking with other plants has increased. The response of the process is often faster. The plant contains very large items of equipment. The scale of possible fire, explosion or toxic release has grown and so has the area which might be affected by such events, especially outside the works boundary.

These factors have greatly increased the potential for loss both in human and in economic terms. This is clear both from the increasing concern of the industry and its insurers and from the historical loss statistics.

The industry has always paid much attention to safety and has a relatively good record. But with the growing scale and complexity involved in modern plants the danger of serious large-scale incidents has been a source of increasing concern and the adequacy of existing procedures has been subjected to an increasingly critical examination.

Developments in other related areas have also had an influence. During the period considered there has been growing public concern about the various forms of pollution, including gaseous and liquid effluents and solid wastes and noise.

It is against this background that the loss prevention approach has developed. It is characteristic of this approach that it is primarily concerned with the problems caused by the depth of technology involved in modern processes and that it adopts essentially an engineering approach to them. As far as possible both the hazards and the protection are evaluated quantitatively.

The clear recognition by senior management of the importance of the loss prevention problem has been crucial to these developments. Progress has been made because management has been prepared to assign to this work many senior and capable personnel and to allocate the other resources necessary.

The management system is fundamental to loss prevention. This involves a clear management structure with well defined line and advisory responsibilities staffed by competent people. It requires the use of appropriate procedures, codes of practice and standards in the design and operation of plant. It provides for the identification, evaluation and reduction of hazards through all stages of a project from research to operation. It includes planning for emergencies.

The development of loss prevention can be clearly traced through the literature. In 1960 the Institution of Chemical Engineers held the first of a periodic series of symposia on *Chemical Process Hazards with Special Reference to Plant Design*. The Dow Chemical Company published its *Process Safety Manual* in 1964. The American Institute of Chemical Engineers started in 1967 an annual series of symposia on Loss Prevention. The European Federation of Chemical Engineers' symposium on *Major Loss Prevention in the Process Industries* at Newcastle in 1971 and the Federation's symposium on *Loss Prevention and Safety Promotion in the Process Industries* (Buschmann, 1974) at Delft are further milestones.

Another indicator is the creation in 1973 by the Institution of Chemical Engineers Engineering Practice Committee of a Loss Prevention Panel under the chairmanship of Mr T.A. Kantyka.

In the United Kingdom the Health and Safety at Work etc. Act 1974 has given further impetus to loss prevention. The philosophy of the *Robens Report* (1972), which is embodied in the Act, is that of self-regulation by industry. It is the responsibility of industry to take all reasonable measures to assure safety. This philosophy is particularly appropriate to complex technological systems and the Act provides a flexible framework for the development of the loss prevention approach.

The disaster at Flixborough in 1974 has proved a turning point. This event has led to a much more widespread and intense concern with the loss prevention problem. It has also caused the government to set up in 1975 an Advisory Committee on Major Hazards. This committee has made far-reaching recommendations for the identification and control of major hazard installations.

It will be apparent that loss prevention differs somewhat from safety as traditionally conceived in the process industries. The essential difference is the much greater engineering content in loss prevention.

This is illustrated by the relative effectiveness of inspection in different processes. In fairly simple plants much can be done to improve safety by visual inspection. This approach is not adequate, however, for the more technological aspects of complex processes.

For the reasons given above loss prevention is currently a somewhat fashionable subject. It is as well to emphasize, therefore, that much of it is not new, but has been developed over many years by engineers whose patient work in an often apparently unrewarding but vital field is the mark of true professionalism.

It is appropriate to emphasize, moreover, that accidents arising from relatively mundane situations and activities are still responsible for many more deaths and injuries than those due to advanced technology.

Nevertheless, loss prevention has developed in response to the growth of a new problem, the hazard of high technology processes, and it does have a distinctive approach and some novel techniques. Particularly characteristic are the emphasis on matching the management system to the depth of technology in the installation, the techniques developed for identifying hazards, the principle and methods of quantifying hazards, the application of reliability assessment, the practice of planning for emergencies and the critique of traditional practices or existing codes, standards or regulations where these are outdated by technological change.

There is an enormous, indeed intimidating, literature on safety and loss prevention. In addition to the symposia already referred to, mention may be made of the *Handbook of Safety and Accident Prevention in Chemical Operations* by Fawcett and Wood (1965); the *Handbook of Industrial Loss*

Prevention by the Factory Mutual Engineering Corporation (1967); and the Industrial Safety Handbook by Handley (1969, 1977). These publications, which are by multiple authors, are invaluable source material.

There is a need, however, in the author's view for a balanced and integrated textbook on loss prevention in the process industries which presents the basic elements of the subject, which covers the recent period of intense development and which gives a reasonably comprehensive bibliography. The present book is an attempt to meet this need.

The book is based on lectures given to undergraduate and postgraduate students at Loughborough over a period of years and the author gladly acknowledges their contribution.

Loss prevention is a wide and rapidly developing field and is therefore not an easy subject for a book. Nevertheless, it is precisely for these reasons that the engineer needs the assistance of a textbook and that the attempt has been considered justified.

The structure of the book is as follows. Chapter 1 deals with the background to the historical development of loss prevention, the problem of large, single-stream plants, and the differences between loss prevention and conventional safety, and between loss prevention and total loss control; Chapter 2 with hazard, accident and loss, including historical statistics; Chapter 3 with the legislation and legal background; Chapter 4 with the control of major hazards; Chapter 5 with economic and insurance aspects; Chapter 6 with management systems, including management structure, competent persons, systems and procedures, standards and codes of practice, documentation and auditing arrangements; Chapter 7 with reliability engineering, including its application in the process industries; Chapter 8 with the spectrum of techniques for identifying hazards from research through to operation; Chapter 9 with the assessment of hazards, including the question of acceptable risk; Chapter 10 with the siting and layout of plant; Chapter 11 with process design, including application of principles such as limitation of inventory, consideration of known hazards associated with chemical reactors, unit processes, unit operations and equipments, operating conditions, utilities, particular chemicals and particular processes and plants, and checking of operational deviations; Chapter 12 with pressure system design, including properties of materials, design of pressure vessels and pipework, pressure vessel standards and codes, equipment such as heat exchangers, fired heaters and rotating machinery, pressure relief and blowdown arrangements, and failure in pressure systems; Chapter 13 with design of instrumentation and control systems, including regular instrumentation, process computers and protective systems; Chapter 14 with human factors in process control, process operators, computer aids and human error; Chapter 15 with loss of containment and dispersion of material; Chapter 16 with fire, flammability characteristics, ignition sources, flames and particular types of process fire, effects of fire and fire prevention, protection and control; Chapter 17 with explosion, explosives, explosion energy, particular types of process explosion such as confined explosions, unconfined vapour cloud explosions and dust explosions, effects of explosion and explosion prevention, protection and relief; Chapter 18 with toxicity of chemicals, toxic release and effects of toxic release; Chapter 19 with commissioning and inspection of plant; Chapter 20 with plant operation; Chapter 21 with plant maintenance and modification; Chapter 22 with storage; Chapter 23 with transport, particularly by road, rail and pipeline; Chapter 24 with emergency planning both for works and transport emergencies; Chapter 25 with various aspects of personal safety such as occupational health and industrial hygiene, dust and radiation hazards, machinery and electrical hazards, protective clothing and equipment, and rescue and first aid; Chapter 26 with accident research; Chapter 27 with feedback of information and learning from accidents; Chapter 28 with safety systems, including the roles of safety managers and safety committees and representatives. There are appendices on Flixborough, Seveso, case histories, standards and codes, institutional publications, information sources, laboratories and pilot plants, pollution and noise, failure and event data, Canvey, model licence conditions for certain hazardous plants, and units and unit coversions.

Many of the matters dealt with, such as pressure vessels or process control, are major subject areas in their own right. It is stressed, therefore, that the treatment given is strictly limited to loss prevention aspects. The emphasis is on deviations and faults which may give rise to loss.

In engineering in general and in loss prevention in particular there is a conflict between the demand for a statement of basic principles and that for detailed instructions. In general, the first of these approaches has been adopted, but the latter is extremely important in safety, and a considerable amount of detailed material is given and references are provided to further material.

The book is intended as a contribution to the academic education of professional chemical and other engineers. Both educational and professional institutions have long recognized the importance of education in safety. But until recently the rather qualitative, and indeed often exhortatory, nature of the subject frequently seemed to present difficulties in teaching at degree level. The recent quantitative development of the subject goes far towards removing these objections and to integrating it more closely with other topics such as engineering design.

In other words, loss prevention is capable of development as a subject presenting intellectual challenge. This is all to the good, but a note of caution is appropriate. It remains true that safety and loss prevention depend primarily on the hard and usually unglamorous work of engineers with a strong sense of responsibility, and it is important that this central fact should not be obscured.

For this reason the book does not attempt to select particular topics merely because a quantitative treatment is possible or to give such a treatment as an academic exercise. The subject is too important for such an approach. Rather the aim has been to give a balanced treatment of the different aspects and a lead in to further reading.

It is also hoped that the book will be useful to practising engineers in providing an orientation and entry to unfamiliar areas. It is emphasized, however, that in this subject above all others, the specialized texts should be consulted for detailed design work.

Certain topics which are often associated with loss prevention, for example included in loss prevention symposia, have not been treated in detail. These include, for example, pollution and noise. The book does not attempt to deal in detail with total loss control, but a brief account of this is given.

The treatment of loss prevention given is based mainly on the chemical, petrochemical and petroleum industries,

but much of it is relevant to other process industries, such as electrical power generation (conventional and nuclear), iron and steel, gas, cement, glass, paper and food.

The book is written from the viewpoint of the United Kingdom and, where differences exist within the UK, of England. This point is relevant mainly to legislation.

Reference is made to a large number of procedures and techniques. These do not all have the same status. Some are well established and perhaps incorporated in standards or codes of practice. Others are more tentative. As far as possible the attempt has been made to give some indication of the extent to which particular items are generally accepted.

There are probably also some instances where there is a degree of contradiction between two approaches given. In particular, this may occur where one is based on engineering principles and the other on relatively arbitrary rules-of-thumb.

The book does not attempt to follow standards and codes of practice in drawing a distinction between the words *should, shall* and *must* in recommending particular practices and generally uses only the former. The distinction is important, however, in standards and codes of practice and it is described in Appendix 4[a].

An explanation of some of the terms used is in order at this point. Unfortunately there is at present no accepted terminology in this field. In general, the problems considered are those of loss, either of life or property. The term *hazard* is used to describe the object or situation which constitutes the threat of such loss. The consequences which might occur if the threat is realized are the *hazard potential*. Associated with the hazard there is a risk, which is the probability of the loss occurring. Such a risk is expressed as a *probability* or as a *frequency*. Probability is expressed as a number in the range 0 to 1 and is dimensionless; frequency is expressed in terms of events per unit time, or sometimes in other units such as events per cycle or per occasion. Rate is also used as an alternative to frequency and has the same units.

The analysis of hazards involves qualitative *hazard identification* and quantitative hazard assessment. The latter term is used to describe both the assessment of hazard potential and of risk. The assessment of risk only is described as *risk assessment*.

In accident statistics the term *Fatal Accident Frequency Rate* (FAFR) has some currency. The last two terms are tautologous and the quantity is here referred to as *Fatal Accident Rate* (FAR).

Further treatments of terminology in this field are given by BS 4200: 1967, by Green and Bourne (1962), by the Council for Science and Society (1977) and by Harvey (1979b).

Notation is defined for the particular chapter at the point where the symbols first occur. In general, a consistent notation is used, but well established equations from standards, codes and elsewhere are usually given in the original notation. A consolidated list of the notation is given at the end of chapters in which a large number of symbols is used.

The units used are in principle SI, but the exceptions are fairly numerous. These exceptions are dimensional equations, equations in standards and codes, and other equations and data given by other workers where conversion has seemed undesirable for some reason. In cases of conversion from a round number it is often not clear what degree of rounding off is appropriate. In cases of description of particular situations it appears pedantic to make the conversion where a writer has referred, for example, to a 1 inch pipe.

Notes on some of the units used are given in Appendix 12[a]. For convenience a unit conversion table is included in this appendix. Numerical values given by other authors are generally quoted without change and numerical values arising from conversion of the units of data given by other authors are sometimes quoted with an additional significant figure in order to avoid excessive rounding of values.

Some cost data are quoted in the book. These are given in pounds or US dollars for the year quoted.

A particular feature of the book is a fairly extensive bibliography of some 5000 references. These references are consolidated at the end of the book rather than at the end of chapters, because many items are referred to in a number of chapters. Lists of selected references on particular topics are given in table form in the relevant chapters.

Certain institutions, however, have a rather large number of publications which it is more convenient to treat in a different manner. These are tabulated in Appendices 4[a] and 5[a], which contain some 2000 references. There is a cross-reference to the institution in the main reference list.

In many cases institutions and other organizations are referred to by their initials. In all cases the first reference in the book gives the full title of the organization. The initials may also be looked up in the Author Index, which gives the full title.

A reference is normally given by quoting the author and, in brackets, the date, e.g. Kletz (1971). Publications by the same author in the same year are denoted by letters of the alphabet a, b, c, etc., e.g. Allen (1977a), while publications by authors of the same surname and in the same year are indicated for convenience by an asterisk against the year in the list of references. In addition, the author's initials are given in the main text in cases where there may still be ambiguity. Where a date has not been determined this is indicated as n.d.

In the case of institutional publications listed in Appendices 4[a] and 5[a] the reference is given by quoting the institution and, in brackets, the date, the publication series, e.g. HSE (1965 HSW Bklt 34) or the item number, e.g. IChemE (1971 Item 7). For institutional publications with a named author the reference is generally given by quoting the author and, in brackets, the initials of the institution, the date and the publication series or item number, e.g. Eames (UKAEA 1965 Item 4).

The field of loss prevention is currently subject to very rapid change. In particular, there is a continuous evolution of standards and codes of practice and legislation. It is important, therefore, that the reader should make any necessary checks on changes which may have occurred.

I would like to thank for their encouragement in this project Professor D.C. Freshwater and the publishers, and to acknowledge the work of many authors which I have used directly or indirectly, particularly that of Dr J.H. Burgoyne and of Professor T.A. Kletz. I have learned much from my colleagues on the Loss Prevention Panel of the Institution of Chemical Engineers, in particular Mr T.A. Kantyka and Mr F. Hearfield, and on the Advisory Committee on Major Hazards, especially the chairman Professor B.H. Harvey, the secretary Mr H.E. Lewis, my fellow group chairmen

---

[a] Appendices 4, 5 and 12 in the first edition correspond to Appendices 27, 28 and 30, respectively, in this second edition.

Professor F.R. Farmer and Professor J.L.M. Morrison and the members of Group 2, Mr K. Briscoe, Dr J.H. Burgoyne, Mr E.J. Challis, Mr S. Hope, Mr M.A. McTaggart, Professor J.F. Richardson, Mr J.R.H. Schenkel, Mr R. Sheath and Mr M.J. Turner, and also from my university colleagues Dr P.K. Andow, Mr R.J. Aird and Dr D.J. Sherwin and students Dr S.N. Anyakora, Dr B. Bellingham, Mr C.A. Marpegan and Dr G.A. Martin-Solis. I am much indebted to Professor T.A. Kletz for his criticisms and suggestions on the text. My thanks are due also to the Institution of Plant Engineers, which has supported plant engineering activities at Loughborough, to the Leverhulme Trust which awarded a Research Fellowship to study *Loss Prevention in the Process Industries* and to the Science Research Council, which has supported some of my own work in this area. I have received invaluable help with the references from Mrs C.M. Lincoln, Mrs W. Davison, Mrs P. Graham, Mr R. Rhodes and Mrs M.A. Rowlatt, with the typing from Mrs E.M. Barradell, Mrs P. Jackson and, in particular, Mrs J. Astley, and with the production from Mr R.L. Pearson and Mr T. Mould. As always in these matters the responsibility for the final text is mine alone.

FRANK P. LEES
Loughborough,
1979

Acknowledgements

Many have helped with the long and tedious production process for this 3rd edition of ***Frank P. Lees Loss Prevention in the Process Industries***. However, I would be seriously remiss if I did not start with Frank P. Lees himself. I have always had great respect and admiration for Frank Lees, the engineer and the educator. After Frank passed away, and late in 2002, our mutual friend, Roy Sanders contacted me with a request from Frank's publisher to take up the job of editing the next version. I had no idea of the enormity of the task and Frank's accomplishment. I must say that this experience has truly humbled me and has given me a new respect and new appreciation for Frank Lees' knowledge, grasp, and mastery of the subject of safety and loss prevention. I am honored and privileged to be the editor of the 3rd edition of ***Frank P. Lees Loss Prevention in the Process Industries***. I have tried to maintain Frank's high standards and appreciate the help that many others have given me, but ultimately any *faux pas* or mistakes in the 3rd edition are all mine.

I want to thank all the people who have helped revise and update the chapters that were carried over from the 2nd edition. In this respect, I would like to mention A.A. Aldeeb, J.A. Alderman, P.C. Berwanger, C.A. Brown, S. Chervin, J. Cowling, W.F. Early, M. Gentile, J.P. Gupta, J.A. Havens, D.C. Hendershot, N. Keren, K. Krishna, S.H. Landis, M.E. Levin, P.N. Lodal, M.E. Livingston, S. Mohindra, D.A. Moore, T.M. O'Connor, S.W. Ostrowski, M. Paradise, J.A. Philley, W.J. Rogers, R.E. Sanders, S.R. Saraf, M.E Sawyer, R.L. Smith, T.O. Spicer, A.E. Summers, Y. Wang, H.H. West, J.L. Woodward, and J. Zanoni. Special thanks go to individuals who helped with the new chapters and appendices: J.A. Philley for the incident investigation chapter; J.P. Gupta and D.C. Hendershot for the inherently safer design chapter; S. Chervin, M.E. Levin, and W.J. Rogers for the reactive chemicals chapter; A.E. Summers for the safety instrumented systems chapter, D.A. Moore for the chemical security chapter and T.M. O'Connor for the new appendix on incident databases.

I also want to thank those who helped with research, literature review, galley proofing, and many other jobs without which such a project is never complete. I would like to specifically mention S. Anand, L.O. Cisneros-Trevino, W. Kowhakul, Y.-S. Liu, Y. Qiao, V. Raghunathan, S. Rajaraman, J. Suardin, M. Vidal, C. Wei, C. Zhang, and Y. Zhou. I would like to make specific mention of K.L. Potucek and L.J. Littlefield who undertook the painful task of converting the pdf files of the 2nd edition to Word format. I would like to thank M.A. Cass and D.K. Startz for administrative support and keeping things going through the long haul.

I would also like to take this opportunity to thank two individuals who have provided more than moral support and encouragement. They are Trevor Kletz and Mike O'Connor. First, I have appreciated Trevor's support for our work at the Mary Kay O'Connor Process Safety Center. I also want to thank him for his pioneering leadership in many areas of process safety. Trevor is really a giant in this field, and as Roy Sanders likes to say, "Trevor does cast a long shadow in the field of process safety." I am proud to have Trevor's friendship and his support. I also want to take this opportunity to thank Mike O'Connor. He has converted his personal tragedy into an opportunity to integrate process safety into education, research, and service activities at universities. He has been a true friend and supporter of the mission and goals of the Center.

I also want to thank Mrs. Elizabeth Lees for being kind, gracious, and helpful throughout this process. I am especially grateful for her hospitality and help during my visit to Loughborough to look through Frank's notes and books.

I am grateful to my mother for her love and everything she has done for me and continues to do. I am indebted to my father for having taught me the desire for learning. He was a humble man who truly believed that, "If you stop learning, you must already be dead." I would also like to thank my wife, Afroza, and our daughters, Joya and Rumki, for their love and support. Quite often a project of this magnitude causes the personal and family life to suffer and my wife and daughters have borne the brunt of it. I appreciate their understanding.

I am sure I have failed to mention everybody who has helped me with the many facets of this project. To them I apologize and want to assure them the oversight is not intended. To everyone who has helped put this 3rd edition together, I extend my heartfelt thanks and warmest gratitude again. I must say that you have helped in a noble cause, spread the word and disseminate information that will, we hope and pray, lead to a safer industry and society.

Terminology

Attention is drawn to the availability in the literature of a number of glossaries and other aids to terminology. Some British Standard glossaries are given in Appendix 27 and other glossaries are listed in Table 1.1.

Notation

In each chapter a given symbol is defined at the point where it is first introduced. The definition may be repeated if there has been a significant gap since it was last used. The definitions are summarized in the notation given at the end of the chapter. The notation is global to the chapter unless redefined for a section. Similarly, it is global to a section unless redefined for a subsection and global to a subsection unless redefined for a set of equations or a single equation. Where appropriate, the units are given, otherwise a consistent system of units should be used, SI being the preferred system. Generally the units of constants are not given; where this is the case it should not be assumed that a constant is dimensionless.

Use of References

The main list of references is given in the section entitled References, towards the end of the book. There are three other locations where references are to be found. These are Appendix 27 on standards and codes; Appendix 28 on institutional publications; and in the section entitled Loss Prevention Bulletin which follows the References.

The basic method of referencing an author is by surname and date, e.g. Beranek (1960). Where there would otherwise be ambiguity, or where there are numerous references to the same surname, e.g. Jones, the first author's initials are included, e.g. A. Jones (1984). Further guidance on names is given at the head of the section References.

References in Appendices 27 and 28 are by institution or author. Some items in these appendices have a code number assigned by the institution itself, e.g. API (1990 Publ. 421), but where such a code number is lacking, use is generally made of an item number separated from the date by a slash, e.g. IChemE (1971/13). Thus typical entries are

API Std 2000: 1992	a standard, found in Appendix 27 under American Petroleum Institute
API (1990 Publ. 421)	an institutional publication, found in Appendix 28 under American Petroleum Institute
HSE (1990 HS(G) 51)	an institutional publication, found in Appendix 28 under Health and Safety Executive, Guidance Booklets, HS(G) series
Coward and Jones (1952 BM Bull. 503)	an institutional publication, found in Appendix 28 under Bureau of Mines, Bulletins

Institutional acronyms are given in the section Acronyms which precedes the Author Index.

There are several points of detail which require mention concerning Appendix 28. (1) The first part of the appendix contains publications of a number of institutions and the second part those of the Nuclear Regulatory Commission. (2) The Fire Protection Association publications include a number of series which are collected in the *Compendium of Fire Safety Data* (CFSD). A typical reference to this is FPA (1989 CFSD FS 6011). (3) The entries for the Health and Safety Executive are quite extensive and care may be needed in locating the relevant series. (4) The publications of the Safety and Reliability Directorate appear under the UK Atomic Energy Authority, Safety and Reliability Directorate. A typical reference is Ramskill and Hunt (1987 SRD R354). These publications are immediately preceded by the publications of other bodies related to the UKAEA, such as the Health and Safety Branch, the Systems Reliability Service and the National Centre for Systems Reliability.

References to authors in the IChemE *Loss Prevention Bulletin* are in the style Eddershaw (1989 LPB 88), which refers to issue 88 of the bulletin.

Explosion

Contents

The second of the major hazards is explosion. Explosion in the process industries causes fewer serious accidents than fire but more than toxic release. When it does occur, however, it often inflicts greater loss of life and damage than fire. Explosion is usually regarded as having a disaster potential greater than that of fire but less than that of toxic release.

The *First Report of the Advisory Committee on Major Hazards* (ACMH) (Harvey, 1976) states

> In the case of flammable materials, the greatest threat arises from the sudden massive escape of those volatile liquids, or gases, which could produce a large cloud of flammable, possibly explosive, vapour. If the cloud were ignited, the effects of combustion would depend on many factors including wind speeds and the extent to which the cloud is diluted with air. The worst consequence could be large numbers of casualties and wholesale damage on site and beyond its boundaries. Nevertheless where combustion has taken place it has generally been on or in the immediate vicinity of the site. An important feature of this threat is the small time interval between the initial escape and the fire or explosion, which could be less than a minute.

The Flixborough disaster was primarily due to a vapour cloud explosion. It was this explosion which caused most of the casualties.

There is a considerable literature on explosions. Much of the information relates to chemical or nuclear explosions and to military applications. Reference can be made here only to a few selected texts. These are *Explosions, Their Anatomy and Destructiveness* (C.S. Robinson, 1944), *Explosion and Combustion Processes in Gases* (Jost, 1946), *Supersonic Flow and Shock Waves* (Courant and Friedrichs, 1948), *The Science of High Explosives* (M.A. Cook, 1958), *Combustion, Flames and Explosions of Gases* (B. Lewis and von Elbe, 1961, 1987), *The Effects of Nuclear Weapons* (Glasstone, 1962; Glasstone and Dolan, 1980), *Explosive Shocks in Air* (Kinney, 1962; Kinney and Graham, 1985), *Explosions in Air* (W.E. Baker, 1973) and *Explosion Hazards and Evaluation* (W.E. Baker *et al.,* 1983).

Selected references on explosion are given in Table 17.1 and on detonation in Table 17.2.

Table 17.1 *Selected references on explosion (see also Tables 17.2, 17.29, 17.36 and 17.61)*

Chan and Greig (1989); FPA (1989 CFSD FS 6011); ILO (1989); Teodorczyk, Lee and Knystautas (1989); Lazari, Burley and Al-Hassani (1991); Makhviladze and Rogatykh (1991); Pineau *et al.* (1991); D.C. Bull (1992); CPD (1992a,b); Opschoor, van Loo and Pasman (1992); Lefebvre *et al.* (1993); Tang and Baker (1998, 1999); Baker *et al.* (1997); Tang, Baker and Cao (1996)

Explosion energy (*see also* Tables 17.29 and 17.36)

Girdhar and Aurora (1977); Hardesty and Kennedy (1977); Kinney and Graham (1985); Crowl (1991, 1992a); CCPS (1994/15)

Gas-filled vessels: Erode (1955, 1957, 1959); Kinney (1962); Kiwan (1970a,b, 1971); W.E. Baker (1973); Strehlow and Ricker (1976); Pohto (1979); Polentz (1980); Aslanov and Golinsky (1989); Crowl (1992a); CCPS (1994/15)

Explosion scaling

Hopkinson (1915); C.J.M. van Wingerden (1989b); Catlin and Johnson (1992)

Flame acceleration, deflagration to detonation transition (DDT) (*see also* Table 17.29)

Markstein (1957); Thibault *et al.* (1982); Lee, ICnystautas and Freeman (1984); Stock, Schildknecth and Geier (1984); S.B. Murray and Lee (1984); Peraldi, ICnystautas and Lee (1986); Nettleton (1987); Lindstedt and Michels (1989); Moen *et al.* (1989); C.K Chan, Lau and Radford (1991)

Pipes, tubes: M.W. Evans *et al.* (1949); Holzapfel and Schon (1965); Craven and Greig (1967); Leyer and Manson (1971); Moen, Murray *et al.* (1982); Rinnan (1982); J.F. Clarke and Kassoy (1984); Picone *et al.* (1984); Taki and Fujiwara (1984); Lee, ICnystautas and Chan (1985); Dunn-Rankin, Barr and Sawyer (1986); Ungiit and Shuff (1989); Dupre *et al.* (1991); Phylaktou, Andrews and Herath (1990); C.K Chan, Lau and Radford (1991); Phylaktou and Andrews (1991a,b); Phylaktou, Foley and Andrews (1993); CCPS (1994/15)
Enclosures, modules: Urtiew (1981); Moen (1982a); Hjertager *et al.* (1984); J.R. Harris and Wickens (1989); Hjertager (1991); K. van Wingerden, Visser and Pasman (1991)
Vapour clouds: Urtiew (1982a); H.G. Wagner (1982); Nettleton (1987); CCPS (1994/15)

Combustion in pipes
Mason and Wheeler (1917, 1920a–c); Chapman and Wheeler (1926, 1927); Penning (1926); de C.O.C. Ellis and Wheeler (1925, 1928a,b); Kirby and Wheeler (1931a,b); H. Robinson and Wheeler (1933); D.T. Williams and Bellinger (1949); Guenoche (1964); Gugan (1974b); Dorge, Pangritz and Wagner (1981); Moen, Lee *et al.* (1982); Hjertager (1984); J.H.S. Lee, ICnystautas and Chan (1985); Hjertager, Bjorkhaug and Fuhre (1988); Hjertager, Fuhre and Bjorkhaug (1988a)

Combustion in partially confined spaces
Abou-Arab, Erayet and Kamel (1991)
Parallel plates: Moen, Donate, ICnystautas and Lee (1980); Moen, Donate, ICnystautas, Lee and Wagner (1980); C.J.M. van Wingerden and Zeeuwen (1983); Hjertager (1984); C.J.M. van Wingerden (1984, 1989c)
Channels: Urtiew (1981); C. Chan, Moen and Lee (1983); Elsworth, Eyre and Wayne (1983); Sherman *et al.* (1985); P.H. Taylor (1986)

Spherical and cylindrical explosions (*see also* Tables 17.13 and 17.29)
Cousins and Cotton (1951a,b); Crouch *et al.* (1952); Vance and Krier (1974); Frankel and Sivashinsky (1983)

Explosions in vessels (*see also* Table 17.13)
Creech (1940); G.F.P. Harris and Briscoe (1967); Perlee, Fuller and Saul (1974 BM RI 7839); Sibulkin (1980); S.R. Moore and Weinberg (1981); Grewer and Klais (1987); Rota *et al.* (1987); Phylaktou, Andrews and Herath (1990); Phylaktou and Andrews (1991b, 1993); Checkel and Thomas (1994); Phylaktou, Andrews and Liu (1994)
Spherical geometry, spherical vessels: Flamm and Mache (1917); Mache (1918); Grumer, Cook and Kubala (1959); Spalding (1960); Spalding and Jain (1961); Spalding, Jain and Samain (1961); Raezer (1961); Pliickebaum, Strauss and Edse (1964); G.F.P. Harris (1967); Nagy, Conn and Verakis (1969 BM RI 7279); D. Bradley and Mitcheson (1976); Groff (1982); Kumar, Tamm and Harrison (1983); McCann, Thomas and Edwards (1985); Champion *et al.* (1986); Hjertager, Bjorkhaug and Fuhre (1988); Cant and Bray (1989); A.A. Evans (1989, 1990, 1991, 1992a,b); Tanaka (1989); Canu *et al.* (1990)
Cylindrical geometry, cylindrical vessels: Jain and Ebenzer (1966); Vance and Krier (1974); Starke and Roth (1986, 1989); Andrews, Herath and Phylaktou (1990)

Pressure piling
Beyling (1906); Grice and Wheeler (1929); Coward and Wheeler (1934); Gleim and March (1952 BM RI 4904); T.A.J. Brown (1959); K.C. Brown and Curzon (1963); Heinrich (1975); J. Singh (1977, 1984, 1994a); Bartknecht (1981a); Boyd *et al.* (1981); Fitt (1981a,b); Zeeuwen (1981); Phylaktou and Andrews (1993)

Other enhanced pressure effects
Kordylewski and Wach (1986, 1988)

Explosions in enclosures, modules
Rasbash (1976b,d); DnV (1979 79-0483); Hirano (1984); Hjertager *et al.* (1984); Hjertager (1986, 1991, 1993); Hjertger, Bjorkhaug and Fuhre (1988); Catlin (1991); Takahashi *et al.* (1991); Catlin and Johnson (1992); Hjertager, Solberg and Nymoen (1992); Phylaktou *et al.* (1992); Catlin, Manos and Tite (1993); Samuels (1993); Phylaktou, Andrews and Liu (1994); K. van Wingerden, Pedersen and Wilkins (1994)

Explosions in buildings
Astbury *et al.* (1970); Cubbage and Moppett (1970); FRS (1971 Fire Res. Note 847, 1974 Fire Res. Note 984, 985); Fry (1971); Astbury, West and Hodgkinson (1972, 1973); Astbury and Vaughan (1972); W.B. Howard (1972); BRE (1973 CP 11/73, 1974 BR9, CP 45/74, 1976 CP 24/76); Bartknecht (1981a); Buckland (1980); Zalosh (1980a); R.J. Harris (1983); Cleaver, Marshall and Linden (1994); Woodward, Thomas (2000)
Ronan Point: H. Griffiths, Pugsley and Saunders (1968)

Bursting vessels
Boyer *et al.* (1958); M.P. Friedman (1961); Garrison (1975); Leslie and Birk (1991); Gelfand *et al.* (1992); Crowl (1999); Baker, Tang, Cao (1996)

Vented explosions
Hjertager (1982a,b, 1986, 1991); P.H. Taylor (1986); Hjertager, Fuhre and Bjorkhaug (1988a,b); Bakke *et al.* (1989); van den Berg, van Wingerden and Verhagen (1989); P.H. Taylor and Bimson (1989); C.J.M. van Wingerden (1989c); Tamanini and Chaffee (1992)
CLICHE: Catlin (1990); Tamanini (1990, 1995, 1996a,b); Tamanini and Valiulis (1996)
FLACS: Hjertager (1982a); Bakke, Bjerketvedt and Bjorkhaug (1990)

Explosive loads
ACDS (1991); Gilbert, Lees and Scffly (1994a–c)

Particular types of explosion
Adsorbers: Anon. (1986 LPB 69, p. 25); CCPS (1993/13)
Air plants: Rotzler *et al.* (1960); Matthews (1961); G.T. Wright (1961); Lang (1962, 1965); Rendos (1963); Boyne (1966)
Air systems, oil films: Mallow (1964a,b); Thoenes 1964; Sichel, Rao and Nicholls (1971); Burgoyne and Craven (1973); Fowle (1973)
Ammonium nitrate: Commentz *et al.* (1921); Kintz, Jones and Carpenter (1948 BM RI 4245); National Board of Fire Underwriters (1948); Hainer (1955); Sykes, Johnson and Hainer (1963); Sykes *et al.* (1963); van Dolah *et al.* (1966 BMI 6747, RI 6773); HSE (1978b); Heemskerk and Schuurman (1989); ACDS (1991)
Asphalt, bitumen tanks: Anon. (1986 LPB 71, p. 71); Trumbore, Williamson and Wolfsberger (1991); Davie, Nolan and Hoban (1993, 1994); Davie, Nolan and Tucker (1993)
Boilers: Ostroot (1976b); Hewison (1983); G.D. Davis (1987); Bond (1990 LPB 93)
Centrifuges: Butterwick (1976); Funke (1976); Lindley (1987)
Chlorine systems: Eichelberger, Smura and Bergenn (1961); Johnsen and Yahnke (1962, 1973); Dokter (1985a,b); Tabata, Kodama and Kotoyori (1987); Bafflou *et al.* (1992)

Compressors: Gibbs (1960); Perlee and Zabetakis (1963 BM RI 8187); Walton (1963); W.L. Ball (1964); Schmitt (1964); Strelzoff (1964); Thoenes (1964); J.A. Rogers (1965); Armistead (1973); Burgoyne and Craven (1973); Fowle (1973); Prentice, Smith and Virtue (1974); HSE (1978b); Anon. (1979 LPB 26, p. 51); Kolodner (1980)
Cooling systems: Mansfield (1990 LPB 94)
Crankcase: Burgoyne, Newitt and Thomas (1954); Burgoyne and Newitt (1955); Mansfield (1956); Freestone, Roberts and Thomas (1965); Rushbrook (1979)
Diesel engines: Anon. (1970d)
Distillation systems: Carrara (1973); Fire Journal Staff (1973a); Freeman and McReady (1971); Jarvis (1971); Keister, Pesetsky and Clark (1971); Griffith and Keister (1973); Kotoyori *et al.* (1976); Kroger (1979)
Driers: K.N. Palmer (1973a); Reay (1977); Bartknecht (1981a); Abbott (1990); Schoofs (1992); Anon. (1994 LPB 119, p. 5)
Drums and small tanks: HSE (1970 Bklt 32); Pinsky, Vickery and Freeman (1990); Anon. (LPB 103, p. 31)
Electrical: Benjaminsen and van Wiechen (1968); Fordham Cooper (1986); Bartels (1990)
Ethylene: Martinet (1984); Vanderwater (1989)
Ethylene oxide systems: Troyan and Levine (1968); Ogawa, Miyake and Matsuo (1992)
Extruders: Anon. (1986 LPB 71, p. 31); Carter (1987 LPB 73); Anon. (1989 LPB 87, p. 3)
Flare systems: Bluhm (1964b); Kilby (1968)
Furnaces: P. Peterson (1967); Kletz (1972c); Ostroot (1972, 1976b); Durrant and Lansing (1976); Anon. (1992 LPB 108, p. 17)
Gas distribution system (public supply): DoEn (1977b); Buckland (1980); R.J. Harris (1983)
Heat exchangers: Zabetakis (1960 BM RI 5645); Bohlken (1961); Mesloh (1964); Lang (1965); Anon. (1987 LPB 74, p. 15); Anon. (1987 LPB 75, p. 22); Cullen (1990)
Hydraulic accumulators: Pratt (1986)
Hydrogen: Kolodner (1980); Anon. (1984x); Nordmo and Emblem (1989); Tamanini *et al.* (1989)
Incinerators: Anon. (1988 LPB 81, p. 17, 1990 LPB 92, p. 29)
Liquefied natural gas: Anon. (1972f); HSE (1978b); ACDS (1991)
Liquefied petroleum gas: HSE (1978b); Rasbash (1979/80); ACDS (1991)
Low temperature fluids: Burgoyne (1965b)
Lubricants: Anon. (1960c); Burgoyne and Craven (1973); Hasegawa (1992)
Mist and spray: Haber and Wolff (1923); Burgoyne and Richardson (1949b); Burgoyne (1957); Eichhorn (1964); J.R. Bowen *et al.* (1971); Vincent and Howard (1976); Vincent *et al.* (1976a,b); Gubin and Sichel (1977); Nettleton (1977b, 1987); Bar-or, Sichel and Nicholls (1981, 1982); Dabora (1982); Sichel (1982a,b); Sichel and Palaniswamy (1985); Bothe, Brandes and Redeker (1986)
Molten metal: Genco and Lemmon (1970)
Molten metal-water: C.F. Epstein (1961); Lipsett (1966); Brauer, Green and Mesler (1968); Flory, Paoli and Mesler (1969); Konway, Mead and Page (1975); HSE (1977/8); Vaughan (1980 SRD R177)
Nitrogen systems: Conklin (1961); Sanders and Nordop (1963); J.A. Rogers (1965); Anon. (1979 LPB 29, p. 151)
Piping: J.B. Smith (1949); Ringer (1985); Anon. (1989 LPB 88, p. 13)
Pollution control equipment: K.N. Palmer (1973a); Bodurtha (1976)
Pumps: Anon. (1987 LPB 74, p. 23)
Rail tank cars: Vanderwater (1989)
Ships: Burgoyne (1965a); Page and Gardner (1971); V.J. Clancey (1981); Blything and Edmonson (1984 SRD R292); ACDS (1991)
Spray driers: Masters (1972–, 1979); N. Gibson and Schofield (1977); Bartknecht (1981a)
Storage tank 'pops': Anon. (1988 LPB 82, p. 12); Kletz (1988 LPB 83)
Superheat: D.L. Katz (1972); R. King (1975a–c, 1976a,b, 1977); R.W. King (1976); Porteous and Blander (1975); Reid (1976)
Tanks, including storage tanks: Kletz (1971); Leiber (1980); HSE (1981 SHW 2125); McDaniel (1986); Anon. (1987 LPB 73, p. 9)
Vaporizers: Wright (1961)
Vent flashback: Burgoyne (1986a); W.B. Howard (1992a,b)
'Blameless' or 'physical' explosions, LNG/water explosions, rapid phase transition explosions, steam explosions Witte, Cox and Bouvier (1970); D.L. Katz and Sliepcevich (1971); Enger and Hartman (1972a); D.L. Katz (1972); W. Nelson (1973a,b); Yang (1973); Opschoor (1974); Porteous and Blander (1975); Porteous and Reid (1976); Reid (1976, 1978); AGA (1977/26); Dincer, Drake and Reid (1977); Briscoe and Vaughan (1978 SRD R131); Witte and Cox (1978); Hogan (1982); Fauske and Henry (1983); McRae (1983); Ogiso, Fujita and Uehara (1986); Ogiso, Takagi and Katagawa (1986); D.C. Bull and Strachan (1992); Fletcher and Theofanous (1994)

17.1 Explosion

17.1.1 The explosion process

An explosion is a sudden and violent release of energy. The violence of the explosion depends on the rate at which energy is released. The energy stored in a car tyre, for example, is capable of causing an explosive burst, but it can be dissipated by gradual release.

There are several kinds of energy which may be released in an explosion. Three basic types are (1) physical energy, (2) chemical energy and (3) nuclear energy.

Physical energy may take such forms as pressure energy in gases, strain energy in metals or electrical energy. Examples of the violent release of physical energy are the explosion of a vessel due to high gas pressure and the sudden rupture of a vessel due to brittle fracture. Another important physical form is thermal energy. In particular, superheat in a liquid under pressure causes flashing off of the liquid if it is let down to atmospheric pressure. However, this is generally important in creating the conditions for an explosion rather than as a source of energy for the explosion itself.

Chemical energy derives from a chemical reaction. Examples of the violent release of chemical energy are explosion of a vessel due to combustion of flammable gas, and explosion of a reactor caused by decomposition of reaction products in a runaway chemical reaction.

Chemical explosions are either (1) uniform explosions or (2) propagating explosions. An explosion in a vessel tends to be a uniform explosion, while an explosion in a long pipe gives a propagating explosion.

Nuclear energy is not considered here. In the present context, it is chemical explosions, and in particular explosions resulting from combustion of flammable gas, that are of prime interest.

17.1.2 Deflagration and detonation

Explosions from combustion of flammable gas are of two kinds: (1) deflagration and (2) detonation.

In a deflagration the flammable mixture burns at subsonic speeds. For hydrocarbon–air mixtures the deflagration velocity is typically of the order of 300 m/s.

A detonation is quite different. In a detonation the flame front travels as a shock wave followed closely by a combustion wave which releases the energy to sustain the shock wave. At steady state the detonation front reaches a velocity equal to the velocity of sound in the hot products of combustion; this is much greater than the velocity of sound in the unburnt mixture. For hydrocarbon–air mixtures the detonation velocity is typically of the order of 2000–3000 m/s. For comparison the velocity of sound in air at 0°C is 330 m/s.

A detonation generates greater pressures and is more destructive than a deflagration. Whereas the peak pressure caused by the deflagration of a hydrocarbon–air mix-air mixture in a closed vessel is of the order of 8 bar, a detonation may give a peak pressure of the order of 20 bar.

A deflagration may turn into a detonation, particularly when travelling down a long pipe. Where a transition from deflagration to detonation is occurring, the detonation velocity can temporarily exceed the steady-state detonation velocity in so-called 'over driven' condition. Deflagration and detonation are discussed further in Sections 17.2, 17.5 and 17.6.

17.1.3 Process industries explosions: explosions vs fires

Some data on 83 large loss fires/explosions over a 5-year period have been given by W.H. Doyle (1969) , and were reproduced in Table 2.14. These data have been expressed by Kletz (1977k) in terms of the proportion of fires and of explosions of different types:

	Proportion (%)
Explosions inside equipment because air got in	11
Explosions inside equipment because of runway reactions or explosive decomposition	23

17.1.4 Process industries explosions: classification of explosions

Explosions in the process industries include the following types:

(1) physical explosions
  (a) mechanical failure of pressure system (within design envelope),
  (b) overpressure of pressure system,
  (c) underpressure of pressure system,
  (d) overtemperature of pressure system,
  (e) undertemperature of pressure system;
(2) condensed phase explosions
  (a) high explosives,
  (b) ammonium nitrate,
  (c) organic peroxides,
  (d) sodium chlorate;
(5) vapour cloud explosions (VCEs);
(6) boiling liquid expanding vapour explosions (BLEVEs);
(7) confined explosions with reaction
  (a) explosion involving vapour combustion,
  (b) reactor explosions,
  (c) other explosions involving liquid phase reactions;
(8) vapour escapes into, and explosions in, buildings (VEEBs);
(9) dust explosions.

17.2 Detonation

A particularly severe form of explosion occurs when an explosive substance detonates. Detonation can occur in liquid and solid explosives, in explosive gas mixtures and in vapour clouds. These aspects of detonation are considered in Sections 17.3, 17.6 and 17.28.

Accounts of detonation, and of shock waves, are given in *Supersonic Flow and Shock Waves* (Courant and Friederichs, 1948), *Theory of Detonation* (Zeldovich and Kompaneets, 1960), *Shock Waves in Chemistry and Physics* (G.N. Bradley, 1962), *Gas Dynamics of Combustion* (Shchelkin and Troshin, 1965), *Shock Waves and Detonations in Gases* (Soloukhin, 1966), *Fundamentals of Combustion* (Strehlow, 1968a), *Detonation* (Fickett and Davis, 1979), *Unconfined Vapour Cloud Explosions* (Gugan, 1979), *The Effects of Nuclear Weapons* (Glasstone and Dolan, 1980), *Explosive Shocks in Air* (Kinney and Graham, 1985), *Principles of Combustion* (Kuo, 1986), *Combustion, Flames and Explosions* of Gases (B. Lewis and von Elbe, 1987) and *Gaseous Detonations* (Nettleton, 1987).

The origins of work on detonations are to be found in explosion disasters, notably in coal mines, and in the mathematical theory of shock waves. Studies by Riemann showed that even starting from smooth initial conditions the movement of compressible gases can lead to formation of discontinuities with a sudden rise in pressure and temperature. The thermodynamics of shock waves were investigated by Hugoniot (1887–89). The extension to reactive systems then led to the detonation theory of Chapman (1899) and of Jouguet (1905) .

The Chapman–Jouguet (CJ) equations, however, were consistent with a number of final states. The choice of final state was made by these workers on the basis of a minimum velocity criterion. Their studies provided a working model which in certain features gave good agreement with experiment and held the field for some 40 years.

A further advance came with the concept of the initiation of combustion by a shock wave travelling ahead of the reaction zone, proposed independently by Zeldovich (1940), von Neumann (1942) and Db'ring (1943). This theory takes into account the finite rate of the chemical reactions.

Later work has shown, however, that the Zeldovitch–von Neumann–Doring (ZND) model is unstable for the case where the reactions are strongly temperature dependent. There still exists, therefore, no comprehensive theory of detonations. Another aspect of interest here is the transition from deflagration to detonation, to which a particular contribution has been made by Shchelkin (Shchelkin and Troshin, 1965).

Much work on detonation utilizes mixtures of fuel with oxygen rather than air. Hence, care should be exercised in reading the literature to check the oxidant to which a particular statement or correlation is applicable.

Selected references on detonation are given in Table 17.2, and on detonability characteristics in Table 17.3.

17.2.1 Detonation waves

In a detonation, a detonation wave passes through the explosive substance. This detonation wave has certain well-defined properties. These are now considered.

The detonation wave may develop by a process of transition. This transition may be illustrated by considering the combustion in a tube of a flammable gas–air mixture which is initially at constant pressure. If ignition occurs and energy is released at one end of the tube, the burnt gases expand. The deflagration front moves at a flame speed which is the sum of the burning velocity and the velocity of the burnt gases. If the flame speed is low enough, the combustion continues at essentially constant pressure, but if the flame speed is sufficiently high for momentum changes to exercise a significant effect, pressure disturbances are created. In this latter case the flame front accelerates and travels as a combustion wave preceded by a shock wave. Further acceleration of the flame front may cause the deflagration to turn into a detonation. The detonation wave then travels with a velocity greater than that of sound in the unburnt gas.

17.2.2 Unidimensional models

Analysis of the behaviour of shock waves with and without reaction was for many years conducted mainly in terms of models in one dimension. Although the deficiencies of these unidimensional models are now recognized, they have been very successful in describing some important properties of the waves.

17.2.3 Non-reactive shock wave Rankin–Hugoniot conditions

It is convenient to consider first the unidimensional model of a planar shock wave in a non-reactive medium. Conventionally, the model is derived for a shock wave acting like a piston compressing the gases before the wave front. It is expressed first with a coordinate system moving with the wavefront as stated by Lewis and von Elbe (1987, p. 535). The basic equations are

$$G = \frac{u_1}{v_1} = \frac{u_2}{v_2} \quad \text{conservation of mass flux} \quad [17.2.1]$$

$$p_1 + \frac{u_1^2}{v_1} = p_2 + \frac{u_2^2}{v_2} \quad \text{conservation of momentum} \quad [17.2.2]$$

$$h_1 + \frac{1}{2}u_1^2 = h_2 + \frac{1}{2}u_2^2 \quad \text{conservation of energy} \quad [17.2.3]$$

with

$$h = e + pv \quad [17.2.4]$$

$$pv = RT \quad [17.2.5]$$

$$v = 1/\rho \quad [17.2.6]$$

where e is the specific internal energy of the gas, h is its specific enthalpy, p is the pressure, u is the velocity of the gas, v is its specific volume, T is its absolute temperature, ρ is its density and the subscripts 1 and 2 refer to the gas entering and leaving the shock wave, respectively. From Equations 17.2.1–17.2.4

$$\Delta h = h_2 - h_1 = \frac{1}{2}(p_2 - p_1)(v_1 + v_2) \quad [17.2.7]$$

$$\Delta e = e_2 - e_1 = \frac{1}{2}(p_2 + p_1)(v_1 - v_2) \quad [17.2.8]$$

Equations 17.2.7 and 17.2.8 comprise the Rankine–Hugoniot (R–H) equation which replaces the integral $\int_{v_1}^{v_2} P\,dV$ of isentropic compression. It can be shown, taking a perfect gas for example, that for the same volume change, Equation 17.2.8 will lead to a larger Δe and therefore a higher temperature than isentropic compression provides. For a very small volume change the RH equation reduces to $dE = -P\,dV$ which is valid for piston velocities up to the velocity of sound. When the piston velocity becomes on the order of magnitude of molecular velocities, the degradation of the kinetic energy of the piston into random molecular motion, that is, thermal energy, makes a significant additional contribution to the increase of internal energy of the compressed gas.

Other useful relations are, from Equations 17.2.1, 17.2.2 and 17.2.6,

$$(\rho_1 u_1)^2 = \frac{p_2 - p_1}{v_1 - v_2} \quad [17.2.9]$$

and from this equation and Equation 17.2.6

$$u_1 = v_1\left(\frac{p_2 - p_1}{v_1 - v_2}\right)^{1/2} \quad [17.2.10]$$

The internal energy change Δe is

$$\Delta e = e_2 - e_1 \quad [17.2.11]$$

$$= \bar{c}_v(T_2 - T_1) \quad [17.2.12]$$

where $\bar{c}_v$is the mean specific heat at constant volume. The particle velocityis w is

$$w = u_1 - u_2 \quad [17.2.13]$$

and it may be written, utilizing Equations 17.2.1 and 17.2.10, as

$$w = (v_1 - v_2)\left(\frac{p_2 - p_1}{v_1 - v_2}\right)^{1/2} \quad [17.2.14]$$

Another parameter of interest is the 'impulse force' i_f, which is a measure of the pressure exerted by the shock wave as it strikes an obstacle. The velocity heads pressure (kinetic energy) exerted is $\rho_2 w^2$. Then, substituting for this term using Equations 17.2.6 and 17.2.14 and adding the static term $(p_2 - p_1)$, the net pressure i is

$$i_f = \frac{v_1}{v_2}(p_2 - p_1) \quad [17.2.15a]$$

The impulse force should be distinguished from the impulse, i, which has units of force times the duration the force is applied, which also equals a change in momentum. The value of i from a blast wave is the area under the positive overpressure portion of the blast wave. For a detonation wave, the positive pressure portion is well approximated as a triangle with a peak pressure p_2 and a plateau pressure p_3:

$$i = \frac{v_1}{v_2}(p_2 - p_1) \quad [17.2.15b]$$

For the case where the coordinates of the system are with respect to a fixed frame of reference, rather than moving with the shock wave, the velocity of the shock wave is

$$D = V_1 + u_1 \quad [17.2.16]$$

where D is the velocity of the shock wave and V_1 is the velocity of the gas entering the shock wave, both in the fixed frame of reference. But since for the unburned gas $V_1 = 0$,

$$D = u_1 \quad [17.2.17]$$

The two coordinate systems are discussed by Kuo (1986) and B. Lewis and von Elbe (1987, p. 535).

From Equations 17.2.10 and 17.2.17

$$D = v_1\left(\frac{p_2 - p_1}{v_1 - v_2}\right)^{1/2} \quad [17.2.18]$$

Values of the shock wave parameters for air calculated by Becker (1922) are shown in Table 17.4.

For the case of detonation, in which a reaction occurs in the shock wave and the energy conservation equation is augmented by a heat input term, as discussed below, D becomes the detonation velocity.

17.2.4 Rankin–Hugoniot curves for ideal gases

The R–H equations show the relation between the initial and final states for a given change of enthalpy across the shock front. For an ideal gas with a constant ratio of specific heats 7, Equation 17.2.7 may be reformulated as

$$\frac{\gamma}{\gamma-1}(p_2v_2 - p_1v_1) = \frac{1}{2}(p_2 - p_1)(v_1 + v_2) \qquad [17.2.19]$$

Table 17.4 *Some shock wave parameters for air (after Becker, 1922)*

p_2/p_1	v_1/v_2	D (m/s)	w (m/s)	T_2 *shock wave* (K)	T_2 *adiabatic compression* (K)	i/p_1
2	1.63	452	175	336	330	1.63
5	2.84	698	452	482	426	11.4
10	3.88	978	725	705	515	34.9
100	7.06	3020	2590	3860	950	699

Equation 17.2.19 (Nettleton) yields in the p–v plane a curve which is a rectangular hyperbole. Such a curve is known as an R–H curve. Various forms of the curve are shown in Figure 17.1. Figure 17.1(a) shows for comparison an R–H curve and a curve for an isentropic process pv^{γ} = constant. Equation 17.2.9 gives a line between a pair of points on the R–H curve which is known as a Rayleigh line. Figure 17.1(a) also shows such a line.

On the assumption that there is no change in the molecular weight or ratio of specific heats of the gas, Equations 17.2.1–17.2.3, 17.2.5 and 17.2.6 yield

$$\frac{p_2}{p_1} = \frac{2\gamma \mathrm{Ma}_s^2 - (\gamma - 1)}{\gamma + 1} \qquad [17.2.20]$$

$$\frac{\rho_2}{\rho_1} = \frac{(\gamma + 1)\mathrm{Ma}_s^2}{(\gamma - 1)\mathrm{Ma}_s^2 + 2} \qquad [17.2.21]$$

$$\frac{T_2}{T_1} = \frac{\left[\gamma \mathrm{Ma}_s^2 - (\gamma - 1)/2\right]\left[((\gamma - 1)/2)\mathrm{Ma}_s^2 + 1\right]}{((\gamma + 1)/2)\mathrm{Ma}_s^2} \qquad [17.2.22]$$

with

$$\mathrm{Ma}_s = u_1/a_1 \qquad [17.2.23]$$

where a is the velocity of sound, Ma is the Mach number and the subscript s is the shock wave.

Figure 17.1 *Rankin–Hugoniot diagram: (a) R–H curve, isentropic curve and Rayleigh line; (b) family of R–H curves for different fractions ξ of completion of reaction; (c) detonation and deflagration regions of the R–H curve; and (d) the Chapman–Jouget state*

A detailed discussion of the properties of the R–H curve is given by Kuo (1986).

17.2.5 Reactive shock wave

Moving on to modelling of a planar shock wave in a reactive medium, or detonation wave, the introduction of a heat input term q into Equation 17.2.7 gives

$$h_2 - h_1 - q = \frac{1}{2}(p_2 - p_1)(v_1 + v_2) \qquad [17.2.24]$$

where q is the energy addition per unit mass, or specific energy input, in the flow behind the shock front. As before, Equation 17.2.24 can be rewritten in the alternative form

$$\frac{\gamma}{\gamma - 1}(p_1 v_1 - p_2 v_2) - q = \frac{1}{2}(p_2 - p_1)(v_1 + v_2) \qquad [17.2.25]$$

As shown in Figure 17.1(b), this equation gives a family of R–H curves for $q = 0$ and a family of R–H curves for various fractions of completion of the combustion reaction, ξ. At $\xi = 1$, the full value of q is released, so these curves also represent fractions of q as ξq.

17.2.6 Chapman–Jouguet model

The CJ model explains why detonations for a given fuel travel at a constant velocity. Equation 17.2.24 is the basis of the CJ model. Equation 17.2.25 is an alternative form for ideal gases.

Figure 17.1(c) shows the regions of the R–H curve for a finite value of q. There are two broad regions. The first, where $p_2 > p_1$ and $v_2 < v_1$, is the region of detonation with a compression wave and the second, where $p_2 < p_1$ and $v_2 < v_1$, is the region of deflagration with a rarefaction wave. The combustion conditions along the curve pass from strong detonation, through weak detonation, then weak deflagration, to strong deflagration.

The CJ equation has not one but a set of solutions. The solution to which its authors came, namely that the velocity of the shock front is the minimum consistent with the conservation laws, is embodied in the CJ hypothesis that

$$a + u_2 = u_1 \qquad [17.2.26]$$

The CJ hypothesis may be explained by reference to Figure 17.1(d). The initial state of the gas is represented by the point O. Three possible final states are shown at S, W and J together with the lines OWS and OJ, the latter being the line of the tangent from O. In the region of S the sum of the velocity of sound and that of the gas exceeds the velocity of the front ($a + u_2 > u_1$) so that any rarefaction occurring in the flow behind the front tends to overtake and weaken it, and thus this state is unstable. The velocity of the front tends towards point J. In the region of W the sum of the velocity of sound and that of the gas is less than the velocity of the wave ($a + u_2 < u_1$) so that any energy release occurring in the flow behind the front is not available to sustain it, and thus this state also is unstable. Again the velocity of the front tends towards point J. Hence J is the only stable state in the detonation region. It can also be shown that in the deflagration region the only stable state is D, where the line OD is that of the tangent from O. Points J and D are known as the upper and lower CJ points.

The angle α of the line OJ is given by $\tan \alpha = (p_2 - p_1)/(v_1 - v_2)$ and from Equation 17.2.9

$$u_1 = v_1 \left(\frac{p_2 - p_1}{v_1 - v_2}\right)^{1/2} = v_1(\tan \alpha)^{1/2} \qquad [17.2.27]$$

In this model the pressure p_2, the velocity u_1 and the Mach number Ma_1 are frequently referred to as the CJ pressure p_{CJ}, the CJ velocity u_{CJ} or D_{CJ} and the CJ Mach number $\mathrm{Ma}_{\mathrm{CJ}}$.

More detailed accounts of the full CJ model equations are given by B. Lewis and von Elbe (1987, p. 538) and Kuo (1986). The latter also gives a calculation scheme for the determination of the CJ parameters.

Work by von Neumann (1942) showed that at the instant when the front arrives there is a sharp, higher pressure, the von Neumann spike.

The shock wave profile yielded by the CJ model is illustrated in Figure 17.2. The shock wave travels as a sharp front. At the instant when the front arrives there occurs the von Neumann spike (point A). Very close to this in time is a lower pressure peak at the CJ plane (point B). Following this the pressure decays to a plateau value (point C).

There are a number of relations which may be used to obtain approximate estimates of the CJ parameters. A very simple equation is the Zeldovich approximation (Zeldovich and Kompaneets, 1960) relating the CJ pressure p_2 to the pressure p_{v} of constant volume combustion:

$$p_{\mathrm{CJ}} \approx 2p_{\mathrm{v}} \qquad [17.2.28]$$

Another equation for the CJ pressure is that given by Weir and Morrison (1954):

$$\frac{p_{\mathrm{CJ}}}{p_1} = \frac{1 + \gamma_1 \mathrm{Ma}_{\mathrm{CJ}}}{1 + \gamma_2} \qquad [17.2.29]$$

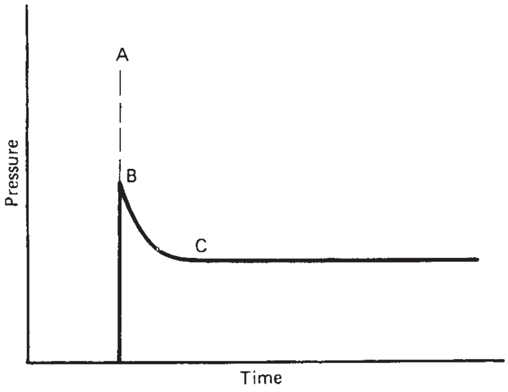

Figure 17.2 *Detonation front in a pipe: A, von Neumann spike; B, CJ peak; C, plateau pressure*

The following approximate equations are given by Nettleton (1987):

$$p_2 \approx \frac{2q(\gamma_2 - 1)}{v_1} \qquad [17.2.30]$$

$$\frac{\rho_2}{\rho_1} \approx \frac{\gamma_1 + 1}{\gamma_1} \qquad [17.2.31]$$

$$u_1 \approx [2q(\gamma_2^2 - 1)]^{1/2} \qquad [17.2.32]$$

These relations are applicable for $\mathrm{Ma}_{\mathrm{CJ}} \geq 4$, which for systems of interest is generally the case.

Some data of Strehlow on the specific heat input and ratio of specific heats γ for stoichiometric mixtures of various fuels for use in CJ model calculations are given by W.E. Baker *et al.* (1983). The data for ethylene are a specific heat input of 3.834 MJ/kg of the mixture and a ratio of specific heats of 1.188. The CJ pressure, temperature and velocity quoted, obtained from relations given by these authors rather than from those quoted above, are 18.63 bar, 2929 K and 1822 m/s, respectively.

The behaviour of detonation waves from combustion of hydrocarbon gases has been investigated by Burgess *et al.* (1968 BM RI 7196) in experiments in pipes of up to 24 in. diameter. An illustration of a detonation in a stoichiometric acetylene–air mixture is described in detail. The von Neumann spike pressure is 34 atm with an ignition delay time of 10^{-6} s. The decay from the von Neumann spike pressure to the CJ, or detonation, pressure of 19 atm occurs in about 10^{-5} s, giving an impulse of $(34+19)/2 \times 14.7 \times 10^{-5} = 4 \times 10^{-3}$ psi. The von Neumann spike is described as too fast to detect by instrumentation, but the CJ peak is detectable. The decay from the CJ pressure to the plateau pressure of 6.7 atm occurs in about 8.5 ms, giving an impulse of about 1.6 psi s.

The experiments confirmed the Zeldovich approximation. Also, the experimental plateau pressure p_{pl} was about 40% of the CJ pressure:

$$p_{\mathrm{pl}} \approx 0.4 p_{\mathrm{CJ}} \qquad [17.2.33]$$

Equations are given for the calculation of the plateau pressure.

The CJ model has proved relatively successful in predicting the detonation pressure, density and velocity in readily detonable mixtures in straight pipes.

Comparisons based on experimental data obtained by B. Lewis and Friauf (1930) for mixtures of hydrogen, oxygen and other gases have been widely quoted. Other work includes that of Berets, Greene and Kistiakowsky (1950) and that of D.G. Edwards, Williams and Breeze (1959). For a 2:1 mixture of hydrogen and oxygen the latter obtained the following values of the detonation parameters:

Pressure (atm)		*Velocity* (m/s)	
Observed	*CJ model*	*Observed*	*CJ model*
18.6	18.6	2825	2853

The observed pressure was the average pressure over 20–80 μs.

17.2.7 Zeldovich–von Neumann–Doring model

A weakness of the CJ model is the assumption that the chemical reaction which is the source of the heat release is infinitely fast. A further advance came with the development of a model which takes account of the finite rate of reaction, and of heat release. The model was formulated independently by Zeldovitch (1940), von Neumann (1942) and Döring (1943), and is known as the ZND model. In this model there is no reaction immediately behind the shock wave and there is an incubation period before the reaction begins. The fractional completion of the reaction is characterized by the parameter ξ, and there is therefore a family of R–H curves for values of ξ between 0 and 1 as in Figure 17.1(b).

The ZND model is more realistic and provides a firmer basis for the development of unidimensional models. One particular use is in predicting the pressure–time profile of the detonation, including the von Neuman spike. Considerable effort was expended from 1950 to 1970 to test the validity of the ZND model. While ZND corrected values were most frequently below the CJ value, they were occasionally larger (Brochet, Manson; Roye and Struck 1963). However, the discrepancies between theory and experiment are less than 1%, which is adequate for engineering predictions.

17.2.8 Taylor expansion wave

The product gases behind the CJ plane expand isentropically and accelerate, so that there is a distribution of particle velocities. This distribution was investigated by G.I. Taylor (1950). The Taylor expansion wave theory provides predictions for the velocity decay behind the CJ wave front.

17.2.9 Deflagration and detonation

Deflagrations are defined by $u_1/a_1 < 1$; for detonations $u_1/a_1 > 1$. Some typical characteristics of deflagrations and detonations have been listed by R. Friedman (1953):

Characteristic ratio	*Deflagration*	*Detonation*
u_1/a_1	0.0001–0.03	5–10
u_2/u_1	4–6 (acceleration)	0.4–0.7 (deceleration)
p_2/p_1	0.98 (slight expansion)	13–55 (compression)
T_2/T_1	4–16 (heat addition)	8–21 (heat addition)
p_2/p_1	0.06–0.25	1.7–2.6

17.2.10 Detonation wave structure

The account of detonation waves which has just been given is a simplified one. In particular, it does not take account of the unsteady and multidimensional features of such waves. In some cases, the detonation wave exhibits behaviour which results in pressures higher than those predicted by unidimensional theories. A case in point is spinning detonation fronts. In certain media the detonation front passing down a tube exhibits a stable spin. A spinning detonation front may be characterized in terms of the wavelength λ of the spin, or ratio of the pitch p of the spin to the diameter d of the tube:

$$\lambda = p/d \qquad [17.2.34]$$

It has been shown by Fay (1952) that

$$\frac{p}{d} = \frac{\pi(\gamma_{\mathrm{o}} + 1)}{\gamma_{\mathrm{o}} k_n} \qquad [17.2.35]$$

where γ_o is the ratio of specific heats of the detonation products and k_n is a Bessel function derivative. The values of γ_o range between 1.2 and 1.4 and k_n has the value 1.841. Equation 17.2.35 may be reformulated as

$$\frac{p}{d} = \frac{\pi d}{a_o k_n} \qquad [17.2.36]$$

where a_o is the velocity of sound in the burned gas.

Experimental evidence indicates that in a spinning front, local pressure ratios occur which are in excess of those predicted by unidimensional theories. Pressure ratios as high as 160 have been obtained in some work.

Another, related behaviour is that of galloping detonation fronts. These show regular oscillations in the velocity of the leading front. The phenomenon appears to be an extension of that of spin occurring in mixtures too close to the limit of detonability for a single transverse front to be supported. The regular peak velocities can exceed the CJ velocity by up to 35%, and the peak pressures shows a similar enhancement. The overdriven phase can persist over the relatively extended length of 0.1 m.

In marginally detonable mixtures, detonations are multidimensional. Several different types of front have been identified. They include equilibrium fronts, which have both constant time-averaged properties and a regularly recurring structure; other fronts which have the first but not the second of these features and transient fronts.

The spinning detonation front is now regarded as a limiting form of multidimensional front. The leading front consists of a number of bulges formed by Mach stems. There are a number of transverse waves orthogonal to the leading front which start at the depressions between the bulges and which reflect from each other and from the walls. There are reaction zones at the leading front and at the transverse waves.

17.2.11 Detonation wave cells

A gas detonation possesses a three-dimensional structure made up of 'cells', a regular pattern of diamond shapes. A good deal of work has been done to characterize these cells and to relate to them the principal features of detonations.

Experimentally the cell structure may be studied from soot patterns formed on smoked foil on the inner surface of the tube. It is found that typically for a cell

$$S \approx 0.6L_c \qquad [17.2.37]$$

where L_c is the length of the cell and S its width.

Related variables are the induction zone length L_i and the induction time τ_i. The induction zone length is the distance between the shock front and the reaction zone front and the induction time the interval between the passage of these two fronts, the relation between the two is

$$L_i = \tau_i \, \mathrm{Ma_s} \, a_o \qquad [17.2.38]$$

where a_o is the speed of sound in the mixture and $\mathrm{Ma_s}$ the Mach number of the shock wave.

With regard to the form of the relation between L_c and L_i, work by Vasiliev, Gavrilenko and Topchian (1972), and others, on fuel–oxygen mixtures indicates that

$$L_c = 10nL_i \quad 5 \leq n \leq 10 \qquad [17.2.39]$$

in other words, $50L_i \leq L_c \leq 100L_i$, where n is a constant. Nettleton (1987) describes the use of hydrocarbon–oxygen mixtures of the value

$$L_c \approx 50L_i \qquad [17.2.40]$$

and of hydrocarbon–air mixtures, except acetylene, of the value

$$L_c \approx 15L_i \qquad [17.2.41]$$

The induction length L_i increases as tube diameter increases. Nikuradse (1933) has shown that in pipe explosions the distance to the establishment of fully developed turbulence is about 60 diameters. A similar proportionality to diameter might be expected for the induction length. The question is discussed by Lewis and von Elbe (1987). The evidence is that the proportionality holds in some cases but not in others.

The cell width S is equivalent to the spacing of the transverse waves. For this spacing, Nettleton (1987) gives the following estimates for mixtures at atmospheric pressure: 1–10 mm for near stoichiometric fuel–oxygen mixtures; 10–100 mm for near stoichiometric fuel–air mixtures and 0.1–1.0 m for lean fuel–air mixtures.

The cell length L_c is related to the critical diameter d_c for transmission of a detonation in a tube, and also across an abrupt expansion. Detonations do not develop in a tube of diameter less than d_c, where d_c depends on fuel composition. In a classic study, Zeldovich, Kogarko and Semenov (1956) found that $d_c/L_i =$ constant for all the gases which they tested.

Further work on this feature has been done by Gvozdeva (1961) and Mitrovanov and Soloukhin (1964). Using acetylene–oxygen mixtures, the latter obtained the relationships

$$d_c = 13S \quad \text{circular tubes} \qquad [17.2.42a]$$

$$d_c = 10S \quad \text{planar channels} \qquad [17.2.42b]$$

Additional work includes that of D.H. Edwards, Thomas and Nettleton (1979), who have shown that the two results are equivalent and suggested that they are of general applicability to detonations.

D.C. Bull *et al.* (1982) have studied the cell length, and the factors influencing it, for a number of gases. For stoichiometric mixtures with air at atmospheric pressure they give the following values of L_c: methane 310 mm, ethane 54 mm, propane 46 mm, *n*-butane 54 mm, acetylene 9.2 mm, ethylene 24 mm and hydrogen 10 mm.

These authors also discuss the relevance of cell size. A planar detonation wave cannot propagate in a channel of width substantially smaller than the half-width of a cell. This feature is relevant to the quenching of detonations.

In the transition from a planar to a spherical detonation wave at an abrupt expansion there is a critical number of cell widths in the planar front to sustain the detonation. For a circular tube this number is 13.

Equation 17.2.42a is a statement of this fact. This feature also is relevant to quenching.

There is a close connection between the cell size and the critical energy E_c for initiation of a spherical detonation. Thus, Zeldovich, Kogarko and Semenov (1956) give the relation

$$E_c \propto \Delta^3 \qquad [17.2.43]$$

where Δ is an induction length, which is related to the cell size.

In the transition from deflagration to detonation there is some indication that the critical turbulent length scales may be of the same order as detonation cell lengths and that systems of different reactivity have a rank order similar to that for cell sizes.

17.2.12 Detonability characteristics

The detonability of fuel–air mixtures is characterized in terms of detonability limits and ignition sources.

There has been some debate about the existence of detonation limits separate from flammability limits, as illustrated in the following comment by Burgess *et al.* (1968 BM RI 7196): 'A consensus has gradually developed that almost any gas mixture that is flammable is also detonable if initiated with a sufficiently strong ignition source'. However, the existence of separate detonability limits is now recognized.

Compilations of data on the flammability of fuels generally do not include detonation limits, although a considerable amount of data are available scattered in the literature.

There are certain features which cast a degree of uncertainty over detonation limits. One is the phenomenon of cool flames. Another is the existence of compounds which are capable of detonation in the absence of an oxidant. Further, a distinction is made in respect of detonation between confined and unconfined situations. Separate detonation limits are quoted for these two situations.

For detonation limits for confined situations measurements are made in tubes. Accounts of such work include those of Michels, Munday and Ubbelohde (1970) and Borisov and Loban (1977). The measurement of detonation limits in unconfined gas clouds is more difficult.

Features of such work have included the use of a containment such as a balloon, a very high energy ignition source and oxygen-enriched mixtures, the results being extrapolated back to the composition of air. Work in this area has been described by Benedick, Kennedy and Morosin (1970) and D. C. Bull, Elsworth and Hooper (1979a,b).

Table 17.5 from Nettleton (1980b) gives detonation limits for a number of fuels in air for confined and unconfined situations. The author's original table gives limits for a large number of compounds and also the limits for mixtures with oxygen. In general, the detonation limits of a particular fuel are narrower than its flammability limits, with the exception of compounds which can detonate in the absence of an oxidant.

There are a number of compounds which can detonate in the absence of an oxidant. One such substance is gaseous acetylene, and extensive precautions are necessary when handling it industrially. Other self-decomposing chemicals include ethylene at pressures in excess of 7 MPa, hydrogen peroxide and ozone. Information on such compounds is given by Bretherick (1985).

Nettleton suggests that any self-decomposing compound should be considered as possibly capable of detonation, but also adds that there is no well-established example of unconfined detonation of a self-decomposing substance.

In view of the relative paucity of data on detonation limits, it is attractive to be able to derive them from the flammability limits. Some correlations have been given by Nettleton (1987, p. 77) for both confined and unconfined detonations. For a number of fuels, which include alkanes and alkenes, he gives the following relations for the lower and upper limits of detonation in a confined situation. Define ϕ as the fuel–air ratio and the subscripts l, st and u to denote the lower limit, stoichiometric and upper limit, respectively. For mixtures with air

$$\log_{10}\phi_l = 1.08\log_{10}\phi_{st} - 0.84 \qquad [17.2.44]$$

$$\log_{10}\phi_u = 1.06\log_{10}\phi_{st} + 0.64 \qquad [17.2.45]$$

and for mixtures with oxygen

$$\log_{10}\phi_l = 0.60\log_{10}\phi_{st} - 0.78 \qquad [17.2.46]$$

$$\log_{10}\phi_u = 1.13\log_{10}\phi_{st} - 0.56 \qquad [17.2.47]$$

The stoichiometric mixture is defined in terms of water and carbon dioxide as the products. For unconfined situations there is a single correlation for mixtures with air or with oxygen. This is

$$\log_{10}\phi_l = 0.51\log_{10}\phi_{st} - 0.81 \qquad [17.2.48]$$

$$\log_{10}\phi_u = 1.17\log_{10}\phi_{st} + 0.60 \qquad [17.2.49]$$

These correlations do not apply to acetylene, for which the detonation limits are wider. Another approach to the

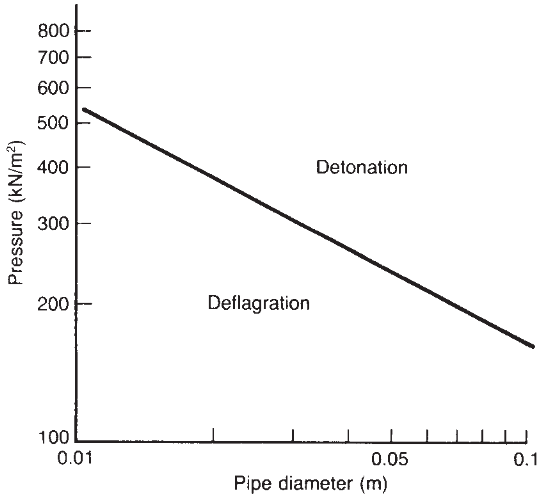

Figure 17.3 *Effect of pipe diameter and pressure on detonability of pure acetylene (after Sargent, 1957)*

prediction of detonation limits is in terms of homologous series.

There is relatively little information available on the influence of initial pressure and initial temperature on detonation limits, in confined situations. The general effect of an increase in initial pressure is to widen the detonation limits, and the same applies to an increase in initial temperature. The widening is more marked for the upper limit.

For acetylene, however, there exists a good deal of information on the effect of initial pressure. For this gas there is a pipe diameter below which only deflagration occurs, but above which detonation is possible, and this diameter is a function of the initial pressure. The correlation for this, which has been widely used in plant design, is shown in Figure 17.3. There is less information on the effect of initial temperature on acetylene, but at temperatures much in excess of 100°C there are likely to be present decomposition products which will affect the detonation limits.

The influence of additives, whether inert gases such as nitrogen or chemically active additives such as halohydrocarbons, presents a complex picture. The general effect of a diluent such as nitrogen is to narrow the detonation limits, particularly the upper limit. The amount of diluent required to suppress detonation tends to be large, but falls off sharply for mixtures close to the detonation limits. With regard to chemically active additives, the action of such additives may be rather specific, and there is some evidence, for example, that an additive effective as a fire extinguishant may not suppress a detonation.

The foregoing account has been concerned with the limits of detonation. However, whereas a mixture close to stoichiometric is, comparatively, readily detonable, one at the limits of detonation is only marginally detonable.

17.2.13 Initiation of detonation waves

The modes of initiation of a detonation differ somewhat from the modes of initiation of a deflagration. In both cases the process may be initiated by a suitable ignition source, but in the case of detonation other important mechanisms to be considered are initiation of a detonation by shock waves and acceleration of a deflagrative combustion into a detonation. It is also necessary to consider the distinction already made between confined and unconfined situations.

A further relevant distinction is that between readily detonable and marginally detonable mixtures. It is by no means clear that the mechanisms of detonation in readily detonable media are those operating in marginally detonable media.

In addition, there is some evidence that detonation may be a stochastic process (Terao, 1977).

In treating detonation by an ignition source, it is usual to speak of strong and weak sources. The terms are convenient but often not well defined. Nettleton (1987) treats as strong those ignition sources which produce a shock or blast wave of velocity greater than the CJ velocity, associated particularly with marginally detonable media and with unconfined systems. These strong ignition sources can range in strength from <10 J from sparks up to some 50 kJ from high explosives.

There is a considerable literature on the initiation of detonations in confined systems, but a large variety of methods have been used, and the interpretation of the findings is not straightforward. A greater degree of uniformity is now obtained by the adoption of standard methods, notably that of Zeldovitch and Kompaneets (1960). In this method a readily detonable mixture and a driving mixture are held in a tube separated by a diaphragm, which is removed seconds before detonation is initiated in the driving mixture. This technique allows the parameters of the driving mixture such as composition and initial pressure to be varied and the effect of the strength of the triggering wave to be investigated. The technique has been adapted to the study of unconfined detonations using an expansion nozzle.

Dealing first with initiation by ignition sources, for confined systems the quantity of interest is the minimum ignition energy for detonation. In principle, this is measured as a spark energy. However, data on this parameter are sparse and generally there is no alternative but to resort to the value of the regular minimum ignition energy (MIE), that for ignition of a flammable mixture.

A large amount of work has been done on initiation of detonation in unconfined vapour clouds by ignition sources such as sparks and high explosives. Here, the ignition energy for detonation is generally expressed as the critical energy E_c for a spherical detonation. The critical energy E_c varies with the concentration of the fuel and has a minimum value E_c^*.

Work on spark initiation of detonation of unconfined clouds has shown that, as in similar work on ignition of flammable mixtures, the results obtained depend on factors such as the spark gap width and efficiency and the rate of energy deposition.

With regard to the strength of the explosive ignition source necessary to induce detonation, work by Bach, Knystautas and Lee (1971) has shown that for direct initiation of spherical detonation waves the rate of deposition of energy into the gas is critical. Reviewing this work, Strehlow (1973b) suggests that charge geometry is probably very important and that this factor may account for the apparent discrepancies in the quantities of explosive required to initiate detonation in the work which he quotes.

In considering the initiation of detonation in an unconfined cloud, the mechanism by which this occurs is of some relevance. It is now believed that when initiation occurs by a source with relatively low energy such as an electrical spark or 10 g of high explosive, the velocity of the initial blast wave decays below the CJ value before significant chemical reaction occurs in the flow, and there may be a propagation as quasi-steady-state velocity before acceleration sets in again and leads to detonation. For the size of charge quoted, the distance over which this overall process occurs is of the order of 10 cm. For larger charges the distance is correspondingly greater, and may thus be appreciable.

Critical energies for initiation of spherical detonation have been obtained by a number of workers. Reviewing these, Nettleton (1987) quotes in particular data given by Carlson (1973) for mixtures of fuel and oxygen. The fuel concentrations in the most readily detonable mixtures lie in the range 20–40% and the values of the critical energy E_c obtained range over two orders of magnitude from <0.11 J for acetylene to 12.5 J for acetaldehyde. He comments that the chemical nature of the fuel strongly influences detonability but that the effect is more complex than one of simple bond strength.

The critical energy E_c for detonation in a spherical cloud is related to the critical diameter d_c for transmission of a detonation from a tube across an abrupt enlargement of area as described below. The determination of d_c therefore provides a means of estimating E_c. Matsui and Lee (1979) use the relation

$$E_c = \frac{\pi p_D u_D}{24 C_D} d_c^3 \qquad [17.2.50]$$

where a is the velocity of sound, p is the absolute pressure and u is the particle velocity and the subscript D denotes the detonation, or CJ, state.

These authors also give a detonation hazard parameter D_H, which they define as

$$D_H = \frac{E_c^*(\text{fuel})}{E_c^*(\text{acetylene})} \qquad [17.2.51]$$

where E_c^* is the minimum critical energy determined.

Work on the critical energy for detonation of fuel–air mixtures using high explosives has been described by D.C. Bull, Elsworth and Hooper (1979a). Figure 17.4 shows their results for the initiation of detonation in mixtures of ethane and air using charges of tetryl. As the graph shows, the mass m of explosive required to give initiation increases rapidly as the ratio of fuel concentration to stoichiometric ratio ϕ diverges from the value for minimum critical energy.

A second mode of initiation of detonation in confined systems is by shock waves. This is amenable to study in shock tubes, and is thus a relatively well-defined situation and has been widely investigated. A shock wave entering a flammable mixture compresses and heats it, typically creating hot spots. The mechanisms involved in the transition to detonation have been elucidated by Oppenheim and coworkers (Urtiew and Oppenheim, 1966, 1968; Lundstrom and Oppenheim, 1969), who found that intense reaction occurs in the highly turbulent region between the leading shock front and the flame, in effect an 'explosion within an explosion', so that the compression fronts created overtake and merge with the leading front, forming a detonation wave.

The third mode of initiation is acceleration of deflagration up to detonation, or 'run up'. Consideration is given first to the general phenomenon and then to run-up distances in confined and unconfined situations.

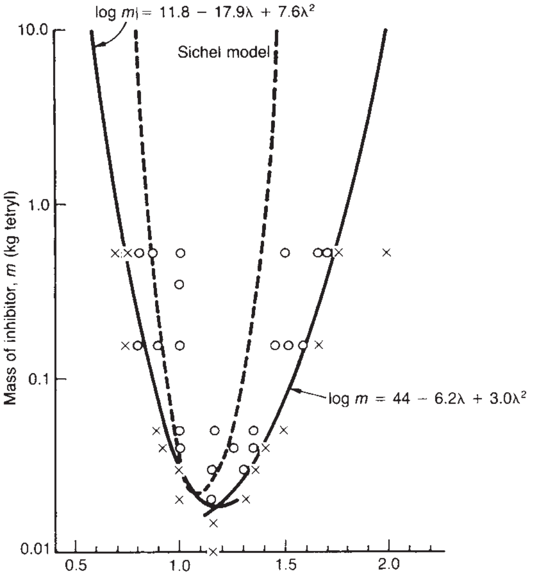

Figure 17.4 *Energy for initiation of explosion in ethane–air mixtures (D.C. Bull, Elsworth and Hooper, 1979a) (Courtesy of the Combustion Institute)*

17.2.14 Deflagration to detonation transition

The deflagration to detonation transition (DDT) has been the subject of a considerable amount of work.

Considering first conditions in confined systems, elucidation of the mechanisms of the DDT in tubes owes much to the work of Oppenheim and co-workers. Accounts include those of Laderman, Urtiew and Oppenheim (1963), Urtiew and Oppenheim (1965, 1966, 1967) and Lundstrom and Oppenheim (1969).

If a flammable mixture is ignited at the open end of a pipe with the other end closed and if the pipe is of sufficiently small diameter for the flow of the unburned gas to be stabilized by viscous drag at the wall, the flame does not accelerate. Outside this laminar steady-state regime, however, the propagation of the flame is always self-accelerating.

The flame acceleration is caused by a number of factors. As the flame moves down the pipe, the turbulent boundary layer grows until it occupies the whole cross-section of the pipe, so that there is a growth in turbulence. As the flame elongates, there is an increase in flame area. The flame creates pressure waves. There is precompression and preheating of the unburned gas ahead of the flame. Shock waves form and a turbulent flame brush is created. At some point, burnout of this turbulent flame brush occurs which intensifies the shock waves. These processes can be sufficient to cause the shock waves to coalesce and form a shock front and for this then to escalate into a detonation.

Another mechanism which can cause the DDT is the impact of a shock wave on the accelerating flame. Studies have been conducted by Markstein (1957) on the effect of the impact of a shock wave meeting a laminar flame head-on. These showed that a rarefaction wave travelled back through the unburned gas and a jet of unburned gas developed which penetrated deeply into the burned gas. The shear between the burned and unburned gas resulted in extreme turbulence and a massive increase in the burning rate. Such an effect may occur when a shock wave travels ahead of the flame and is then reflected back into it.

The sequence of events in the DDT is summarized by Kuo (1986) as follows: (1) an accelerating laminar flame, with flame wrinkling and compression waves; (2) formation of a shock front; (3) creation of a turbulent flame brush; (4) onset of an explosion within an explosion, with transverse waves; (5) development of a spherical shock behind the shock front; (6) interactions of the transverse waves with the shock front, retonation wave and reaction zone and (7) establishment of a steady wave, leading to a shock–deflagration ensemble, or detonation.

Kuo distinguishes four modes of transition, classified according to the location of the explosion within an explosion. Since generation of any particular pattern depends on minute inhomogeneities, the detailed sequence of events in the DDT is not reproducible.

17.2.15 Run-up distances in confined situations

There is a good deal of information on run-up distances for particular mixtures and pipes, but a general correlation has been lacking.

An attempt to remedy this deficiency has been made by Nettleton (1987, p. 119), in terms of the distance X_s between the origin of the flame and the position at which shock is produced. He gives for this

$$X_s = \beta(\gamma + 1)X_f \qquad [17.2.52]$$

with

$$X_f = \frac{2c^2}{(\gamma + 1)^2 \beta^2 g_f} \qquad [17.2.53]$$

$$g_f = f(\varepsilon S_u) \qquad [17.2.54]$$

where c is the speed of sound in the uncompressed gas, g_f is the acceleration of the flame, S_u is the maximum fundamental burning velocity, X_f is the distance from the origin of the flame to its position at the time at which the shock first forms, X_s is the distance from the origin to the position at which the shock is produced, β is the ratio of the velocity of the flow just ahead of the flame to that of the flame, γ is the ratio of specific heats of the reactants and ε is the expansion ratio. The value used for β is 0.9.

Nettleton gives a number of graphs comparing predictions of the distance X_s for shock formation with experimental values of the run-up distance X_d. The curves given by the model appear to have the general shape of, but do not always coincide with, the experimental ones. Specifically, the model predicts correctly the marked increase in run-up distance near the detonation limits.

It is suggested by Nettleton that if use is made of a run-up distance determined experimentally, this should be divided by a safety factor of 2 to allow for possible differences between the pipe used in the experiments and that on the plant. With regard to the factors which influence the run-up distance, one of the most important is pipe diameter. Here, there are a number of features which influence run-up but which vary with diameter. Thus, for example, in larger pipes the effect of viscous drag will be less but the surface roughness may be greater. It is clear from experiments that the run-up distance increases as the diameter increases, but the precise form of the relationship obtained varies. Nettleton quotes three sets of results, one in pipes of diameter $d \leq 102$ mm showing $X_d \propto d^{0.44}$, one in pipes of $d \leq 51$ mm showing $X_d \propto d^{0.5}$ and one with $X_d \propto d^{1.25}$, but states that there is general agreement that for large pipes $X_d \propto d$.

Another factor which affects the run-up distance is the surface roughness of the pipe. Essentially, any feature which promotes turbulence will tend to reduce the run-up distance. Such features include internal welds and bellows.

There is relatively little information available on the influence on run-up distances of initial pressure, initial temperature or additives. However, evidence confirms that run-up distance decreases with increasing pressure with $X_d \propto pm$ where $-0.4 < m < -0.8$ except for materials that decompose in the absence of oxygen.

Attention is drawn by Nettleton to the fact that where pressure piling may occur, the probability of occurrence increases with the induction distance.

17.2.16 Run-up distances in unconfined situations

Turning now to acceleration of deflagration to detonation in unconfined systems, it is appropriate at this juncture to point out that the occurrence of a detonation in a vapour cloud which is truly unconfined has been a matter of some debate. The nature of, and models for, vapour cloud explosions are discussed in Section 17.28. Here, consideration is confined to the process of flame acceleration in the cloud. This is closely linked to the question of the minimum size of cloud for a detonation to occur.

A model for the direct formation of a spherical detonation has been given by J.H.S. Lee and Moen (1980). This is the shock wave amplified coherent energy release (SWACER). The energy from the ignition source is assumed to create a gradient of temperature and of active species such that as the wave expands, each successive shell has a different induction time. Where there exists a suitable relation between this gradient and that of the decaying blast, the reaction zone couples to the leading front and a detonation wave forms.

There are certain features of combustion in a vapour cloud in the open which have been identified as possibly capable of promoting flame acceleration. One is heat radiation from the burning part of the cloud. It has been shown experimentally that heat flux can be such as to heat up incombustible particles ahead of the flame front so that they become ignition sources. Another is inhomogeneities in the cloud.

More importantly the interaction of flame fronts with plant structure is widely recognized as the key factor in flame acceleration to destructive deflagrations or detonations. This is treated in Section 17.2.19. It is also of interest to know whether there is a minimum diameter $d_{\min}$ of a vapour cloud to support a detonation. Nettleton (1987) states that experience of deflagration in vapour clouds indicates that $d_{\min} \geq 50$ m.

Moen, Donate *et al.* (1981), in work directed to the measurement of detonation limits, have studied the effect of tube diameter on the fuel concentration at the limit of detonability, which they take as the occurrence of single-head spin. They give results showing for ethylene–air mixtures the variation of the tube diameter for the transition from multiheaded detonation to single-head spin. They take the cell length L_c as proportional to the tube diameter, and express the correlation in terms of cell length also.

They then equate the above diameter to the critical diameter d_c and propose that this be taken as an indication of the minimum cloud diameter d_{min} for detonation. Thus for the stoichiometric concentration of 6.5% ethylene, they obtain $L_c = 46$ mm and, using Equations 17.2.37 and 17.2.42a, $S = 28$ mm and $d_c = 359$ mm $= 0.36$ m. Similarly for a 3% concentration they obtain $L_c = 0.9$ m, $S = 0.54$ m and $d_c = 7$ m.

17.2.17 Interaction between detonation and confinement

The foregoing has given an account of the general behaviour of detonations, essentially in tubes. It is now necessary to consider the interaction of a detonation wave with confinements in general.

There is no comprehensive theory for the interaction of a detonation wave with a confinement of arbitrary geometry. It is possible that a deterministic theory may be precluded by the stochastic properties already referred to.

The pressure profiles occurring in confined detonations have a number of characteristic features. The pressures generated exhibit wide variations in magnitude and duration. Anomalously high pressures can be generated by reinitiation of combustion in previously quenched regions of the gas.

Treatments of the interaction between a detonation wave and its confinement are mainly for non-reactive shock waves. Two principal theoretical descriptions are the two-shock theory and the method based on the work of Chester (1954), Chisnell (1957) and Whitham (1974), known as Chester–Chisnell–Whitham (CCW) analysis.

In general, theory in its current state is not able to predict peak local pressures or pressures on confining surfaces, but is helpful in understanding how interaction with confinements can result in fronts with properties different from those predicted by unidimensional models.

Models of a number of standard cases occurring with a confined detonation wave are treated by Nettleton (1987), using mainly CCW theory. These cases include (1) diffraction of a shock wave at an isolated wall, (2) normal reflection of a shock wave, (3) transmission of a detonation wave through an abrupt expansion and (4) propagation of a detonation through a bend or junction.

For diffraction at an isolated wall, the situation considered is a shock wave travelling parallel to a horizontal surface and then encountering another surface, or wall, at an angle θ_w to the horizontal. At some critical angle θ_{cr} there occurs transition to regular reflection. Three cases are treated: case 1, a wall at a negative angle with $\theta_w < 0$; case 2, a wall at a positive angle less than the critical, hence $0 < \theta_w < \theta_{cr}$, and case 3, a wall at a positive angle greater than critical but less than perpendicular, hence $\theta_{cr} < \theta_w < 90°$.

Normal reflection of a detonation wave may occur in various configurations. These include reflection at a sharp 90° bend and at the wall of a spherical vessel. Essentially, the situation is that the use of unidimensional theory tends to overpredict the pressures generated, but that multidimensional theory is difficult to apply.

The transmission of a detonation wave through an abrupt expansion is a case of some importance. It constitutes a symmetrical, and therefore relatively simple, instance of a change from a planar front to a curved one and involves progression of the detonation from the pipe into a hemispherical detonation. It is therefore relevant to the critical diameter d_c of the pipe for the establishment of a hemispherical detonation and thus to the quenching of detonations and to the critical energy for the initiation of hemispherical detonations.

Nettleton gives a treatment of this case involving a combination of CCW analysis and Shchelkin (1959) instability theory.

He also describes a number of theoretical approaches to the derivation of a relation between the critical diameter d_c for quenching and the critical energy E_c for spherical detonation. Sloan and Nettleton (1975) have studied the case of a planar non-reactive shock wave emerging from a nozzle into a large space. Within the decaying shock envelope there exists a truncated cone, the front edge of which is travelling at the velocity of the incident front and which does work on the surrounding gas. A similar situation pertains for a detonation emerging from the nozzle. This case has been treated by Urtiew and Tarver (1981), who equate the work done with the critical energy. The work done W is

$$W = \int_0^{t_c} p u_{CJ} A_t \, dt \qquad [17.2.55]$$

where A_t is the area of truncation, p the pressure of the planar detonation, t_c the time at which the heads of the expansion fan cross the axis of symmetry and u_{CJ} the gas velocity behind the CJ front. But

$$t_c = \frac{L_c}{S} \frac{(d_c - d_o)/2}{D_{CJ}} \qquad [17.2.56]$$

where d is a diameter of the nozzle, D_{CJ} is the CJ velocity, L_c is the length of a detonation cell, S is the width of the cell and the subscripts c and o denote critical and actual, respectively. Then, integrating Equation 17.2.55 using Equation 17.2.56 and noting that for spherical symmetry $E_c = 2W$

$$E_c = \frac{\pi p_{CJ} u_{CJ}}{4 D_{CJ}} \frac{L_c}{S} \left(\frac{d_c}{d_o} - 1 \right)^3 \qquad [17.2.57]$$

Equation 17.2.57 gives a relationship between the critical diameter d_c and the critical energy E_c. It has been shown by Nettleton (1987) that the equation gives a good fit to the data for mixtures of hydrocarbons with air and with oxygen obtained by Matsui and Lee (1979).

The propagation of a detonation through a bend is another case which is important but which has received rather less attention. There has been some success with CCW analysis of the early stages of the propagation of non-reactive shock waves round the bend, but rather less in the later stages as the process becomes more complicated due to interactions of wave systems set up at opposing walls.

Where the shock wave is in a reactive medium, the situation is yet more complex. Experimental work on detonation entering bends by Edwards, Nettleton and coworkers (D.H. Edwards *et al.*, 1981; D.H. Edwards, Thomas and Nettleton, 1983) has shown that steady detonation is re-established, but the distances at which re-establishment occurs and the locations of pressures higher than the CJ pressure depend on the configuration. Figure 17.5 by D.H. Edwards *et al.* (1981) shows a sketch

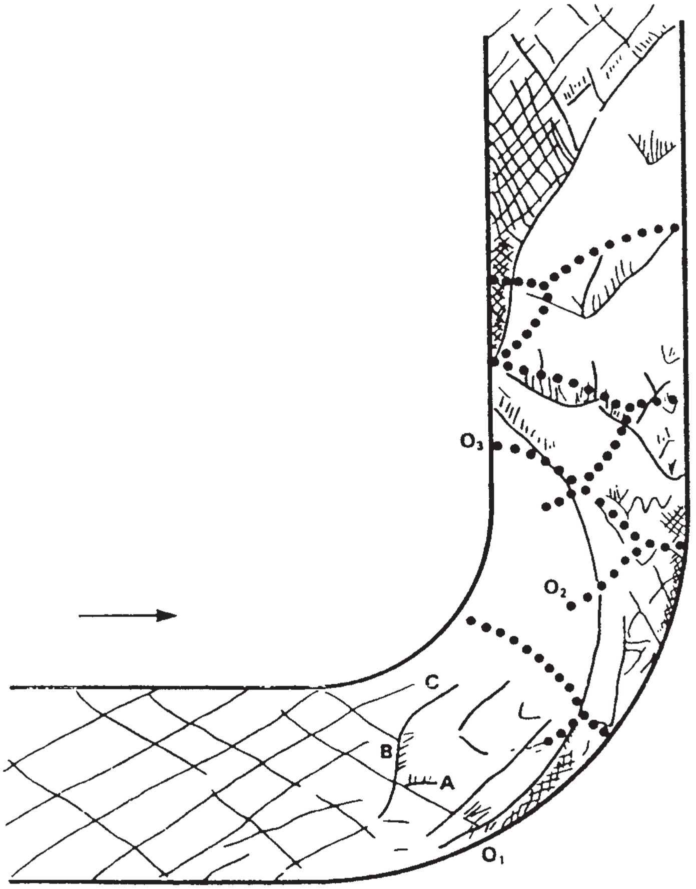

Figure 17.5 *Sketch of a smoke foil record of re-establishment of detonation in a sharp bend (D. H. Edwards et al., 1981). from this work of a smoke-foil record of the re-establishment of a detonation in a sharp bend.

The patterns on, and damage to, the inner surface of such bends are characteristic, and thus in incident investigation may provide evidence of the occurrence of a detonation.

In addition to the interaction of a detonation wave with a confining envelope, the detonation wave may also interact with an adjacent gaseous medium. Some situations of interest are those where the adjacent medium is (1) an inert gas, (2) a gas mixture of uniformly decreasing concentration and (3) a gas mixture with concentration variations. The first case is relevant to any use of devices containing inert gas for the suppression of detonations. The other two cases have relevance to possible detonations in vapour clouds, which will in general have both concentration gradients and pockets of high and low concentration. Nettleton (1987) gives an account of some research findings which bear on these phenomena.

In the absence of an adequate treatment of the interaction between the detonation wave and its confinement, the common practice of comparing predicted pressures and static strength is likely to continue.

17.2.18 Damage caused by detonation to confinement

The treatment of the damage caused by detonations differs depending on whether the detonation is confined or unconfined. The effects of explosions in the open, whether fast deflagrations or detonations, are considered in Sections 17.31–17.42. The account here is limited to confined detonations.

The general effects of confined detonations are evident from the explosions which have occurred inside plant over the years. A review has been given by Strehlow and Baker (1976). Accounts of some of these incidents are given in Appendix 1.

One classic case is the explosion at Whiting, Indiana, in 1955 described by Jacobs *et al.* (1957) and Randall *et al.* (1957) (Case History A22).

Generally, the amount of information which can be gleaned from an incident of detonation inside plant is limited, because crucial items of data are missing.

Two general points on damage caused by detonations may be noted. One is that the evidence indicates that the damage done by a dynamic loading is no greater than that which would be expected from the corresponding static loading. The other is that ductility appears to have little effect on the dynamic bursting pressure.

The present state of knowledge does not permit a fundamental prediction of the damage to plant by a detonation occurring in it. As already described, there is no comprehensive theory to support the reliable estimation of the pressures generated in complex plant. Further, understanding of the mechanisms and modes of damage caused by confined detonations is imperfect.

Some general guidance is provided by the work which has been done to determine the effective pressures generated in a detonation. C. Campbell, Littler and Whitworth (1932) carried out experiments in which a copper disc at the end of a tube was sheared by a detonation in the tube. They found that the pressure at which failure occurred was close to the CJ pressure. In other words, it was less than the pressure spike and still less than the reflected pressure.

Approaches to the prediction of the pressures occurring in a detonation have been described above. Then, given an estimate of this pressure, an attempt may be made to estimate the damage either from theoretical models or experimental correlations.

It can be shown that the force exerted by a suddenly applied load of a duration much longer than the time constant of the object impacted can be up to twice that produced by the corresponding load slowly applied. This provides a general theoretical indication of the force which a detonation may be expected to exert.

The behaviour of the wall of a pipe as a detonation passes along it has been modelled in terms of the acceleration, velocity and deformation, both elastic and plastic, of the wall. Some simplified models are given by Nettleton (1987), drawing on work such as that of Randall and Ginsburgh (1961) and de Malherbe *et al.* (1966).

17.2.19 Effect of congestion on explosions

The effect of turbulence and turbulence-generating obstacles and structure can be a dominant factor in determining the flame speed and peak overpressure in a deflagration. Rasbash *et al.* (1976e) suggest that for indoor explosions, the turbulent flame speed is typically 1.5–5 times the laminar flame speed. For enclosures of a room or laboratory size, where turbulence is developed by furniture or similar objects, they suggest a factor of 1.5. For large enclosures where explosions propagate through large openings connecting parts of the structure, a factor of 5 is likely and appropriate. With a high-pressure jet discharging indoors, the authors advise that a turbulence factor might be as high as 8 or 10.

For outdoor or partially confined deflagrations, empirical estimation methods developed by Baker *et al.* (1994, 1997) and the multienergy method by van den Berg (1985) and van Wingerdon *et al.* (1989) apply a similar factor to account for congestion. These factors range over three orders of magnitude to predict the peak overpressure. Risk-planning studies usually incorporate a detailed determination of the congestion and turbulence-inducing structure in a plant setting. These effects are discussed further in Section 17.28.4.

17.3 Explosives

Although the properties, manufacture, handling, storage and transport of high explosives are outside the scope of this book, it is necessary to make some brief mention of them.

Accounts of explosives are given in *Explosives, Their Anatomy and Destructiveness* (C.S. Robinson, 1944), *The Science of High Explosives* (M.A. Cook, 1958), *Prevention of and Protection against Accidental Explosion of Fuel and Other Hazardous Mixtures* (E. Cohen, 1968) and *Detonics of High Explosives* (Johansson and Persson, 1970).

Explosives are relevant to loss prevention in two areas in particular. These are (1) estimation of effects of explosions and (2) control of manufacture, handling, storage and transport of explosive materials.

Many of the data available on explosions and their effects and many of the methods of estimating these effects relate to explosives. In particular, the methods developed for calculating the effects of explosions are based mainly on the high explosive trinitrotoluene (TNT).

The hazard of explosives has long been recognized, and an approach has been developed for their control. Some aspects of this approach are applicable in the chemical industry also.

Selected references on explosives are given in Table 17.6.

17.3.1 Explosions of high explosives

In an explosion caused by a high explosive the rate of energy release is particularly rapid, and the explosion has high shattering power, or 'brisance'.

A high explosive produces, therefore, a quite distinct type of explosion. The shock wave from such an explosion has a very short duration time. Differences in the types of explosion are a weakness in the application of correlations based on explosions of high explosives to other explosion situations.

Nevertheless, the TNT equivalent model is widely used in explosion calculations for estimating the effects of explosion on process plant.

17.3.2 Scaling laws

The effects of the explosion of a high explosive are generally determined using a scaling law. A principal parameter which characterizes an explosion is its overpressure. The overpressure generated by the explosion of a explosive is discussed in detail in Section 17.25. It is shown there that overpressure p^{o} is a function of scaled distance z.

$$p^{\mathrm{o}} = f(z) \qquad [17.3.1]$$

with

$$z = \frac{r}{W^{1/3}} \qquad [17.3.2]$$

where p^{o} is the peak overpressure, r is the distance, W is the mass of explosive and z is the scaled distance. Equation 17.3.2 implies that for a given overpressure the distance is related to the mass of explosive by a cube root law:

$$r \propto W^{1/3} \qquad [17.3.3]$$

Damage done by the explosion of an explosive has been correlated mainly by insurance companies in terms of damage circles within which defined degrees of damage occur. The radius R of such a damage circle is related to the mass W of explosive approximately by a cube root law:

$$R \propto W^{1/3} \qquad [17.3.4]$$

Another effect of an explosion of a high explosive is the formation of a crater. A cube root law applies to the relation between the radius r_{c} of the crater and the mass W of explosive:

$$r_{\mathrm{c}} \propto W^{1/3} \qquad [17.3.5]$$

In the storage of explosives the limit of distance between one store of explosive and the next is set by the risk of sympathetic detonation. A mean detonation distance r_{50} can be defined at which there is a 50% chance of sympathetic detonation occurring. It is found that this mean detonation distance 750 is also related to the mass W of explosive by a cube root law:

$$r_{50} \propto W^{1/3} \qquad [17.3.6]$$

17.3.3 Housing damage

A scaling relation for blast damage to housing has been given by Jarrett (1968):

$$R = \frac{kW^{1/3}}{\left[1 + \left(\frac{7000}{W}\right)^2\right]} \qquad [17.3.7]$$

where R is the distance (ft), W the mass of explosive (lb) and k a constant. The constant k defines the degree of damage which may be expected to the average British dwelling house. It is based on the analysis of damage in 24 well-documented explosions and in wartime bombing. The following categories of damage are defined:

		k
A	Almost complete demolition	9.5
B	50–75% external brickwork destroyed or rendered unsafe and requiring demolition	14
Cb	Houses uninhabitable – partial or total collapse of roof, partial demolition of one or two external walls, severe damage to Load-bearing partitions requiring replacement	24
Ca	Not exceeding minor structural damage, and partitions and joinery wrenched from fittings	70
D	Remaining inhabitable after repair – some damage to ceilings and tiling, more than 10% window glass broken	140

For damage to process buildings, the Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE) defines the following levels (1996).

Level	*Building Damage*
1 Minor	Onset of visible damage. Repairs are only needed for cosmetic reasons. Building is reusable following an explosion
2A Moderate	Localized building damage. Building performs function and can be used: however, major repairs are required to restore integrity of structural envelope. Total cost of repairs is moderate
2B Moderate	Widespread building damage. Building cannot be used until major repairs are completed. Total cost of repairs is significant, approaching replacement cost of building
3 Major	Building has lost structural integrity and may collapse due to environmental conditions (i.e. wind, snow or rain). Total cost of repairs exceeds replacement cost of building
4 Collapse	Building fails completely. Repair is not feasible

17.3.4 Quantity–distance relations

In the handling of explosives separation distances are governed by quantity–distance relations. An account of the quantity–distance relations used in Britain has been given by Jarrett (1968).

The principal explosion effects of the different categories of explosive are:

Category X:	missiles and slight blast effects, projected ammunition;
Category Y:	radiant heat;
Category Z:	missiles and major blast effects, cratering, earth shock;
Category ZZ:	major blast effects, cratering, earth shock.

The quantity–distance relations are used for (1) storage distances, (2) process building distances, and (3) public building and traffic distances. The process building distances are also known as intraline distances.

The storage of explosives involves the hazard of explosion of the stored material. Explosives tend to be sensitive to shock. They also tend to deteriorate in storage. In particular, there is the hazard of sympathetic detonation of one store of explosives by another adjacent store.

Although sympathetic detonation is important, it is not the only explosion effect which has to be taken into account. Other effects include flame spread, heat radiation, missiles and blast. Jarrett quotes a number of quantity–distance relationships of the general form

$$R = kW^n \qquad [17.3.8]$$

where R is the distance, W is the mass of explosive, k is a constant and n is an index. The index n lies in the range $\frac{1}{3}$–$\frac{1}{2}$.

For storage distances for category Z explosive in shells filled with RDX/TNT explosive the basis of separation is sympathetic detonation. For this case Jarrett gives the relation

$$R = 12W^{1/3} \qquad [17.3.9]$$

where R is the distance (ft) and W the mass of explosive (lb).

For intraline and public buildings distances for category Y explosive the basis of separation is heat radiation. For these cases the relations given by Jarrett are, respectively,

$$R = 8W^{1/3} \qquad [17.3.10]$$

and

$$R = 3.2W^{1/2}, \quad W < 10{,}000 \qquad [17.3.11a]$$

$$R = 16W^{1/3}, \quad W > 10{,}000 \qquad [17.3.11b]$$

For intraline and public building distances for category Z explosive the basis of separation is blast effects. The relevant relation is Equation 17.3.7.

17.3.5 Sympathetic detonation

Explosives are normally stored in separate stacks with a separation distance between each stack so as to reduce the probability of detonation of one stack as a result of detonation of an adjacent one. The effect is known as sympathetic detonation.

A model for the propagation of an explosion by sympathetic detonation has been described by Masso and Rudd (1968). The blast effect B is assumed to be given by the relation

$$B = \frac{kW^{n_1}}{r^{n_2}} \qquad [17.3.12]$$

where B is the blast effect, r is the distance, W is the mass of explosive, k is a constant and n_1 and n_2 are indices. The probability p of further detonation of the pressure-sensitive material is taken as

$$p = B/B^* \qquad [17.3.13]$$

where B^* is the blast effect required for certainty of detonation. Then, a general model for propagation of detonation is

$$p = 0, \quad p' < T \qquad [17.3.14a]$$

$$p = p', \quad T < p' < 1 \qquad [17.3.14b]$$

$$p = 1, \quad \text{otherwise} \qquad [17.3.14c]$$

with

$$p' = \frac{kW^{n_1}}{B^* r^{n_2}} \qquad [17.3.15]$$

where T is the threshold of p′ below which no propagation occurs.

The simplest model described by the authors consists of a linear array of explosive components in n sites. The probability that the detonation reaches the jth site but does not continue to the $(j+1)$th site is as follows. The component of the initiating site detonates with certainty. The probabilities of detonation of components in the second, third and jth sites are $p, p^2, \ldots, p^{j-1}$. If the component at the jth site has detonated, the probability that the component at the $(j+1)$th site does not detonate is $(1-p)$. This yields the following relation for $P(j)$, the probability that j sites are involved in the detonation chain:

$$P(j) = (1-p)p^{j-1}, \quad 1 \leq j \leq (n-1) \qquad [17.3.16a]$$

$$P(j) = p^{j-1}, \qquad j = n \qquad [17.3.16b]$$

Various more complex models are also given by these authors.

17.3.6 Controls on explosives

The explosives industry has no choice but to exercise the most stringent controls to prevent explosions. Some of the basic principles which are applied in the management of hazards in the industry have been described by R.L. Allen (1977a). There is an emphasis on formal systems and procedures. Defects in the management system include:

> A defective management hierarchy... Inadequate establishments... Separation of responsibilities from authority, and inadequate delegation arrangements.... Inadequate design specifications or failures to meet or to sustain specifications for plants, materials and equipments.
>
> Inadequate operating procedures and standing orders.... Defective cataloguing and marking of equipment stores and spares....
>
> Failure to separate the inspection function from the production function....
>
> Poor inspection arrangements and inadequate powers of inspectorates....
>
> Production requirements being permitted to over-ride safety needs....

The measures necessary include:

> The philosophy for risk management must accord with the principle that, in spite of all precautions, accidents are inevitable. Hence the effects of a maximum credible accidents at one location must be constrained to avoid escalating consequences at neighbouring locations.... Siting of plants and processes must be satisfactory in relation to the maximum credible accident.... Inspectorates must have delegated authority – without reference to higher management echelons – to shut down hazardous operations following any failure pending thorough evaluation....
>
> No repairs or modifications to hazardous plants must be authorized unless all materials and methods employed comply with stated specifications.... Components crucial for safety must be designed so that malassembly during production or after maintenance and inspection is not possible....
>
> All faults, accidents and significant incidents must be recorded and fed back without fail or delay to the Inspectorate....

A fuller checklist is given by Allen.

R.L. Allen (1977b) also discusses the relevance of these principles to the chemical industry, and to Flixborough in particular. He suggests that the probability of such accidents can be greatly reduced if the chemical industry uses these well-proved methods. The principles are essentially those described elsewhere in this book.

In addition to these basic management aspects, the special precautions necessary in the manufacture and storage of explosives are instructive in relation to process plant hazards. Here, some basic principles are (1) minimization of inventory, (2) minimization of exposure, (3) use of blast walls and (4) separation by distance.

In explosives manufacture and storage the scale of the potential accident is reduced by minimizing the inventory of material and the number of people. The application of these concepts to process plant is discussed in Chapters 11 and 20.

Much use is made in the explosives industry of blast walls, cubicles and barricades. An account of their design has been given by Callahan (1968).

The only completely reliable protection with explosives, however, is distance. It is normal practice, therefore, to allow generous distances in both manufacture and storage. The principle of separation is applicable to process plant also, as described in Chapter 10, although it should be added that it does not necessarily follow that it is economically justifiable to require separation to be such as to give absolute protection.

There is much to learn from the explosives industry in managing the hazards on process plant, but, as always, methods developed for a similar, but not identical, problem need to be adapted to the needs of the process industries.

17.4 Explosion Energy

As already stated, an explosion is a sudden and violent release of energy. Discussions of explosion energy are given in the *High Pressure Safety Code* (B.C. Cox and Saville, 1975) and by Kinney (1962), Kinney and Graham (1985), Burgess *et al.* (1968 BM RI 7196), Eisenberg, Lynch and Breeding (1975), W.E. Baker *et al.* (1983), Crowl (1991, 1992a,c) and the (1994/15).

The energy released in an explosion on a process plant is normally one of the following: (1) chemical energy, (2) fluid expansion energy and/or (3) vessel strain energy.

The distribution of energy between the blast wave and missiles and any crater formation needs also to be considered as does the effect of the height above ground at which the explosion occurs.

17.4.1 Chemical energy

In considering the energy release in a chemical explosion, it is convenient to consider first condensed phase explosives, or high explosives, and then flammable gases and liquids.

The energy release in a chemical explosion is a function of the nature and state of the reactants and of the products. In general, the explosion products are not well defined. As the gas mixture cools, the chemical equilibrium shifts and the transient products disappear.

A condensed phase explosive contains its own oxygen so that it can explode even in the absence of air. It is conventional to assume certain nominal products of explosion. Explosives may be classified on the basis of nominal oxygen distribution. An oxygen-rich explosive has excess oxygen and the nominal products contain molecular oxygen and incombustible gases such as CO_2 and H_2O. An oxygen deficient explosive gives combustible gases such as CO and H_2 among the nominal products. The actual gases generated by explosives contain a mixture of all these products.

A flammable organic gas or vapour which explodes in excess air is normally assumed to yield incombustible gases such as CO_2 and H_2O. The same applies to a condensed phase explosive which undergoes combustion in excess air. Accurate distribution of products can be predicted using chemical equilibrium programs such as the one developed for rocket exhausts by NASA (McBride and Gordon, 1991).

The quantities which characterize a high explosive are discussed by Kinney and Graham (1985). Those of interest here are (1) the energy of explosion, (2) the heat of explosion and (3) the heat of combustion.

The energy in an explosion is of two different kinds: (1) thermal energy and (2) work energy. That part of the energy transferred due to temperature difference is termed the heat of explosion.

The differences between the heat of explosion, the energy of explosion and the heat of combustion may be explained by reference to the methods by which they are measured for an explosive, as described by Kinney and Graham. The heat of combustion is determined by causing the substance to burn in air in a bomb calorimeter and measuring the heat evolved.

The heat of explosion is determined in a similar manner, but using inert gas instead of air. The substance is placed in a bomb calorimeter, air is replaced with inert gas, the substance is initiated and the heat evolved is measured.

Measurement of the energy of explosion is carried out by encasing the substance in a heavy sheath of metallic gold. The explosion flings the gold casing against the bomb wall, where it gives up its kinetic energy as heat, so that in this case the heat measured now includes this energy as well as that transferred by temperature difference.

The relative magnitude of these quantities may be illustrated by considering the values for TNT as given by Kinney and Graham (1985): heat of combustion = 15,132 J/g, energy of explosion = 4850 J/g, heat of explosion = 2710 J/g.

The heat of explosion corresponds to the internal energy change for the explosion ΔE. In order to estimate the effects of an explosion it is necessary to know the energy of explosion. This is the work energy, or work. This work is done by the expansion of the gas and is given by

$$W = -\int_1^2 P \, \mathrm{d}V \qquad [17.4.1]$$

where P is the absolute pressure, V is the volume and W is the work of expansion. This is the energy transferred in the explosion as work done on the blast wave and missiles. The integral of Equation 17.4.1 is difficult to evaluate, and it is more convenient to work directly in terms of the initial and final values of the thermodynamic properties. The quantity generally used is the Helmholtz free energy change ΔA:

$$-\int_1^2 P \, \mathrm{d}V \approx \Delta A \qquad [17.4.2]$$

Treatments of the relationship between the work and the Helmholtz free energy change are given by Kiefer, Kinney and Stuart (1954) and W.J. Moore (1962).

The actual energy released in an explosion tends to be somewhat less than the Helmholtz free energy change. One reason is that the process is not reversible. Another is that the products of combustion of the explosion are usually at a temperature higher than ambient.

Often, data are not available on the Helmholtz free energy change for a compound, but are available for the Gibbs free energy change. For many substances, including hydrocarbons, the difference is not great and the error involved in using the Gibbs instead of the Helmholtz free energy is small.

The following thermodynamic relations, which apply to a reversible process at constant temperature and pressure, are useful in explosion calculations. For absolute quantities

$$H = E + PV \qquad [17.4.3]$$

$$A = E - TS \qquad [17.4.4]$$

For isothermal change in a system

$$\Delta H = \Delta E + \Delta(PV) \qquad [17.4.5]$$

$$\Delta A = \Delta E - T\Delta S \qquad [17.4.6]$$

$$\Delta F = \Delta H - T\Delta S \qquad [17.4.7]$$

where ΔA is the Helmholtz free energy change, ΔE is the internal energy change, ΔF is the Gibbs free energy change, ΔH is the enthalpy change, ΔS is the entropy change and T is the absolute temperature.

The energy of explosion is usually calculated at standard conditions of 25°C and atmospheric pressure.

The internal energy change for the explosion reaction is

$$\Delta E = \left(\Delta E_f^{\mathrm{o}}\right)_{\mathrm{p}} - \left(\Delta E_f^{\mathrm{o}}\right)_{\mathrm{r}} \qquad [17.4.8]$$

where the superscript o denotes the standard state and the subscript f the formation value, p the products and r the reactants. The enthalpy change for the reaction is

$$\Delta H = \left(\Delta H_f^{\mathrm{o}}\right)_{\mathrm{p}} - \left(\Delta H_f^{\mathrm{o}}\right)_{\mathrm{r}} \qquad [17.4.9]$$

The entropy change for the explosion reaction, or entropy of explosion, is

$$\Delta S = (S)_{\mathrm{p}} - (S)_{\mathrm{r}} \qquad [17.4.10]$$

The Helmholtz free energy change ΔA for the explosion reaction is given by Equation 17.4.6, or alternatively by

$$\Delta A = (\Delta A_f)_{\mathrm{p}} - (\Delta A_f)_{\mathrm{r}} \qquad [17.4.11]$$

For the entropy and Helmholtz free energy per mole of the reactants and products, assuming ideal gases,

$$S = S^{\mathrm{o}} - R \ln p \qquad [17.4.12]$$

$$A = A^{\mathrm{o}} + RT \ln p \qquad [17.4.13]$$

where R is the universal gas constant. For liquids and solids, the second term on the right-hand side of Equations 17.4.12 and 17.4.13 is negligible.

The Helmholtz free energy change may be calculated from thermodynamic data in several ways. One is to calculate ΔE from Equation 17.4.8 and ΔS from Equation 17.4.10

using Equation 17.4.12 to obtain S, and then to calculate ΔA from Equation 17.4.6. Alternatively, ΔA may be calculated from Equation 17.4.11, using Equation 17.4.13 to obtain ΔA_f.

The entropy term $T\Delta S$ is significant where there is a large difference between the number of moles of the reactants and of the products. This is the case for condensed phase explosives, but usually not for flammable gases and vapours. Where the change in the number of moles is not significant

$$\Delta A \approx \Delta E \qquad [17.4.14]$$

the enthalpy change may also be written as

$$\Delta H = \Delta E + \Delta nRT \qquad [17.4.15]$$

where Δn is the change in the number of moles. Where the change in the number of moles is not significant

$$\Delta H \approx \Delta E \qquad [17.4.16]$$

Thus, for explosions of flammable gases and vapours it is often possible to make certain approximations which simplify the task of obtaining the necessary data on thermodynamic properties.

For the explosive combustion of hydrocarbon clouds the method generally used is to determine the enthalpy change ΔH, which is usually obtained from the heat of combustion ΔH_c, and to apply to this an 'explosion efficiency', or yield factor, as discussed below.

The enthalpy change of the reaction ΔH may be calculated from the standard enthalpies of formation using Equation 17.4.9. Alternatively, it may be obtained from the heat of combustion.

If the heat of combustion is that of a gas and if the final water product is also gaseous, then the enthalpy change for the reaction is equal to the heat of combustion. Generally, however, the heat of combustion is given for a final water product which is a liquid. In this case the standard heat of combustion with liquid water product ΔH^o_{clw} should be corrected by a term which allows for the latent heat of vaporization of water ΔH_{vw}, to give the standard heat of combustion with water product as vapour ΔH^o_{cvw}.

$$\Delta H^o_{cvw} = \Delta H^o_{clw} + n_w \Delta H_{vw} \qquad [17.4.17]$$

where ΔH_{cvw} is the heat of combustion with the final water product as vapour, ΔH_{clw} is the heat of combustion with the final water product as liquid, ΔH_{vw} is the latent heat of vaporization of water and n_w is the number of moles of water. This correction is usually of the order of 5–10% for hydrocarbons.

Sometimes the heat of combustion is given for a liquid rather than a gas. In this case the standard heat of combustion for a liquid ΔH^o_{cl} should be corrected by a term which allows for the latent heat of vaporization of the liquid ΔH_v to give the standard heat of combustion for the vapour:

$$\Delta H^o_{cv} = \Delta H^o_{cl} - \Delta H_v \qquad [17.4.18]$$

where ΔH_{cl} is the heat of combustion with initial reactant as liquid, ΔH_{cv} the heat of combustion with initial reactant as vapour and ΔH_v the latent heat of vaporization.

As an illustration of the calculation of the energy of explosion of an explosive, consider the calculation of the energy of explosion of TNT in the absence of air. Following Kinney (1962) the explosion reaction is assumed to be

$$C_7H_5O_6N_3 \rightarrow C + 6CO + 2.5H_2 + 1.5N_2 \qquad [17.4.19]$$

The thermodynamic data are

	ΔE^o_f (kcal/mol)	S° (cal/mol K)
$C_7H_5O_6N_3$	−13.0	65
C	0	1.361
CO	−26.722	47.301
H_2	0	31.211
N_2	0	45.767

The molecular weight of TNT is 227.

Then, the internal energy of explosion from Equation 17.4.8 is

$$\begin{aligned}\Delta E &= (\Delta E^o_f)_p - (\Delta E^o_f)_r \\ &= \{(1 \times 0) + [6 \times (-26.722)] + (2.5 \times 0) \\ &\quad + (1.5 \times 0)\} - [1 \times (-13.0)] \\ &= -147.3 \text{ kcal/mol} \\ &= -147{,}300 \text{ cal/mol} \\ &= -147{,}000/227 \\ &= -649 \text{ cal/g of TNT}\end{aligned}$$

The entropy of explosion from Equations 17.4.10 and 17.4.12 is

$$\Delta S = (S^o - R \ln p)_p - (S^o)_r$$

The entropy of mixing terms is:

	p	$-R \ln p$
CO	0.6	1.016
H_2	0.25	2.753
N_2	0.15	3.767

Then, the entropy of explosion is

$$\begin{aligned}\Delta S &= \{(1 \times 1.361) + [6 \times (47.301 + 1.016)] \\ &\quad + [2.5 \times (31.211 + 2.753)] \\ &\quad + [1.5 \times (45.767 + 3.767)]\} - (1 \times 65) \\ &= 385.5 \text{ cal/mol K}\end{aligned}$$

Hence, the energy of explosion from Equation 17.4.6 is given by

$$\begin{aligned}\Delta A &= \Delta E - T\Delta S \\ &= -147{,}300 - (298 \times 385.5) \\ &= -262{,}180 \text{ cal/mol} \\ &= -262{,}180/227 \\ &= -1155 \text{ cal/g of TNT}\end{aligned}$$

The experimental value of the energy of explosion of TNT is quoted by Kinney as 1120 cal/g. Kinney gives an alternative calculation which utilizes instead Equations 17.4.11 and 17.4.13, but gives an identical result.

Other values of the energy of explosion of TNT have been discussed by Burgess *et al.* (1968 BM RI 7196).

An alternative explosion reaction without air given by Ornellas (1967) is

$$C_7H_5O_6N_3 \rightarrow 3.7C + 2CO + 1.3CO_2 + 0.1CH_4 + 0.5H_2 + 1.6H_2O + 1.3N_2 + 0.2NH_3 \quad [17.4.20]$$

For this reaction the energy of explosion given is 1093 cal/g.

If the combustion of TNT takes place in the presence of excess air, the conventional explosion reaction is

$$C_7H_5O_6N_3 + O_2(\text{excess}) \rightarrow 7CO_2 + 2.5H_2O + 1.5N_2 \quad [17.4.21]$$

For this reaction the energy of explosion, or rather combustion, given is 3600 cal/g.

The energy of explosion of TNT is widely utilized as a reference value. The energy used is normally that for explosion in the absence of air. The value of this energy of explosion which is used here is 1120 cal/g of TNT, as given by Kinney.

As an illustration of the calculation of the enthalpy change in the explosion of a flammable gas, consider the calculation of that for an acetylene–air mixture. The explosion reaction is assumed to be

$$C_2H_2 + 2.5O_2 \rightarrow 2CO_2 + H_2O \quad [17.4.22]$$

The thermodynamic data are

	ΔH_f^o (kcal/mol)
C_2H_2	54.194
O_2	0
CO_2	−94.052
H_2O (g)	−57.798

Then, the enthalpy change for the explosion from Equation 17.4.9 is

$$\begin{aligned} \Delta H &= (\Delta H_f^o)_p - (\Delta H_f^o)_r \\ &= \{[2 \times (-94.052)] + [(1 \times (-57.798)]\} \\ &\quad - [(1 \times 54.194) + (2.5 \times 0)] \\ &= -300.096 \text{ kcal/mol} \end{aligned}$$

Alternatively, the heat of combustion may be used. The standard heat of combustion of acetylene is

$$\Delta H^o_{\text{clw}} = -310.615 \text{ kcal/mol}$$

This value is for acetylene gas, so no correction is required for the state of the reactant, but the value assumes that the final water product is liquid. The latent heat of water is

$$\Delta H_{\text{vw}} = 9.7 \text{ kcal/mol}$$

Hence the corrected standard heat of combustion of acetylene is

$$\begin{aligned} \Delta H^o_{\text{cvw}} &= -310.615 + 9.7 \\ &= -300.915 \text{ kcal/mol} \end{aligned}$$

ΔH is then equal to this value of ΔH^o_c and agrees well with that calculated earlier.

These methods of calculating the energy of explosion of flammable gases and vapours are those which are normally used for industrial explosion calculations.

The foregoing methods assume that the hot product gases are cooled back to standard conditions. The effect on the enthalpy change in the explosion of assuming other termination conditions is illustrated by the calculations given by Burgess *et al.* (1968 BM RI7196) for the combustion of a stoichiometric acetylene–air mixture. Some cases are considered in Table 17.7. For the bomb calorimeter the final mixture composition is CO_2 16.1%, H_2O 8.1% and N_2 75.8%, but for the other cases there are other products present such as CO, H_2, O, H and OH.

Calculations of this kind are relevant to the estimation of the energy available in explosion processes in process plant and pipelines.

There are available extensive tabulations of thermodynamic properties at standard conditions (25°C, atmospheric pressure). Tabulations of thermodynamic properties are given in National Bureau of Standards (NBS) Circular 461 Selected Values of Properties for Hydrocarbons (1947), NBS Circular 500 Selected Values of Chemical Thermodynamic Properties (1952) and NBS Circular 270-3 Selected Values of Chemical Thermodynamic Properties (1969), in the *NBS JANAF Thermochemical Tables* (Stull and Prophet, 1971) and in American Petroleum Institute (API) Research Project 44 Selected Values of Hydrocarbons and Related Compounds (Rossini, 1952; C.C. Williams, 1975). Thermodynamic properties of explosives are listed by Kinney (1962) and Kinney and Graham (1985).

Thermodynamic properties may also be estimated by theoretical methods, which are generally based on group contributions. A number of methods are described by Reid and Sherwood (1958, 1966), Reid, Prausnitz and Sherwood (1977) and Reid, Prausnitz and Poling (1987).

Table 17.7 *Characteristics of four combustion processes for acetylene in air*[a,b] *(after Burgess et al., 1968 BM RI 7196)*

	Final pressure (atm)	*Final temperature* (K)	$-\Delta H$ (cal/g of initial mixture)
Bomb calorimeter	1	298	842
Open flame	1	2537	692
Constant volume explosion	9.78	2918	630
Detonation	19.56	3230	550

[a] The legend to the authors' table refers to 'stoichiometric acetylene–air'.

[b] The original table gives the heat released in terms of the enthalpy change (−ΔH), as shown here. The heat released at constant pressure, as in the open flame case, is an enthalpy change, that released at constant volume, as in the bomb combustion cases, is an internal energy change.

Thermodynamic properties of selected substances are given in Table 17.8.

17.4.2 Gas expansion energy

Explosions can also be caused by gas or liquid under high pressure. The energy released in an explosive expansion of a compressed gas is again given by Equation 17.4.1.

Considering an ideal gas, for 1 mol of the gas, the limiting value of the energy of explosion, assuming an ideal gas and isothermal expansion, is

$$W = \int_1^2 P \, \mathrm{d}V \approx T\Delta S = RT \ln(P_1/P_2) \qquad [17.4.23]$$

where the subscript 1 denotes the initial state and 2 the final state.

Assuming isentropic expansion, the limiting value of the energy of explosion is

$$W = \frac{P_1V_1 - P_2V_2}{\gamma - 1} \qquad [17.4.24]$$

or eliminating V_2 using PV^{γ} = constant

$$W = \frac{P_1V_1}{\gamma - 1}\left[1 - \left(\frac{P_2}{P_1}\right)^{(1-\gamma)/\gamma}\right] \qquad [17.4.25]$$

where γ is the ratio of the gas specific heats.

17.4.3 Liquid expansion energy

The energy released in an explosive expansion of a liquid is

$$U_l = \frac{1}{2}\beta P^2 V \qquad [17.4.26]$$

where U_l is the liquid strain energy, V is the volume of the vessel and β is the bulk modulus of the liquid.

17.4.4 Vessel metal strain energy

The elastic strain energy in a cylindrical vessel neglecting the ends is given by Manning and Labrow (1971) as

$$U_m = \frac{P^2V}{2E}\left[\frac{3(1-2\nu) + 2K^2(1+\nu)}{K^2 - 1}\right] \qquad [17.4.27]$$

where E is Young's modulus, K is the diameter ratio, U_m is the metal strain energy and ν is Poisson's ratio. The elastic strain energy of the metal is usually small compared with the chemical and fluid expansion energies.

17.4.5 Vessel burst energy: ideal gas

For the energy of explosion in the bursting of a vessel containing fluid under pressure, it is necessary to distinguish between cases where the fluid can be treated as an ideal gas and those where it cannot.

Taking the ideal gas case first, there are a number of treatments available. Accounts include those of Erode (1955, 1959), Kinney (1962), W.E. Baker (1973), Adamczyk (1976), Strehlow and Ricker (1976), W.E. Baker *et al.* (1983), the CCPS (1994/15) and Crowl (1999).

The literature reveals a variety of approaches based on different treatments of the thermodynamics. The two most widely used relations appear to be those of Erode (1959) and of W.E. Baker (1973).

In the treatment given by Erode (1959) the energy of explosion is the energy required to raise the pressure of the gas at constant volume from atmospheric pressure to the initial, or burst, pressure. It is thus the difference in the

internal energies of the gas at the initial and final pressures. The internal energy is

$$E = \frac{PV}{\gamma - 1} \qquad [17.4.28]$$

where E is the internal energy, P is the absolute pressure in the vessel and V is the volume of the vessel. Brode's equation is

$$E_{\mathrm{Br}} = \frac{(P_1 - P_{\mathrm{o}})V}{\gamma_1 - 1} \qquad [17.4.29]$$

where E_{Br} is Brode's energy of explosion, P is the absolute pressure, V is the volume of the vessel and the subscripts 1 and o denote 'initial vessel' and 'atmospheric', respectively.

The treatment of W.E. Baker (1973) is based on the work done on the surroundings in an isentropic expansion. Baker's equation is

$$E_{\mathrm{Ba}} = \frac{P_1 V_1 - P_{\mathrm{o}} V_2}{\gamma_1 - 1} \qquad [17.4.30]$$

where E_{Ba} is Baker's energy of explosion and the subscripts 1 and 2 denote the initial and final conditions. For an isentropic expansion (PV^{γ} =constant). Equation 17.4.30 can be written as

$$E_{\mathrm{Ba}} = \frac{P_1 V_1}{\gamma_1 - 1}\left[1 - \left(\frac{P_{\mathrm{o}}}{P_1}\right)^{(\gamma-1)/\gamma}\right] \qquad [17.4.31]$$

A third relation for the energy of explosion is that given by Kinney (1962). This is based on work done in isothermal expansion and is

$$E_{\mathrm{Ki}} = nRT\ \ln(P_1/P_{\mathrm{o}}) \qquad [17.4.32]$$

where E_{Ki} is Kinney's energy of explosion and n is the number of moles.

Other expressions for the energy of explosion include those of Adamczyk (1976) and Aslanov and Golinsky (1989).

Aslanov and Golinsky (1989) extend Baker's approach to take into account the internal energy of the air displaced by the expanding gas. Their expression, which contains an additional term to allow for this effect, is

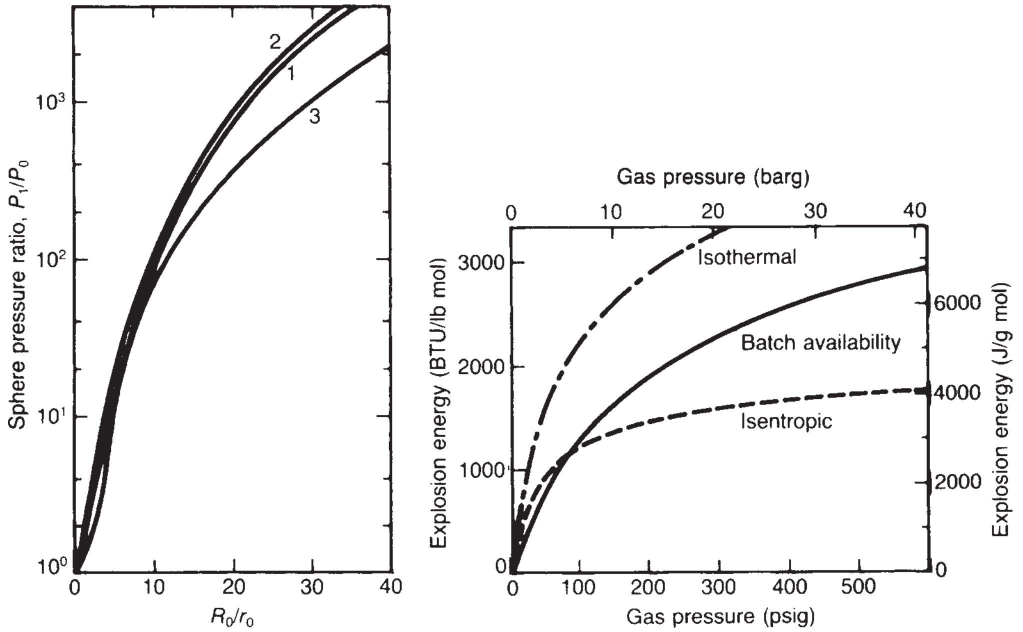
$$E_{\mathrm{AG}} = \frac{P_1 V_1 - P_{\mathrm{o}} V_2}{\gamma_1 - 1} + \frac{P_{\mathrm{o}}(V_2 - V_1)}{\gamma_{\mathrm{o}} - 1} \qquad [17.4.33]$$

where E_{AG} is the Aslanov–Golinsky energy of explosion. Comparisons of the expressions for energy of explosion have been given by Strehlow and Ricker (1976) and the CCPS (1994/15). The former define a scaling radius

$$R_{\mathrm{o}} = \left(\frac{E}{P_{\mathrm{o}}}\right)^{1/3} \qquad [17.4.34]$$

where R_{o} is the scaling radius (m).

They then compare the results given by the equations for the energy of explosion of Erode, Baker and Kinney at a given actual distance r_{o} and dimensionless distance $R_{\mathrm{o}}/r_{\mathrm{o}}$ as shown in Figure 17.6(a). At higher pressure ratios the results given by the Kinney equation diverge from those



(a) (b)

Figure 17.6 Energy of explosion in a vessel burst (a) Comparison by Strehlow and Ricker (1976): curve 1, model of Srode (1955), curve 2, model of W.E. Baker (1953); and curve 3, model of Kinney (1962) (Courtesy of the American Institute of Chemical Engineers). (b) Comparison by Crowl (1992a) (Courtesy of Butterworth–Heinemann) given by the other equations. They recommend the use of the Erode equation.

The CCPS (1994/15) give plots of the ratio of the energies of explosion given by Baker, by Adamczyk and by Aslanov and Golinksy to that given by Erode. This comparison indicates that the values yielded by the other expressions tend to those of the Erode equation at higher pressures, but there is a considerable divergence at lower pressures. For the latter they state that the ratio of values obtained from the different models is as high as 4. In the method given for vessel bursts the CCPS uses the Erode equation.

The preferred method for the estimation of the explosion energy of gas-filled vessels appears to be that of Erode. The main alternative is that of Baker. The method of Kinney considerably overestimates the explosion energy.

The following version of the Erode equation in terms of TNT equivalence has been given in the *Second Canvey Report* (HSE, 1981a):

$$E = 1.43 \times 10^{-6} \frac{(P_1 - P_o)V}{\gamma^{-1}} \qquad [17.4.35]$$

where E is the explosion energy (te of TNT), P_1 the initial pressure in the vessel (kPa), P_o is the pressure of the surroundings (kPa) and V is the volume of the vessel (m^3).

As an illustration, consider the energy of explosion of 1 kmol of air at 100 bar and 20°C. The volume V of the gas is

$$\begin{aligned} V &= znRT/P \\ &= 0.970 \times 10^3 \times 8.314 \times 293/(100 \times 10^5) \\ &= 0.236 \text{ m}^3 \end{aligned}$$

with the compressibility factor, z, by the Peng–Robinson equation of state = 0.970. Using the Erode Equation 17.4.29, the explosion energy E_{ex} is

$$\begin{aligned} E_{ex} &= [(100 - 1) \times 10^5 \times 0.236]/(1.4 - 1) \\ &= 0.584 \times 10^7 \text{ J} \\ &= 5.84 \times 10^3 \text{ kJ} \\ &= 1.39 \times 10^6 \text{ cal} \end{aligned}$$

The energy in this explosion is thus equivalent to the following quantity of TNT:

$$\begin{aligned} &= \frac{1.39 \times 10^6}{1120} \\ &= 1243 \text{ g of TNT} \end{aligned}$$

The distribution of this energy is discussed below.

17.4.6 Vessel burst energy: non-ideal gas, vapour, flashing liquid

For the energy of explosion in the bursting of a vessel containing fluid under pressure which is not an ideal gas but a non-ideal gas, vapour or flashing liquid, the foregoing approach is not suitable.

In this case the energy of explosion is obtained as the difference in the internal energy between the initial and final states assuming an isentropic expansion, using suitable thermodynamic diagrams or tables.

Since it is the specific internal energy e which is of interest and since thermodynamic data tend to be given in terms of specific enthalpy, use may be made of the relation

$$h = e + pv \qquad [17.4.36]$$

where e is the specific internal energy, h is the specific enthalpy, p is the absolute pressure and v is the specific volume.

The initial condition of the fluid is defined in terms of the variables P_1, v_1, S_1 and H_1 and the final condition in terms of the variables P_2, v_2, S_2 and H_2, where S is the specific entropy and the subscripts 1 and 2 denote the initial and final states. An isentropic expansion is performed from P_2 to P_1, where the latter equals atmospheric pressure P_o, so that

$$S_2 = S_1 \qquad [17.4.37]$$

The enthalpy change $(h_1 - h_2)$ is obtained, and from this the internal energy change $(e_1 - e_2)$ using Equation 17.4.36. Then

$$E_{ex} = n(E_1 - E_2) \qquad [17.4.38]$$

where E_{ex} is the energy of explosion and n the number of moles.

For expansion of a vapour there are several different cases which may arise. The fluid may be (1) a vapour superheated in both states, (2) a vapour wet in both states or (3) a vapour superheated in state 1 but wet in state 2.

The vapour mass fraction may be expressed as

$$x = \frac{\phi - \phi_f}{\phi_g - \phi_f} \qquad [17.4.39]$$

where ϕ is a variable, and the subscripts f and g denote saturated liquid and saturated vapour, respectively. In this equation the variable ϕ may be replaced by s, e or h, depending on the thermodynamic path (s = constant entropy, etc.).

The following equation given by the CCPS is useful in interpolating in thermodynamic tables:

$$e_2 = (1 - x)h_f + xh_g - (1 - x)p_0v_f - xp_0v_g \qquad [17.4.40]$$

The CCPS gives data on the work of expansion for a limited set of fluids, namely ammonia, carbon dioxide, ethane, isobutane, nitrogen, oxygen and propane.

17.4.7 Energy distribution in an explosion

The energy distribution in an explosion is shown schematically in Figure 17.7. Only a fraction of the total energy in the explosion appears in the blast wave or the missiles. Some is dissipated as radiation and thermal energy. Other energy appears as potential and kinetic energy, in the explosion products and, eventually, in the fragments.

17.4.8 Energy distribution in a vessel burst explosion

For vessel rupture the effects of an explosion with a given energy release depend on the way in which the energy is distributed.

The total energy E_s in a system is the sum of the chemical energy E_1, the fluid expansion energy E_2 and the vessel strain energy E_3:

$$E_s = E_1 + E_2 + E_3 \qquad [17.4.41]$$

For a catastrophic or near-catastrophic failure of a vessel the *High Pressure Safety Code* gives the energy distribution shown in Table 17.9. The energy in the shock, or blast, wave

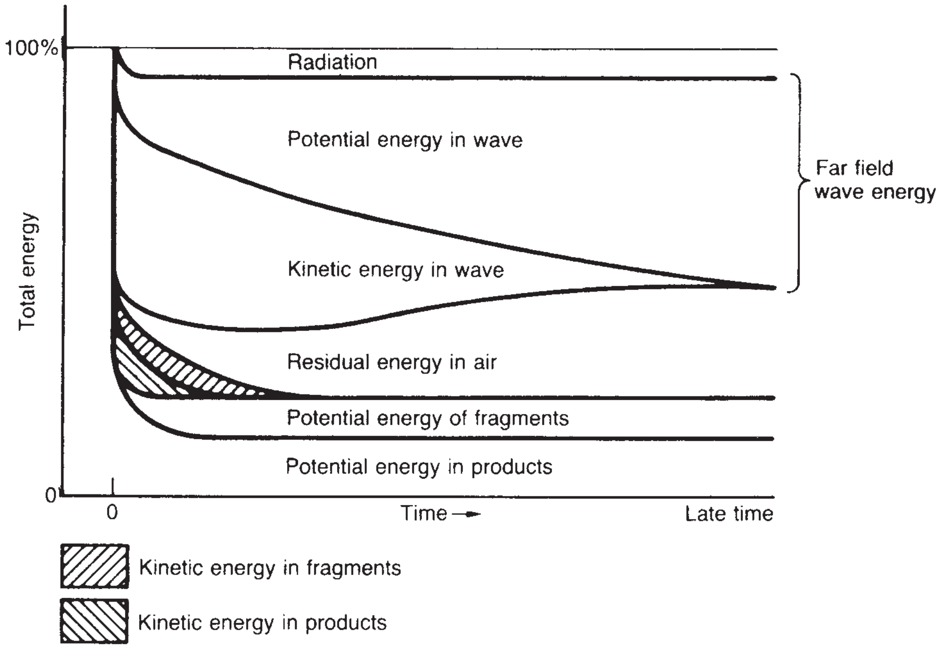


Figure 17.7 *Schematic energy distribution in a chemical explosion (after Strehlow and Baker, 1976; Stull, 1977)*

Table 17.9 *Approximate distribution energy of explosion of a bursting vessel (after B.G. Cox and Seville, 1975)*

	Shock wave energy	*Fragment kinetic energy*
Complete shattering of vessel due to brittle failure	$0.8E_s$	$0.2E_s$
Ejection of a major vessel section such as an end closure of a short, large bore vessel	$0.4E_s$	$0.6E_s$

is given for this case as between 40% and 80% of the explosion energy. A value of 50% is often used. The energy in the fragments is given for the case considered as between 20% and 80%.

The explosion energy in vessel rupture and its partition between blast and missiles is discussed further in Section 17.27. The energy imparted to missiles in also considered in Section 17.34.

17.4.9 Energy of a vapour cloud explosion: yield factor

In a vapour cloud explosion the energy in the blast wave is generally only a small fraction of the energy theoretically available from the combustion of all the material in the cloud. The ratio of the actual energy in the explosion to that theoretically available is variously termed the 'explosion efficiency', 'yield factor' or simply 'yield'.

This ratio is referred to here as the yield factor, or yield, and has a value less than unity. It is to be distinguished from the yield ratio, described in the next subsection.

If it is assumed that all the flammable material in the cloud is available for combustion, the combustion energy theoretically available is the product of the total mass of flammable material and the heat of combustion. This gives a 'gross' efficiency. On this basis, explosion efficiencies are typically 1–10%.

Typically, however, only the part of the cloud which is within the flammable range is considered giving rise to a 'net' efficiency.

Often, the fraction of mass in the flammable range is up to an order of magnitude less than the total cloud. Consequently, explosion efficiencies calculated on this basis tend to be as much as an order of magnitude greater than those based on combustion of the whole cloud.

The energy of vapour cloud explosions is discussed further in Section 17.28.

17.4.10 Blast energy of ground level explosion: yield ratio

A large proportion of explosions of interest in process plants occur at ground level. For such an explosion the ground forms a barrier to the explosion. For an explosion at ground level the blast wave has a strength that corresponds to an apparent energy of explosion which exceeds that for a free-air explosion by a yield ratio lying between 1 and 2. In other words, for a ground level explosion the apparent energy to be used in the correlations for the blast wave parameters is multiplied by the yield ratio, typically 2.

In general, the yield ratio is determined by two factors. These are:

(1) explosion symmetry;
(2) crater formation.

A free-air explosion has spherical symmetry, whilst a ground level explosion with three degrees of freedom to expand has hemispherical symmetry. On the basis of symmetry alone, the apparent energy in the blast wave from a ground level explosion will be twice that in the blast wave from a free-air explosion. In other words, the yield ratio of the ground level explosion will be 2.

If, however, energy is expended in crater formation the yield ratio will be less. This is typically the case with ground level explosions of condensed phase explosives. Thus, for example, yield ratios for TNT explosions at or near ground level frequently lie in the range 1.5–2. A typical value of the yield ratio for high explosives at ground level is 1.8.

On the other hand, vapour cloud explosions tend not to give a crater. There was no crater formed, for example, at Flixborough. Thus, for a vapour cloud explosion at ground level the yield ratio approaches.

As already described, the effective energy release in a vapour cloud explosion is only a small fraction of the total energy theoretically available and the ratio of these two energies is expressed as an explosion efficiency. If an explosion efficiency is utilized, it should be used in conjunction with the same yield ratio as was used in its original derivation. Frequently this yield ratio is not stated, but it appears in many cases to be unity.

For an explosion such as the bursting of a pressure vessel due to high gas pressure at ground level the explosion energy absorbed by the ground is generally smaller than for a condensed phase explosion. Again the value of the yield ratio lies nearer to 2.

It is not always clear what assumption should be made concerning the yield ratio, and it may be necessary to exercise judgement. For the calculation of the maximum peak overpressure from an explosion the conservative assumption is a yield ratio of 2.

The term 'yield ratio' is used in work on condensed phase explosives (e.g. Kinney and Graham, 1985) and is therefore retained here, despite its similarity to the yield factor described in the previous subsection. The yield ratio has a value greater than unity. However, where only symmetry and not cratering is in question, use is also made here of the alternative term 'symmetry factor'. This is identical to the yield ratio if cratering is disregarded and has a value greater than unity.

These considerations relate solely to the method of estimating the energy imparted to the blast wave. The actual energy of explosion remains the same whether the explosion is in free air or at ground level. In particular, the energy imparted to fragments is unaffected.

In some cases, equations for energy of explosion are quoted with a factor of 2 already incorporated. These equations are solely for use in estimating the blast wave parameters.

17.4.11 Energy of explosion from thermodynamic availability

As indicated, the energy of explosion obtained from the Helmholtz free energy change is an approximation. Its use has been criticized by Crowl (1991) on the grounds that it applies to a constant temperature process, whereas in a real explosion the initial state of the substance may be at some higher temperature and/or pressure.

Accounts of the concept of availability are given by Keenan (1941) and Vogler and Weissman (1988). It has been applied by Crowl to the energy of explosion in general and in particular to explosions associated with combustion of gases (Crowl, 1991, 1992a) and with vessel bursts (Crowl, 1992a,c).

The treatment here is confined to its application to the estimation of the energy of explosion in the cases of a vessel burst explosion and a chemical explosion Crowl (1992a).

For a vessel burst the explosion energy is the change in batch availability. Assuming ideal gas behaviour,

$$\Delta B = -R\left[T_a \ln\left(\frac{P_1}{P_a}\right) - T_1\left(1 - \frac{P_a}{P_1}\right)\right] \\ -C_p\left[T_a \ln\left(\frac{T_2}{T_1}\right) - (T_2 - T_1)\right] \qquad [17.4.42]$$

where ΔB is the change in batch availability (kcal/mol), C_p is the specific heat at constant pressure (kcal/mol K), P is the absolute pressure (Pa), R is the universal gas constant (kcal/molK), T is the absolute temperature (K) and the subscripts a, 1 and 2 denote ambient, initial state and final state, respectively.

For the case where the initial and final temperatures are equal to the ambient temperature ($T_1 = T_2 = T_a$), Equation 17.4.42 reduces to

$$\Delta B = -RT_a\left[\ln\left(\frac{P_1}{P_a}\right) - \left(1 - \frac{P_a}{P_1}\right)\right] \qquad [17.4.43]$$

Crowl compares the energy of explosion in a vessel burst, obtained from the isentropic and isothermal expansion treatments of Baker and of Kinney, given above as Equations 17.4.31 and 17.4.32, with his values from his method, in Figure 17.6(b). The graph indicates that compared with the thermodynamic availability method the isentropic expansion method generally underestimates the energy of explosion, whilst the isothermal expansion method always overestimates it. In an isentropic expansion the final temperature is in fact not the ambient temperature but a much lower temperature. He advises against the use of the isentropic expansion method for the determination of the energy of explosion in vessel bursts.

As an illustration, consider the case given by Crowl. This is the determination of the energy of explosion of a cylinder containing 45.4 kg of nitrogen at 1.53×10^4 kPa at 298 K with an ambient pressure of 100 kPa. The mass of gas is thus 1.621 kgmol (45.5/28). Then, from Equation 17.4.43

$$\Delta B = -2.39 \text{ kcal/mol} = -1621 \times 2.39 = -3870 \text{ kcal}$$

For a chemical explosion the explosion energy is the change in batch availability. For the energy change where the initial conditions of a gas/air mixture are ambient temperature and pressure,

$$\Delta B = (B)_{pr} - (B)_r \qquad [17.4.44]$$

where

$$B = \sum_{i=1}^{m} n_i(\phi_{oi} + RT_a \ln x_i) \qquad [17.4.45]$$

where B is the batch availability (kcal/mol), n_i is the number of moles of species i, m is the number of species, x_i is the mole fraction of species i, ϕ_o is the standard batch availability (kcal/mol) and subscripts pr and r denote the products and reactants, respectively.

If the gas/air mixture is at a pressure other than ambient, the batch availability of the reactants is adjusted by the addition of the term

$$\delta B = nRT_a\left[\ln\left(\frac{P_1}{P_a}\right) - \left(1 - \frac{P_a}{P_1}\right)\right] \qquad [17.4.46]$$

For the special case of explosion of a substance in stoichiometric combustion in pure oxygen at standard temperature and pressure the energy of explosion is simply the batch availability ϕ_o of the substance.

Two cases of chemical explosion given by Crowl are considered by way of illustration. The first is the calculation of the energy of explosion for the stoichiometric combustion of methane in air:

$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$ (g)

The energy of explosion is obtained from Equation 17.4.44 using Equation 17.4.45 for the batch availability *B*. Considering 1 mol of methane:

Initial state

Species	*Moles,* n_i	*Mole fraction,* x_i	*Standard availability*		*Batch availability*
			ϕ_{oi} (cal/mol)	$RT_a \ln x_i$	B (cal/mol)
CH_4	1.00	0.0951	195,500	−1,393	194,107
O_2	2.00	0.1901	0	−983	−1,966
N_2	7.52	0.7148	0	−199	−1,496
Total	10.52				190,645

and

Final state

Species	*Moles,* n_i	*Mole fraction,* x_i	*Standard availability*		*Batch availability*
			ϕ_{oi} (cal/mol)	$RT_a \ln x_i$ (cal/mol)	B (cal/mol)
CO_2	1.00	0.0951	0	−1,393	−1,393
H_2O	2.00	0.1901	2,054	−983	2,142
N_2	7.52	0.7148	0	−199	−1,496
Total	10.52				−747

Then,

$$\begin{aligned}\Delta B &= (-747) - (190{,}645)\\ &= -191{,}392 \text{ cal/mol of methane}\end{aligned}$$

The second case is the energy of explosion of a mixture of 85% methane and 15% oxygen initially at 1 atm and 298 K. The stoichiometry for the combustion products is as follows: CH_4 77.5%, O_2 0%, CO_2 7.5% and H_2O 15%. Proceeding as before and considering 1 mol of mixture,

Initial state

Species	*Moles,* n_i	*Mole fraction,* x_i	*Standard availability*		*Batch availability*
			ϕ_{oi} (cal/mol)	$RT_a \ln x_i$ (cal/mol)	B (cal/mol)
CH_4	0.85	0.85	195,500	−96.2	166,096
O_2	0.15	0.15	0	−1,123	−168
Total	1.00				165,925

and

Final state

Species	*Moles,* n_i	*Mole fraction,* x_i	*Standard availability*		*Batch availability*
			ϕ_{oi} (cal/mol)	$RT_a \ln x_i$ (cal/mol)	B (cal/mol)
CH_4	0.775	0.775	195,500	150.7	151,396
O_2	0	0	0		
CO_2	0.075	0.075	0	−1,535	−115
H_2	0.15	0.15	2,054	−1,123	−140
Total	1.000				151,141

Further, from Equation 17.4.46

$\delta B = 830$ cal

Then,

$$\begin{aligned}\Delta B &= (151{,}374) - (165{,}925 + 830)\\ &= -15{,}381 \text{ cal/mol of mixture}\end{aligned}$$

Crowl states that the energy of explosion computed using the thermodynamic availability method is always less than that obtained from the heat of combustion method. For stoichiometric mixtures the difference is of the order of 5–10%, but for other conditions such as non-stoichiometric mixtures and higher initial pressure and temperature the difference can be substantial.

The application of the method requires the use of data on the standard availability, which is not one of the thermodynamic quantities normally listed. Crowl (1992a) provides a table of standard availabilities for quite a large number of substances.

The following values are given for the standard availability of some common gases at standard conditions (1 atm, 298 K) and final state (H_2O (1)):

Substance	*Standard availability,* ϕ_o (kcal/mol)
Methance	195.5
Ethane	350.73
Propane	503.93
n-Butane	656.74
Ethylene	318.18
Propylene	467.81
Acetylene	295.21
Hydrogen	56.69
O_2 (g)	0
CO_2 (g)	0
H_2O (l)	0

17.5 Deflagration inside Plant

The explosion of a flammable mixture in a process vessel or pipework may be a deflagration or a detonation. These two types of explosion differ fundamentally and require different countermeasures. Both types, but particularly detonation, can be very destructive.

The conditions for a deflagration to occur are that the gas mixture is within the flammable range and that there is a source of ignition or that the mixture is heated to its autoignition temperature.

The conditions for a detonation to occur are similar except that in this case the mixture should be within the detonable range. If the source of ignition is sufficiently strong, detonation may be initiated directly. Alternatively, a deflagration may undergo transition to a detonation. This transition occurs in pipelines but is most unlikely to occur in vessels.

17.5.1 Sources of ignition

The sources of ignition usually considered are those outside the process plant, but ignition sources can occur inside vessels and pipework also. These include:

(1) flames and hot surfaces;
(2) sparks;
(3) chemicals
    (a) unstable compounds,
    (b) reactive compounds and catalysts,
    (c) pyrophoric iron sulphide;
(4) static electricity;
(5) compression.

This list is sufficient to show that there is no shortage of possible ignition sources inside the plant. The wide variety of conditions which can cause ignition is illustrated by the fact that compressed air at 60 psig striking a suitably shaped depression in the end of a piece of wood can ignite the latter (W.G. High, 1976).

If a flammable mixture may be present, precautions should be taken to eliminate all ignition sources. But it is prudent to assume that, despite these efforts, a source of ignition will at some time occur.

Ignition can also occur if the flammable mixture is heated to its autoignition temperature.

17.5.2 Deflagration in vessels

For a deflagration at constant volume in a sphere the maximum explosion pressure is

$$\frac{P_2}{P_1} = E \qquad [17.5.1]$$

with

$$E = \frac{n_2 T_2}{n_1 T_1} \qquad [17.5.2a]$$

$$= \frac{M_1 T_2}{M_2 T_1} \qquad [17.5.2b]$$

where E is the expansion ratio, M is the molecular weight of the gas mixture, n is the number of moles in the gas mixture, P is the absolute pressure, T is the absolute temperature and the subscripts 1 and 2 denote the initial and final states, respectively.

For deflagration of hydrocarbons the ratio of the maximum explosion pressure to the initial pressure is quoted as being approximately 8 for hydrocarbon–air mixtures and 16 for hydrocarbon–oxygen mixtures (Zabetakis, 1965 BM Bull. 627; W.G. High, 1976). These values apply for initial pressures in the range 1–40 bar, for initial temperatures in the range 0–300°C and for relatively small volumes of a few cubic metres.

However, as described in Section 17.7, the values quoted for the final pressure attained in deflagration in a closed vessel are often underestimated due to the use of constant pressure rather than constant volume assumptions. On the correct basis of constant volume combustion, for hydrocarbon–air mixtures the ratio of the maximum explosion pressure to the initial pressure is approximately as follows:

$$\frac{P_2}{P_1} \approx 10 \qquad [17.5.3]$$

This is the order of pressure rise in deflagrative combustion, for example, in the results given in Table 17.7.

For conventionally designed pressure vessels the bursting pressure P_b is of the order of

$$\frac{P_b}{P_1} \approx 4 - 5 \qquad [17.5.4]$$

Hence in the absence of explosion relief the deflagration of a hydrocarbon–air mixture is easily capable of bursting a pressure vessel.

If the explosion relief is to be effective, it must act within a period which is generally much less than 1 s. Methods of explosion relief are available which do this and are discussed in Section 17.12.

17.5.3 Pressure piling

If an explosion occurs in a compartmented system in which there are separate but interconnected spaces, a situation can arise in which the pressure developed by the explosion in one space causes a pressure rise in the unburnt gas in an interconnected space, so that the enhanced pressure in the latter becomes the starting pressure for a further explosion. This effect is known as pressure piling, or cascading.

The type of system geometry in which pressure piling is liable to occur is illustrated in Figure 17.8(a). If the initial explosion occurs in space A, this may cause pressure piling in space B. If the final pressure in A is ξ times the initial pressure, a simplified argument would suggest that the final pressure in B might in the worst conceivable case be two times the initial pressure in both spaces.

An account of pressure piling has been given by Fitt (1981a,b). The phenomenon of pressure piling was first detected by Beyling (1906) in work on flameproof electrical equipment and has subsequently been studied by a number of workers. Table 17.10 lists some of the experimental work done on pressure piling.

Fitt distinguishes between studies done on compartmented tube systems and linked tube systems, as shown in Figures 17.8(a) and (b), respectively. He also points out that there are two separate effects, which he calls flame front projection (FFP) and peak pressure enhancement (PPE).

The first causes a very rapid rise of pressure, the second an enhanced final pressure.

Fitt states that in compartmented systems, pressure piling is observed with low compartment volume ratios (v_1/v_2) and high connecting orifice-to-enclosure diameter ratios, whereas in link tube systems a volume ratio of at least 5 : 1 appears to be required for peak pressure enhancement. He suggests that there is a mechanism of pressure piling in compartmented systems which is suppressed in link tube systems.

The enhancement of pressure is limited by the fact that the total pressure volume energy cannot exceed that which would arise in an uncompartmented enclosure. If pressure piling occurs in one space, the maximum pressure in the remaining space must be reduced. At some stage the pressure differential will cause back venting, which lowers the peak value.

For hydrocarbon–air mixtures the maximum pressure obtained in combustion is at least eight times the initial pressure. Thus, taking a peak pressure enhancement factor of 4, the maximum pressure obtained with pressure piling would be of the order of 30. Pressure piling can therefore give a very large increase in the maximum pressure rise in the plant.

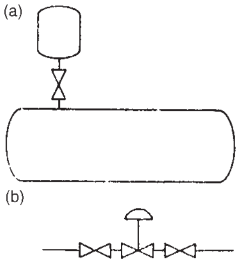

Figure 17.8 *Plant configuration to illustrate pressure pilling: (a) compartmented tube system and (b) linked tube system*

With regard to design to avoid pressure piling, Fitt states that in link tube systems the peak pressure enhancement is unlikely to exceed a factor of 4. This is the maximum enhancement obtained in the experiments given in Table 17.10. The peak pressure enhancement in compartmented tube systems is less predictable, and such systems should be avoided. Pressure piling may be significant not only in the main process plant but in other equipment also. As already mentioned, much of the work on pressure piling has been concerned with flameproof equipment. This aspect is considered further in Chapter 16.

17.5.4 Deflagration in pipes

Whereas in a vessel, deflagration results in a pressure rise which is uniform throughout the vessel, this is not so in a pipe, where the explosion velocity and explosion pressure can change along the length of the pipe.

An account of deflagration in pipes has been given by Bartknecht (1981a). He defines three cases:

Case 1: pipe open at one end, ignition at open end;
Case 2: pipe open at one end, ignition at closed end;
Case 3: pipe closed at both ends.

In order to understand the phenomena involved, it is necessary to consider all three cases. The explosion velocity is given by the relation

$$u_{\mathrm{ex}} = \phi u_{\mathrm{n}} + u_{\mathrm{d}} \qquad [17.5.5]$$

Table 17.10 *Some experiments on pressure piling (after Fitt, 1981a)*

Worker(s)	*Apparatus*	*Compartment volume ratio*
Beyling (1906)	Compartmented pipe	2
Beyling (1906)	Linktube	11.7
Grice and Wheeler (1929)	Link tube	12 and 16.7
Coward and Wheeler (1934)	Compartmented pipe	Many compartments
Gleim and March (BM 1952 RI 4908)	Compartmented pipe	1.0–7.0
T.A.J. Brown (1959)	Link tube	13.5
J. Singh (1977)	Link tube	5.0–32.0
Bartknecht (1981a)	Link tube	5.0

	Larger compartment diameter or side (cm)	*Conneting passage diameter* (cm)	*Maximum observed peak pressure enhancement ratio*
Beyling (1906)	33.5	3.0	1.3
Beyling (1906)	33.5	2.0	2.3
Grice and Wheeler (1929)	45.8[a] and 50	2.5	2.0
Coward and Wheeler (1934)	30.6	2.5	Not studied[b]
Gleim and March (BM 1952 RI 4908)	30.6[a]	5.1–25.4	4.0
T.A.J. Brown (1959)	15.2	0.6–2.5	4.0
J. Singh (1977)	30.5	1.3–5.1	3.7
Bartknecht (1981a)			3.1

[a] Square section.
[b] Flame front projection.

where u_d is the displacement velocity, u_{ex} is the explosion velocity, u_n the normal burning velocity and ϕ the ratio of the area of the flame front to the cross-sectional area of the pipe. The displacement velocity u_d is the velocity of the unburned mixture, and the explosion velocity is the visible flame velocity. The equation applies to all three cases, but for that of an open pipe with ignition at the open end the displacement velocity is zero. For ignition at the closed end (case 2) it is high, being some 80–90% of the explosion velocity. In this latter case only part of the gas mixture, theoretically 1/7, is burned within the pipe, the rest being ejected from the open end and burned outside. The high displacement velocity also results in much higher turbulence, a higher flame front area and a higher value of ϕ, in this latter case.

For an open pipe with ignition at the closed end with large diameter pipes ($\geq$400 mm) the explosion velocity exhibits an approximately linear increase along the length of the pipe. With smaller diameter pipes this continuous increase is no longer observed. As the pipe diameter is decreased, a critical diameter is reached at which the flame propagation no longer occurs.

For an open pipe with ignition at the closed end the explosion pressure P_{ex} increases linearly with the logarithm of explosion velocity, as shown in line 1 of Figure 17.9(a). This effect is independent of pipe diameter.

Thus, in the case of a 1600 mm diameter pipe, 10 m long, open at one end, Bartknecht quotes, for ignition at the open end, values of u_{ex} and P_{ex} of 4 m/s and 0.02 bar and, for ignition at the closed end, values of 150 m/s and 0.2 bar, respectively.

If the flow is highly turbulent and if the pipe is long enough, the explosion velocity can reach a value such that detonation, or quasi-detonation, occurs. The reference to quasi-detonation applies particularly to methane. It is difficult to cause methane to detonate, and although it exhibits detonation-like behaviour, the flame front and shock wave can separate, whereas in a normal detonation they are coupled.

Table 17.11 shows the pipe lengths required for run-up to detonation for the three gases methane, propane and hydrogen with flame jet ignition in pipes of 100, 200 and 400 mm diameter. Section 17.2.15 treats run-up distance for weaker ignitions.

Turning to the case of a pipe closed at both ends (case 3), and considering first a quiescent gas mixture, experimental results given by Bartknecht show that the explosion velocity initially increases along the length of the pipe due to a high displacement velocity, but since the gas is confined, the displacement velocity and the explosion velocity then decrease. For gases such as methane and propane, the net effect is to cause the explosion velocity to pass through a maximum, and for the value of that maximum to be less than that attained in an open pipe with ignition at the closed end. There is in effect a braking action. Hydrogen constitutes an exception: the explosion velocity is the same in both configurations and does not pass through a maximum.

If the gas mixture is turbulent, however, there is no such braking action. In this case in a pipe closed at both ends all three gases will run up to detonation, or quasi-detonation. The distance required to do this is longer than for a pipe with one end open, but is less than 30 m.

For a pipe closed at both ends, the explosion pressure again increases linearly with the explosion velocity, but since all the gas is burned the explosion pressure is several bar higher than for the open pipe case, as shown in line 2 in Figure 17.9(a).

The pressures developed in detonation, or quasi-detonation, of the three gases mentioned in pipes of 100 and 200 mm diameter with flame jet ignition are shown in Table 17.12. There are several points worthy of note. The pressures tend to be higher in the small diameter pipe. The pressures on the end flange P_{pf} are some three times those on the pipe wall P_{pw}. And the pressures given by hydrogen are less than those given by the other two gases.

Considering the simple case of a flame accelerating down a pipe closed at the end distant from the ignition source, the pressure in the gas ahead of the flame may rise due not only to a shock wave close to the flame front but possibly also due to a shock wave reflected from the end of the pipe. It is estimated by Nettleton (1987) that the pressure in the unburned gas may rise by a factor of 2–5.

A separate but related phenomenon is wave interactions associated with the advancing detonation wave. An example is the retonation wave in a pipe closed at the end where ignition occurs. This retonation wave is created at the same time as the detonation wave itself. It travels back through the burned gas, is reflected and then travels forwards again and, since the velocity of sound in the burned gas is much higher than in the unburned gas, overtakes the detonation wave. The latter thus becomes overdriven for a short distance, before it becomes attenuated by the Taylor expansion effect.

17.5.5 Plant design

The hazard of an explosion should in general be minimized by avoiding flammable gas–air mixtures inside a plant. It is bad practice to rely solely on elimination of sources of ignition.

If the hazard of a deflagrative explosion nevertheless exists, the possible design policies include (1) design for full explosion pressure, (2) use of explosion suppression or relief, and (3) the use of blast cubicles.

It is sometimes appropriate to design the plant to withstand the maximum pressure generated by the explosion. Often, however, this is not an attractive solution. Except for single vessels, the pressure piling effect creates the risk of rather higher maximum pressures. This approach is liable, therefore, to be expensive.

An alternative and more widely used method is to prevent overpressure of the containment by the use of explosion suppression or relief. This is discussed in more detail in Section 17.12.

In some cases the plant may be enclosed within a blast resistant cubicle. Total enclosure is normally practical for energy releases up to about 5 kg TNT equivalent. For greater energy releases a vented cubicle may be used, but tends to require an appreciable area of ground to avoid blast wave and missile effects.

It is more difficult to design for a detonative explosion. A detonation generates much higher explosion pressures. Explosion suppression and relief methods are not normally effective against a detonation. Usually, the only safe policy is to seek to avoid this type of explosion.

Direct initiation of detonation in ordinary flammable gas–air mixtures is generally improbable. Avoidance of detonation depends mainly, therefore, on elimination of conditions under which transition from deflagration to detonation can occur in equipment such as pipelines.

Where a significant explosion hazard exists, the possible consequences of explosion should be reviewed.

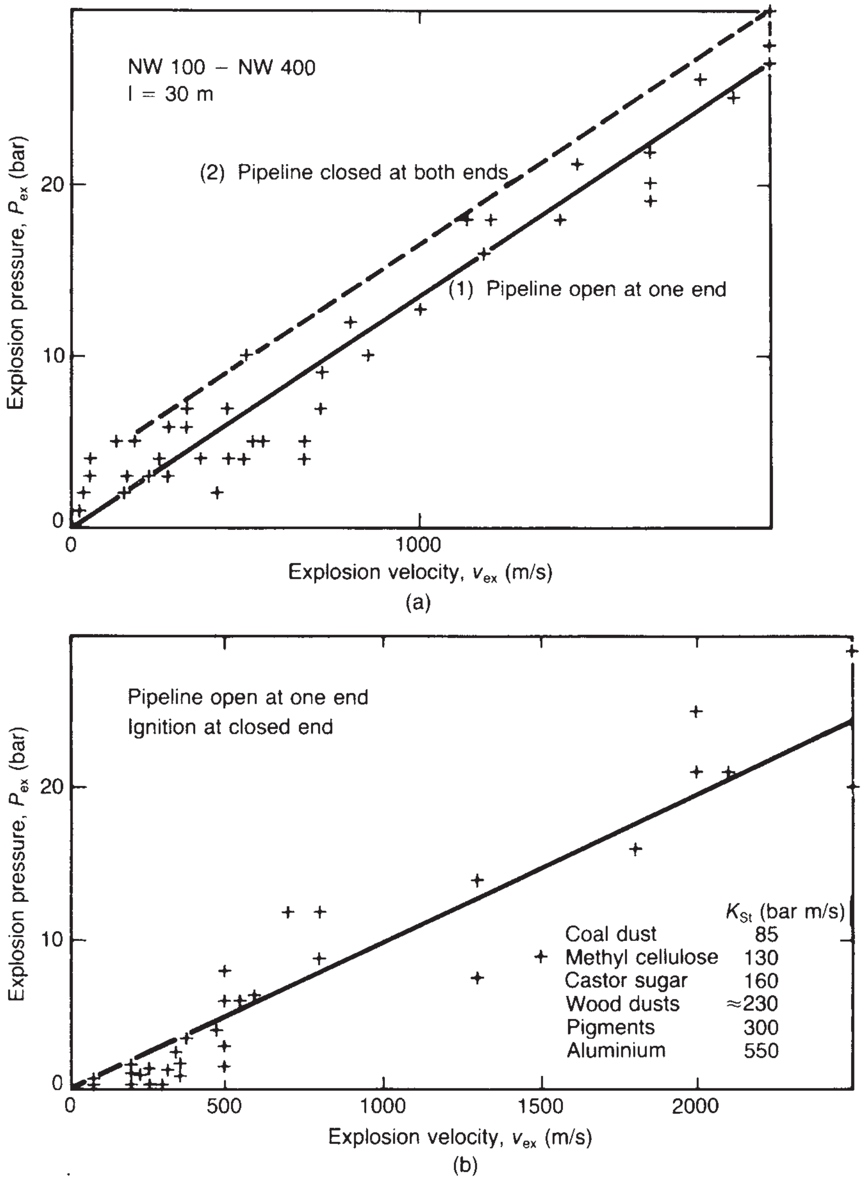

Figure 17.9 *Explosion pressure in pipes (after Bartknecht, 1981a). (a) Flammable gas: line 1, flammable gas in a pipe of diameter 100–400 mm and length 30 m open at one end; line 2, flammable gas in a pipe of the same dimensions closed at both end. (b) Flammable dusts: dusts with K_{st} values of 85–550 bar m/s in a pipe of diameter 400 mm length 40 mm open at one end with ignition at the closed end (Courtesy of Elsevier Science)*

17.6 Detonation inside Vessels and Pipes

Detonation of a flammable gas–air mixture may occur by direct initiation of detonation by a powerful ignition source or by transition from deflagration.

The transition from deflagration to detonation requires a strong acceleration of the flame front. It occurs in pipelines but is very improbable in vessels. The transition from deflagration to detonation is a complex process. The properties of the detonation, however, are fairly well defined and depend essentially on the properties and condition of the unburnt gas.

17.6.1 Detonation in vessels

A general account of the pressures which may be generated by detonation inside a plant has been given in Section 17.2. In practical terms, the peak pressure ratio P_2/P_1 resulting from a detonation of a hydrocarbon–air mixture in a

Table 17.11 *Pipe lengths (m) for acceleration to detonation (after Bartknecht, 1981a) (Courtesy of Springer-Verlag)*

Gas	*Pipe diameter* (mm)		
	100	200	400
Methane	12.5	18.5	>30
Propane	12.5	17.5	22.5
Hydrogen	7.5	12.5	12.5

Table 17.12 *Some pressures (bar) in a pipeline closed at both ends following a detonation, or quasi-detonation (after Bartknecht, 1981a) (Courtesy of Springer-Verlag)*

Gas	*Pipe diameter,* 100 mm		*Pipe diameter,* 200 mm	
	P_{pw}	P_{pf}	P_{pw}	P_{pf}
Methane	32	100	25	80
Propane	35	95	25	75
Hydrogen	23	56	23	40

containment such as a vessel is about 20:

$$\frac{P_2}{P_1} \approx 20 \qquad [17.6.1]$$

This is the order of pressure rise, for example, in the experiment reported in Table 17.7.

17.6.2 Detonation in pipes

The transition from deflagration to detonation was discussed in Sections 17.2 and 17.5, where information was given on the run-up length to detonation and on the pressures exerted both on the pipe wall and on the end flange.

Accounts of detonation in pipes have been given by a number of workers, including Craven and Greig (1967), Munday (1971b) and Bartknecht (1981a).

Craven and Greig describe experimental work on the pressure generated by the detonation of ammonia–nitrous oxide mixtures in 3 and 4 in. pipes initially at atmospheric pressure. Determinations were made of the incident pressure and of the reflected pressure. The latter was determined from the distortion suffered by test plates bolted to the end of the pipe. It was found that the velocity, the incident pressure and the reflected pressure all rose rapidly with distance from the ignition source to a peak value and then fell to a lower, plateau value. Thus, the transition from deflagration to detonation was associated with high but unstable velocities and pressures. In the 3 in. pipe with a 50 : 50 ammonia–nitrous oxide mixture the incident pressure peak and plateau values were about 1250 and 370 psi, and the reflected pressure peak and plateau values were about 4800 and 1100 psi, respectively.

The effects of detonation in a pipe system vary. In some cases damage is confined to blank ends and sudden changes of direction. In other cases the pipe may be ripped open from end to end.

17.6.3 Pressure piling

The phenomenon of pressure piling has been discussed in Section 17.5.

17.6.4 Plant design

Essentially, the preferred approach in plant design to the hazard of detonation in vessels and pipes is prevention rather than protection.

Where an estimate is to be made of the ability of a plant to withstand detonation, the approach generally adopted is to use a unidimensional method such as the CJ model. Such models work reasonably well in the simple case of a readily detonable mixture in straight pipe. In any event, there is a lack of a more comprehensive treatment adapted to design.

The traditional approach has been to compare the pressures obtained from a unidimensional model with the static pressures which the plant can withstand. Some of the weaknesses of this approach have been described in Section 17.2. The pressures predicted by unidimensional models are well below those produced by real detonation waves. The method does not take into account the difference between rapidly and slowly applied loads nor the interaction between the shape of the pressure profile and the response time of the confining structure.

The pressures predicted for detonations inside plant tend to be so high that containment is impractical except for certain limited cases such as straight pipes which are of small diameter and/or are open-ended.

However, from an assessment of the limited experimental evidence, Nettleton (1987) concludes that the traditional approach just described appears to be a safe one. The tests were conducted, conservatively, with stoichiometric mixtures for which the detonation pressures are relatively predictable.

With regard to mechanical design, the velocity of an elastic wave in a metal usually exceeds the detonation velocity. This points to separate treatment of the arrivals of the elastic wave and of the detonation wave itself.

In designing against explosions, an approach usually considered is to accept a degree of plastic deformation. A discussion of the planned deformation approach and of the practical problems in implementing it is given by Nettleton (1987). Essentially, it is limited to the early stages of flame acceleration. Nettleton also gives guidance on the local strengthening of plant at vulnerable points.

17.6.5 Protection against detonation

Where protection against detonation is to be provided, the preferred approach is to intervene in the processes leading to detonation early rather than late.

Attention is drawn first to the various features which tend to promote flame acceleration, and hence detonation. Minimization of these features therefore assists in inhibiting the development of a detonation. To the extent practical, it is desirable to keep pipelines small in diameter and short; to minimize bends and junctions and to avoid abrupt changes of cross-section and turbulence promoters.

For protection, the following strategies are described by Nettleton (1987): (1) inhibition of flames of normal burning velocity, (2) venting in the early stages of an explosion, (3) quenching of flame–shock complexes, (4) suppression of a detonation, and (5) mitigation of the effects of a detonation.

Methods for the inhibition of a flame at an early stage are described in Chapter 16. Two basic methods are the use of flame arresters and flame inhibitors.

Flame arresters are described in Section 17.11. The point to be made here is that although an arrester can be effective in the early stages of flame acceleration, siting is critical since there is a danger that in the later stages of a detonation it may act rather as a turbulence generator.

The other method is inhibition of the flame by injection of a chemical. Essentially, this involves detection of the flame followed by injection of the inhibitor. At the low flame speeds in the early stage of flame acceleration, there is ample time for detection and injection. This case is taken by Nettleton to illustrate this is a gas mixture with a burning velocity of about 1 m/s and expansion ratio of about 10, giving a flame speed of about 10 m/s, for which a separation between detector and injection point of 5 m would give an available time of 0.5 s.

In the early stage of an explosion, venting may be an option. The venting of explosion in vessels and pipelines is discussed in Sections 17.12 and 17.13, respectively.

It may be possible in some cases to seek to quench the flame–shock complex just before it has become a fully developed detonation. The methods are broadly similar to those used at the earlier stages of flame acceleration, but the available time is drastically reduced; consequently, this approach is much less widely used. Two examples of such quenching given by Nettleton are the use of packed bed arresters developed for acetylene pipelines in Germany, and widely utilized elsewhere, and the use in coal mines of limestone dust which is dislodged by the flame–shock complex itself.

The suppression of a fully developed detonation may be effected by the use of a suitable combination of an abrupt expansion and a flame arrester. As described earlier, there exists a critical pipe diameter below which a detonation is not transmitted across an abrupt expansion, and this may be exploited to quench the detonation. Work on the quenching of detonations in town gas using a combination of abrupt expansion and flame arrester has been described by Cubbage (1963).

An alternative method of suppression is the use of water sprays, which may be used in conjunction with an abrupt expansion or without an expansion. The work of Gerstein, Carlson and Hill (1954) has shown that it is possible to stop a detonation using water sprays alone.

17.6.6 Some limitations

There are two principal mechanisms which create pressures which exceed those predicted by the unidimensional models and against which it is difficult to design. One is the pressure piling and wave interaction effects described above which occur during the development of the detonation wave. The other, which applies to the detonation condition itself, arises from instabilities in the combustion behind the leading front. The effects are enhanced in marginally detonable mixtures and by interactions with the confinement.

17.7 Explosions in Closed Vessels

The deflagration of a flammable gas mixture in a closed vessel is important in itself and in relation to venting of the vessel. It is closely related to the combustion of a flammable dust mixture in a vessel. Quantification requires the measurement of flame speed and burning velocity. The two parameters of main interest in explosion in a closed vessel are the maximum pressure P_m and the rate of pressure rise, particularly the maximum rate $(dP/dt)_{max}$.

17.7.1 Energy release and final conditions

As described in Section 17.5, for a deflagration at constant volume, in a sphere, the maximum explosion pressure is

$$\frac{P_2}{P_1} = \frac{n_2 T_2}{n_1 T_1} \qquad [17.7.1]$$

where n is the number of moles in the gas mixture, P is the absolute pressure, T is the absolute temperature and the subscripts 1 and 2 denote the initial and final state, respectively. The determination of the maximum pressure therefore involves the calculation of the final temperature.

Combustion in a closed vessel is a constant volume process. The heat of reaction and the gas specific heats applicable to it are those at constant volume. The relevant thermodynamic quantity is the internal energy. Thus, the final temperature should be obtained by equating the internal energy of the products to the internal energy of the reactants and the heat of reaction at constant volume.

The computation of the final temperature is frequently done making the incorrect assumption of constant pressure conditions. The problem is discussed by S.M. Richardson, Saville and Griffiths (1990). It is a common, but incorrect, practice to take the final temperature as the adiabatic flame temperature. This is incorrect because the adiabatic flame temperature is a constant pressure quantity. The constant volume flame temperature is appreciably higher.

The aforementioned authors give an example which illustrates the extent of the error. For a stoichiometric mixture of propane and air, which contains 3.98% propane, at initial conditions of pressure 1 bara and temperature 290 K (17°C), the calculated final conditions for adiabatic constant volume combustion are pressure 10.2 bara and temperature 2850 K (2577°C). This compares with values quoted in the literature of final pressure 7.6 bara and temperature 2198 K (1925°C).

The authors state that the difference between the heat of reaction at constant volume and that at constant pressure is not great. The main source of error lies in the difference between the gas specific heat at constant volume and that at constant pressure.

Thus, in constant volume combustion both the final temperature and the final pressure are considerably higher than for combustion at constant pressure.

17.7.2 Experimental studies

There have been a large number of experimental studies of combustion in vessels, both closed and vented. Many of these have been concerned with the venting process, but the proportion of the total work done on closed vessels is appreciable.

Research on combustion in closed vessels has been undertaken for a number of purposes, of which three may be mentioned here. One is the determination of burning velocity. Burning velocity and its measurement have been discussed in Chapter 16. Some models incorporating burning velocity which may be used for its determination are described in this section. Experimental work related to burning velocity includes that of Fiock and Marvin (1937a,b), Fiock *et al.* (1940), Manton, von Elbe and Lewis (1953) and Eschenbach and Agnew (1958).

The second area of work is the investigation of the various factors which influence explosion development in a closed vessel. Here, particular mention needs to be made of the extensive programme of work undertaken at the Bureau of Mines (BM), an account of which is given by Nagy and Verakis (1983). It is illustrated by the work of Nagy *et al.* (1971 BM RI 7507) on the effect of variables such as initial pressure, initial temperature and vessel size and shape. Other work includes that of Kratz and Rosecrans (1922), Ellis and Wheeler (1925, 1928b), Fenning (1926), Rallis, Garforth and Steinz (1965) and G.F.P. Harris (1967).

The third area is studies of detonation, as opposed to deflagration. The BM is again well represented in work in this area, by investigations such as that of Burgess *et al.* (1968 BM RI 7196). Other work includes that of Manson and Ferri (1953) and Pliickebaum, Strauss and Edse (1964).

An account of the findings concerning the effects of the various influencing factors investigated in this work is given below.

One particular outcome of the experimental work may be mentioned at this point. When the flame front reaches a certain radius there is a marked increase in its velocity. At this point the ratio of the pressure to the initial pressure P/P_0 becomes strongly influenced by the expansion ratio E.

Plate 15, from the work of R.J. Harris (1983), shows the development of the flame within a vessel with the latter stages influenced by the presence of a vent.

17.7.3 Factors influencing closed vessel explosions

The maximum pressure and the rate of pressure rise in a closed vessel explosion are affected by a number of factors. These are discussed by Bartknecht (1981a), R.J. Harris (1983), Nagy and Verakis (1983) and Lunn (1984b, 1992). They include:

(1) vessel size and shape;
(2) fuel;
(3) fuel–air ratio;
(4) vessel fractional fill;
(5) initial pressure;
(6) initial temperature;
(7) initial turbulence;
(8) ignition source.

A factor which may affect both explosion parameters is heat transfer from the flame and the hot gas to the vessel wall. This can be significant if the vessel has a high aspect, or length/diameter, ratio or if the combustion is relatively slow.

The vessel shape to which most treatments apply is a compact vessel with a length/diameter ratio not exceeding 3. For a compact vessel, maximum pressure is theoretically independent of vessel size and shape if heat transfer is neglected. In practice, maximum pressures tend to show some scatter, but this is random. Maximum pressure may be less than theoretical if the mixture is slow burning. Mixtures close to the lower explosibility limit tend to burn relatively slowly. The rate of pressure rise depends on vessel size and shape. The effect of vessel volume is illustrated in Figure 17.10.

In one series of tests it was found that for cubical, rectangular and spherical vessels the rate of pressure rise was proportional to the ratio of the vessel surface S to its volume V. If the vessel shape is such as to promote heat transfer, the rate of pressure rise is reduced.

In an elongated vessel the flame front travels along the axis compressing the unburned gas. The rate of pressure rise is increased compared with that in a more compact vessel. The maximum pressure, though, tends to be less. However, for initial pressures greater than atmospheric, both parameters are enhanced by elongation, as described below.

If the initial pressure is atmospheric, most fuels give a maximum explosion pressure of 8–9 bara.

Both the maximum pressure and rate of pressure rise have maximum values at a fuel concentration close to the stoichiometric value, and decrease as the concentration moves away from this towards the explosibility limits. The effect is shown in Figure 17.11.

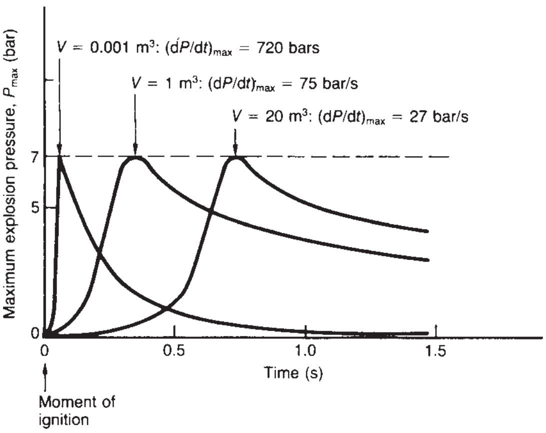

Figure 17.10 *Explosions in closed vessels: effect of vessel volume (Bartknecht, 1981a). Propane at stoleniometric concentration (Courtesy of Elsevier Science)*

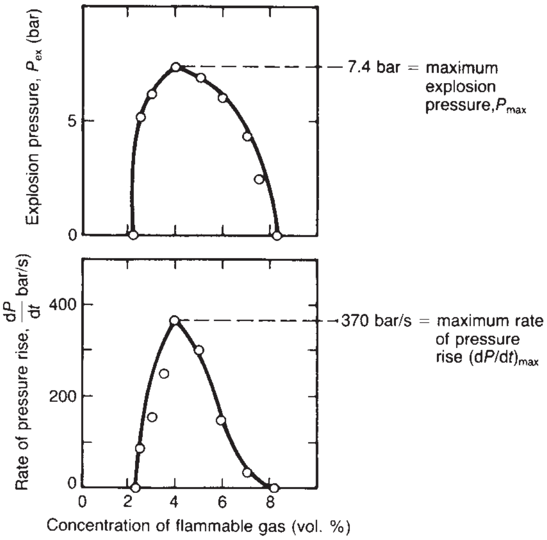

Figure 17.11 *Explosions in closed vessels: effect of gas concentration (Bartknecht, 1981a) (Courtesy of Springer-Verlag)*

If the vessel is only partially filled by the fuel–air mixture, the maximum pressure varies in an approximately linear manner with the fractional fill.

In compact vessels over a limited range of initial pressure the maximum pressure increases linearly with the initial pressure. The rate of rise of pressure is a function of the initial pressure. One set of relations for this are those of Nagy and Verakis which are given below.

In elongated vessels the effect of initial pressure is different, as shown in Figure 17.12, smaller for a spherical vessel and larger for an elongated one. At atmospheric pressure the maximum explosion pressure in the larger vessel is slightly less than that in the smaller one, but at higher initial pressures it is much greater. The maximum rate of pressure rise should be less in the larger vessel, but it is actually higher.

The initial temperature affects the maximum pressure, the rate of pressure rise and the final temperature. The maximum pressure decrease as the initial temperature increases is due to the decrease in density of the fuel–air mixture. The following equation has been used to fit some experimental results

$$\frac{P_m}{P_o} = k_1 + \frac{k_2}{T_o} \qquad [17.7.2]$$

where P is the absolute pressure and T is the absolute temperature, the subscripts m and o denote maximum and initial, respectively, and k_1 and k_2 are constants. The rate of pressure rise is essentially independent of the initial temperature, because there are two opposing effects, the lower expansion ratio and the faster burning rate. The final temperature T_e increases linearly with the initial temperature:

$$T_e = k_3 + k_4 T_o \qquad [17.7.3]$$

where k_3 and k_4 are constants.

For compact vessels the initial turbulence has only a slight effect on the maximum pressure, but has a strong effect on the rate of pressure rise. This is illustrated in Figure 17.13. Turbulence increases the flame speed. Nagy and Verakis describe experiments on methane–air mixtures where turbulence was created by injecting the fuel–air mixture. In the concentration range 8–12% the effective burning velocity increased by a factor of 5. This factor is generally known as the coefficient of turbulence α. At lower concentrations a value of 8 was obtained for α. For elongated vessels initial turbulence can affect the maximum pressure.

Scheuermann (1994) has described work on the modelling of turbulence relevant to explosions of gas or dust in closed or vented vessels. He correlates the ratio of the laminar and turbulent burning velocities in terms of the velocity component u'.

In a spherical vessel the location of the ignition source has a slight effect on the maximum pressure, but a marked effect on the rate of pressure rise. The rate of pressure rise is greatest for central ignition. The rate of pressure rise increases with the strength of the ignition source.

17.7.4 Modelling of closed vessel explosions

The principal case considered is deflagration in a closed spherical vessel. Treatments of the problem typically produce relations for the pressure P, the rate of change of pressure (dP/dt), the radius r_b of the burned gas core, the rate of change of this radius (dr_b/dt) and the burning velocity S_u.

17.7.5 Elementary relations

These treatments make use of certain common relations and before describing the principal models it is convenient

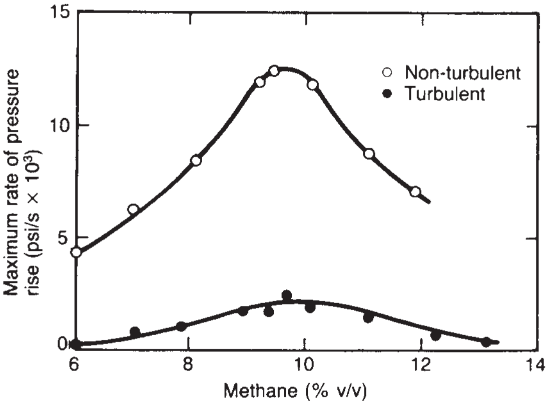

Figure 17.13 *Explosions in closed vessels: effect of initial turbulence (Nagy and Verakis, 1983)*

to give some of these relations. For combustion of a flammable gas mixture in a spherical vessel

$$V_o = V_u + V_b \qquad [17.7.4]$$

$$m_o = m_u + m_b = m_u n_u + m_b n_b \qquad [17.4.5]$$

$$m_o = V_o \rho_o \qquad [17.7.6]$$

$$m_u = V_u \rho_u \qquad [17.7.7]$$

$$m_b = V_b \rho_b \qquad [17.7.8]$$

$$n_u = \frac{m_u}{M_u} \qquad [17.7.9]$$

$$n_b = \frac{m_b}{M_b} \qquad [17.7.10]$$

$$\mathrm{d}V_b = -\mathrm{d}V_u \qquad [17.7.11]$$

$$\mathrm{d}m_b = -\mathrm{d}m_u \qquad [17.7.12]$$

$$V_o = \frac{4\pi R_o^3}{3} \qquad [17.7.13]$$

$$V_i = \frac{4\pi r_i^3}{3} \qquad [17.7.14]$$

$$V_b = \frac{4\pi r_b^3}{3} \qquad [17.7.15]$$

$$n = \frac{m_b}{m_o} \qquad [17.7.16]$$

$$1 - n = \frac{m_u}{m_o} \qquad [17.7.17]$$

$$n = \frac{V_i}{V_o} = \frac{r_i^3}{R_o^3} \qquad [17.7.18]$$

$$\frac{\mathrm{d}n_b}{\mathrm{d}t} = -\frac{m_u}{m_b}\frac{\mathrm{d}n_u}{\mathrm{d}t} \qquad [17.7.19]$$

Since some authors work in mass terms and others in molar terms, the gas laws are needed in both forms. For mass specific volume v and molar specific volume v

$$Pv = \frac{RT}{M} \qquad [17.7.20]$$

$$= R_g T \qquad [17.7.21]$$

$$R_g = \frac{R}{M} \qquad [17.7.22]$$

$$Pv = RT \qquad [17.7.23]$$

For the total volume V

$$PV = \frac{mRT}{M} \qquad [17.7.23]$$

$$PV = mR_g T \qquad [17.7.24]$$

$$PV = n_j RT \qquad [17.7.25]$$

and specifically

$$PV_o = n_o RT \qquad [17.7.26]$$

$$PV_u = n_u RT_u \qquad [17.7.27]$$

$$PV_b = n_b RT_b \qquad [17.7.28]$$

$$\rho = \tfrac{1}{v} \qquad [17.7.29]$$

For the compression of gas

$$Pv^{\gamma} = \text{ constant} \qquad [17.7.30]$$

$$P\rho^{-\gamma} = \text{constant} \qquad [17.7.31]$$

$$TP^{(1-\gamma)/\gamma} = \text{constant} \qquad [17.7.32]$$

$$RTP^{(1-\gamma)/\gamma} = \text{constant} = F \qquad [17.7.33]$$

$$PV^{1/\gamma} = \text{constant} = F \qquad [17.7.34]$$

For a spherical flame front

$$A_n = 4\pi r_b^2 \qquad [17.7.35]$$

$$\frac{\mathrm{d}V_b}{\mathrm{d}r_b} = A_f \qquad [17.7.36]$$

$$\frac{\mathrm{d}m_b}{\mathrm{d}t} = A_f \rho_u S_u \qquad [17.7.37]$$

$$\frac{\mathrm{d}r_b}{\mathrm{d}t} = S_f \qquad [17.7.38]$$

$$S_f = u_u + S_u \qquad [17.7.39]$$

$$S_f = ES_u \qquad [17.7.40]$$

$$E = \frac{\rho_u}{\rho_b} = \frac{n_b}{n_u}\frac{T_b}{T_i} \qquad [17.7.41a]$$

where a is the radius of the spherical vessel, A_f is the area of the flame front, E is the expansion ratio, m is the mass of gas, M is the molecular weight, η is the fractional degree of combustion, n (with subscript) is the number of moles of gas, P is the absolute pressure, r is the radius, R is the universal gas constant, R_g is the mass basis gas constant, S_f is the flame speed, S_u is the burning velocity, t is time, T is the absolute temperature, m_u is the velocity of the unburned gas into the flame front, v is the specific mass volume of the gas, V is the total volume, γ is the ratio of gas specific heats, v is the specific molar volume of the gas, ρ is the mass density and the subscripts b, o and u denote burned, initial and unburned, respectively. V_0 is the volume of the vessel and m_0 the mass of gas in the vessel. The subscript i refers to the initial state of the burned gas and j to any gas state. The area A_n is the ideal (geometric) area normal to the flame direction. The actual flame area of the wrinkle and folding flame front, A_f, is a multiple α (where $\alpha > 1$) of A_n. Expanding the definition of the expansion ration, E, Equation 17.7.41 using Equation 17.7.7 and 17.7.8:

$$E = \frac{m_u}{V_u}\frac{V_b}{m_b} \qquad [17.7.41b]$$

Substituting for volume from the ideal gas law, Equation 17.7.23

$$\frac{V_b}{V_u} = \frac{m_b}{m_u}\frac{T_b}{T_u}\frac{M_u}{M_b}\frac{P_o}{P_b} \qquad [17.7.41c]$$

gives

$$E = \frac{M_u}{M_b}\frac{T_b}{T_u}\frac{P_o}{P_b} \qquad [17.7.41d]$$

In an unconfined explosion, approximated by a vented enclosed explosion, the pressure ratio P_o/P_b is approximately unity and E is approximately:

$$E \cong \frac{M_u}{M_b}\frac{T_b}{T_u} \qquad [17.7.41e]$$

The molecular weights of burned and unburned gases are constant, as are the initial temperature and adiabatic flame temperature, so the expansion ratio is constant in a constant pressure explosion.

Use is also made of the approximations

$$r_b = S_f t \qquad [17.7.42]$$

$$E^2(E-1) \cong E^3 \qquad [17.7.43]$$

17.7.6 Zabetakis model

Zabetakis (1965 BM Bull. 627) has given the following equation for the pressure rise resulting from combustion in a closed spherical vessel:

$$\frac{\Delta P}{P_o} = \frac{K S_u^3 t^3}{V} \qquad [17.7.44]$$

with

$$\Delta P = P - P_o \qquad [17.7.45]$$

where K is a constant. Hence,

$$\frac{P}{P_o} = 1 + \frac{K S_u^3 t^3}{V} \qquad [17.7.46]$$

According to Nagy and Verakis, Equation 17.7.44 is in the first instance an empirical one, but both they and other workers have derived it theoretically, as described below. Differentiating Equation 17.7.46 gives

$$\frac{dP}{dt} = \frac{3KP_o S_u^3 t^2}{V} \qquad [17.7.47]$$

For a given explosion pressure $t \propto V^{1/3}$ and hence

$$\left(\frac{dP}{dt}\right)V^{1/3} = \text{constant} \qquad [17.7.48a]$$

$$= K_G \qquad [17.7.48b]$$

Equations 17.7.48 are usually applied to $(dP/dt)_{max}$ but are strictly applicable only where (dP/dt) is measured at the same pressure in each volume.

17.7.7 Flamm and Mache model

In one of the earliest treatments of the problem, Flamm and Mache (1917) derived the equation

$$1 - n = \frac{RT_o}{RT_u(\gamma_b - \gamma_u)/(\gamma_u - 1) + K(\gamma_b - 1)}\frac{P_e - P}{P_o} \qquad [17.7.49]$$

where K is a constant and the subscript e denotes the end.

17.7.8 Flock and Marvin model

Fiock and Marvin (1937a,b) derived the following equation for the burning velocity:

$$S_u = \frac{dr_b}{dt} - \frac{a^3 - r_b^3}{3P\gamma_u r_b^2}\frac{dP}{dt} \qquad [17.7.50]$$

17.7.9 Lewis and von Elbe model

Another early treatment was that of B. Lewis and von Elbe (1951) (also Manton, von Elbe and Lewis, 1953). Starting with Equation 17.7.33 and the relation

$$V_o = \frac{R}{P}\left(n_e \int_0^n T_{bP}\, dn + n_o T_u(1-n)\right) \qquad [17.7.51]$$

where T_{bP} is the absolute temperature corresponding to pressure P, they derive Equation 17.7.49 of Flamm and Mache.

Then, from Equation 17.7.49 for $n = 0$, $T_u = T_o$ and $P = P_o$ and noting that for practical cases

$$RT_o(\gamma_b - \gamma_u)/(\gamma_u - 1) << K(\gamma_b - 1) \qquad [17.7.52]$$

they derive the following approximation

$$n = \frac{P - P_o}{P_e - P_o} \qquad [17.7.53]$$

Equation 17.7.53 is often used in the differential form

$$\frac{dn}{dt} = \frac{1}{P_e - P_o}\frac{dP}{dt} \qquad [17.7.54]$$

For the burned gas core they define two radii: r_i the radium before ignition of the gas and r_b the radius after expansion. Then utilizing Equation 17.7.19 for the radius before expansion

$$r_i = a\left(\frac{P - P_o}{P_e - P_o}\right)^{1/3} \qquad [17.7.55]$$

and utilizing Equations 17.7.17 and 17.7.27 for the radius after expansion

$$V_u = \frac{n_o R T_u(1-n)}{P} \qquad [17.7.56]$$

$$r_b = a\left(1 - \frac{P_o T_u}{P T_o}(1-n)\right)^{1/3} \qquad [17.7.57]$$

$$r_b = a\left[1 - \frac{P_o T_u}{P T_o}\left(\frac{P_e - P}{P_e - P_o}\right)\right]^{1/3} \qquad [17.7.58]$$

with

$$T_u = T_o\left(\frac{P}{P_o}\right)^{(\gamma_u - 1)/\gamma_u} \qquad [17.7.59]$$

For the burning velocity, the volume of an element of the shell of the burned gas core before expansion is

$$4\pi r_i^2\, dr_i \qquad [17.7.60]$$

at P_i and T_i, and the volume after expansion is

$$4\pi r_i^2\, dr_i\left(\frac{T_u P_o}{T_o P}\right) \qquad [17.7.61]$$

But this volume is also equal to

$$4\pi r_b^2 S_u \, dt \qquad [17.7.62]$$

Equating Equations 17.7.61 and 17.7.62 and applying Equation 17.7.59

$$S_u = \left(\frac{r_i}{r_b}\right)^2 \left(\frac{P_o}{P}\right)^{1/\gamma_u} \frac{dr_i}{dt} \qquad [17.7.63]$$

17.7.10 O'Donovan and Rallis model

The following treatment by O'Donovan and Rallis (1959) supplements those of the last two sets of workers. From Equations 17.7.17, 17.7.24 and 17.7.32

$$V_u = V_o(1-n)\left(\frac{P_o}{P}\right)^{1/\gamma_u} \qquad [17.7.64]$$

From Equations 17.7.15 and 17.7.64

$$V_b = V_o\left[1-(1-n)\left(\frac{P_o}{P}\right)^{1/\gamma_u}\right] \qquad [17.7.65]$$

$$r_b = a\left[1-(1-n)\left(\frac{P_o}{P}\right)^{1/\gamma_u}\right]^{1/3} \qquad [17.7.66]$$

or rearranging Equation 17.7.66

$$n = 1-\left(1-\frac{r_b^3}{a^3}\right)\left(\frac{P_o}{P}\right)^{1/\gamma_u} \qquad [17.7.67]$$

Equating the volume rate of change of the unburned gas passing through the flame front with that of the unburned gas in its actual state of adibiatic compression

$$4\pi r_b^2 S_u = 4\pi r_i^2 \left(\frac{dr_i}{dt}\right)\left(\frac{T_u P_o}{T_o P}\right) \qquad [17.7.68]$$

Hence

$$S_u = \frac{dr_i}{dt}\left(\frac{r_i}{r_b}\right)^2\left(\frac{P_o}{P}\right)^{1/\gamma_u} \qquad [17.7.69]$$

Also from Equation 17.7.19

$$\frac{dn}{dt} = \frac{3r_i^2}{a^3}\frac{dr_i}{dt} \qquad [17.7.70]$$

From Equations 17.7.69 and 17.7.70

$$S_u = \frac{a^3}{3r_b^2}\left(\frac{P_o}{P}\right)^{1/r_u}\frac{dn}{dt} \qquad [17.7.71]$$

Then noting that in Equation 17.7.67 both r_b and P are functions of time and differentiating n in that equation with respect to t and substituting for dn/dt in Equation 17.7.71 gives Equation 17.7.50 of Fiock and Marvin.

17.7.11 Nagy and Verakis model

Nagy and Verakis (1983) give treatments for both ideal gas and adiabatic expansion. Their starting point is the rate of production of the burned mass. Assuming $M_b = M_u$,

$$\frac{dn_b}{dt} = \frac{\alpha A_t S_u P}{RT_u} \qquad [17.7.72]$$

where α is a flame area factor which allows for the difference between the nominal area of the flame front and the actual area, which is higher due to flame wrinkling. Also

$$\frac{M_b}{M_u}\frac{T_u}{T_b} = \frac{P_o}{P_e} \qquad [17.7.73]$$

From Equations 17.7.27 and 17.7.28, differentiating with respect to t and assuming $M_b = M_u$ so that $dn_u/dt = -dn_b/dt$

$$V\frac{dP}{dt} = \frac{dn_b}{dt}(RT_b - RT_u) \qquad [17.7.74]$$

From Equations 17.7.72–17.7.74

$$\frac{dP}{dt} = \frac{\alpha A_f S_u P(P_e - P_o)}{VP_o} \qquad [17.7.75]$$

In order to integrate Equation 17.7.75 it is necessary to express A_f as a function of P. From Equations 17.7.15 and 17.7.35

$$A_f = 4_\pi\left(\frac{3V_b}{4\pi}\right)^{2/3} \qquad [17.7.76]$$

and from Equations 17.7.5, 17.7.9, 17.7.10, 17.7.27 and 17.7.28 and again assuming $M_b = M_u$ so that $n_0 = n_u + n_b$

$$V_b = V\frac{1-P_o/P}{1-P_o/P_e} \qquad [17.7.77]$$

From Equations 17.7.75, 17.7.76 and 17.7.77

$$\frac{dP}{dt} = \frac{\alpha S_u P_e^{2/3}}{VP_o}(P_e - P_o)^{1/3}(1-P_o/P)^{2/3}P \qquad [17.7.78]$$

Integration of Equation 17.7.78 is difficult, but an approximate solution over a limited range is

$$P = P_o + (P_e - P_o)\left(\frac{P_e}{P_o}\right)^2\left(\frac{\alpha S_u t}{3V}\right)^3, \quad P_o \le P \le 2P_o \qquad [17.7.79]$$

Equation 17.7.79 is similar to Equation 17.7.46 of Zabetakis. Equating the two equations gives the value of the constant K in the latter equation as

$$K = \frac{4}{3}\frac{\pi}{P_o}(P_e - P_o)\left(\frac{P_e}{P_o}\right)^2 \qquad [17.7.80]$$

The authors also treat the adiabatic case, which leads to rather complex relationships.

17.7.12 Model of Perlee, Fuller and Saul

Perlee, Fuller and Saul (1974 BM RI 7839) have derived Equation 17.7.46 and have determined the value of the constant K. Differentiating Equation 17.7.27 with respect to n_b and Equation 17.7.28 with respect to n_b

$$V_u \, dP + P \, dV_u = RT_u \, dn_u + Rn_u \, dT_u \qquad [17.7.81]$$

$$V_b \, dP + P \, dV_b = RT_b \, dn_b + Rn_b \, dT_b \qquad [17.7.82]$$

Hence

$$dP\,[V_o(1-\alpha_u) + V_b(\alpha_u - \alpha_b)] = -R\left[T_b - T_u\left(\frac{M_b}{M_u}\right)\right]dn_u \qquad [17.7.83]$$

with

$$\alpha_u = \frac{\gamma_u - 1}{\gamma_u} \qquad [17.7.84]$$

$$\alpha_b = \frac{\gamma_b - 1}{\gamma_b} \qquad [17.7.85]$$

But from Equations 17.7.9, 17.7.12, 17.7.35 and 17.7.37

$$\frac{dn_u}{dt} = -4\pi r_b^2 \frac{\rho_u S_u}{M_u} \qquad [17.7.86]$$

Then from Equations 17.7.83 and 17.7.86

$$\frac{dP}{dt} = \frac{3\gamma_u P(E-1)S_u r_b^2}{a^3 + r_b^3\left(\frac{\gamma_u}{\gamma_b} - 1\right)} \qquad [17.7.87]$$

with E as defined by Equation 17.7.41 or alternatively

$$E = \frac{M_u T_b}{M_b T_u} \qquad [17.7.88]$$

then from Equations 17.7.40, 17.7.42 and 17.7.87

$$\frac{d\ln P}{dt} = \frac{3\gamma_u P(E-1)}{a}\left(\frac{S_u E t}{a}\right)^2 S_u \qquad [17.7.89]$$

Integrating Equation 17.7.89

$$\ln\left(\frac{P}{P_o}\right) = \gamma_u E^2 (E-1)\left(\frac{S_u}{a}\right)^3 t^3 \qquad [17.7.90]$$

Introducing the approximation

$$\ln\left(\frac{P_o + \Delta P}{P_o}\right) \approx \frac{\Delta P}{P_o} \qquad [17.7.91]$$

$$\frac{\Delta P}{P_o} = \gamma_u E^2 (E-1)\left(\frac{S_u}{a}\right)^3 t^3 \qquad [17.7.92]$$

$$= \frac{K S_u^3 t^3}{V} \qquad [17.7.93]$$

with

$$K = \frac{4}{3}\pi E^2 (E-1)\gamma_u \qquad [17.7.94]$$

17.7.13 Harris model

An alternative relation for the rate of pressure rise is derived by R.J. Harris (1983). From Equations 17.7.8 and 17.7.37 where r_s is the radius of the vessel

$$V_b \frac{d\rho_b}{dt} + \rho_b \frac{dV_b}{dt} = A_f \rho_u S_u \qquad [17.7.95]$$

$$\frac{dV_b}{dt} = \frac{dV_b}{dr_b}\frac{dr_b}{dt} = 4\pi r_b^2 \frac{dr_b}{dt} = A_n S_f \qquad [17.7.96]$$

Then from Equations 17.7.36, 17.7.38, and 17.7.95

$$V_b \frac{d\rho_b}{dt} + \rho_b A_n S_f = A_f \rho_u S_u \qquad [17.7.97]$$

But initially dP/dt is small and so is $d\rho_b/dt$. Hence Equation 17.7.97 reduces to

$$S_f = \alpha\left(\frac{\rho_u}{\rho_b}\right) S_u \qquad [17.7.98]$$

$$= \alpha E S_u \qquad [17.7.99]$$

which relates the flame speed to the burning velocity. The coefficient of turbulence, α, relates A_f to A_n.

Initially, when the pressure rise is low, it is possible to make the assumption that T_u and T_b are constant, termed by the author the isothermal assumption. Then differentiating Equations 17.7.27 and 17.7.28 and adding the resulting equations and utilizing Equation 17.7.4 and 17.7.12 gives

$$V\frac{dP}{dt} = \left(\frac{RT_b}{M_b} - \frac{RT_u}{M_u}\right)\frac{dm_b}{dt} \qquad [17.7.100]$$

From Equations 17.7.7, 17.7.37, 17.7.27, 17.7.98 and 17.7.100

$$V\frac{dP}{dt} = A_f P(E-1)S_u \qquad [17.7.101]$$

From Equations 17.7.35, 17.7.40, 17.7.42 and 17.7.101

$$\frac{dP}{dt} = \frac{4\pi P S_u^3 E^2 (E-1)t^2}{V} \qquad [17.7.102]$$

Integrating Equation 17.7.102

$$\frac{P}{P_o} = \exp\left(\frac{4\pi E^2 (E-1)(\alpha S_u t)^3}{3V}\right) \qquad [17.7.103]$$

For a spherical vessel of radius a:

$$\frac{P}{P_o} = \exp\left(\frac{E^2(E-1)}{r_s^3}(\alpha S_u t)^3\right) \qquad [17.7.104]$$

17.7.14 Bradley and Mitcheson model

D. Bradley and Mitcheson (1976) derive what they call a universal expression for the rate of pressure rise. From Equations 17.7.8, 17.7.12, 17.7.35 and 17.7.37 they obtain for the unburned gas

$$\frac{d[(r_s^3 - r_b^3)\rho_u]}{dt} = -3r_b^2 \rho_u S_u \qquad [17.7.105]$$

and for the burned gas

$$\frac{d(r_b^3 \rho_b)}{dt} = 3r_b^2 \rho_u S_u \qquad [17.7.106]$$

From Equations 17.7.31 and 17.7.105 it can be shown that

$$\frac{dP}{dt} = \frac{3r_b^2 \gamma_u P}{r_s^3 - r_b^3}\left(\frac{dr_b}{dt} - S_u\right) \qquad [17.7.107]$$

which can be rearranged to give Equation 17.7.50 of Fiock and Marvin (1937a,b).

From Equations 17.7.4, 17.7.5, 17.7.7, 17.7.12, 17.7.27, 17.7.31, 17.7.35 and 17.7.37 Bradley and Mitcheson derive

$$\frac{dP}{dt} = \frac{3S_u \rho_u}{r_s \rho_o}(P_e - P_o)\left[1 - \left(\frac{P_o}{P}\right)^{1/\gamma_u}\frac{P_e - P}{P_e - P_o}\right]^{2/3} \qquad [17.7.108]$$

They also give Equation 17.7.108 in dimensionless universal equation.

17.7.15 Morton and Nettleton model

Morton and Nettleton (1977) give the following treatment. Consider an element of the burned gas shell of inner radius r and outer radius $r + \delta r$. If the shell is moving with velocity $u(r)$, then after time δt the inner radius is equal to

$$r + u\, dt \qquad [17.7.109]$$

and the outer radius is equal to

$$r + \delta r + \left(u + \frac{\mathrm{d}u}{\mathrm{d}r}\delta r\right)\mathrm{d}t \qquad [17.7.110]$$

The initial volume of the element is

$$V = 4\pi r^2\ \delta r \qquad [17.7.111]$$

After time $\mathrm{d}t$ the area of the shell is

$$4\pi(r + u\ \mathrm{d}t)^2 \qquad [17.7.112]$$

and the thickness is

$$\left\{r + \delta r\left[u + \left(\frac{\mathrm{d}u}{\mathrm{d}r}\delta r\right)\right]\mathrm{d}t\right\} - (r + u\ \mathrm{d}t) \qquad [17.7.113a]$$

or

$$\delta r\left(1 + \frac{\mathrm{d}u}{\mathrm{d}r}\mathrm{d}t\right) \qquad [17.7.113b]$$

Subtracting the initial volume given by Equation 17.7.111 from the volume after the time increment $\mathrm{d}t$ given by Equations 17.7.112 and 17.7.113 gives

$$\frac{1}{V}\frac{\mathrm{d}V}{\mathrm{d}t} = \frac{\mathrm{d}u}{\mathrm{d}r} + \frac{2u}{r^2} \qquad [17.7.114]$$

By logarithmic differentiation of Equation 17.7.30

$$\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}t} = -\gamma\frac{1}{V}\frac{\mathrm{d}V}{\mathrm{d}t} \qquad [17.7.115]$$

Hence, from Equations 17.7.114 and 17.7.115

$$\frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}t} = -\gamma\left(\frac{\mathrm{d}u}{\mathrm{d}r} + \frac{2u}{r}\right) \qquad [17.7.116]$$

Integrating Equation 17.7.116 with the boundary conditions

$$r = a;\quad u_1 = 0 \qquad [17.7.117a]$$

$$r = 0;\quad u_2 = 0 \qquad [17.7.117b]$$

where the subscripts 1 and 2 denote unburned gas and burned gas, respectively, gives

$$u_1 = \frac{1}{3\gamma_1 P}\left(\frac{a^3 - r^3}{r^2}\right)\frac{\mathrm{d}P}{\mathrm{d}t} \qquad [17.7.118]$$

$$u_2 = \frac{-r}{3\gamma_2 P}\frac{\mathrm{d}P}{\mathrm{d}t} \qquad [17.7.119]$$

Now consider a stationary flame front with a flow of unburned mixture into the front and of burned mixture away from the front. By conservation of mass

$$u_1 - u_2 = (E - 1)S_\mathrm{u} \qquad [17.7.120]$$

From the definition of burning velocity S_u

$$\frac{\mathrm{d}r}{\mathrm{d}t} = u_1 + S_\mathrm{u} \qquad [17.7.121]$$

From Equations 17.7.118 and 17.7.121

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{3\gamma_1 Pr^2}{a^3 - r^3}\left(\frac{\mathrm{d}r}{\mathrm{d}t} - S_\mathrm{u}\right) \qquad [17.7.122]$$

From Equations 17.7.118–17.7.120

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{3\gamma_1 Pr^2 S_\mathrm{u}(E - 1)}{a^3 - (1 + \gamma_1/\gamma_2)r^3} \qquad [17.7.123]$$

Equating Equations 17.7.122 and 17.7.123 gives

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{ES_\mathrm{u}[a^3 - (1 + \gamma_1/E\gamma_2)r^3}{[a^3 - (1 - \gamma_1/\gamma_2)r^3} \qquad [17.7.124]$$

Then, from Equations 17.7.123 and 17.7.124

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \left(\frac{E - 1}{E}\right)\frac{3\gamma_1 Pr^2}{[a^3 - (1 - \gamma/E\gamma_2)r^3]}\frac{\mathrm{d}r}{\mathrm{d}t} \qquad [17.7.125]$$

Integrating Equation 17.7.125 with the boundary condition

$$r = 0;\quad P = P_\mathrm{o} \qquad [17.7.126]$$

gives

$$\frac{P}{P_\mathrm{o}} = \left(\frac{a^3}{a^3 - (1 - \gamma_1/E\gamma_2)r^3}\right)^{\gamma_1(E-1)/(E-\gamma_1/\gamma_2)} \qquad [17.7.127]$$

The authors point out that their model is not formulated in terms of the rate of flame spread. It gives the maximum pressure as a function of the expansion ratio, but not explicitly of the burning velocity. However, the expansion ratio increases with burning velocity, since it increases with flame temperature, which in turn increases with burning velocity.

17.7.16 Fairweather and Vasey model

The Fairweather and Vassey model (1982) develops a full treatment of a transient explosion in a totally confined or vented enclosure. It treats spherical, cubical or rectangular enclosures. The authors'treatment of venting and transient pressure build-up with incomplete venting typifies an approach generally adapted subsequently (for example Yao, 1974). Although the model is thorough, it is not yet suitable as a basis for explosion vent sizing because it depends on an empirical treatment of flame speed and flame acceleration (Harris, 1983, p. 77).

The treatment by Fairweather and Vasey (1982) makes allowance for two features not usually taken into account. One is the fact that due to the existence of dissociation reactions the polytropic assumption, though valid for the unburned gas, is not valid for the burned gas. The other is heat loss to the vessel by radiation. They give the heat balance

$$m_\mathrm{u}U_\mathrm{u} + m_\mathrm{b}U_\mathrm{b} - Q = m_\mathrm{o}C_\mathrm{n} - m_\mathrm{u}C_\mathrm{n} \qquad [17.1.128]$$

with

$$U_\mathrm{u} = \frac{R(T_\mathrm{u} - T_\mathrm{o})}{(\gamma_\mathrm{u} - 1)M_\mathrm{u}} \qquad [17.7.129]$$

$$U_\mathrm{b} = h_\mathrm{b} - \frac{R(T_\mathrm{b} - T_\mathrm{o})}{M_\mathrm{b}} \qquad [17.7.130a]$$

where C_n is the calorific value of the mixture, h is the enthalpy, Q is the thermal energy lost from the burned products and U is the internal energy.

The heat loss, Q, is found by assuming that the gases and the surface of the vessel are grey bodies. The rate of heat loss as given by Hottel and Sarofim (1967) is:

$$\frac{\mathrm{d}Q}{\mathrm{d}t}=\frac{a_g A_b \sigma(T_b^4-T_u^4)}{\left[\frac{a_g}{E_b}+\frac{A_b}{A_u}\left(\frac{1}{E_u}-1\right)\right]} \qquad [17.7.130b]$$

with

$$a_g=\frac{E_b^2}{2E_b-E_w} \qquad [17.7.130c]$$

where E_b, E_u, and E_w are the emissivities of the burned gases, the unburned gases and the wall respectively and σ is the Stephan Boltzman constant. Equation 17.7.131 is integrated numerically and the heat balance Equation 17.7.128 is solved implicitly for the burned gas temperature, T_B.

The vent rate of burned and unburned gas is found from the ideal gas venting equations. At low pressure (when venting is adequate), P/P_o is less than the choke pressure ratio:

$$\frac{P}{P_o}<\left[\frac{1+\gamma}{2}\right]^{\gamma/\gamma-1} \qquad [17.7.130d]$$

and venting flow m_v (split between burned, m_{bv} and unburned gases, m_{uv}) is subsonic and:

$$\frac{\mathrm{d}m_v}{\mathrm{d}t}=C_D A_V\left\{\left[\frac{2\gamma P\rho}{\gamma-1}\right]\left[\frac{P_o}{P}\right]^{2/\gamma}\left[1-\left(\frac{P_o}{P}\right)^{(\gamma-1)/\gamma}\right]\right\}^{0.5} \qquad [17.7.130e]$$

In the event that venting area is inadequate and the pressure in the enclosure exceeds the choke pressure; flow is sonic and:

$$\frac{\mathrm{d}m_v}{\mathrm{d}t}=C_D A_V\left\{\gamma P\rho\left[\frac{\gamma+1}{2}\right]\frac{(1+\gamma)}{(1-\gamma)}\right\}^{0.5} \qquad [17.7.130f]$$

The mass remaining in the enclosures at any time is:

$$m_u+m_b=m_o-(m_{uv}+m_{bv}) \qquad [17.7.130g]$$

The pressure in the vessel is assumed equal for the burned and unburned gases. The pressure of the unburned gases is compressed isentropically from its original volume using:

$$V_u=V_o\frac{m_u}{m_o}\left(\frac{P}{P_o}\right)^{1/\gamma_u} \qquad [17.7.130h]$$

$$\left(\frac{P}{P_o}\right)^{1/\gamma_u}=\frac{V_o}{V_u}\frac{m_u}{m_o} \qquad [17.12.152]$$

The model is completed using the ideal gas equation of state 17.7.23 for the burned and unburned gases.

In order to determine the mass burning rate, the model must calculate the flame area, A_f, from the volume of burnt gas at each time step. Inside a rectangular box enclosure, when the spherical flame reaches the enclosure walls, the volume takes the form of a sphere minus truncated spherical caps. Once the flame reaches an enclosure edge where the walls join, the flame may be assumed to expand in cylindrical symmetry. This approach was used also by Chappell (1973) who maintained the flame radius constant at the point where the geometry changes. This procedure leads to a discontinuity in the pressure profile. This discontinuity need not occur if the burned volume is kept constant instead of the flame radius.

Treating the flame geometry as a truncated sphere allows finding the area burned and unburned gases passing the vent area. This is used to find the relative vent volume of burned and unburned gases.

17.7.17 Singh model

The foregoing models are for spherical vessels. A treatment which covers cylindrical geometries also has been given by J. Singh (1988b). From Equations 17.7.7, 17.7.12 and 17.7.37

$$\frac{\mathrm{d}P}{\mathrm{d}t}=-A_f S_u\left(\frac{\mathrm{d}V_u}{\mathrm{d}P}+\frac{V_u}{\rho_u}\frac{\mathrm{d}\rho_u}{\mathrm{d}P}\right)^{-1} \qquad [17.7.131]$$

By logarithmic differentiation of Equation 17.7.31

$$\frac{\mathrm{d}\rho}{\mathrm{d}P}=\frac{\rho}{\gamma P} \qquad [17.7.132]$$

Hence from Equations 17.7.131 and 17.7.132

$$\frac{\mathrm{d}P}{\mathrm{d}t}=-A_f S_u\left(\frac{V_u}{\gamma_u P}+\frac{\mathrm{d}V_u}{\mathrm{d}P}\right)^{-1} \qquad [17.7.133]$$

Equations 17.7.6, 17.7.7, 17.7.17 and 17.7.31, writing the latter in the form

$$\frac{\rho_o}{\rho_u}=\left(\frac{P_o}{P}\right)^a \qquad [17.7.134]$$

with

$$a=\frac{1}{\gamma_u} \qquad [17.7.135]$$

yield

$$V_u=V_o(1-n)\left(\frac{P_o}{P}\right)^a \qquad [17.7.136]$$

Differentiating Equation 17.7.136 with respect to P and combining the result with Equation 17.7.133 gives

$$\frac{\mathrm{d}P}{\mathrm{d}t}=\frac{A_f S_u}{V_o}\left(\frac{P_o}{P}\right)^{-a}\left(\frac{\mathrm{d}n}{\mathrm{d}P}\right)^{-1} \qquad [17.7.137]$$

In order to solve Equation 17.7.137 it is necessary to have a relation between P and n. A simple approach is to use Equations 17.7.4, 17.7.6, 17.7.8 and 17.7.16, which gives

$$V_u=V_o(1-n/\alpha) \qquad [17.7.138]$$

with

$$\alpha=\rho_b/\rho_o \qquad [17.7.139]$$

Then, from Equations 17.7.136 and 17.7.138

$$n=\alpha\left(\frac{(P/P_o)^a-1}{\alpha(P/P_o)^a-\alpha}\right) \qquad [17.7.140]$$

There remains, however, a difficulty in that ρ_b, and hence a, varies throughout the burnt gas region. Again, it is necessary to adopt a simplified approach. From Equations 17.7.23b for the burnt gas

$$\rho_b = \left(\frac{\bar{M}_b P}{R\bar{T}_b}\right) \qquad [17.7.141]$$

and for gas at the end of combustion

$$\rho_e = \left(\frac{\bar{M}_e P_e}{R\bar{T}_e}\right) \qquad [17.7.142]$$

where $\bar{M}$ is the mean molecular weight.

Hence from Equation 17.7.139 and noting that for a closed volume $\rho_b = \rho_e$

$$\alpha = \left(\frac{\bar{M}_b \bar{T}_e P}{\bar{M}_e \bar{T}_b P_e}\right) \qquad [17.7.143]$$

One simplification of Equation 17.7.143, where $\bar{M}_b \simeq \bar{M}_e$, is

$$\alpha = \left(\frac{\bar{T}_e P}{\bar{T}_b P_e}\right) \qquad [17.7.144]$$

In fact the values of n obtained from Equation 17.7.144 differ only slightly from those obtained from the further simplification

$$\alpha \cong \frac{P}{P_e} \qquad [17.7.145]$$

Then, from Equations 17.7.140 and 17.7.145

$$n = \left(\frac{P}{P_e}\right)\left(\frac{(P/P_o)^a - 1}{(P/P_o)^a - (P/P_e)}\right) \qquad [17.7.146]$$

So far the treatment is general with respect to vessel geometry. For a specific geometry it is necessary to characterize the area of the flame front A_f. Consider first combustion in a spherical vessel. For this case

$$\left(\frac{r_b}{r_s}\right)^3 = \left(\frac{V_b}{V_o}\right) \qquad [17.7.147]$$

Combining Equations 17.7.4, 17.7.136 and 17.7.147

$$r_b = r_s\left[1 - (1-n)\left(\frac{P_o}{P}\right)^a\right]^{1/3} \qquad [17.7.148]$$

From Equation 17.7.137

$$S_u = \frac{V_o}{A_f}\left(\frac{P_o}{P}\right)^a \left(\frac{dn}{dP}\right)\left(\frac{dP}{dt}\right) \qquad [17.7.149]$$

Then, from Equations 17.7.148 and 17.7.149

$$S_u = \frac{r_s(P_o/P)^a}{3[1-(1-n)(P_o/P)^a]^{2/3}}\left(\frac{dn}{dP}\right)\left(\frac{dP}{dt}\right) \qquad [17.7.150]$$

For combustion in a cylindrical vessel Singh considers a vessel length L and radius r_c, where $L > r_c$. He distinguishes between central ignition and end ignition, and for each of these cases takes a two-stage approach. For combustion in a cylindrical vessel with central ignition he gives the following treatment. Initially, the flame expands symmetrically in all directions. When the radius r_b, of the flame is approximately equal to the radius r_c of the vessel, the flames begins to distort. It is assumed that the flame front then separates into two parts and that these two parts of the flame front then travel as two hemispherical shells of radius r_c in opposite directions until they reach the ends of the cylinder. For the first stage of this process substituting for n from Equation 17.7.146 into Equation 17.7.150 gives

$$\frac{d\bar{P}}{d\bar{t}} = G_1 P^{-a}\left\{1 - \bar{P}^{-a}\left[1 - \frac{\bar{P}}{\bar{P}_e}\left(\frac{\bar{P}^a - 1}{\bar{P}^a - \bar{P}/\bar{P}_e}\right)\right]\right\}^{2/3}\left(\frac{dn}{d\bar{P}}\right)^{-1} \qquad [17.7.151]$$

and

$$\frac{dn}{d\bar{P}} = \left[\left(\frac{\bar{P}}{\bar{P}_e}\right)\frac{a(\bar{P} - \bar{P}/\bar{P}_e)\bar{P}^{(a-1)} - (\bar{P}^a - 1)(a\bar{P}^{(a-1)} - 1/\bar{P}_e}{(\bar{P}^a - \bar{P}/\bar{P}_e)^2}\right] + \left[\frac{1}{\bar{P}_e}\left(\frac{\bar{P}^{-a} - 1}{\bar{P}^a - \bar{P}/\bar{P}_e}\right)\right] \qquad [17.7.152]$$

with

$$\bar{P} = \frac{P}{P_o} \qquad [17.7.153]$$

$$\bar{P}_e = \frac{P_e}{P_o} \qquad [17.7.154]$$

$$\bar{t} = \frac{tS_u}{r_s} \qquad [17.7.155]$$

$$G_1 = 3 \qquad [17.7.156]$$

where the overbar denotes 'dimensionless'. Transition from the first stage to the second stage occurs at pressure $\bar{P}_x$ such that

$$r_b = G_2 r_s\left(\frac{\bar{P}_x^a - 1}{\bar{P}_x^a - \bar{P}_x/\bar{P}_e}\right)^{1/3} \qquad [17.7.157a]$$

$$= r_c \qquad [17.7.157b]$$

with

$$G_2 = 1 \qquad [17.7.158]$$

where now r_s is the radius of the sphere equal in volume to the cylinder. Hence

$$r_s = \left(\frac{3r_c^2 L}{4}\right)^{1/3} \qquad [17.7.159]$$

For the second stage the total flame area is

$$A_f = 4\pi r_c^2 \qquad [17.7.160]$$

Also

$$V_o = \pi r_c^2 L \qquad [17.7.161]$$

Then, from Equations 17.7.53, 17.7.137, 17.7.160 and 17.7.161

$$\frac{dP}{dt} = \frac{4S_u}{L}(P_e - P_o)\left(\frac{P_o}{P}\right)^{-a} \qquad [17.7.162]$$

Integrating Equation 17.7.162 gives

$$\bar{t} = \frac{(L/r_s)\bar{P}^{(1-a)}}{G_3(\bar{P}_e - 1)(1 - a)} + \frac{S_u K_1}{r_s} \quad [17.7.163]$$

with

$$G_3 = 4 \quad [17.7.164]$$

for central ignition. The constant K_1 satisfies the condition that transition occurs at time $\bar{t}_x$ where the latter is obtained from Equation 17.7.151. The treatment for a cylindrical vessel with end ignition is similar. In this case

$$\left(\frac{r_b}{r_s}\right)^3 = \left(\frac{2V_b}{V_o}\right) \quad [17.7.165]$$

and hence

$$r_b = 2^{1/3} r_s \left[1 - (1 - n)\left(\frac{P_o}{P}\right)^a\right]^{1/3} \quad [17.7.166]$$

Equations 17.7.151 and 17.7.157 apply but with

$$G_1 = 3/2^{1/3} \quad [17.7.167]$$

$$G_2 = 2^{1/3} \quad [17.7.168]$$

For the second stage the total area of the flame is

$$A_f = 2\pi r_c^2 \quad [17.7.169]$$

Hence

$$\frac{dP}{dt} = \frac{2S_u}{L}(P_e - P_o)\left(\frac{P_o}{P}\right)^{-a} \quad [17.7.170]$$

For transition, Equation 17.7.163 applies but with

$$G_3 = 2 \quad [17.7.171]$$

17.8 Explosions in Buildings

Many process plants are in buildings. It is also necessary, therefore, to consider explosions occurring inside buildings.

A leak of flammable gas or liquid may create a flammable atmosphere inside a building and give rise to an explosion. Such leaks may occur from plant processing flammable fluids, from activities involving such fluids or from fuel gas supplies. In enclosed conditions, dispersion of the leaked gas is poor and the hazard is therefore much enhanced.

An area of prime concern in respect of explosions in buildings is the hazard of gas explosions in dwellings, and much of the work done relates to this. An account is given in *Gas Explosions in Buildings and Heating Plant* (R.J. Harris, 1983).

17.8.1 Building explosion incidents

Statistical information on the hazard of explosions in buildings has been given by F. Morton (1970), Mainstone (1973 BRE CP 11/73, 1974 BRE BR9, 1983 BRE CP 2/83) and Taylor and Alexander (1974 BRE CP 45/74).

A number of case histories of building explosions have been described by Mainstone (1976 BRE CP 24/76). One of the most severe building explosions was that at Ronan Point in 1968, which was the subject of an official report (H. Griffiths *et al.,* 1968).

Analyses of the factors bearing on gas explosions in buildings have been given by Mainstone (1973 BRE CP 11/73, 1976 BRE CP 24/76) and Taylor and Alexander (1974 BRE CP 45/74).

17.8.2 Ventilation of buildings

Movement of air in a building may be due to natural or forced draught ventilation. Natural draught ventilation may be either thermal driven or wind driven. In the former case the movement of air is caused by the temperature difference between the inside and the outside of the building, while in the latter it is caused by the pressure of the wind on the side of the building.

General guidance on natural ventilation is given in BS 5925: 1991 *Code of Practice: Ventilation Principles and Designing for Natural Ventilation*. Typical natural ventilation rates are in the range 0.5–3 air changes per hour.

Guidance on ventilation in relation to flammable and toxic gases is given by Leach and Bloomfield (1973, 1974 BRE CP 36/74).

For forced draught ventilation, guidance is given in BS 5720: 1979 *Code of Practice for Mechanical Ventilation and Air Conditioning in Buildings*. Forced draught ventilation is provided by fans. With forced draught ventilation rates can be not only higher but more dependable.

Human comfort sets a limit to the ventilation rate which can be used under normal conditions. A typical rule of thumb is that the upper limit of the air velocity for comfort is about 0.5 m/s.

There is no reason, however, why the ventilation rate should be limited to a low level in an emergency. In such a situation additional ventilation may be brought into play.

A more detailed discussion of ventilation is given in Chapter 10.

17.8.3 Gas accumulation and mixing in buildings

If a leak occurs, the part of the enclosure which is affected depends on the density of the gas, the height of the leak source and the ventilation pattern. The normal ventilation pattern is upward flow. Harris describes experimental work which shows that with this ventilation pattern for a gas with a density lighter than air, such as methane, a high gas concentration tends to build up in the space above the leak source. This situation is illustrated in Figure 17.14.

If the ventilation pattern is downward flow, which is rather unusual, this situation no longer pertains, and high gas concentration can occur below the leak source.

For a gas with a density heavier than air with an upward ventilation pattern the buoyancy and the ventilation act in oppositive directions, and in this case a high concentration will tend to build up in the whole space.

Thus, for the normal arrangement of upward flow ventilation the space liable to have a high gas concentration should be taken as the space above the leak for a light gas and as the whole space for other gases.

For practical purposes, the space liable to have a high concentration may be assumed to be perfectly mixed, and the gas concentration in the space may be determined from the equation for a single, perfectly mixed stage, which may be written for this case as

$$\tau \frac{dC}{dt} = C_i - C \quad [17.8.1]$$

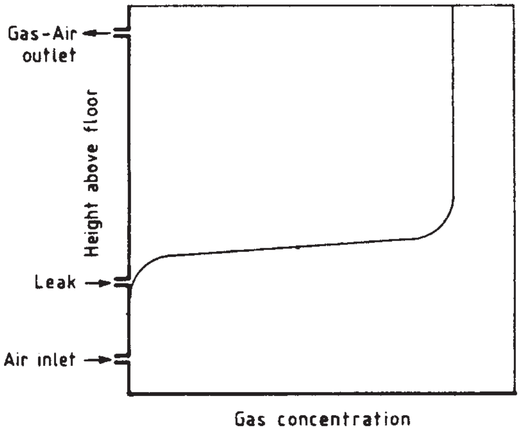

Figure 17.14 *Concentration from a leak of gas lighter than air under conditions of upward ventilation (after R. J. Harris, 1983) (courtesy of British Gas)*

with

$$C_i = Q_g/Q \qquad [17.8.2]$$

$$Q = Q_g + Q_a \qquad [17.8.3]$$

$$\tau = V/Q \qquad [17.8.4]$$

where C is the volumetric concentration in the space, C_i is an effective inlet volumetric concentration defined by Equation 17.8.2, Q is the total volumetric flow rate, Q_a is the volumetric flow of air, Q_g is the volumetric flow of contaminant gas, t is the time, V is the volume of the space and τ is the volume/throughput ratio, or time constant.

Then for an increase in concentration starting from the time of release

$$\frac{C}{C_i} = 1 - \exp\left(-\frac{t}{\tau}\right) \qquad [17.8.5]$$

and for a decrease in concentration starting from cessation of the release with a concentration C_o at that time

$$\frac{C}{C_o} = \exp\left(-\frac{t}{\tau}\right) \qquad [17.8.6]$$

In this latter case the value of Q to be used in Equation 17.8.3 is $Q = Q_a$, since $Q_g = 0$.

17.8.4 Some structural features of buildings

Much of the work done on explosions in closed containments applies to vessels. There are some significant differences between vessels and buildings.

A building is generally rectangular in shape and the volume enclosed is relatively large. The increase in size and in aspect ratio compared with a vessel can create difficulties in scaling up correlations developed for small compact vessels. Moreover, phenomena which are relatively insignificant on the smaller scale can become important on the larger one.

The space in a building tends to contain obstructions. There are usually multiple compartments which are connected to each other. The presence of obstacles will tend to increase turbulence. So also will the existence of multiple compartments, since gas flowing through open internal doorways will generate turbulence.

The building itself is generally not very strong. An explosion pressure of 7 N/m^2 (1 psi) is often quoted as that at which a typical brick building may be destroyed. On the other hand, a normal building will have walls which contain weaker members which will fail and in so doing provide vents so that the explosion pressure does not rise as high as it otherwise would.

The static pressures at which certain building components fail have been given by Rasbash (1969c) and Astbury *et al.* (1970) and are quoted by Lunn (1984b). Some typical values are:

	Failure pressure (kN/m^2)
Windows (normal)	3–4.6
Windows (strained)	1, or even 0.2
Chipboard (19 mm)	7
Brick wall (114 mm)	Survived at 23, destroyed at 35
Brick wall (228 mm)	Survived at 70, destroyed at 105

It has been suggested by Buckland (1980) that the explosion pressure should not exceed 21 kN/m^2 if the building is to avoid serious damage.

Another relevant feature is the natural period of the building. Rasbash (1969c) quotes a value of 40 ms as a typical natural period for the slabs and floors of a building. W.B. Howard and Karabinis (1980) give further details of natural periods. See also *TNO Green Book* (1989, p. 34). Structural damage to buildings from explosions is considered in more detail in Section 17.32.

17.8.5 Gas explosions in buildings

Some features of gas explosions in buildings have been discussed by Rasbash (1969c). The maximum unvented pressure created in an unvented building by the explosion of the most explosive gas mixture is of the order of 7 bar. A 30 m^3 room requires about 2.5 kg of fuel to give such a mixture. The energy of this fuel is equivalent to some 20 kg of TNT.

The pressure from such an explosion will build up relatively gradually, giving a duration of several hundred milliseconds compared with about 1 ms for a condensed phase explosion. Rasbash quotes for a vented explosion with low turbulence a typical duration of 300 ms. But he also gives for the explosion of the most explosive mixture of town gas with high turbulence a duration in the range 20–150 ms.

An account of experimental work on venting of gas explosions in buildings has been given by W.B. Howard and Karabinis (1980, 1982). They state that the durations of the explosions were in the range 40–150 ms. Experimental pressure–time profiles showed that the pressure impulse is well approximated by a triangle with equal rise and decay times.

17.8.6 Modelling of gas explosions in buildings

The pressure in deflagrations in a closed system was considered in Section 17.7. The treatment given there is applicable in broad outline to an explosion in a building, but, as indicated above, there are some important differences. The model of R.J. Harris (1983) described in that section is for explosion in a building, and gives the pressure and rate of pressure rise during the initial stages of the explosion.

Most of the models available for explosions in buildings are for vented explosions. These are considered in Section 17.14. One of these is the model of Runes (1971, 1972). The Runes equation is intended for the design of explosion relief for a building. It has been used, however, by W.B. Howard (1972) to estimate the explosion effects in an explosion incident in a building with open vents.

17.8.7 Condensed phase explosions in buildings

Experiments in which TNT charges were detonated inside a chamber have been described by Weibull (1968). The work was done to develop a nuclear blast simulator in which it would be possible to obtain arbitrary values of peak pressure and duration of the blast wave. The chambers used were provided with a variable vent opening.

Weibull states that in this system the peak pressure would be determined mainly by the mass of the explosive and the duration mainly by the area of the vent opening.

The pressure measured showed several very high initial spikes of very short duration which were reckoned to have minimal effect on the heavy walls of the chamber. The pressure, which had a long duration relative to the period of the walls, was taken as the blast load acting on them. The area of the vent opening had insignificant effect on the smoothed peak pressure. This pressure was given by the equation

$$p = K(m/V)^a \qquad [17.8.7]$$

where p is the peak pressure (bar), m is the mass of explosive (kg), V is the volume of the chamber (m^3), K is a constant and a is an index. The value of K is 22.5 and that of a is 0.72. Further information on pressures in enclosures estimated as a function of a TNT equivalent charge is given in Section 17.26 in the context of design of barriers.

17.9 Explosions in Large Enclosures

The type of large enclosure which is envisaged here is exemplified by an offshore module. It is with such enclosures that the account given in this section is primarily concerned.

An offshore module tends to have a high aspect, or length/diameter ratio, and to contain a number of obstructions in the form of equipment and pipework.

The overpressure generated in the combustion of a vapour cloud is due to two effects. One contribution to the overpressure comes from the production of a large quantity of hot burned gas, the volume production. The other is due to the effect of the flame speed. The overpressure which might occur due to the volume production would be up to about 8 bar, whereas the overpressure due to the flame speed effect might have any value up to that associated with a detonation.

Much work has been done on the development of explosion overpressures in vapour clouds. This work has shown that in the part of the cloud that is free of obstacles the flame speed is relatively low. If the flame passes first through a region which is unobstructed, then through one which is obstructed and finally through one which is unobstructed, the flame accelerates on entering the obstructed region and decelerates on leaving it. The flame speed in the obstructed space can reach quite high values.

Merc X (1992, 1998) conducted experiments in which two congested areas, each 2 m wide, are separated by an open, uncongested area of width 0.5, 1 and 2 m. He found that if mostly small-sized piping creates the turbulence, the decay is rapid and the flame speed reaches a low level within a few metres. Otherwise, more than 3–5 m may be needed for the flame speed to slow to non-damaging levels.

17.9.1 Experimental studies

Work on the generation of overpressures in vapour clouds has been done primarily in connection with the explosion of vapour clouds in the open. This work is described in Section 17.28. Most accounts of explosion in semi-confined spaces derive from, or are closely related to, this work.

An account of the experiments to determine the overpressures which might be generated in an offshore module was given by Vasey (1989) in evidence to the Piper Alpha Inquiry. The experimental rig used consisted of an enclosure 46.5 m long, 5 m wide and 4 m high with one end consisting of a confined section, a long box, with an open end, and then an open section, a gallery enclosed only by transparent polyethylene sheet to contain the gas mixture. Obstacle array supports were located every 1.5 m along both the confined and the open sections. The obstacles consisted of 3 m lengths of 0.18 m pipes or 0.18 m wide planks. The flame speed was sufficiently high so that venting to the side through the sheet did not occur and high overpressures were attained.

Work was done using both natural gas–air and propane–air mixtures. With a natural gas mixture a flame speed of 500 m/s was obtained and the overpressure was several bar. With a propane mixture the flame accelerated to detonation, and the overpressure, both measured and calculated, was about 18 bar.

17.9.2 Simulation models

Several models have been developed to simulate the development of an explosion in a semi-confined space such as an offshore module.

The FLACS model of the Christian Michelsen Institute (CMI) is a computational fluid dynamics (CFD) model which solves the fundamental equations of fluid flow taking account of turbulence and combustion. The three-dimensional Navier–Stokes equations, suitably amplified to include the effects of turbulence and combustion, are cast in discrete form, employing a finite volume technique, and are solved implicitly. Turbulence is modelled in terms of eddy viscosity, and combustion in terms of turbulent, mixing-limited reaction. The space modelled is divided into a grid of 'boxes' of volume 1 m^3. Normal assumptions are that the flammable gas cloud is a quiescent homogeneous stoichiometric mixture so that the effects of any concentration differences within the gas cloud, any ventilation air flow or a continuing leak source are neglected. Ignition is modelled as a weak ignition source by assuming that at time 0 half of the flammable mixture in one of the boxes has undergone combustion so that the temperature of the gas in the box is correspondingly increased. Accounts of the model have been given by Hjertager (1982a) and by Bakke, Bjerkevedt and Bjorkhaug (1990).

The CLICHE model of British Gas is based on a spherical flame front. It was originally intended for use in simulating explosions in vessels with a high degree of confinement and low flame speeds, but has been extended to allow simulation of different geometries and flow conditions. It has been used to investigate flame acceleration through obstacles and the generation of overpressures much higher than those for which it was originally intended. An account of the model has been given by Catlin (1990).

CFD modelling is discussed further in Section 17.28 in relation to vapour cloud explosions.

17.9.3 Computer codes

There are several computer codes based on simulation models of the type just described.

These codes include FLACS at the CMI (Bakke, Bjerkevedt and Bjorkhaug, 1990), EXSIM (Hjertager *et al.*, 1994), CLICHE at British Gas (Catlin, 1990) and, at the TNO, BLAST (van den Berg, 1980) and REAGAS (van de Berg, 1989).

The FLACS suite of codes comprises a front end program CASD which captures details of the structure of the module and the equipment in it, a program which processes this information into a form in which it can be utilized by the main program, the FLACS code proper.

The FLACS code has been validated by comparison of the results of code simulations with measurements made in experiments on explosions in scale models of modules with 1 : 33 and 1 : 5 scale. The overpressures predicted by the code lie within ±30% of those in the model experiments with perhaps 1 case in 20 lying outside this range, corresponding to a confidence level of some 95%. The variability of the model experiments themselves is of the same order.

The FLACS code was used at the Piper Alpha Inquiry to investigate the overpressures which would have resulted from an explosion in one of the modules, as described in Appendix 19. Results from CLICHE were also given in evidence.

Plate 28 illustrates typical output from the FLACS code, showing the contours of the unburnt fuel, the burnt combustion products and the overpressures and the wind velocity vectors.

17.10 Explosion Prevention

Prevention of gas and vapour explosions in general depends on (1) avoidance of flammable mixtures and (2) elimination of sources of ignition. These general requirements for explosion prevention have already been discussed.

For plant, or closed, systems an important method of eliminating flammable mixtures which merits further consideration is (3) atmosphere control. This is discussed below.

Other aspects of explosion prevention which have already been discussed include avoidance of runaway chemical reactions and excessive fluid pressures.

Selected references on explosion prevention, protection and relief are given in Table 17.13.

17.10.1 Atmosphere control

The hazard of explosion can be much reduced by control of the atmosphere to render it non-flammable. This control is often effected by the use of an inert gas.

The atmosphere control of process plant has been discussed by Craven (1975). An account of inerting in tankers has been given by Halvorsen (1975).

In general, the use of atmosphere control is a much more reliable method than the elimination of sources of ignition, which is very difficult to achieve. Craven comments:

> The elimination of ignition sources is often promoted as an alternative to atmosphere control to prevent explosions. There are few situations in the process industries today in which this philosophy can be seriously defended.
>
> Only in the simplest situations – such as isolated liquid storage – can the elimination of ignition sources seriously compete with atmosphere control as the first line of defence.

For an atmosphere which may contain flammable gas, air and inert gas, Craven distinguishes four regions. These are:

Region I: flammable mixture;
Region II: fuel-lean mixture;
Region III: oxygen-deficient mixture;
Region IV: fuel-rich mixture.

The atmosphere is non-flammable in all but the first of these regions. Atmosphere control is often effected by the use of inert gas, but this is not the only option. In some cases it is more appropriate to operate in the fuel-rich region.

Some operations and equipments in which atmosphere control is practised are (1) reactors, (2) storage tanks, (3) head tanks, (4) centrifuges, (5) driers, and (6) pneumatic conveyors.

Generally, in an oxidation reactor the off-gas is deficient in oxygen. The oxygen concentration is usually analysed, and action is taken if it rises. This action may be to shut off an air or oxygen feed to the reactor or to inject inert gases.

Such trip systems are required to act very rapidly, and time delays can be a problem. There may also be difficulties in gas sampling due to vapour drops or solid particles. In some cases, therefore, other measurements, such as reactor temperature, may be used to complement the oxygen measurement by giving advanced warning of abnormal conditions.

Storage tanks containing flammable liquids are often blanketed with inert gas. The quantity of inert gas required can be large due to the movements of the liquid surface. An economical system is the use of breather vacuum valves which admit inert gas only when the liquid level falls.

The effectiveness of inerting in reducing the probability of storage tank fire/explosion has been discussed by Kletz (1971).

Inert gas blanketing is also frequently provided in constant head tanks for flammable liquids. Difficulties are often experienced, however, in maintaining an inert atmosphere in a head tank fitted with an overflow, because the return pipe from the overflow tank tends to act as an air entrainment pump. This problem can be eliminated by fitting suitable gas balance lines.

An inert atmosphere is necessary in centrifuges handling flammable liquids as described in Chapter 11. Again, the consumption of inert gas may be high due to air ingress during operation, but the use of gas balance lines can effect appreciable reductions.

The provision of inert atmospheres in dust-handling plant is considered in Section 17.46. The quantity of inert gas used must not be excessive if inerting is to be economic. It is important, therefore, to seek to minimize inert gas consumption.

For a perfectly mixed system the concentration changes effected by a ventilating air or purge gas flow are given by the equation

$$\frac{c}{c_o} = \exp\left(-\frac{QT}{V}\right) \qquad [17.10.1]$$

where c is the volumetric concentration of the component in the system atmosphere, Q is the volumetric flow of gas through the vessel, t is the time, V is the volume of the vessel and the subscript o denotes the initial value. Equation 17.10.1 may be rewritten as

$$\log_{10}\left(\frac{c}{c_o}\right) = -\frac{E}{2.3} \qquad [17.10.2]$$

with

$$E = Qt/V \qquad [17.10.3]$$

where E is the number of changes of atmosphere. Thus, the concentration of a component in the system atmosphere can be reduced by a factor of 10 by 2.3 changes and by a factor of 100 by 4.6 changes.

Purging can be effected more economically, however, if the flow regime is plug flow rather than perfect mixing. Plug flow can often be achieved if the vessel is one with a very high aspect ratio, such as a tall column or a pipeline. Other situations which allow plug flow are buoyant displacement with a cold gas and gravitational displacement of a heavy vapour.

If the density difference between the atmosphere to be purged and the purge gas is small, turbulent mixing is usually achieved. For a simple vessel such as a storage tank without baffles, Craven states that such mixing should be enhanced by the use of gas jets directed across the tank with final velocities in the remote corners of 300 ft/min. He gives the following equation for the nozzle velocity required to give an air velocity of 300 ft/min along the jet axis in the remote corners

$$\frac{u_o}{u_x} = \frac{1}{K}\frac{X}{D} \qquad [17.10.4]$$

where D is the diameter of the jet orifice (ft), u_o is the nozzle velocity (ft/min), u_x is the required velocity (ft/min) (=300), X is the distance from the jet to the most remote corner (ft) and K is a constant (=6).

17.11 Explosion Protection

Explosion protection and relief include the following aspects:

(1) containment;
(2) separation;
(3) flame arresters;
(4) automatic isolation;
(5) automatic explosion suppression;
(6) explosion venting of vessels;
(7) explosion venting of pipes and ducts;
(8) explosion relief of buildings;
(9) explosion relief of large enclosures;
(10) venting of chemical reactors.

Deflagration and detonation inside plants has been discussed in Sections 17.5 and 17.6, and explosion in closed vessels specifically in Section 17.7.

Protection by containment of the explosion is a potential design option, but as discussed in Section 17.5, it is usually not practicable except for small-scale plants.

Another method of containment is the use of blast walls and barricades, and of blast cubicles. The design of such blast protection is described in the *High Pressure Safety Code* (B.C. Cox and Saville, 1975) and by W.G. High (1967) and CaUahan (1968).

Separation as a method of protection is discussed in relation to plant siting and layout in Chapter 10 and in relation to storage in Chapter 22. It is also considered in Section 17.3 in terms of the quantity–distance relations used for storage of explosives.

Methods of explosion protection and relief are described in *Dust Explosions and Fires* (K.N. Palmer, 1973a) and *Explosions* (Bartknecht, 1981a). Health and Safety Executive (HSE) guidance is given in *Guide to the Use of Flame Arresters and Explosion Reliefs* (the HSE *Explosion Relief Guide*) (1965 HSW Bklt 34). Relevant US codes are NFPA 69: 1992 *Explosion Prevention Systems* and NFPA 68: 1994 *Deflagration Venting.*

Selected references on explosion prevention, protection and relief are given in Table 17.13.

17.11.1 Flame arresters

A flame arrester, or flame trap, is a device used to prevent the passage of a flame along a pipe or duct.

A flame arrester is generally an assembly of narrow passages through which gas or vapour can flow, but which are too small to allow the passage of flame.

Typical applications of flame arresters are on vents of storage tanks containing flammable liquids, on pipe systems supplying fuel gas to burners, on certain pipelines conveying flammable gases within the plant and on flare stacks. Flame arresters are also used on exhausts of engines working in atmospheres with a flammability hazard and on crankcases of small engines.

Accounts of flame arresters include those given in the *CCPS Guidelines* book by Grossell (2001), in the HSE *Explosion Relief Guide* (1965 HSW Bklt 34) and by H. Phillips (1972b), Barton, Carver and Roberts (1974), W.B. Howard, Rodehorst and Small (1975), W.B. Howard (1982, 1992a,b), Kletz (1982c), Thorne (1982), Lunn and Przybylski (1985), H. Phillips and Pritchard (1986), Capp (1992, 1994) and G.O. Thomas and Oakley (1993).

An extensive programme of work on flame arresters was conducted in the 1960s by the Joint Fire Research Organization (JFRO) at the Fire Research Station at Borehamwood. Accounts of this work have been given by K.N. Palmer and co-workers (e.g. K.N. Palmer and Tonkin, 1963; K.N. Palmer and Rogowski, 1967; J.P. Davies, Palmer and Rogowski, 1973; Rogowski, 1980).

The United Kingdom has had certain long-standing but limited legal requirements for the use of flame arresters, on diesel engines in mines and on equipment using acetylene above 0.62 barg. Their use is recommended in codes.

17.11.2 Flame arresters: modes of combustion

In general, combustion may take the form of a deflagration or a detonation. The characteristics of these two forms of combustion have been described above.

A deflagration has a flame speed of 3–500 m/s and generates overpressures of 8–11 bara. A detonation has flame speeds of 500–2000 m/s and overpressures of 11–100 + bara.

Flame arresters are generally distinguished as end-of-line or in-line arresters. An end-of-line arrester is designed to prevent the passage of a deflagration from the downstream to the upstream side.

An in-line arrester should be able to stop either a deflagration or a detonation passing in either direction. Although it is often assumed that detonation presents the more difficult duty, this is not necessarily so. Some detonations are overdriven (meaning the flame speed temporarily exceeds the coustic speed), and if this is a possibility the arrester needs to be able to handle this form of detonation.

Definition of the nature of the flame with which an arrester may have to cope is difficult, so that in principle it may be necessary to allow for both deflagration and detonation, possibly including overdriven detonation.

It should be appreciated that even if a flame arrester prevents the passage of the detonation flame, it does not stop the detonation shock wave.

17.11.3 Flame arresters: types of arrester

The types of flame arrester used are described in the *HSE Guide* and FPA FS 6012 in Grossell (2001) and by H. Phillips and Pritchard (1986) and W.B. Howard (1992a)., Grossell defines three types of arrester:

Type 1 arresters with multiple small channels;
Type 2 hydraulic devices;
Type 3 velocity flame stoppers.

Some principal type 1 flame arresters are

(1) sheet metal arresters
    (a) planar sheet metal arresters,
    (b) cylindrical sheet metal arresters (crimped ribbon arresters);
(2) perforated plate arresters;
(3) perforated block arresters;
(4) sintered arresters;
(5) expanded metal arresters;
(6) parallel plate arresters;
(7) wire gauze arresters;
(8) wire pack arresters;
(9) packed bed arresters.

Figure 17.15 illustrates some of these types of arrester.

The operation of a type 1 arrester is generally treated in terms of the mechanism of quenching and heat loss. These are a large part of the story, but not the whole, as discussed by H. Phillips and Pritchard (1986).

Desirable properties of a flame arrester are high free cross-sectional area available for flow, low resistance to flow and freedom from blockage; a high capacity to absorb the heat of the flame and the ability to withstand mechanical shock, including explosion.

Sheet metal arresters are of two main types. The planar type consists of thin, planar sheets with corrugations or protuberances stacked in a block. The cylindrical type is constructed by winding a thin corrugated metal ribbon to form a cylindrical assembly. This type is also known as a crimped ribbon arrester.

Crimped ribbon arresters are an important type of arrester and are available in a range of designs. These arresters have about 80% free cross-sectional area, can be manufactured to close tolerances, are robust enough to withstand mechanical and thermal shock and can be made to quench violent explosions.

Wire gauze arresters have a lower free area, which with fine gauzes is less than 50%. They also tend to be less effective and less robust. They have a limited ability to quench flame and are not suitable for violent explosions. A limited enhancement of arrester effectiveness can be obtained by using a number of wire gauze arresters in series as a combined pack.

Perforated plate arresters have a lower free area than gauzes, but higher heat capacity and greater mechanical robustness than wire gauzes, but they are little more effective and again are not suitable for violent explosions.

Perforated metal blocks can also be used as arresters.

Sintered arresters again have a low free area and high flow resistance. Their main use is on flammable gas detectors and on welding equipment.

Parallel, or stacked, plate arresters have a low free area and high flow resistance, but can be designed to quench violent explosions. They are used particularly on the exhausts of internal combustion engines.

Wire pack arresters are made by compressing a pack of wire which has been knitted or assembled at random. This type of arrester tends not to have very reproducible characteristics.

Packed bed arresters are vertical containers fitted with pebbles, Raschig or Pall rings or similar packings. The packing may be irrigated with water or oil. The size of the

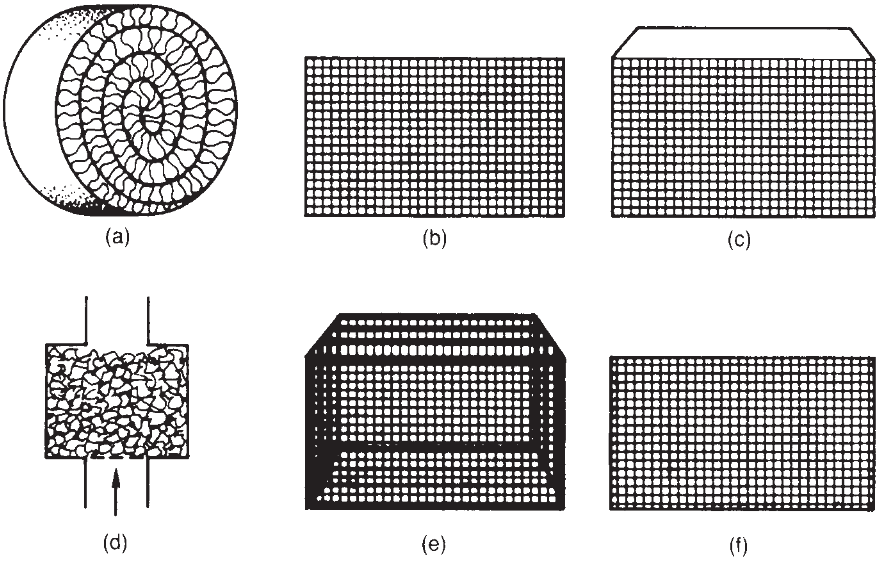

Figure 17.15 *Some type of flame arrester (after Fire Protection Association, 1989 FS 6012): (a) crimpled ribbon arrester; (b) perforated metal sheet; (c) perforated metal block; (d) box of pebbles or ceramic rings; (e) wire gauzes; and (f) construction of a gauze arrester*

passages is not well defined. This type of arrester has high flow resistance. Such an arrester can quench a violent explosion, but movement of packing due to such an explosion can result in arrester failure. A more detailed account of packed bed arresters is given by W.B. Howard (1992a).

The design of a flame arrester depends on the combustion properties of the flammable mixture and on the function and location of the arrester.

The size of the aperture through the arrester is determined by the quenching distance of the flammable mixture. Quenching distances have been discussed in Chapter 16. The diameter of the aperture of an arrester should be smaller than the quenching diameter by at least 50%. The performance of an arrester is affected by the temperature. The quenching distance increases as the temperature increases. It is approximately inversely proportional to the square root of the absolute temperature.

In general, such flame arresters are cheap, can be easily installed and are readily replaced if damaged. They do present some problems, however, due to their fine structure. These include high pressure drop and blockage. They are not suitable, therefore, in dusty or polymerizing gases. The maintenance of an arrester is relatively simple, but it is essential that it should not be neglected if the device is to function properly when required.

17.11.4 Flame arresters: hydraulic devices

Hydraulic, or liquid seal, arresters contain a liquid, usually water, which serves to break up the gas stream into bubbles and so prevents passage of the flame. This type of arrester operates on a quite different principle from that of the other types described. The arrester is effective only if the liquid level is maintained and the gas flow is kept within the range in which it is broken into bubbles.

Hydraulic arresters exist which are reported to be effective in preventing flame propagation in both directions. Tests to establish this on a particular arrester design have been described by Flessner and Bjorklund (1981).

A particular kind of hydraulic arrester is the linde hydraulic valve developed for acetylene duty. This is described by Flessner and Bjorklund (1981).

Hydraulic arresters are discussed further by W.B. Howard (1992a), with comments on the extent to which the various kinds of arrester are in general use.

17.11.5 Flame arresters: velocity flame stoppers

A velocity flame stopper is an arrester used in end-of-line applications. Its function is to prevent a flame passing from the downstream to the upstream side.

It operates on a quite different principle from other types of arrester. This principle is to ensure that the velocity of the upstream gas passing through the arrester is sufficiently high to prevent a flame propagating through the arrester from the downstream side.

The velocity flame stopper is discussed by W.B. Howard (1992a). For the velocity necessary to prevent flashback through apertures larger than those which would give quenching, Howard quotes the equation of Hajek and Ludwig (1960):

$$u_{\mathrm{T}} = 0.2015 g_{\mathrm{L}} D \qquad [17.11.1]$$

where D is the internal diameter of the pipe (m), g_{L} is the laminar velocity gradient (m/s)/m and u_{T} the turbulent flashback velocity (m/s). The parameter g_{L} is also termed the critical boundary velocity gradient. This parameter is a function of the gas and of its concentration. It tends to have a maximum value at a concentration somewhat above the stoichiometric. The following maximum values are based on the work of Grumer, Harris and Rowe (1956 BM RI 5225):

Gas	*Maximum laminar velocity gradient,* g_{L} (s^{-1})
Methane	400
Ethane	650
Propane	600
Ethylene	1,500
Propylen	700
Hydrogen	10,000

Howard recommends that for normal design the minimum velocity through the holes of a velocity flame stopper should be four times the turbulent flashback velocity given by Equation 17.11.1.

A velocity flame stopper is effective only as long as there is a sufficient gas flow through it. Ensuring a reliable gas flow may not be a simple matter, and in such cases a regular flame arrester may be a more attractive alternative.

Velocity flame stoppers are used particularly on certain gas flows to furnaces.

17.11.6 Flame arresters: conservation vents

Storage tanks are commonly provided with conservation vents to allow them to ‘breathe’. Over the years there has been some debate as to whether it is necessary to incorporate a flame arrester in such a vent. The question is discussed in Chapter 22. The view has emerged that a conservation vent acts, in effect, as a velocity flame stopper and that a separate flame arrester is not necessary.

17.11.7 Flame arresters: critical flame speed

It was shown by Palmer at the Fire Research Station (FRS) that a crucial variable in the performance of flame arresters is the flame velocity incident on the arrester, or critical flame speed. The critical flame speed is discussed by H. Phillips and Pritchard (1986), drawing largely on the FRS work on propane–air mixtures at atmospheric pressure. A simple model based on heat abstraction from the flame yields the following relation:

$$u = 0.95 \frac{n y p_{\mathrm{o}}}{p} \qquad [17.11.2]$$

where n is the number of apertures per unit area of arrester surface (cm^{-2}), p is the explosion pressure at the arrester, p_{o} is atmospheric pressure, u is the flame speed at the arrester (m/s) and y is the thickness of the arrester elements (cm). This equation includes the term (p_{o}/p), which takes into account the explosion pressure. The authors state that for the system considered this equation gave reasonable agreement, with a number of qualifications, including the facts that it applies only to crimped ribbon arresters of a particular design and to propane–air mixtures. They also quote the following empirical equation:

$$u = 0.38\frac{ay}{d^2} \qquad [17.11.3]$$

where a is the fractional free area of the arrester, d is the diameter of the apertures (cm), u is the flame speed at the arrester (m/s) and y is the thickness of the arrester elements (cm). This equation applies to crimped ribbon, wire gauze and perforated plate arresters. For the former, d is taken as the hydraulic mean diameter. The equation does not taken into account the explosion pressure and is therefore limited to applications where the pressure does not rise substantially above atmospheric; the authors instance a short length of straight pipe.

17.11.8 Flame arresters: minimum effective safe gap

The selection of flame arresters is largely based on the minimum effective safe gap (MESG) of the fuel. This is defined as the smallest gap between parallel metal surfaces that will not allow propagation of an ignition. The theory of suppression by narrow gaps is discussed by Phillips (1972). Compilations of MESG are provided by the National Academy of Sciences report to the US Coast Guard (1975), the National Materials Advisory Board (1982), NFPA 497 (1997) and Britton (2000).

The purpose of MESG measurement is to specify the degree of integrity required for 'explosion proof' electrical equipment. See NFPA 70 (2002), National Electrical Code (NEC) and NFPA 497 (1997). A classification of flame arrester specifications was introduced into the *US National Electrical Code* (NEC) Article 500 in 1935, in four groups, A, B, C, D, ranging from Class D suitable for relatively unreactive fuels to Class A suitable for very reactive fuels. The four fuel groups 'complemented the design of electrical equipment used in hazardous (classified) locations and were defined based on the level of hazard associated with explosion pressures of specific atmospheres and the likelihood that the effects of that explosion could be transmitted outside the enclosure' (NFPA 497). The typical materials for each group as defined in the NEC are listed below.

Flame arrester class	*Typical materials*	*Upper limit defining material*	*US Coast Guard*	*MESG* (mm), *Westerberg apparatus*	*NFPA 497*
D	Acetone[a]		1.02	n/a	1.02
D		Propane	0.90	0.92	0.97
C	Diethyl Ether		0.86	0.30	0.83
C		Ethylene	0.71	0.69	0.65
B	Hydrogen		0.10	0.08	0.28
A	Acetylene		<0.02	0.08	0.25

[a] Naphtha, gasoline, petroleum, alcohols, acetone, lacquers, solvent vapours, natural gas.

Differences in measured values of MESG arise between measurement devices. The values listed above are from Britton (2000), who discusses the reasons for differences, as does Phillips (1981).

Considerable use has been made of the MESG for key compounds to separate chemicals into the groups. There is some variability in the choice of the 'border material'. For example, the National Materials Advisory Board originally selected gasoline to define the border between Classes C and D. Gasoline has an MESG by the Westerberg apparatus of 0.74 mm (0.029 in.), but is a poorly defined mixture and MESG measurements of gasolines vary. Propane has since become the NEC border material for Groups C and D. Ethylene is currently the NEC border material for Groups C and B. However, the US Coast Guard's demarcation between Groups C and D is 0.90 mm and is inconsistent with the NEC demarcation of only 0.75 mm. The NFPA 497 has 'grandfathered' certain gases under their original NEC groupings. For example, diethyl ether continues to be listed as NEC Group C even though it would be NEC Group D based on its listed MESG (0.83 mm using the IEC apparatus). Britton (2000) has suggested revisions in the present grouping system.

The 1997 revision of NFPA 497 provides an equation for estimating the MESG of mixtures (Breisch, 2000). The equation is described as a 'form of Le Chatelier's equation' although there is a distinct difference in application with respect to the treatment of inert components.

17.11.9 Flame arresters: applications and requirements

The duty which the arrester performs depends on the nature of the system and on the location of the arrester.

One basic distinction is between (1) end-of-line and (2) in-line arresters. The typical application of an end-of-line arrester is on the vent of an atmospheric storage tank. The function of such an arrester is primarily to stop a flame arising from ignition of vapour vented. The flame is thus of low speed and at atmospheric pressure.

In-line arresters are used in plant pipework and the demands placed on them are much more severe and varied. They may have to deal not only with deflagrations but also with detonations.

Some of the differences in application which arise from the location of the arrester and of the ignition source are discussed in the HSE *Guide*, which distinguishes the following three standard situations: (1) ignition at the open end of a duct, (2) ignition at the closed end of a duct, and (3) ignition near the arrester. These situations are shown in Figure 17.16.

Another minor distinction is between a stationary and a flowing mixture. Consider first a stationary mixture. If ignition occurs at the open end of the duct, the arrester is required only to quench the flash of flame. This requires absorbing the heat from the hot gases. If ignition occurs at the closed end of the duct, the arrester must quench the flame and withstand the pressure created by combustion within the duct, some cooling of the hot gases occurs by the duct walls.

Now consider a flowing mixture. Assume that in Figure 17.16 the flow is from left to right. If ignition occurs in the open end and the gas velocity is high, the flame may be swept out of the duct or may stabilize on the end of the duct or at a restriction in the duct. In either case the arrester is unaffected. But if the gas velocity is low, the flame will stabilize on the arrester. If ignition occurs at the closed end of the duct or near the arrester, the flame may again stabilize on the arrester and eventually allow a temperature and ignition breakthrough.

Thus, if a flame arrester is installed in a system in which the gas mixture is flowing, there is a risk of stabilization of the flame and overheating of the arrester. It is necessary, therefore, to arrange for this condition to be detected and for the gas flow to be shut off when it occurs.

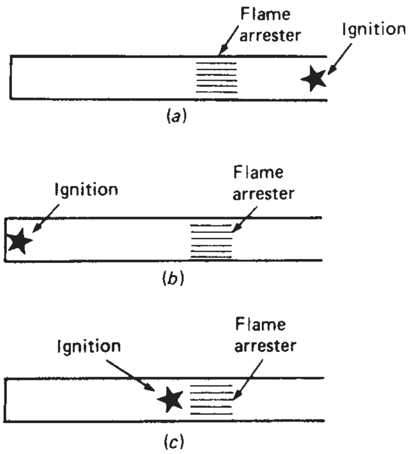

Figure 17.16 *Ignition situations relevant to the design of flame arresters (after Health and Safety Executive, 1965 HSW Bkk 34): (a) ignition at open end of duct; (b) ignition at closed end of duct; and (c) ignition near arrester (Courtesy HM Stationery Office)*

The function which a flame arrester is required to perform therefore varies. In some cases it is required only to prevent simple flashback, but in others, where hot gases may be forced through it or where flame may stabilize on or near the arrester, it must also be capable of absorbing a considerable quantity of heat. For the latter duties it is necessary not only that the arrester have apertures smaller than the quenching diameter but also that it have sufficient mass and suitable material of construction to absorb heat.

In many applications a flame may arrive at the arrester from either direction and the arrester needs to be capable of stopping the flame in both cases.

17.11.10 Flame arresters: HSE *Guide*

It is convenient at this juncture to consider the guidance on flame arresters given by the HSE *Explosion Relief Guide*. This guide is based on the work in the 1950s and in 1960 at the FRS. Unless otherwise stated, it applies to gas mixtures at atmospheric pressure.

For crimped metal, wire gauze and perforated plate arresters the following equation is given in the HSE *Guide* for the calculation of the maximum flame speed for a deflagration at atmospheric pressure which can be quenched by an arrester:

$$u = 0.5\frac{ay}{d^2} \qquad [17.11.4]$$

where a is the fractional free area, d is the diameter of the aperture (in.), u is the flame speed (ft/s) and y is the thickness of the arrester (in.).

Equation 17.11.4 is applicable to deflagration but not to detonation. The value of the flame speed u includes a safety factor which takes account of experimental scatter. For non-circular apertures the equivalent hydraulic diameter should be used.

For crimped metal arresters, the equivalent diameter for a right angle isosceles triangle is 0.83 times the crimp height. The thickness of a crimped metal arrester should be at least 0.5 in. For a wire gauze arrester, Equation 17.11.4 applies only to a single layer of gauze. For a single layer of gauze the thickness y is twice the wire diameter.

An increase in allowable flame speed of about 20% of the original value may be obtained for each additional layer up to a maximum of 5, but further increase gives no additional advantage.

For detonations, only crimped metal arresters are considered by the HSE *Guide*. It quotes the following equation for the maximum flame speed obtained by Cubbage (1959) for the stoppage of town gas–air mixture detonations by arresters with crimp height of 0.017 in.:

$$y = 1.3u^{1/5} - 4.4 \qquad [17.11.5]$$

The HSE *Guide* emphasizes the limited amount of work then available on the arrest of detonations.

The use of these equations requires data on flame speeds. Flame speed is a function not only of the flammable mixture but also of the system geometry. In particular, there exists a ‘run-up’ length over which there is a considerable acceleration of flame speed. The HSE *Guide* gives data on flame speed for several gas–air mixtures as a function of the run-up length in straight smooth pipes of up to 12 in. diameter.

For propane–air mixtures, the flame speeds given for run-up lengths of 1, 5, 10 and 35 ft are 16, 230, 330 and 330 ft/s, respectively, for ignition near the open end of the pipe, and 110, 380, 420 and 490 ft/s, respectively, for ignition near the closed end of the pipe. For other run-up distances the higher neighbouring flame speed value should be used.

These flame speeds for propane are typical of saturated hydrocarbons. There are, however, a number of substances, for example, ethylene, which have higher flame speeds.

The HSE *Guide* also recommends that for certain substances, for example, hydrogen, and for all substances in pipe lengths greater than 35 ft, detonations giving pressures up to 500 psig should be assumed.

For propane–air mixtures, the detonation velocity is about 5800 ft/s. For town gas–air mixtures it is about 7000 ft/s. The HSE *Guide* gives the following equation for detonation velocity:

$$u = 300[(\gamma^2 - 1)Q]^{1/2} \qquad [17.11.6]$$

where Q is the heat of detonation (cal/g) of the gas mixture, u is the detonation velocity (ft/s), and γ is the ratio of specific heats of the gas mixture at the combustion temperature.

Equations 17.11.5 and 17.11.6 apply to gas mixtures at atmospheric temperature and pressure. At higher pressures flame speed is not greatly affected, but the volumetric heat release increases in proportion to absolute pressure. The effect of higher temperature is more complex. An increase in temperature raises the burning velocity but reduces the volumetric heat release.

If the flammable gas is mixed not with air but with oxygen or even oxygen-enriched air, there is a strong possibility of detonation. Such mixtures can give detonation velocities up to 12,000 ft/s and detonation pressures up to 1,000 psig.

The basic design options are to keep the pipe length below 35 ft or to design for detonation. The former option includes the use of explosion relief vents to eliminate pipe runs of more than 35 ft.

If the pipe is not a straight smooth duct, but contains bends or obstacles, much higher flame speeds may be reached. A single right angle bend can cause a substantial increase in flame speed. In such cases it is necessary to use explosion relief much more liberally or to design for detonation.

17.11.11 Flame arresters: environment

As described above, flame arresters differ in their applications. Arresters also differ considerably in the environment in which they are required to function, particularly in-line arresters but also end-of-line arresters.

In discussing the environment of a flame arrester, H. Phillips and Pritchard (1986) consider (1) the upstream volume, (2) the arrester matrix, and (3) the downstream volume. They define these regions in terms of the direction of flame propagation, which is not necessarily that of gas flow. This terminology is followed here, but in this section only.

The ignition source is by definition located in the upstream volume. The properties of the flame arriving at the arrester are determined by conditions in this space. These include the pressure, temperature and gas mixture composition. They also include the shape of the space, the run-up distance and, of great importance, features that affect the flow into the arrester. The authors cite cowls on end-of-line arresters and bends and obstacles in the pipework upstream of an in-line arrester.

Even if the arrester stops the flame from passing through, the hot gases leaving the arrester may reignite. Whether they do so depends on the conditions in the downstream volume. Reignition is governed by the balance between the heat generated by reaction of the hot gases leaving the arrester and the cooling due to mixing with cool gas or air. This mixing will depend on features tending to promote turbulence in the downstream space.

17.11.12 Flame arresters: testing

An account of British practice in the testing of flame arresters is given by H. Phillips and Pritchard (1986).

They classify tests into (1) tests on end-of-line arresters, (2) deflagration tests on in-line arresters, (3) detonation tests on in-line arresters and (4) endurance burning tests. A similar account of US practice is given by the US Coast Guard.

One issue in the testing of arresters is definition of the conditions for which the arrester is to be tested. An arrester at a particular location may be required to deal with a number of different flame conditions.

Another issue is the selection of test gas mixtures which are representative of other mixtures of interest to the designer. One approach to this is to utilize the gas groups as defined in the standards on hazardous area classification, described in Chapter 16 or the US Coast Guard classification.

A third issue is the definition of the 'worst case' conditions.

The test conditions for end-of-line arresters typically involve low flame speeds and atmospheric pressure. Use is made of the hazardous area classification (HAC) gas groups, except for endurance burning.

The deflagration testing of in-line arresters is complicated by the fact that performance depends not only on flame speed but also on pressure. A typical test sequence is to increase the run-up distance in lengths of straight pipe and determine the flame speed at which failure occurs. This procedure does not, however, take account of pressure, and experience indicates that it is not necessarily sufficient to use a safety factor based solely on the relation between run-up distance and flame speed at atmospheric pressure. In view of these problems, the authors recommend that an arrester be tested under conditions which approximate as closely as possible those under which it is to be used.

The detonation testing of in-line arrester is usually based on a steady-state detonation, with CJ velocity. This does not allow for the possibility that the detonation may be overdriven. In a practical application it may be uncertain whether an overdriven detonation could occur. The authors emphasize that an in-line arrester should be tested for both deflagration and detonation conditions. It should not be assumed that if the arrester is satisfactory for detonation, it will be so for deflagration also, since cases have occurred where this was not the case.

With regard to overdriven detonations, they state that it is uncertain whether flame arresters are effective against such detonations.

The arrester should be tested for its ability to stop a flame travelling from either direction.

A flame arrester must also pass an endurance burning test to ensure that it will not fail if a flame becomes stabilized on it. In this test the gas mixture is adjusted to obtain a maximum value for the flame temperature and the endurance period of the arrester is then determined. Flashback of the flame should not occur during the test when the gas is turned off.

For this type of test the use of the HAC gas groups, based on the maximum experimental safe gap (MESG) and the minimum igniting current (MIC), is unsatisfactory. The authors discuss alternative approaches.

The testing of arresters is also discussed by W.B. Howard (1992a). He instances the case of a flame arrester which was found to be satisfactory for detonations of mixtures of air with propane but not with propylene, despite the fact that the fundamental burning velocities of these two gases are comparable, being 46 and 52 cm/s, respectively. The MESG for propane and propylene are, respectively, 0.97 and 0.91 mm (NFPA 97, Britton, 2000).

The test procedures for in-line arresters utilize straight pipes. In practical applications the pipework is likely to contain features such as bends and valves.

Both sets of authors emphasize the unsatisfactory state of the art in the testing of flame arresters. There are a large number of arrester designs and a wide range of applications, with variations in system geometry, gas mixtures and ignition sources. There is a paucity of published scientific work on which general design methods might be based. The message is therefore that if there is doubt as to the suitability of an arrester in a particular application, tests should be conducted which simulate as closely as possible the set of worst case conditions in that application.

17.11.13 Flame arresters: codes and standards

Flame arresters are the subject of a number of codes and standards in different countries. These are reviewed by H. Phillips and Pritchard (1986), W.B. Howard (1992a) and Britton (2000).

In the United Kingdom BS 7244: 1990 covers the testing of arresters, as described in the next subsection. In the United States the Underwriters Laboratories standard UL 525-1984 deals with construction and testing. Germany has legally backed standards on the same aspects, as described by Leineman (1970).

The International Maritime Organization (IMO) also has requirements for flame arresters (1984 MSC Circ. 373).

The testing of flame arresters is covered by BS 7244: 1990 Specification for Flame Arresters for General Use. The standard requires that an arrester withstand a fixed number of flame and detonation tests without flame propagating through the arrester.

An account of the practicalities of testing against this standard is given by G.O. Thomas and Oakley (1993).

17.11.14 Flame arresters: design features

There are a number of design features which are crucial to the effectiveness of a flame arrester. These relate to (1) mechanical strength, (2) flame endurance, (3) instrumentation, and (4) blockage avoidance.

For an in-line application, the arrester, its housing and the adjacent pipework should be able to withstand the shock from a detonation. This is a prime requirement in the selection of the type of arrester to be used.

The arrester element itself needs to have adequate mechanical strength. Use may be made of additional strengthening in the form of reinforcing grids across both faces of the arrester.

One expedient which is sometimes used to reduce the impact on the arrester is to set the arrester in a holder of enlarged cross-section. It has been found in practice that this does not always provide the degree of reduction of impact expected.

Another measure taken by some manufacturers is the provision of baffles to break up the detonation wave as it approaches the arrester, but there is little published on the performance of these devices.

An in-line arrester generally presents an appreciable resistance to flow. Data on pressure drop through arresters have been correlated by Quinton (1962).

Both end-of-line and in-line arresters are subject to blockage. Both types are vulnerable to dust and corrosion products. An end-of-line arrester may also suffer blockage from sand, fibres and crystallized or polymerized vapours. There may also be more exotic forms of blockage such as birds nests.

Some protection may be afforded by the use of a screen on an end-of-line arrester or a filter for an in-line arrester.

An arrester, whether end-of-line or in-line, should be able to withstand a flame stabilized on it. An endurance burning test may be required to confirm this.

The instrumentation of arresters is discussed in the following section.

In some installations the end-of-line arrester is heated to prevent blockage by condensed products. Where this is done it should be confirmed, by tests if necessary, that the arrester operates satisfactorily at the higher temperature.

With an end-of-line flame arrester there may be a risk to the plant from impingement of the flame.

A short vent pipe is sometimes used to prevent this. W.B. Howard (1992a) recommends that the arrester should be no more than five pipe diameters from the end of the pipe.

17.11.15 Flame arresters: instrumentation

An in-line flame arrester should be provided with instrumentation which will give an alarm to signal the presence of a flame and to take any appropriate protective action.

A common arrangement is two temperature sensors, one on each side of the arrester and close to it. The sensors should have rapid response and the trip level should be low enough to ensure effective protective action. If the sensors are sufficiently accurate, their response sequence can also indicate in which direction the flame has travelled.

The protective action might consist of the operation of fast-response isolation valves. It is desirable to detect the presence of flame on an end-of-line arrester also, again using temperature sensors.

17.11.16 Flame arresters: inspection and maintenance

As a protective device, a flame arrester should be entered in the inspection schedule and inspected at suitable intervals.

It should have pressure tappings either side to allow the pressure drop across it to be measured. There should be adequate access to allow this to be done and to permit removal if necessary.

In general, a blocked arrester should be cleaned by blowing air or steam through it or by washing. It should not be cleaned, however, in any way which is liable to enlarge the apertures, such as rodding out.

17.11.17 Flame arresters: alternatives to arresters

It should not be assumed that a flame arrester is necessarily the right solution. Depending on the situation, it may be preferable to consider an alternative approach such as the use of automatic isolation or explosion suppression.

These alternatives are now briefly considered. They find application particularly in protection against dust explosions and a fuller account is given in Section 17.47.

17.11.18 Automatic isolation

In some systems, the passage of an explosion from one section to another may be prevented by automatic high speed isolation. An account of this method is given in FPA FS 6012: 1989 *Flammable Liquids and Gases: Explosion Control* and NFPAI2A (1997).

A typical installation is illustrated in Figure 17.17. Very rapid detection and valve closure are necessary.

The design of such a system requires information on the rate of pressure rise caused by the expected explosion. This information is also required for the design of automatic explosion suppression systems and is discussed below in relation to the latter. From the data on the rate of pressure rise a suitable high speed detector can be chosen. The shut-off valve must also operate very quickly. One method of achieving rapid closure is the use of explosives.

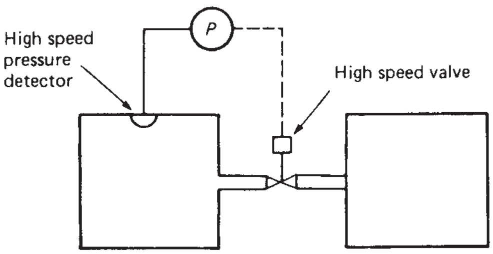

Figure 17.17 System for automatic isolation installed in a pipe

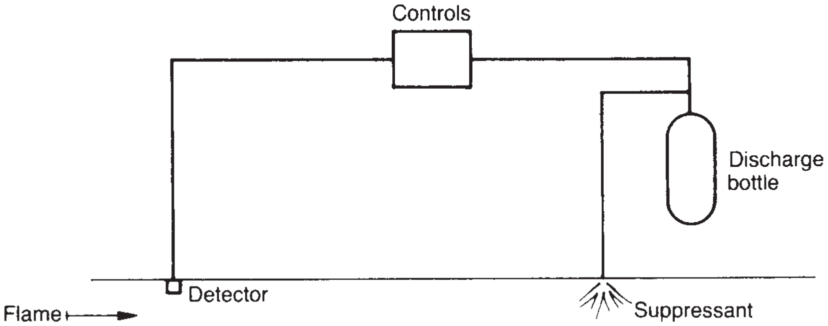

Figure 17.18 System for automatic explosion suppression installed in a pipe

Isolation protects only the section isolated and not the section in which the explosion occurs. The application of automatic high speed isolation appears to be fairly limited.

17.11.19 Automatic explosion suppression

A developing explosion may be detected and suppressed using an automatic high speed suppression system.

Accounts of automatic explosion suppression are given in FPA FS 6012: 1989 and FS 6015: 1974 *Explosible Dusts, Flammable Liquids and Gases: Explosion Suppression* and by Grabowski (1965) and K.N. Palmer (1973a).

A typical explosion suppression system in a pipe is illustrated in Figure 17.18.

An explosion suppression system for a vessel, and the principles of operation of such a system, are shown in Figure 17.19. Again, very rapid detection and suppression are required.

The basic data for the design of an explosion suppression system are given by the explosion pressure curve for the gas. A typical curve is shown in Figure 17.20 as curve 1.

This information is used to estimate the required response time of the detector and of the suppressant in order to limit the explosion pressure to a specified value. The pressure response typically obtained with explosion suppression is shown in curve 2 of Figure 17.20.

Broadly, the rate of rise of pressure follows the cube law given in Equation 17.7.48, as described in Section 17.6, but factors such as vessel geometry and turbulence effects make prediction difficult.

The main suppressants used to be halons such as bromochlorodifluoromethane and chlorobromomethane. Now, with environment restraints on the use of chlorofluorocarbon substitutes are used, as discussed in NFPAI2A (1997). The quantity of liquid agent commonly specified is 2.14 l/m^3 of protected space. The suppressant is discharged by an electrically fired detonator within 1 ms of the closure of the detonator contacts.

The size and shape of vessel to which explosion suppression can be effectively applied is not unlimited. FS 6015: 1974 stated that explosion suppression is applicable to vessels with a volume of up to 115 m^3 and for flammable gas mixtures for which the maximum explosion pressure is generated in not less than 40 ms.

Developments in technology have tended to expand these limits, as described in relation to dusts in Section 17.47.

With an automatic explosion suppression system operating, the maximum pressure of the suppressed explosion is typically reached in about 10 ms.

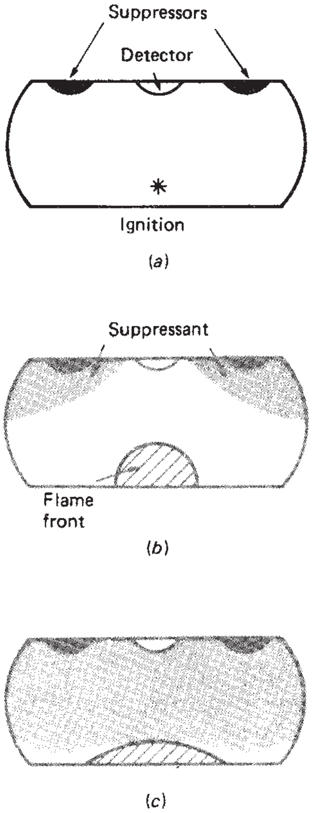

Figure 17.19 System for automatic suppression of an explosion in a vessel (after Fire Protection Association, 1974 FS 6015): (a) initial ignition; (b) suppressors activated; and (c) suppression nearly complete

A potential disadvantage of automatic explosion suppression is the risk of spurious trips. This has not proved sufficiently serious, however, to discourage its use.

Automatic explosion suppression systems are widely used.

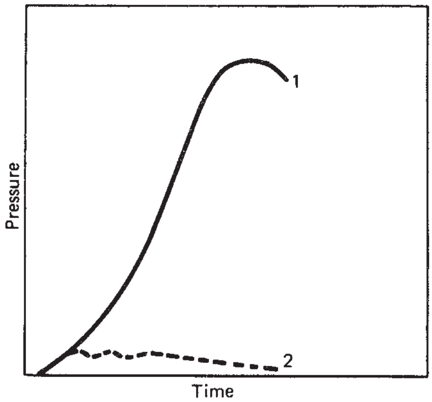

Figure 17.20 *Typical explosion pressure curves for an automatic suppression system: curve 1, explosion pressure in absence of suppression; cure 2, explosion pressure with suppression operating*

17.11.20 Explosion relief and venting

A quite different approach is to relieve the explosion by venting. Explosion venting is applied to (1) vessels, (2) pipes and ducts, (3) buildings, (4) large enclosures, (5) reactors and (6) storage vessels.

If this option is adopted, it is necessary to consider not only the venting itself, but also the disposal of the material vented, which may not be a trivial problem.

Explosion relief of vessels is treated in Section 17.12, of pipes and ducts in Section 17.13, of buildings in Section 17.14, of large enclosures in Section 17.15 and of reactors in Sections 17.16–17.23.

17.12 Explosion Venting of Vessels

One of the options for the protection of a vessel against a gas explosion is the use of explosion venting, also referred to as explosion relief.

Accounts of explosion venting are given in *Explosions* (Bartknecht, 1981a), *Development and Control of Dust Explosions* (Nagy and Verakis, 1983), *Gas Explosions in Buildings and Heating Plants* (R.J. Harris, 1983) and *Venting Gas and Dust Explosions – A Review* (Lunn, 1984b, 1992). All of these except the book by Harris also deal with dust explosions.

Explosion venting is also dealt with in NFPA 68: 2002 *Deflagration Venting*.

The notation used in explosion venting is particularly liable to cause confusion. The term 'maximum explosion pressure' refers generally to a closed, or unvented, explosion, but occasionally it refers to a vented explosion. Pressure is defined sometimes as an absolute pressure, sometimes as a gauge pressure and sometimes as a pressure in excess of the initial pressure. Explosion venting of vessels is a topic in which there are a large number of empirical equations in particular sets of units. Some equations are quoted here in their original form in British units, but generally the use of SI units is preferred. However, with the latter, unless otherwise stated, where units are given, the common practice of giving pressure in kilopascals has been followed. In some subsections equations are given without units, and in these cases any consistent set of units is applicable. Further information on the units used is given in the Notation.

In the account given here, the maximum pressure in a vented system is referred to as the reduced pressure, P_{red}.

The definition of reduced pressure P_{red} as absolute or gauge is not always clearly stated in the original papers and sometimes has to be inferred.

17.12.1 Factors influencing explosion venting

The various factors which influence the maximum pressure and the rate of rise of pressure in an explosion in a closed vessel were described in Section 17.7. They are relevant to vented explosions also.

One factor which assumes particular significance for a vented explosion is the location of the ignition source. Different models have been developed for vented explosions with different locations of the ignition source, as described below.

17.12.2 Experimental studies of venting

There have been a number of experimental studies of explosion venting. Some of the principal studies are listed in Table 17.14.

Early work on explosion relief was done by Cousins and Cotton (1951a,b), who studied a range of containers with L/D ratios varying from 1.41 to 22.1. The relief was a bursting disc. The gases used were propane and hydrogen.

Another early study was carried out at the Midlands Research Station (MRS) of the Gas Council by Cubbage and Simmonds (Cubbage and Simmons, 1955a,b; Simmonds and Cubbage, 1960). Their work was concerned with the explosion venting of industrial drying ovens. The experiments were done on ovens which were approximately cubical and with a variety of vent conditions. The principal gas used was town gas. The pressure profile resulting from an explosion with explosion relief was of the form shown in Figure 17.21. The initial pressure peak at A was followed by a second, higher peak at B

Other experimental studies which have yielded data sets against which correlations can be tested include those of Burgoyne and Wilson (1960), G.F.P. Harris and Briscoe (1967), Yao and co-workers (Yao *et al.*, 1969; Yao, 1974) and Zalosh (1980b).

Experimental studies on larger containments which are often referred to in relation to explosion venting of vessels include those of the Committee for Explosion Research (1958) in Sweden, Dragosavic (1973), Solberg, Pappas and Skramstad (1980, 1981) and Buckland (1980).

17.12.3 Phases of vented explosion

A vented explosion passes through three phases: the initial confined explosion phase, the vent removal phase and the venting phase.

The pressure–time profiles obtained in venting experiments may exhibit as many as three peaks, although in many cases one or more of these peaks is absent or runs into another peak. Explanations of this multiple-peak behaviour have been given by Anthony (1977/78), R.J. Harris (1983) and Lunn (1984b).

The first peak occurs when the vent opens. The magnitude of this peak is a function of the vent opening pressure P_{v} and the vent inertia w.

The second peak is associated with an increase in the rate of combustion as the burned gas core grows. The magnitude of this peak is a function of two factors. One is

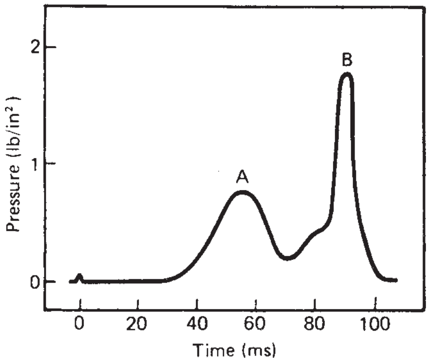

Figure 17.21 *Explosion venting of vessels: typical explosion pressure curve obtained in explosion venting of an enclosure in work of Cubbage and Simmonds (1960) (courtesy of the Institution of Chemical Engineers)*

the features which may give an enhanced combustion rate. These include shear turbulence and stretching of the flame towards the vent. The other factor is the flow resistance, which depends on the vent size and on any vent ducting.

The third peak is associated with the venting of burned gas. When the burned gas starts to vent, the volumetric flow increases markedly, since the burned gas density is much less than that of the unburned gas.

The first peak may be weak or absent if the vent is an open one. It tends to be large if the vent opening pressure or vent inertia is high. But if the vent area is small so that there is little vent outflow before the second peak arrives, the first peak merges into the second one. This may also occur if the vent opening pressure is sufficiently high.

The second peak may be weak if the rate of combustion is slow or the vent area large. Conversely it is large if the rate of combustion is high and the vent area is small. In the former case the second peak may merge into the first one.

In the later stages of venting the explosion may exhibit various types of oscillatory behaviour as evidenced by the pressure trace.

Some typical pressure profiles are illustrated in Figure 17.22. Other examples of the multiple peaks obtained in explosion venting are given in Section 17.15.

Another feature of the venting process is the effect of the vent pressure on the combustion process. For a vessel with a relatively low vent area, if the vent pressure is set at a low value, the explosion pressure tends to exceed the vent pressure. The phenomenon has been studied by G.F.P. Harris and Briscoe (1967), who attribute it to a large increase in the flame area when the vent is opened. This is illustrated in Figure 17.23.

17.12.4 Oscillatory behaviour

Pressure–time profiles of a vented explosion often show marked oscillatory behaviour in the later stages. The significance of this is that combustion oscillations can greatly increase the combustion rate, particularly in the later stages, and can result in higher pressures. The effect becomes relatively more important as the scale increases, but it may not be negligible even for vessels. Oscillation in explosion venting was described by Zalosh (1980b), who obtained high, delayed, oscillatory second peaks in the pressure–time profile using propane.

Oscillatory behaviour in explosion venting of a spherical vessel with a vent tube attached has been investigated by Kordylewski and Wach (1988).

One type of oscillatory behaviour is that due to acoustic oscillation. For an acoustic oscillation Kordylewski and Wach used the relation

$$f_a \approx \frac{c\lambda_1}{2\pi r_s} \qquad [17.12.1]$$

where c is the speed of sound in the medium, f_a is the frequency of the oscillation, r_s is the radius of the spherical vessel and λ_1 is a constant. The value of λ_1 is 4.4934.

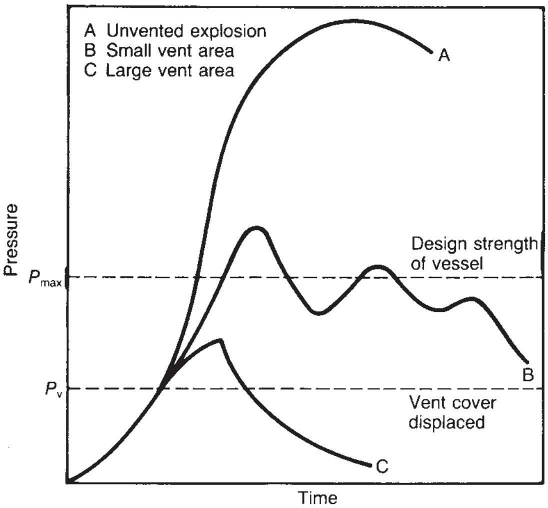

Figure 17.22 *Explosion venting of vessels: generalized explosion pressure curves for closed and vented vessels (Field, 1982; reproduced by permission of Elsevier Science Publishers)*

Formulae for this and other geometries are given in *Formulas for Natural Frequency and Mode Shape* (Blevins, 1979).

Another type of oscillatory behaviour is that due to Helmholtz oscillation. For Helmholtz oscillation Kordylewski and Wach used the relation

$$f_H = \frac{c}{2\pi}\left(\frac{A_v}{L + \alpha V}\right)^{1/2} \qquad [17.12.2]$$

with

$$a = 0.255D \qquad [17.12.3]$$

where A_v is the vent area, D is the duct diameter, f_H is the frequency of Helmholtz oscillation, L is the length of the duct, V is the volume of the vessel and α is a correction factor.

The occurrence and strength of combustion oscillations depend on the concentration of the gas mixture. Thus, in the work of Zalosh (1980b) just described, oscillations were observed for propane concentrations only in the range 5.0–5.5%.

The oscillations tend to be more marked just on the fuel-rich side of the stoichiometric ratio. C.J.M. van Wingerden (1989c) found, using 9.5 and 10% methane–air mixtures, that whilst the former was the stoichiometric concentration it was the latter which was more sensitive to oscillatory combustion.

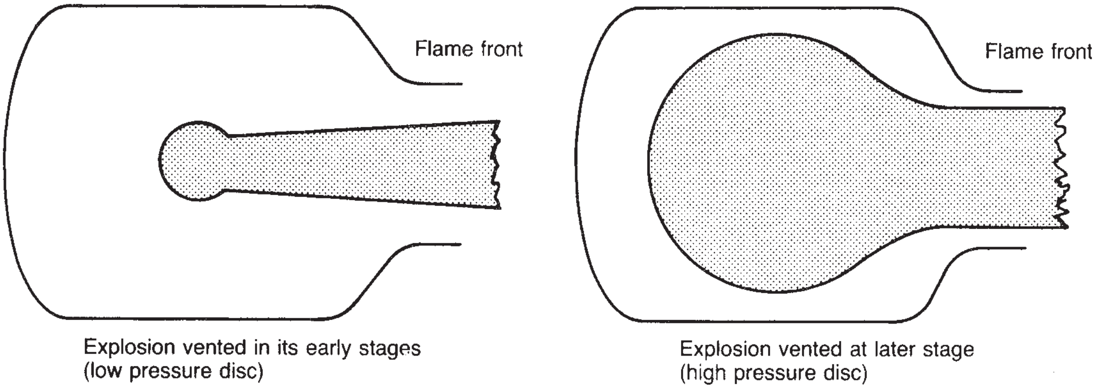
17.12.5 Empirical and semi-empirical methods

As already indicated, the venting of an explosion is a complex process. It is therefore difficult to model theoretically. This has led to the development of a number of empirical and semi-empirical methods and scaling laws.

17.12.6 Vent ratio and vent coefficient

Work on explosion venting makes frequent use of two quantities, the vent ratio and the vent coefficient. The vent ratio f is defined as the ratio of the vent area A_v to the volume vented V:

$$f = A_v/V \qquad [17.12.4]$$



Explosion vented in its early stages (low pressure disc)

Explosion vented at later stage (high pressure disc)

Figure 17.23 *Explosion venting of vessels: distortion of flame front on opening of vent (G.F.P. Harris and Briscoe, 1967) (Courtesy of the Combustion institute)*

The vent coefficient K is defined as

$$K = A_c/A_v \qquad [17.12.5]$$

with

$$A_c = L_1L_2 \qquad [17.12.6]$$

where A_c is the area of the smallest cross-section of the enclosure (m^2), A_v is the vent area (m^2), L_1 and L_2, for a rectangular enclosure, are the dimensions of the two smallest sides (m).

The vent coefficient is therefore dimensionless, but the vent ratio is not.

These two quantities are discussed further below, particularly in relation to scaling methods.

17.12.7 Rasbash method

An early equation for the reduced pressure P_{red} in a vented explosion, or vented explosion pressure, was that of Rasbash (1969c), who gave the following equation for the maximum pressure in a vented explosion in a building:

$$P_{red} = 1.5P_v + 0.5K \qquad [17.12.7]$$

with

$$K = A_c/A_v \qquad [17.12.8]$$

where A_c is the area of the smallest cross-section of the enclosure (ft^2), A_v is the total area of combustion vents (ft^2), K is the venting ratio, P_{red} is the reduced pressure, or maximum pressure reached during the venting of combustion (gauge) ($lb_f/in.^2$) and P_v is the pressure within the building space at which the vent opens (gauge) ($lb_f/in.^2$). In SI units these equations become

$$P_{red} = 1.5P_v + 3.5K \qquad [17.12.9]$$

where P_{red} is the reduced pressure (gauge) (kPa) and P_v is the pressure within the building space at which the vent opens (gauge) (kPa).

Rasbash stated that Equation 17.12.9 was based on a collation of information on experimental work on venting using particularly propane and referred to work on explosion relief of ducts (Rasbash and Rogowski, 1960b).

There are a number of restrictions on the use of Equation 17.12.9. They may be summarized as

$$L/D \leq 3; \quad 1 \leq K \leq 5; \quad w \leq 24; \quad P_v \leq 7 \qquad [17.12.10]$$

where w is the inertia of the vent (kg/m^2). In addition, the pressure should be virtually exhausted after the vent has moved a few millimetres.

Equation 17.12.9 applies to propane. For natural gas and for town gas which contains 60% H_2, the pressures reached are, respectively, about 0.8 and 2.5 times that given by Equation 17.12.9 (Mainstone, 1971).

If the flammable mixture is turbulent when ignited or becomes turbulent during the combustion, pressures considerably higher than those given in Equation 17.12.9 may be generated.

In subsequent work, Rasbash, Drysdale and Kemp (1976) modified Equation 17.12.9 to include a term for the vent inertia

$$P_{red} = AP_v + P_I + BK \qquad [17.12.11]$$

with

$$P_I = \frac{0.20Kw + 1.17}{V^{1/3}} \qquad [17.12.12]$$

$$w = W_v/A_v \qquad [17.12.13]$$

where P_I is the back pressure due to the inertia of the vent (gauge) (kPa), w is the inertia of the vent (kg/m^2) and W_v is the mass of the vent cover (kg). The values of the constants given are 1–1.5 kPa for A and 2.5 kPa for B; the value commonly used for A is 1.5.

The authors then generalize Equation 17.12.11 to make it applicable to other flammable gases:

$$P_{red} = 1.5P_v + S_u(P_I + 2.5K)/0.45 \qquad [17.12.14]$$

where S_u is the maximum fundamental burning velocity (m/s). The constant 0.45 represents the maximum fundamental burning velocity of propane.

Finally, Rasbash, Drysdale and Kemp introduce a turbulence factor f so that Equation 17.12.14 becomes

$$P_{red} = 1.5P_v + fS_u(P_I + 2.5K)/0.45 \qquad [17.12.15]$$

They suggest for f a value of 1.5 for a single room, but modify this considerably for certain conditions. For a situation where the explosion propagates from one room to another they propose for f a value of 5, and for a high pressure leak of liquid petroleum gas (LPG) values of 8 or even 10.

For comparison with equations derived by other workers it is helpful to combine Equations 17.12.11 and 17.12.12, to give

$$P_{red} = 1.5P_v + \frac{0.20KwS_u}{0.45V^{1/3}} + \frac{1.17S_u}{0.45V^{1/3}} + \frac{2.5S_uK}{0.45} \qquad [17.12.16]$$

The relative importance of the terms in Equation 17.12.16 may vary. If P_v is high, P_{red} approximates to it, whilst if P_v is low, P_{red} may be appreciably higher than P_v. If K is low (high A_v), P_{red} approximates to P_v whilst if K is high, P_{red} may again be higher than P_v.

Equation 17.12.11 has been widely used for the explosion relief of buildings. It is considered further in Section 17.14.

17.12.8 Cubbage and Simmons method

The pressure profile obtained by Cubbage and Simmonds in their work on drying ovens was described above. The relation obtained by these authors for the first pressure peak (peak A in Figure 17.21) is

$$P_1 = \frac{0.437KwS_u}{V^{1/3}} + \frac{2.817S_u}{V^{1/3}} \qquad [17.12.17]$$

and that for the second peak (peak B in Figure 17.21) is

$$P_2 = 5.8S_uK \qquad [17.12.18]$$

where K is the vent coefficient, P_1 and P_2 are, respectively, the first and second pressure peaks (gauge) (kPa), S_u is the maximum fundamental burning velocity (m/s), V is the volume of the vessel (m^3) and w is the inertia of the vent (kg/m^2).

In contrast to Rasbash's method, Cubbage and Simmonds's method is based on separate equations for the two pressure peaks. The first of their equations depends only on the inertia w of the vent panel, the second only on the vent coefficient K, whilst the vent opening pressure P_v does not appear.

17.12.9 Runes method

In contrast to the two empirical correlations just described, the equation given by Runes (1972) for the vent area of a large container or building has some theoretical basis. It is based on equating the volume production rate and the volumetric vent outflow. The volume production rate is

$$Q_m = A_m u_f (E - 1) \qquad [17.12.19]$$

with

$$A_m = \pi L_1 L_2 \qquad [17.12.20]$$

where A_m is the maximum area of the flame front (ft^2), E is the expansion ratio, L_1 and L_2, are the two smallest dimensions of the enclosure (ft), Q_m is the rate of volume production (ft^3/s) and u_f is the flame speed (ft/s). The volumetric vent outflow is

$$Q_v = YC_d A_v (2g \times 144\Delta P/\rho)^{1/2} \qquad [17.12.21]$$

where C_d is the coefficient of discharge, g is the acceleration due to gravity (ft/s^2), ΔP is the vented explosion pressure (gauge) ($lb_f/in.^2$), equivalent to P_{red}, Q_v is the volumetric vent outflow (ft^3/s), Y is a constant which takes account of the expansion of the gas as it discharges and ρ is the density of the gas (lb/ft^3). The value of C_d is 0.6, and Y is usually unity.

Runes takes $Y = 1$, $C_d = 0.6$, $g = 32.2$ and $\rho = 0.085$, and obtains

$$Q_v = 200 A_v \ \Delta P^{1/2} \qquad [17.12.22]$$

(Equation 17.12.22 is obtained from Equation 17.12.21 by substituting the numerical values given by Runes. He actually gives not Equation 17.12.21 but one in which the right-hand side is $YC_d A_v 2g(144\Delta P)^{1/2}/\rho$, but this is evidently a typographical error. This error has caused some confusion in the expressions quoted in the literature for the Runes constant C, described below.) Then, from Equations 17.12.19, 17.12.20 and 17.12.22

$$A_v = \frac{\pi L_1 L_2 u_f (E-1)}{200 \Delta P^{1/2}} \qquad [17.12.23]$$

$$= \frac{C L_1 L_2}{\Delta P^{1/2}} \qquad [17.12.24]$$

with

$$C = \frac{\pi u_f (E-1)}{200} \qquad [17.12.25]$$

where C is a constant.

The value of the constant C is discussed in more detail in Section 17.14 on explosion venting of buildings. Runes himself did not assign a value to the constant, though from Equation 17.12.25 $C = 0.108u_f$. As described in Section 17.14, W.B. Howard (1972) assigned a value to C of 1.2 by inserting the value for propane of $u_f = 11$ ft/s. However, in the same paper Howard also made his own calibration of the constant based on an incident involving ethanol for which he took $u_f = 24$ ft/s and thus obtained a value of $C = 2.6$ (1.2 × 24/11).

The constant C is best regarded as an empirical one which allows for the actual flame speed under the conditions of turbulence in the enclosure. NFPA 68: 1978 gives for C in British units for use in Equation 17.12.24 a value of 2.6 for gases such as propane and other gases with a similar burning velocity. A higher value is recommended for gases with a higher burning velocity. The suggested value for ethylene is 4 and that for hydrogen 6.4.

In SI units Equation 17.12.24 is

$$A_v = C \frac{L_1 L_2}{\Delta P^{1/2}} \qquad [17.12.26]$$

where A_v is the necessary building vent area (m^2), L_1 is the smallest dimension of the rectangular building enclosure to be vented (m), L_2 is the second smallest dimension of that building (m), P is the maximum internal building pressure (gauge) (kPa) and C is a constant.

NFPA 68: 1978 gives for C in metric units for use in Equation 17.12.26 a value of 6.8 for gases such as propane and others gases with a similar burning velocity, whilst the suggested value for ethylene is 10.5 and that for hydrogen is 17.

Equation 17.12.26 has been widely used for the explosion relief of buildings. It is considered further in Section 17.14. NFPA 68: 1994 gives a relationship similar to Equation 17.12.26; this is described in Section 17.14.

17.12.10 Decker method

The method described by Decker (1971) is based on somewhat similar considerations to that of Runes. The approach is again to equate the volume production rate and the volumetric vent outflow;

$$Q_v = \frac{dP}{dt} \frac{V}{P_v} \qquad [17.12.27]$$

$$= V/t \qquad [17.12.28]$$

where P is the pressure ($lb_f/in.^2$), P_v is the vent pressure ($lb_f/in.^2$), Q_v is the volumetric vent outflow (ft^3/s), t is time (s) and V is the volume of the vessel (ft^3). For the vent area he then obtains

$$A_v = k \frac{dP}{dt} V \left(\frac{\bar{M}}{T}\right)^{1/2} \frac{1}{P_v} \qquad [17.12.29]$$

where A_v is the vent area (ft^2), $\bar{M}$ is the mean molecular weight of the gas, T is the absolute temperature of the burnt gases (°R) and k is a constant. The temperature T of the burnt gases is of the order of 3600°R. The treatment by Lowenstein (1958) is rather similar. The value of the constant k is 1/132.

17.12.11 Dragosavic method

Dragosavic (1973) has given equations for the first and second peak pressures in explosions in rooms in dwellings. For the first peak pressure

$$P_1 = P_v + C \qquad [17.12.30]$$

and for the second peak pressure

$$P_2 = AP_v + B/f^2 + C \qquad [17.12.31]$$

with

$$f = A_v/V \qquad [17.12.32]$$

where P_1 and P_2 are, respectively, the first and second peak pressures (gauge) (kPa), P_v is the vent opening pressure (kPa), f is a vent ratio (m^{-1}) and A, B and C are constants. The values of A, B and C for natural gas–air mixtures are 0.5, 0.04 and 3.0 kPa, respectively. Equation 17.12.30 applies to enclosures with open and closed vents. Equation 17.12.31 represents an envelope of the experimental values and therefore overestimates the second peak pressure.

17.12.12 Cubbage and Marshall method

Cubbage and Marshall (1973) have obtained the relation

$$P_{red} = P_v + 2.44(KwS_u^2/V^{1/3}) \qquad [17.12.33]$$

where K is the venting coefficient, P_{red} is the reduced pressure (gauge) (kPa), P_v is the vent opening pressure (gauge) (kPa), S_u is the maximum fundamental burning velocity (m/s), V is the volume of the vessel (m^3) and w is the inertia of the vent (kg/m^2).

17.12.13 Other methods

The following further equations for explosion venting are quoted by Lunn. Rasbash has given the two equations

$$P_{red} = P_v + 7.76S_uK \qquad [17.12.34]$$

$$P_{red} = (P_v + 7.76K)S_uK \qquad [17.12.35]$$

where K is the venting coefficient, P_{red} is the reduced pressure (gauge) (kPa), P_v is the vent opening pressure (gauge) (kPa) and S_u is the fundamental burning velocity (m/s).

Burgoyne and Wilson (1960) have given the following equation for their work on pentane–air systems:

$$P_{red} = 68 \log_{10}(K) - 28.6 \qquad [17.12.36]$$

where K is the venting coefficient and P_{red} is the reduced pressure (gauge) ($lb_f/in.^2$).

17.12.14 Scaling methods

Empirical equations have the limitation that they cannot be used with confidence outside the range of experimental data on which they are based. An alternative empirical approach is the use of scaling laws validated over a wide range of experimental conditions.

There are two principal methods based on scaling laws which are used for gas explosion venting: the vent ratio method and the vent coefficient method. Traditionally, in Britain the vent coefficient method has been used for venting of gas explosions and the vent ratio method for venting of dust explosions, but there is no logical basis for this.

17.12.15 Vent ratio method

The vent ratio f is defined as

$$f = A_v/V \qquad [17.12.37]$$

where A_v is the vent area, f is the vent ratio and V is the volume of the enclosure.

The simple application of the vent ratio method is the use of a constant vent ratio.

It is found in practice that in scaling up from small scale tests, the use of a constant vent ratio tends to overestimate the vent area required. The following alternative treatment given by Lunn addresses this problem. The relationship between the rate of pressure rise and the volume of the vessel is given by the cube root law (17.7.48)

$$\frac{dP}{dt}V^{1/3} = \text{constant} = K_G \qquad [17.12.38]$$

Following an approach similar to that of the Decker method, as given in Equation 17.12.29, but using P_{red} rather than P_v, the volumetric venting flow Q_v, and hence the vent area required, is

$$A_v \propto \frac{dP}{dt}\frac{V}{P_{red}} \qquad [17.12.39]$$

Hence, for the vent ratio

$$fV^{1/3} = \text{constant} \qquad [17.12.40]$$

This approach implies that the cube root law is applicable to vented vessels also. It is the basis of the Bartknecht nomograph method described below

A common method of characterizing the vent area required is to plot the reduced explosion pressure as a function of vent ratio. Numerous such plots are given by Lunn.

17.12.16 Vent coefficient method

The vent coefficient K is defined as

$$K = A_c/A_v \qquad [17.12.41]$$

with

$$A_c = L_1/L_2 \qquad [17.12.42]$$

where A_c is the area of the smallest cross-section of the enclosure, K is the vent coefficient and L_1 and L_2 are the two smallest dimensions of the enclosure.

For a cubical enclosure of volume V if $L_1 = L_2 = (\pi/6)^{1/3}$, $D = 0.80D$

$$A_c = V^{2/3} \qquad [17.12.43a]$$

$$L_1L_2 = V^{2/3} \qquad [17.12.43b]$$

The following treatment by Lunn gives the relation between the vent coefficient and the reduced pressure. Again, following Decker and using Equation 17.12.29 with P_{red} together with Equations 17.12.38, 17.12.41 and 17.12.43

$$P_{red} \propto K \qquad [17.12.44]$$

The characteristics of the vent ratio and vent coefficient methods have been explored by N. Gibson and Harris

(1976), as shown in Figure 17.24. Their experimental results for pentane, and also those for class St 2 dusts, are well fitted using the vent coefficient with $K = 3$. Also shown are curves for various vent ratios. The two methods exhibit an increasing divergence in the predicted vent areas as the vessel volume increases.

A critique of vent coefficient scaling has been given by Zalosh (1980b). He carried out experiments with a range of containment volumes from 0.17 to 33.5 m^3, and found that such scaling is valid for volumes up to 12 m^3 but that for larger volumes the relationship breaks down due apparently to effects related to flame speed.

17.12.17 The K_G method

The K_G method developed by Bartknecht is based on the cube root law given in Equation 17.12.38. The cube root law in terms of the maximum rate of pressure rise is

$$\left(\frac{dP}{dt}\right)_{max} V^{1/3} = K_G \qquad [17.12.45]$$

and in terms of the rate of pressure rise with venting

$$\left(\frac{dP}{dt}\right)_{P_{red}} V^{1/3} = K_G \qquad [17.12.46]$$

Thus, for the same reduced pressure the vent ratio f also follows the cube root law

$$fV^{1/3} = \text{constant} \qquad [17.12.47]$$

As described by Bartknecht (1981a), Donat and Bartknecht have carried out extensive experimental work on vented explosions using the Ciba–Geigy 20 l sphere. They apply the cube root law of Equation 17.12.45 and determine the value A_v for values of the gas factor K_G, the vent opening pressure P_{stat} and the reduced explosion pressure P_{red}.

The results of their work are given in the form of a series of nomographs for the determination of the vent area A_v for particular values of the vessel volume V, the initial pressure P_o and the vent explosion pressure P_{red}. Each nomograph is for a particular value of K_G degree of initial turbulence and strength of ignition source. For gases the values given for K_G are as follows:

	K_G (bar m/s)
Methane	55
Propane	75
Coke gas	140
Hydrogen	550

For solvents the value used is that for propane. The nomographs give the vent area A_v as

$$A_v = f(V, K_G, P_{stat}, P_{red}) \qquad [17.12.48]$$

where P_{red} is the reduced pressure and P_{stat} the vent opening pressure and V is the volume of the vessel.

The derivation of these nomographs has been described by Lunn, Brookes and Nicol (1988) and in NFPA 68: 1994, and is discussed further in Section 17.48.

There is a separate nomograph for each of the four gases mentioned. The vent opening pressure P_{stat} is given as a parameter. The three values of P_{stat} are 0.1, 0.2 and 0.5 barg. The range of values of P_{red} is 0.2–2.0 barg.

The nomographs are valid within a limited range of conditions. They are for a quiescent mixture and a weak

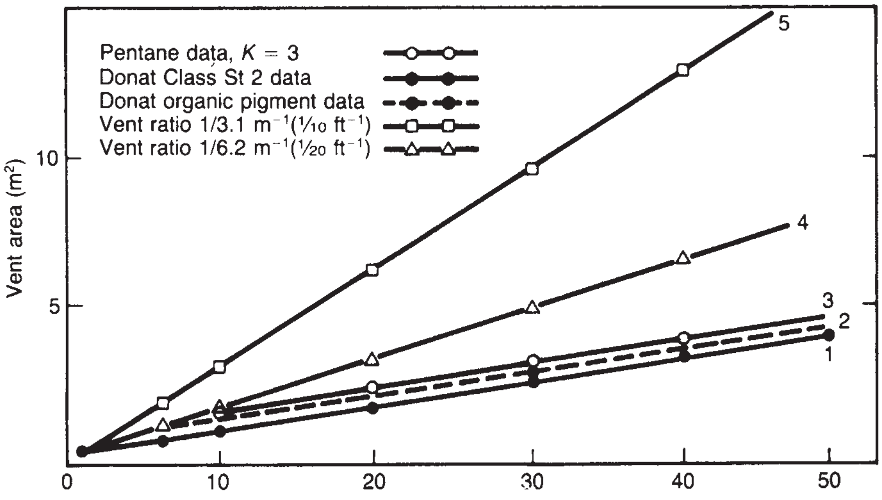


Figure 17.24 Explosion venting of vessels: some vent ratio and vent coefficient predictions (N. Gibson and Harris, 1976): (1) Donat's results for St 2 dust; (2) Donat's results for organic pigment; (3) results for pentane with vent coefficient $K = 3$; (4) vent ratio 1/6.2 m^2/m^3; and (5) vent ratio 1/3.1 m^2/m^3. Maximum pressure rise 48 kPa and vent rupture pressure 7–14 kPa (courtesy of the American Institute of Chemical Engineers)

ignition source (10 J). Their use is not recommended for $V > 1000\ \text{m}^3$, $P_{\text{stat}} < 0.1$ barg and $P_{\text{red}} < 0.2$ or >2.0 barg.

Experiments have shown that above a reduced pressure P_{red} of 2.0 barg, a well-defined correlation of P_{red} cannot be obtained, which is the reason for the upper limit in the nomographs.

The K_G nomograph method was adopted in NFPA 68: 1988, and the nomographs in Figure 17.25 are those given in the 1994 version NFPA 68.

The use of the nomographs is illustrated in Figure 17.26. For a vessel of volume V, enter on the right-hand graph, move up to the desired value of the reduced pressure P_{red}, move left on the left-hand graph to the desired value of the vent opening pressure P_{stat} and then move down to the required vent area A_v.

The vent area given by the nomographs is illustrated in Figure 17.27 for a 1 m^3 vessel with a vent opening pressure $P_{\text{stat}} = 0.1$ barg.

The nomographs may be used for other gases by interpolation of the K_G values. They may be used for stronger ignition sources if the K_G value for the gas with that ignition source is known.

In Bartknecht's method, if the mixture is not quiescent, the effect of turbulence must be taken into account. The information available on this is limited. But for large vent area A_v and low reduced pressure P_{red} (≤ 2 bara) turbulence has little effect and the nomographs may be used as they stand. For small A_v and high P_{red} (>2 bara) A_v should be increased by a correction term ΔA_v, where

$$\Delta A_v = 0.08 V^{2/3} \qquad [17.12.49]$$

Bartknecht states that this treatment is applicable only to methane, propane and solvent vapours and for $P_{\text{stat}} \leq 0.1$ barg. This correction is not accepted yet by NFPA 68.

The initial, or operating, pressure on which the nomographs are based is 1 bara, but they may be used without correction up to a value of 1.2 bara. Data outside this range were not available when the nomographs were formulated, but Bartknecht states that for higher operating pressures it should be assumed that for a given vent area the reduced explosion pressure is proportional to the operating pressure.

An equation equivalent to the Bartknecht nomographs has been given by Simpson (1986). His equation is

$$A_v = aV^b \exp(cP_{\text{stat}}) P_{\text{red}}^d \qquad [17.12.50]$$

where the units are A_v (m^2), P_{red} (barg), P_{stat} (barg) and V (m^3). The range of validity of the equation is

$$1 \leq V \leq 1000; \quad 0.1 \leq P_{\text{stat}} \leq 0.5; \quad P_{\text{stat}} + 0.1 \leq P_{\text{red}} \leq 2$$

Values of the constants in Equation 17.12.50 are given in Table 17.15. Equation 17.12.50 is quoted in NFPA 68: 1994.

17.12.18 Experimental studies of venting relations

A review of experimental studies comparing the predictions of empirical and semi-empirical equations with experimental results is given by Lunn.

The equations recommended by Lunn as the most versatile are Equation 17.12.11 of Rasbash and Equations 17.12.17 and 17.12.18 of Cubbage and Simmonds. The Runes equation (Equation 17.12.22) contains the constant C, which is too dependent on the particular conditions from which it was derived. The Decker equation (Equation 17.12.29) gives upper limits of P_{red} which are often reasonable but in other cases are overestimates. The Dragosavic equations (Equations 17.12.30 and 17.12.31) are limited to methane–air mixtures, and the Burgoyne and Wilson equation (Equation 17.12.36) to pentane–air mixtures. Rasbash's other equations (Equations 17.12.34 and 17.12.35) are limited to low turbulence, and of the two relations Equation 17.12.34 is superior to Equation 17.12.35 in all cases. The Cubbage and Marshall equation (Equation 17.12.33) is limited to methane–air mixtures as the dependency on the square of the burning velocity tends to give overestimates of P_{red} for gases with high burning velocity.

17.12.19 Modelling of explosion venting

The modelling of combustion in an unvented vessel was described in Section 17.7. Models have also been developed on similar lines for combustion in vented vessels.

17.12.20 Vent outflow equations

The outflow from a vented vessel may be subsonic or sonic. Equations for both types of flow were given in Chapter 15. As the absolute pressure P in the vessel increases relative to atmospheric pressure P_a the ratio η ($= P_a/P$) decreases. When this ratio falls below a critical value η_c ($= 2/(\gamma+1)^{\gamma/(\gamma+1)}$) sonic flow occurs. The mass outflow per unit area G_v from the vessel is then

$$G_v = C_d f_v \qquad [17.12.51]$$

with

$$f_v = f_{v1} \qquad [17.12.52]$$

$$f_{v1} = f_{vsb1} \quad \text{subsonic flow} \qquad [17.12.53a]$$

$$= f_{vs1} \quad \text{sonic flow} \qquad [17.12.53b]$$

$$f_{vsb1} = \left\{ 2P\rho \frac{\gamma}{\gamma-1} \left[\left(\frac{P_a}{P}\right)^{2/\gamma} - \left(\frac{P_a}{P}\right)^{(\gamma+1)/\gamma} \right] \right\}^{1/2} \qquad [17.12.54]$$

subsonic flow

$$f_{vs1} = \left[P\rho\gamma \left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/(\gamma-1)} \right]^{1/2} \quad \text{sonic flow} \qquad [17.12.55]$$

where C_d is the coefficient of discharge, γ is the ratio of gas specific heats and ρ is the density of the gas. An alternative form of these equations utilized in some models is

$$f_v = (P\rho\gamma)^{1/2} f_{v2} \qquad [17.12.56]$$

$$f_{v2} = f_{vsb2} \quad \text{subsonic flow} \qquad [17.12.57a]$$

$$= f_{vs2} \quad \text{sonic flow} \qquad [17.12.57b]$$

with

$$f_{vsb2} = \frac{f_{vbs1}}{(P\rho\gamma)^{1/2}} \quad \text{subsonic flow} \qquad [17.12.58]$$

$$f_{vs2} = \frac{f_{vs1}}{(P\rho\gamma)^{1/2}} \quad \text{sonic flow} \qquad [17.12.59]$$

For common gases such as air ($\gamma = 1.4$) the value of η_c is about 0.5.

Two other vent outflow relations which are sometimes used for small pressure drops in the subsonic flow range, for which near-isothermal conditions apply, are

$$f_v = f_{v3} \qquad [17.12.60]$$

or

$$f_v = f_{v4} \qquad [17.12.61]$$

with

$$f_{v3} = [2\rho_o(P - P_a)]^{1/2} \qquad [17.12.62]$$

$$f_{v4} = [2\rho_a P_a \ln(P/P_a)]^{1/2} \qquad [17.12.63]$$

where ρ_a is the density of the gas at atmospheric pressure.

Table 17.15 *Explosion venting of vessels: values of parameters for an equation equivalent to the Bartknecht nomographs (after Simpson, 1986) (Courtesy of American Institute of Chemical Engineers)*

Gas	*Parameter*			
	a	*b*	*c*	*d*
Methane	0.105	0.770	1.23	−0.823
Propane	0.148	0.703	0.942	−0.671
Coke gas	0.150	0.695	1.38	−0.707
Hydrogen	0.279	0.680	0.755	−0.393

17.12.21 Benson and Burgoyne model

In an early treatment of the problem, Benson and Burgoyne (1951) gave the following model for combustion venting of a spherical vessel. From Equation 17.7.15 the rate of increase of the volume V_b, of the burned gas expanding as a sphere of radius r_b is

$$\frac{dV_b}{dt} = 4\pi r_b^2 \frac{dr_b}{dt} \qquad [17.12.64]$$

The flame speed is

$$\frac{dr_b}{dt} = \frac{EW}{\rho_u} \qquad [17.12.65]$$

where E is the expansion ratio defined by Equation 17.7.41, W is the mass rate of combustion and ρ_u the density of the unburned gas. It is pointed out by Lunn that according to Bradley and Mitcheson E in Equation 17.12.65 and the following equations should be replaced by $E-1$. Hence, from Equations 17.12.64 and 17.12.65

$$\frac{dV_b}{dt} = \frac{4\pi r_b^2 W(E-1)}{\rho_u} \qquad [17.12.66]$$

The rate of increase of the burned volume is at a maximum when $r_b = r_v$, the radius of the vessel, so that

$$\left(\frac{dV_b}{dt}\right)_{\max} = \frac{4\pi r_v^2 W(E-1)}{\rho_u} \qquad [17.12.67]$$

The volumetric vent flow Q_v at the venting pressure P_{red} through a vent area A_v is

$$Q_v = \frac{C_d A_v f_v}{\rho_u} \qquad [17.12.68]$$

Then, equating the maximum rate of increase of the burned volume given by Equation 17.12.67 with the volumetric vent outflow in Equation 17.12.68

$$A_v = \frac{4\pi r_v^2 W(E-1)}{C_d f_v} \qquad [17.12.69]$$

The density of the unburned gas ρ_u is obtained assuming adiabatic compression:

$$\rho_u = \rho_o \left(\frac{P_{red}}{P_o}\right)^{1/\gamma} \qquad [17.12.70]$$

17.12.22 Yao model

A numerical model for explosion venting of vessels has been given by Yao and co-workers (Yao *et al.*, 1969; Yao, 1974). The method is intended for venting of low pressure explosions.

The explosions are characterized by a pressure–time profile with two peaks. The model can be made to fit these two peaks fairly well, but to do so requires the use of a turbulence correction factor χ, which allows for effects which enhance the burning velocity or the flame area and is in effect a parameter that can be tuned to fit the experimental results.

Yao (1974) defines a venting parameter α such that

$$\alpha = \frac{(2C_d A_v a)^{1/2}}{S_u V} \left(\frac{P_o}{\rho_{uo}}\right)^{1/2} \left(\frac{\rho_{bo}}{\rho_{uo}}\right)^{7/6} \qquad [17.12.71]$$

and a venting area parameter G,

$$G = aA_v/V \qquad [17.12.72]$$

where a is a characteristic length (which for a spherical vessel is the radius), ρ_{bo} is the density of the burned gas at the initial pressure and ρ_{uo} is the density of the unburned gas at the initial pressure.

Then for a given maximum explosion pressure ΔP_m

$$\alpha \propto G \qquad [17.12.73]$$

and for varying maximum explosion pressure

$$\Delta P_m = f(\alpha) \qquad [17.12.74]$$

Yao gives plots of ΔP_m for the second peak as a function of α showing both experimental and theoretical results.

17.12.23 Bradley and Mitcheson method

D. Bradley and Mitcheson (1978) have given two models for combustion venting of a spherical vessel, one an analytical model and the other a numerical, or computer, model. They treat both subsonic and sonic flow and both venting of unburned gas and venting of burned gas.

They define the following parameters:

$$\bar{A} = \frac{C_d A_v}{A_s} \qquad [17.12.75]$$

$$\bar{S} = \frac{S_v}{a_v}\left(\frac{\rho_{uv}}{\rho_{bv}} - 1\right) \qquad [17.12.76]$$

$$\bar{S}_o = \frac{S_o}{a_{uo}}\left(\frac{\rho_{uo}}{\rho_{bo}} - 1\right) \qquad [17.12.77]$$

with

$$a_{uo} = (P_o \gamma_u/\rho_{uo})^{1/2} \qquad [17.12.78]$$

where a is the velocity of sound, $\bar{A}$ is the vent area ratio, A_s is the surface area of the spherical vessel, A_v is the vent area, C_d is the coefficient of discharge, P is the pressure, S is the burning velocity, ρ is the gas density, the subscripts b, o, u and v denote burned, initial, unburned and at vent conditions, respectively, and an overbar denotes dimensionless.

The authors state that on the assumption that the initial pressure in the vessel and the external pressure are equal, it can be shown that

$$\frac{\bar{S}}{\bar{A}} \geq f_{v2} \qquad [17.12.79]$$

The vent area A_v is that which is just sufficient to vent the volume of gas.

Bradley and Mitcheson give the following volume balance on the gas. The volumetric rate of increase of burned gas is

$$= S_v A_s \frac{\rho_{uv}}{\rho_{bv}} \qquad [17.12.80]$$

The volumetric rate of decrease of unburned gas is

$$= S_v A_s \qquad [17.12.81]$$

Hence, the net rate of increase of gas volume is

$$= S_v A_s \left(\frac{\rho_{uv}}{\rho_{bv}} - 1\right) \qquad [17.12.82]$$

The mass rate of venting is

$$\frac{dm_v}{dt} = C_d A_v (P_v \rho_{uv} \gamma)^{1/2} f_{v2} \qquad [17.12.83]$$

where m_v is the mass vented and P_v the pressure at the vent. Although not given by Bradley and Mitcheson, the further steps in the derivation are evidently as follows. The volumetric rate of venting is

$$\frac{dV_v}{dt} = C_d A_v \left(\frac{P\gamma}{\rho_{uv}}\right)^{1/2} f_{v2} \qquad [17.12.84]$$

where V_v is the volume vented. But

$$\left(\frac{P_v \gamma}{\rho_{uv}}\right)^{1/2} = a_v \qquad [17.12.85]$$

where a_v is the velocity of sound at the vent conditions. Then, equating the net rate of increase of gas volume given by Equation 17.12.82 with the volumetric rate of venting given by Equation 17.12.84 together with Equation 17.12.85 yields the relation given in Equation 17.12.79 but with an equality. These authors also give the relation

$$\frac{\bar{A}}{\bar{S}_o} \geq f_{v2} \zeta \qquad [17.12.86]$$

with

$$\zeta_u = \frac{S_v(\rho_{uv}/\rho_{bv} - 1)}{S_o(\rho_{uo}/\rho_{bo} - 1)} \left(\frac{P_a}{P_v}\right)^{(\gamma_u - 1)/2\gamma_u} \qquad [17.12.87]$$

for the venting of unburned gas and

$$\zeta_b = \zeta_u \left(\frac{\gamma_u \rho_{bv}}{\gamma_b \rho_{uv}}\right)^{1/2} \qquad [17.12.88]$$

for the venting of burned gas, where ζ is the vent flow coefficient. The value of γ in the term f_{v2} in Equation 17.12.86 should also be the appropriate one for unburned or burned gas as the case may be.

17.12.24 Rust model

Rust (1979) has derived the following model for explosion venting of a spherical vessel:

$$V_{fl} = 4/3\,\pi r^3 \qquad [17.12.89]$$

with

$$r = ut \qquad [17.12.90]$$

and

$$V_t = EV_{fl} \qquad [17.12.91]$$

with

$$E = P_{max}/P_o \qquad [17.12.92]$$

$$= V_f/V \qquad [17.12.93]$$

$$\frac{P}{P_o} = \frac{V_t}{V} \qquad [17.12.94]$$

where E is the expansion ratio, P is the absolute pressure, P_{max} is the absolute maximum pressure of the unvented explosion, P_o is the absolute initial pressure, r is the radius of the burned gas before expansion, t is time, u is the velocity of the flame front, V is the volume of the sphere, V_f is the volume of burned gas after expansion at the end of combustion, V_{fl} is the volume of burned gas before expansion and V_t is the volume of burned gas after expansion. Then, from Equations 17.12.89–17.12.92

$$V_t = 4/3\,\pi u^3 t^3 \frac{V_f}{V} \qquad [17.12.95]$$

$$= 4/3\,\pi u^3 t^3 \frac{P_{max}}{P_o} \qquad [17.12.96]$$

But from Equations 17.12.92, 17.12.93 and 17.12.94

$$\frac{P}{V_t} = \frac{P_{max}}{V_f} \qquad [17.12.97]$$

Then, from Equations 17.12.95 and 17.12.97

$$P = 4/3\,\pi u^3 t^3 \frac{P_{max}}{V} \qquad [17.12.98]$$

Hence

$$P = \frac{Kt^3}{V} \qquad [17.12.99]$$

with

$$K = 4/3\,\pi u^3 P_{max} \qquad [17.12.100]$$

From Equation 17.12.99

$$t = \frac{(PV)^{1/3}}{K^{1/3}} \qquad [17.12.101]$$

and from Equations 17.12.96 and 17.12.100

$$V_t = Kt^3/P_o \qquad [17.12.102]$$

Equating the volume production rate $\mathrm{d}V_t/\mathrm{d}t$ with the vent outflow Q_v

$$Q_v = \frac{\mathrm{d}V_t}{\mathrm{d}t} \qquad [17.12.103]$$

differentiating Equation 17.12.102 with respect to t and substituting for t from Equation 17.12.101 gives

$$Q_v = \frac{3(PV)^{2/3}K^{1/3}}{P_o} \qquad [17.12.104]$$

For the volumetric vent outflow Rust uses the relation for subsonic flow

$$Q \propto A_v \Delta P^{1/2} \qquad [17.12.105]$$

where ΔP is the pressure difference. Rust sets P in Equation 17.12.104 equal to $P_{\max}$ to give a maximum flow requirement and ΔP in Equation 17.12.105 equal to the reduced explosion gauge pressure P_{red} and introduces a shape factor F to take account of non-spherical vessels, defined as

$$F = A_F/A_S \qquad [17.12.106]$$

where A_F is the largest spherical surface in the enclosure and A_S the surface area of the sphere having the same volume as the enclosure. Then, from Equations 17.12.104 and 17.12.105 the vent area is

$$A_v = \frac{kF(P_{\max}V)^{2/3}K^{1/3}}{P_{\mathrm{red}}^{1/2}} \qquad [17.12.107]$$

where P_{red} is the reduced pressure (gauge) and k a constant.

In British units, A_v (ft^2), k(lb$_f$ft/s^3), $P_{\max}$(lb$_f$/ft^2), P_{red} (lb$_f$/ft^2) and V(ft^3), the value of k is 8.35 x 10^{-5}.

17.12.25 Nagy and Verakis model

Nagy and Verakis (1983) have derived models for the following cases:

(1) venting of cylinder
  (a) ignition at closed end,
  (b) ignition at vent end,
  (c) ignition at center;
(2) venting of sphere
  (a) ignition at centre.

The gas laws are used in the form

$$P_o V = n_o R T_u \qquad [17.12.108]$$

$$P_m V = n_o R T_b \qquad [17.12.109]$$

$$P V_b = n_b R T_b \qquad [17.12.110]$$

$$P(V - V_b) = n_u R T_u \qquad [17.12.111]$$

where n is the number of moles (lb mol), P is the absolute pressure (lb$_f$/in.^{2}), R is the universal gas constant (lb ft^3/in.^{2} mol °R), T is the absolute temperature (°R) and V is the volume (ft^3) and the subscripts b, m, o and u denote burned, final, initial and unburned. Also, from Equations 17.12.108 and 17.12.109

$$\frac{T_b - T_u}{T_u} = \frac{P_m - P_o}{P_o} \qquad [17.12.112]$$

For the vent gas outflow the authors use the following equations:

$$\frac{\mathrm{d}n_e}{\mathrm{d}t} = \frac{k_{v1}A_v}{T^{1/2}}(P - P_o)^{1/2} \quad \text{subsonic flow} \qquad [17.12.113]$$

and

$$\frac{\mathrm{d}n_e}{\mathrm{d}t} = \frac{k_{v2}A_v}{T^{1/2}}P \quad \text{sonic flow} \qquad [17.12.114]$$

where A_v is the vent area (ft^2), P_o is the atmospheric pressure (lb$_f$/in.^{2}), k_{v1} (mol in.°R$^{1/2}$/lb$^{1/2}$ft^{2}s) and k_{v2} (mol in.°R$^{1/2}$/lb$^{1/2}$ ft^2 s) are constants and the subscript e denotes the end of combustion. The values of the constants in these units are $k_{v1} = 20.6$ and $k_{v2} = 2.63$. These values incorporate a mean molecular weight for the vented gas, the value used being that of air ($M = 29$). The mass balance is

$$\frac{\mathrm{d}n_u}{\mathrm{d}t} + \frac{\mathrm{d}n_b}{\mathrm{d}t} + \frac{\mathrm{d}n_e}{\mathrm{d}t} = 0 \qquad [17.12.115]$$

The rate of pressure rise is obtained by differentiating Equations 17.12.110 and 17.12.111 with respect to *f* and adding them to give

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{1}{V}\left(\frac{\mathrm{d}n_u}{\mathrm{d}t}RT_u + \frac{\mathrm{d}n_b}{\mathrm{d}t}RT_b\right) \qquad [17.12.116]$$

Then, combining Equations 17.12.115 and 17.12.116 gives

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{1}{V}\left[\frac{\mathrm{d}n_b}{\mathrm{d}t}R(T_b - T_u) - \frac{\mathrm{d}n_e}{\mathrm{d}t}RT_u\right] \qquad [17.12.117]$$

The rate of burned gas production is

$$\frac{\mathrm{d}n_b}{\mathrm{d}t} = -\frac{\alpha A P S_u}{RT_u} \qquad [17.12.118]$$

where A is the area of the flame front (ft^2), S_u is the burning velocity (ft/s) and α is the coefficient of turbulence.

The treatment for the individual cases, which is for an open vent, is then as follows. The case of subsonic flow is considered first.

Venting of cylinder, ignition at closed end

For venting of a cylinder with ignition at the closed end, Equations 17.12.113, 17.12.117 and 17.12.118 yield

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{\alpha P S_u}{L}\left(\frac{P_m - P_o}{P_o}\right) - \frac{RT_u k_{v1}(A_v/V)}{T_u^{1/2}}(P - P_o)^{1/2} \qquad [17.12.119]$$

where L is the length of the cylinder (ft).

Setting $\mathrm{d}P/\mathrm{d}t = 0$ for the vent condition and also setting P as the vent pressure P_{red} and rearranging gives

$$\frac{P_{\mathrm{red}}}{(P_{\mathrm{red}} - P_o)^{1/2}} = \frac{RT_u k_{v1} P_o L(A_v/V)}{T_u^{1/2}\alpha S_u(P_m - P_o)} \qquad [17.12.120]$$

Equation 17.12.120 is sometimes referred to as the Pittsburgh method. For venting of burned gas the term $T_b^{1/2}$ replaces $T_u^{1/2}$, in the denominator of the term on the right–hand side to give

$$\frac{P_{\rm red}}{(P_{\rm red}-P_{\rm o})^{1/2}} = \frac{RT_{\rm u}k_{\rm v1}P_{\rm o}L(A_{\rm v}/V)}{T_{\rm b}^{1/2}\alpha S_{\rm u}(P_{\rm m}-P_{\rm o})} \qquad [17.12.121]$$

Venting of cylinder, ignition at vent end

Venting of a cylinder with ignition at the vent end differs in that burned gas is vented from the start so that

$$\frac{{\rm d}n_{\rm b}}{{\rm d}t} = \frac{\alpha APS_{\rm u}}{RT_{\rm u}} - \frac{k_{\rm v1}A_{\rm v}}{T_{\rm b}^{1/2}}(P-P_{\rm o})^{1/2} \qquad [17.12.122a]$$

$$\frac{{\rm d}n_{\rm e}}{{\rm d}t} = \frac{k_{\rm v1}A_{\rm v}}{T_{\rm b}^{1/2}}(P-P_{\rm o})^{1/2} \qquad [17.12.122b]$$

and hence

$$\frac{{\rm d}P}{{\rm d}t} = \frac{\alpha PS_{\rm u}}{L}\left(\frac{P_{\rm m}-P_{\rm o}}{P_{\rm o}}\right) - \frac{RT_{\rm b}k_{\rm v1}(A_{\rm v}/V)}{T_{\rm b}^{1/2}}(P-P_{\rm o})^{1/2} \qquad [17.12.123]$$

Venting of cylinder, ignition at centre

Venting of a cylinder with ignition at the centre is rather more complex in that there are two flame fronts travelling out from the centre. For the rate of rise of pressure P_1 on the closed end side

$$\frac{{\rm d}P_1}{{\rm d}t} = \frac{\alpha P_1S_{\rm u}}{L}\left(\frac{P_{\rm m}-P_{\rm o}}{P_{\rm o}}\right) - \frac{RT_{\rm u}k_{\rm v1}(A_{\rm v}/V)}{T_{\rm u}^{1/2}}(P_1-P_{\rm o})^{1/2} \qquad [17.12.124]$$

and for the rate of rise of the pressure P_2 on the vent end side

$$\frac{{\rm d}P_2}{{\rm d}t} = \frac{\alpha P_2S_{\rm u}}{L}\left(\frac{P_{\rm m}-P_{\rm o}}{P_{\rm o}}\right) - \frac{RT_{\rm u}k_{\rm v1}(A_{\rm v}/V)}{T_{\rm b}^{1/2}}(P_2-P_{\rm o})^{1/2} \qquad [17.12.125]$$

Summing these two rates of pressure rise gives

$$\frac{{\rm d}P}{{\rm d}t} = \frac{2\alpha PS_{\rm u}}{L}\left(\frac{P_{\rm m}-P_{\rm o}}{P_{\rm o}}\right) - R\left(T_{\rm u}^{1/2}+\frac{T_{\rm u}}{T_{\rm b}^{1/2}}\right)k_{\rm v1}(A_{\rm v}/V)(P-P_{\rm o})^{1/2} \qquad [17.12.126]$$

Venting of sphere, ignition at centre

It might be thought that venting of a sphere is a simple case, but this is not so, since the flame front distorts as the gas flows through the vent. The rate of rise of the pressure is considered in two stages. For the period before the burned gas reaches the vent

$$\frac{{\rm d}P}{{\rm d}t} = \frac{\alpha PAS_{\rm u}}{V}\left(\frac{P_{\rm m}-P_{\rm o}}{P_{\rm o}}\right) - \frac{RT_{\rm u}k_{\rm v1}(A_{\rm v}/V)}{T_{\rm u}^{1/2}}(P-P_{\rm o})^{1/2} \qquad [17.12.127]$$

and for the period after $T_{\rm b}^{1/2}$ replaces $T_{\rm u}^{1/2}$ in the denominator of the second term on the right-hand side.

The relations for sonic flow may be obtained in a similar manner using Equation 17.12.114.

Summarizing the various cases, Nagy and Verakis state that the most representative relationship for venting is Equation 17.12.121 for the venting of a cylinder with ignition at the closed end. It is that equation which is referred to by Lunn as the Pittsburgh method.

Effect of vent opening pressure

The effect of the vent opening pressure $P_{\rm v}$ has been allowed for by Nagy and Verakis by modifying Equation 17.12.121 to give

$$\frac{P_{\rm red}+\Delta P_{\rm v}}{(P_{\rm red}-P_{\rm o})^{1/2}} = \frac{RT_{\rm u}k_{\rm v1}P_{\rm o}L(A_{\rm v}/V)}{T_{\rm b}^{1/2}\alpha S_{\rm u}(P_{\rm m}-P_{\rm o})} \qquad [17.12.128]$$

where $\Delta P_{\rm v}$ is the overpressure at which the vent opens ($\rm lb_f/in.^2$ g).

17.12.26 Singh method

J. Singh (1979b, 1988b) has described a method of vent sizing based on the venting parameter $(A/S_{\rm o})$ of Bradley and Mitcheson described above.

These latter workers defined a maximum pressure rise $\Delta P_{\rm m}$ above the initial pressure and gave a number of plots of $\Delta P_{\rm m}$ vs $(\bar{A}/\bar{S}_{\rm o})$ The plot given by Singh is shown in Figure 17.28. The full lines represent sets of data reported by various workers, the dashed lines approximate upper and lower limits on these data. The change of slope in the lines is due to the transition from subsonic to sonic flow as the pressure rises.

The equations given by Singh for the two sets of lines are as follows. The basic equation is

$$\Delta P_{\rm m} = k(\bar{A}/\bar{S}_{\rm o})^{-n} \qquad [17.12.129]$$

with for the upper limit lines

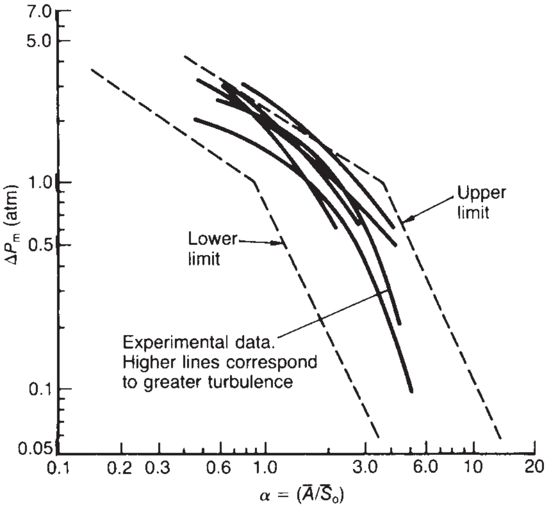

Figure 17.28 *Explosion venting of vessels: effect of normalized vent ratio on maximum pressure rise (J. Singh, 1979b) (Courtesy of Chemical Engineering)*

$k = 12.32, \quad n = 2, \quad \Delta P_m \leq 1$

$k = 2.4, \quad n = 0.7, \quad \Delta P_m > 1$

and for the lower limit lines

$k = 0.77, \quad n = 2, \quad \Delta P_m \leq 1$

$k = 0.91, \quad n = 0.7, \quad \Delta P_m > 1$

where $\bar{A}$ is the dimensionless vent area, ΔP_m is the maximum pressure rise (atm), $\bar{S}_o$ is the dimensionless burning velocity at the initial conditions and k is a constant.

The lower limit lines correspond to situations with essentially zero turbulence. If the burning velocity term in the venting parameter is adjusted to allow for an enhancement of burning velocity by turbulence by a factor of about 4 the upper limit lines are obtained. In other words, the difference in the two sets of lines is mainly due to turbulence.

The burning velocity term of the venting parameter is defined in Equation 17.12.77. The density ratio term may be approximated by the relation

$$\frac{\rho_{uo}}{\rho_{bo}} = \frac{T_{fo}}{T_{uo}} \qquad [17.12.130]$$

where T_f is the adiabatic flame temperature (K), ρ is the density of the gas (kg/m^3) and the subscripts b, o and u denote burned, initial and unburned, respectively. The density ratio tends to lie in the range 7.5–8.5 for most fuels.

J. Singh (1988b) has extended his treatment to non-spherical vessels. From Equation 17.7.137 the rate of pressure rise dP/dt is proportional to the area A_f of the flame front. The following areas apply to different vessel geometries:

$$A_f = 4\pi r_s^2 \quad \text{sphere} \qquad [17.12.131a]$$

$$= A_s \qquad [17.12.131b]$$

$$A_f = 4\pi r_c^2 \quad \text{long cylinder with central ignition} \qquad [17.12.132a]$$

$$= 4A_x \qquad [17.12.132b]$$

$$A_f = 4\pi r_c^2 \quad \text{long cylinder with end ignition} \qquad [17.12.133a]$$

$$= 2A_x \qquad [17.12.133b]$$

where A_f is the area of the flame front (m^2), A_s is the surface area of the sphere (m^2), A_x is the cross-sectional area of the cylinder (m^2), r_c is the radius of the cylinder (m) and r_s is the radius of the sphere (m).

Singh's method is to treat A_s in the venting parameter as equivalent to A_f and to adjust it for non-spherical vessels according to the above relations.

The results of the method are illustrated in Table 17.16.

***Table 17.16** Explosion venting of vessels: overpressures (pressure above vent opening pressure, ΔP_m) in non-spherical vessels using Singh's method (after J. Singh, 1988b) (Courtesy of Butterworth–Heinemann)*

Vent area (m^2)	*Experimental* (bar)	*Theoritical* (bar)	
		Unmodified[a]	*Modified*[b]

0.1	0.24	3.01	0.22
0.067	0.37	4.0	0.48
0.02	1.22	9.31	1.81

[a] Calculated using Equation 17.12.129, unmodified.

[b] Calculated using Equation 17.12.129, modified by using Equation 17.12.132 or 17.12.133.

17.12.27 Method of Epstein, Swift and Fauske

Epstein, Swift and Fauske (1986) have developed a model for explosion venting of a spherical vessel on the following lines. The mass balance is

$$\frac{dm_u}{dt} + \frac{dm_b}{dt} + \frac{dm_e}{dt} = 0 \qquad [17.12.134]$$

The mass production of burned gas is

$$\frac{dm_b}{dt} = 4\pi r_b^2 \rho_u \phi S_u \qquad [17.12.135]$$

and the mass vent outflow is

$$\frac{dm_e}{dt} = A_v G_v \qquad [17.12.136]$$

where ϕ is a turbulence correction factor. The densities of the unburned and burned gas are

$$\frac{\rho_u}{\rho_{uo}} = \left(\frac{P}{P_o}\right)^{1/\gamma_b} \qquad [17.12.137]$$

$$\frac{\rho_b}{\rho_{bo}} = \left(\frac{P}{P_o}\right)^{1/\gamma_b} \qquad [17.12.138]$$

The volume of the closed vessel is

$$V = \frac{m_u}{\rho_u} + \frac{m_b}{\rho_b} \qquad [17.12.139]$$

Then substituting for ρ_u and ρ_b from Equations 17.12.137 and 17.12.138 in Equation 17.12.139 and then differentiating the latter with respect to t, eliminating dm_u/dt and dm_b/dt using Equations 17.12.135 and 17.12.136, solving for dP/dt, setting $\gamma_u = \gamma_b$ and applying Equation 17.12.139 again yields

$$\frac{V}{\gamma_b}\frac{d \ln P}{dt} = 4\pi r_b^2 \left(\frac{\rho_u}{\rho_b} - 1\right)\phi S_u - \frac{A_v G_v}{\rho_u} \qquad [17.12.140]$$

Combining Equations 17.12.135 and 17.12.138, differentiating with respect to time and combining the result with Equation 17.12.140 to eliminate dP/dt yields

$$4\pi r_b^2 \frac{dr_b}{dt} = 4\pi r_b^2 \left[\left(\frac{\rho_u}{\rho_b}\right)\phi S_u - \frac{r_b}{3V}\right]\left[4\pi r_b^2 \left(\frac{\rho_u}{\rho_b} - 1\right)\phi S_u - \frac{A_v G_u}{\rho_u}\right] \qquad [17.12.141]$$

Dividing Equation 17.12.140 by Equation 17.12.141 gives

$$\frac{1}{\gamma_b}\frac{d \ln P}{dt} = \frac{B(\rho_u/\rho_b - 1)Z^{2/3} - 1}{B[\rho_u/\rho_b - (\rho_u/\rho_b - 1)Z]Z^{2/3} + Z} \qquad [17.12.142]$$

with

$$B = \frac{\rho_u \phi S_u A_s}{A_v G_v} \qquad [17.12.143]$$

and

$$Z = \frac{4\pi r_{\mathrm{b}}^3}{3V} \qquad [17.12.144]$$

where B is a dimensionless burning number and Z a dimensionless burned volume. For sonic flow Epstein, Swift and Fauske use

$$G_{\mathrm{v}} = (2P\rho_{\mathrm{u}})^{1/2} \qquad [17.12.145]$$

Making a number of additional assumptions the authors derive

$$\frac{P_{\mathrm{f}}}{P_{\mathrm{o}}} = \frac{P_{\max}}{P_{\mathrm{o}}}\left(\frac{\lambda + B}{1 + B}\right)^{\gamma_{\mathrm{b}}} \qquad [17.12.146]$$

with

$$\lambda = \frac{(P_{\mathrm{set}}/P_{\mathrm{o}})^{1/\gamma_{\mathrm{b}}} - 1}{(P_{\max}/P_{\mathrm{o}})^{1/\gamma_{\mathrm{b}}} - 1} \qquad [17.12.147]$$

where P_{set} is the vent opening pressure and λ is a dimensionless vent opening pressure.

The vent area A_{v} may be obtained from the burning number B defined by Equation 17.12.143.

The model contains a number of approximations. The authors compared their results with results given from the computer model of Bradley and Mitcheson and obtained a good fit, leading them to conclude that the approximations were justified.

This model has been extended by Swift and Epstein (1987) for subsonic flow. For subsonic flow they use

$$G_{\mathrm{v}} = C_{\mathrm{d}}[2P\rho_{\mathrm{u}}(1 - (P_{\mathrm{a}}/P)]^{1/2} \qquad [17.12.148]$$

where P_{a} is atmospheric pressure. They derive an equation equivalent to Equation 17.12.146 for sonic conditions as

$$\frac{P_{\mathrm{f}}}{P_{\mathrm{a}}} = 1 + \left[\left(\frac{P_{\max}}{P_{\mathrm{o}}}\right)^{1/\gamma_{\mathrm{b}}} - 1\right]^2 B^2 \qquad [17.12.149]$$

where P_{f} is the absolute final pressure of the vented explosion, or the reduced pressure.

Then rearranging Equation 17.12.149 and substituting for B from Equation 17.12.143 gives

$$A_{\mathrm{v}} = \frac{A_{\mathrm{s}}\rho_{\mathrm{u}}\phi S_{\mathrm{u}}}{C_{\mathrm{d}}G_{\mathrm{v}}}\frac{[(P_{\max}/P_{\mathrm{o}})^{1/\gamma_{\mathrm{b}}} - 1]}{(P_{\mathrm{f}}/P_{\mathrm{o}} - 1)^{1/2}} \qquad [17.12.150]$$

17.12.28 Other models

Morton and Nettleton's model for explosion in a closed vessel was described in Section 17.7. The model may be used to determine the vent opening pressure for a given proportion of burned gas in the total gas vented.

As an illustrative example, consider the plot of the pressure ratio P/P_{o} vs the radius ratio r/a shown in Figure 17.29. From this figure a spherical vessel of 5 m radius (520 m$^{3)}$ with a vent designed to open at 1 barg ($P/P_{\mathrm{o}} = 2$) will have a value of r/a of 0.77. Hence, the volume of unburned gas will be 280 m^3 and that of burned gas 240 m^3 at the start of venting.

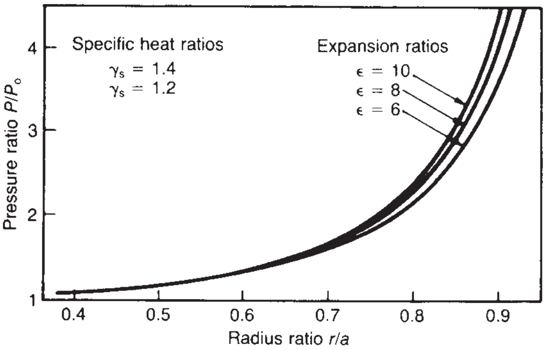

Figure 17.29 *Explosion venting of vessels: variation of pressure with flame radius in a spherical vessel (V.M. Morton and Nettleton, 1977) (Courtesy of the Combustion Institute)*

The model of Fairweather and Vasey (1982) for explosion in a closed vessel was described in Section 17.7. The treatment given by these authors also extends to explosion venting. The mass production of burned gas is given by Equation 17.7.37. The mass vent outflow of gas is obtained from Equation 17.12.51. The mass of unburned gas is given by

$$m_{\mathrm{u}} + m_{\mathrm{b}} = m_{\mathrm{o}} - m_{\mathrm{e}} \qquad [17.12.151]$$

The volume of unburned gas is obtained assuming adiabatic compression of the initial gas:

$$V_{\mathrm{u}} = V_{\mathrm{o}}\frac{m_{\mathrm{u}}}{m_{\mathrm{o}}}\left(\frac{P}{P_{\mathrm{o}}}\right)^{-1/\gamma_{\mathrm{b}}} \qquad [17.12.152]$$

The volume of burned gas is obtained from Equation 17.7.4. The temperatures of the unburned and burned gases are obtained from Equations 17.7.9, 17.7.10, 17.7.27 and 17.7.28.

17.12.29 Elongated vessels

Vessels which have a length/diameter (L/D) ratio of 3 or less may be regarded as compact, those with an L/D greater than that as elongated.

For L/D ratios greater than 6, the usual practice is to install one vent for each section divided lengthwise to lengths L_i such that each L_i/D is approximately 3.

In their early studies of venting, Cousins and Cotton (1951a) investigated a range of L/D ratios from 1.41 to 22.1. The systems which they studied are given in Table 17.14.

They did experiments with 5% propane–air and 40% hydrogen–air mixtures, with open vents and with initial pressures of 0, 15 and 45 psig and measured the maximum pressure of the vented explosion. They expressed their results in terms of plots of this maximum pressure against the vent ratio. Some of the results are shown in Figure 17.30. They show that there is a reasonable correlation with vent ratio across the L/D range investigated.

The work of Singh, described above, also covers elongated vessels with an L/D ratio up to 30.

Further treatment of venting of high L/D containers is given in Section 17.13 on the explosion venting of pipes and ducts.

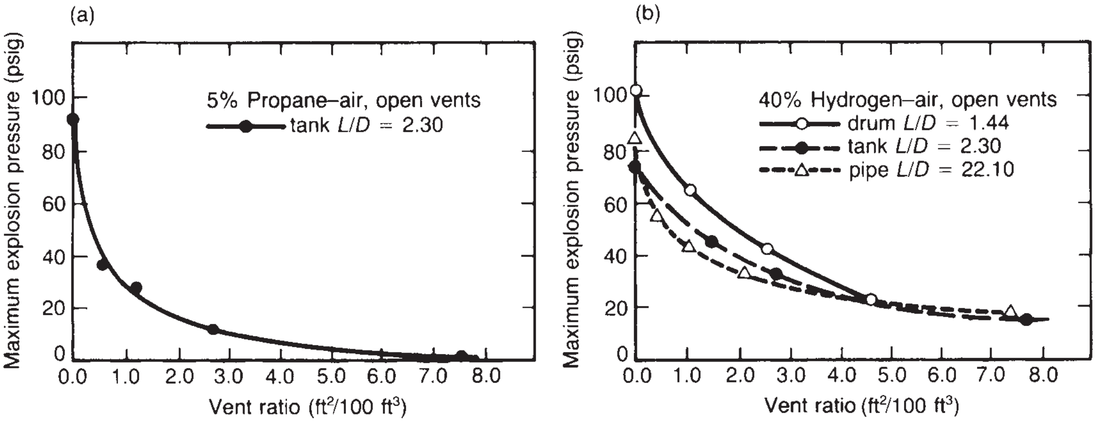

Figure 17.30 *Explosion venting of vessels: effect of vessel aspect ratio on maximum explosion pressure (Cousins and Cotton, 1951a): (a) 5% propane–air mixture in a tank (L/D = 2.30) and (b) 40% hydrogen–air mixture in a drum (L/D = 1.44), tank (L/D = 2.30), and pipe (L/D = 22.1) (Courtesy of Chemical Engineering)*

17.12.30 Critique of available methods

The methods available for the prediction of the vented explosion pressure have been reviewed by Lunn. Of the empirical methods, his preferred methods are those of Cubbage and Simmonds and of Rasbash.

For the Cubbage and Simmonds method to be applicable it is necessary that the vent opening pressure should not exceed 7 kPa and that the vent panel have a low inertia. For these conditions the second peak equation of these authors gives good results. For finite vent opening pressure the results are not so good, since the method does not take vent opening pressure into account.

For finite vent opening pressures up to 7 kPa Lunn states that the first three terms of the Rasbash equation give good results for the first peak.

For high vent opening pressures, Lunn recommends the use of the data given by Cousins and Cotton or the Bartknecht K_G method for good results.

Lunn states that the methods of Cubbage and Marshall, Runes, Decker, Dragosavic and Burgoyne and Wilson are not recommended for general use.

Of the theoretical methods which he reviews, that of Bradley and Mitcheson gives an upper bound.

17.12.31 Venting phenomena

If the vent is an open one, venting will result in the emergence of flame. The flame may be substantial. C.J.M. van Wingerden (1989c) has reported a jet flame 18 m long.

If the vent has a duct, there is potential for unburned gas to undergo further combustion in the duct, possibly resulting in overpressure in the duct. The ducting needs to be designed to avoid this.

17.12.32 Reaction force due to venting

Venting causes a back reaction on the vessel. The determination of this force may be approached by considering the flow from the vessel or the pressure in the vessel.

A fundamental treatment based on the flow is given by Duncan, Thorn and Young (1960) and by Leung (2002). The mass vent flow from the vessel is $A_v \rho u$, the mass vented in time t is $A_v \rho u t$, its momentum is $A_v \rho u^2 t$ and the rate of change of momentum is $A_v \rho u^2$. The force is equal to the rate of change of momentum thus

$$F_r = A_v \rho u^2 \qquad [17.12.153]$$

where A_v, is the vent area, F_r is the force due to back reaction, t is the time, u is the velocity of the fluid and ρ is the density of the fluid.

Alternatively, the force may be obtained from the maximum pressure P_{red} in the vessel during venting.

The reaction force has also been measured in tests. NFPA 68: 1994 gives the following empirical equation for the reaction force, applicable only to enclosures without ducts:

$$F_r = 1.2 A_v P_{red} \qquad [17.12.154]$$

where A_v is the vent area (in.^{2}), F_r is the reaction force (lb$_f$) and P_{red} is the reduced pressure (gauge) (lb$_f$/in.^{2}).

NFPA 68 states that the reaction force can be considered as equivalent to a force applied at the geometric centre of the vent. It warns, however, against assuming that the forces on two opposing vents will cancel out, since one vent may open before the other.

It further states that equivalent static force on the structure supporting the vented enclosure is given by Equation 17.12.154 but with the constant 1.2 replaced by 0.62.

Back reaction forces due to venting are also discussed in Chapter 12.

17.12.33 Vent ducting effects

It has been found that the presence of a vent duct can have a marked effect on the maximum pressure in a vented explosion.

Figure 17.31 is a graph from the work of Pineau, Giltaire and Dangreux (1978), showing the pressure in the vessel and in the duct as a function of duct length for a 10 m^3 vented vessel.

Typically, the maximum pressure rises rapidly with the initial increase in the length of the tube and then reaches a plateau or increases or decreases at a much slower rate. This effect was described by Sagalova and Resnick (1962) for dust explosions and has been observed by Kordylewski and Wach (1986, 1988) for gas.

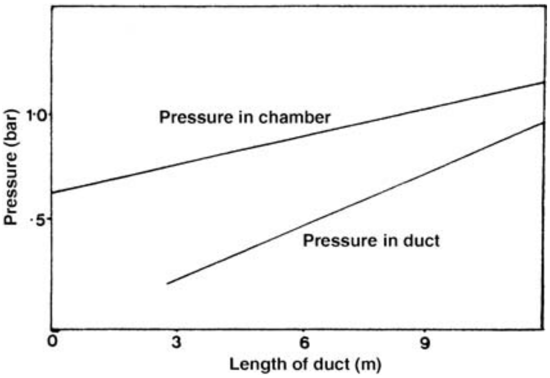

Figure 17.31 *Explosion venting of vessels: effect of vent duct on pressure in a 10 m^3 vessel (Cross and Farrer, 1982; after Pineau, Giltaire and Dangreaux, 1978)*

The latter conducted experiments using a 22 l vessel with vents and vent tubes of 21, 25 and 35 mm diameter. The gas used was town gas. They were unable to account for the increase in the maximum pressure by the flow resistance of the duct and instead considered turbulence, secondary explosions, acoustic oscillations and Helmholtz oscillations to be responsible. They found that acoustic oscillations can increase the maximum overpressure by 203 times for tube length in the range 0–20 diameters.

17.12.34 Vent design

Design of a vent system based on a vent panel includes consideration of the following features: (1) reduced explosion pressure, (2) vent opening pressure, (3) vent area, (4) vent distribution, (5) vent opening, and (6) vent panel.

The reduced explosion pressure for a vented explosion will be determined by the mechanical strength of the containment. Explosion venting is used for low-strength as well as high-strength equipment.

The vent opening pressure also needs to be set before the vent area can be calculated. The values of the vent opening pressure P_{stat} to which the Bartknecht nomographs apply are $0.1 \le P_{\text{stat}} \le 0.5$ barg.

The distribution of the vent area determined is generally not critical for vessels, though it may be more important for buildings and modules.

The time of opening of the vent can affect the pressure developed. A sudden opening, such as occurs with a bursting disc, tends to increase turbulence. A smooth opening is desirable to minimize turbulence.

The design of the vent panel itself is important.

17.12.35 Vent panel design

Some features which need to be taken into account in the design of the vent panel itself are (1) panel material, (2) panel inertia, (3) relieving fasteners, (4) panel restraint system, (5) guarding, and (6) maintainability.

Detailed guidance on vent panel design is given in the *HSE Guide* and in NFPA 68: 1994.

The guidance given by W.B. Howard and Karabinis (1980) for vent panels for explosion venting of buildings is outlined in Section 17.14.

17.12.36 Vent panel dynamics

The static pressure required to move a vent panel slowly may be quite low, but the pressure needed to impart a high acceleration to the panel so that it moves rapidly may be much higher. Thus

$$F = Ma \qquad [17.12.155]$$

and hence dividing by the area A of the panel

$$P = wa \qquad [17.12.156]$$

with

$$w = M/A \qquad [17.12.157]$$

where a is the acceleration of the panel, F is the force on the panel, M is the mass of the panel, P is the pressure and w is the weight per unit area of the panel.

An analysis of vent panel dynamics has been given by Rust (1979). He considers the following five situations:

(1) Panel moves by translation; vertical panel; horizontal translation.
(2) Panel moves by translation; horizontal panel; vertical translation.
(3) Panel hinged along width; vertical panel; horizontal rotation.
(4) Panel hinged along width; horizontal panel; vertical rotation against gravity.
(5) Panel hinged along width; horizontal panel; vertical rotation with gravity.

Figure 17.32 illustrates cases (1) and (3).

For a panel of width W and length L which moves by translation a distance S to give a peripheral area WL equal to the vent area A_{v} the peripheral area is $2S(W+L)$. Equating these two areas

$$S = \frac{WL}{2(W + L)} \qquad [17.12.158]$$

At pressure P the acceleration a of the panel is

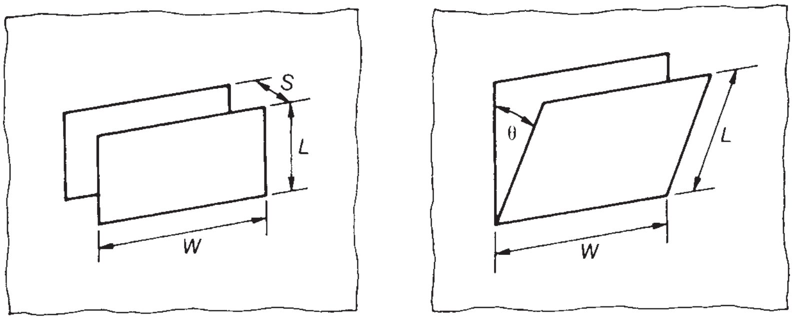
$$a = PA_{\text{v}}/M \qquad [17.12.159]$$

where M is the mass of the panel. From Equations 17.12.99 and 17.12.159

$$a = \frac{Kt^3 A_{\text{v}}}{VM} \qquad [17.12.160]$$

Integrating Equation 17.12.160 to obtain the velocity v attained by the panel with the initial condition $t = t_{\text{v}}$, $v = 0$, where t_{v} is the time of start of venting, and integrating again to obtain the distance s travelled by the panel with the initial condition $t = t_{\text{v}}$, $s = 0$, substituting at $t = t_{\text{v}}$ pressure $P = P_{\text{v}}$, the vent opening pressure, and defining a panel 'density' D,

$$D = Mg/A_{\text{v}} \qquad [17.12.161]$$



Translation Rotation

Figure 17.32 *Explosion venting of vessels: movement of vent panels for release of gas (Rust, 1979) (Courtesy of Chemical Engineering)*

where g is the acceleration due to gravity, yields

$$S = g\left(\frac{V}{K}\right)^{2/3}\frac{C}{D} \qquad [17.12.162]$$

with

$$C = \frac{P^{5/3}}{20} - \frac{P_{\mathrm{v}}^{4/3}P^{1/3}}{3} + \frac{P_{\mathrm{v}}^{5/3}}{5} \qquad [17.12.163]$$

where P is the pressure (gauge) ($\mathrm{lb_f/ft^2}$) and P_{v} is the vent opening pressure (gauge) ($\mathrm{lb_f/ft^2}$). Relations for the other cases are derived in a similar manner. For cases of rotation, the angle θ to give the vent area is

$$\theta = \frac{W}{W+L} \qquad [17.12.164]$$

and an additional constant E is obtained,

$$E = \frac{P^{2/3}}{2} - P_{\mathrm{v}}^{1/3}P^{1/3} + \frac{P^{2/3}}{2} \qquad [17.12.165]$$

Table 17.17 summarizes Rust's equations for vent panel dynamics. In his worked example, in Equations 17.12.163 and 17.12.165 Rust uses a corrected vent opening pressure $P_v' = (P_{\mathrm{v}} + D)$, where D is the 'density' of the vent panel ($\mathrm{lb/ft^2}$) and P_v' is the corrected vent opening pressure (gauge) ($\mathrm{lb_f/ft^2}$), instead of P_{v}.

Table 17.17 *Explosion venting of vessels: equations for vent panel dynamics given by Rust (after Rust, 1979) (Courtesy of Chemical Engineering)*

Horizontal translation	$s = g\left(\frac{V}{K}\right)^{2/3}\frac{C}{D}$
Horizontal rotation	$\theta = \frac{3g}{2L}\left(\frac{V}{K}\right)^{2/3}\frac{C}{D}$
Vertical translation upward	$s = g\left(\frac{V}{K}\right)^{2/3}\left(\frac{C}{D} - E\right)$
Vertical rotation against gravity	$\theta = \frac{3g}{2L}\left(\frac{V}{K}\right)^{2/3}\left(\frac{C}{D} - E\right)$
Vertical rotation with gravity	$\theta = \frac{3g}{2L}\left(\frac{V}{K}\right)^{2/3}\left(\frac{C}{D} + E\right)$

17.12.37 Vent details

Guidance on details of vents for enclosures, both buildings and equipment, is given in NFPA 68: 1994. The vents considered are (1) open or unobstructed vents and (2) closed or sealed vents.

Open vents are applicable to buildings rather than equipment. With a building it is often not practical to have a completely open aperture, but there are various arrangements which can provide good vents. They include louvres, open roof vents and hangar-type doors which can be moved to one side when an operation which may need to be vented is in progress.

Closed vents may be used for either buildings or equipment. Features which can constitute a vent closure for a building or room include a door, window, movable sash, roof or wall panel or skylight. On equipment a vent closure may take the form of a charging door or inspection port, a dedicated venting device or a diaphragm. Diaphragm materials described include paper, cloth, plastic and metal. The diaphragm may be provided with a cutter.

17.12.38 Vent duct design

The effect of a vent duct on the reduced explosion pressure has already been mentioned. There is available guidance to assist in allowing for this effect.

Correlations due to Bartknecht are shown in Figures 17.33 and 17.34. Figure 17.33, given originally by Bartknecht (1981a), gives the relationship between the reduced explosion pressure with the duct and that without a duct. There are two lines, the parameter being the duct length. Figure 17.34 gives a further correlation for the same relationship, but in this case the parameter is the gas velocity.

Both correlations were given in NPFA 68: 1988, but only the first is retained in NFPA 68: 1994.

17.12.39 Safe discharge

Explosion venting gives rise to three effects: a pressure wave, and discharges of flame and unburned material. All three effects need to be handled safely.

If the material discharged is sufficiently toxic, this may invalidate the venting option.

17.13 Explosion Venting of Ducts and Pipes

In general, where combustion of a flammable gas mixture occurs in a duct or pipe, there is a possibility that if the duct

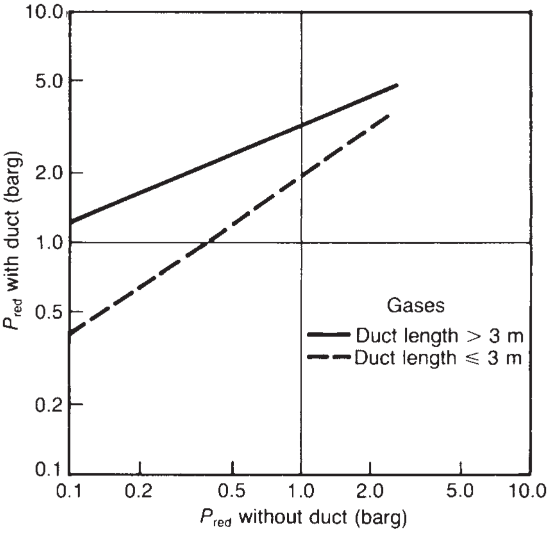


Figure 17.33 Explosion venting of vessels: effect of length of vent duct on reduced pressure (NFPA 68: 1994). See text for details (reproduced with permission from NFPA 68 Deflagration Venting, © 1994, National Fire Protection Association, Quincy, MA 02269). See note to Figure 17.25

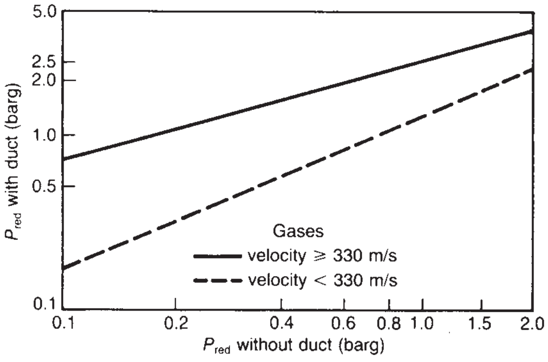

Figure 17.34 Explosion venting of vessels: effect of velocity in vent duct on reduced pressure (NFPA 68: 1994). See text for details (reproduced with permission from NFPA 68 Deflagration Venting, © 1994, National Fire Protection Association, Quincy, MA 02269). See note to Figure 17.25

is long enough the flame front will accelerate to the point where the deflagration turns into a detonation. Detonation is considered in Section 17.6 and is not considered further in this section, which deals with the explosion venting of deflagrations.

The venting of elongated vessels was described in Section 17.12. The methods given there cover the venting of containers with length/diameter (L/D) ratios up to 30.

Accounts of explosion venting of ducts are given in the *Guide to the Use of Flame Arresters and Explosion Reliefs* (HSE, 1965 HSW Bklt 34), *Explosions* (Bartknecht, 1981a), *Venting Gas and Dust Explosions* (Lunn, 1984b) and in NFPA 68: 1994 *Deflagration Venting.*

17.13.1 Experimental studies

The design methods for explosion relief of ducts have tended to draw heavily on experimental work at the JFRO by Rasbash and Rogowski (Rasbash and Rogowski, 1960a,b; Rogowski and Rasbash, 1963).

The duct dimensions used in the experiments were from 3 in. (76 mm) and 6 in. (152 mm) diameter to 12 in. (305 mm) square section and from 6 to 30 ft (1.8–9 m) long. Most of the experiments were done using propane–air and pentane–air mixtures.

The results of the work are summarized by Lunn (1984b) as follows. For a base case in which a single open vent was located at one end of a straight, unobstructed duct with the ignition source either 15 cm from the closed end or a quarter of the way along the duct and with the most explosive concentration of the gas–air mixture, the vented explosion pressure P_{red} at any position along the duct was proportional to the ratio of the vent area to the cross-sectional area of the duct, or vent coefficient, K, the constant of proportionality ranging from 5.6 to 12.6 for the conditions $6 < L/D < 30$ and $2 < K < 32$. For a vent coefficient K of unity, the maximum explosion pressure P_{max} was proportional to L/D, the constant of proportionality being 0.49 for the conditions $6 < L/D < 48$. The pressure and proportionality constants in the relations just described are in SI units (kPa). Lower vented explosion pressures were obtained when the ignition source was located near the vent or when a given vent area was provided by distributing a number of small vents along the duct.

More recent work is that described by Bartknecht (1981a). The account given by Bartknecht of explosions, both deflagrations and detonations, was summarized in Section 17.5. His recommendations for protection of pipes, which are a combination of containment and relief, are described below.

Work on combustion in pipes has drawn attention to several distinguishing phenomena which are relevant to the design of explosion venting for such systems. If a flammable mixture is ignited in a vessel and then enters an attached pipe, the flame front at the point of entry is fully developed and turbulent. It propagates much more strongly than one arising from spark ignition in the pipe itself.

A flame front travelling down a pipe tends to accelerate, with possible run-up to detonation. In addition, turbulence promoters such as bends and valves can cause sudden accelerations of the flame front.

If a flame front travels down an inadequately vented pipe and then enters a vessel containing a flammable mixture, it does so as a jet flame which constitutes a massive ignition source, which can cause a violent explosion in the vessel.

17.13.2 *HSE Guide* method

The methods given in the *HSE Guide* are based on the work of Rasbash and Rogowski just described. Essentially, the same methods were used in NFPA 68: 1978, which was superseded by a revision in 1988. Since the methods in the revision of NFPA 68 are a development from this work, although the link is no longer so clear, the *HSE Guide* method is described first.

Unless otherwise stated, *HSE Guide* methods are applicable to gas mixtures at atmospheric pressure. They are applicable to ducts with an L/D ratio of 6 or more. Other methods are available for vessels with an L/D ratio of 3 or less. For containers with an L/D ratio greater than 3 but less than 6 the use of methods for vessels with an L/D ratio of 3 or less is increasingly conservative as the L/D ratio approaches 6.

In designing explosion vents for ducts the following cases are distinguished:

(1) Gas velocity <10 ft/s
    (a) straight unobstructed ducts with $L/D < 30$,
    (b) straight unobstructed ducts with $L/D > 30$,
    (c) ducts containing obstacles;
(2) Gas velocity 10–60 ft/s
    (a) unobstructed ducts,
    (b) ducts containing obstacles.

The design of vent areas is essentially based on the relations between the maximum pressure P and the vent coefficient K.

If the gas is stationary or has a velocity less than 10 ft/s, the duct is straight and unobstructed and the L/D ratio is less than 30, only one relief opening is generally sufficient. The maximum pressure is given by the equation

$$P = k_1 \frac{L}{D} + k_2 K \qquad [17.13.1]$$

where D is the diameter of the duct (ft), K is the ratio of the cross-sectional area of the duct to the vent area, or vent coefficient, L is the length of the duct (ft), P is the maximum pressure ($\mathrm{lb_f/in.^2}$) and k_1 and k_2 are constants. The values of the constant k_1 and k_2 are:

K	k_1	k_2
1	0.07	0
1–2	0.035	0.9
2–23	0	1.8

If a single vent is used, it should be placed as near as possible to the most probable location of the ignition source, but if this latter is uncertain, the vent should be placed near the centre of the duct.

For this vent system, a vent weighing not more than 2 $\mathrm{lb/ft^2}$ and held by springs or magnets is suitable. An alternative relief is a bursting disc designed to burst at a pressure one half of the maximum pressure given in Equation 17.13.1.

If the gas has a velocity less than 10 ft/s and the duct is straight and unobstructed, but the L/D ratio is greater than 30, it is necessary to have more than one relief opening. The maximum pressure is given by the equation

$$P = k_3 \frac{L_1}{D} + k_4 \qquad [17.13.2]$$

where L_1 is the distance between relief openings (ft) and k_3 and k_4 are constants. The values of the constants k_3 and k_4 and the maximum value of the distance between relief openings $L_{1\mathrm{max}}$ (ft) are:

K	$L_{1\mathrm{max}}$ (diameters)	k_3	k_4
1	60	0.04	0
2	30	0.06	0.1
4	20	0.07	0.2
8	15	0.08	0.3

The open end of a long duct may be regarded as an explosion relief opening. In this context an open end is an end leading without restriction to atmosphere or to a vessel which is itself provided with explosion reliefs or to a room of volume 200 times greater than that of the duct. For such an open end $K = 1$.

If the end of a duct is not open or if it may be regarded as restricted, an explosion relief should be located as near as possible to the end. For this vent system also, vents weighing not more than 2 $\mathrm{lb/ft^2}$ of vent area and held by springs or magnets are suitable.

If at a gas velocity of less than 10 ft/s the duct contains obstacles or features such as sharp right angle elbows or tees, the maximum pressure resulting from an explosion is greatly increased. An obstacle blocking only 5% of the cross-sectional area of the duct can increase the maximum pressure by a factor of 2–3, whilst an orifice blocking 30% of the duct area can increase the pressure by a factor of 10.

Any bend sharper than a long, sweeping, smooth bend and any obstruction blocking more than 5% of the cross-sectional area of the duct should be regarded as an obstacle.

If there is a long straight duct connected to an obstacle, then to reduce the maximum pressure to 2 $\mathrm{lb_f/in.^2}$, explosion relief openings of size $K = 1$ should be located as near as possible to the obstacle and at 6 diameters on either side of it. Thereafter, the straight unobstructed section of the duct may be treated in the usual way.

For a vent system around an obstacle, a vent weighing not more than 3 $\mathrm{lb/ft^2}$ and held by springs or magnets is suitable.

If the gas has a velocity of 10–60 ft/s and the duct is straight and unobstructed, the explosion relief openings required to limit the maximum pressure resulting from an explosion to 2 $\mathrm{lb_f/in^2}$. are as follows:

D (ft)	L_1/D	K
≤1.5	12	1
–	6	2
1.5–2.5	9	1
–	5	2

For this vent system, the weight of vents depends on the velocity of the gas. For gas velocities of 25 and of 25–60 ft/s, the vents should weigh not more than 10 and 5 $\mathrm{lb/ft^2}$, respectively. The vents may be held by springs or magnets.

If at a gas velocity of 10–60 ft/s the duct contains obstacles, additional explosion relief openings are required. If there is a long straight duct connected to an obstacle, explosion reliefs of size $K = 1$ should be located at 3 diameters on either side of the obstacle and again at 6 diameters on either side of it. Thereafter, the straight unobstructed section of the duct may be treated in the usual way.

For this case, the maximum duct diameter for which information was available is 1.5 ft.

For this vent system, the weight of the six vents nearest the obstacle again depends on the velocity of the gas. For gas velocities below 25 and of 25–60 ft/s, the vents should weigh not more than 3 and 1.5 lb/ft^2, respectively. The vents may be held by springs or magnets.

For gases other than propane, the maximum pressure may be calculated from the maximum pressure for propane using the relation

$$P_2 = \frac{S_u^2}{2.2} P_1 \qquad [17.13.3]$$

where P_1 is the maximum pressure resulting from an explosion for propane (lb$_f$/in^2.), P_2 is the maximum pressure resulting from an explosion for a gas other than propane (lb$_f$/in.^{2}) and S_u is the maximum fundamental burning velocity of the gas other than propane (ft/s). The value of 2.2 derives from the square of the maximum fundamental burning velocity of propane, which is 1.5 ft/s.

Alternatively, for a given maximum pressure the distance between neighbouring vents L_1 may be calculated using the relation

$$L_2 = \frac{2.2}{S_u^2} L_1 \qquad [17.13.4]$$

where L_1 is the distance between relief openings for propane (ft) and L_2 is the distance between relief openings for a gas other than propane (ft).

Vent closures should be designed so that a degree of deterioration or lack of maintenance does not cause the design maximum pressure resulting from the explosion to be exceeded. Closures should be robust and leak-tight. Methods of holding vent closures include springs, magnets and hinges. Further details of vent closure are given in the *HSE Guide*.

It is pointed out by Lunn (1984b) that the experimental data on which these recommendations are based are sparse. He suggests that the maximum pressure correlates as well with vent ratio A_v/V as with vent coefficient K. Figure 17.35 shows the data given by Lunn for vented ducts in support of this argument.

He is also critical of the use of Equation 17.13.3 to extrapolate from propane to other gases. Figure 17.35 shows a curve for the maximum pressure in hydrogen–air mixtures calculated from Equation 17.13.3 which differs appreciably from the experimental curve also shown in the figure.

On the basis of the work of Cousins and Cotton (1951a) he suggests as an alternative that if explosion pressures for a particular gas have been measured in a compact enclosure, then for a duct with $L/D < 30$ and with the same vent ratio these pressures represent upper bounds on the pressures likely to occur in the duct.

17.13.3 Bartknecht method

Bartknecht states that experience has shown that explosions may cause considerable damage in pipes even if reliefs are installed.

He suggests that the effectiveness of such reliefs is doubtful, that if they are used they need to be installed every 1–2 m and that such a design is suitable only for use on pipes which are outdoors.

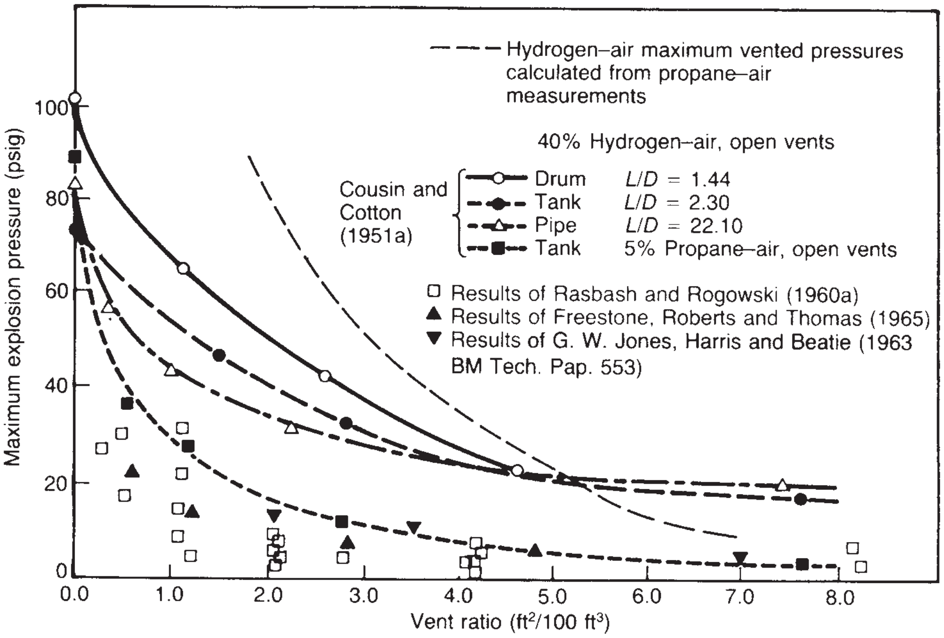

Figure 17.35 Explosion venting of ducts and pipes: maximum explosion pressure in vessels of different aspect ratios (Lunn, 1984b) (Courtesy of the Institution of Chemical Engineers)

He recommends instead that the pipe should be designed to contain the explosion, which means in practice that it should have a design pressure of at least 10 bar. Such a pipe will withstand even the very high but very short peak pressures associated with detonations.

In this design approach, reliefs are still required but are limited to handling the much higher pressures which occur at end flanges or bends. These must be provided with vents if they are not to be destroyed.

The venting must occur along the axis of the pipe. Relief which is based on flow at right angles to the axis gives much higher pressures for deflagrations and is quite ineffective for detonations. Further, the whole cross-sectional area of the pipe must be utilized for the vent.

As described in Section 17.5, the explosion velocity and explosion pressure developed in a pipe open at one end tend to be higher than in a closed pipe. It follows that if the vent opens too soon, it may aggravate the situation. Therefore, the vent opening pressure should be set sufficiently high to prevent the development of excessive explosion pressure.

One way of achieving this is to use an activated vent in which the explosion pressure is detected by a suitable sensor which causes the vent to open.

Relief devices which can be used include bursting discs and vent doors. The latter have the advantage that they seal the vent opening after effecting relief. However, relief of a pipe is a more demanding duty for a vent door and experience shows that it is not easy to get a suitable design. Many of those tested have either blown off or failed to reseat to give a tight closure.

Another device which might in principle be used is the spring-loaded valve. The explosion pressure forces the valve cover outwards against the force of the springs and the gas vents through the annulus so formed. However, there has been a problem in obtaining a satisfactory design of valve.

17.13.4 NFPA 68 method

As already mentioned, the method of explosion venting for ducts given in NFPA 68: 1988 and 1994 differs from that given in the 1978 edition, which essentially followed the *HSE Guide*.

The method given in NFPA 68: 1994 which is described here is that for the explosion venting of pipes, ducts and elongated vessels operating at or near atmospheric pressure. The pressure is given in the code in terms of the reduced pressure P_{red}, which is expressed as a gauge pressure. The treatment applies to pipes in which the reduced pressure P_{red} is limited to 0.2 barg.

For ducts of non-circular cross-section, the relevant diameter is taken as the hydraulic mean diameter.

Two basic situations are distinguished: (1) a pipe with a single vent consisting of an open end and (2) a pipe with multiple vents.

NFPA 68 gives several graphs to assist in the design of vents for the relief of deflagrations in pipes. The figures apply to flow in smooth, straight pipes. Some are applicable only to propane, but a formula is given which permits them to be applied to certain other gases also, as described below. They are also applicable to dusts, but with restrictions on the St class.

Figure 17.36 is used to determine the maximum allowable length of smooth, straight pipe or vessel which is closed at one end and vented at the other. If the L/D ratio is greater than that shown, there is a risk of detonation. The graph is applicable to propane and to dusts, a distinction being made between dusts with $K_{st} \leq 200$ and $K_{st} > 200$.

Figure 17.37 gives the reduced pressure P_{red} for deflagration of propane in a pipe with a single vent at one end and with an initial velocity <2 m/s.

Figure 17.38 gives the reduced pressure for deflagration of gases and dusts in a pipe with multiple vents for an initial velocity <2 m/s. The limits for gas are a burning velocity ≤1.3 times that of propane and for dusts $K_{st} \leq 300$.

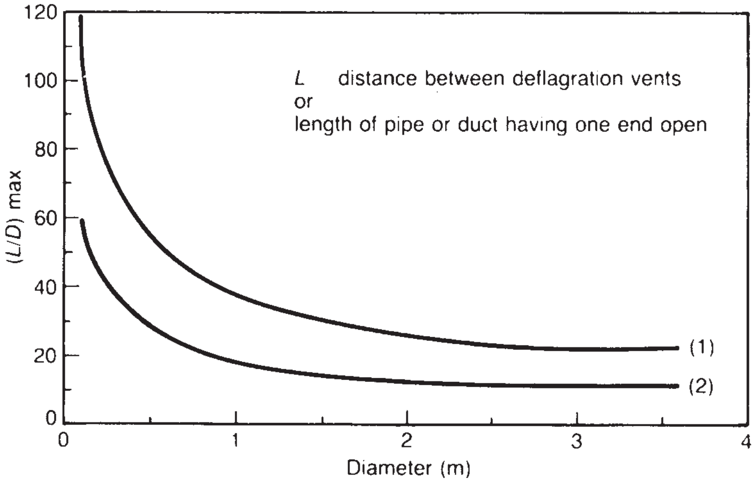

Figure 17.36 *Explosion venting of ducts and pipes: maximum allowable length of a pipe vented at one end, or maximum allowable distance between vents, for gases and dusts (NPFA 68: 1994): (1) dusts with* $K_{st} \leq 200$ *bar m/s and (2) propane, dust with* $K_{st} > 200$ *bar m/s. See text for details (reproduced with permission from NPFA 68 Deflagration Venting, © 1994, National Fire Protection Association, Quincy, MA 02269). See note to Figure 17.25*

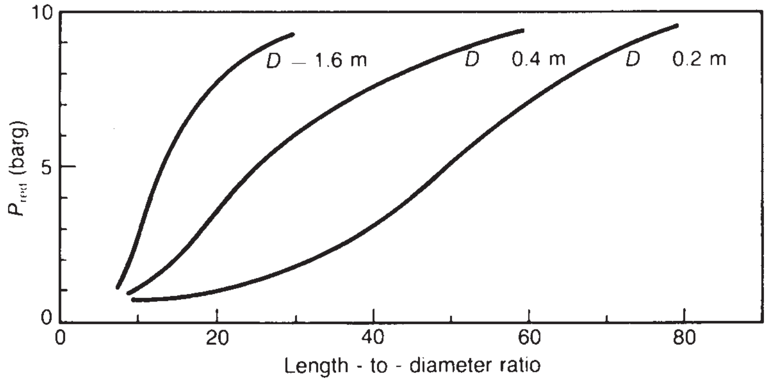

Figure 17.37 *Explosion venting of ducts and pipes: reduced explosion pressure in deflagration of propane–air mixtures in a smooth, straight pipe or duct closed at one end (NPFA 68: 1994). Initial flow velocity <2 m/s. See text for details (reproduced with permission from NFPA 68 Deflagration Venting, © 1994, National Fire Protection Association, Quincy, MA 02269). See note to Figure 17.25*

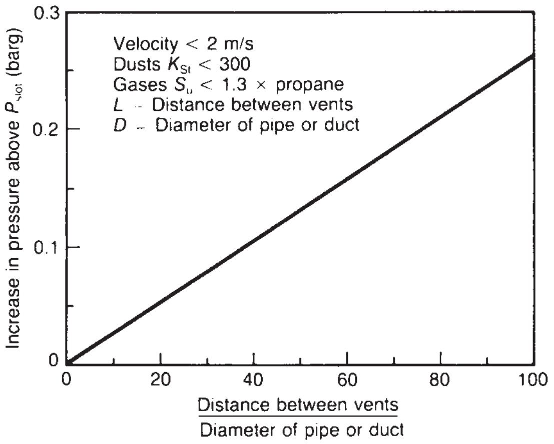

Figure 17.38 *Explosion venting of ducts and pipes: reduced explosion pressure in pipe with multiple vents for deflagration of gases and dusts (NPFA 68: 1994). Initial flow velocity<2 m/s, gas burning velocity≤ 1.3 × burning velocity of propane, dust* K_{st} *≤ 300 bar m/s. See text for details (reproduced with permission from NFPA 68 Deflagration Venting, 1994, National Fire Protection Association, Quincy, MA 02269). See note to Figure 17.25*

Figure 17.39 gives the spacing of multiple vents for the particular case where, for deflagration of gases and dusts, it is required to limit the reduced pressure to 0.2 bar and where the initial velocity is in the range 2–20 m/s. The limits for gas are a burning velocity ≤1.3 times that of propane and for dusts $K_{\mathrm{st}} \leq 300$.

For gases other than propane which have a burning velocity not exceeding 1.3 times that of propane the following formulae are given:

$$L_{\mathrm{x}} = \left(\frac{S_{\mathrm{p}}}{S_{\mathrm{x}}}\right)^2 L_{\mathrm{p}} \qquad [17.13.5]$$

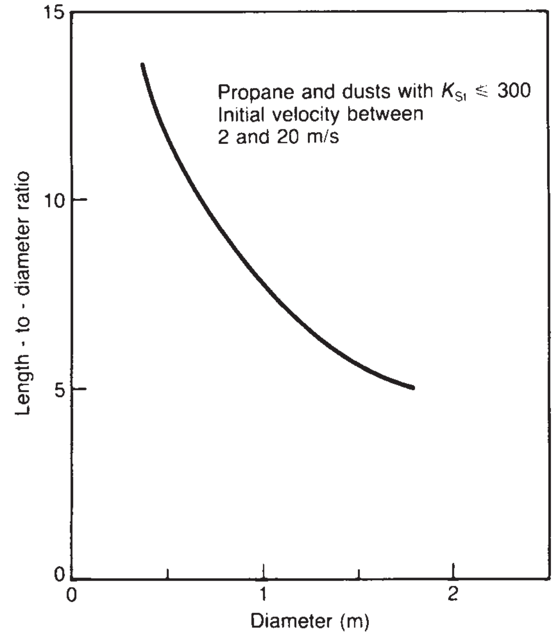

Figure 17.39 *Explosion venting of ducts and pipes: vent spacing to prevent reduced explosion pressure exceeding 0.2 barg for deflagration of gases and dusts (NPFA 68: 1994). Initial flow velocity between 2 and 20 m/s; propane gas, dust* K_{st} *≤ 300 bar m/s. See text for details (reproduced with permission from NPFA 68 Deflagration Venting, © 1994, National Fire Protection Association, Quincy, MA 02269). See note to Figure 17.25*

$$P_{\mathrm{red,x}} = \left(\frac{S_{\mathrm{x}}}{S_{\mathrm{p}}}\right)^2 P_{\mathrm{red,p}} \qquad [17.13.6]$$

where L is the maximum distance between vents, P_{red} is the reduced pressure, S is the maximum fundamental burning velocity and the subscripts p and x denote propane and the gas in question.

When the initial velocity exceeds 20 m/s, the gas burning velocity exceeds 1.3 times that of propane or the dust K_{st} value exceeds 300, the distance between vents should not exceed 1–2 m.

Further, for gases, there is additional guidance in respect of obstacles, which include an elbow, tee, flow splitter, orifice or valve, or any feature which blocks more than 5% of the cross-sectional area of the pipe. In such cases in designing for a reduced pressure of ≤ 0.2 bar, there should be placed on each side of the obstacle two vents, at distances from the obstacle of 3 and 6 diameters. If the design is for a reduced pressure >0.2 bar, it is sufficient to use on each side of the obstacle one vent at a distance of 3 diameters from it. The code states that there is insufficient information to allow corresponding guidance to be given for dusts.

With regard to the vents, the total vent area at each location should be at least equal to the cross-sectional area of the pipe. This area may be provided by one or more vents. For an individual vent, an area exceeding the cross-sectional area of the pipe is not effective in further reducing the pressure of a deflagration.

The release pressure of the vents should be set as far below the reduced pressure P_{red} as practical, but in any event should not exceed half the reduced pressure. The mass of the vent closures should not exceed 2.5 lb/ft^2.

NFPA 68 gives a number of worked examples illustrating the application of the above guidance. These include an example involving the specification of the vents on a drier system consisting of the drier itself and a dust collector.

17.14 Explosion Relief of Buildings

An account was given in Section 17.8 of explosions in buildings. In this section explosion relief of such buildings is considered. The relief of dust explosions in buildings is considered in Section 17.48.

Accounts of explosion relief of buildings are given in *Gas Explosions in Buildings and Heating Plants* (R.J. Harris, 1983) and *Venting Gas and Dust Explosions* (Lunn, 1984b) and by Rasbash (1969c), Runes (1972) and W.B. Howard (1972). A relevant code is NFPA 68: 1994 *Deflagration Venting*.

A building is usually too weak to withstand a high explosion pressure and may be blown apart by a sustained pressure of 1 psig (0.07 bar) or even less. Nevertheless, for buildings containing flammable materials it is often appropriate to provide explosion venting. This gives the building a degree of protection against explosions resulting from such causes as leaks and spillages.

Explosion relief of buildings may be regarded as intermediate between explosion relief of vessels and explosion relief of large enclosures such as offshore modules.

17.14.1 Relief by failure of weak components

Most buildings have a number of weaker components such as windows and doors which will fail at a lower pressure than the main structure and to this extent will act as vents.

The designer may take advantage of this fact to provide at least part of the vent area in the form of regular openings with the components deliberately designed to fail at pressures which make them an integral part of the total venting arrangements.

17.14.2 Experimental studies

There have been a number of experimental studies of explosion venting of buildings and large enclosures. Some of the principal studies are listed in Table 17.18.

Reviews on work on explosion relief of buildings have been given by Rasbash (1969c), Butlin (1975 FRS Fire Res. Note 1026) and R.J. Harris (1983).

Early work on explosion relief of a large enclosure of 200 m^3 was carried out by the Committee for Explosion Research (1958) in Sweden. This work is described in Section 17.15. It was particularly valuable in that it was an early contribution and was done on a large scale so that it has provided evidence on scale-up and on phenomena of large scale.

Work at Potters Marston on the characteristics of and damage done by vented explosions in buildings has been described by Astbury *et al.* (1970) and Astbury, West and Hodgkinson (1972, 1973).

Table 17.18 *Explosion venting of buildings and modules: some experimental studies*

Investigator(s)	*Vessel or enclosure*			
	Type and dimensions (m)	*Volume* (m^3)	*Relief*	*Gas mixture*
Committee for Explosion Research (1958)	Rectangular enclosure, 8.8 × 5.8 × 3.7–4.15 height	199		
Dragosavic (1973)	Rectangular enclosure, 4 × 3 × 2.6	20.8	Vents	Methane
Solberg, Pappas and Skramstad (1980, 1981)	Rectangular enclosure, 4 × 3.5 × 2.5	35	Open vents	Propane
W.B. Howard and Karabinis (1980)	Rectangular building	81		Propane
Buckland (1980)	Rectangular enclosure, 3.7 × 3.0 × 2.4 height		Vents	Natural gas
A.J. Harrison and Eyre (1986, 1987a,b)	Rectangular enclosure, 5.92 × 2.38 × 2.16	30.4	Open vents?	Natural gas equivalent, propane
C.J.M. van Wingerden (1989c)	Rectangular enclosure, 4.0 × 3.7 × 2.6	38.5	Open vents?	Methane

Dragosavic (1972a,b, 1973) has described work at TNO, and has given an equation correlating the results, as described in Section 17.12.

Following an explosion incident in a process plant building, reported earlier by W.B. Howard (1972), explosion relief experiments were performed by W.B. Howard and Karabinis (1980, 1982) on a test building 5.5 × 4.5 × 3 m high. The building contained obstacles to simulate process plant equipment. The tests provided information on potential for structural damage, on explosion venting, and particularly on the Runes constant, and on vent system design.

17.14.3 Empirical and semi-empirical methods

The methods available for the explosion relief of buildings are essentially a subset of those already given for explosion venting of vessels.

Two methods which have been widely used are those of Rasbash (1969c) and Runes (1972). Both methods were in fact developed in the first instance for the relief of buildings.

The methods preferred by R.J. Harris (1983) are those of Cubbage and Simmonds (Cubbage and Simmonds 1955a–c; Simmonds and Cubbage 1960) and Cubbage and Marshall (1973). Harris gives a theoretical model for the initial rate of pressure rise and initial pressure in an explosion in a building, but not for a vented explosion in a building; for the latter he refers to the model of Fairweather and Vasey (1982). These methods have all been developed by British Gas and thus may be considered to constitute a coherent set of methods for this problem.

17.14.4 Rasbash method

An equation for the maximum pressure in a vented explosion in a building has been given by Rasbash (1969c). This equation has been described in Section 17.12.

In the form given by Rasbash, Drysdale and Kemp (1976) the equation is

$$P_\mathrm{red} = 1.5P_\mathrm{v} + fS_\mathrm{u}(P_\mathrm{I} + 2.5K)/0.45 \qquad [17.14.1]$$

with

$$P_\mathrm{I} = \frac{0.20Kw + 1.17}{V^{1/3}} \qquad [17.14.2]$$

$$K = A_\mathrm{c}/A_\mathrm{v} \qquad [17.14.3]$$

where A_c is the smallest cross-sectional area of the building space (m^2), A_v is the total area of combustion vents (m^2), f is a turbulence factor, if is the venting ratio, P_I is the back pressure due to inertia of the vent (gauge) (kPa), P_red is the maximum pressure reached during the venting of combustion, or reduced pressure (kPa), P_v is the pressure within the building space at which the vent opens (gauge) (kPa), S_u is the maximum fundamental burning velocity of the gas (m/s), V is the volume of the enclosure (m^3) and w is the inertia of the vent (kg/m^2).

A fuller account of Equation 17.14.1, including details of the parameters and range of validity, is given in Section 17.12.

Equation 17.14.1 has been widely used for the explosion relief of buildings.

17.14.5 Runes method

Another equation which has been widely used for the explosion relief of buildings is that of Runes (1972). This equation also has been described in Section 17.12. The Runes equation is

$$A_\mathrm{v} \frac{CL_1L_2}{\Delta P^{1/2}} \qquad [17.14.4]$$

with

$$C = \frac{\pi u_f(E-1)}{200} \qquad [17.14.5]$$

where A_v is the vent area (ft^2), E is the expansion ratio, L_1 and L_2 are the two smallest dimensions of the building (ft), ΔP is the vented explosion overpressure (lb$_\mathrm{f}$/in.^{2}), u_f is the flame speed (ft/s), ρ is the density of the gas (lb/ft^3) and C is a constant ((lb$_\mathrm{f}$/in.^{2})$^{1/2}$. Runes did not actually give a value of the constant C beyond that which can be calculated for specific cases using Equation 17.14.4.

Runes considered that his equation gives conservative but reasonable vent areas. He presented several worked examples showing that by comparison with the then current version of NFPA 68 his equation gave reasonable values and avoided the more extreme vent areas which the latter sometimes gave. He also gave a comparison with the results of the Bromma explosion venting tests.

Following an explosion incident, W.B. Howard (1972) made proposals for modification of the Runes equation. The explosion occurred in a building which contained process plant equipment and had an area of 5335 ft^2 of open windows and of weak components which would act as vents. The end wall was estimated to be able to withstand a static pressure of 7 kPa. This wall was blown off, some portions falling as integral sections, but not forming missiles. Part of the side walls were also blown out and the other end wall was cracked.

Howard first took one of Runes's examples and substituted numerical values to obtain for the case of a gas mixture with a nominal flame speed u_f of 11 ft/s the equation

$$A_\mathrm{v} = \frac{1.2L_1L_2}{\Delta P^{1/2}} \qquad [17.14.6]$$

thus giving by comparison with Equation 17.14.4 a Runes constant of 1.2. He substituted the values of A_v and ΔP for the explosion incident, and obtained for the flame speed u_f a value of 24 ft/s. Then, taking the ratio of the two flame speeds (24/11) he proposed that the value of the Runes constant be increased to 2.6 (1.2 × 24/11), in effect calibrating the Runes constant from this incident.

In SI units Equation 17.14.4 becomes

$$A_\mathrm{v} = C\frac{L_1L_2}{P^{1/2}} \qquad [17.14.7]$$

where A_v is the vent area (m^2), L_1 is the smallest dimension of the rectangular building enclosure to be vented (m), L_2 is the second smallest dimension of that building (m), P is the maximum internal building pressure (kPa) and C is a constant. The maximum internal building pressure P is that which can be withstood by the weakest building member which it is desired should not vent or break.

Equation 17.14.7 is believed to apply to buildings with a nominal length/width, or L/D, ratio up to 3. In a rectangular building where L_1 and L_2 are unequal, D should be taken as $(L_1L_2)^{1/2}$. For a building in which the L/D ratio is greater than 3, the space should be divided into units each of which has an L/D ratio of not more than 3.

The basis of the Runes constant has been explained in Section 17.12. It is discussed by Lunn (1984), who regards it as conservative. The value of the constant was obtained by Howard. The flame speed originally used by Runes was 3.35 m/s for propane–air, whereas that quoted by Howard for ethanol–air is 7.31 m/s, which introduces a factor of 2.2 on Runes' original formulation.

NFPA 68: 1978 gives for C a value in metric units of 6.8 for gases such as propane and others with a similar burning velocity, but a higher value for gases with a higher burning velocity. The suggested value for ethylene is 10.5 and that for hydrogen is 17.

17.14.6 Harris methods

The method used by R.J. Harris (1983) is based on the Cubbage and Simmonds equations given earlier as Equations 17.12.17 and 17.12.18,

$$P_1 = \frac{(4.3Kw + 28)S_u}{V^{1/3}} \tag{17.14.8}$$

$$P_2 = 58S_u fK \tag{17.14.9}$$

with

$$K = A_s/A_v \tag{17.14.10}$$

where A_s is the area of the side of the enclosure (m^2), A_v is the vent area (m^2), K is the venting ratio, P_1 is the first peak pressure (mbar), P_2 is the second peak pressure (mbar), S_u is the burning velocity (m/s) and V is the volume of the enclosure (m^3).

Harris also utilizes the Cubbage and Marshall equation given earlier as Equation 17.12.33,

$$P_m = P_v + 23\frac{Kw(fS_u)^2}{V^{1/3}} \tag{17.14.11}$$

with

$$P_v = a/A_v \tag{17.14.12}$$

where P_m is the maximum pressure reached during venting (mbar), P_v is the pressure at which the vent opens (mbar), S_u is the maximum fundamental burning velocity of the gas (m/s) and w is the inertia of the vent (kg/m^2). The constant a is numerically equivalent to the failure pressure of a panel of unit area.

As an illustration of the use of these two equations, Harris gives the example of the calculation of the explosion relief for a furnace 5 × 5 × 5 × 5 m fired by natural gas with a limit of 3 m^2 on the size of any one vent panel. The maximum pressure rise is to be limited to 250 mbar, and the panel inertia is 10 kg/m^2. The burning velocity is taken as 0.45 m/s, the turbulence factor as 3, and the constant a is 40.

Then, by the method of Cubbage and Simmonds, taking the maximum pressure as that occurring in the second pressure peak as given by Equation 17.14.9

$$\begin{aligned} A_v &= \frac{58 \times (3 \times 0.45) \times 5^2}{250} \\ &= 7.83 \text{ m}^2 \\ K &= 5^2/7.83 \\ &= 3.2 \end{aligned}$$

This indicates the need for three panels.

For the method of Cubbage and Marshall, Harris recast Equation 17.14.11 in the following forms. For a relief panel in the side with the largest cross-section:

$$A_v = \frac{1}{P_m}\left[a + 23A_s wf^2 S_u^2/V^{1/3}\right]; \quad K = \frac{A_s}{A_v}$$

and for panels on any other side

$$A_v = \frac{1}{P_m}\left[a + 23V^{1/3}wf^2 S_u^2\right]; \quad k = \frac{V^{2/3}}{A_v}$$

$$A_v = \frac{1}{250}[40 + 23 \times (5^2)^{1/3} \times 10 \times (3 \times 0.45)^2] = 8.5$$

$$K = (5^3)^{2/3}/8.5 = 2.9$$

This again indicates the need for three panels.

17.14.7 NPFA68 method

Explosion relief of buildings is treated in NFPA 68: 2002. The approach adopted has evolved over the years. That used in the 1974 edition was to calculate the vent area A_v using both the Rasbash and the Runes equations and to take the larger of the two areas. The 1978 edition gave only the Runes equation.

For the venting of low strength enclosures, including buildings, NFPA 68: 2002 gives the following equation:

$$A_v = C\frac{A_s}{P_{red}^{1/2}}, \quad P_{red} \leq 0.1 \tag{17.14.13}$$

where A_s is the internal surface area of the enclosure (m^2), A_v is the vent area (m^2), P_{re} is the maximum internal overpresssure which can be withstood by the weakest structural element not intended to fail (bar) and C is a venting constant (bar$^{1/2}$).

For the venting constant the code gives in metric units a value of 0.045 bar$^{1/2}$ for gases which have a fundamental burning velocity less than 1.3 times that of propane. The value of the constant for methane is 0.037 bar$^{1/2}$.

NFPA 68: 1994 gives an illustrative example of the use of Equation 17.14.13 involving a building of fairly complex shape.

17.14.8 Relief of multiple compartments

It is possible that the leak of flammable gas enters more than one compartment of the building and that an explosion in one compartment may propagate to another. An event in which explosions propagate in this way is known as a cascade explosion.

There are several factors which may cause the pressure in the second compartment to be higher than that in the first. The explosion in the first compartment may cause compression of, and turbulence in, the gas in the second compartment.

Cubbage and Marshall (1973) performed experiments using two interconnected rooms each of which had a volume of 28 m^3. They derived the following equation for the vented explosion pressure P_2 in the second compartment following ignition:

$$P_2 = (k_2P_1 + k_2P_1^2)^{0.5} \tag{17.14.14}$$

with

$$k_1 = \frac{V_2}{V_1}\left(46(Kw)_{2\text{av}}\frac{S_\text{u}^2}{V_2^{0.33}}\right) \qquad [17.14.15]$$

$$k_2 = \frac{V_2}{V_1}\frac{K_2}{K_{12}} \qquad [17.14.16]$$

where K_1, K_{12} and K_2 are the vent coefficients for compartment 1, between compartments 1 and 2 and for compartment 2, $(Kw)_{2\text{av}}$ is the average value of Kw for compartment 2, P_1 and P_2 are the vented explosion pressures of compartment 1 and of compartment 2 (mbar), V_1 and V_2 are the volumes compartment 1 and compartment 2 (m^3), respectively and k_1 and k_2 are constants.

The experiments were done with large vent openings. It is uncertain how far the results can be extrapolated. Harris recommends against their general use.

17.14.9 Vent design

It is preferable that the vent areas should be located on different walls of the building rather than concentrated all on one wall.

Vent panels for buildings should have the lowest practicable inertia. The release pressure for a vent panel should be as low as possible relative to the expected wind pressures. An appropriate value is usually in the range 1–1.5 kPa.

A vent panel should be restrained by a device such as a hinge or chain to prevent it flying off the building if it does open. Consideration should be given to the space into which the panel is to open.

Materials which shatter into pointed fragments should not be used for vent panels. In particular, asbestos cement-type board is unsuitable.

It may be necessary to provide railings along the edge of the floor near a vent panel to prevent people accidentally knocking the panel open and falling out.

An account of the guidance in NFPA 68 on design of vents for enclosures generally, including buildings, has been given in Section 17.12.

17.15 Explosion Relief of Large Enclosures

An account was given in Section 17.9 of explosion in a large enclosure such as an offshore module. In this section explosion relief of such an enclosure is considered.

17.15.1 Relief by structural collapse

Explosion relief of a large enclosure may occur in two ways. The relief may take place exclusively through vent apertures which already exist and which are intended as vents or it may also take place through apertures which are created by the explosion itself. In the latter case the extent of the relief opening will depend on the degree of structural collapse and hence on the strength of the explosion.

Such relief may be investigated using one of the computer codes for simulation of a semi-confined explosion. In this case it will usually be necessary to adopt an iterative procedure, calculating initially the strength of the explosion without structural collapse, determining the degree of collapse for this maximum strength explosion and gradually adjusting the strength of the explosion and the degree of structural collapse until a match is obtained.

17.15.2 Experimental studies

Experiments on large vented explosions using a steel module of dimension 2.5 × 3.5 × 4 m, and hence 35 m^3 volume, were performed by Solberg, Pappas and Skramstad (1981). Vent openings extended all the way along the front wall and could be varied in steps of 0.25 m^2. A propane–air mixture was used.

Tests were done with the ignition source at three different locations: at the centre of the module, at the vent opening and at the rear wall. In all cases the overpressure gave two peaks. Typical overpressure traces are shown in Figure 17.40.

With central ignition the overpressure rose until the hot burned gas began to flow through the vent. The volumetric flow then increased, the density of the gas being less. The pressure rise was arrested. This effect also inhibited the backward propagation of the flame front towards the rear wall. The arrest of this flame front created just the conditions which favour Taylor instability. Under these conditions the flame front breaks up into a large number of fronts propagating in many directions. There is a massive increase in the rate of combustion and a large increase in the overpressure. This is illustrated in Figure 17.41.

This phenomenon was not limited to the case of central ignition. It occurred with ignition at the vent opening also. For Taylor instability a major part of the flame must be able to propagate away from the vent opening, but the distance between the ignition source and the opening is not important.

With the ignition source at the rear wall the course of the explosion was different. In this case there was less scope for Taylor instability. However, there was still a strong second peak. This was thought to be due probably to the shear between the high-velocity burned gas and the low-velocity unburned gas and the consequent enhancement of turbulence at the flame front. This is illustrated in Figure 17.42.

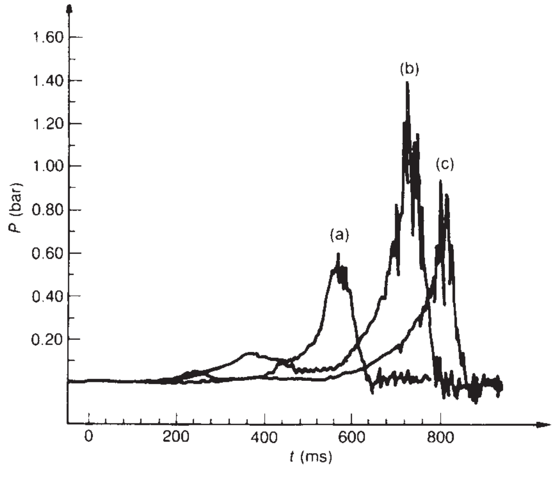

Figure 17.40 *Explosion venting of large enclosures: profiles of overpressure for explosions with different locations of the ignition source – 1: (a) rear wall ignition, (b) central ignition, and (c) front wall ignition (Solberg, Pappas and Skramstad, 1981). P, pressure; t, time (Courtesy of the Combustion Institute)*

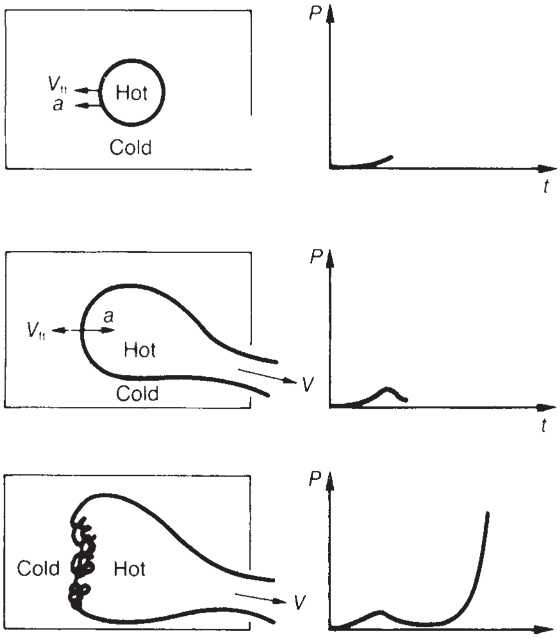

Figure 17.41 *Explosion venting of large enclosures: development of a vented explosion with central ignition showing Taylor instability (schematic) (Solberg, Pappas and Skramstad, 1981). P, pressure; t, time (Courtesy of the Combustion Institute)*

The authors also explored the validity of vent coefficient scaling ($A_v/V^{2/3}$ = constant). They found that for large volumes such scaling was not valid and was not conservative. They concluded that whereas combustion in small volumes is characterized by a small, spherical flame front, in larger volumes combustion instabilities dominate.

Experiments on generation of overpressures in vapour clouds have been described by A.J. Harrison and Eyre (1986, 1987a,b). This work included investigation of the ignition of a vapour cloud by a jet flame issuing from a vented chamber. In this work it was observed that when unburned gas displaced from the chamber was ignited by the emerging flame, there occurred a rapid combustion of the displaced gas, near spherical in form and located a few metres from the vent opening. They termed this an 'external explosion'. They noted that a similar phenomenon had been reported by Solberg, Pappas and Skramstad (1980).

Overpressure traces showing the external explosion are given in Figure 17.43. Figure 17.43(a) shows the overpressure at the rear wall of the chamber and Figure 17.43(b) that just outside the chamber. The peak caused by the external explosion occurs first.

The blast wave from the external explosion is shown in Figure 17.44. The overpressure is constant for some distance from the vent opening to a virtual centre and then falls off, the decay being proportional to the reciprocal of the distance from that centre.

C.J.M. van Wingerden (1989c) has reported experiments to investigate the various effects which may enhance the overpressures obtained in large vented explosions. He lists

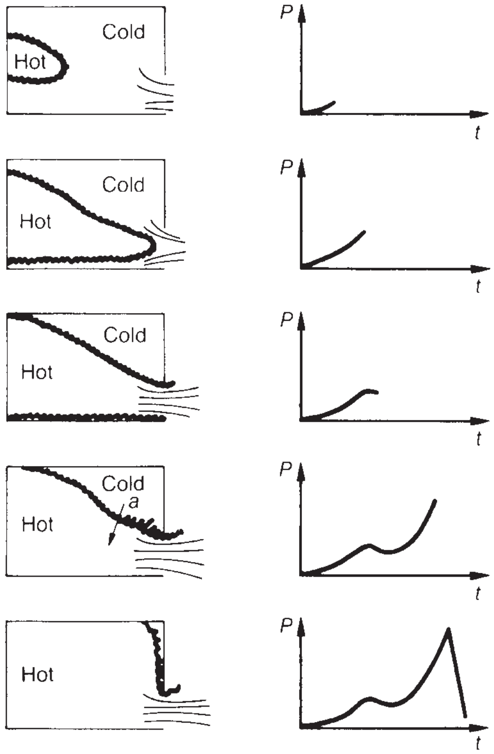

Figure 17.42 *Explosion venting of large enclosures: development of a vented explosion with rear wall ignition (schematic) (Solberg, Pappas and Skramstad, 1981). P, pressure; t, time (Courtesy of the Combustion Institute)*

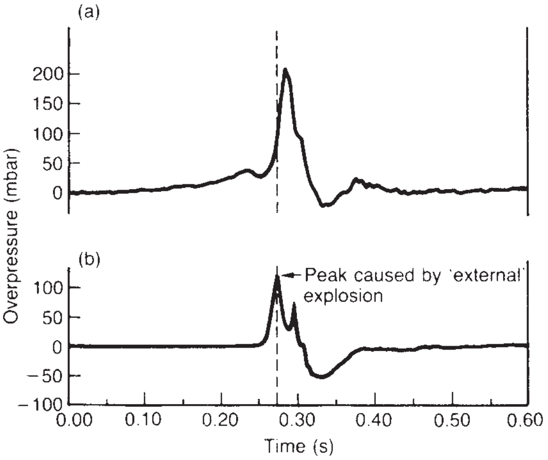

Figure 17.43 *Explosion venting of large enclosures: profiles of overpressure inside and outside the enclosure showing effect of external explosion: (a) overpressure at rear wall and (b) overpressure just outside enclosure (A.J. Harrison and Eyre, 1986; reproduced with permission)*

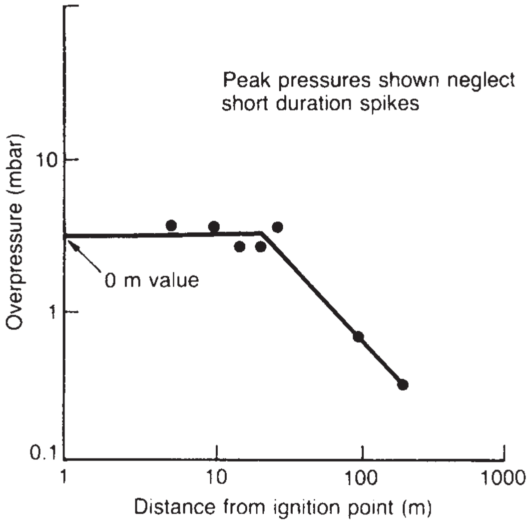

***Figure 17.44** Explosion venting of large enclosures: decay of overpressure outside enclosure (A.J. Harrison and Eyre, 1987a) (Courtesy of Combustion Science Technology)*

as possible enhancing mechanisms shear turbulence, oscillatory combustion and Taylor instability.

The tests were performed using a chamber 2.6 × 3.7 × 4.0 m, and hence a volume of 38.5 m^3, and methane–air mixtures. Features investigated included vent area, vent shape, ignition source location, effect of an obstacle and gas concentration.

The overpressure traces obtained had two peaks. Van Wingerden attributes the first to opening of the vent cover and the second, which was generally larger than the first, to oscillatory combustion. An acoustic wave generated during the combustion process enhances combustion and creates higher overpressures. A frequency analysis showed a maximum at a frequency of 120 Hz, corresponding to the fundamental mode of the chamber with the wave standing between the two side walls. The repeatability of this mechanism was low, however, and the overpressures obtained varied by a factor of nearly 2.

An external explosion occurred and had the effect of making the pressure peaks rather sharp.

Overpressures measured with vent areas <5.2 m^2 were low, but high overpressures were obtained with vent areas >5.2 m^2. No explanation was found for this anomalous effect. Vent shape and vent opening pressure had little effect. There was a wide scatter of overpressures for different vent opening pressures.

The location of the ignition source affected the overpressure traces but had little influence on the maximum overpressures obtained. Central ignition and ignition at the vent opening gave a maximum overpressure due to oscillatory combustion, whilst rear wall ignition gave a maximum overpressure due to the external explosion.

Tests were done with a single obstacle which, depending on its orientation blocked 12 or 23% of the cross-section of the chamber. With this configuration, overpressure traces with three peaks were obtained. Van Wingerden attributes the first to the opening of the vent, the third to oscillatory combustion and the second to turbulent combustion in the wake of the obstacle proceeding outside the enclosure. This second peak increased as the distance between the ignition source and the obstacle increased. The peak was at a maximum when this distance was large.

Gas concentrations used were 9.5 and 10% methane–air mixtures. Oscillatory behaviour was obtained more readily with the latter and this was used in most of the work.

The venting of the explosion gave rise to long flame jets, up to 18 m in length.

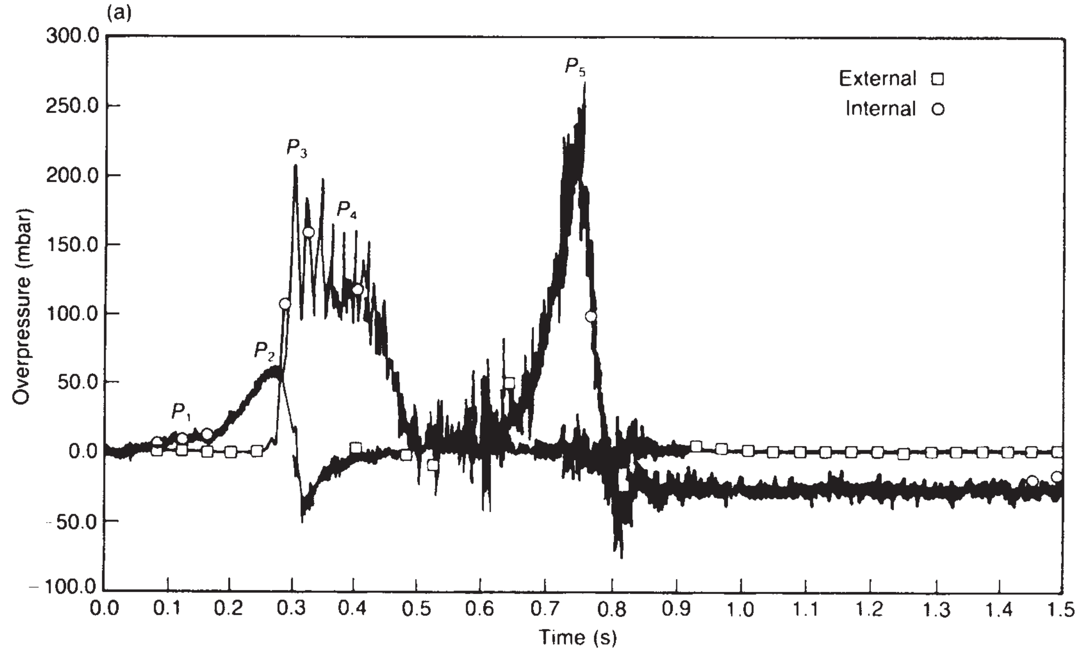
The overpressure due to the blast wave outside the chamber was also measured. There were two pressure peaks, the first due to the external explosion and the second due to the internal explosion. With central ignition the two peaks were comparable, whilst with rear wall ignition the external explosion effect was dominant. Essentially, the strength of the blast wave depended on the external explosion. The overpressure was constant for some distance from the vent opening and then decayed inversely with the distance as seen in Figure 17.44.

A review of the experimental evidence on the overpressures which might occur due to an explosion in a vented module was given to the Piper Alpha Inquiry by Chamberlain (1989). He drew attention to the complexity of the phenomena involved and illustrated this by reference to the overpressure traces shown in Figure 17.45. Figure 17.45(a) is for a case with central ignition and exhibits five peaks: peak 1 at vent panel rupture, peak 2 at flame emergence from the vent, peak 3 at the moment of external explosion, peak 4 due to Helmholtz oscillations and peak 5 due to acoustic coupling oscillations. The maximum peak pressure is at peak 5 at about 200 mbar. Figure 17.45(b) is for rear wall ignition. With ignition near the wall the oscillations are severely damped and peaks 2 or 3 dominate. In this particular case, the maximum peak pressure is at peak 3 at about 550 mbar.

17.15.3 Influencing factors

Some of the factors which influence the severity of a large vented explosion have been described by Chamberlain (1989). They include the fuel, the fuel/air ratio, the initial turbulence, the location of the ignition source, the size of the enclosure, the degree of obstruction and the vent area. The severity is increased if the fuel is a reactive one and if the fuel–air mixture is near stoichiometric. Initial turbulence will enhance the severity, but the effect is not readily quantifiable. The location of the ignition source has a strong effect. For a space with only one vent, locating the ignition source furthest from the vent will tend to give the highest overpressures. The severity tends to increase with the volume of the enclosure and to decrease with the vent area.

Obstacles tend to have a very strong effect on the severity of the explosion. The effect depends on the number, dimensions and profile of the obstacles and on the resultant blockage ratio. Considering an obstructed region of grid arrays, the overpressure increases exponentially with the number of arrays. For obstacle dimensions a worst case diameter of between 5 and 25 cm has been observed in experiments. The effect of an obstacle having a sharp profile is about twice that of one with the same cross-section but with a rounded profile. The overpressure increases exponentially with blockage ratio. As far as the scale of the



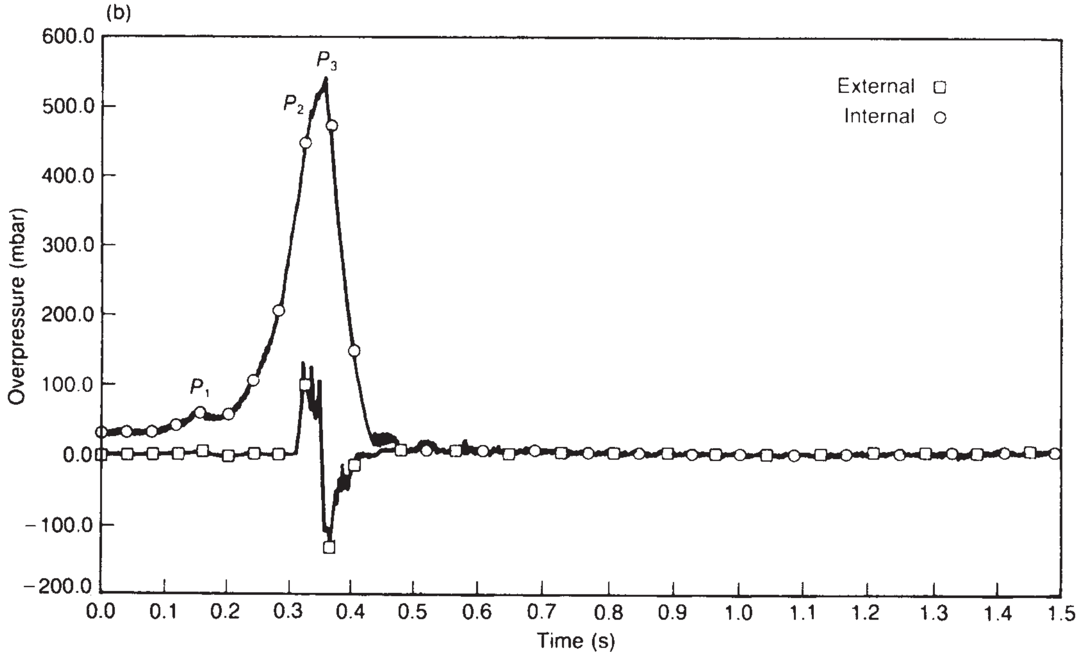


Figure 17.45 *Explosion venting of large enclosures: profiles of overpressure for explosions with different locations of the ignition source – 2 (Chamberlain, 1991; after A.J. Harrison and Eyre, 1987b) (Courtesy of the Institution of Chemical Engineers)*

obstacles is concerned, large scale obstacles have a considerably smaller effect than corresponding configurations of small scale obstacles.

The initial temperature has only slight influence as does the strength of the ignition source, leaving aside flame jet ignition.

17.15.4 External explosion

The occurrence of an external explosion has already been mentioned. The effect has been discussed by Chamberlain (1989).

The external explosion occurs because the advancing flame front expels unburned fuel from the vent. The external flow has a large and strong coherent structure and entrains a considerable quantity of air. When the flame emerges it constitutes a strong ignition source for this external flammable cloud and the external explosion can be severe. Its magnitude depends on the mass of fuel expelled, which in turn depends on the location of the ignition source. If all the fuel in the internal space is consumed before the flame reaches the vent, an external explosion will not occur. The external explosion will be weakened if the gas cloud is displaced far from the vent or if it is strongly diluted with air.

The influence of the external explosion on the internal overpressures is negligible where the latter exceeds 1 bar. At lower internal overpressures, however, the external explosion can have a marked effect. The larger the vent area and the lower the internal overpressure, the larger the relative contribution of the external explosion. Thus, the external explosion is a factor which works against the attempt to limit the internal overpressures. There is some evidence that the importance of the external explosion increases with scale.

17.15.5 Computer codes

The computer codes available for the simulation of an explosion in a semi-confined enclosure were described in Section 17.9. These codes may be used, as there indicated, to investigate the course of an explosion with little or no venting, but their main application is to study situations in which there is appreciable venting.

There also exist codes designed specifically for venting calculations. One of these is the VENTEX code of Shell. This incorporates a semi-empirical model based on extensive experimentation. The code is used mainly for preliminary screening to investigate the effect of different parameters prior to use of more fundamental models. The VENTEX code calculates first the overpressure in an empty enclosure at the instant when the flame reaches the vent, then the amplifying effect of obstacles and finally the effects of the external explosion.

17.15.6 Design methods

There is no full satisfactory fundamental method of predicting the overpressure from an explosion in a large vented enclosure. The available empirical equations are of limited use. They have usually been derived for empty vessels and tend not to take into account complicating factors such as internal obstacles or external explosions.

More useful are computer codes and model experiments. The former include the fundamental models incorporated in computer codes such as FLACS and CLICHE and the semi-empirical models of codes such as VENTEX. The use of the large CFD codes tends to be expensive.

Scale model experiments provide an alternative, or complement, to computer codes. This approach also is expensive.

Both computer codes and model experiments tend to involve a degree of extrapolation. It needs to be borne in mind that some phenomena become more significant as scale increases.

17.16 Venting of Reactors

The reactors which are considered here are liquid-phase reactors, essentially those capable of an exothermic reaction runaway.

It has long been the practice to protect such reactors against overpressure by the use of some form of relief such as a bursting disc or pressure relief valve. The overpressure protection of reactors was described in Chapter 11.

In this section an account is given of methods of sizing the vent for a reactor. Methods have progressed from early empirical correlations to methods based on various types of model, both simplified analytical models and full unsteady-state models embodied in computer codes.

One point is worth emphasizing at the outset. This is that in reactor venting it is the volumetric flow which is important.

The need for adequate vent sizing methods is evidenced by a number of incidents of reactor overpressure which have been attributed to the undersizing of the reactor vent.

Vent sizing of reactors is a complex and specialist matter. The account given here is no more than an overview.

17.16.1 Venting scenarios

The vent system for a reactor should be designed for the worst case scenario which is reasonably foreseeable. The scenarios considered should include fire engulfment as well as reaction runaway.

17.16.2 FIA method

An early method of vent sizing was the Factory Insurance Association (FIA) method, described by Sestak (1965). The method is an empirical one in which vent area is plotted as a function of reactor volume and reaction class. The graphical relations may be represented by the following approximate equation:

$$A = KV^{0.92} \qquad [17.16.1]$$

where A is the vent area (in.^{2}), V is the reactor capacity (US gal) and k is a constant. The constant k has the approximate values 0.0056, 0.021 and 0.095 ($V \leq 10{,}000$) for exothermic reactions, categories A–D, with very low, low and moderately high heat releases, and 0.48 ($V \leq 4000$) for reactions with extraordinarily high heat releases. The value of k of 0.0056 is also used for endothermic reactions. The vent areas are given not as single lines but as bands of approximately ±50% about the values given by Equation 17.16.1.

The FIA method is relatively simple to apply and has been widely used. Examples of its use have been given by Harmon and Martin (1970).

A number of authors have discussed the method, including Duxbury (1976, 1980) and Fauske (1984a,b).

Fauske (1984b) has given the quantification of the FIA chart shown in Figure 17.46. This interpretation is based on the equation given by Fauske for the vent area of a vapour

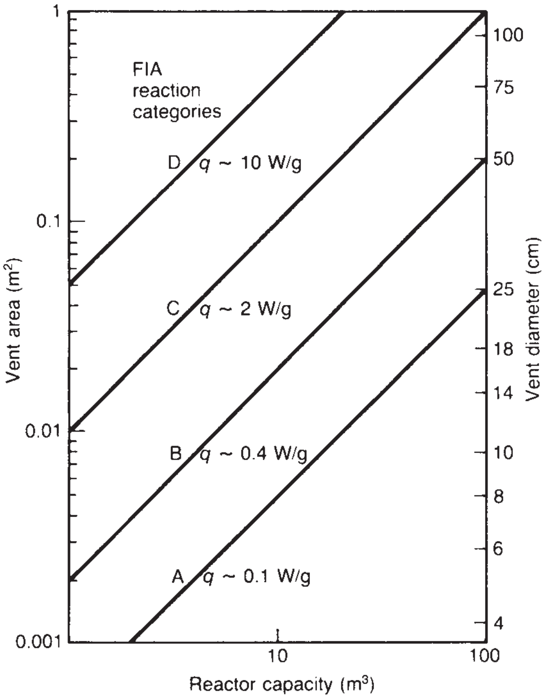

Figure 17.46 *Venting of chemical reactors: interpretation of FIA vent sizing method (Fauske, 1984b); q, energy release rate (Courtesy of the American Institute of Chemical Engineers)*

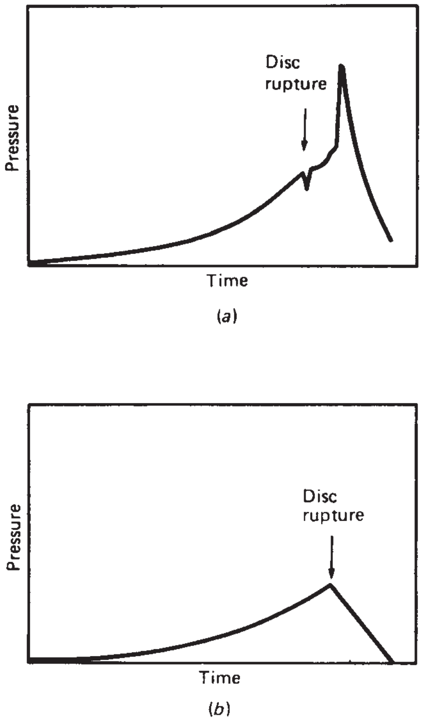

Figure 17.47 *Venting of chemical reactors: typical pressure curves for a runaway reaction (after Harmon and Martin, 1970): (a) vent area inadequate; (b) vent area adequate (Courtesy of the American Institute of Chemical Engineers)*

pressure system, given below as Equation 17.19.3, with properties of water ($\rho_1 = 1000\ \text{kg/m}^3$, $C = 4.18$ kJ/kg K and $T = 373$ K) and for an overpressure of 20%. The heat release rate q for the reaction categories A–D is quantified as shown in the figure.

Industrial Risk Insurers (IRI), the successor to FIA, withdrew the FIA method from its engineering procedures in the 1970s and recommended the use of other methods (Davenport, 1977c).

17.16.3 Monsanto correlation

Another simple method of vent sizing is the Monsanto correlation (W.B. Howard, 1973). This method is one of those included in a review given by Fauske (1984a). The correlation is used for sizing vents for runaway phenol–formaldehyde reactions. It is

$$D = 0.3V^{1/2} \qquad [17.16.2]$$

where D is the diameter of the vent (in.) and V is the volume of the reaction mass (US gal). The correlation is applicable for a self-heat rate of the order of 6.5°C/min and a set pressure of 15–16 psia. This implies a horizontal vent line to prevent build-up of static pressure due to liquid head.

17.16.4 Vent flow

The venting of a liquid-phase reactor is generally treated by determining (1) the flow of material which must be vented to prevent excessive overpressure and (2) the vent area required to effect this discharge.

The problem is complicated by the fact that it is difficult to predict whether the fluid discharged will be (1) a vapour, (2) a liquid or (3) a two-phase vapour-liquid mixture. Methods have been developed based on each of these assumptions. In general, the assumption of a single phase yields a simpler treatment, but the assumption of two-phase flow is more realistic.

It has often been observed that in practice the fluid vented from a reactor is not a vapour, but is either a liquid or a vapour-liquid mixture. Descriptions of incidents in which the charge was vented as either a liquid or a vapour–liquid mixture are given by Boyle (1967), Harmon and Martin (1970), Huff (1973, 1977a) and Duxbury (1976).

The general shape of the pressure curve for the venting of a runaway reaction as given by Harmon and Martin (1970) is shown in Figure 17.47. Figure 17.47(a) shows the curve for a runaway polymerization of ethyl acrylate with a vent of inadequate area and Figure 17.47(b) that for a runaway polymerization of methyl methacrylate with an adequate vent area.

17.16.5 All vapour venting method

An approach to reactor venting which has frequently been adopted is that based on venting of the vapour from the boiling liquid reaction mass. This involves calculating the maximum allowable liquid temperature, which is related by the vapour pressure to the maximum allowable pressure, and then determining the rate of reaction and of heat generation at this temperature, the rate of vapour evolution and hence the flow of vapour to be generated. The vent area is then

$$A = W/G \qquad [17.16.3]$$

with

$$W = \frac{r(-\Delta H_r)V}{\Delta H_v} \qquad [17.16.4]$$

where A is the vent area (m^2), G is the mass flux (kg/m^{2}s), ΔH_r is the heat of reaction (negative for exothermic reaction) (kJ/kg), ΔH_v is the latent heat of vaporization (kJ/kg), r is the rate of reaction (kg/m^{3}s), V is the volume of the reaction mass (m^3) and W is the mass flow (kg/s).

The vent mass flux G is determined by standard methods for vapour flow.

17.16.6 All liquid venting method

As mentioned above, however, it is known that in some cases the fluid is vented as a liquid or a vapour–liquid mixture.

An alternative approach, therefore, is to size the vent on the basis of discharging the whole reaction mass as a liquid. The required flow is calculated from the rate of reaction and of heat generation at the maximum liquid temperature and the time required to heat the reaction mass to this temperature.

Then

$$W = m_o/\Delta t \qquad [17.16.5]$$

with

$$\Delta t = \frac{m_o C \Delta T}{r(-\Delta H_r)V} \qquad [17.16.6]$$

where C is the specific heat of the reaction mass (kJ/kg K), m_o is the initial mass in the vessel, or the reaction mass (kg), Δt is the time interval to the maximum allowable pressure (s) and ΔT is the temperature difference at equilibrium between the initial pressure and the maximum allowable pressure (K).

The vent area is again determined from Equation 17.16.3. The vent mass flux G is determined by standard methods for liquid flow.

It is found that in some cases the all vapour venting method gives the larger area and in others the all liquid venting method does.

17.16.7 Boyle method

A method based on the all liquid venting approach has been described by Boyle (1967). The method given by Boyle is based on the pressure–time curve for the reactor. This may be obtained from the reaction rate or by experiment. Effectively, the method separates the calculation of the vent area from that of the vent flow. The latter is determined from the time for the reactor pressure to rise to the maximum allowable pressure. The former is estimated using the pressure in the reactor at the relief point.

A statement of the Boyle model has been given by Leung (1986b) as follows:

$$W = \frac{m_o}{\Delta t_p} \qquad [17.16.7]$$

where Δt_p is the emptying time (s).

Leung also refers to the relation given by Fauske (1984b) for the emptying time

$$\Delta t_p = \frac{\Delta T}{(\mathrm{d}T/\mathrm{d}t)_s} \qquad [17.16.8]$$

where ΔT is the temperature rise corresponding to the overpressure ΔP (°C) and $(\mathrm{d}T/\mathrm{d}t)_s$ is the self-heat rate at the set pressure (°C/s).

Boyle recommends that the vent area be calculated by both the all vapour venting and the all liquid venting methods, that the larger area be used and that a factor of safety of 2–3 be applied to the area so obtained.

A critique of Boyle's method is given by Duxbury (1980). In general, provided the flow is single phase the method tends to give vent sizes on the high side and thus to be conservative.

There is evidence from the work of Harmon and Martin (1970) that Boyle's method may underestimate the vent areas for larger reaction vessels. It gives for such vessels vent areas which are in some cases considerably less than those obtained by the FIA method. Further evidence is given by Huff (1973, 1977a).

The method given by Boyle is not conservative for situations in which two-phase flow occurs. It is still possible, however, to use the first part of the method to calculate the flow to be vented, but to use two-phase flow methods for the vent sizing.

A modified Boyle method which takes account of two-phase flow has been described by Duxbury (1976). The two-phase flow calculations are performed using a fluid flow code.

17.16.8 Huff method

A method of vent sizing based on a much more comprehensive reactor model, including reaction kinetics and two-phase flow relations and embodied in a computer code, has been described by Huff (1973).

Huff also gives a comparison of the different methods of calculating vent sizes for liquid-phase reactors. For the case which he considers the two-phase flow model is more conservative that the FIA method or the all vapour venting and all liquid venting methods.

This model has undergone further development as described by Huff (1977a,b, 1982a,b, 1984a).

One version of this model (Huff 1977a,b, 1982a,b) has come to be known as the pseudo-steady-state model (e.g. Duxbury and Wilday, 1989).

Duxbury (1980) describes this model as a two-phase venting method for reactions in which pressure and temperature peak simultaneously. Huff states that it is conservative for reactions in which pressure peaks first.

A statement of the Huff model has been given by Leung (1986b) as follows:

$$W = \frac{m_o}{\tau_t} - \frac{\beta}{2\tau_t^2}\left[\left(1 + \frac{4m_o\tau_t}{\beta}\right)^{1/2} - 1\right] \qquad [17.16.9]$$

with

$$\beta = \frac{h_{fg} V}{q_m v_{fg}} \qquad [17.16.10]$$

$$\tau_t = \Delta t_p + \frac{h_{fg}}{q_m}(x_m - x_o) \qquad [17.16.11]$$

$$x_m = \frac{V/m_m - v_f}{v_{fg}} \qquad [17.16.12]$$

$$m_m = m_o - W_{\tau t} \qquad [17.16.13]$$

where h_{fg} is the latent heat of vaporization (kJ/kg), m is the reaction mass in the vessel (kg), q is the heat release rate per unit mass (kW/kg), x is the mass fraction of vapour, or quality, v_f is the specific volume of the liquid (m^3/kg), v_{fg} is the specific volume change between the vapour and liquid phases (m^3/kg), β is a parameter, τ_t is the turnaround time for temperature (s) and the subscripts m and o denote peak and initial pressure (or temperature), respectively.

17.16.9 BPF method

Another full unsteady-state model is that developed for phenolic resin reactors by the British Plastics Federation (BPF) and described by Booth *et al.* (1980).

17.16.10 Scale-up methods

An alternative approach to the vent sizing of liquid phase reactors is scale-up from experimental tests. Such extrapolation is valid, however, only if similarity exists between the test and full-scale systems.

Some of the conditions which must be met before similarity can be assumed are listed by Duxbury (1976). Thus, for polymerization reactions he suggests that the basis for scaling up, though not for scaling down, might be a constant ratio of vent area to reactor volume. This accords quite well with the FIA method in which vent area increases with reactor volume to the power 0.92.

17.16.11 ICI methods

Reviews of methods of vent sizing used in ICI have been given by Duxbury (1976, 1980) and by Duxbury and Wilday (1987, 1989, 1990). An account of the ICI scheme is given in Section 17.21.

17.16.12 Reaction parameters

As already indicated, there are a number of reactor parameters which are relevant to reactor venting. They include: P_s, set pressure (Pa); $(dT/dt)_s$ self-heat rate, at set pressure (°C/s); Q_g, volumetric gas evolution rate (m^3/s); Q_v, volumetric vapour evolution rate (m^3/s).

17.16.13 Source term

The flow entering the vent may be a homogeneous vapour–liquid equilibrium mixture or, if vapour disengagement occurs, a vapour. The size of vent required is different for the two cases.

When the reactor pressure is reduced due to venting, the liquid becomes superheated and vapour bubbles are formed, causing liquid swell. Unless vapour disengagement occurs, a two-phase mixture will enter the vent. Vapour disengagement does tend to occur in non-foamy system, though not in foamy ones.

Definition of the source term for the flow entering the vent is therefore of some importance. This is considered in Chapter 15 by a so-called coupling equation.

17.16.14 Relief devices

The relief devices normally used for venting of liquid-phase reactors are bursting discs or pressure relief valves.

It is necessary to allow for two-phase flow through these devices. This is dealt with in Chapter 15.

17.16.15 Relief disposal

The material vented must be disposed of safely. Relief disposal is considered in Sections 17.22 and 17.23.

17.16.16 Containment

In certain cases, as discussed by Duxbury (1976), containment of a possible runaway reaction may be an attractive alternative to venting. This may be so, for example, if the peak pressure attainable is close to the working pressure or if it is less than the minimum design pressure for a vessel of that size or if there are special venting problems such as blockage of the vent lines.

The application of this concept to reactors has been developed by Wilday (1991). An account is given in Chapter 12.

17.16.17 Instrumented systems

Another design option for reactor venting is the use of an instrumentation and control system designed to ensure that overpressure does not occur and thus to eliminate the need for venting. This approach is discussed in Chapters 11–13.

17.16.18 Design conservatism

It is generally desirable in design to adopt a conservative approach, but in reactor venting, care is needed in defining what this means. A low mass velocity through the vent is conservative with regard to determination of the vent area. But it is not conservative with respect to pressure drops in the system, reaction forces caused by the venting or load on the relief system.

17.17 Venting of Reactors and Vessels: DIERS

17.17.1 DIERS

It was recognized towards the end of the 1970s that understanding of reactor relief was deficient and that methods of vent sizing were inadequate and a major international cooperative project, DIERS, was initiated to remedy this. This project is now described.

17.17.2 DIERS project

A major project on reactor venting was undertaken during the mid-1980s by the Design Institute for Emergency Relief Systems (DIERS) of the American Institute of Chemical Engineers (AIChE) with sponsorship from a large international group of companies. The main contractor was Fauske and Associates Inc., and results from the project and its aftermath have been the subject of a series of publications by Fauske and co-workers, notably Epstein, Grolmes, Leung and Swift. Overviews of the project have been given by H.G. Fisher (1985, 1991).

The work is described in the *DIERS Project Manual*, which gives an overview and contains chapters on the following aspects: vapour disengagement; relief system flow;

large scale tests; high viscosity flashing flow; mechanical design, containment and disposal; bench-scale apparatus and the SAFIRE computer code.

Some principal elements of the work are given in the Technology Summary. This deals with the behaviour of the vapour in the vessel and with vapour–liquid flow in the vent line and gives emergency relief system (ERS) design methods. It also deals with fire relief of storage vessels.

The DIERS project involved an extensive investigation of the behaviour of the fluid venting through the vent line. It included study of the vapour disengagement in the vessel and of the fluid flow through the vent. The work showed that there are different types of reaction systems and that the behaviour of these systems is different. A major finding was that the flow at the vent tends to be a two-phase vapour–liquid flow. Methods of ERS design were developed for the different systems. These included simplified methods, a computer model and a scale-up method. A bench-scale apparatus was designed capable of determining the principal design parameters.

There is a DIERS Users Group which is described by H.G. Fisher (1989). A newsletter of the group has been carried in Plant/Operations Progress.

17.17.3 Influencing factors

The overall venting behaviour of reaction system depends on a number of factors. They include (1) reaction regime, (2) vapour disengagement, (3) fluid viscosity and (4) vent line length. It is necessary to allow for these factors in design, and in particular to take them into account in scale-up from bench scale to full scale.

17.17.4 Reaction regimes

The different types of reaction system, or reaction regimes, distinguished in the work are

(1) vapour-generating system;
(2) gas-generating system;
(3) hybrid system.

A vapour-generating system is one in which the total pressure is the system vapour pressure. In other words, the system contains one or more high vapour pressure components. When the vent opens, tempering of the reaction occurs due to the cooling associated with the latent heat of vaporization. Such a system is also referred to as a high vapour pressure, or vapour pressure, system or a tempered system.

In a gas-generating system, by contrast, there is no high vapour pressure component, and the total pressure is that of the gaseous components. The reaction is not tempered and its course is essentially independent of the venting process. Such a system is also referred to as a gassy system or a non-tempered system.

The intermediate case is that of a hybrid system, and its behaviour is intermediate between that of a pure vapour pressure system and a pure gassy system. A degree of tempering occurs.

17.17.5 Vessel behaviour

The nature of the fluid which enters the vent depends on the flow regime in the vessel when the vent opens, and the vessel is depressurized. There are two flow regimes, the bubbly, or foaming, regime and the churn turbulent regime. In the former there is little vapour disengagement and the vapour–liquid mixture entering the vent line is essentially the same as that in the vessel itself. In the latter regime there is significant vapour disengagement.

Methods exist which allow an estimate to be made for vapour disengagement in systems with pure substances, but not in reacting systems.

In practice, therefore, for venting of a reaction mass it is generally necessary to fall back on the default assumption that there is no vapour disengagement and that the fluid entering the vent is a homogeneous two-phase vapour–liquid mixture.

A considerable amount of work was done, however, to increase understanding of liquid swell and vapour disengagement. An account of these aspects is given in Chapter 15.

17.17.6 Bench-scale equipment: apparatus

As already indicated, it is sometimes preferable to base the vent design on experimental tests. There are, however, certain pitfalls in scale-up from bench to full scale. A suitable design of test apparatus provides a safeguard against these. The design of such apparatus was another task undertaken in the DIERS project.

A low heat capacity test cell was designed with a capacity of 120 ml and a ϕ factor of about 1.05. As stated in Chapter 11, the ϕ factor is the ratio of the heat capacity of the sample plus cell to that of the sample alone, and a value close to unity means that the temperature rise measured is close to the actual temperature rise of the sample. This equipment is generally referred to as the bench-scale apparatus and is also known as the vent sizing Package (VSP). This apparatus is shown in Figure 17.48. It has been described by Fauske and Leung (1985) and Fauske (1988a).

Another apparatus, distinct from the VSP and developed later, is the reactive system screening tool (RSST), described

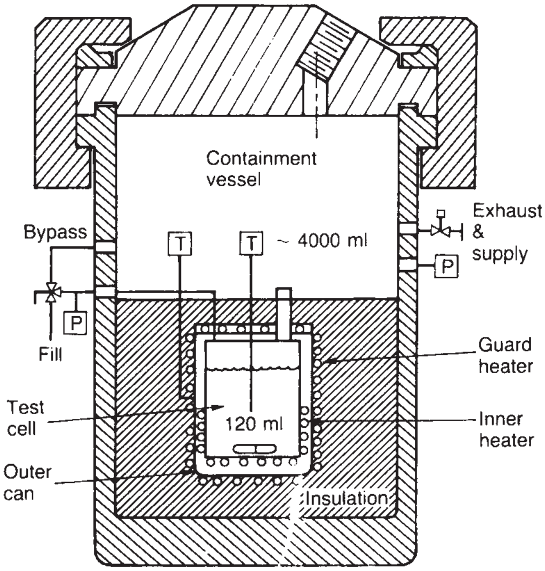

Figure 17.48 Venting of chemical reactors: Vent Sizing Package (Fauske and Leung, 1985) (Courtesy of the American Institute of Chemical Engineers)

by Creed and Fauske (1990). The RSST is a test cell with a capacity of about 10 ml and a ϕ factor of about 1.04. The authors state that the ease of use approaches that of DSC and the accuracy that of the VSP. The RSST may be used for the measurement of the rate of temperature rise, and hence the energy release rate in a vapour pressure system, or to determine the rate of pressure rise, and hence the gas evolution rate in a gassy system. It may also be used for direct scale-up.

17.17.6 Bench-scale equipment: application

For a vapour pressure system, it is necessary for vent sizing to know the rate of temperature rise, or self-heat rate, and hence the energy release rate. This may be measured using the VSP.

In addition, if the reaction mixture is highly viscous and the vent flow likely to be laminar, the apparatus may be used to determine the vent flow.

For a gassy system, the information required is the rate of pressure rise and hence the peak gas evolution rate. The VSP may be used to measure this. It may also be used to obtain the vent flow, though generally gassy systems are not particularly viscous.

These reaction parameters are then used in the appropriate vent sizing relationships.

Alternatively, the VSP may also be used to carry out direct scale-up.

The application of the bench scale equipment, and the relationships with which it is used, are described further in Section 17.19.

17.17.7 Vent flow models

A number of models for vent flow were developed by DIERS. These are given in the Technology Summary and have been described in papers by Fauske and co-workers. An account of these models is given in Section 17.18.

17.17.8 Vent area

DIERS developed methods for the sizing of vents for vapour pressure, gassy and hybrid systems. These are outlined in the Technology Summary and described by Fauske and co-workers. Section 17.19 gives an account of these methods.

In some cases it may be possible to use vent sizing correlations without resort to experimentation, but in other cases experimental work is essential.

17.17.9 Scale-up

The bench-scale equipment may be used to determine the vent area by vent area/reaction mass scaling using direct scaling relationships. This approach is to be distinguished from the use of the apparatus to determine parameters such as self-heat rate or gas evolution rate which are then utilized in vent sizing equations which require these parameters.

17.17.10 Numerical model

The DIERS project also involved the development of a numerical model of the venting of a reactor based on a full set of differential equations for the reaction kinetics and thermal and fluid flow effects. The model is essentially an unsteady-state heat balance with supporting equations. This model is referred to as the integral model and is the basis of the computer code SAFIRE described below. An account of the model has been given by Grolmes and Leung (1985).

17.17.11 SAFIRE code

The integral model is the core feature of the computer program SAFIRE (System Analysis for Integrated Relief Evaluation) developed as part of the project. This has been described by Grolmes and Leung (1985).

The program requires as input, data on the physical and thermodynamic properties of the mixture, the reaction stoichiometry and kinetics, the vessel and vent line geometry and selection of the flow model assumptions.

The vessel geometries handled are a vertical cylinder, a horizontal cylinder and a sphere. The vent entry location can be at the top or bottom of the vessel. The vent may be an effectively frictionless nozzle, a nozzle fitted with a safety relief valve or a vent line in which friction is significant. The latter may have a single segment, two segments with a change of cross-section or three segments with a safety relief valve followed by a change in cross-section.

Vessel flow regimes incorporated are all vapour, all liquid, homogeneous mixture and partial disengagement regimes. Vent line flow models are as follows. There are both all vapour flow and all liquid flow models. Nozzle models include the ERM, the homogeneous equilibrium flashing model and the frozen homogeneous model. For long vent lines the models are the homogeneous equilibrium model and the slip equilibrium model.

The program may be run in three modes: pre-relief, post-relief or combined.

The authors describe the use of the code to simulate a number of experimental tests on styrene and ethylbenzene.

17.17.12 Experimental tests

The DIERS programme included a series of experimental tests, both at laboratory scale and on a larger scale. An account of the larger scale tests in Phase III of the project has been given by Grolmes, Leung and Fauske (1985).

The test vessels used were a 32 l vessel and a 2200 l vessel. The latter had a 12,000 l catchtank.

A set of 70 tests were performed, including 25 with the larger vessel. Water was used in 15 tests with the smaller vessel and 20 tests with the larger one. Using ethylbenzene, four tests were performed in the smaller vessel and none in the larger, whilst using styrene 16 tests were done in the smaller vessel and five in the larger.

The configurations studied included both top and bottom vent locations and both nozzles and long vent lines.

The systems tested were all vapour pressure systems. The principal feature investigated in the tests was vapour disengagement. The work showed that vapour disengagement and the associated churn turbulent regime were confined to non-foaming and non-viscous systems.

17.17.13 Non-Arrhenius behaviour

The low heat capacity test cell was used to investigate a number of systems. One of the effects observed is noteworthy.

As described by Fauske (1985a), tests were performed on a 50/50 mixture of zinc peroxide/zinc oxide at two different heating rates. The test at the lower heating rate obeyed the classic Arrhenius relation between temperature and reaction rate as evidenced by the pressure rise, that at the higher heating rate did not, but gave a much sharper pressure rise, presumably due to a hot spot.

17.18 Venting of Reactors and Vessels: Vent Flow

A general account of two-phase flow models was given in Chapter 15. The account given here is confined to those models used for the venting of reactors and storage vessels.

There are a number of relations used in the DIERS work for the mass flux of fluid flowing out of the vent and down the vent line. Accounts are given by Fauske (1984b,c, 1985a), Grolmes and Leung (1985) and Leung (1986b) and in the Technology Summary.

Leung (1986b) has reviewed flow models for venting of a vapour pressure, or tempered, system. He considers frictionless flow and a short vent line ($L/D < 50$). The models include:

(1) the non-flashing liquid flow;
(2) the homogeneous equilibrium model;
(3) the equilibrium rate model;
(4) the homogeneous non-equilibrium model;
(5) the slip equilibrium model.

For a simple orifice in the side of a vessel the outflow may be determined by treating the fluid as a non-flashing liquid.

For other cases the homogeneous equilibrium model (HEM) is generally the most appropriate. It gives lower flows over the entire two-phase region and is to this extent conservative for ERS design. However, it is realistic rather than overly conservative and agrees well with experimental data. The original HEM model is somewhat complex and requires extensive thermodynamic data, but a more convenient version requiring only stagnation properties has been developed by Leung (1986a).

An alternative model is the equilibrium rate model (ERM) of Fauske (1985b), who has developed the model to deal with a number of different situations.

For the all-liquid inlet condition, Leung has given a version of his approximate HEM model which is similar in form to the ERM model, as described below.

The equilibrium condition is closely approached for pipes longer than 0.1 m. Where the vent line is shorter than this, the homogeneous non-equilibrium model of R.E. Henry and Fauske (1971), the HFM model, may be used to estimate the flow.

Leung also discusses the use of the slip equilibrium model (SEM) of F.J. Moody (1965).

Some of the principal flow models are now described. An account of those used in the DIERS work is given in the Technology Summary.

17.18.1 Vapour pressure systems

A family of flow models for venting of vapour pressure systems has been described by Fauske (1984a,b, 1985a,b) in the context of DIERS, in particular the ERM. The base case is choked non-equilibrium flashing frictionless flow. For this case Fauske gives

$$G \approx \frac{h_{fg}}{v_{fg}}\left(\frac{1}{NTC}\right)^{1/2} \qquad [17.18.1]$$

with the dimensionless quantity N:

$$N \approx \frac{h_{fg}^2}{2\Delta P\,\rho_l K^2 v_{fg}^2 TC} + 10L \qquad [17.18.2]$$

where K is the discharge coefficient, L is the length of the vent pipe (m), ΔP is the total available pressure drop (Pa), T is the absolute temperature (K), ρ_l is the density of the liquid (kg/m^3) and N is a non-equilibrium parameter. For a sharp-edged orifice K is 0.61 and C is the system heat capacity.

For no vent line ($L = 0$) Equation 17.18.1 reduces to

$$G = K(2\Delta P_{\rho l})^{1/2} \qquad [17.18.3]$$

For a vent line long enough for equilibrium conditions to apply ($L \geq 0.1$ m) the parameter N is unity, and Equation 17.18.1 becomes

$$G = \frac{h_{fg}}{v_{fg}}\left(\frac{1}{TC}\right)^{1/2} \qquad [17.18.4]$$

There is an alternative formulation of Equation 17.18.4 based on the relation between vapour pressure P and temperature T:

$$G = \frac{dP}{dT}\left(\frac{T}{C}\right)^{1/2} \qquad [17.18.5]$$

Equation 17.18.5 implies

$$\left(\frac{dP}{dT}\right)^2 \frac{T}{C} = \left(\frac{h_{fg}}{v_{fg}}\right)^2 \frac{1}{TC} \qquad [17.18.6]$$

Equations 17.18.4 and 17.18.5 are the ERM. For venting the rate of change of pressure with temperature is $\Delta P/\Delta T$. In Fauske's work for this model the mass flux is frequently written as G_{ERM} so that

$$G_{ERM} = \frac{\Delta P}{\Delta T}\left(\frac{T}{C}\right)^{1/2} \qquad [17.18.7]$$

where ΔP is the overpressure (Pa) and ΔT is the temperature rise corresponding to overpressure ΔP (°C). Further, it is assumed in the model that the flow is turbulent. Where this aspect is emphasized the mass velocity is written as G_T so that

$$G_T = \frac{\Delta P}{\Delta T}\left(\frac{T}{C}\right)^{1/2} \qquad [17.18.8]$$

Equation 17.18.8 is used where there is homogeneous equilibrium flow, there is a moderate overpressure ($\approx 20\%$) and the flow is turbulent.

Normally the vent line will be long enough for equilibrium flow to be assured. For the case where there is a very short vent line ($0 < L < 0.1$ m), the mass flow may be obtained by interpolation between Equations 17.18.3 and 17.18.8.

For a long vent line Fauske (1989a) introduces into Equation 17.18.8 a correction factor F to give

$$G_T = F\frac{\Delta P}{\Delta T}\left(\frac{T}{C}\right)^{1/2} \qquad [17.18.9]$$

with

$$F = f(L/D) \qquad [17.18.10]$$

where D is the diameter of the vent line (m) and F is a correction factor for vent line length.

The flow correction factor F is a function of the length/diameter ratio L/D. Slightly different correlations have been given in different papers. That currently used for vapour pressure systems is that given by Fauske, Grolmes and Clare (1989), and is:

L/D	F
0	1.0
50	0.8
100	0.7
200	0.6
300	0.55
400	0.5

The original values of F were 0.85, 0.75, 0.65 and 0.55 at L/D ratios of 50, 100, 200 and 400, respectively (Fauske, 1989a).

If the flow is highly viscous, it may be laminar. The relation given by Fauske (1987b, 1989a) for the mass velocity G_L for this case is

$$G_L \approx \left(\frac{h_{fg}}{v_{fg}}\right)^2 \frac{1}{TC}\frac{1}{32\mu} D \frac{D}{L} \qquad [17.18.11]$$

$$= \left(\frac{dP}{dT}\right)^2 \frac{T}{C}\frac{1}{32\mu} D \frac{D}{L} \qquad [17.18.12]$$

where D is the diameter of the vent line (m) and μ is the viscosity (kg/ms).

In practice the liquid viscosity for the reaction mixture is generally not known. In this case, therefore, the bench-scale apparatus may be used to determine the mass flow. Relations for this case are given by Fauske (1989a) in terms of the required vent diameter and are therefore described in Section 17.19.

17.18.2 Gassy systems

For gassy systems one DIERS approach is to utilize the bench-scale apparatus to determine the flow.

Leung and Fauske (1987) have used for such systems the method of Tangren, Dodge and Seifert (1949). Leung (1992b) has also given a method of his own.

Fauske (1985a) gives as a reasonable upper bound for the mass velocity the relation

$$G = [2(P_s - P_a)\rho_l(1-\alpha)]^{1/2} \qquad [17.18.13]$$

where P_a is the atmospheric pressure (Pa), P_s is the set pressure (Pa) and α is the initial vapour fraction. Equation 17.18.13 is suitable for use where some overestimation of flow may be acceptable such as in sizing of the relief equipment.

17.18.3 Hybrid systems

For hybrid systems there is again no entirely satisfactory flow relation, and one DIERS approach is to utilize the bench-scale apparatus to determine the flow.

For a hybrid system Fauske (1985b) gives the following approximate relations:

$$G \approx (2P_{g\rho_l} + G^2_{ERM})^{1/2} \qquad [17.18.14]$$

with

$$G_{ERM} \approx \frac{P_v}{P}\frac{dP}{dT}\left(\frac{T}{C}\right)^{1/2} \qquad [17.18.15]$$

$$P = P_v + P_g \qquad [17.18.16]$$

where P_g is the partial pressure of the gas (Pa) and P_v is the partial pressure of the vapour (Pa).

17.18.4 Storage vessels

For flow of a flashing liquid from the liquid space of a storage vessel, Fauske (1985b) distinguishes between a saturated liquid and a subcooled liquid. For a saturated liquid he gives

$$G = 0.6[2(P_o - P_a)\rho_l]^{1/2}, \quad L = 0 \qquad [17.18.17]$$

$$G_{ERM} = \frac{\Delta P}{\Delta T}\left(\frac{T}{C}\right)^{1/2}, \quad L > 0.1 \text{ m} \qquad [17.18.18]$$

where P_o is the absolute stagnation pressure (Pa). For a subcooled liquid Fauske gives

$$G = 0.6[2(P_o - P_a)\rho_l]^{1/2}, \quad L = 0 \qquad [17.18.19]$$

$$G = [2(P_o - P(T_o))\rho_l + G^2_{ERM}]^{1/2}, \quad L > 0.1 \text{ m} \qquad [17.18.20]$$

where T_o is the absolute stagnation temperature (K).

17.18.5 Vapour pressure systems: homogeneous equilibrium model

The family of flow relations given above is that of Fauske and the principal model is the ERM. An alternative model for equilibrium flow is the HEM.

This model has been formulated in convenient form by Leung (1986b), who gives the following relations. For the high and low quality regions, respectively, the equations are

$$\frac{G}{(P/v)^{1/2}} = \frac{0.66}{\omega^{0.39}}, \quad \omega < 4.0 \qquad [17.18.21a]$$

$$\frac{G}{(P/v)^{1/2}} = \frac{0.6055 + 0.1356\ln\omega - 0.0131(\ln\omega)^2}{\omega^{0.5}}, \quad \omega \geq 4.0 \qquad [17.18.21b]$$

with

$$\omega = \frac{xv_{fg}}{v} + \frac{CTP}{v}\left(\frac{v_{fg}}{h_{fg}}\right)^2 \qquad [17.18.22]$$

$$v = v_f + xv_{fg} \qquad [17.18.23]$$

where P is the pressure (Pa), v is the specific volume of the mixture (m^3/kg) and ω is the critical flow scaling parameter.

For an all liquid inlet flow, Equation 17.18.21 may be approximated by

$$G \approx 0.9\frac{h_{fg}}{v_{fg}}\left(\frac{1}{TC}\right)^{1/2} \qquad [17.18.24]$$

This equation is similar in form to Equation 17.18.4 except for the factor 0.9. The flow given by it is termed by Grolmes and Leung (1984) the limiting flow.

Leung (1986b) has given a set of models for vent sizing for vapour pressure systems, which is described in Section 17.20. These models are independent of the expression used for the mass velocity G, but the flow model quoted in that account is the HEM as just outlined.

17.19 Venting of Reactors and Vessels: Vent Sizing

Some of the methods available for vent sizing prior to the DIERS project were described in Section 17.16. An account is now given of methods developed in DIERS.

The bench-scale apparatus used in some of the methods is described in Section 17.17.

17.19.1 Vapour pressure systems

For a vapour pressure system, it is necessary to know the self-heat rate. One option for obtaining this is the use of the bench-scale apparatus. But it may be possible to determine it without resort to experiment.

Given the self-heat rate, the following simplified method has been described by Fauske (1984b) for the vent area:

$$A = \frac{V_\rho}{G\Delta t_\mathrm{v}} \qquad [17.19.1]$$

with

$$\Delta t_\mathrm{v} = \frac{\Delta TC}{q_\mathrm{s}} \qquad [17.19.2]$$

where q_s is the energy release rate at the set pressure (kW/kg), Δt_v is the venting time (s) and ρ is the density of the reaction mass (kg/m^3).

Combining Equations 17.19.1 and 17.19.2 with Equation 17.18.7 gives

$$A = V_\rho (TC)^{-1/2} \frac{q_\mathrm{s}}{\Delta P} \qquad [17.19.3]$$

Equations 17.18.7 and 17.19.3 are based on the assumption that the flow in the vent line is homogeneous equilibrium flow and that it is turbulent and intended for use where there is a modest overpressure in the range 10–30%, say 20%.

For a frictionless vent line, Equation 17.19.3 predicts a vent area larger by a factor of less than 2 than that given by the integral model, assuming homogeneous vessel behaviour and homogeneous equilibrium flow.

The mass flow is relatively insensitive to the length/diameter ratio L/D. It varies by less than a factor of 2 for L/D up to 400. Most vent lines are 5–10 m in length.

17.19.2 Vapour pressure systems: high viscosity systems

For a high viscosity system, the flow in the vent line is likely to be laminar. The bench-scale apparatus may be used to determine an actual flow. Then, as described by Fauske (1989), the diameter of the full scale vent line may be obtained from the relations

$$D_\mathrm{L} = D_\mathrm{T} \qquad G_\mathrm{o}(D_\mathrm{T}/D_\mathrm{o}) \geq G_\mathrm{T} \qquad [17.19.4a]$$

$$\approx \left(D_\mathrm{T}^2 D_\mathrm{o} \frac{G_\mathrm{T}}{G_\mathrm{o}}\right)^{1/3} \qquad G_\mathrm{o}(D_\mathrm{T}/D_\mathrm{o}) < G_\mathrm{T} \qquad [17.19.4b]$$

where D_L is the diameter of the full scale vent line for laminar flow (m), D_o is the diameter of the vent line in the bench-scale apparatus (m), D_T is the diameter of the full-scale vent line for turbulent flow (m), G_o is the mass velocity in the bench-scale apparatus (kg/m^{2}s), G_T is the mass velocity at full scale in turbulent flow (kg/m^{2}s).

According to the Technology Summary, viscous effects on level swell are generally not important if the liquid viscosity is below 100 kPa s.

17.19.3 Vapour pressure systems: Fauske nomograph

For a vapour pressure system, a generalized vent sizing nomograph based on Equation 17.19.3 was published in 1984 by Fauske (1984a). A revised nomograph, given below, was published in 1988.

This initial nomograph was based on the assumptions of turbulent flow and a modest overpressure.

Fauske (1984a) has compared the nomograph method with some of the earlier methods of vent sizing described above. He considers three different duties, one for the Monsanto method, one for the BPF and Huff methods, and one for the SAFIRE method. His results may be summarized as follows:

Method	*Vent area* (m^2) *from:*	
	Method named	*Nomograph*
Monsanto	Area = 0.0125 m^2/1000 kg	Area = 0.012 m^2/1000 kg
BPF	Area = 0.026 m^2/1000 kg	Area = 0.0145 m^2/1000 kg
Huff code	Diameter = 33.7 cm	Diameter 34 cm
SAFIRE code	Diameter = 15.8 cm ($L/D \approx 100$) = 18 cm ($L/D \approx 400$)	Diameter ≈ 18.5 cm

17.19.4 Vapour pressure systems: revised Fauske nomograph

A revised method for vapour pressure systems, and an associated nomograph, have been given by Fauske, Grolmes and Clare (1989). The relation given for the vent area is

$$A = \frac{5}{2} \frac{Q_\mathrm{v}}{F(TC)^{1/2} P_\mathrm{s}} \frac{\alpha_\mathrm{d} - \alpha_\mathrm{o}}{1 - \alpha_\mathrm{o}} \qquad [17.19.5]$$

where α is the void fraction and the subscripts d and o denote the disengagement and initial, or freeboard, value, respectively.

The flow reduction factor F used in Equation 17.19.5 is given in Table 17.19, column 1.

Figure 17.49 is a nomograph based on Equation 17.19.5. The nomograph is for the following conditions: $C = 2500$ J/kg K, $T = 400$, $\alpha_\mathrm{d} = 1$ and $L/D = 0$. It is therefore applicable to the case of no vapour disengagement.

17.19.5 Vapour pressure systems: extended method for vapour disengagement

As described by Grolmes, Leung and Fauske (1983), interpretation of the DIERS data has shown that during two-phase venting relatively large deviations in the equilibrium between the vapour and the liquid may exist.

The implications are discussed by Fauske (1989a). It is virtually impossible to predict the vapour/liquid ratio entering the vent line. The absence of equilibrium means that following actuation of the relief the temperature continues to rise, but without a corresponding overpressure. In due course a 'turnaround', or 'turnover', of temperature occurs.

Fauske states that in most practical systems there is likely to be only modest superheating (10–20°C) and that temperature turnaround should be assured before the onset of vapour disengagement. The rate of loss of reaction mass can be assumed to be largely independent of the vapour/liquid ratio of the mixture entering the vent line.

On these assumptions, an extension of the method was developed which takes into account vapour disengagement, as described by Fauske (1987a,b). The extension requires information on the self-heat rate. The relation given for the vent area, assuming turbulent flow, is

$$A = \frac{1}{2}\frac{m_{\mathrm{o}}(\mathrm{d}T/\mathrm{d}t)_{\mathrm{s}}(\alpha_{\mathrm{d}} - \alpha_{\mathrm{o}})}{F(T/C)^{1/2}\Delta P(1 - \alpha_{\mathrm{o}})}, \quad 0.1 \le \frac{\Delta P}{P_{\mathrm{s}}} \le 0.3 \qquad [17.19.6]$$

where ΔP is the overpressure (Pa).

Table 17.19 Venting Chemical reactors: flow reduction factor F in Fauske vent sizing correlations (Fauske, Grolmes and Clare, 1989) (Courtesy of American Institute of Chemical Engineers)

L/D	*All vapour flow* I	*Vapour pressure system, two-phase flashing flow* II	*Gassy system, two-phase non-flashing flow* III
0	1.0	1.0	1.0
50	0.8	0.8	0.71
100	0.7	0.7	0.58
150	0.65	0.65	0.50
200	0.60	0.60	0.45
250	0.58	0.58	0.41
300	0.55	0.55	0.38
350	0.52	0.52	0.35
400	0.50	0.50	0.33

The loss of reaction mass at time of turnaround, given by Fauske (1988a, 1989a), is

$$G \approx \frac{1}{A\Delta t_{\mathrm{v}}} m_{\mathrm{o}} \frac{\alpha_{\mathrm{d}} - \alpha_{\mathrm{o}}}{1 - \alpha_{\mathrm{o}}} \qquad [17.19.7]$$

where Δt_{v} is the time to temperature turnaround (s), given by

$$\Delta t_{\mathrm{v}} \approx \frac{2\Delta T}{(\mathrm{d}T/\mathrm{d}t_{\mathrm{s}})} \qquad [17.19.8]$$

17.19.6 Gassy systems

For gassy systems, it is necessary to know the peak gas generation rate. It is usually necessary to use the bench-scale apparatus to obtain this.

Then, as given in the Technology Summary (Equation 2.4) the vent area is

$$A = \frac{Q_{\mathrm{g}}(1 - \alpha)\rho_{\mathrm{l}}}{G} \qquad [17.19.9]$$

$$= \frac{Q_{\mathrm{g}} m}{GV} \qquad [17.19.10]$$

where m is the mass of mixture in the vessel (kg) and Q_{g} is the peak volumetric gas evolution rate (m^3/s).

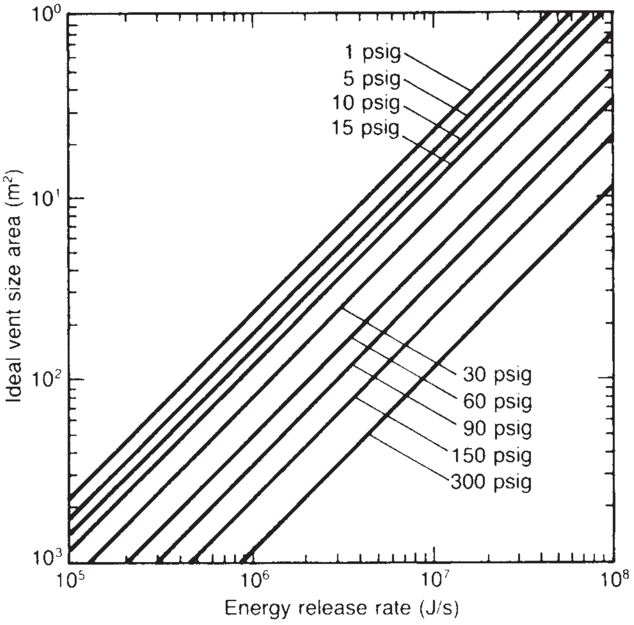

Figure 17.49 Venting of chemical reactors: nomograph for vent sizing for a vapour pressure system (Fauske, Gmimes and Clare, 1989) (Courtesy of the American Institute of Chemical Engineers)

17.19.7 Gassy systems: Fauske nomograph

A method for gassy systems, and an associated nomograph, have been given by Fauske, Grolmes and Clare (1989). The relation given for the vent area is

$$A = \left(\frac{1}{2}\right)^{1/2} \frac{Q_g}{F} \left(\frac{\rho_l}{P - P_a}\right)^{1/2} \qquad [17.19.11]$$

where P is the absolute pressure (Pa) and P_a is the absolute atmospheric pressure (Pa). (In the authors' paper the term $P - P_a$ is written as P where the latter is a gauge pressure.)

The flow reduction factor F for use in Equation 17.19.11 is given in Table 17.19, column 3.

Figure 17.50 is a nomograph based on Equation 17.19.11. The nomograph is for the following conditions: $\rho_l = 1000\ \mathrm{kg/m^3}$ and $L/D = 0$.

17.19.8 Hybrid systems

For hybrid systems, the situation is more complex. The behaviour of the system depends on whether it is tempered or non-tempered.

Untempered hybrid systems have generally to be treated as gassy systems.

A relation for the vent area at initiation of homogeneous two-phase venting, reflecting the worst case, is given in the Technology Summary (Equation 2.5) as follows:

$$A = \frac{(Q_g + Q_v)_{\rho_l}(1 - \alpha)}{G} \qquad [17.19.12]$$

where Q_g is the peak volumetric gas evolution rate (m^3/s) and Q_v is the peak volumetric vapour evolution rate (m^3/s).

Tempered hybrid systems may be treated as tempered systems, provided it is assured that the system really is tempered and will continue to be so until the reaction is complete.

Effective tempering can occur well before the peak volume generation rate.

Leung and Fauske (1987) have described the application of Leung's method to a tempered hybrid system.

17.19.9 Bench-scale equipment

As already described, the bench-scale equipment may be used in three different ways: (1) to determine the required flow, (2) to determine the parameters for the calculation of flow, and (3) to effect direct scale-up.

There are certain pitfalls in the use of bench-scale apparatus. These are described in the accounts given by Fauske and co-workers together with the precautions necessary to avoid them (Fauske, 1984a, 1985a).

The inaccuracies due to high thermal inertia, or ϕ value, are minimized in the DIERS apparatus by its design.

The viscosity of the reaction mass is often not known and the possibility may exist that the vent flow will be not turbulent but laminar. This can be checked by measuring the vent flow in the bench-scale test.

An important feature for both vapour pressure and gassy systems is the effect of reactor height, since the superficial velocity is a function of height and is therefore much larger at the full scale than at bench-scale.

There is a possibility that with vapour pressure systems the volumetric vent flow may be high at bench-scale because the flow is all vapour rather than two-phase and/or because it is non-equilibrium due to insufficient relaxation length.

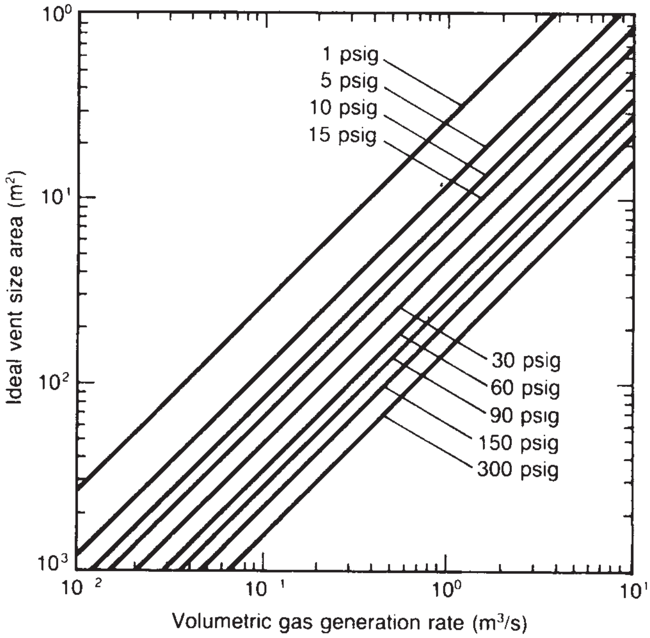

Figure 17.50 *Venting of chemical reactors: nomograph for vent sizing for a gassy system (Fauske, Grolmes and Clare, 1989) (Courtesy of the American Institute of Chemical Engineers)*

With a vapour pressure or hybrid tempered system it is necessary to ensure that the system remains tempered throughout by running the reaction to term. It is also necessary to confirm that there are no further reaction exotherms.

17.19.10 Direct scale-up

A method for direct scale-up from the bench-scale apparatus, applicable only to vapour pressure systems, has been described by Fauske (1984c). An experiment is performed with bottom venting and with a vent line long enough to ensure equilibrium flow ($L > 0.1$ m) and the adiabatic rise time Δt_A and vessel emptying time Δt_E are determined. The vent area of the full scale reactor is then obtained as

$$A_{LS} = A_T \frac{\Delta t_E}{\Delta t_A} \frac{V_{LS}}{V_T} \qquad [17.19.13]$$

where A is the vent area (m^2), Δt_A is the measured adiabatic rise time (s), Δt_E is the measured vessel emptying time (s) and the subscripts LS and T denote large scale and test, respectively.

For gassy systems Fauske (1985a) states that use of top venting on the bench-scale apparatus and direct scale-up on a vent area/reactor volume basis is suitable.

17.19.11 Validation

The DIERS project and the subsequent work have included a number of validation exercises.

The Technology Summary describes the validation of the method for vapour pressure systems against incidents described by Burchett (1980) and a large-scale styrene/ethylbenzene test.

The Burchett incidents involved runaways of chloroprene reactions. The first was in a 11,355 litre vessel with a 0.010 m bursting disc set at 0.3 MPa and an equivalent-sized vent pipe, which vented safely. The second incident was in a 7570 litre vessel with a bursting disc of the same size, but set at 0.61 MPa, which resulted in vessel rupture. On the assumption of churn turbulent flow it is predicted that both vessels should vent safely, whilst on the assumption of homogeneous venting (homogeneous vessel behaviour and homogeneous equilibrium vent flow), the prediction is that the first vessel would vent safely but that the second would not, which is what happened.

These incidents are also treated by Fauske (1984c).

The method for vapour pressure systems has also been compared by Fauske (1984a) with the results from a number of methods, as described in Section 17.19.2.

Test data for some 55 systems, tempered and non-tempered, have been given by Leung and Fauske (1987). They give comparisons with the vent area predicted by the FIA method.

Fauske (1989a) gives some experimental data obtained on both bench-scale and large scale equipment, as shown in Table 17.20. The table shows the measured mass velocities together with the values obtained by calculation from Equation 17.18.12 and by scale-up.

Kirch, Magee and Stuper (1990) compare the DIERS method with a method used by their company based on scale-up using a constant ratio of the vent area to the charge volume.

17.19.12 Illustrative examples

A variety of illustrative examples are given in the Technology Summary and by Fauske and co-workers.

The main examples in the Technology Summary are in Appendix D, which gives calculations for determination of the flow regime into the vent and of the mass velocity with homogeneous flow and with partial vapour disengagement for a nozzle vent and for a long line vent.

Leung (1986b) gives two examples: one is the styrene polymerization described by Huff (1982b) and the other a phenolic reaction described by the BPF (1979) and Booth *et al.* (1980).

Leung and Fauske (1987) deal with the following types of system: type Ia, a vapour pressure, tempered system; type Ib, a gassy tempered system and type II a non-tempered system. These are illustrated by a phenol–formaldehyde reaction, a hydrogen peroxide reaction and a hypothetical gassy reaction, respectively. They give illustrative examples for all three cases.

Examples illustrating the application of the methods to check existing plant are given by Fauske (1988a), who deals with a vapour pressure system for three cases: (1) without vapour disengagement, (2) with disengagement, and (3) check for potential viscosity effect (none found).

Fauske and Leung (1985) describe a study of the reaction runaway for an 80% styrene/20% ethylbenzene reaction which combines elements of validation and illustration. This system is a vapour pressure system and is foamy. The mass velocity was calculated from Equation 17.18.5, which requires no experimental data. The vent area was obtained from the model of Leung, Equation 17.20.18 with its supporting Equation 17.20.19, described below. This requires the self-heat rates at the set and turnaround temperatures. The bench-scale apparatus was used to obtain these self-heat rates. It was also used to check the mass velocity determined from Equation 17.18.5. This agreed within 10%

Table 17.20 *Venting of chemical reactors: some experimental data, bench-scale and large scale, on the venting of runaway reactions of polystyrene/ethylbenzene (Fauske, 1989a) (Courtesy of American Institute of Chemical Engineers)*

Vent diameter (m)	*Vent length/vent diameter*	*Stagnation conditions*				*Mass velocity* (kg/m^{2}s)

***Table 17.21** Venting of chemical reactors: illustrative calculation of vent sizing for reactor with vapour pressure system (after Fauske and Leung, 1985) (Courtesy of American Institute of Chemical Engineers)*

A Scenario

Liquid specific head $C = 2520$ kJ/kg K
Initial reaction mass $m_o = 5000$ kg
Reactor volume $V = 7.78\ \mathrm{m}^3$
Set pressure $P_s = 5.15 \times 10^5$ Pa
Set temperature $T_s = 491$ K
$\mathrm{d}P/\mathrm{d}T = 8246$ Pa/K
$(\mathrm{d}T/\mathrm{d}t)_s = 0.25°\mathrm{C/s}$
$(\mathrm{d}T/\mathrm{d}t)_m = 0.33°\mathrm{C/s}$
Mass velocity $G = 3640\ \mathrm{kg/m^2, s}$

B Vent sizing

Using Equation 17.20.19:

$$q = \tfrac{1}{2}2520(0.25 + 0.33) = 0.735\,\mathrm{kW/kg}$$

Using Equation 17.20.18

$$A = \frac{5000 \times 735}{3640\left[([7.78/5000](491 \times 8546)^{1/2} + (2520 \times 11.6)^{1/2}\right]^2}$$
$$= 0.016\,\mathrm{m}^2$$

confirming the validity of Equation 17.18.5 which assumes turbulent flow.

Estimates of vent size were made for a range of overpressures using Equation 17.20.18. Estimates were also made using SAFIRE. There was excellent agreement between the two.

Table 17.21 shows the calculations given by the authors for the vent area using Equation 17.20.18 for this case.

In addition, a kinetic model for this reaction, given by Husain and Hamilec (1978), was used to predict the temperature and pressure profiles of the reaction. The predictions agreed well with the profiles measured in the bench-scale apparatus.

17.19.13 Safety factors

Whatever method of vent sizing is used, a safety factor should be applied, having regard to the accuracy of the method itself and of the data used.

There is relatively little guidance given on this by Fauske and co-workers or by DIERS, but the problem has been discussed by Duxbury and Wilday (1990). These authors describe several methods for vent sizing and mention certain safety factors. The safety factor to be applied is specific to the particular method and in each case the safety factor should be applied before a choice is made between the methods.

Safety factors are discussed further in Section 17.21 and Appendix 13.

17.20 Venting of Reactors and Vessels: Leung Model

Another model for vent sizing both of reactors and of storage vessels which has found wide acceptance has been given by Leung (1986b).

The model gives relations for vent sizing. The equations for vent area contain the vent flow mass velocity, but the model may be regarded as independent of the vent flow correlation used. The author does, however, state his own homogeneous equilibrium model (Leung, 1986a).

The model applies to vapour pressure systems, which give the tempering effect. It includes relations for the following cases:

(1) reactors
    (a) homogeneous venting,
    (b) all vapour or all liquid venting;
(2) storage vessels
    (a) homogeneous venting,
    (b) all vapour or all liquid venting.

The basic relations of the model and the treatments of these cases are now described.

17.20.1 Elementary relations

The unsteady-state mass and energy balances for the vessel, reactor or storage vessel are

$$\frac{\mathrm{d}(\rho V)}{\mathrm{d}t} = -W \qquad [17.20.1]$$

$$\frac{\mathrm{d}(\rho V u)}{\mathrm{d}t} = Q - W\left(u_1 + \frac{P}{\rho_1}\right) \qquad [17.20.2]$$

where P is the absolute pressure, Q is the heat generation or input rate, T is the absolute temperature, u is the specific internal energy, V is the volume of the vessel, W is the mass flow from the vessel, ρ is the density and the subscript 1 denotes vent inlet. Combining Equations 17.20.1 and 17.20.2 leads to

$$\rho V \frac{\mathrm{d}u}{\mathrm{d}t} = Q - W\left(u_1 - u + \frac{P}{\rho_1}\right) \qquad [17.20.3]$$

But

$$m = \rho V \qquad [17.20.4]$$

$$\rho = 1/v \qquad [17.20.5]$$

$$v = v_f + x v_{fg} \qquad [17.20.6]$$

$$u = u_f + x u_{fg} \qquad [17.20.7]$$

$$h = u + Pv \qquad [17.20.8]$$

where h is the specific enthalpy, h_{fg} is the latent heat of vaporization, m is the mass of material in the vessel, x is the mass fraction of the vapour, or quality, and the subscript f denotes liquid and fg liquid–vapour transition. Then, from Equations 17.20.3 and 17.20.4–17.20.8

$$m\left(\frac{\mathrm{d}u_f}{\mathrm{d}T} + x\frac{\mathrm{d}u_{fg}}{\mathrm{d}T}\right)\frac{\mathrm{d}T}{\mathrm{d}t} = Q - W[(x_1 - x)u_{fg} + Pv_1] - m u_{fg}\frac{\mathrm{d}x}{\mathrm{d}t} \qquad [17.20.9]$$

Noting that $\mathrm{d}V/\mathrm{d}t = 0$, Equation 17.20.1 may be expressed as

$$\frac{\mathrm{d}m}{\mathrm{d}t} = -w \qquad [17.20.10]$$

With constant phase properties Equation 17.20.10 becomes

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{Wv}{mv_{\mathrm{fg}}} \qquad [17.20.11]$$

For an ideal gas and a nearly full vessel a practical approximation is obtained by reformulating the left-hand side of Equation 17.20.9 to give

$$mx\left\{(C_{\mathrm{pg}} - R) + (1 - x)\left[C_{\mathrm{pf}} - T\left(\frac{\mathrm{d}v_{\mathrm{f}}}{\mathrm{d}T}\right)\left(\frac{\mathrm{d}P}{\mathrm{d}T}\right)\right]\right\}\frac{\mathrm{d}T}{\mathrm{d}t} = Q - W[(x_1 - x)u_{\mathrm{fg}} + P_{\mathrm{V}_1}] - mu_{\mathrm{fg}}\frac{\mathrm{d}x}{\mathrm{d}t} \qquad [17.20.12]$$

where C_{pf} is the specific heat at constant pressure of the liquid, C_{pg} is the specific heat at constant pressure of the vapour and R is the gas constant. Then, from Equations 17.20.11 and 17.20.12

$$mC\frac{\mathrm{d}T}{\mathrm{d}t} = Q - Wh_{\mathrm{fg}}\left(x_1 + \frac{v_{\mathrm{f}}}{v_{\mathrm{fg}}}\right) \qquad [17.20.13]$$

where C is the specific heat at constant volume of the liquid, the assumption being made that $C_{\mathrm{pf}} \approx C_{\mathrm{vf}} \approx C$.

Equation 17.20.13 is used to derive expressions for the vent area for the specific cases.

The vent area is given by the relation

$$W = GA \qquad [17.20.14]$$

where A is the area of the vent and G is the mass velocity of the vent flow.

17.20.2 Reactor venting: homogeneous venting

For a reactor with homogeneous venting

$$x_1 = x \qquad [17.20.15]$$

$$v_1 = v = V/m \qquad [17.20.16]$$

Hence, Equation 17.20.13 becomes

$$mC\frac{\mathrm{d}t}{\mathrm{d}t} = mq - GA\frac{V}{m}\frac{h_{\mathrm{fg}}}{v_{\mathrm{fg}}} \qquad [17.20.17]$$

where q is the heat release rate per unit mass.

On certain assumptions and utilizing Equations 17.20.1 and 17.20.14, Equation 17.20.17 can be integrated to yield

$$A = \frac{m_{\mathrm{o}}q}{G\left[\left(\frac{V}{m_{\mathrm{o}}}\frac{h_{\mathrm{fg}}}{v_{\mathrm{fg}}}\right)^{1/2} + (C\Delta T)^{1/2}\right]^2} \qquad [17.20.18]$$

with arbitrary average

$$q = \frac{1}{2}C\left[\left(\frac{\mathrm{d}T}{\mathrm{d}t}\right)_{\mathrm{s}} + \left(\frac{\mathrm{d}T}{\mathrm{d}t}\right)_{\mathrm{m}}\right] \qquad [17.20.19]$$

where m_{o} is the initial mass in the vessel and the subscripts m and s denote peak pressure or temperature and relief set pressure, respectively. For zero overpressure, Equation 17.20.18 reduces to

$$A_{\mathrm{o}} = \frac{m_{\mathrm{o}}q_{\mathrm{s}}v_{\mathrm{fg}}}{Gvh_{\mathrm{fg}}} \qquad [17.20.20]$$

where A_{o} is the area of the vent for zero overpressure.

17.20.3 Reactor venting: all vapour or all liquid venting

For a reactor with all vapour or all liquid venting

$$v_{\mathrm{i}} = v_{\mathrm{g}} \quad \text{all vapour venting} \qquad [17.20.21]$$

$$= v_{\mathrm{f}} \quad \text{all liquid venting} \qquad [17.20.22]$$

where the subscript i denotes phase (either g or f). Hence Equation 17.20.13 becomes

$$mC\frac{\mathrm{d}T}{\mathrm{d}t} = mq - GAv_{\mathrm{i}}\frac{h_{\mathrm{fg}}}{v_{\mathrm{fg}}} \qquad [17.20.23]$$

This equation can be integrated to give

$$T_{\mathrm{m}} - T_{\mathrm{s}} = \frac{m_{\mathrm{o}}q}{GAC}\left(1 - \frac{A}{A_{\mathrm{o}}}\right) + \frac{v_{\mathrm{i}}h_{\mathrm{fg}}}{v_{\mathrm{fg}}C}\ln\left(\frac{A}{A_{\mathrm{o}}}\right) \qquad [17.20.24]$$

with

$$A_{\mathrm{o}} = \frac{m_{\mathrm{o}}q_{\mathrm{s}}v_{\mathrm{fg}}}{Gv_{\mathrm{i}}h_{\mathrm{fg}}} \qquad [17.20.25]$$

For zero overpressure, Equation 17.20.24 reduces to the correct limit with $A = A_{\mathrm{o}}$.

17.20.4 Storage vessel venting: homogeneous venting

For a storage vessel with homogeneous venting

$$Q = Q_{\mathrm{T}} \qquad [17.20.26]$$

where Q_{T} is the total heat input. Hence, Equation 17.20.13 becomes

$$mC\frac{\mathrm{d}T}{\mathrm{d}t} = Q_{\mathrm{T}} - GA\frac{V}{m}\frac{h_{\mathrm{fg}}}{v_{\mathrm{fg}}} \qquad [17.20.27]$$

This equation can be integrated to give

$$T_{\mathrm{m}} - T_{\mathrm{s}} = \frac{Q_{\mathrm{T}}}{GAC}\left[\ln\left(\frac{m_{\mathrm{o}}}{V}\frac{Q_{\mathrm{T}}}{GA}\frac{v_{\mathrm{fg}}}{h_{\mathrm{fg}}}\right) - 1\right] + \frac{Vh_{\mathrm{fg}}}{m_{\mathrm{o}}Cv_{\mathrm{fg}}} \qquad [17.20.28]$$

For zero overpressure, Equation 17.20.28 reduces to the correct limit

$$A_{\mathrm{o}} = \frac{Q_{\mathrm{T}}m_{\mathrm{o}}v_{\mathrm{fg}}}{GVh_{\mathrm{fg}}} \qquad [17.20.29]$$

A comparison of the reactor and storage vessel cases may be made by setting $Q_{\mathrm{T}} = m_{\mathrm{o}}q$ and $v = V/m_{\mathrm{o}}$. Equations 17.20.20 and 17.20.29 are then equivalent.

Leung refers to the work of Forest (1985), who has given a relationship which is equivalent to, but differs slightly in form from, Equation 17.20.29 and which has found application to the fire exposure of storage vessels.

17.20.5 Storage vessel venting: all vapour or all liquid venting

For a storage vessel with all vapour or all liquid venting, utilizing again $v_i = v_g$ and $v_i = v_f$ for the two cases, respectively, Equation 17.20.13 becomes

$$mC\frac{dT}{dt} = Q_T - GAv_i\frac{h_{fg}}{v_{fg}} \qquad [17.20.30]$$

For all vapour venting, it is assumed that the design is for no overpressure. The right-hand side of Equation 17.20.30 is set to zero to yield

$$A_o = \frac{Q_T v_{fg}}{G v_g h_{fg}} \qquad [17.20.31]$$

For all liquid venting, it is assumed that temperature turnaround occurs at a point where the vessel contains 10% of its initial inventory. Equation 17.20.30 can then be integrated to yield

$$A = \frac{Q_T}{G\left(v_f\dfrac{h_{fg}}{v_{fg}} + \dfrac{C\Delta T}{e}\right)} \qquad [17.20.32]$$

where e is the base of natural logarithms (= 2.303). For zero overpressure, Equation 17.20.32 reduces to

$$A_o = \frac{Q_T v_{fg}}{G_{v_g} h_{fg}} \qquad [17.20.33]$$

17.20.6 Illustrative examples

Leung gives illustrations of the effect of these different assumptions on the vent areas required for venting of reactors and storage vessels. His results are shown in Figure 17.51. Figure 17.51(a) shows an example for a reactor with a phenolic reaction and Figure 17.51(b) one for an LPG storage vessel.

17.21 Venting of Reactors and Vessels: ICI Scheme

Accounts of the approach to vent sizing for reactors used in ICI have been given by Duxbury and Wilday (1987, 1989, 1990). These provide a useful insight into the way in which one company has integrated the DIERS methods with other methods. The description given here is based unless otherwise stated on the most recent paper. The basic notation is the same as that used in Section 17.20.

17.21.1 Set pressure and overpressure

An effective, or redefined, set pressure is defined as the pressure at which the relief device is known to be fully open. For a bursting disc this will correspond to the nominal set pressure plus any tolerances or to the maximum specified bursting pressure. For a safety valve the redefined set pressure will often be 10% above the nominal set pressure. Similarly, an effective, or redefined, overpressure is defined as the difference between the redefined set pressure and the maximum pressure attained during the venting process. These definitions differ from those in some standards, including the British Standards, but are implicit in much of the DIERS work.

17.21.2 Vent sizing methods

Duxbury and Wilday (1989) give a list of vent sizing methods. This list is given in Table 17.22. All the methods, except method M, may, in appropriate circumstances, be applicable to vapour pressure systems.

17.21.3 Vent flow

The methods used for estimation of vent flow described by Duxbury and Wilday (1990) are those applicable to vapour pressure systems. Use is made of the ERM given in Equations 17.18.4 and 17.18.5 where it is applicable. Where it is not applicable, a fluid flow code is utilized.

If venting is through a safety valve, it is usually sized using the ERM, but where the pipework is significant, a fluid flow code is used to check pressure drops upstream and downstream. If venting is through a bursting disc the vent line flow correction factor provided for use with the ERM model is used for preliminary estimates, but since it is applicable only to a vent line with constant diameter and no static head changes, the final calculation is done using the fluid flow code.

17.21.4 Vapour pressure systems

For vapour pressure systems, use is made of Leung's method, as given in Equation 17.20.18. The assumption of homogeneous equilibrium flow is safe and generally realistic and the method gives a safe and usually acceptable vent size.

An alternative and sometimes more convenient formulation of Equation 17.20.18,

$$A = \frac{m_o q}{G\left[\left(\dfrac{V}{m_o}T_m\left(\dfrac{dP}{dT}\right)_m\right)^{1/2} + (C\Delta T)^{1/2}\right]^2} \qquad [17.21.1]$$

where subscript m denotes the mean value between the set pressure (as redefined) and the maximum allowable pressure.

The authors term this the Leung long-form equation (method J).

Where it is suitable, use is also made of Fauske's method for vapour pressure systems. This is the enhanced method which takes account of vapour disengagement, as given in Equation 17.19.6 (method K).

The Fauske method is used in conjunction with the Leung method. In the first instance it provides a check. If the two methods are significantly different, the calculations are reviewed. A significantly smaller answer from the Fauske method would not be accepted without rechecking the conditions for applicability and checking that the vent is large enough for all vapour venting.

Appropriate safety factors are then applied for each method. One safety factor is associated with the uncertainties in the data. If 'safe' values have been used, this safety factor is taken as unity. Another safety factor is associated with uncertainties in the vent flow calculation. Typically, this safety factor is in the range 1–2 on flow, or area, the larger values being typical for two-phase flow in long lines. A detailed treatment of safety factors by Duxbury is given in Appendix 13.

The vent sizes from the two methods so obtained are then compared. The final vent size is taken as the smaller of the two.

Q	Wilday's method for homogeneous venting at high overpressure	Duxbury and Wilday (1989)

This hand calculation method is generally both convenient and sufficient. The main effort required is associated with definition of the worst case conditions and gathering of data rather than with the vent sizing as such. Other methods are used only if both methods are judged to be inapplicable or if the vent size obtained is unacceptably large.

Before applying either method it is necessary to review its applicability.

The DIERS documentation states that Leung's method is limited to effective overpressures of 0–50%. It tends in fact to overestimate the vent size for higher overpressures. In order to permit integration, the model assumes constant various quantities such as physical and thermodynamic properties, heat evolution rate and vent capacity per unit area. The values of the parameters at the set pressure and maximum allowable pressure may be compared in order to assess the error and the extent to which the model may tend to oversize the vent.

The Fauske method is based on the ERM with a correction factor for vent line length. It is limited to overpressures in the range 10–30% and to turbulent flow.

In most cases the Fauske method is used without taking vapour disengagement into account and thus with α_d set equal to unity.

For those cases where credit is to be taken for vapour disengagement, it is necessary to perform the following check. The Fauske method is regarded as potentially unsafe if early vapour disengagement occurs, which in this context means disengagement occurring before the pressure would otherwise have turned around during two-phase venting. The method is therefore used only if disengagement would have occurred after the turnaround. Duxbury and Wilday (1989) have derived the following criterion which must be satisfied for safe use of the method:

$$q < \frac{GAh_{fg}v_f^2}{Vv_{fg}(1-\alpha_d)^2} \qquad [17.21.2]$$

where α_d is the void fraction at disengagement.

17.21.5 Vapour pressure systems: enhancements of Wilday

Duxbury and Wilday (1989) describe two enhancements to the Leung method (method J) for vapour pressure systems developed by Wilday.

The first of these (method P) is for the case where there is vapour disengagement part-way through the venting, with two-phase flow in the early part and all vapour flow in the later part and, further, the disengagement occurs before the pressure would have turned around during homogeneous venting. It is based on an adaptation of Leung's model. The following additional equations may be written:

$$m = V(1-\alpha)/v_f \qquad [17.21.3]$$

and, neglecting the vapour phase mass,

$$m_o = V(1-\alpha_o)/v_f \qquad [17.21.4]$$

where α is the void fraction and α_o is the initial void fraction.

Then, combining Equations 17.20.1 and 17.20.17 of Leung and Equations 17.21.3 and 17.21.4 gives

$$A = \frac{qV(\alpha-\alpha_o)}{Gv_f\left(\dfrac{h_{fg}v_{fg}(\alpha-\alpha_o)}{v_{fg}(1-\alpha_o)(1-\alpha)} + C\Delta T\right)} \qquad [17.21.5]$$

This method is valid only if vapour disengagement occurs before the point at which pressure turnaround would have occurred in homogeneous venting. Otherwise it gives too small a vent area and is unsafe. Before pressure turnaround the rate of temperature rise dT/dt in a vapour pressure system is positive, and hence from Equation 17.20.17

$$mq > GA\frac{V}{m}\frac{h_{fg}}{v_{fg}} \qquad [17.21.6]$$

which with Equation 17.21.3 gives the criterion

$$q > \frac{GAh_{\mathrm{fg}}v_{\mathrm{f}}^2}{Vv_{\mathrm{fg}}(1-\alpha_{\mathrm{d}})^2} \qquad [17.21.7]$$

The second method given by Wilday (method Q) is based on Leung's model for homogeneous venting (method J). The assumption underlying this model is that the physical properties, heat release rate and mass velocity are constant. Wilday's method involves dividing the available pressure range into stages in which it is more reasonable to assume these quantities constant. Again, criteria are given for the applicability of the method.

17.21.6 Gassy systems

For gassy systems, the principal method of vent sizing is based on maintaining the pressure constant.

The vent is sized so that the two-phase volumetric flow at the maximum allowable pressure exceeds the peak volumetric gas generation rate at that pressure. The vent sizing equation given is Equation 17.19.9. An appropriate safety factor should then be applied as described in Section 17.21.4.

Use of the Fauske nomograph for gassy systems, Figure 17.50, would be limited to making preliminary estimates. Mention is also made of the treatment of gassy systems by Leung and Fauske (1987).

For gassy systems, use may also be made of direct scale-up, which may well give a smaller vent area due to early loss of reactant. Alternatively, the vent may be sized by simulation using a numerical model. Again, for the reason just given, this may give a smaller vent.

A note of caution is sounded in that for gassy systems it may be unsafe to make the assumption of homogeneous two-phase venting. This assumption gives the maximum rate of emptying the reactor. If some disengagement occurs, liquid will remain in the reactor and the peak gas generation rate may be reached. A larger vent may then be required than for the relatively low gas generation rate occurring earlier in the relief process.

17.21.7 Hybrid systems

For hybrid systems, the appropriate method depends on whether the reaction is tempered. For tempered hybrid systems, it is first necessary to check that the reaction will remain tempered throughout. Reference is made to the treatment of such systems by Leung and Fauske (1987).

Untempered hybrid systems usually have to be treated as gassy systems. Use would be made of Equation 17.19.9 provided the vent size obtained is not excessive. The flow Q_g to be used in that equation is the total volumetric evolution of both gas and vapour.

17.21.8 Illustrative examples

The illustrative examples of vent sizing for a vapour pressure system and a gassy system given by Duxbury and Wilday (1990) are summarized in Table 17.23.

17.22 Venting of Reactors: Relief Disposal

17.22.1 General considerations

The problem of reactor relief does not stop with the venting. There remains the question of the disposal of the vented materials, which is often not trivial. The engineering of relief disposal is therefore a topic in its own right. An account is given by Kneale (1984).

The legal requirement is that any venting should be to 'a safe place'. Discharge to atmosphere may meet this requirement, but such discharge is increasingly constrained.

The options for disposal are (1) discharge and dispersion, (2) destruction, and (3) containment.

A full definition of the relief requirements is as important for the design of the disposal system as for that of the relief device itself. Cases which should be considered include cooling failure during normal reaction, runaway of reaction for other reasons, explosion due to runaway or thermal instability, fire, overpressure by gas and overfilling by liquid.

The relieving process may be violent, and all equipment connected to the relief device, however remotely, should be designed for the hydraulic and mechanical forces released. This includes not only the inlet and outlet lines to the device but vessel and line supports, foundations and foundation bolts, and building structures.

Some common causes of deficiencies in relief disposal systems include failure to allow for (1) the presence of another phase, (2) the presence of fine particles, and (3) variation in emission with time.

A general strategy for relief disposal is shown in Figures 17.52 and 17.53. Liquid and solid are to be treated or contained and treated later, whilst liquid is contained and treated later.

Gas should be discharged to atmosphere only if it can be dependably diluted below any flammable and/or toxic limits which have to be met. Relations for the dispersion of such discharges are given in Chapter 15.

A study by Gerardu (1981) concluded that it is often simpler and safer to vent a pressure relief valve directly to the atmosphere, provided the hazard of ignition is allowed for.

It should be appreciated, however, that emergency discharge from a reactor is a transient process and that towards the end of this process the discharge will lose momentum and will tend to slump. This stage may well be the most hazardous, but also the most difficult to model.

Vents for the discharge of flammable gas to the atmosphere may be equipped with flame arresters, but where it is considered that the maintenance of such arresters cannot be guaranteed, they are often omitted.

Gas relieved is often sent to flare. The efficiency of destruction of combustible gas in a flare can be high; studies have shown combustion efficiencies well in excess of 99% (B.C. Davis, 1983). An alternative means of dealing with gas is scrubbing. A major factor in the choice of system is whether the scrubber has the function of handling a normal process gas stream or of treating the emergency vent gas only. In the latter case the options are to run with liquid constantly circulating or to start up automatically when venting starts. The cost of continuous circulation can be high, but it is not usual to rely on automatic start-up. Problems which can occur with scrubbers are boiling due to the high heat load imposed by the vent gas and carryover of spray.

Another option for handling the vented material is containment in a separate containment vessel, or catchtank. If the vent stream contains liquid or solid this is the appropriate design. Systems vary widely in complexity depending on the duty.

***Table 17.23** Venting of chemical reactors: illustrative calculations of vent size for reactors with (A) a vapour pressure system and (B) a hybrid system treated as a gassy system (after Duxbury and Wilday, 1990) (Courtesy of Institution of Chemical Engineers)*

A Example of vapour pressure system

	Reactor pressure (bara)		
	3.2	4.2	*Average*
Bubble point temperature (°C)	110	120.5	115.3
Liquid density (kg/m^3)	847	835	841
Vapour density (kg/m^3)	3.75	4.62	4.19
Liquid specific heat (J/kg K)	1960	1960	1960
Latent heat (J/kg)	6.749×40^5	6.630×10^5	6.690×10^5
dP/dT (Pa/K)	8300	9500	
v_{fg} (m^3/kg)	0.2655	0.2153	0.2404
Heat release rate (W/kg)	1150	1660	1405

Reactor volume = 2.1 m^3
Reaction mass = 1500 kg
Vessel design pressure = 2.86 barg
Bursting disc pressure[a] = 3.20 bara
Vent line length/diameter = 200

Maximum allowable pressure = 1.1 × 2.86 = 3.15 barg = 4.16 bara
Allowable overpressure = 4.16 − 3.20 = 0.96 bar

For mass velocity at 3.2 bara, using Equation 17.18.9 with a correction factor $F = 0.65$:

$$G = 0.65 \times 8300 \times \left(\frac{383}{1960}\right)^{1/2} = 2385\,\text{kg/m}^2\,\text{s}$$

Alternatively, using Equation 17.18.4:

$$G = 0.65 \times \frac{6.749 \times 10^5}{0.2655}\left(\frac{1}{1960 \times 383}\right)^{1/2} = 1907\,\text{kg/m}^2\,\text{s}$$

Since the difference between these two estimates is appreciable, a rigorous fluid flow method was used to obtain the following estimate:

$$G = 2264\,\text{kg/m}^2\,\text{s}$$

A similar calculation for the mass flux at 4.16 bara gave

$$G = 2688\,\text{kg/m}^2\,\text{s}$$

The average of these two mass fluxes is:

$$G = (2264 + 2688)/2 = 2476\,\text{kg/m}^2\,\text{s}$$

Applying a safety factor of 2 on mass flux:

$$G = 2476/2 = 1238\,\text{kg/m}^2\,\text{s}$$

Allowable temperature rise $\Delta T = 120.5 - 110 = 10.5$ K

(1) Using Leung's method, Equation 17.20.18:

$$A = \frac{1500 \times 1405}{1238\left[\left(\frac{2.1 \times 6.690 \times 10^5}{1500 \times 0.2404}\right)^{0.5} + (1960 \times 10.50)^{0.5}\right]^2} = 0.04\,\text{m}^2; \quad D_v = 0.226\,\text{m}$$

Alternatively, using Equation 17.21.1:

$$\left(\frac{dP}{dT}\right)_m = \frac{(4.16 - 3.2) \times 10^5}{120.5 - 110} = 9143\,\text{Pa/K}$$

$$A = \frac{1500 \times 1405}{1238\left[\left(\frac{2.1 \times 388 \times 9143}{1500}\right)^{0.5} + (1960 \times 10.50)^{0.5}\right]^2} = 0.0372\,\text{m}^2; \quad D_v = 0.218\,\text{m}$$

Table 17.23 *(continued)*

(2) Using Fauske's method, Equation 17.19.6; assume no vapour disengagement so that $\alpha_D = 1$

$$\left(\frac{\mathrm{d}T}{\mathrm{d}t}\right)_s = \left(\frac{q_m}{C_m}\right)_s = \frac{1150}{1960} = 0.587\ \mathrm{K/s}$$

For vent line $L/D = 200$ with a correction factor $F = 0.65$

$$A = \frac{1}{2}\,\frac{1500 \times 0.587}{0.65(383/1960)^{1/2} \times 0.96 \times 10^5}\,\frac{(1-\alpha_o)}{(1-\alpha_o)} = 0.016\ \mathrm{m}^2$$

Applying a safety factor of 2 on vent area:

$A = 2 \times 0.016 = 0.032\ \mathrm{m}^2$; $D_v = 0.202\ \mathrm{m}$

The difference between the vent area given by Leung's method and that given by Fauske's method, after application of the safety factor of 2, is some 20%.

B Example of hybrid system treated as gassy system

Molecular weight of liquid	65
Liquid density at 95°C (kg/m^3)	800
Latent heat (J/kg)	2.76×10^5
Heat release rate (W/kg)	53
Temperature for peak reaction rate (°C)	95
Peak gas evolution rate (l/kg s)[b]	0.146
Reactor volume (m^3)	5.0
Reaction mass (kg)	3200
Maximum allowable pressure (bara)	4.8

From a separate calculation, the mass velocity, including the safety factor, is found to be 2400 kg/m^2 s:

$$\text{Vapour evolution rate} = \frac{3200 \times 53}{2.76 \times 10^5} = 0.614\ \mathrm{kg/s}$$

Volumetric vapour evolution rate at 4.8 bara and 95°C:

$$= \frac{0.614}{65} \times 22.4 \times \frac{368}{273} \times \frac{1.013}{4.8} = 0.06\ \mathrm{m^3/s}$$

Volumetric gas evolution rate at 4.8 bara and 95°C:

$$= 0.146 \times 10^{-3} \times 3200 \times \frac{368}{298} \times \frac{1.013}{4.8} = 0.122\ \mathrm{m^3/s}$$

Liquid volume in reactor $= 3200/800 = 4.0\ \mathrm{m}^3$

Void fraction $\alpha = (5.0 - 4.0)/5.0 = 0.2$

Using Equation 17.19.9:

$$A = \frac{(0.060 + 0.122) \times 800(1 - 0.2)}{2400} = 0.0485\ \mathrm{m}^2; \quad D_v = 0.249\ \mathrm{m}$$

[a] Maximum specified bursting pressure.

[b] Volume (l) measured at atmospheric pressure and 25°C.

Apart from the cost, some problems which arise with containment are (1) reaction forces, (2) undetected leakage, (3) testing, and (4) plugging of lines.

The reaction forces affect the containment vessel as they do the whole system. A leak occurring undetected across the relief system may fill the containment. Testing of the system requires careful thought.

A review of reaction forces has been given by Woods and Thornton (1967) and Leung (2002).

Studies have also been made on particular configurations. The forces on a system consisting of a reactor and a containment vessel separated by a bursting disc have been analysed by Porter (1982), and the interactive effects of bursting discs in a relief manifold by Beveridge and Jones (1984).

Relief venting can give rise to appreciable noise. Sonic flow across a pressure relief device is a very efficient noise generator. The tall vertical stack frequently used for dispersion tends to broadcast noise. Work by Shearer (1969) has shown that at a distance of 200 ft from a vent the noise level in decibels for a wide range of vent flows can be approximated by 25 $\log_{10} V$, where V is the volumetric discharge (scfh).

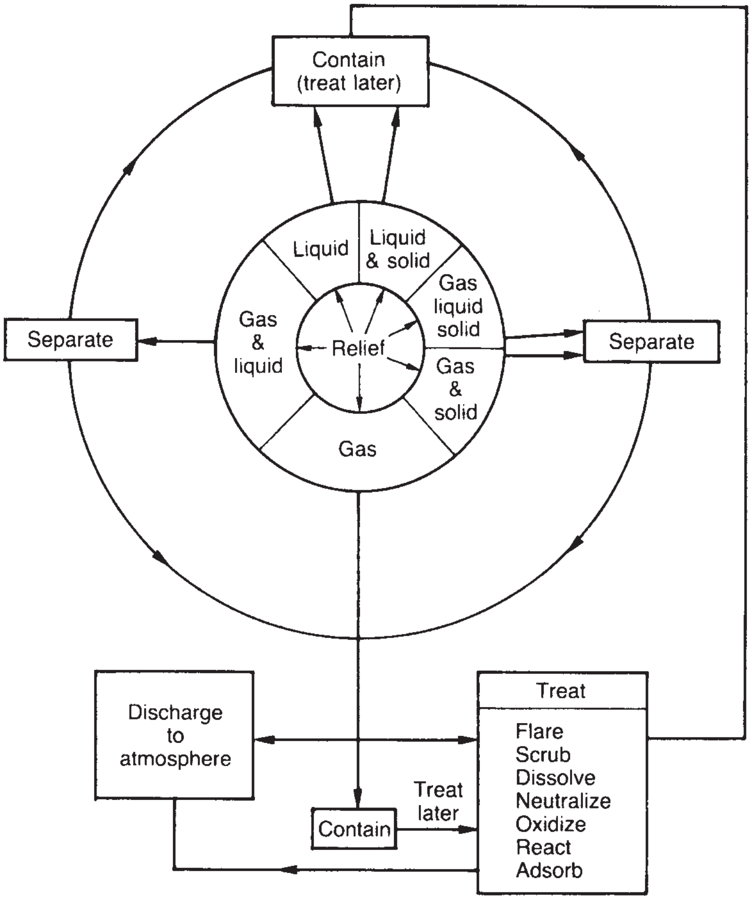

Figure 17.52 *Venting of chemical reactors: a taxonomy for relief disposal (Kneale, 1984) (Courtesy of the Institution of Chemical Engineers)*

This was confirmed experimentally for a range of flows from 1 to 3000 scfh regardless of the initial pressure and temperature. See also Perry and Green (1997 pp. 8–74).

In view of the problems associated with venting, the alternative of containment within the reactor vessel should be considered. Kneale suggests that if vacuum collapse may occur, the vessel should preferably be designed for full vacuum. As far as concerns overpressure he proposes that the vessel design criterion should depend on the expected frequency of overpressure. If overpressure is expected to be a very rare event (say once in 100–10,000 years) the vessel may be designed for overstress beyond the yield point but within the bursting strength, whereas if it is expected more frequently (say once in 10–100 years), a stronger design is appropriate.

Kneale describes a number of incidents arising from reactor venting.

17.22.2 Two-phase relief flows

As already described, there has been growing appreciation, further stimulated by the DIERS work, that it is generally necessary that the relief disposal system for a reactor be capable of handling a two-phase vapour–liquid mixture.

Discussions of the implications of the need to dispose of two-phase mixtures and proposals for dealing with the problem have been given by Fauske (1986a, 1987b), H.G. Fisher (1991) and Fauske and Grolmes (1992).

In particular, more guidance has become available on knockout and catchment facilities.

17.22.3 Knockout drums and catchtanks

Treatments of the design of knockout drums and catchtanks are given in API RP 521: 1990, by the BPF (1979) and by Grossel (1986, 1990b). Further references are given in API RP 521 and in Fthenakis (1993, Chapter 14).

API RP 521 gives a method for the sizing of a knockout drum which has been widely used. The basis is the provision of a cross-sectional area sufficient to ensure that the liquid droplets are not entrained in the vapour. The relation given is

$$u_\mathrm{d} = 1.15\left(\frac{gd(\rho_\mathrm{l} - \rho_\mathrm{v})}{C\rho_\mathrm{v}}\right)^{1/2} \qquad [17.22.1]$$

where d is the particle diameter (m), g is the acceleration due to gravity (m/s^2), u_d is the dropout velocity (m/s), ρ_l is

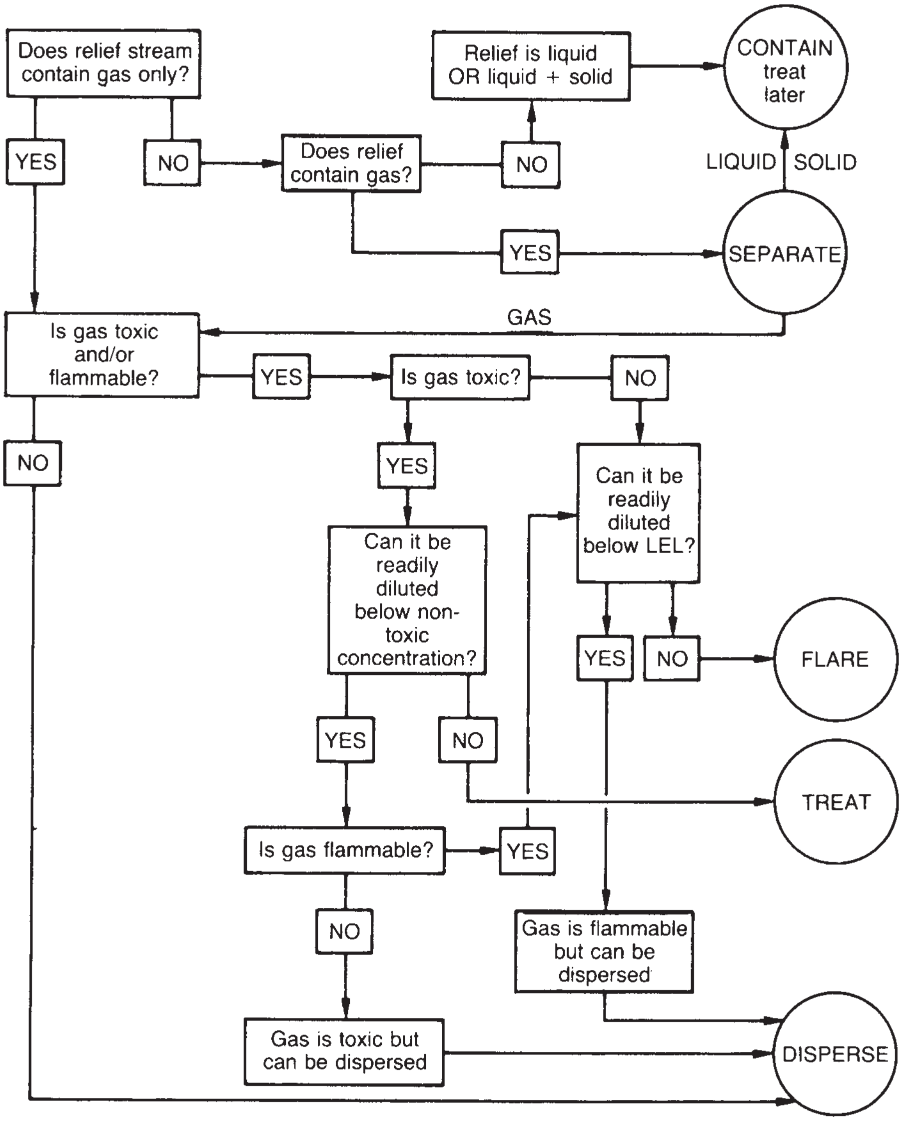

Figure 17.53 *Venting of chemical reactors: decision tree for relief disposal (Kneale, 1984). LEL, lower explosive limit (Courtesy of the Institution of Chemical Engineers)*

the density of the liquid (kg/m^3), ρ_v is the density of the vapour (kg/m^3) and C is the drag coefficient.

The drag coefficient C is given by Figure 17.54 in which

$$C(\mathrm{Re})^2 = 0.13 \times 10^8 \frac{\rho_v d^3(\rho_l - \rho_v)}{\mu^2} \qquad [17.22.2]$$

where μ is the viscosity of the gas (cP).

The selection and design of knockout drums and catchtanks has been described by Grossel (1986). There are a number of reasons why such devices may be needed. In a large proportion of cases the fluid entering the relief disposal system is a two-phase mixture, so that it is necessary to separate the vapour from the liquid, and the liquid is hot and flammable, toxic and/or corrosive.

Grossel describes the following types of knockout and catchtank systems: (1) horizontal drum plus catchtank, typical of a refinery or petrochemical plant where space is not restricted; (2) cyclone separator plus catchtank, typical of chemical plant with less space available; (3) cyclone separator with integral catchtank, capable of handling a large vapour flow; (4) open tank; (5) quencher knockout drum/catchtank; (6) multi-input knockout drum/catchtank, with connections from a group of reactors; and (7) cyclone knockout drum. The first two of these systems are shown in Figure 17.55.

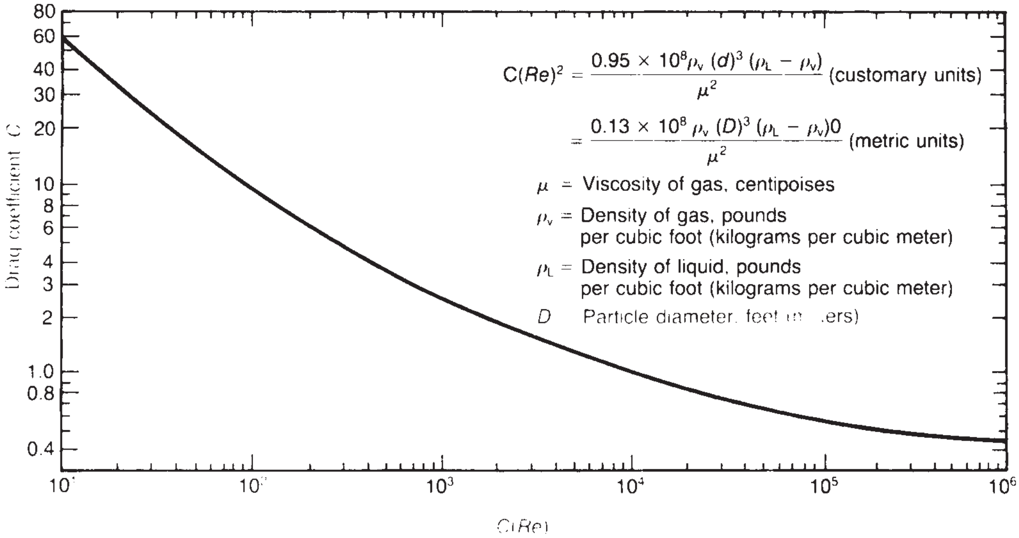

Figure 17.54 *Venting of chemical reactors: drag coefficient for knockout drum design (API RP 521: 1990) (Courtesy of the American Petroleum Institute)*

The open tank system may be used where the relief fluid contains an explosive mixture which it is judged better to release direct to atmosphere than to contain. The quencher knockout drum/catchtank system is used to condense out condensable vapour.

Principal factors in the design of such systems are a volume sufficient to hold the liquid and, for non-cyclone systems, a cross-sectional area sufficient to prevent liquid entrainment.

Expressions are given for the allowable vapour velocity u of the general form

$$u = k\left(\frac{\rho_l - \rho_v}{\rho_v}\right)^{1/2} \qquad [17.22.3]$$

where k is a constant.

For cyclone separators the design requirement may diverge somewhat from that for conventional applications. For a high flow, short duration emergency relief, some mist may be tolerable in the outlet, and a high vapour velocity may be acceptable.

For quench tanks critical features are the suppression pool and quencher arm. The quench liquid should be compatible with the reaction mass to be quenched. The quantity of quench liquid in the pool should be sized so that its temperature rise after condensation of the condensable vapour does not exceed a suitable value. Grossel gives two further rules-of-thumb for the quench fluid. One is that the quantity should be some 2–3 times by volume that of the reaction mass and the other that the exit temperature of the vapour leaving the pool should be at least 10°C below its saturation temperature.

The design of the quench arm is also important. The device is prone to water hammer. Grossel gives several rules-of-thumb for this feature also. One is the limitation of the size of the holes to 1/4 in., since high hole velocities are desirable and large holes may result in water hammer. The other is that the hole area should be at least as great as the cross-sectional area of the inlet pipe from the relief device.

The relief pipework should be as short and as straight as possible. An account of the design of such piping has been given by Chambard (1980).

Consideration should be given to the pressure drop through the relief disposal train and its effect on the back-pressure at the reactor vent.

Guidance is also given by Grossel on mechanical design of the catchtank. He suggests a minimum design pressure of 50 psig. The tank should be able to withstand a deflagration without rupture, though it may deform. Some companies use a design pressure of 125–150 psig.

The blowdown loads should be taken into account. Operation of a relief device creates reaction and impact forces. The reaction vessel is subject to reaction force and impact force due to slugs. Both reactor vessel and piping are affected by fluid acceleration wave forces. A quasi-steady state jet force occurs at the containment vessel.

Further, a quencher vessel is subject to impact force, condensation vibrations and final water hammer. The impact force is due to the impact of the fluid. The final water hammer occurs at the end of blowdown, when, if the reactor has been vented through a bursting disc, condensation can lead to a high flow back into the vent line and reactor vessel.

Grossel states that the catchtank should itself be provided with a bursting disc relieving into the catch-tank vent line to handle continued reaction and fire engulfment, but also that this device is not necessary if its size turns out to be less than that of the aforementioned vent line.

Another design of separator is the vortex separator of Muschelknautz and Mayinger (1986, 1990) described in the CCPS *Guidelines for Vapor Release Mitigation* (1988/4). This separator may be mounted directly above the reactor and may be used to separate the liquid from the vapour prior to the relief device.

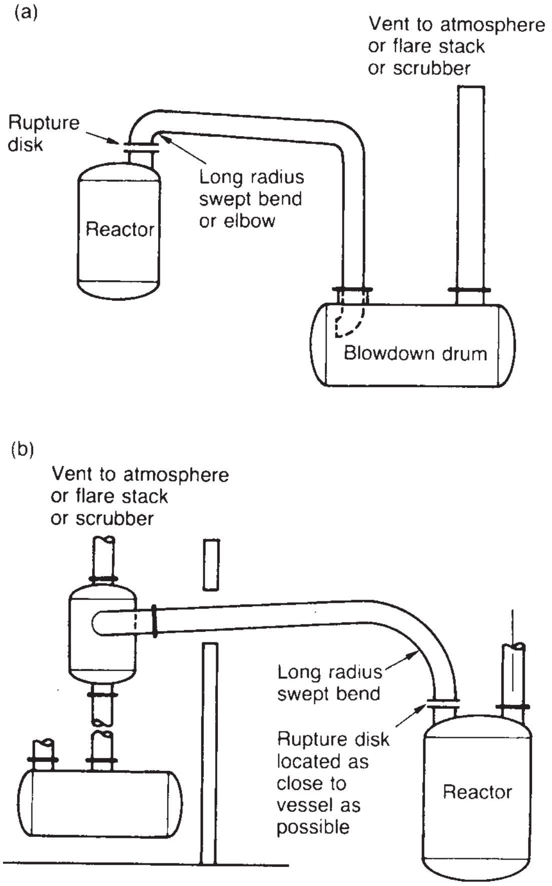

Figure 17.55 *Venting of chemical reactors: blowdown systems (Grossel, 1986): (a) horizontal blowdown drum and (b) knockout drum with separate catchtank (Courtesy of the American Institute of Chemical Engineers)*

17.22.4 Quench systems

The handling of a two-phase mixture in the relief disposal system poses a number of potential problems which have been discussed by Fauske (1986a).

The typical relief train consists of a separator, a scrubber and a flare. A two-phase relief requires a separator, but the typical system has these defects: (1) the relief is liable to be foamy and difficult to separate; (2) the size of the separator is often larger than that of the reactor; (3) the potential may exist for reaction runaway in the separator; and (4) the instantaneous flow may be very high and the flow of scrubbing fluid needs to be correspondingly high.

The method of disposal which Fauske favours to overcome these difficulties is the use of a suitable quench system. This should quench the vapour so that scrubber and/or flare are eliminated, apart from any arrangements needed to deal with small amounts of non-condensables. The selection of the quench fluid is critical, particularly if the reaction mixture has potential for explosive decomposition.

17.23 Venting of Reactors: CCPS Work

The CCPS has done work with a view to providing guidance on relief disposal. An outline of draft *Guidelines for Effective Handling of Emergency Release Effluents* has been given by Huff (1992). He describes a methodology for characterizing and handling the relief flow.

The purpose of the guidelines is to provide sufficient information to allow the non-specialist to do the design of the relief disposal system in more than nine cases out of 10 and to be able to identify those which need to be handled by a specialist. Such cases are typically systems which are chemically reactive, contain fractionating multicomponent systems or fluids near their critical point or involve relief from distributed systems such as long pipe heaters.

The main heads of the guidelines may be summarized as:

(1) relief scenarios;
(2) characterization of flow from protected system;
(3) applicable standards and codes;
(4) relief devices;
(5) flow through relief devices;
(6) installation of relief devices;
(7) disposal scenarios;
(8) disposal strategies;
(9) characterization of flow in relief system.

Guidance is given on the formulation of the relief scenarios and identification of a credible worst case. The problem of scenarios with a high degree of uncertainty is highlighted. Approaches to reducing the relief requirement, such as elimination of aggravating features and the use of alternatives to relief, are described. A checklist is given of events for which relief may be required.

Events in the protected system which may need relief include for non-reactive fluids shut-in pipework and thermal expansion, excess of heating or lack of cooling, and fire exposure, and for reactive fluids runaway reactions.

The characterization of the flow to be handled concentrates particularly on two-phase flow. The mixture vented may be two-phase or it may be superheated so that it becomes two-phase in the relief system. During venting, two-phase flow may stop and start. Information is provided on fluid properties, including mixture properties and phase equilibrium.

The terminology and requirements of standards and codes relevant to relief are summarized, both in respect of the relief pressures and the relief devices. The relief devices recognized in the American National Standards Institute (ANSI) system are described. Guidance is given on sizing and on sources of data. Auxiliary components are also described such as block and diverting valves, bleed system components and non-bleed relief monitors.

The guidelines deal with the selection of relief devices, calculation of the flow through relief devices, sizing of the associated pipework and definition of the flow through the relief disposal system. Methods are given for the calculation of the flow through relief devices, both nozzles and piping, starting with the fundamental equations and following through with working forms of these equations. Devices dealt with include gas safety valves, liquid relief valves, low pressure devices, bursting discs and open vents. Fluids considered include compressible gases and vapours, subcooled liquids, two-phase gas–liquid mixtures and two-phase flashing vapour–liquid mixtures.

The installation of relief devices is treated, including pressure drops in the pipework, provisions to ensure drainage and prevent freezing, static head and siphoning for low pressure devices and backflow from header connections. Mechanical aspects are also considered, including reaction forces.

Guidance is given on the formulation of the disposal scenarios and identification of a credible worst case, which need not necessarily be the same as the worst case for relief. The potential for vent flows in each phase should be considered and a worst case identified for each phase. The maximum flows and volume to be handled should be determined.

The strategies for relief disposal and the various options are described.

The characterization of the flow in the relief system is considered, including volatility, foaming behaviour and state of aggregation of phases.

17.24 Venting of Storage Vessels

It is necessary to protect storage vessels against overpressure and this is done by fitting vents. Principal sources of overpressure are operational deviations and fire, but there are numerous other sources, as described in Chapter 20. The fire protection of storage vessels is discussed in Chapter 16.

Fire is not the sole potential source of heat input to a storage vessel. Many chemicals held in storage have the potential to undergo exothermic reaction. Any external heat source, including fire, may act as an initiator. Addition of water may be another. This effect should be taken account of in considering the venting requirements for storage.

17.24.1 Fire behaviour of atmospheric storage tanks

Work on the fire behaviour and on vent sizing for storage vessels has been described by Fauske, Epstein, Grolmes and Leung (1986) and Fauske (1987a).

Vent sizing for atmospheric storage tanks has traditionally been based on all vapour flow. The aim of the study was to check whether this approach is adequate. The implication of the need to consider two-phase flow would be a large increase in vent size. As a first approximation the increase in vent area required would be of the order of the square root of the ratio of the vapour and liquid densities $(\rho_g/\rho_l)^{1/2}$.

This concern was addressed in an extension of the DIERS project. The work is described in Chapter 15. It was concluded that liquid swell in an externally heated storage tank is essentially limited to the boiling two-phase boundary layer and that for a non-foaming liquid all vapour venting would appear adequate, provided the tank is not completely filled with liquid.

However, for an atmospheric storage tank, it is necessary to avoid entrainment of liquid in the vapour vented. The relation given for the vent area is

$$A = \frac{Q_T}{h_{fg}\rho_g u} \qquad [17.24.1]$$

where A is the area of the vent, h_{fg} is the latent heat of vaporization, Q_T is the total heat input to the tank and u is the velocity of vapour through vent.

The limiting value of the velocity u in Equation 17.24.1 for an atmospheric storage tank is the entrainment velocity u_E:

$$u = u_E \qquad [17.24.2]$$

The relation given for the entrainment velocity is that of Kutateladze (1972):

$$u_E \approx 3.0\left(\frac{\sigma g \rho_l}{\rho_g^2}\right)^{1/4} \qquad [17.24.3]$$

where g is the acceleration due to gravity, ρ_l is the density of the liquid and σ is the surface tension of the liquid.

Fauske (1987a) states that a safety factor of 2 on the vent area determined from Equations 17.24.1–17.24.3 should be adequate even for a foamy liquid.

A criterion for the onset of liquid entrainment in a storage vessel exposed to fire has been given by Epstein, Fauske and Mauser (1989). They consider a hemispherical surface centred on a vent at the centre of the top of a vertical cylindrical vessel. The velocity across this surface is

$$u_s = \frac{1}{2}\left(\frac{a}{s}\right)^2 u_o \qquad [17.24.4]$$

where a is the radius of the vent, s is the radius of the hemisphere, u_s is the velocity across the hemispherical surface and u_o is the velocity up the vent. Onset of entrainment occurs when the velocity u_s attains a critical value u_{scr} at the height $h = s$. Then, from Equation 17.24.4

$$h = a\left(\frac{u_o}{2u_{scr}}\right)^{1/2} \qquad [17.24.5]$$

The authors state that this work indicates that rather small freeboard volumes can be tolerated without the occurrence of two-phase venting.

For vessels which can withstand substantially higher pressures, the approach given by Fauske is to take the velocity u in Equation 17.24.1 as

$$u \approx 2\Delta P/\rho_g \qquad [17.24.6]$$

where ΔP is the pressure drop through the vent system. He states that a factor of 2 on the vent area determined from Equations 17.24.1 and 17.24.6 is generally consistent with a modest overpressure of some 10–30% above the relief pressure even for a foamy liquid.

Further relationships for the vent area for storage vessels with non-foamy liquid have been given by Fauske, Grolmes and Clare (1989). For an atmospheric storage tank

$$A = \frac{Q_v}{3Fh_{fg}[\sigma g(\rho_l - \rho_g)]^{1/4}\rho_g^{1/2}} \qquad [17.24.7]$$

where F is the flow reduction factor and Q_v is the energy release rate. This equation is based on all vapour flow with no entrained liquid.

For a storage vessel capable of withstanding substantially higher pressure

$$A = \frac{Q_v(R_m T)^{1/2}}{0.62Fh_{fg}P_s} \qquad [17.24.8]$$

where P_s is the absolute set pressure, R_m is the mass basis gas constant and T is the absolute temperature. This equation is based on all vapour critical flow.

Fauske, Grolmes and Clare (1989) describe an approach to vent sizing for storage tanks based on relating the external heating rate to an equivalent self-heat rate and give a graph for checking uninsulated and insulated vessels.

17.24.2 Designs for protection of storage vessels

Fauske (1988b, 1989b) has described a number of designs for the protection of atmospheric storage tanks and pressure storage vessels against fire and the hazard of BLEVE.

For atmospheric storage tanks, two designs are given, both involving double wall construction. In one design the intermediate space is filled with water. In the other design there is an air space with facility to inject heating or cooling medium through the space.

For pressure storage vessels, the vessels considered are spheres and there are again two design proposals. The first has an internal spherical baffle so that on fire engulfment the liquid swell would occur in the annulus between the outer wall and the baffle, with liquid being 'pumped' from the bottom to the top of the baffle and then falling down into the centre of the vessel while the vapour is vented. In the other design there is a double wall construction with the vessel held inside a tank, the intermediate space being filled with water.

17.25 Explosive Shock in Air

One of the main effects of an explosion is the creation of a shock wave, or blast wave. This blast wave generates overpressures which may injure people and damage equipment and buildings.

Accounts of explosive shock in air are given in *The Effects of Nuclear Weapons* (Glasstone, 1962) and its later edition (Glasstone and Dolan, 1980), *Explosive Shocks in Air* (Kinney, 1962) and its later edition (Kinney and Graham, 1985), *Explosions in Air* (W.E. Baker, 1973) and *Explosion Hazard and Evaluation* (W.E. Baker *et al.*, 1983).

The situation of prime interest here is that of a chemical explosion at the ground surface and it is this which is mainly considered.

The description given of the explosion is based, unless otherwise stated, on an explosion of high explosive such as TNT.

17.25.1 The blast wave

An explosion in air is accompanied by a very rapid rise in pressure and by the formation of a shock wave. An account of the phenomena involved is given by Glasstone (1962).

The shape of the pressure profile near the centre depends on the type of explosion involved. The initial shape differs for explosions of high explosives, nuclear weapons and flammable vapour clouds.

The initial pressure profile for nuclear explosions is probably the most readily defined. The pressure at the edge of the fireball is approximately twice that at the centre.

With detonations the shock wave travels outwards with the higher pressure parts moving at higher velocities. After it has travelled some distance the shock wave reaches a constant limiting velocity which is greater than the velocity of sound in the air, or in the unburnt gas in the case of a vapour cloud. The shock wave has a profile in which the pressure rises sharply to a peak value and then gradually tails off. As the shock wave travels outwards the peak pressure at the shock front falls.

At some distance from the explosion centre the region of positive pressure, or overpressure, in the shock wave is followed by a region of negative pressure, or underpressure. The underpressure is quite weak and does not exceed about 4 psi.

An idealized representation of the blast wave is given in Figure 17.56. This shows the pressure pulse as a function of distance from the explosion centre with time as the parameter. The shock wave reaches points A,B,C and D at times 1, 2, 3 and 4, respectively, and at these times its pressure profile is as illustrated. The shape of the curve at point A is not shown, since it depends on the type of explosion. As the wave moves outwards, however, the influence of the nature of the explosion declines and the wave establishes a profile which is common to all types of explosion. The curves at points B–D and times 2–4 show the decrease in peak overpressure. The curve at point D and time 4 shows both positive and negative pressures.

The variation of overpressure with time at such a point is illustrated in Figures 17.57(a) and (b). Important parameters are the peak overpressure p°, the arrival time t_a, the duration time t_d, which is the duration of the positive phase, and the decay parameter a, which defines the shape of the decay curve in the positive phase. For a deflagration the rising pressure is gradual and for a detonation it is abrupt.

The peak overpressure p° is more correctly described as the peak side-on overpressure or peak incident overpressure, in order to distinguish it from other peak overpressures such as the peak reflected overpressure described below. The peak side-on overpressure is the peak overpressure occurring at the side of a structure being passed by the blast wave.

There are several equations which are used to describe the positive phase of the overpressure decay curve of Figure 17.57. A widely used one is the modified Friedlander equation (Kinney, 1962)

$$p = p^\circ(1 - t/t_d \exp(-\alpha t/t_d) \qquad [17.15.1]$$

where p is overpressure, p° is the peak overpressure, t is the time, t_d is the duration time and α is the decay parameter. Another common equation applicable at or below about

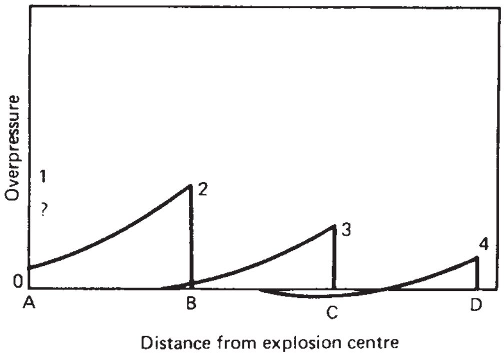

Figure 17.56 *Idealized representation of development of detonation blast waves*

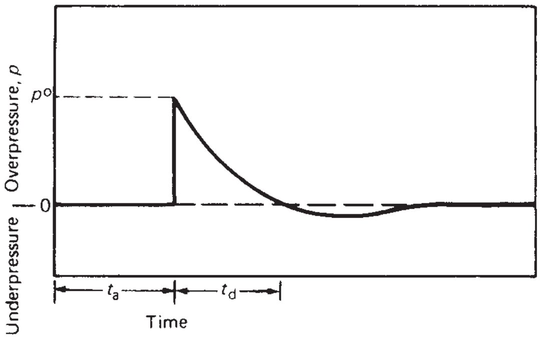

Figure 17.57 Variation of overpressure from a blast wave with time at a fixed point

10 psi is Equation 17.25.1 with the decay parameter set equal to unity. Information on the decay of overpressure is given by Glasstone (1962, p. 124).

Other important properties of the blast wave, described by Glasstone (1962), are the shock velocity, the particle velocity, or peak wind velocity, behind the shock wave, the peak dynamic pressure and the peak reflected overpressure. The shock velocity is given by

$$U = c_o\left(1 + \frac{\gamma + 1}{2\gamma}\frac{p^\circ}{p_a}\right)^{1/2} \qquad [17.25.2a]$$

where c_o is the velocity of sound in air, p_a is the absolute ambient pressure (ahead of the shock front), U is the shock velocity and γ is the ratio of specific heats of air. For air $\gamma = 1.4$ and hence

$$U = c_o\left(1 + \frac{6p^\circ}{7p_a}\right)^{1/2} \qquad [17.25.2b]$$

The particle velocity is given by

$$u = \frac{c_o p^\circ}{\gamma p_a}\left(1 + \frac{\gamma + 1}{2\gamma}\frac{p^\circ}{p_a}\right)^{-1/2} \qquad [17.25.3a]$$

where u is the particle velocity. For $\gamma = 1.4$

$$u = \frac{5c_o p^o}{7p_a} + \left(1 + \frac{6p^o}{7p_a}\right)^{-1/2} \qquad [17.25.3b]$$

The peak dynamic pressure q° is defined as

$$q^o = \frac{1}{2}\rho u^2 \qquad [17.25.4]$$

where q° is the peak dynamic pressure and ρ is the density of air (behind the shock front). This can be shown to be

$$q^o = \frac{p^{o2}}{2\gamma p_a + (\gamma - 1)p^o} \qquad [17.25.5a]$$

For $\gamma = 1.4$

$$q^o = \frac{5}{2}\frac{p^{o2}}{7p_a + p^o} \qquad [17.25.5b]$$

The peak reflected overpressure p_r^o, which occurs if the blast wave strikes a flat surface at normal incidence, is

$$p_r^o = 2p^o + (\gamma + 1)q^o \qquad [17.25.6a]$$

For $\gamma = 1.4$

$$p_r^o = 2p^o + 2.4q^o \qquad [17.25.6b]$$

Then, substituting for q° from Equation 17.25.5b

$$p_r^o = 2p^o\left(\frac{7p_a + 4p^o}{7p_a + p^o}\right) \qquad [17.25.7]$$

As stated earlier, the distinction between the peak incident overpressure, or simply the peak overpressure, p° and the peak reflected overpressure p_r^o is important, and it should always be made clear which overpressure is being referred to.

The peak dynamic pressure is less than the peak overpressure at low values of these two pressures, but greater at higher values. Equation 17.25.5b shows that the cross-over point is about 70 psi (4.83 bar).

The peak reflected overpressure is shown by Equation 17.25.6b to approach a value of twice the peak overpressure for weak shocks in which the peak dynamic pressure is negligible, but to approach a value of eight times the peak overpressure for strong shocks in which the peak dynamic pressure is dominant.

This maximum factor of 8 by which the peak reflected pressure exceeds the peak overpressure is frequently quoted. It depends, however, on the validity of the assumptions underlying Equation 17.25.6b.

17.25.2 Blast scaling

The characteristics of the blast wave produced by an explosion are generally determined by the application of scaling laws.

As described in Section 17.3 in relation to explosives, there are a number of scaling laws which relate explosion effects such as overpressure, damage circle radius, crater radius and sympathetic detonation distance.

For the blast wave from an explosion the scaling relation which is much the most widely used is the 'cube root' law, which was first enunciated by Hopkinson (1915). This law states that when two charges of the same explosive and geometry but of different size are detonated in the same atmosphere, self-similar shock waves are produced at the same scaled distances. The scaled distance is defined as

$$z = \frac{r}{W^{1/3}} \qquad [17.25.8]$$

where r is the distance, W is the mass of explosive and z is the scaled distance. It should be noted that the Hopkinson scaled distance is not dimensionless.

Strictly, the relevant scaling variable is the energy E rather than the mass of explosive W, but for a particular explosive it is usual to assume that the energy released is proportional to the mass of explosive.

The cube root index in the scaling law is related to the fact that energy is deposited into a spherical, or hemispherical, region, the volume of which varies with the cube of the radius. Other scaling laws are described by W.E. Baker (1973).

Another parameter which may be used in blast scaling is the yield factor λ, which is defined as

$$\lambda = \left(\frac{W}{W_o}\right)^{1/3} \qquad [17.25.9]$$

and the subscript o denotes the reference value.

Since from Equation 17.25.8 self-similar shock effects occur at the same scaled distance

$$z = \frac{r_o}{W_o^{1/3}} = \frac{r}{W^{1/3}} \qquad [17.25.10]$$

or, introducing the yield factor from Equation 17.25.9,

$$r = \lambda r_o \qquad [17.25.11]$$

where r_o is the reference distance.

If in Equation 17.25.9, $W_o = 1$, then λ is numerically equal to $W^{1/3}$; and Equation 17.25.11 reduces to Equation 17.25.8 with r_o numerically equal to z.

The application of the Hopkinson scaling laws to the principal blast parameters is now considered.

17.25.3 Peak overpressure

An important parameter of the blast wave is the peak side-on overpressure p^o. The scaling relation for this parameter is

$$p^o = f(z) \qquad [17.25.12]$$

Equation 17.25.12 states that a given peak overpressure occurs at a given scaled distance.

This scaling law implies, for example, that for a given peak overpressure an increase in the mass of explosive by a factor of 1000 corresponds to an increase in the distance from the explosion by a factor of 10.

The decay of the peak overpressure is given by Equation 17.25.1.

The peak overpressure is frequently presented in the form of the ratio

$$p_s = \frac{p^o}{p_a} \qquad [17.25.13]$$

where p_a is the ambient pressure and p_s is the scaled pressure.

17.25.4 Arrival and duration time

Blast scaling applies to the time parameters arrival time and duration time. The Hopkinson scaled time τ is defined as

$$\tau = \frac{t}{W^{1/3}} \qquad [17.25.14]$$

where t is the time and τ is the scaled time. It should be noted that scaled time is not dimensionless. Then, from Equation 17.25.14

$$\tau = \frac{t_o}{W_o^{1/3}} \qquad [17.25.15]$$

where t_o is a reference time. The scaled arrival time and the scaled duration time are thus

$$\tau_a = \frac{t_a}{W^{1/3}} \qquad [17.25.16]$$

and

$$\tau_d = \frac{t_d}{W^{1/3}} \qquad [17.25.17]$$

where t_a is the arrival time, τ_a is the scaled arrival time and τ_d the scaled duration time.

In terms of the yield factor λ

$$t = \lambda t_o \qquad [17.25.18]$$

where t_a is a reference time.

17.25.5 Dynamic pressure

Another important parameter of the blast is the peak dynamic pressure q°. This is defined by Equation 17.25.4 and may be obtained from Equation 17.25.5.

Information on the decay of the dynamic pressure is given by Glasstone (1962).

17.25.6 Overpressure impulse

Further important parameters of the blast are the overpressure and dynamic impulses. The positive phase overpressure impulse, overpressure impulse, or simply impulse, i_p is the integral of the overpressure during the positive phase:

$$i_p = \int_0^{t_d} p \, dt \qquad [17.25.19]$$

Substituting Equation 17.25.1 in Equation 17.25.19 gives

$$i_p = p^o t_d \left(\frac{1}{\alpha} - \frac{1}{\alpha^2}[1 - \exp(-\alpha)]\right) \qquad [17.25.20]$$

The simplifying assumption is sometimes made that the impulse takes the form of a triangle. In this case it may be approximated by

$$i_p \approx 1/2 p^o t_d \qquad [17.25.21]$$

The overpressure impulse i_p is another parameter of the blast wave to which scaling is applied. The Hopkinson scaled impulse i_s is defined as

$$i_s = \frac{i_p}{W^{1/3}} p^o t_d \qquad [17.25.22]$$

17.25.7 Dynamic pressure impulse

The dynamic pressure impulse i_q is

$$i_q = \int_0^{t_d} q \, dt \qquad [17.25.23]$$

As for the overpressure impulse, it is often assumed that the dynamic pressure impulse takes the form of a triangle so that it may be approximated by

$$i_q \approx 1/2q^o t_q \qquad [17.25.24]$$

Information on the impulse and duration time for the dynamic pressure is not as readily available as for the corresponding parameters for overpressure. The following empirical relation is given for the dynamic pressure impulse by Richmond and Fletcher (1971):

$$\ln R = \frac{5.4054 + 1.1067 \ln W - \ln i_q}{2.3201} \qquad [17.25.25]$$

where i_q is the dynamic pressure impulse (psi s), R is the distance (ft) and W is the mass of explosive (lb) as TNT equivalent.

17.25.8 Air bursts

So far the account given of the blast wave is a general one, and no distinction has been made between a burst occurring in free air and one occurring on the ground surface.

If the explosion is an air burst, or an explosion which occurs at some height above ground level, the behaviour of the shock waves on reaching the ground surface is rather more complex. The situation may be explained by reference to Figure 17.58. As shown in Figures 17.58(a) and (b), the incident shock I strikes the ground and gives rise to a reflected shock wave R. The reflected shock wave passes through an atmosphere which has already been heated and compressed by the incident wave. It therefore travels faster and tends to overtake the incident wave. Where this happens, the two waves fuse at the triple point T and form a Mach system M below this point, as shown in Figure 17.58(c). The Mach stem is a shock front similar to that generated by ground level explosions.

For moderate heights the Mach stems forms at a distance from the ground which is approximately equal to the height of the explosion (Glasstone, 1962, figure 3.67a).

17.26 Condensed Phase Explosions

An explosion of a high explosive is referred to as a condensed phase explosion. The explosive which serves as the reference standard is TNT.

In this section consideration is given primarily to the characteristics of the explosion itself. The effects of the explosion are considered in detail later. However, an account is first given of some incidents involving high explosives.

17.26.1 Condensed phase explosion incidents

Condensed phase explosions include explosions of munitions, commercial explosives and ammonium nitrate. An account of early accidental condensed phase explosions is given in *History of Explosions* (Assheton, 1930). Some further incidents are detailed in *Darkest Hours* (Q.R. Nash, 1976) and *Handbuch Störfalle* (Kier and Mffller, 1983). Apart from this, information has to be sought mainly in the accounts of individual explosions. Incident data are also available from the Explosions Incidents Data Service (EIDAS) data bank of the Safety and Reliability Directorate (SRD).

Appendix 1 includes a section devoted to accidental condensed phase explosions. Some principal explosions are given in Table 17.24, with incidents involving munitions and commercial explosives listed in Section A and those involving ammonium nitrate in Section B. Further information on these incidents is given in Table A1.2 in Appendix 1. The criteria for inclusion of condensed phase explosion incidents in both these tables is that the incident is a major one, that it is of technical interest and/or that it is frequently referenced. The tables give only a small sample of the condensed phase explosions which have occurred.

In the early years of the chemical industry, many of the worst incidents involved condensed phase explosives, including ammonium nitrate.

Incidents involving munitions and commercial explosives include the explosion of the munition ship Mont Blanc in the harbour at Halifax, Nova Scotia, in 1917, in which 1963 people were killed (Case History A3). Within a radius of about three quarters of a mile, destruction was almost complete. It was estimated that 95% of the glass in the city was broken.

Also in 1917 there was an explosion at a munitions works in Silvertown, London, and another, less well-known, explosion at a chemical works at Ashton, Manchester (Case Histories A4 and A2, respectively).

In 1989 there was an explosion of a load of commercial explosives on a road vehicle at Peterborough in the United Kingdom (Case History A125). This incident has significance for the transport of explosives.

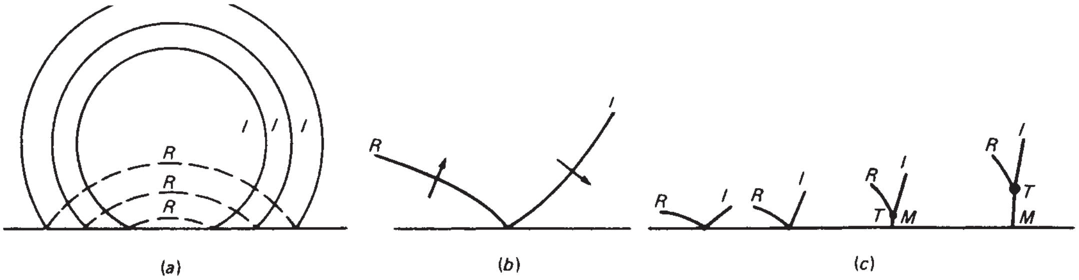

Figure 17.58 *Blast waves produced by an air burst: (a) development of blast wave; (b) incident and reflected waves; and (c) development of Mach stem. I, incident wave; R, reflected wave; M, Mach stem; T, triple point*

Table 17.24 Some condensed phase explosion incidents

Date	*Location*	*Explosive*[a]	*Plant/transport*	*Deaths/injuries*
A Munitions and commercial explosives				
1913	Mexico city	Dynamite	Road vehicle	41+, ≈ 100i
1917	Ashton, UK			
	Halifax, Nova Scotia	Munitions	Ship	1963d, ≈ 8000i
	Silvertown, UK	TNT	Munitions works	69d, 426i
1944	Fauld,UK	Munitions	Munitions store	68d, 22i
1956	Cali, Columbia	Munitions, dynamite	Seven road vehicles	≈1200d
1971	Waco, GA	Explosives	Road vehicle	5d, 33i
1985	Checotah, OK	Munitions	Road vehicle	0d, 49i
1989	Peterborough, UK	Explosives	Road vehicle	1d, 107i
1990	Meerut, India	Explosives	Road vehicle	50d
1991	Thung Maproah, Thailand	Dynamite	Road vehicle	123d
B Ammonium nitrate				
1918	Morgan, NJ			64d
1921	Oppau, Germany		Chemicals works	561d
1942	Tessenderloo, Belgium			>100d
1944	Bombay Docks, India		Ship	>350d, 1800i
1947	Brest, France		Ship	21d
1947	Texas City, TX		Two ships	552d, ≈3000i

[a] Only the main item of the load is given. In some cases there were other items such as detonators, boosters, etc.

Turning to ammonium nitrate, the explosion at Oppau in 1921 resulted from the use of blasting powder to break up stored piles of the material (Case History A5). It created a crater 250 ft in diameter and 50 ft deep, destroyed hundreds of houses and killed 561 people.

The explosions at Texas City in 1947 occurred in two ships, the Grandcamp and the High Flyer, both of which were carrying ammonium nitrate (Case History A16). They damaged thousands of buildings, hurled missiles several miles and killed 552 people. The fires burned for nearly a week.

17.26.2 TNT explosion model

The blast characteristics of a TNT explosion are important in their own right and are also sometimes used in modelling other types of explosion. There is available much more information on explosions of explosives, particularly TNT, than for other cases.

Sources of information on the blast characteristics from the explosion of TNT charges include *Structural Defence* (Christopherson, 1946), *The Effects of Nuclear Weapons* (Glasstone, 1962; Glasstone and Dolan, 1980), *Explosive Shock in Air* (Kinney, 1962; Kinney and Graham, 1985), *Hazards of Chemical Rockets and Propellants Handbook* (Jensen, 1972), *Explosions in Air* (W.E. Baker, 1973) and *Explosion Hazard and Evaluation* (W.E. Baker *et al.*, 1983) and work by Hoffman and Mills (1956), Goodman (1960), Kingery and Pannill (1964), Kingery (1966), Swisdak (1975) and Kingery and Bulmash (1984).

In principle, the blast characteristics of a TNT explosion depend on the mass and shape of the charge and also on the point(s) of ignition.

For a TNT explosion the two standard types of reference data are those for explosions from a point source and from a spherical charge. The blast parameters for the two explosions are slightly different. For overpressure, for example, the initial effect of a finite charge size is to reduce the overpressure very close to the charge relative to that from a point source. This effect holds for a distance of some five charge diameters. At greater distances, however, the overpressure from a spherical charge is greater, being approximately equivalent to that from a point source with one-third greater energy release.

Other features which affect the blast characteristics include the location relative to sea level and the meteorological conditions.

There is a degree of scatter in the experimental results for condensed phase explosions, including TNT explosions. W.E. Baker *et al.* (1983, figures 2 and 3) give for high explosives a plot of peak overpressure vs scaled distance for which the highest and lowest curves of peak overpressure differ in parts by almost an order of magnitude. The most recent data on the plot was from W.E. Baker (1973). On the other hand, work on the measurement of peak overpressure from TNT explosions has continued, and it is to be expected that the more recent results are more accurate.

The two reference standards for data on a TNT explosion are a free air burst (where the blast wave is not affected by interaction with the ground), which has spherical symmetry, and a surface burst, which has hemispherical symmetry.

The principal parameters of the blast wave from a TNT explosion are the peak side-on overpressure p°, the impulse of the positive phase i, the duration of the positive phase t_d and the arrival time t_a. Values of these parameters may be presented in scaled or unscaled form. The scaled forms are those given in Equations 17.25.13, 17.25.22, 17.25.17 and

17.25.16, respectively. Thus, the unscaled and scaled forms of the parameters in SI units are:

	Unscaled	*Scaled*
Peak overpressure	p°(Pa)	$p_s = p^\circ/p_a(-)$
Impulse	i_p (Pa s)	$i_s = i_p/W^{1/3}$(Pa s/kg$^{1/3}$)
Duration time	t_d (s)	$\tau_d = t_d/W^{1/3}$ (s/kg$^{1/3}$)
Arrival time	t_a (s)	$\tau_a = t_a/W^{1/3}$ (s/kg$^{1/3}$)

where p_a is atmospheric pressure (Pa) and W is the mass of explosive (kg).

Values for TNT explosion parameters which appear to have gained general acceptance are those determined at the Ballistics Research Laboratory, Aberdeen Proving Ground, Maryland, by Kingery and co-workers (Kingery and Pannill, 1964; Kingery, 1966). A review of the data from this and other work has been made by Kingery and Bulmash (1984), who give data and correlations both for free air bursts and surface bursts.

Figure 17.59(a) is a plot of the four parameters mentioned for a free-air burst (spherical symmetry) based on the data of Kingery and Bulmash. The graph is plotted in terms of the scaled parameters p_s, i_s, τ_d and τ_a. Figure 17.59(b) is the corresponding plot for a surface burst (hemispherical symmetry), again from Kingery and Bulmash.

Other widely used values for TNT explosions are those of W.E. Baker *et al.* (1983) and Kinney and Graham (1985). Baker *et al.* give a graph (their figure 2.45) for free-air bursts which is broadly similar to Figure 17.59(a), but which also includes several other parameters. Kinney and Graham give a graph for peak overpressure and data in tabular form for all four parameters treated here.

Work quoted by Kingery and Bulmash includes that of Goodman (1960), Kingery (1966), W.E. Baker (1973), Swisdak (1975) and Reisler, Pettit and Kennedy (1976, 1977), and that quoted by Kinney and Graham includes that of Hoffman and Mills (1956), Goodman (1960), Keefer *et al.* (1966) and Kingery (1966).

Table 17.25 shows a comparison of the values for free-air bursts by Kingery and Bulmash with those of Kinney and Graham.

As an illustration of the use of the Figure 17.59, consider the determination from Figure 17.59(a) for a free-air burst of the values of the peak overpressure p° and the impulse i_p for a charge weight W of 8 kg of TNT at a distance of 10 m with ambient pressure 1.01×10^5 Pa. Then

$$\begin{aligned} z &= 10/8^{1/3} \\ &= 5\,\mathrm{m/kg^{1/3}} \\ p_s &= 0.31 \\ p^\circ &= p_s \times p_a \\ &= 0.31 \times 1.01 \times 10^5 \\ &= 0.313 \times 10^5\,\mathrm{Pa} \\ i_s &= 3.6 \times 10^{-4}\,\mathrm{Pa\,s\,kg^{1/3}} \\ i_p &= i_s \times W^{1/3} \\ &= 3.6 \times 10^{-4} \times 8^{1/3} \\ &= 7.2 \times 10^{-4}\,\mathrm{Pa\,s} \end{aligned}$$

The original graphs given by Kingery and Bulmash are plots showing the unscaled parameters p°, i_p, t_d and t_a for an explosion involving 1 kg of TNT ($W=1$). The graphs given in Figure 17.59 are the same plots but with the parameters shown as scaled.

Also shown on the full curve in Figure 17.59(a) are the effects on the peak overpressure, in the far field of surface temperature inversion, labeled 1, and unstable atmosphere, z. Under surface temperature inversion conditions there can be a two- or three-fold increase in peak overpressure.

The variation of the blast parameters may also be expressed in the form of equations. Kingery and Bulmash use for the peak overpressure p°, impulse i_p, duration time t_d and arrival time t_s of a 1 kg explosion of TNT correlations of the following form. For a given parameter ϕ the relations are

$$U = a + b \log_{10} z \qquad [17.26.1]$$

$$\log_{10} \phi = \sum_{i-0}^{n} c_i U_i \qquad [17.26.2]$$

The values of the constants in these equations given by these authors are shown in Table 17.26. In these equations the units of the parameters are as shown in the table.

Kinney and Graham have given their values of the peak overpressure, impulse and duration time from an explosion of 1 kg of TNT in the form of network equations. In SI units for the scaled peak overpressure p_s

$$p_s = \frac{808[1 + (z/4.50)^2]}{[1 + (z/0.048)^2]^{1/2}[1 + (z/0.32)^2]^{1/2}[1 + (z/1.35)^2]^{1/2}} \qquad [17.26.3]$$

for the impulse

$$i_p = \frac{0.067[1 + (z/0.23)^4]^{1/2}}{z^2[1 + (z/1.55)^3]^{1/2}} \qquad [17.26.4]$$

and for the scaled duration time

$$\frac{t_d}{W^{1/3}} = \frac{980[1 + (z/0.54)^{10}]}{[1 + (z/0.02)^3][1 + (z + 0.74)^6][1 + (z/6.9)^2]^{1/2}} \qquad [17.26.5]$$

where p_s is the scaled peak overpressure, i_p is the impulse (bar ms), t_d is the duration time (ms), W is the mass of explosive (kg) and z is the scaled distance (m/kg$^{1/3}$).

It has already been mentioned that the blast parameters for a surface burst (hemispherical symmetry) can be obtained from those for a free-air burst (spherical symmetry) by using in the relations for the latter a charge weight suitably modified to account for the concentration of energy into the hemisphere rather than the sphere. The presumption is that this yield ratio, or symmetry factor, should be 2, and it is this value which is commonly used.

Table 17.27 gives a comparison between values of the peak overpressure, impulse and duration time for a surface burst calculated directly from the surface burst model and values calculated from the free-air burst model using a

***Table 17.27** Comparison of the side-on blast parameters for a surface explosion calculated (1) from a surface explosion relation and (2) from a free-air explosion relation*

Scaled distance, z (m/kg$^{1/3}$)	*Hemispherical model*			*Scaled distance, z* (m/kg$^{1/3}$)	*Spherical model using yield factor of 2*		
	p^o (Pa)	i_p (Pa s)	t_d (s)		p^o (Pa)	i_p (Pa s)	t_d (s)
0.5	48.7×10^5	1.66×10^2	2.81×10^{-4}	0.4	57.4×10^5	1.73×10^2	2.87×10^{-4}
2.5	1.72×10^5	1.09×10^2	2.36×10^{-3}	2	1.95×10^5	1.16×10^2	2.33×10^{-3}
5	0.432×10^5	5.93×10^1	3.79×10^{-3}	4	0.465×10^5	6.27×10^1	3.86×10^{-3}

yield ratio of 2, based on the Kingery and Bulmash data for these two cases. Thus, in using the free-air burst model, the modified charge weight used is $2W$, which introduces a correction factor of $2^{1/3}$ ($=1.26$). The scaled distance to be used for the free-air burst case is therefore that for the surface burst case divided by 1.26. The scaled parameters are then obtained. No further correction is required for the peak overpressure, which is scaled not by charge weight but by ambient pressure, but for the two parameters for which charge weight (or rather its cube root) is the scaling factor, the impulse and the duration time, the scaled values are multiplied by 1.26 to convert them to the unscaled values.

17.26.3 TNT explosion model: methods of Baker *et al.*

Work on the correlation of blast parameters which is frequently utilized is that of W.E. Baker *et al.* (1983). Some discussion of their treatment is therefore necessary.

Using Hopkinson scaling Equation 17.25.8 the authors present TNT graphs for (1) side-on blast parameters, (2) normally reflected blast parameters and (3) additional side-on blast parameters (their figures 2-45, 2-46 and 2-47, respectively). These graphs cover a large number of blast parameters and a wide range of scaled distance.

In the second method or energy scaling described earlier in W.E. Baker *et al.* (1975), the scaled distance is expressed as

$$\bar{R} = r\left(\frac{p_o}{E_{ex}}\right)^{1/3} \qquad [17.26.6]$$

where E_{ex} is the explosion energy (J), p_o is the absolute pressure of the ambient air (Pa), r is the distance (m) and $\bar{R}$ is the scaled distance. The scaled overpressure is defined as

$$\bar{P}_s = \frac{p_s}{p_o} - 1 \qquad [17.26.7]$$

where p_s is the absolute peak side-on pressure (Pa) and $\bar{P}_s$ is the scaled peak side-on overpressure. The scaled impulse is defined as

$$\bar{I} = \frac{i_s a_o}{P_o^{2/3} E_{ex}^{1/3}} \qquad [17.26.8]$$

where a_o is the speed of sound in the gas (m/s), i_s is the side-on impulse (Pa s) and $\bar{I}$ is the scaled side-on impulse.

Figures 17.60 and 17.61 show the curves for scaled peak side-on overpressure and scaled impulse given by W.E. Baker *et al.* (1975) for pentolite.

The actual peak side-on overpressure $\bar{P}_s$ and side-on impulse $\bar{T}$ are then obtained from Equations 17.26.7 and 17.26.8.

This second method, utilizing Equations 17.27.7–17.27.9, is also that used by Baker and co-workers for the treatment of vessel burst explosions and vapour cloud explosions, as described in Sections 17.27 and 17.28, respectively.

17.26.4 TNT equivalent model

In the absence of models for other types of explosion, such as vessel burst or vapour cloud explosion, it has frequently been the practice to model such explosions by estimating the energy of the explosion, calculating the TNT equivalent and then treating the explosion as if it were one from a TNT charge, a TNT equivalent model.

For example, the TNT equivalent model was used by Brasie and Simpson (1968) in an investigation of vapour cloud explosions.

However, the characteristics of the blast from the explosion of a TNT charge are significantly different from those given by other explosions. The pressure developed by a TNT explosion confined within the boundaries of the charge is of the order of half a million bar, which is very much higher than that within a bursting vessel or vapour cloud.

Comparing the profile of the peak overpressure from a TNT explosion with that from a vapour cloud explosion, in the near field the peak overpressure of the TNT explosion is higher, in the far field it is less. One consequence of this is that the use of the TNT equivalent model is not conservative in the far field.

The duration time of a TNT explosion is relatively short. This contrasts with a vapour cloud explosion, for which the duration time, and hence the impulse, is longer. This is another feature which is not conservative in the use of the TNT equivalent model.

A further discussion of the application of the TNT equivalent model to vapour cloud explosions is given in Section 17.28.

17.27 Vessel Burst Explosions

Turning now to types of explosion more typical of process plant, consideration is given first to vessel bursts in which the energy of explosion derives from the pressure in the vessel and the explosion is essentially physical rather than chemical.

17.27.1 Experimental studies

Only a small amount of experimental work on the bursting of gas-filled vessels is reported in the literature. Boyer *et al.* (1958) performed tests on the bursting of small gas-filled

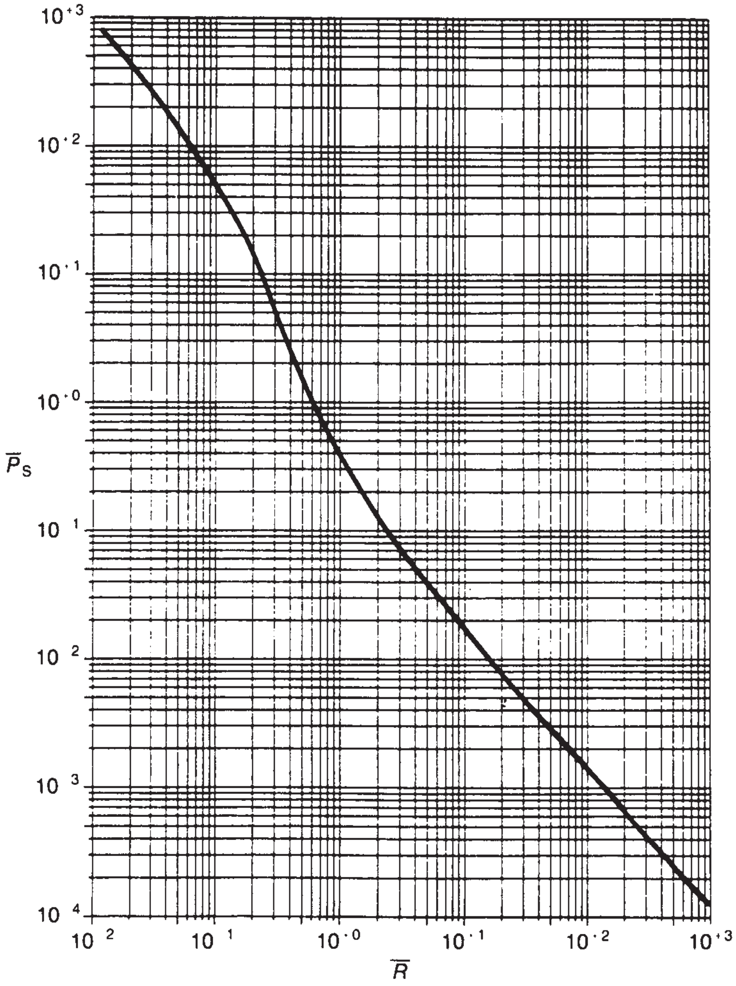

Figure 17.60 *Scaled peak side-on overpressure (W.E. Baker et al., 1975)*

glass spheres. Another set of small scale experiments using such apparatus is that of Esparza and Baker (1977). In this latter work the spheres ranged up to 102 mm in diameter and the burst pressures up to 5.25 MPa.

Experiments with metal containers were conducted by Pittman (1972a,b), using volumes up to 0.17 m^3. The burst pressures were about 4 MPa for cylindrical vessels and 55 MPa for spherical ones. Subsequently, Pittman (1976) carried out tests on 0.28 m^3 metal spheres with burst pressures up to 100–345 MPa.

17.27.2 Empirical features

This work brings out several relevant empirical features.

The work of Pittman (1972a,b), which involved high pressures, demonstrates the need to take into account in estimating the energy of explosion for such cases the non-ideal behaviour of the gas. The differences between the behaviour of the blast wave from a condensed phase explosion and that from a vessel burst are illustrated in the work of Esparza and Baker (1977), who found that for the latter the blast wave tended to have a lower overpressure, a longer positive phase duration, a larger negative impulse and a stronger second shock.

17.27.3 Vessel burst pressure

The explosion energy in a vessel burst is a function of the initial pressure, which in turn depends on the failure scenario. The higher the pressure, the larger the explosion.

Three cases may be distinguished: (1) overpressure, (2) mechanical failure and (3) fire engulfment.

If the vessel fails because it is exposed to a high operating pressure and because the pressure relief has failed, the vessel will burst at a pressure which is some factor of the design pressure, typically for mild steel a factor of 4. This is the worst case.

If a mechanical failure of the vessel occurs, which may be due to a metallurgical defect, corrosion or impact, the burst pressure will be the operating pressure.

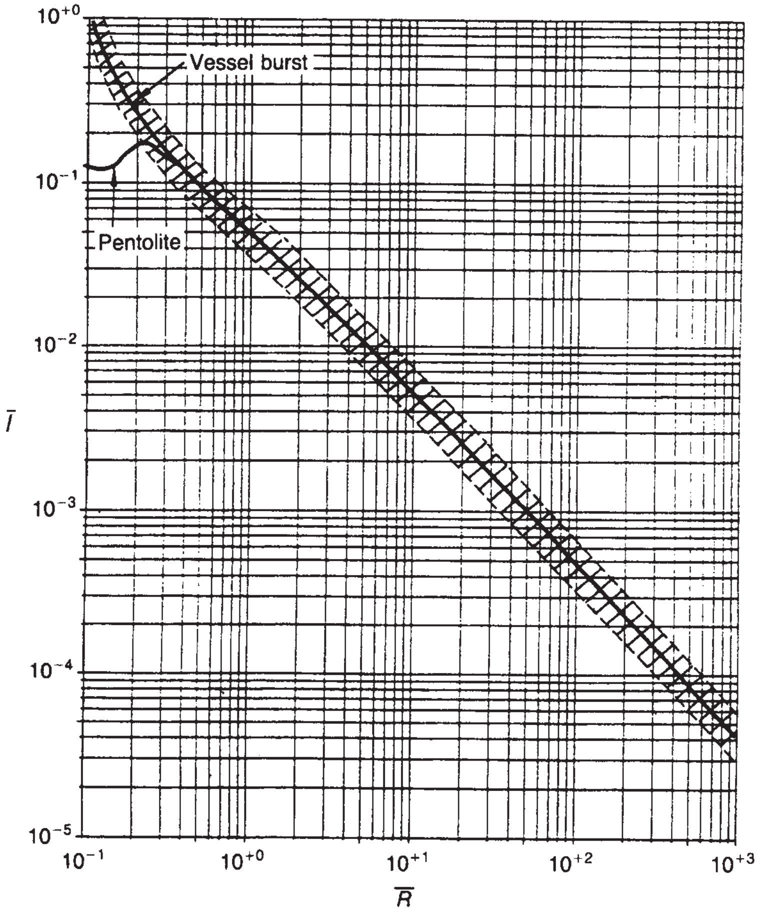

Figure 17.61 *Scaled side-on impulse for a pentolite explosion (W.E. Baker et al., 1975)*

If the vessel fails due to fire engulfment, but with the pressure relief operating, the pressure at burst will be the accumulation pressure. This is the typical scenario of a BLEVE.

17.27.4 Vessel burst energy distribution

The estimation of the energy of the explosion in a vessel burst is discussed below, but it is appropriate first to consider briefly the distribution of this energy.

In principle, the energy available will be partitioned as energy in (1) vessel expansion, (2) vessel rupture, (3) blast and (4) fragments.

If failure is due to high operating pressure, some expansion of the vessel occurs. However, this can be neglected both because the energy is provided to the system prior to the burst and because it is very small anyway.

Some energy is required to rupture the vessel, but this too is very small. The Centre for Chemical Process Safety (CCPS) gives a value of 1–10 kJ for the rupture of a pressure vessel; an explosion with 100 times this energy would still be regarded as small.

Essentially therefore, the energy available goes into the blast and the fragments. The proportion which goes as kinetic energy in the fragments has been briefly discussed in Section 17.4 and is considered again in Section 17.34.

17.27.5. Vessel burst modelling

There have also been studies involving the numerical and analytical modelling of vessel bursts. In some cases the main interest of the work has been with other types of explosion for which the bursting of a gas-filled sphere serves as a limiting case.

Investigations involving numerical and parametric modelling have been described by W.E. Baker *et al.* (1975), Erode (1955), Adamczyk (1976), Guiraio and Bach (1979), Chushkin and Shurshlov (1982) and Raju and Strehlow (1984).

The study most relevant here is that of W.E. Baker *et al.* (1975), who conducted a parametric exploration of vessel bursts and developed a method of estimating the blast parameters analogous to that for a condensed phase explosion.

Also of interest is the work of Adamczyk (1976) which indicates that vessel burst explosions approximate in the far field to condensed phase explosions only for high pressure and temperature ratios.

The investigation by Guiraio and Bach (1979) was concerned with fuel–air explosions. They studied cases of a combustion process in which the reactants are converted instantaneously to products and found that for such cases only some 27–37% of the combustion energy was converted to work.

Raju and Strehlow (1984) studied the effect of a non-spherical source in the form of a combustible gas mixture. The initial gas cloud had the form of an ellipse rotated on its major axis, or spheroid oriented with its major axis perpendicular to the ground. The lead shock wave was elliptical but tended towards sphericity as the wave moved out. This is explained by the facts that the strength of the initial shock wave varied with the direction and that strong shock waves tend to travel faster than weak ones.

17.27.6. Model of Baker *et al.*: basic method

A method for the estimation of the blast parameters for the bursting of a gas-filled pressure vessel is now described. The method is that of W.E. Baker *et al.* (1975), and relates to a free-air burst of a massless spherical vessel containing an ideal gas. The background to this method has just been described and the account here concentrates on its application.

The explosion energy is obtained from the Erode model given as Equation 17.4.29.

Applying the second method of Baker and co-workers, based on Equations 17.26.6–17.26.8, the scaled distance R is calculated, using Equation 17.26.6.

The scaled peak overpressure is then obtained from Figure 17.62(a), using the curve for high explosive, and the scaled impulse from Figure 17.63, or from Figure 17.61, which covers a wider range.

The actual peak side-on overpressure p_s and side-on impulse i_s are then obtained from Equations 17.26.7 and 17.26.8.

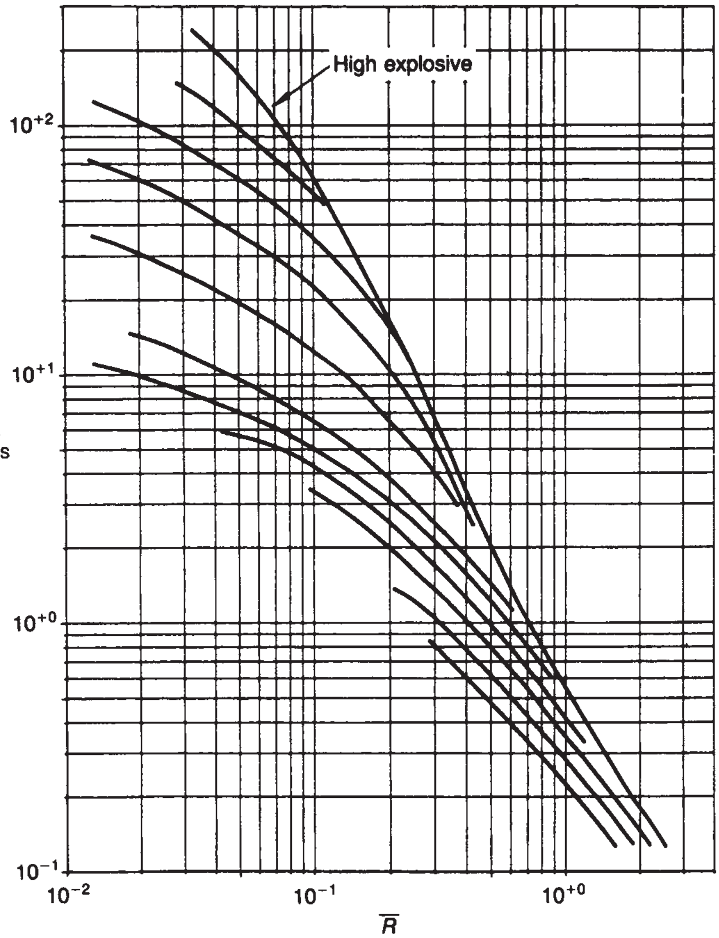

Figure 17.62 *Scaled peak side-on overpressure for a vessel burst explosion (W.E. Baker et al., 1975)*

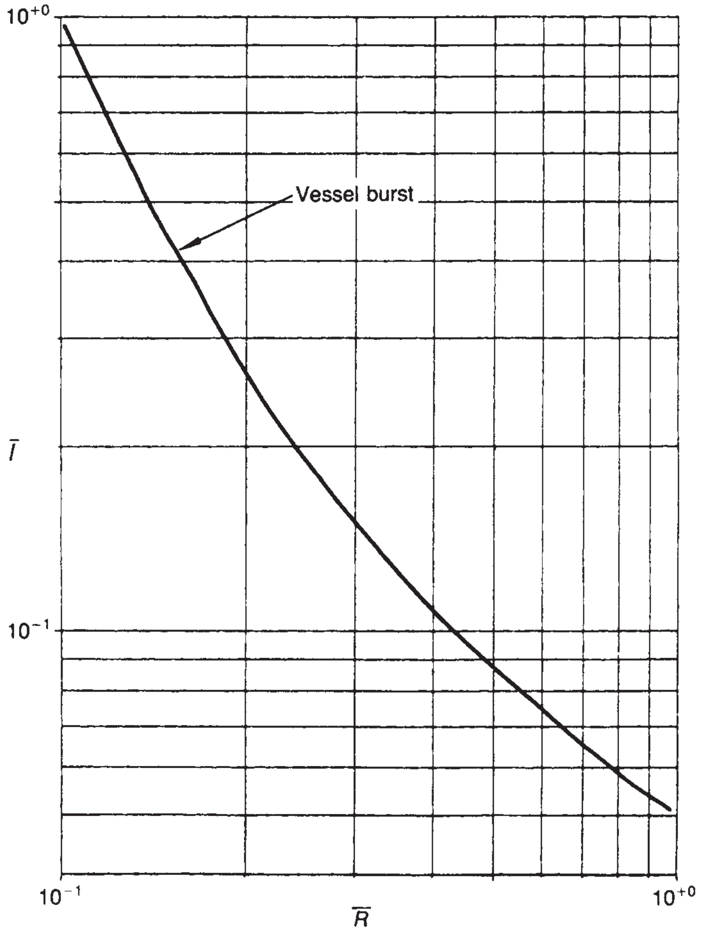

Figure 17.63 *Scaled side-on impulse for a vessel burst explosion (W.E. Baker et al., 1975)*

This method is oriented to the estimation of the blast parameters in the far field, and its accuracy in the near field is limited. There are two checks which should be made with regard to the latter.

The first check is on the value of the scaled distance $\bar{R}$. If this is less than 2, use should be made of a modification to the method appropriate for the near field, which is described below. The other check is on the value of the peak side-on overpressure p_s, discussion of which is deferred.

The near field modification is as follows. First an effective radius for the equivalent hemisphere formed by the initial gas volume is calculated:

$$r_o = \left(\frac{3V_1}{2\pi}\right)^{3/4} \qquad [17.27.1]$$

where r_o is the effective radius of the equivalent hemisphere (m) and V_1 is the volume of the gasified vessel (m^3). The corresponding scaled distance $\bar{R}_o$ is then calculated using Equation 17.26.6. The peak side-on overpressure is then determined using, in conjunction with Equation 17.26.7, the relation

$$\frac{p_1}{p_o} = (\bar{P}_{so}+1)\left(1 - \frac{(\gamma_1-1)(a_o/a_1)\bar{P}_{so}}{\{2\gamma_o[2\gamma_o+(\gamma_o+1)]\bar{P}_{so}\}^{1/2}}\right)^{-2\gamma_1/(\gamma_1-1)} \qquad [17.27.2]$$

where a is the velocity of sound (m/s), p_o is the absolute pressure of the ambient air (Pa), p_1 is the absolute initial pressure of the gas (Pa), $\bar{P}_{so}$ is the scaled peak side-on overpressure at $\bar{R}_o$, γ is the ratio of the specific heats and subscripts o and 1 denote ambient air and compressed gas in the vessel, respectively.

Equation 17.27.2 is an implicit equation. It may be solved by the usual methods for such equations. Alternatively, use may be made of graphs given for convenience by the authors. One of these is shown in Figure 17.64.

The method then proceeds as follows. The pair of values of $\bar{R}$ and $\bar{P}_{so}$ is used to locate the 'starting point' on

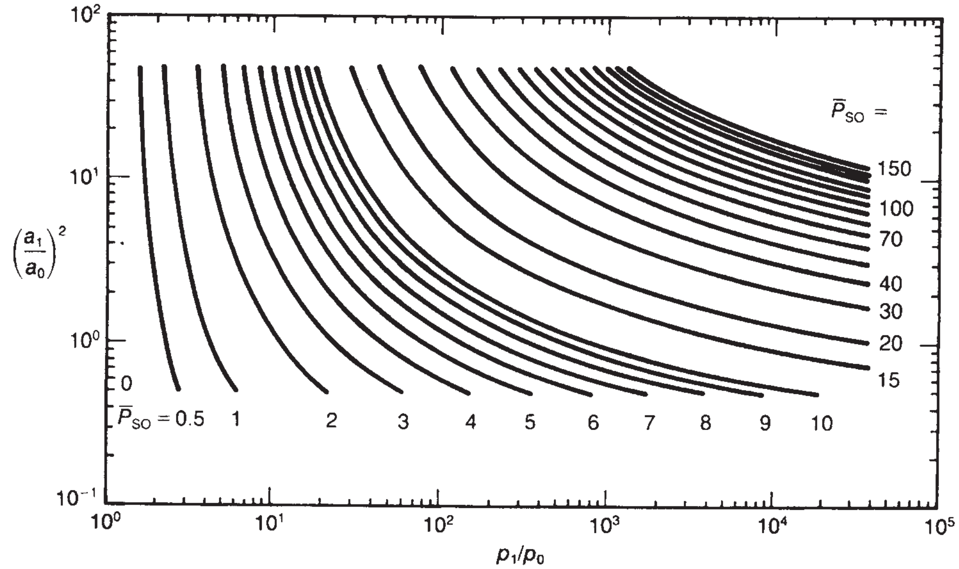

Figure 17.64 *Scaled peak side-on overpressure in the near field for a vessel burst explosion (W.E. Baker et al., 1975).* $\gamma_1 = 1.4$

Figure 17.62. This identifies a particular curve in the family of curves on Figure 17.62 and this curve is then used in making further estimates of the scaled peak overpressure.

As indicated earlier there is a further check to be made, on the value of the peak side-on overpressure p_s. It is possible that the value calculated for p_s exceeds the initial pressure in the vessel. If so, p_s should be set equal to this initial pressure.

17.27.7 Model of Baker *et al.*: extensions of method

As already stated, the method just described applies to the free-air burst of a massless spherical vessel containing an ideal gas. There are several extensions which may be needed in practical cases. These relate to (1) non-ideal fluids, (2) energy imparted to fragments, (3) bursts at ground level and (4) other vessel geometries.

For the ideal gas case, the energy of explosion is obtained from the Erode model as given in Equation 17.4.29. For the cases of non-ideal gas, vapour or flashing liquid use should be made of the alternative method described in Section 17.4.

This gives the total energy available. Any energy imparted to the fragments should then be subtracted from this value to obtain the energy participating in the blast.

For the case of a burst at ground level, this blast energy is then multiplied by the usual factor of 2 before it is used in Equations 17.26.6 and 17.26.8 to obtain the blast wave parameters. Baker *et al.* have given sets of adjustment factors for two types of departure from the basic model. One set is for use with cylindrical as opposed to spherical vessels. The other set is for a spherical vessel slightly elevated above the ground. These are shown in Table 17.28.

Table 17.28 *Method of Baker et al. for blast parameters from a vessel burst: adjustment factors (W.E. Baker et al., 1975)*

A Adjustment factors for cylindrical vessels

$\bar{R}$	*Multiplier for:*	
	$\bar{P}_s$	$\bar{I}$
<0.3	4	2
$0.3 \le \bar{R} \le 1.6$	1.6	1.1.1
$1.6 \le \bar{R} \le 3.5$	1.6	1
>3.5	1.4	1

B Adjustment factors for spherical vessels slightly elevated above the ground

$\bar{R}$	*Multiplier for:*	
	$\bar{P}_s$	$\bar{I}$
<1	2	1.6
>1	1.1	1

17.27.8 COPS method

The CCPS *Fire and Explosion Model Guidelines* (1994/15) include as part of the method for a BLEVE a method for vessel burst explosions. The energy of the explosion is obtained using the CCPS method for that described in Section 17.4. The blast parameters are then obtained using the method of Baker and co-workers described in Section 17.27.6 with the extension given in Section 17.27.7. The *Guidelines* give sample problems for BLEVEs in which use is made of the vessel burst model. These problems are described in Section 17.3.2.

17.28 Vapour Cloud Explosions

When a cloud of flammable vapour burns, the combustion may give rise to an overpressure or it may not. If there is no overpressure, the event is a vapour cloud fire, or flash fire, and if there is overpressure, it is a vapour cloud explosion (VCE).

A VCE is one of the most serious hazards in the process industries. VCEs do occasionally occur and they tend to be very destructive.

A feature of a vapour cloud is that it may drift some distance from the point where the leak has occurred and may thus threaten a considerable area.

The relative importance of the VCE hazard has grown in recent years. Whereas in the early days of the chemical industry the largest disasters tended to be those caused by explosives, including ammonium nitrate, many of the largest disasters are now due to VCEs.

Accounts of VCEs include those given in *Unconfined Vapour Cloud Explosions* (Gugan, 1979), *Explosion Hazard and Evaluation* (W.E. Baker *et al.* 1983), *Fuel–Air Explosions* (Q.H.S. Lee and Guirao, 1982a) and *Major Chemical Hazards* (V.C. Marshall, 1987) and those by Brasie and Simpson (1968), Strehlow (1973b), Strehlow and Baker (1976), V.C. Marshall (1976a,c,d), Davenport (1977b, 1983), Kletz (1977d), J.H.S. Lee *et al.* (1977), Slater (1978a), Wiekema (1980, 1983a,b, 1984), J.H.S. Lee (1983), Pikaar (1983) and Rasbash (1986b).

Until the early 1980s a VCE was generally referred to as an unconfined vapour cloud explosion (UVCE). However, since in combustion of a vapour cloud the occurrence of overpressure tends to occur due to the presence of structures and obstacles and of partial confinements, the term 'unconfined' is now generally omitted.

There are many gaps in the state of knowledge on VCEs and there is no completely satisfactory theoretical model, although much progress has been made in modelling. The practical approaches tend to combine theoretical and empirical inputs.

In this section consideration is confined to the characteristics of the explosion itself. The effects of the explosion are considered below.

The energy of the explosion of a vapour cloud is normally computed as the product of the heat of combustion and a yield factor, as described in Section 17.4 and discussed further below. In this section the energy of explosion, or explosion energy, is used in this sense.

Selected references on VCEs are given in Table 17.29.

17.28.1 Vapour cloud explosion incidents

There are a number of compilations of major VCEs. V.C. Marshall (1987) gives details of some 11 such compilations. The principal lists are those of Strehlow (1973b), Davenport (1977b, 1983), Gugan (1979), the ACMH (Harvey, 1979b), Wiekema (1983a,b, 1984) and Lenoir and Davenport (1992). The account by Davenport (1977b) also lists incidents in which a vapour cloud formed but did not explode.

It is emphasized by their compilers that the lists may be incomplete, since the extent to which incidents are reported varies between different countries. Where the lists include unignited vapour clouds, these are particularly likely to be incomplete, since such clouds are often not reported.

Selected experimental work

Fuel–air explosions: Kiwan (1970a,b, 1971)

Early field trials of combustion in unconfined vapour clouds: Lutzke (1971); Humbert-Basset and Montet (1972); AGA (1974); MITI (1976); Raj, Moussa and Aravamuden (1979a,b)

Early work on detonation in unconfined vapour clouds: Lind (1975); D.C. Bull, Ellsworth and Hooper (1979a,b)

Combustion in unconfined vapour clouds – closely controlled tests: Lind and Whitson (1977); Deshaies and Leyer (1981); Okasaki, Leyer and Kageyama (1981); Schneider and Pfortner (1981); Brossard *et al.* (1985); R.J. Harris and Wickens (1989)

Combustion in unconfined vapour clouds – field trials: Blackmore, Eyre and Summers (1982); MIT-GRI Safety and Res. Workshop (1982); Goldwire *et al.* (1983); Hirst and Eyre (1983); Zeeuwen, van Wingerden and Dauwe (1983)

Combustion in vapour clouds with obstructions – closely controlled tests: Dorge, Pangritz and Wagner (1981); C.J.M. van Wingerden and Zeeuwen (1983); A.J. Harrison and Eyre (1986, 1987a); R.J. Harris and Wickens (1989)

Combustion in vapour clouds with obstructions – field trials: Zeeuwen, van Wingerden and Dauwe (1983)

Jet ignition of vapour clouds: Schildknecht and Geiger (1982); Schildknecht (1984); Schildknecht *et al.* (1984); Stock and Geiger (1984); Moen *et al.* (1985); A.J. Harrison and Eyre (1987a); McKay *et al.* (1988)

Combustion of turbulent jets: Seifert and Giesbrecht (1986); Stock (1987)

Combustion following vessel burst: Giesbrecht *et al.* (1981)

Combustion of a pipeline leak: Hoff (1983)

Hydrogen explosions

Bulkley and Jacobs (1966); Berman (1982); Tamm, Harrison and Kumar (1982); L. Thompson (1982); Hawksley (1986 LPB 68); V.C. Marshall (1987)

Suppression by water sprays

Acton, Sutton and Wickens (1990); D.C. Bull (1992); Brenton, Thomas and Al-Hassan (1994)

As mentioned above, VCEs have come to increasing prominence. Strehlow (1973b) lists the numbers of vapour cloud explosions as follows:

1930–39, 4
1940–49, 12
1950–54, 17
1955–59, 17
1960–64, 18
1965–69, 25
1970–72 (Jan.), 15

The *Second Report* of the ACMH (Harvey, 1979b) refers to Strehlow's work and to more recent data and comments that the frequency of VCEs has increased from about four per decade to a rate of over 60 per decade.

Some principal VCE incidents are given in Table 17.30. The estimates of the quantities released in the table are given as quoted in the literature; most appear to refer to the total quantity originally in the containment, but may in some cases refer to the flammable vapour in the cloud. Other incidents are given in Table A1.2. Further lists of VCE incidents illustrating particular points are given in Tables 17.33 and 17.34 below. Experimental work on VCEs is listed in Table 17.31.

Four VCEs in particular have been particularly influential. In 1967 a very destructive VCE occurred at the refinery at Lake Charles in Lousiana after an escape of liquid isobutylene due to a valve failure; there were seven deaths (Case History A40). The fires burned for 2 weeks. In 1968 a slops tank in the refinery at Pernis in the Netherlands boiled over and the explosion of the resultant vapour cloud killed two people and destroyed an appreciable fraction of the refinery (Case History A41). Another massive VCE took place in 1970 at Port Hudson, Missouri, where liquid propane leaked from a pipeline into a valley; on this occasion there were no fatalities (Case History A52).

In 1974 in Flixborough in the United Kingdom a large escape of cyclohexane from a temporary pipe on a train of reactors gave rise to a vapour cloud which exploded with a TNT equivalent of some 16 te. The explosion demolished much of the works and killed 28 people, and the fires burned for over a week. This incident, which is described in Appendix 2, was particularly influential in the development of major hazard controls in the United Kingdom and in the EC.

These were not, however, the first major VCEs. Two major explosions which occurred earlier at Ludwigshafen, Germany, in 1943 and 1948, were more destructive of human life, resulting, respectively, in 57 and 207 deaths. In the second incident the explosion was caused by an escape of dimethyl ether when a rail tank car overheated in the sun and burst (Case History A17). For this explosion the TNT equivalent has been estimated as 20 te.

VCEs have continued to occur. Also, in 1974, only a few months after Flixborough, there was an escape of propane following a rail tank car accident in a marshalling yard at Decatur, Illinois, which caused seven deaths and did extensive damage (Case History A71).

In 1975 at Beek in the Netherlands an escape of propylene, apparently from brittle fracture of a feed drum on a depropanizer, gave rise to a VCE which killed 14 and caused extensive damage to the works (Case History A75).

[d] V.C. Marshall (1987).

One of the most serious VCEs in recent years, however, has been that of a cloud of isobutane vapour at Pasadena, Texas, in 1989, which caused 23 fatalities and resulted in as serious a business loss as Piper Alpha. This incident, is described in Appendix 6.

Also, in 1989 there occurred at Ufa in the Soviet Union a vapour cloud explosion much more disastrous in human terms (Case History A127).

17.28.2 Empirical features

Some observations and generalizations can be made by analysing explosion incidents.

A compilation of VCE incidents and corresponding statistical data has been presented by Davenport (1977b). These data relate to 43 incidents where overpressures were created, of which 32 were in industrial plant, 8 in transport and 3 elsewhere. Of those in industrial plant,

D Combustion of a pipeline leak		
Hoff (1983)	Gas pipeline	Natural gas

8 were in refineries and 24 in the petrochemical industries.

The sources of spill material in the industrial plant incidents were:

Process equipment	24
Storage tank	4
Transportation vehicle within plant	3
Unknown	1

The modes of release for all incidents were:

Vessel failure	13
Piping, valves or fittings failure	26
Release from venting facilities	3
Unknown	1

In a further paper, Davenport (1983) has given additional incidents but without statistical data.

Some questions which are capable of resolution by an empirical approach are

(1) frequency of release;
(2) quantity of material released;
(3) fraction of material vaporized;
(4) probability of ignition of cloud;
(5) distance travelled by cloud before ignition;
(6) time delay before ignition of cloud;
(7) probability of explosion rather than fire;
(8) existence of a threshold quantity for explosion;
(9) efficiency of explosion.

Early discussions of these problems were given by Strehlow (1973b), V.C. Marshall (1976a) and Kletz (1977j).

An early but fairly comprehensive treatment of the empirical features of vapour cloud explosions was given by Kletz (1977j), and this is now described. He gives estimates of the frequency of such explosions as shown in Table 17.32. A special pipeline is one on which special care can be taken, such as a short pipe without pumps or other intervening equipment between two vessels. A severe duty pump is one on a very hot or very cold liquid. The figure for pressure vessel failure is based on the data of Phillips and Warwick (1968 UKAEA AHSB(S) R162) and Engel (1974).

On items where the frequency of leaks is high there is a strong case for emergency isolation valves. The fitting of emergency isolation valves on a normal pipeline is usually impractical, but may well be justified on a pump. Kletz suggests that if a remotely controlled emergency isolation valve is fitted, it may be assumed that it will be operated within 5 min, but that if only a local isolation is available, it should be assumed that it will not be operated and that the leak continues until it is isolated by other means or until all the inventory has leaked out.

The material escaping may be a gas, or a volatile liquid, superheated or subcooled. Flashing superheated liquids tends to give rise to the largest vapour clouds. Most VCEs have been caused by such flashing liquids. It is suggested by Kletz that the fraction vaporized be obtained from the common rule of thumb that the amount of liquid spray formed equals the amount of vapour formed by adiabatic flash. Thus, if the fraction of liquid vaporized is as high as a half, this assumption implies that all the liquid turns into vapour and spray.

There are few data from which the probability of ignition can be estimated. Kletz suggests that for large leaks (>10 t) this probability is greater than 1 in 10 and perhaps as high as 1 in 2. For small leaks the probability of ignition is much less. Kletz quotes a value of 10^{-4} for small leaks on polyethylene plants, where the high pressure causes good jet mixing.

The distance drifted by a cloud of flammable vapour depends on the situation. The drift determines the explosion centre and the blast intensity near this. It has less effect on the blast intensity further away. Kletz states that there is no reported case of a cloud drifting a significant distance in a factory before exploding. He suggests that the assumption of no drift is probably good enough for most calculations but that a drift of 100 m may occur in 1 case in 5 or 10. The distance drifted by the cloud before ignition is unlikely to be great in any industrial or urban area.

***Table 17.32** Estimated frequencies of VCE (after Kletz, 1977j)*

	Frequency (explosions/ plant-year)[a]
(1) Caused by failure of pressure vessel	10^{-5b}
Pipeline – special pipeline	10^{-5}–10^{-4}
–normal pipeline	10^{-4}–10^{-3}
Pump – normal pump	10^{-2}
– severe duty pump	10^{-1}
Reciprocating compressor	10^{-1}
(2) Caused by leak from	10^{-2}–10^{-1}
Batch reactor	
Tanker-filling house	10^{-2}–10^{-1}

[a] Plant is defined as a major unit such as ethylene or aromatics plant or collection of smaller units – something smaller than a typical UK works or US plant.

[b] The estimated failure rate of a pressure vessel is 10^5/vessel-year.

In open situations with few sources of ignition the vapour cloud may drift much further. In the Port Hudson explosion (NTSB 1972 PAR-72-01) the cloud travelled 1500 ft in a long plume before igniting. In the flash fire at Austin (NTSB 1973 PAR-73-04), ignition did not occur until the cloud had travelled 2400 ft. Data on the distance travelled by the vapour cloud in 81 rail tank car spills have been given by G.B. James (1947–48), who states that 58 % found a source of ignition within 50 ft and 76 % within 100 ft and all which ignited did so within 300 ft.

A separate but related question is the time delay before ignition. Strehlow (1973b) states that a delay as long as 15 min has been reported. The quantity of material which can accumulate in this time may be very large. The explosion can be a large one, however, even if the time delay is short. The delay before ignition at Flixborough was probably in the range 30–90 s. An estimate of 45 s has been widely quoted.

In many instances the cloud is formed from a turbulent momentum jet. This was the case at Flixborough. In such situations the cloud may reach an equilibrium size within about 10–20 s. Once such a steady state has been reached, the mass of material available in the cloud for combustion does not increase, even if there is an appreciable delay before ignition.

The probability that ignition will cause an explosion rather than a flash fire depends on complex factors, some of which are discussed below. Kletz states that there is about one serious VCE every 2 years; Strehlow reports about five VCEs/flash fires per year and these two factors in combination perhaps support the view that about one vapour cloud ignition in 10 gives an explosion.

A number of vapour releases have been analysed by V.C. Marshall (1976a), as shown in Table 17.33. The table indicates that whereas the larger releases have resulted in explosions, the smaller ones have produced fires instead. The data given show no explosions in clouds of less than 15 t. Marshall has also pointed out, however, that the explosion at Beek in 1975 involved a release of only about 5.5 t and therefore tends to undermine this argument. In addition, the data of Davenport (1977b) include a number of

***Table 17.33** Some data on quantity released and on occurrence of fire or explosion in vapour clouds (after V.C. Marshall, 1976a)*

Location	*Date*	*Chemical* (t)	*Quantity*	*Deaths*	*Nature of incident*	*Further details*

		Butane	15.5		Fire	
		Butane	7.7		Fire	
Los Angeles, CA		Butane	2.0		Fire	
		Methane	1.0		Fire	
		Propane	0.06		Fire	

explosions of vapour clouds containing less than 15 t of flammable material.

The question of whether there is a minimum size of cloud below which an explosion will not occur has been much discussed, and a threshold quantity of 10–151 has been suggested.

It is argued by Kletz that there is no theoretical basis and no detailed survey to support the assumption that there is a threshold quantity for an explosion to occur. In one well-attested case a fraction of a ton of methane exploded, causing serious damage. Moreover, there have been a number of experiments with balloons filled with flammable mixtures in which violent explosions have been obtained with quantities of less than 1 t. Kletz concludes that although it may not be correct to assume a threshold quantity, the probability of an explosion certainly appears to be much less if the quantity is small. He suggests that if there are 10 t of vapour, the probability of explosion is at least 1 in 10, whereas if there is 1 t or less the probability of explosion is of the order of 1 in 100, or, more likely, 1 in 1000.

The ratio of the energy in the blast wave to the energy theoretically available from the heat of combustion, or efficiency of explosion, is another quantity about which much uncertainty exists. The fraction of the heat of combustion that is used to produce the blast wave usually lies between 1 and 10% based on the total mass released.

The Bureau of Mines is sometimes quoted as recommending the use of an explosion efficiency of 10%. Kletz points out, however, that this should be taken in conjunction with another recommendation that the quantity of material considered should be that leaking within 30 s.

Kletz suggests that is the release is fairly rapid, it is reasonable to assume an explosion efficiency of 1%, whereas if it is not, an overall efficiency becomes meaningless and it is necessary to attempt to calculate the amount within the flammable range and within congested regions.

Burgess and Zabetakis (1973 BM RI 7752) have given such a calculation for the Port Hudson explosion (Case History A52).

In some cases a much higher explosion efficiency has been reported. Davenport gives an explosion efficiency of 25–50% for a vapour cloud explosion at Decatur, Illinois, in 1974 but this value may well be anomalous; it is discussed in the account of the incident (Case History A71).

Values of the explosion efficiency, or yield factor, are not always quoted on the same basis, and this is a cause of variation in the figures. Sometimes the value quoted is based on the total amount of vapour in the cloud and sometimes on that part of the vapour which is within the flammable range. The two may differ by a factor of 10 or more. Thus, Kletz points out that although the yield factor at Port Hudson is widely quoted as being 20%, this is based on the part of the cloud which was within the flammable range. Based on the whole cloud the value is 7.5%. Further variability is introduced by the fact that the total quantity of vapour released is generally subject to uncertainty. A typical factor of uncertainty is 2.

Kletz' account of the empirical features of VCEs is intended primarily as a guide to plant design. It may be regarded as an integrated treatment such that using the various empirical values given the result obtained is reasonable. The application of the values may be less valid if used as part of an eclectic approach.

Kletz (1979b) has applied this approach to obtain guidance on plant layout. This was described in Chapter 10.

More recently, Wiekema (1984) has carried out a statistical study on some 165 vapour cloud ignitions. Incidents were not included where no ignition occurred or where ignition was virtually simultaneous with the release, as in a BLEVE. On the other hand, no incident was excluded simply because some information on it was lacking. The study is based on reported incidents and, as the author points out, is therefore a biased sample.

The features selected for analysis are given under the following headings: (1) mass, (2) reactivity, (3) ignition source, (4) drift, (5) explosion, (6) location, (7) delay, (8) fatalities, (9) injured, and (10) domino effects. The gas is classed as being of high, medium or low reactivity; the ignition sources as continuous or non-continuous; the combustion as a flash fire or explosion; the location as containing obstacles and therefore being semi-confined or as being free from obstacles and not semi-confined; and the situation as one where vulnerable objects were absent and a domino effect was not possible, where such objects were

present and a domino effect occurred and where such objects were present but no domino effect occurred.

The results of the survey are shown in Figure 17.69. Since for many incidents some information was lacking, the number of cases given for each of the subfigures varies. Most of the releases were of medium reactivity materials. For these the analysis gave the results shown in Table 17.34.

Wiekema draws from his analysis the following conclusions:

(1) In 87 out of 165 incidents the distance within which ignition occurred was known. More than 60% of these 87 vapour clouds were ignited within 100 m from the location of the spill. In only 2% of these cases did the vapour cloud drift more than 1 km before ignition took place.
(2) In 150 out of 165 incidents it was known whether an explosion or flash fire occurred. In nearly 60% of these cases the ignition resulted in an explosion; in the other cases a flash fire occurred.
(3) In 143 out of 165 incidents the number of fatalities was known. In about 40% of these cases there were no fatalities and in 25% no one was hurt.
(4) The amount spilled did not influence the probability of an explosion for the investigated incidents in the spill range 1–100 te.
(5) Explosions occurred only in semi-confined situations and never in unconfined situations.
(6) A short delay time to ignition enhanced the probability of an explosion.
(7) For delay times to ignition larger than half-an-hour only flash fires occurred.
(8) Outside the combustible cloud no one was killed due to primary blast effects.
(9) For flash fires the number of injured was of the same order as the number of fatalities. For explosions the number of injured was one order of magnitude larger than the number of fatalities.

VCE is one of the hazards considered in the two Convey Reports. The treatment given in these reports is described in Appendix 7.

17.28.3 Combustion in vapour clouds

The combustion of vapour clouds in the open air was already a subject of research before the four major explosions just mentioned, but their occurrence provided a further stimulus to work on what was then generally referred to as unconfined VCEs.

Fundamental aspects of VCEs have been discussed by various authors, including Brasie and Simpson (1968), Strehlow (1973b), Gugan (1976, 1979), Munday (1976a,b), Anthony (1977a), V.J. Clancey (1977a), J.H.S. Lee *et al.* (1977), W.E. Baker *et al.* (1983), J.H.S. Lee (1983b), Pikaar (1983) and D.C. Bull (1992).

'Open-air' explosions usually occur with at least part of the vapour cloud in a congested region of a processing plant. Except in rare instances these explosions are deflagrations. Deflagrations can be highly damaging.

In the early work much attention centred on the question of detonation of the vapour cloud. Detonations are more damaging than deflagrations, but the distinction can often be expressed as detonations produce smaller fragments.

It is known that flame speeds obtained in vapour clouds are greater than the normal burning velocity. Strehlow quotes a burning velocity of 9 m/s for stoichiometric hydrogen–oxygen mixtures as measured on a bunsen burner and velocities of 68–120 m/s obtained using balloons. These velocities are typical of a flash fire rather than an explosion. The acceleration of the flame in a vapour cloud and the influence of factors such as apertures and turbulence has been the subject of many experiments. A major focus is to determine what degree of turbulation induction will accelerate flame speed to a deflagration let alone a detonation. Some of the problems associated with detonation are:

(1) which fuels have a high reactivity leading to detonations;
(2) existence of detonability limits;
(3) occurrence of unconfined detonation;
(4) direct initiation of detonation;
(5) characteristics of flame propagation;
(6) transition from deflagration to detonation.

Only a few fuels are considered highly reactive and can detonate lacking confinement. These include ethylene, acetylene, ethylene oxide and methyl nitrate.

There are in the literature statements to the effect that the limits of detonability are essentially the flammability limits. Thus, Burgess *et al.* (1968 BM RI 7196) state: 'A consensus has gradually developed that almost any gas mixture that is flammable is also detonable if initiated with a sufficiently energetic source.'

It has been shown, however, that detonability limits are in fact distinct from flammability limits, but they are more complex and more difficult to measure. Information on detonability limits for spherical detonation is especially sparse and the limits are a function of the strength of the ignition source. Detonability limits were discussed in Section 17.2 and are considered further below.

The violence of some VCEs suggests that they might well be detonations, but the occurrence of detonation as opposed to deflagration in an unconfined vapour cloud was for a long time considered to be highly unlikely, even impossible. However, in an account of the Port Hudson explosion Strehlow (1973b) stated: 'The Port Hudson explosion is a proven example of an accidental vapour-cloud detonation'. And again: 'There is no question but that detonation has occurred in accidental explosions, or that detonation can be initiated without delay in an unconfined cloud using a sufficiently strong ignition source.' He also stated: 'More commonly, the vapour cloud simply deflagrates. However, deflagration velocities are commonly observed to be quite high and extensive blast damage can occur even for this type of vapour-cloud combustion, particularly if the cloud contains a sufficiently large volume of combustible mixture at the time of ignition'.

The problem which concerned workers in this area, however, was the initiation of detonation. As Munday (1976a) commented: 'It seems highly unlikely that detonative combustion occurs in unconfined conditions unless a priming confined or condensed explosive source is ignited'.

In the Port Hudson explosion it is believed that the cloud may have been ignited by a strong ignition source in a building enveloped by the cloud.

As the debate developed in the mid-1970s there was some reversion to the view that detonation in vapour clouds is highly unlikely. There are difficulties in envisaging the mechanism by which the flame speed in an unconfined cloud can accelerate to such a degree as to reach the speeds characteristic of detonation. The consensus view developed that if detonation occurs, it is likely to be associated with special circumstances, such as the occurrence of an initiating detonation within the cloud or interaction of the blast wave with structures, resulting in flame acceleration and higher local pressures.

The *Second Report* of the ACMH (Harvey, 1979b) probably represented current opinion in stating in its discussion of the Port Hudson incident: 'Since no other single case is on record, and many deliberate attempts to detonate unconfined hydrocarbon/air clouds have failed, it would seem more justifiable to regard the occurrence of true detonation in an unconfined vapour cloud as so improbable as to be disregarded for design purposes'.

As far as direct initiation of detonation is concerned, Strehlow states that direct initiation of detonation in a vapour cloud can occur if the ignition source is sufficiently strong, and quotes experiments which demonstrate this. This has since been confirmed by further research, including both work directed to determination of detonability limits and other work directed to vapour cloud detonation as such.

It is possible that a deflagration may turn into a detonation. The dominant view has been that this is difficult to envisage in a truly unconfined situation, but the shock waves to promote the transition might arise from interaction with structures.

Although much work has been done, and continues to be done, on the detonation of vapour clouds, the focus of attention has gradually shifted to the effect of confinement on the flame and, in particular, on the conditions which promote its acceleration to very high flame speeds.

The view which emerges from this work is that significant overpressure in vapour cloud combustion tends to be associated with a degree of confinement and that the extent of this overpressure is highly dependent on the details of the confinement.

With this model the mass of flammable gas available to participate in the explosion is not the total flammable mass but that part which is within the confinement.

Another feature which is better appreciated is the importance of the initial combustion zone. This may be envisaged as a spherical zone in which the flame front expands until it breaks through the envelope of the cloud. Once this happens, relief occurs and the pressure falls. It follows from this that the overpressure developed depends on features such as cloud height and vertical confinement.

Traditionally, vapour clouds have been treated as hemispherical, but in practice many vapour clouds are pancake shaped. Increasingly, this feature is being taken into account in studies of vapour cloud combustion.

It will be apparent from the foregoing that VCEs are not yet well understood. Experimental studies have therefore been undertaken to improve understanding, while design approaches have been developed based on correlation of empirical features. These aspects are now described.

17.28.4 Experimental studies

There is now a considerable body of experimental work on VCEs. Reviews include those of J.H.S. Lee (1983b), Pikaar (1985), D.C. Bull (1992) and the CCPS (1994/15).

Some experimental studies of vapour cloud fires and VCEs are given in Table 17.31. A listing of experimental work suitable for the testing of VCE models is given by Madsen and Wagner (1994).

The review by Pikaar (1985) covers (1) release phenomena, (2) vapour cloud generation and dispersion, (3) vapour cloud combustion, and (4) interactions. Vapour cloud combustion is divided into (1) combustion of premixed clouds and (2) combustion of fuel-rich clouds. The combustion of premixed clouds covers (1) combustion in open terrain, (2) influence of partial confinement and obstacles, and (3) pressure waves. The interactions considered are (1) the effect of deliberate dispersion by water sprays and (2) the effective lower flammability limit following dispersion.

In his review, D.C. Bull (1992) covers large scale work on both vapour clouds in the open and vapour mixtures in large enclosures such as modules, and gives the following classification of the research done:

State		*Phase*	
		Single	*Aerosol +hybrid*
'Unconfined'	Intially quiescent	A	B
	Initially turbulent	C	D
With congestion	Intially quiescent	E	(F)
	Initially turbulent	G	(H)
With congestion	Intially quiescent	I	J
	Initially turbulent	K	(L)
With congestion and confinement	Intially quiescent	M	(N)
	Initially turbulent	O	(P)

No large scale work was found in the classes shown in parentheses.

The review by the CCPS (1994/15) is under the following headings: (1) unconfined deflagration under controlled conditions, (2) unconfined deflagration under uncontrolled conditions and (3) partially confined deflagration.

A. Combustion of dispersed vapour clouds

A1. Work on fuel–air explosions. Much research has been done on the use of fuel–air explosion (FAE) weapons. Although this work is mainly in the military domain and unpublished, some accounts are available (e.g. Kiwan 1970a,b, 1971). Fuels used include ethylene oxide, propylene oxide, *n*-propyl nitrate and methyl acetylene/ propadiene/ propylene (MAPP). Further information is given by W.E. Baker *et al.* (1983).

A2. Early field trials of combustion in unconfined vapour clouds. Early work on the combustion of unconfined vapour clouds includes the field trials on liquified natural gas (LNG) described by Liitzke (1971), Humbert-Basset and Montet (1972), the American Gas Association (AGA) (1974) and Raj, Moussa and Aravamudan (1979a,b) and those on ethylene by the Ministry of International Trade and Industry (MITI) (1976).

The large scale tests on LNG carried out by Gaz de France (Humbert-Basset and Montet, 1972), described earlier, included experiments in which ignition sources were disposed at the edge of the cloud. The main purpose in this case was to obtain a cross-check on the cloud concentrations.

Tests on the explosion of ethylene–air mixtures in the open were carried out as part of the experiments, described earlier, conducted by MITI (1976) in Japan. In one test an ethylene–air mixture containing 4.08 kg of ethylene and giving a 7% mixture in air was held in a polyvinyl chloride tent and exploded by a detonator. The blast pressure was 4.9 bar at 5 m and 0.49 bar at 20 m distance. It was correlated by a straight line on a log–log plot of peak overpressure vs scaled distance. The TNT equivalent of the explosion was estimated as 49.2 kg. The duration time was 10 ms at 10 m distance. It was concluded that for flammable gas explosions the TNT equivalent model fits reasonably well for the peak overpressure, but that the duration time is rather longer.

A3. Early work on detonation in unconfined vapour clouds. A major theme in early research on VCEs was the definition of the conditions under which detonation might occur.

It is known that the transition from deflagration to detonation is difficult to induce in an unconfined vapour cloud, and investigations have concentrated on features which promote defregration to detonation transition (DDT), such as obstacles and partial confinement.

The problem was approached from two directions. One was the study of flame speeds in unconfined clouds. Work by Lind (1975) indicated early on that flame speeds, and overpressures, in truly unconfined vapour clouds are very low.

Other work was directed to the study of the potential modes of detonation and the conditions for their occurrence. This includes research on (1) the direct initiation of detonation, (2) the deflagration to detonation transition (DDT), (3) the effect of obstructions and of partial confinement, and (4) the minimum size of cloud for detonation.

Work on direct initiation of explosions has frequently utilized an explosive charge. Typical is the work of Bull, Elsworth and Hooper (1979a) on the detonation limits of ethane–air mixtures. A review of work in which detonation has been induced using an explosive charge is given by Bull (1979).

A small amount of research has been done to establish the size of cloud in which overpressures can be induced. Thus, Maurer *et al.* (1977) have shown that overpressures can occur in even very small clouds of mass 0.5–500 kg. Fundamental approaches to the estimation of the minimum size of cloud in which detonation might occur have been described in Section 17.2. Some fundamental aspects of detonation in vapour clouds have also been discussed in Section 17.2, including DDT and minimum cloud size.

The consensus which emerged from this work on detonation in vapour clouds was that it is more fruitful to focus attention primarily on the conditions associated with high flame acceleration and high deflagration overpressure rather than on detonation as such.

A4. Combustion in unconfined vapour clouds: closely controlled tests. A number of workers have performed experiments on combustion of gas–air mixtures inside soap bubbles or balloons. They include Lind and Whitson (1977), Deshaies and Leyer (1981), Okasaki, Leyer and Kageyama (1981), Schneider and Pfortner (1981), Brossard *et al.* (1985), A.J. Harrison and Eyre (1986, 1987) and R.J. Harris and Wickens (1989). The flame speeds for gases of moderate or low reactivity obtained were low (≤24 m/s) as were the overpressures (≤0.06 bar), where measured.

The rig used by A.J. Harrison and Eyre (1986, 1987) is shown in Figure 17.65. It represents a sector of a pancake-shaped vapour cloud. For natural gas and propane the

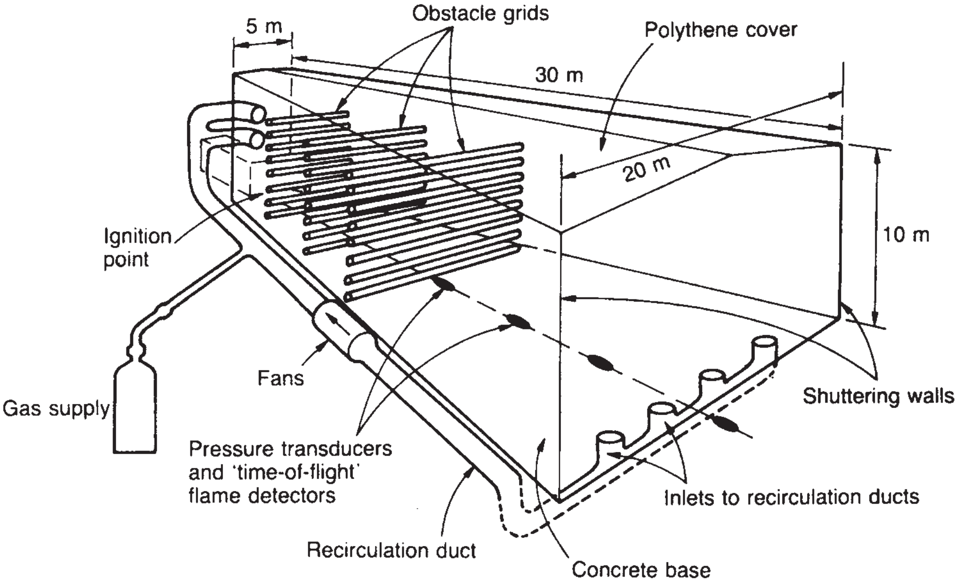

Figure 17.65 *Experimental work on vapour cloud explosions: rig representing a sector of a shallow, cylindrical cloud (A.J. Harrison and Eyre, 1986) (Courtesy of Institution of Chemical Engineers)*

flame speeds and overpressures obtained in the absence of a high-energy ignition source or obstructions were low.

R.J. Harris and Wickens (1989) conducted tests in a tent-type rig of rectangular cross-section and 45 m long with a plywood floor and with polyethylene sheeting on the sides and roof. The gases used were natural gas, propane, cyclohexane and ethylene. The basic experiment was to fill the rig with a stoichiometric mixture, ignite it at one end and measure the flame speeds and overpressures generated.

One set of experiments was conducted without any obstruction of the space in the rig and without confinement of the ignition region. For this base condition the flame speeds observed were about twice those measured in the laboratory. The authors give the following data:

Gas	*Laminar burning velocity* (m/s)	*Flame speed* (m/s)	
		Laboratory tests	*Rig tests*
Natural gas	0.45	3.1	8
LPG	0.52	3.6	10
Cyclohexane	0.52	3.6	10
Ethylene	0.83	5.8	19

Thus, without obstructions the flame speeds obtained were low.

The last two sets of investigators also performed experiments using obstructions, as described below.

This research has thus provided further confirmation that the flame speeds in unconfined vapour clouds of moderate or low reactivity substances are not such as to give high overpressures and deflagrations, let alone detonations.

In balloon tests, high reactivity gases gave rather higher flame speeds (acetylene 38 m/s and hydrogen 84 m/s), still less than the deflagration range.

A5. Combustion in unconfined vapour clouds: field trials. The early 1980s saw a number of large scale field trials on dense gas dispersion, some of which were supplemented by trials involving cloud ignition.

Accounts of this work are given by Blackmore, Eyre and Summers (1982) for trials with LNG and propane at the Maplin Sands site, Hogan (1982), MIT-GRI (1982) and Goldwire *et al.* (1983) for LNG trials at China Lake and Zeeuwen, van Wingerden and Dauwe (1983) for propane trials at Musselbanks.

For LNG the maximum flame speed observed was 13.3 m/s at China Lake, and for propane 28 m/s at Maplin Sands and 32 m/s at Musselbanks.

Field trials on combustion of vapour clouds are also considered in Chapter 16 in relation to flash fires.

A6. Combustion in vapour clouds with obstructions: closely controlled tests. The absence of evidence in work on unconfined vapour clouds of flame speeds sufficiently high to give high overpressures has led to investigation of the effect of obstacles in promoting flame acceleration.

Controlled tests using obstacles have been conducted by Db'rge, Pangritz and Wagner (1981), C.J.M. van Wingerden and Zeeuwen (1983), A.J. Harrison and Eyre (1986, 1987) and R.J. Harris and Wickens (1989).

The apparatus in the work of Db'rge, Pangritz and Wagner (1981) contained a wire mesh, whilst that of C.J.M. van Wingerden and Zeeuwen (1983) consisted of a 60 × 60 cm plate with 1 cm vertical obstacles placed on it.

Using in their rig a blockage ratio of 40% with six grids of pipe-type obstacles, A.J. Harrison and Eyre (1986, 1987) obtained in one test on natural gas a flame speed of 119 m/s and an overpressure of 0.21 bar. They observed that the flame accelerated on entering the obstructed region and decelerated on leaving it. The tests showed that with natural gas a high degree of congestion is required to obtain high flame speeds and overpressures.

R.J. Harris and Wickens (1989) utilized the 45 m long tent-type rig already described. Again the gases used were natural gas, propane, cyclohexane and ethylene. The obstructions were placed in the central portion of the rig. The effect of these was to cause the deflagration flame to accelerate. On entering the subsequent unobstructed portion the flame decelerated again. This is illustrated in Figure 17.66(a), which shows results for cyclohexane. The flame speeds obtained were up to 10 times higher than for the unobstructed case.

Both of the last two sets of investigators studied the effect of a strong ignition source. A.J. Harrison and Eyre (1987) utilized a jet flame emerging from a partially confined region. Using natural gas, they observed in one test a flame speed of 170 m/s and an overpressure of 0.71 bar.

R.J. Harris and Wickens (1989) conducted tests with a strong ignition source using cyclohexane and propane. The tests involved the use of a central obstructed region and a modified method of ignition, obtained by confining the end region in which ignition took place. In experiments on cyclohexane the flame emerged from this region with a flame speed of about 150 m/s. The results obtained are illustrated in Figure 17.66(b), which shows that the flame ran up to detonation in the obstructed portion and that the detonation was maintained when it entered the subsequent unobstructed portion. The detonation velocity was 1700 m/s. The corresponding velocities for propane were 300 m/s leaving the confined region and 1800 m/s for detonation.

Overall, the work of Harris and Wicken illustrated the effect of a combination of fuel reactivity, ignition conditions and an obstructed region. It showed that with an obstructed region and an ignition source giving a high initial flame speed more reactive fuels can run up to detonation. On the other hand it also confirmed the much lower flame speeds associated with natural gas.

A7. Combustion in vapour clouds with obstructions: field trials. Experiments on the effect of obstacles on the course of VCEs have also been carried out on the field scale. Zeeuwen, van Wingerden and Dauwe (1983) have described work at TNO on field trials using obstacles which complement the small scale work described earlier. Tests were conducted both without and with partial confinement. For the former, two types of obstacle were used: a set of large horizontal pipes and a set of sewer pipes, each 1 m in diameter and 2 m high, stood on end. The latter system, shown in Figure 17.67, consisted of seven rows of 10 pipes on a 3 m pitch. In some tests this array was open at the top and in

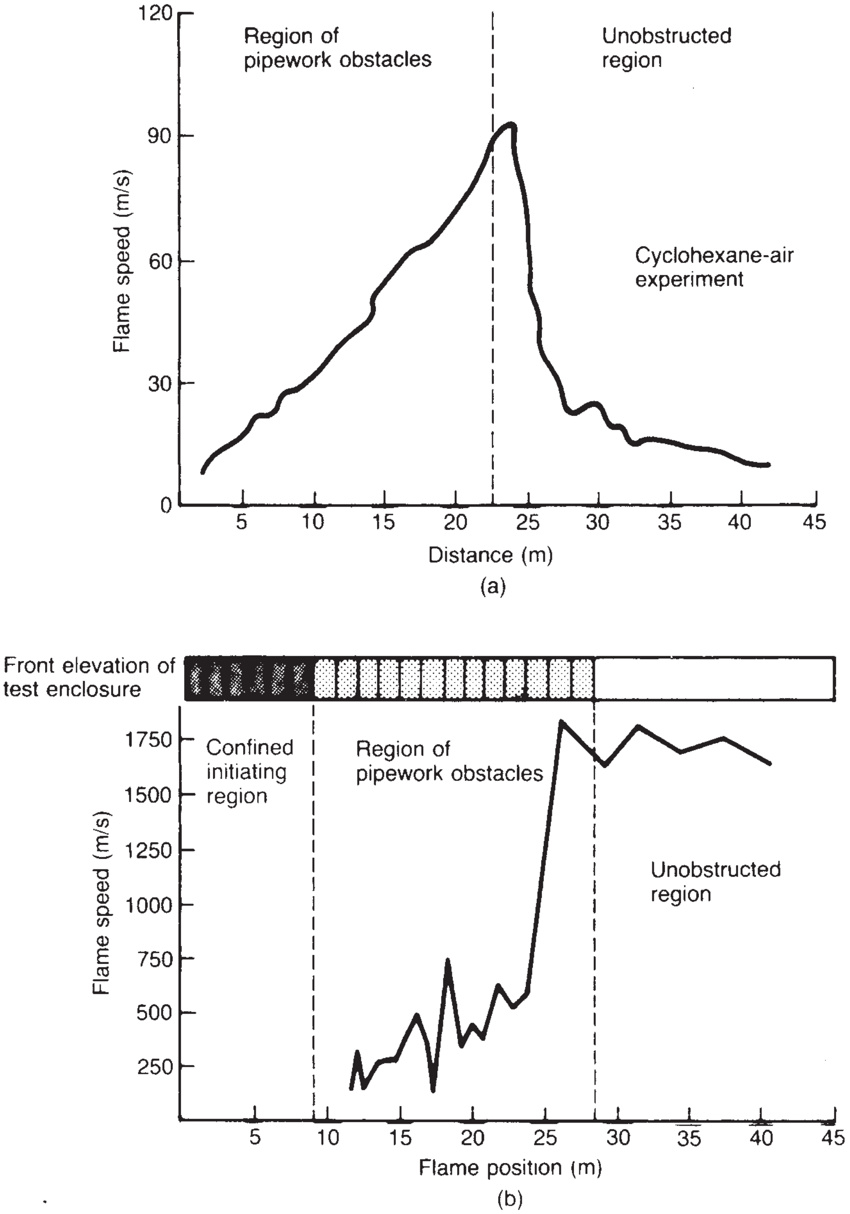

Figure 17.66 *Experimental work on vapour cloud explosions: effects of obstructions and of jet flame ignition (R.J. Harris and Wickens, 1989): (a) flame acceleration on entering obstructed region and flame deceleration on leaving it and (b) flame accelertion on entering obstructed region with transition to detonation, following jet flame ignition. Cyclohexane in both cases (Courtesy of the Institution of Gas Engineers)*

others it was partially or totally covered. The vapour clouds consisted of 1000 kg of propane, which was introduced over a period of some 1–2 min through a water pond 15 m in diameter and 1 m high. The dimensions of the cloud within the flammable limits were estimated as 130 m long, 75 m wide and 2 m high. In the tests without obstacles the flame speed was generally low at 3–10 m/s, although one case was recorded of 32 m/s, and no overpressure was measured. In the tests with horizontal pipes the flame accelerated to 16 m/s at the pipes and then fell again.

In the tests with the vertical pipes uncovered the flame speed was similar to the unconfined case. In the tests with cover, the area covered was 7 × 7 m^2, then 13 × 13 m^2 and finally the whole array. In all but the first of these tests the

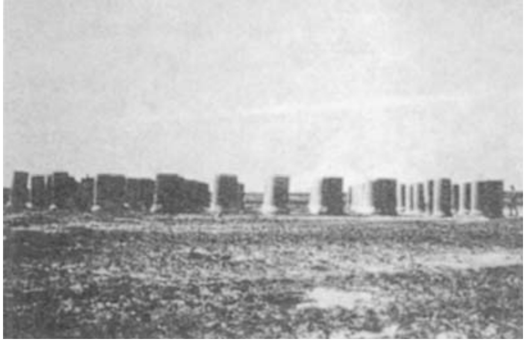

Figure 17.67 Experimental work on vapour cloud explosions: obstacle array for field trials (Zeeuwen, van Wingerden and Dauwe, 1983) (Courtesy of the American Institute of Chemical Engineers)

flame speed increased in the covered area and decreased beyond it. With the array completely covered the flame accelerated continuously, and flame speeds of 50–66 m/s were obtained, as were maximum overpressures of 20 mbar in the cloud and 6 mbar 75 m away.

A8. Combustion in partially confined vapour clouds without or with obstructions: work using tubes. The foregoing account indicates that the flame speed in a vapour-air mixture is affected by partial confinement as well as by obstacles. Investigators have studied a number of different geometries, notably (1) tubes, (2) parallel plates, and (3) channels, the first two being representative, respectively, of one- and two-dimensional flame propagation.

Work on the behaviour of flames in tubes antedates interest in VCEs. Early work on this topic was carried out by Chapman and Wheeler (1926, 1927) and their co-workers, using both empty tubes and tubes containing obstacles. An account of this work has been given in Chapter 16.

Combustion in tubes, especially shock tubes, is the staple of research on detonation and has been the subject of innumerable studies.

A series of investigations using tubes specifically related to vapour cloud explosions has been described by Lee, Moen, Hjertager and co-workers (C. Chan *et al.*, 1980; Moen, Lee *et al.*, 1982; Hjertager, 1984; J.H.S. Lee, Knystautas and Chan, 1985). Other work includes that of Wagner and co-workers (Db'rre, Pangritz and Wagner, 1981) and Andrews and co-workers (Andrews, Herath and Phylaktou, 1990; Phylaktou and Andrews, 1991a,b).

Moen, Lee *et al.* (1982) and Hjertager (1984) carried out experiments in a pipe 2.5 m in diameter and 10 m long containing obstructions. The former obtained for methane overpressures of 4 bar and the latter for propane pressures of 13.9 bar.

Subsequently, Hjertager and co-workers (Hjertager, Bjorghaug and Fuhre, 1988; Hjertager, Fuhre and Bjorghaug, 1988a) performed similar experiments with a non-homogeneous mixture more representative of that from a plant leak. For non-stoichiometric mixtures the pressures obtained tended to be less than those with a stoichiometric homogeneous mixture. For non-homogeneous mixtures the pressures were equal to or less than those for homogeneous mixtures.

A9. Combustion in partially confined vapour clouds without or with obstructions: work using parallel plates. The second widely used system is a pair of parallel plates. Among the investigators who have studied this configuration are Moen, Donate, Knystautas and Lee (1980), Moen, Donate, Knystautas, Lee and Wagner (1980), C.J.M. van Wingerden and Zeeuwen (1983), Hjertager (1984) and C.J.M. van Wingerden (1984, 1989).

Moen, Donate, Knystautas and Lee (1980) used plates 60 cm in diameter with obstacles, and obtained for methane flame speeds up to 130 m/s, whilst further work by Moen, Donate, Knystautas, Lee and Wagner (1980) using 2.5 × 2.5 m plates, again with methane, gave flame speeds up to 400 m/s and overpressures of 0.64 bar.

In the work of C.J.M. van Wingerden and Zeeuwen (1983), already mentioned, experiments were carried out in a closed vessel using a configuration consisting of vertical sticks held either on a single plate or between two plates. Enhancements of flame speed were observed in the confined volume, but these were much greater where the space was confined by the second, top plate. The increases in flame speed were attributed to two mechanisms. One is the stretching of the flame front as it passes through the opening between the obstacles and the other is the folding and wrinkling of the flame front due to turbulence. The authors discuss the relative importance of these two factors, which is somewhat complex.

Using a 0.5 m disc with obstructions Hjertager (1984) obtained a flame speed of 160 m/s and an overpressure of 0.8 bar for methane and a flame speed of 225 m/s and overpressure of 1.8 bar for ethylene.

In work by C.J.M. van Wingerden (1984 CEC EUR 9541 EN/II) on ethylene using 4 × 4 m plates with obstacles a flame speed of 420 m/s and an overpressure of 0.7 bar were obtained.

C.J.M. van Wingerden (1989) also used a plate apparatus to perform experiments with a range of gases of differing reactivity: methane, propane, ethylene and acetylene. He showed that reactivity can be related to the laminar flame speed and that this can be used as the basis for a method of scaling in VCE work.

A10. Combustion in partially confined vapour clouds without or with obstructions: work using channels. The third configuration to have attracted investigation is the channel on which work has been reported by Urtiew (1981), C. Chan, Moen and Lee (1983), Elsworth, Eyre and Wayne (1983), Sherman *et al.* (1985), P.H. Taylor (1986) and P.H. Taylor and Bimson (1989).

Working with ethylene in an open channel containing baffles Urtiew (1981) obtained a flame speed of 20 m/s.

C. Chan, Moen and Lee (1983) also used a channel with baffles and with a top containing perforations such that the degree of top confinement could be varied. For methane with high confinement a flame speed of 120 m/s was observed, but with only 10% confinement this figure fell to 30 m/s.

The experiments by P.H. Taylor (1986) also involved a perforated duct top in which the top confinement could be varied. Working with propane he obtained a flame speed of 80 m/s with a 50% blockage ratio and an 88% confinement.

Elsworth, Eyre and Wayne (1983), in tests relevant to a spill between a vessel and a jetty, investigated using an open channel the behaviour of propane systems both premixed and simulating a liquid propane spill, using baffles in some tests. The maximum flame speed in the premixed tests was 12.3 m/s.

The work on channels brings out the effect of top venting in reducing the flame speeds in vapour-air mixtures.

A11. Jet ignition of vapour clouds. Other work on VCEs includes studies of the effect of a strong ignition source in the form of a flame jet issuing into the cloud.

Work on this form of strong ignition source by A.J. Harrison and Eyre (1987) and R.J. Harris and Wickens (1989) has been described above. It was shown to yield high flame speeds and even detonation.

B. Combustion of turbulent jets. Leaving now the combustion of dispersed vapour clouds to consider that in other vapour–air release scenarios, another important case is that of the turbulent free jet. It was ignition of such a jet which gave rise to the explosion at Flixborough.

Work on this problem has been described by Seifert and Giesbrecht (1986) and Stock (1987). The former workers studied ignition of jets of methane and of hydrogen. Measurements were taken of the flame velocities and of the overpressures and duration times at different distances from the cloud.

Stock (1987) investigated jets of propane and measured overpressures within the cloud. The work included investigations of the effect of obstacles and partial confinement. For the particular configurations studied, partial confinement with 0.5 m high obstructions within 2 m high parallel walls, the overpressure in the cloud increased by a factor of about 4.

C. Combustion following vessel burst. Another release scenario is that of the rupture of a vessel, reported in accounts by Maurer, Giesbrecht, Seifert and co-workers. The account by Maurer *et al.* (1977) was concerned primarily with experiments on the dispersion aspects but included some results for the overpressure from the physical burst. Giesbrecht *et al.* (1981) have described the explosion resulting from ignition of the flammable vapour cloud formed.

The experiments were done using vessels ranging in size from 0.226 to 1.0 l, containing propylene at 40–60 bar. Figure 17.68 shows a plot of the variation of the principal variables with the initial mass in the vessel. Also shown on the plot are the extrapolations for the VCEs at the BASF works at Ludwigshafen in 1943 and 1948 and at Flixborough in 1974.

D. Combustion of a pipeline leak. Another scenario investigated is that of the ignition of a leak of flammable vapour from a pipeline. Work on this has been done by Hoff (1983).

His tests involved full bore ruptures of a 10 cm diameter gas pipeline operating at 60 bar. Ignition was effected by firing a bullet at the gas jet. The flame speeds observed

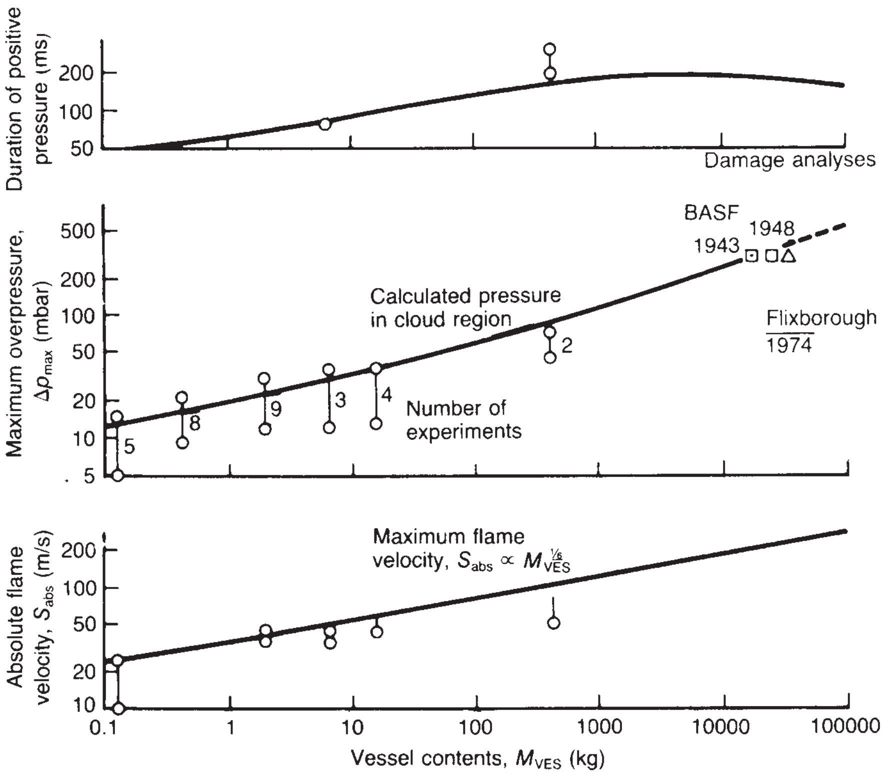

Figure 17.68 Experimental work on vapour cloud explosions: flame velocity, peak overpressure and duration time in explosions of flammable vapour cloud formed following vessel burst (Giesbrecht et al., 1981) (Courtesy of German Chemical Engineering)

were of the order of 15 m/s, and the overpressure at a distance of 50 m was measured as 1.5 mbar.

E. Some factors affecting combustion of dispersed vapour clouds. It is useful at this stage to summarize some of the salient points on the combustion of dispersed vapour clouds brought out by the experimental work just described. The summary is mainly confined to qualitative observations.

Fuel reactivity. One important factor which determines the flame speeds and overpressures attained is the reactivity of the fuel.

Fuels are generally classed as being of low, moderate or high reactivity. Methane may be considered of low reactivity, propane of moderate reactivity and acetylene of high reactivity.

A classification developed by the Factory Mutual Research Company (FMRC) (1990) from the work of D.J. Lewis (1980d) is given in Section 17.28.9. In this classification, although more reactive than methane, propane and butane are classed as low reactivity fuels.

Cloud inhomogeneity: flame speed and overpressure. The standard vapour–air mixture used in most work on VCEs has been stoichiometric and homogeneous. Only a small amount of work has been done involving more realistic vapour–air mixtures. The work appears to indicate that whilst flame speeds tend to be lower in mixtures which depart significantly from the stoichiometric, in spaces where the mass of vapour is such that good mixing would give a mixture close to stoichiometric it is unwise to assume that the flame speed will be much reduced by a degree of inhomogeneity.

Cloud inhomogeneity: effective lower flammability limit. It has long been appreciated that due to concentration fluctuations pockets of flammable vapour–air mixture of a concentration above the lower flammability limit (LFL) may occur beyond the nominal envelope bounded by the concentration corresponding to the LFL.

It is conventional to take this effect into account by using an effective LFL and to treat that part of the cloud calculated to be within this effective LFL as potentially flammable. A common practice has been to take the effective LFL as half the actual LFL, in other words taking a peak-to-average, or P/A, ratio of 2. This is illustrated in the work of Feldbauer *et al.* (1972) used in the hazard assessment done for the *First Canvey Report*, as described in Appendix 7.

The problem has been discussed by Pikaar (1985), who points out that it may be approached either from the standpoint of gas dispersion or that of combustion. As regards dispersion, there is no doubt that the P/A concentration ratio can be high. On the other hand, combustion of vapour clouds in large field trials such as those at Maplin Sands indicates that pockets of gas can be ignited without igniting the main cloud.

On the basis of such considerations, Pikaar proposes the use of a P/A ratio of 1.4.

A discussion of this problem from the viewpoint of gas dispersion is given in Chapter 15.

Cloud shape. The typical vapour cloud formed by dispersion of a dense gas is pancake shaped. This has a significant effect on combustion in the cloud.

One consequence of this cloud geometry is that the gas is able to expand, or vent, through the top of the cloud, so that there is less compression of the unburned gas ahead of the flame front and the flame speed is correspondingly lower. The same thing has been found for aspect ratio, with long, narrow vapour clouds, overpressures are lower because energy escapes out the sides of the congested area as the flame progresses.

Another effect relates to the possibility of detonation in the cloud. There is a minimum cloud thickness for detonation to occur, this thickness being a function of the cell size, which is characteristic of the gas. For the fully unconfined case the thickness needs to be of the order of 10–13 cell sizes, whilst for the practical case of a cloud bounded by the ground it is about 5–6.5 cell sizes.

Obstructions and partial confinement. The experimental work described demonstrates that the flame speed is enhanced by the presence of obstructions, but it also indicates that the extent of this enhancement varies. For a low reactivity gas without even partial confinement the increase may be relatively limited.

The addition of partial confinement in combination with obstructions can result in a much greater enhancement of flame velocity.

Obstruction configuration. One type of obstruction which has been used by several workers is a series of grids set one behind the other at regular intervals and consisting of horizontal cylinders simulating pipework. For the particular experimental set-up, correlations have been obtained of the effect on flame speed of variables such as the blockage ratio, the spacing and the construction of the grid.

Ignition source strength. Another enhancing factor is the strength of the ignition source. The strong ignition sources principally investigated are explosives and jet flames. The latter are regarded as a credible ignition source.

Experiments on jet flame ignition have involved obstacles and some partial confinement also. They have shown that in combination with these other factors this form of ignition can give high flame speeds and in some cases detonation.

Combination of enhancing effects. The principal enhancing effects mentioned are fuel reactivity, obstacles, partial confinement and jet flame ignition. The experimental evidence suggests that these factors are most effective in producing high flame speeds, even detonation, where they are present in combination.

Water sprays. There have been a number of studies on the use of water spray to mitigate the effects of a flammable gas release by dispersing it.

Pikaar (1985) sounds a note of caution on the use of water sprays, in so far as they increase the turbulence in the cloud and could thereby make things worse. He refers to the work of Eggleston, Herrera and Pish (1976), in which flame speeds were apparently increased, although opinions differ on the interpretation of this work.

17.28.5 Vapour Cloud Explosion modelling

Although there are many gaps in the understanding of VCEs, considerable progress has been made in modelling such explosions.

Work on fundamental models has been described by a number of authors, including G.I. Taylor (1946), F.A. Williams (1965), Kuhl, Kamel and Oppenheim (1973), Strehlow (1975, 1981), Munday (1975a,b, 1976a,b), Gugan (1979), Wiekema (1980), W.E. Baker *et al.* (1983) and van den Berg (1985).

Other work has been directed to the correlation of experimental results and to the development of semi-empirical models. This includes the work of C.J.M. van

Wingerden (1989), C.J.M. van Wingerden, van den Berg and Opschoor (1989), C.J.M. van Wingerden, Opschoor and Pasman (1990) and K. van Wingerden, Pedersen and Wilkins (1994).

Some of the approaches to modelling have been described by Munday (1976a). These are:

(1) point source models
  (a) TNT equivalent model,
  (b) self-similarity model;
(2) fuel-air cloud model;
(3) bursting vessel model;
(4) piston model
  (a) constant velocity piston model,
  (b) accelerating piston model.

In the TNT equivalent model the explosion is taken to be equivalent to that of a TNT explosion with the same energy of explosion. This model is therefore an empirical one, but it was for some time virtually the only practical model available. It was considered in Section 17.26 and is discussed further below.

The TNT equivalent model has a single parameter, the mass of TNT. It can be made more flexible by the introduction of a second parameter, the height above ground zero at which the explosion occurs. The effect of increased height is to reduce the overpressures near the centre. The use of an arbitrary assumed explosion height is useful in obtaining better fits to overpressures assessed from damage in actual explosions.

In the self-similarity model, the blast parameters such as peak overpressure are correlated in terms of the ratio of radial distance to time. In its simplest form the model gives a power law relation for the variation of peak overpressure with distance.

In the fuel–air cloud model it is assumed that a detonation propagates through the fuel–air mixture without any expansion of the cloud. However, there is some expansion of a burning cloud during a deflagration. A shock wave with a high peak overpressure is produced at the cloud boundary. With combustion thus complete, subsequent decay of the shock wave is similar to that for the point source models.

Another approach is to assume that the fuel–air mixture undergoes combustion in a hemispherical vessel, defined by the cloud boundary, and that when combustion is complete, the vessel bursts. The state of the gas, after combustion but before bursting, is determined by standard methods. Subsequent decay of the shock wave may be calculated by numerical solution of wave propagation equations.

A widely used method has been to treat the flame front as a constant velocity piston. Early work on the piston model was done by G.I. Taylor (1946). This approach has been taken forward by Kuhl, Kamel and Oppenheim (1973), Strehlow (1981), Tang and Baker (1999) and other workers.

Figure 17.70 illustrates the variation of the overpressure with time in the TNT equivalent model and constant velocity piston models of a VCE.

The constant velocity piston approach has also been used by Wiekema (1980) at TNO. His model is a practical one and is quite widely used. It is described below.

Van den Berg (1985) at TNO has developed this work to produce a multienergy (ME) model, also described below, which reflects the fact that the main energy release is from the confined parts of the cloud.

Finally, TNO have presented an empirical model for the damage circles caused by a VCE.

Before considering these models, however, mention should be made of several other concepts which are important in modelling.

One of these is that of flame acceleration. Some of the factors which influence this have been considered by C.J.M. van Wingerden and Zeeuwen (1983) in their work on the influence of obstacles. They describe two effects which enhance flame speed. One is the stretching of the flame front as it passes through an opening. The flame front velocity V_f is

$$V_f = \frac{\rho_u S}{\rho_b} \qquad [17.28.1a]$$

$$= \frac{\rho_u}{\rho_b}\frac{A_f S_L}{A_o} \qquad [17.28.1b]$$

where A_f is the disturbed flame surface area, A_o is the undisturbed flame surface area, S is the burning velocity, S_L is the laminar burning velocity, ρ is the gas density and the subscripts b and u denote burned and unburned, respectively. For the case where this effect, rather than that of turbulence, is the dominant factor a simple relation may be derived for the flame acceleration. If the flame front velocity is V_{fo} before an obstacle and V_{f1} after it, then

$$V_{f1} = V_{fo}(1 + \Delta A/A) \qquad [17.28.2]$$

where $\Delta A/A$ is the relative increase in flame surface area. Hence, the flame front velocity V_{fn} after n obstacles is

$$V_{fn} = V_{fo}(1 + \Delta A/A)^n \qquad [17.28.3]$$

with n in terms of flame front radius, r, and pitch, p:

$$n = r/p \qquad [17.28.4]$$

or, if the flame front velocity V_{fo} entering the obstacles is some multiple α of the base value V_L.

$$\frac{V}{V_L}(r) = \alpha(1 + \Delta A/A)^{(r-r_o)/p} \qquad [17.28.5]$$

where r_o is the radius at the entry to the obstacles.

Another basic concept is the relation between the flame velocity, u, and the overpressure generated, ΔP. This has been derived by several workers in the form $\Delta P \alpha \frac{1}{2} pu^2$, where p is the density of the unburned vapour. Figure 17.71 shows a typical plot of this relation.

17.28.6 Mass of fuel

The estimation of the mass of fuel within the flammable range in the vapour cloud is not entirely straightforward. For a defined release scenario the mass of fuel within the flammable range may be estimated using gas dispersion models. This is discussed in Chapter 15 and has been reviewed by a CCPS book (Woodward, 1997).

Many of the expressions given are based on models for neutral density gas. Treatments used on such models have been given by Burgess *et al.* (1975), Eisenberg, Lynch and Breeding (1975), V.J. Clancey (1977a), van Buijtinen (1980),

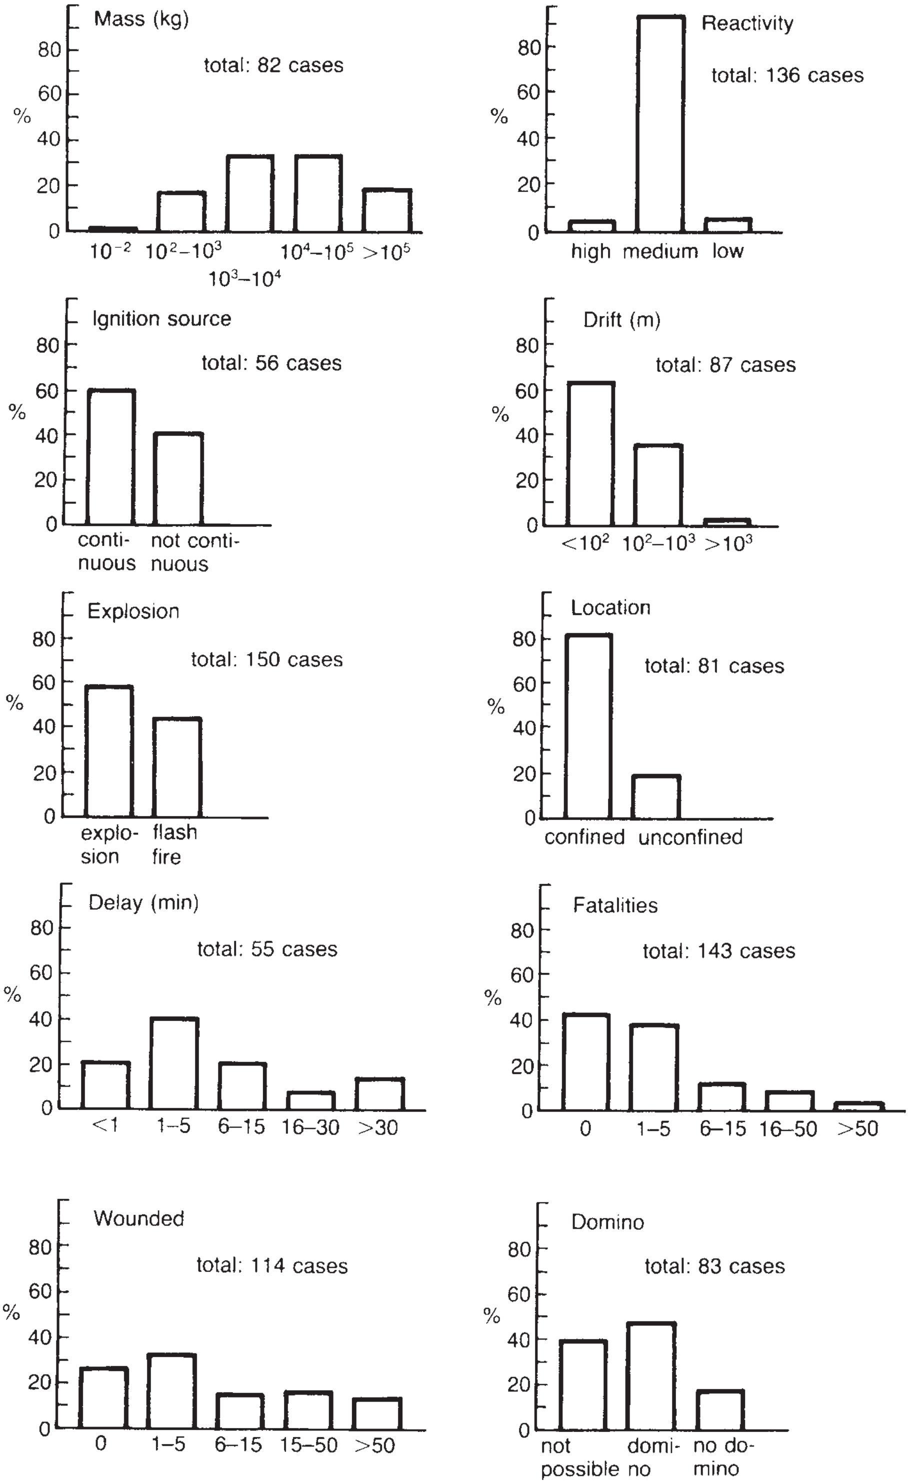

Figure 17.69 *Histograms showing selected features of a vapour cloud explosion (Wiekema, 1984) (Courtesy of Elsevier Science Publishers)*

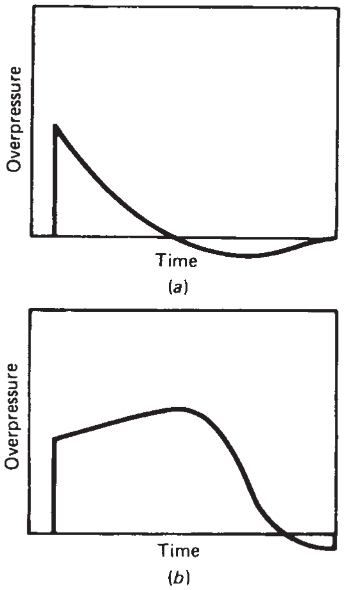

Figure 17.70 *Variation of overpressure with time in TNT equivalent and constant velocity piston models of an vapour cloud explosion (after Munday, 1976a): (a) TNT equivalent model and (b) constant velocity piston model (Courtesy of the Institution of Chemical Engineers)*

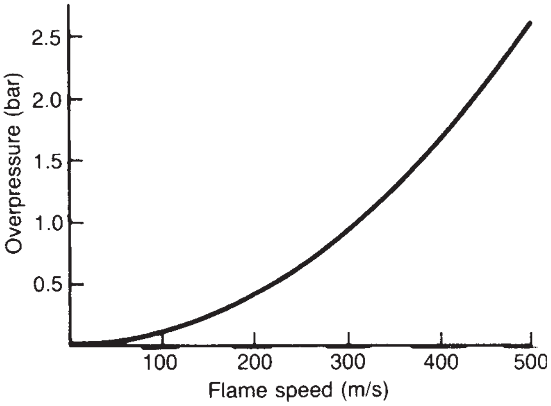

Figure 17.71 *Overpressure in a vapour cloud deflagration as a function of flame speed (R.J. Harris and Wickens, 1989; after Kuhl, 1981) (Courtesy of the Institution of Gas Engineers)*

J.G. Marshall (1977, 1980), Hesse (1991) and the TNO Yellow Book (1997).

Generally, dense gas dispersion models will be more appropriate. The typical dense model is a box or slab model in which the gas cloud is defined in terms of its radius and height. For an instantaneous release box model the gas concentration within the cloud is assumed to be uniform. In such a model the available mass of fuel remains constant, until at some time the concentration falls below the lower flammability limit. Or for a continuous release a slab model takes the variation of concentration with distance into account so that the available mass of fuel changes with distance.

Some problems concerning the definition of the mass of fuel have been identified and discussed by R.A. Cox (1981). He reviews the merits of basing estimates on the mass within the flammable range, or flammable mass, or the total mass released. The ratio of the flammable mass to the total mass released is likely to be highly variable. It will be small for a large inventory escaping through a small hole, but may be as high as half for an instantaneous burst. In view of this variability the blanket application of a single explosion efficiency is not likely to give accurate results.

Cox discusses but dismisses suggestions that there may be lower and upper limits to the size of cloud which can explode. He draws attention to the Badische Anilin und Soda Fabrik (BASF) work, mentioned above, which shows that overpressures can be induced in clouds of 0.5 kg mass. As for the suggestion of an upper limit of 50 te, he concludes that there is no real evidence for this either.

Cox draws attention to the fact that where the release is a turbulent jet there may be entrainment into the jet of fuel from outside the flammable envelope. In the absence of such entrainment the mass in the cloud is often quite modest, but it can be appreciably enhanced by entrainment.

Various authors have developed procedures for the determination of the size of the vapour cloud, generally for design purposes and frequently for use with a TNT equivalent model. Some of these are described in Chapter 15.

17.28.7 Energy of explosion

The energy of explosion in a VCE is usually only a small fraction of the energy available as calculated from the heat of combustion. This point has already been discussed in Section 17.4. As stated there, the explosion efficiency, or yield factor, may be quoted on the basis of the total mass released or of the flammable mass. Although the latter is the more fundamental basis, the former is the more convenient and the more common.

Values of the yield factor in VCEs discussed by Kletz were quoted in Section 17.27.5.

The *Second Report* of the ACMH (Harvey, 1979b) discusses the location and design of works buildings, and in this context suggests that a yield factor of 3% be provisionally assumed. In some cases a much higher yield factor has been reported. Davenport gives a yield factor of 25–50% for a VCE at Decatur, Illinois, in 1974. Similarly, Gugan (1979) quotes for this case a yield factor of 32–65%. This anomaly has been examined by V.C. Marshall (1980d), who concludes that the TNT equivalent quoted is not well founded, being based on a small number of damage points which lie well within the scatter of points obtained for the Flixborough explosion. He presents evidence of damage to support the view that the strength of the explosion at Decatur was not more, and was probably less, than that at Flixborough.

The yield factor is discussed further in Section 17.28.14.

17.28.8 TNT equivalent model

The TNT equivalent model has been widely used to model VCEs. The TNT equivalent model has been widely applied to VCEs, as described by van den Berg (1985). It is one of the types of model used in the CCPS methodology. It also has its critics, who regard it as obsolete. An example of this viewpoint is the account by Pasman and Wagner (1986).

An early application was that of Brasie and Simpson (1968), who used it to study the damage from three accidental explosions.

The TNT equivalent model was also used by Sadee, Samuels and O'Brien in their investigation of the VCE at Flixborough. In this case a two-parameter model was used, utilizing the height of the explosion as well as the mass of TNT. This work is described in Appendix 2.

There are, however, important features of a VCE which differentiate it from one of TNT. These include (1) the large volume of the cloud, (2) the lower overpressure at the explosion centre, (3) the different initial shape of the blast wave, and (4) the longer duration time of the blast wave.

A discussion of these characteristics has been given by Baxen and Baker (1991) and in the *Second Report* of the ACMH (Harvey, 1979b). The report gives the following estimate for the size of the vapour cloud in the Flixborough explosion:

Flixborough 0.5×10^6 m^3

St Paul's Cathedral (internal volume) 0.2×10^6 m^3

The overpressure at the explosion centre of a vapour cloud is much less than at that of a TNT explosion. The report suggests that a theoretical upper limit might be calculated related to the pressure which would be achieved if the equivalent mass of TNT after detonation were confined within particular boundaries under adiabatic conditions. For a TNT explosion the boundaries would be those of the TNT charge and the pressure developed would be about 0.5 million bar. For a VCE the boundaries would be those of the cloud and the pressure developed would be about 8 bar. In both cases the practical upper limit of overpressure would be some fraction of the theoretical maximum value, particularly for a vapour cloud. The report suggests that on the basis of the rather meagre data available the practical upper limit is probably about 1 bar at the centre and about 0.7 bar at the boundary of the cloud.

The overpressure at the explosion centre at Flixborough may have been about these values, as discussed in Appendix 2.

In a VCE the shape of the initial blast wave is different from that in a TNT explosion. But it is frequently assumed that after the blast wave has travelled a certain distance it becomes indistinguishable in form from the wave of a TNT explosion. In other words, it assumes the shape shown in Figure 17.57.

The shape of the overpressure profile according to the TNT equivalent model and to some possible models of VCEs is shown in Figure 17.72.

The apparent TNT equivalence of a VCE changes with distance. In the far field the quantity of TNT required to obtain a fit for the overpressure tends to be appreciably higher than in the near field.

The blast wave from a VCE also differs from that of a TNT explosion in duration time. The duration time of a VCE is generally considered to be appreciably longer than that of the equivalent TNT explosion.

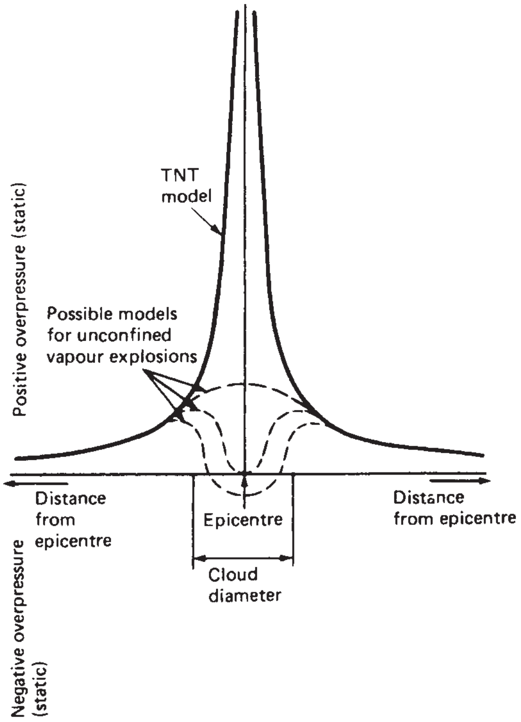

Figure 17.72 *Overpressures given by the TNT equivalent model and by some possible models of vapour cloud explosion (V.C. Marshall, 1976c) (Courtesy of the American Institute of Chemical Engineers)*

Thus, TNT gives a 'hard' explosion with high overpressure and short duration time, whilst a vapour cloud gives a 'soft' explosion with low overpressure and long duration time. The lower overpressure reduces the relative destructiveness but the longer duration time increases it.

There is, however, little information on the duration time for VCEs. This is a serious deficiency, because a knowledge of duration time is needed for the design of works buildings.

The *Second Report* of the ACMH suggests, in the context of the design of works buildings and in conjunction with the assumed overpressure of 1 bar at the cloud centre, that a duration time of 30 ms be provisionally assumed.

17.28.9 TNT equivalent models: influencing factors and special features

Some of the various TNT equivalent models developed tend to emphasize a particular influence on or feature of VCEs. These include (1) the reactivity of the fuel, (2) the effect of cloud size, (3) the effect of obstructions, (4) the variation of TNT equivalence with distance, and (5) the peak overpressure at the edge of the cloud. The treatments of these factors are of value quite apart from their use in the particular models.

For the reactivity of the fuel, the FMRC (1990) has developed the following classification, based on the work of D.J. Lewis (1980d):

Class		*TNT equivalence* (%)
I	Relatively unreactive materials (e.g. propane, butane and ordinary flammable materials)	5
II	Moderately reactive materials (e.g. ethylene, diethyl ether, acrolein)	10
III	Highly reactive materials (e.g. acetylene)	15

In the method given by Prugh (1987a) the effect of cloud size is taken into account by making the yield of the explosion a function of the mass of fuel in the cloud.

Two different approaches to the effect of obstructions are used in the methods of Exxon (n.d.) and R.J. Harris and Wickens (1989). In the Exxon method a distinction is made between a cloud in the open and one in partially obstructed terrain. In that of Harris and Wickens the mass participating in the explosion is limited to that in the part of the cloud in the obstructed area.

The variation of TNT equivalence with distance is taken into account by Prugh (1987a) by the use of a virtual distance method in which the virtual distance is a function of the mass of fuel involved in the explosion. The effective distance is then the sum of the virtual distance correction and the actual distance; by this expedient he obtains a single curve to fit the far field overpressures and approximate those in the near field.

The concept of virtual distance is also utilized by R.J. Harris and Wickens (1989), but in this case to obtain a match for the peak overpressure at the edge of the cloud.

All these approaches have something to offer, but there does not appear to be any single method which incorporates them all.

17.28.10 TNT equivalent models: Brasie and Simpson model

The basic TNT equivalent model was stated in a classic paper by Brasie and Simpson (1968). Their expression for the TNT equivalent is now generally written in the form

$$W_{\mathrm{TNT}} = \alpha \frac{W \Delta H_c}{E_{\mathrm{TNT}}} \qquad [17.28.6]$$

where E_{TNT} is the energy of explosion of TNT (kJ/kg), ΔH_c is the heat of combustion of the hydrocarbon (kJ/kg), W is the mass of hydrocarbon (kg), W_{TNT} is the equivalent mass of TNT (kg) and α is the yield factor.

Brasie and Simpson noted that the values quoted for the energy of explosion of TNT varied between 1800 BTU/lb (4190 kJ/kg) and 2000 BTU/lb (4650 kJ/ kg), and adopted the latter.

From analysis of three VCE incidents they obtained values of the yield factor of 0.03–0.04, and on this basis proposed for use tentative values, intended to be conservative, of 0.02 in the near field and 0.05 in the far field, taken as that where the peak overpressure is 1 psi or less.

Brasie and Simpson also gave a graph and a table of damage vs peak overpressure, and made proposals for damage estimation.

17.28.11 TNT equivalent models: ACMH model

The *Second Report* of the ACMH (Harvey, 1979b) discusses the problem of VCEs. In particular, it gives an equation for the cloud size, a suggested value for the explosion efficiency and an overpressure curve based on the TNT equivalent model. This information taken as a whole may be regarded as a form of model.

The relation for cloud size was quoted as equation 15.46.47, and the suggested value of the yield was given as 0.03, as described in Section 17.27.7. The curve for peak overpressure is reproduced in Figure 17.73. The curve utilizes a damage classification based on bomb damage to dwelling houses in the Second World War. The classes given in the report as most relevant are:

Damage classification	*Damage*
A	Almost complete demolition
B	So severe as to necessitate demolition
Cb	House uninhabitable but not totally irreparable

'Glass damage' is expressed as the percentage of windows broken.

17.28.12 TNT equivalent models: Harris and Wickens model

The experimental work of R.J. Harris and Wickens (1989) has been described in Section 17.28.3. These authors also present a model of the TNT equivalent type. In the Harris and Wickens model, the mass of gas participating in the VCE is restricted to the confined and congested part of the plant, and that in the unconfined part of the cloud is neglected. The yield on this more limited mass is taken as 0.20. The energy of explosion of TNT is taken as 4.6 MJ/kg and the heat of combustion of the hydrocarbon as 46 MJ/kg, a difference of a factor of 10. Then, from the relation

$$M_{\mathrm{TNT}} = \alpha \frac{M_{\mathrm{gas}} E_{\mathrm{gas}}}{E_{\mathrm{TNT}}} \qquad [17.28.7]$$

the authors obtain

$$M_{\mathrm{TNT}} = 2 M_{\mathrm{gas}} \qquad [17.28.8]$$

where E_{gas} is the heat of combustion of the hydrocarbon (MJ/kg), E_{TNT} is the energy of explosion of TNT (MJ/kg), M_{gas} is the mass of gas (in the confined/congested region) (te), M_{TNT} is the mass of TNT (te) and α is the yield factor. Equation (17.28.8) is obtained from Equation 17.28.7 with $E_{\mathrm{gas}} / E_{\mathrm{TNT}} = 10$ and $\alpha = 0.20$. Then, taking for the density for the hydrocarbon–air mixture a low value of 0.08 kg/m^3 (normal densities at 20 C are around 1.3 kg/m^3), yields from Equation 17.28.8

$$M_{\mathrm{TNT}} = 16 \times 10^{-5} V \qquad [17.28.9]$$

where V is the volume of gas (in the confined/congested region) (m^3).

The blast correlation used is that of the ACMH as given in Figure 17.73 (TNT curve).

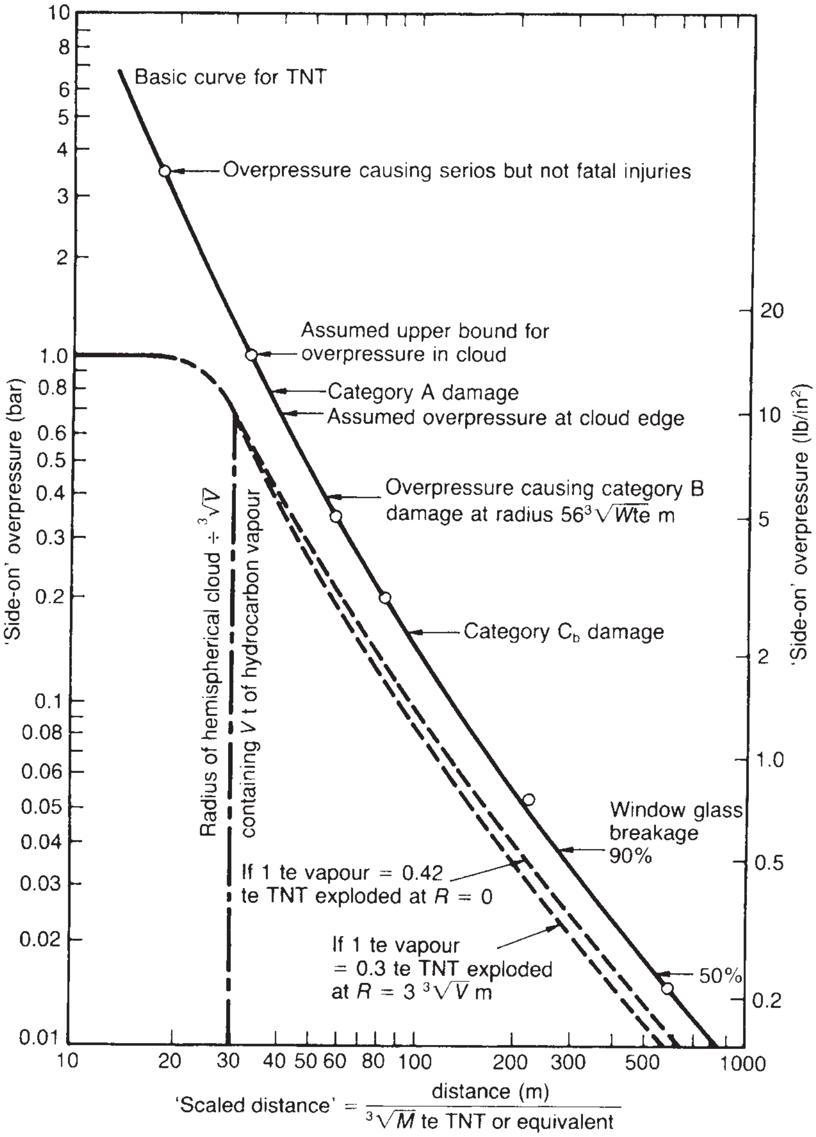

***Figure 17.73** Peak side-on overpressure for a vapour cloud explosion: ACMH correlation (Harvey, 1979b) (Reproduced by permission of HM Stationery Office. Copyright. All rights reserved)*

As already described, these authors obtained for the peak overpressure at the edge of the vapour cloud a value of 4 bar, rather than the value of 1 bar proposed by the ACMH. They take this finding into account by determining the scaled distance for an overpressure of 4 bar on the ACMH graph, which is 16 (m/te$^{1/3}$) and proposing the use of an effective scaled distance of

$$16 + \frac{R}{(M_{\mathrm{TNT}})^{1/3}} \qquad [17.28.10]$$

where R is the actual distance (m). This is effectively a virtual source correction.

17.28.13 TNT equivalent models: other models

In addition to those just described, several other TNT equivalent models for VCEs have been developed, published or unpublished. They include those of Exxon (n.d.), Eichler and Napadensky (1977), Prugh (1987a), the FMRC (1990) and IRI (1990). These are reviewed by the CCPS (1994/15).

As already indicated, such models tend to differ in the methods used for (1) the mass of vapour participating in the explosion and (2) the yield factor of the explosion. Other differences relate to (3) the value used for the energy of explosion of TNT and (4) the correlation used for the peak overpressure of TNT.

Several of these models include a procedure for estimating the mass of flammable vapour which participates in the explosion. This aspect of the models is considered in Chapter 15.

The other main distinguishing feature of the models is in the estimation of the yield factor. This is considered in the next section.

The CCPS states that values used for the explosion energy of TNT lie in the range 4140–4650 kJ/kg, the same as that considered by Brasie and Simpson.

The blast correlations used in the models are given in Section 17.28.15.

The methods described are coherent procedures considered by their authors to give reasonable results. It is not appropriate to abstract particular features and use them indiscriminately. Each model is a 'package deal'.

It should also be borne in mind that models are developed for different purposes. The majority are essentially guides to the plant designer, particularly in relation to plant layout and control room design. Care should be exercised in applying such a model to hazard assessment or incident investigation.

17.28.14 TNT equivalent models: yield factor

The values used in the models mentioned for the yield factor are

Method	*Scenario/comment*	*Yield factor*
Brasie and Simpson	Near field	0.02
	Far field	0.05
ACMH		0.03
Exxon	Open terrain	0.03
	Partially confined and obstructed terrain	0.10
Eichler and Napadensky		0.02–0.40
Prugh	Mass of vapour cloud = 100 kg	0.02
	Mass of vapour cloud = 10^6 kg	0.70
Harris and Wickens	Mass in obstructed region only	0.20
FMRC	Relative non-reactive material	0.05
	Moderately reactive material	0.10
	Highly reactive material	0.15
IRI		0.02

The model of Eichler and Napadensky is for safe separation distances between nuclear power plants and transport routes and refers to the far field (peak overpressure 1 psi (0.07 bar)) and is evidently conservative. The higher of the two values given by Prugh refers to a very large cloud.

17.28.15 TNT equivalent models: blast correlation

The graphical correlations used for the peak overpressure from a TNT explosion are principally the following: Glasstone (1962) (Brasie and Simpson) and Glasstone and Dolan (1980) (IRI); V.C. Marshall (1976c) (ACMH); ACMH (Harris and Wickens); Kingery and Panill surface bursts (1964) (Exxon); and the US Army, Navy and Air Force (1990) (the Tri-Service Manual) (FMRC).

The ACMH correlation is based on that of V.C. Marshall (1976c). This has been reproduced in the literature with different scaled distances. In the ACMH graph the mass used in the scaled distance is in tonnes, in the graph given by the CCPS (1994/15) the mass is explicitly stated to be in kilograms.

17.28.16 TNT equivalent models: yield ratio

For completeness in the treatment of the TNT equivalent model, it is convenient to deal at this point with the question of the yield ratio, or symmetry factor.

As explained earlier, if a free-air burst correlation is used for the blast parameters, but the application is to a ground burst, an appropriate yield ratio is applied to the actual energy of explosion, or equivalent mass of TNT, to obtain an effective energy, or mass, for use in calculation of the scaled distance.

The simple, and conservative, approach is to take this yield ratio as 2.

The value of the yield ratio is discussed by the CCPS (1994/15). It suggests that the value of the yield ratio will generally lie in the range 1.7–2. The lower value may be preferred if the epicentre of the explosion is slightly above the ground.

17.28.17 Taylor model

An early model of a VCE was given in a classic paper by G.I. Taylor (1946). He considers small pressure disturbances, as in acoustics, so that the system equations can be linearized. The treatment which he describes is in terms of an expanding piston for which from the conservation equations in spherical geometry he obtains the wave equation

$$r^2 \frac{\partial^2 \phi}{\partial t^2} = a_o^2 \left[\frac{\partial}{\partial r} \left(r^2 \frac{\partial \phi}{\partial r} \right) \right] \qquad [17.28.11]$$

with the velocity potential ϕ such that

$$u = \frac{\partial \phi}{\partial r} \qquad [17.28.12]$$

$$p - p_o = -\rho_o \frac{\partial \phi}{\partial t} \qquad [17.28.13]$$

where a_o is the speed of sound, p is the absolute pressure, p_o is the ambient pressure, r is the radial distance, t is the time, u is the velocity, ρ_o is the density of the ambient gas and ϕ is the velocity potential. The term $(p - p_o)$ is thus the overpressure.

The boundary condition used is such that the velocity of the medium is equal to that of the piston. From this Taylor obtains the velocity potential as

$$\phi = a_o \frac{M_p^3}{1 - M_p^2} \frac{(r - a_o t)^2}{r} \qquad [17.28.14]$$

and hence

$$\bar{p} = 2\gamma \frac{M_p^3}{1 - M_p^2} \left(\frac{a_o}{r} - 1 \right) \qquad [17.28.15]$$

with

$$\bar{p} = \frac{p - p_o}{p_o} \qquad [17.28.16]$$

where M_p is the Mach number of the piston, $\bar{p}$ is the dimensionless overpressure and γ is the ratio of the specific heats.

Equating the mass within the piston flow field and that within the flame flow field yields the following relation between the piston and flame Mach numbers:

$$M_p^3 = M_f^3\left(\frac{\alpha - 1}{\alpha}\right) \qquad [17.28.17]$$

where M_f is the flame Mach number and α is the expansion ratio.

17.28.18 Strehlow model

The VCE model given by Strehlow (1981) also follows the acoustic approach, but utilizes a constant velocity piston.

It was shown by Stokes (1849) that a source of mass with mass flow $\dot{m}(t)$ generates a sound wave in three dimensions which has an overpressure that is proportional to the mass addition acceleration $\ddot{m}(t)$. Lighthill (1978) gave this concept the specific formulation

$$p - p_o = \frac{\ddot{m}(t - r/a_o)}{4\pi r} \qquad [17.28.18]$$

where a_o is the velocity of sound, p is the absolute overpressure, p_o is the ambient pressure and r is the characteristic radius of the source region. Here, $\ddot{m}(t)$ is replaced by $\ddot{m}\,(t - r/a_o)$ because the wave is propagating away from the source at the velocity of sound.

Then, for deflagrative combustion the effective rate of volume addition $\dot{v}(t)$is related to that of mass addition $\ddot{m}(t)$:

$$\ddot{m}(t) = \rho_o \dot{V}(t) \qquad [17.28.19]$$

where ρ_o is the initial density of the gas.

The acceleration of volume addition can be expressed in terms of the rate of change of the flame surface. Hence

$$\ddot{m}(t) = \gamma\rho_o\left(\frac{V_b - V_u}{V_u}\frac{d}{dt}[S_u(t)A_f(t)]\right) \qquad [17.28.20]$$

where A_f is the effective frontal area of the flame, S_u is the burning velocity, V_b is the specific volume of the burned gas and V_u the specific volume of the unburned gas.

Then, from the expression for the velocity of sound in an ideal gas $a_o^2 = p_o/p_o$ and from Equations 17.28.18 and 17.28.20

$$\bar{p} = \frac{\hat{q}}{4\pi r a_o^2 \gamma}\frac{d[S_u(t)A_f(t)]}{dt} \qquad [17.28.21]$$

with

$$\hat{q} = \gamma\frac{V_b - V_u}{V_u} \qquad [17.28.22]$$

where $\bar{p}$ is the dimensionless overpressure, $\hat{q}$ is the dimensionless rate of energy addition and γ is the ratio of specific heats.

For a constant velocity flame, Equation 17.28.21 reduces to

$$\bar{p} = \frac{\hat{q}}{4\pi r a_o^2 \gamma} S_u \frac{dA_f(t)}{dt} \qquad [17.28.23]$$

Then, for spherical geometry, utilizing in Equation 17.28.23 the relations for the area, radius and velocity of the flame front

$$A_f = 4\pi r_f^2 \qquad [17.28.24]$$

$$\frac{dr_f}{dt} = S_b = u_f \qquad [17.28.25]$$

$$S_b = S_u\frac{V_b}{V_u} \qquad [17.28.26]$$

and the definition of $\hat{q}$, applying the constant velocity flame relation

$$r_f = S_b t \qquad [17.28.27]$$

and substituting for t the term $(t - r/a_o)$, yields

$$\bar{p} = 2\gamma\left(1 - \frac{V_u}{V_b}\right)\left(\frac{V_b}{V_u}\right)^2 M_{su}^3\left(\frac{a_o t}{r} - 1\right) \qquad [17.28.28]$$

where M_{su} is the Mach number in the unburned gas.

The relation between this model and that of Taylor at low flame speeds may be demonstrated as follows. Using Taylor's relation between the flame and piston Mach numbers, Equation 17.28.17, and the relations

$$\alpha = V_b/V_u \qquad [17.28.29]$$

$$M_f = M_{su}\frac{V_b}{V_u} \qquad [17.28.30]$$

where u_f is the velocity of the flame front. If $M_p \ll 1$ or for low values of the flame Mach number M_f, the denominator in Equation 17.28.15 is approximately unity and Equation 17.28.28 is equivalent to Equation 17.28.15.

Equation (17.28.23) is a general relation which may be applied to vapour clouds of different geometries. The different cases may be examined by substituting different expressions for A_f and hence dA_f/dt. For spherical geometry utilizing for A_f Equation 17.28.24 gives

$$\bar{p} = \frac{2\hat{p}S_u^2 r_f}{r a_o^2}\frac{V_b}{V_u}, \quad r \geq r_f \qquad [17.28.31]$$

Using alternative expressions for the flame area A_f and the rate of change of the flame radius dr_f/dt, Strehlow obtains expressions for the overpressure in explosions of vapour clouds of other geometries and other points of ignition. These include an ellipsoid, a cigar-shaped cloud with end point ignition and pancake clouds with centre and with edge ignition. Thus, for a pancake cloud

$$A_f = 2\pi r_f H \qquad [17.28.32]$$

where H is the height of the cloud. Then

$$\bar{p} = \frac{\hat{q}S_u^2 H V_b}{2a_o^2 r_{obs} V_u} \qquad [17.28.33]$$

where r_{obs} is the distance of the observer from the centre of the cloud.

Strehlow also obtains an order of magnitude estimate of the effect of cloud size. For an overpressure of 0.1 bar at a

***Table 17.35** Strehlow model for VCE: effect of burning velocity and flame area (after Strehlow, 1981) (Courtesy of American Institute of Chemical Engineers)*

A $dS_u/dt = 0$

S_u (m/s)	dA_f/dt (m^2/s)
1	1.7×10^7
10	1.7×10^6
100	1.7×10^5

B $dA_f/dt = 0$

A_f (m^2)	dS_u/dt (m/s^2)
10^2	1.7×10^5
10^4	1.7×10^3
10^6	1.7

distance 100 m from the cloud centre and with a velocity of sound of 350 m/s Equation 17.28.21 reduces to

$$A_f \frac{dS_u}{dt} + S_u \frac{dA_f}{dt} = 1.6 \times 10^7 \text{m}^3/\text{s}^2 \qquad [17.28.34]$$

Then, the use of the alternative limiting assumptions $dS_u/dt = 0$ and $dA_f/dt = 0$ allows values of dA_f/dt and dS_u/dt, respectively, to be calculated. Table 17.35 shows the values given by Strehlow. The table shows that even for a high flame velocity the rate of increase of flame area must also be very high to generate even a weak blast wave, while only a very large flame area, with a very large acceleration, is able to produce a weak blast wave. He concludes that for a significant overpressure to be generated by deflagrative combustion alone a very large cloud is required.

Further development of this approach for clouds of different aspect ratios has been described by Raju and Strehlow (1984).

17.28.19 Model of Kuhl, Kamel and Oppenheim

In another classic paper, Kuhl, Kamel and Oppenheim (1973) presented an 'exact' similarity solution for the conservation equations which they give in the form

$$\frac{F}{2Z}\frac{dF}{dZ} = \frac{Z - (1-F)^2 + (\gamma - 1)(1-F)F}{3Z - (1-F)^2} \qquad [17.28.35]$$

$$\frac{F}{X}\frac{dX}{dF} = \frac{-Z + (1-F)^2}{3Z - (1-F)^2} \qquad [17.28.36]$$

with

$$F = \frac{u}{U_s X} \qquad [17.28.37]$$

$$Z = \left(\frac{a}{U_s X}\right)^2 \qquad [17.28.38]$$

$$X = \frac{r}{r_s} \qquad [17.28.39]$$

where a is the speed of sound, r is the radial distance, r_s is the radial distance of the leading shock, u is the particle velocity and U_s is the velocity of the leading shock.

Their model is based on a constant velocity piston. The leading shock travels ahead of the piston with the flame front in between.

In the form given, the model has to be solved numerically.

The authors explored the implication of their model for flame speeds ranging from 0.5 to 120 m/s. The maximum overpressure ratio obtained was 6, with flame speeds of 5–10 m/s being associated with overpressure ratios of the order of 0.05–0.10. They give a set of curves showing the strong increase of overpressure with flame speed.

17.28.20 Williams model

A number of workers have obtained approximate analytical solutions of the constant velocity piston case based on self-similarity. The model of F.A. Williams (1976), also discussed by Anthony (1977a), is illustrative of this approach.

In the model it is assumed that ignition occurs at a point source, that the flame front which develops travels out from the 'core' at a flame speed S and that the pressure waves produced by the flame generate a weak shock which travels ahead of the flame at a velocity $V(t)$ which varies with time. It is also assumed that the pressure and density in the 'shell' between the flame and shock fronts are constant.

Then, for spherical symmetry the model equation for conservation of momentum across the shock wave is

$$p_1 - p_o = \rho_o \left(\frac{dR}{dt}\right)^2 \left(1 - \frac{\rho_o}{\rho_i}\right) \qquad [17.28.40]$$

or in dimensionless form

$$p = 1 + (1 - K)\left(\frac{dy^2}{d\tau}\right) \qquad [17.28.41]$$

The other basic equations, also in dimensionless form, are for conservation of mass for a sphere of radius R,

$$\theta p x^3 + \frac{(y^3 - x^3)}{K} = y^3 \qquad [17.28.42]$$

and for conservation of mass for the burned core,

$$\frac{x^2 s}{K} = \frac{d}{d\tau}(\theta p x^3/3) \qquad [17.28.43]$$

The similarity solution is

$$s = \frac{Kq\theta p(p-1)^{1/2}}{(1 - K\theta P)^{1/3}(1-K)^{1/6}} \qquad [17.28.44]$$

with

$$p = p_1/p_o \qquad [17.28.45a]$$

$$s = S/a_o \qquad [17.28.45b]$$

$$x = r/R_o \qquad [17.28.46a]$$

$$y = R/R_o \qquad [17.28.46b]$$

$$\theta = T_o/T_2 \qquad [17.28.47a]$$

$$K = r_o/r_1 \qquad [17.28.47b]$$

$$\tau = a_o t/R_o \qquad [17.28.47c]$$

where a_o is the speed of sound $(=(p_o/\rho_o)^{1/2})$, p_i is the absolute pressure in region i, r is the flame radius, R is the shock radius, R_o is the initial value of the shock radius, S is the flame speed, t is the time, T_i is the absolute temperature in region i, ρ_i is the gas density in region i and τ is the dimensionless time. The subscripts o, 1, 2 of p, T and ρ refer, respectively, to conditions in the undisturbed gas, the shocked gas (shell) and the burnt gas (core). The variables K, θ and p are time dependent.

The model yields a number of interesting results. One is that from Equation 17.28.40 the shock wave pressure has a well-defined upper limit. Another is that for transition to detonation the flame speed must be an appreciable fraction of the speed of sound:

$$s > (K/3)[(p-1)(1-K)]^{1/2} \qquad [17.28.48]$$

17.28.21 Other similarity models

The model just described is one a number of approximate analytical models.

A review of this work is given by the CCPS (1994/15), which presents for some of the models a set of graphs of the flow field parameters, in each of which the curves of particular workers are compared with those of the 'exact' solution.

17.28.22 Gugan model

In his review of VCEs, Gugan (1979) includes a model based on self-similarity which he uses to examine the characteristics of such explosions. This model is not in the mainstream of VCE models, but constitutes an interesting approach, particularly to behaviour in the near field.

The blast wave from a VCE is inherently unstable, and at a point quite close to the centre of the explosion it transforms into a shock wave. Beyond this transformation point, in the far field, no distinction can be made between a condensed phase explosion and a VCE on the basis of the shock wave. But between the explosion centre and the transformation point, in the near field, some interesting features emerge.

Gugan uses the following relation for the pressure profile:

$$p = \frac{p_c t}{2}\left[1 + \cos\left(\frac{\pi r}{at}\right)\right], \quad 0 < r \le at \qquad [17.28.49]$$

where a is the velocity of sound in the normal atmosphere, p is the pressure, p_c is the pressure at the centre of the explosion, r is the distance from the centre of the blast symmetry and t is the time. The term $p_c t$ is therefore the pressure at the centre of the explosion. The form of curve given by this equation is the 'companion to the cycloid'.

Utilizing the relations for the energy E contained in the compressed gases $E = \int V\,\mathrm{d}p$ and for the relation between the pressure p and the volume V for an isentropic expansion $\int V\,\mathrm{d}p = \gamma \int V\,\mathrm{d}p$ (where γ is the ratio of the gas specific heats) together with Equation 17.28.49, Gugan obtains for the pressure at the centre of the explosion

$$\dot{p}_c t = \frac{E_o}{0.57(at_o)^3} \qquad [17.28.50]$$

where E_o is the total energy release and t_o is the time of termination of the rapid energy release. Equation 17.28.50, and alternative relations derived by the author, provide the value of the term $p_c t$ in Equation 17.28.49 and allow estimates to be made of the pressure profile.

The author compares the relation which he derives for the pressure profile from a VCE with that from a condensed phase explosion. These relations indicate that for the same energies and distances, the amplitude of the shock wave from a condensed phase explosion exceeds that from a VCE by one or two orders of magnitude. Yet the shock waves from VCEs are very destructive. He concludes that this is due to the longer duration time of the positive phase in VCEs and suggests that the factor of 2, which is sometimes given for the ratio of the duration time in a VCE to that in a condensed phase explosion, is probably an underestimate.

Gugan defines an explosion efficiency 77:

$$\eta = E_e/E_u \qquad [17.28.51]$$

where E_e is the explosive energy release and E_u is the vapour cloud energy release. For the latter

$$E_u = m\Delta H_c \qquad [17.28.52]$$

where ΔH_c is the heat of combustion and m is the mass of fuel in the cloud. He obtains for the explosion efficiency expressions of the general form

$$\eta = \frac{f(m; \Delta H_c; M; \epsilon; v)}{f(R)} \qquad [17.28.53]$$

where M is the molecular weight of the vapour, n is the stoichiometric ratio and v is the flame speed.

The expression for the explosion efficiency shows the efficiency as a function of various characteristics of the fuel. In the near field it falls off rapidly with distance R, being inversely proportional to R^3.

This model proved controversial and was criticized by Ale and Bruning (1980). One feature is the decay of efficiency, which did not appear to sit well with the effects of actual explosions. A review has been given by H. Phillips (1981b).

17.28.23 Baker–Strehlow model

Strehlow, Luckritz and co-workers conducted numerical studies, using the CLOUD code, exploring for spherical geometry the characteristics of flames travelling at constant velocity and with acceleration (Luckritz, 1977; Strehlow *et al.*, 1979) and obtained relationships for the blast wave parameters. This work was extended by W.E. Baker *et al.* (1983) to yield the Baker–Strehlow method for VCEs.

The scaled peak overpressure and the scaled impulse given by this method are shown in Figures 17.74 and Figure 17.75, respectively. The scaled variables are given by Equations 17.26.7–17.26.9. The graphs are for spherical symmetry.

Figures 17.74 utilizes two Mach numbers, M_w, which relates to fixed coordinates, and M_{su}, which is relative to the gases moving ahead of the flame front. The relationship between these two Mach numbers is discussed by Strehlow *et al.* (1979). At high Mach numbers $M_{su} \rightarrow M_w$. The solid lines in the figure represent numerical calculations, and the broken lines extensions of Taylor's model to the very low Mach number range. Also shown in the figure are curves

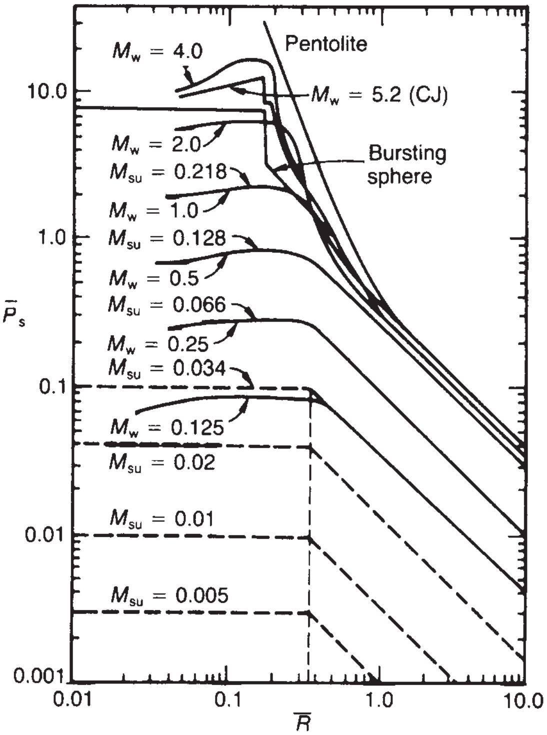

Figure 17.74 *Scaled peak side-on overpressure for a vapour cloud explosion (Strehlow et al., 1979). Curves and Mach numbers are explained in the text (Courtesy of the Combustion Institute)*

for pentolite, for a bursting sphere and for detonation (CJ curve).

The method requires values of the energy of explosion and the flame speed. The explosion energy may be determined using one of the methods described in Section 17.28.14 in relation to the TNT equivalent model. The flame speed is estimated by considering the effect of the combination of factors known to influence it: the reactivity of the fuel, the strength of the ignition source and the degree of confinement and congestion.

17.28.24 Wiekema model (TNO shock wave model)

Three models of VCE have been developed by TNO. The first of these is the shock wave model described in the Yellow Book and by Wiekema (1980). The model is also known as the expanding piston or piston blast model. It allows the peak overpressure and the duration time of the explosion to be estimated.

The model is a composite one derived from separate models for deflagration and detonation in the cloud. Considering first the model for deflagration, it has been shown by Strehlow, Savage and Vance (1973) that given the pressure–time profile it is possible to derive the energy of an explosion. Wiekema uses this result, inverting it to obtain the pressure–time profile from an arbitrary energy release.

The cloud is assumed to be a hemisphere of unburnt gas volume V_o which expands during the combustion process to a hemisphere volume V_1. In this process the energy added to the unburnt gas is assumed to be added by a hemispherical piston, this process effectively replacing the combustion process. This energy E_o is

$$E_o = \int_0^\infty p \frac{dV}{dt} dt \qquad [17.28.54a]$$

$$\approx p_o(V_1 - V_o) \qquad [17.28.54b]$$

$$= n_1 R_g T_1 - n_o R_g T_o \qquad [17.28.54c]$$

$$= p_o V_o \left[\frac{n_1 T_1}{n_o T_o} - 1 \right] \qquad [17.28.54d]$$

where E_o is the total energy of the explosion (J), n is the number of moles, p is the absolute pressure (Pa), R_g is the universal gas constant (J/mol K), T is the absolute temperature (K), V is the volume (m^3) and the subscripts o and 1 denote initial and final conditions, respectively. But

$$E_o = \frac{2}{3} \pi R_o^3 E_c \qquad [17.28.55]$$

where E_c is the energy of combustion per unit volume (J/m^3) and R_o is the radius of the initial cloud (m).

A characteristic explosion length L is defined as

$$L = \left(\frac{E_o}{P_o} \right)^{1/2} \qquad [17.28.56a]$$

$$= \left(\frac{2}{3} \pi R_o^3 \frac{E_c}{p_o} \right)^{1/3} \qquad [17.28.56b]$$

where L is the characteristic length (m), and a parameter λ as

$$\lambda = \frac{L}{t_b} \qquad [17.28.57]$$

where t_b is the time (s) at which the expansion process is incomplete. A reduced distance $\bar{R}$, reduced overpressure $\bar{P}$, reduced time t and reduced duration time $\bar{T}$ are then defined as follows :

$$\bar{R} = \frac{R}{L} \qquad [17.28.58]$$

$$\bar{P} = \frac{p - p_o}{p_o} \qquad [17.28.59]$$

$$\bar{t} = \frac{t}{t_b} \qquad [17.28.60]$$

$$\frac{\bar{T} = t_+ c_o}{L} \qquad [17.28.61]$$

where c_o is the local velocity of sound (m/s), R is the distance (m) and t_+ is the duration time (s).

The reduced overpressure is taken as inversely proportional to the reduced distance:

$$\bar{P} = \frac{A}{\bar{R}} \qquad [17.28.62a]$$

$$= \frac{AL}{R} \qquad [17.28.62b]$$

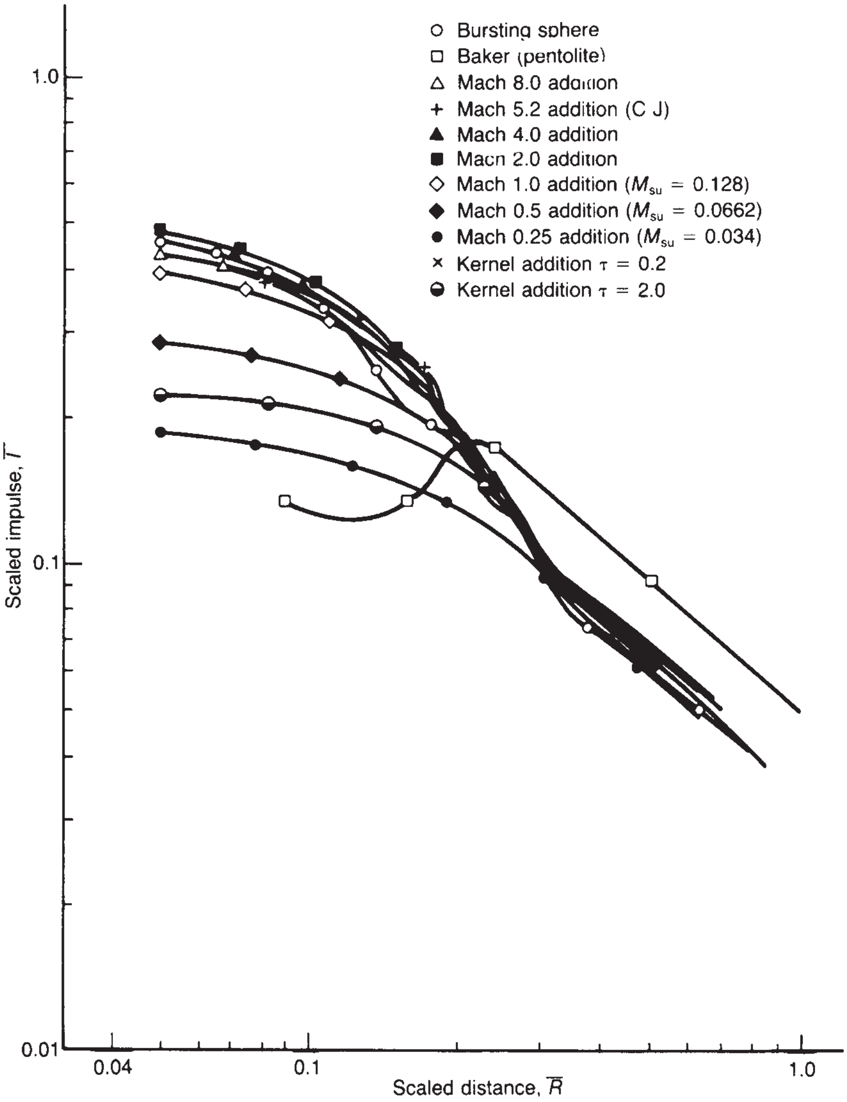

Figure 17.75 *Scaled side-on impulse for a vapour cloud explosion (Strehlow et al., 1979) (Courtesy of the Combustion Institute)*

where A is a constant. From shock wave theory

$$U_{\mathrm{sw}} = \frac{\mathrm{d}R}{\mathrm{d}t} \quad [17.28.63a]$$

$$= c_{\mathrm{o}}\left(1 + \frac{\gamma + 1}{4\gamma}\bar{P}\right) \quad [17.28.63b]$$

where U_{sw} is the velocity of the shock wave (m/s) and γ the ratio of specific heats for air. Taking $\gamma = 1.4$,

$$\frac{\mathrm{d}R}{\mathrm{d}t} = c_{\mathrm{o}}\left(1 + \frac{3}{7}\bar{P}\right) \quad [17.28.64a]$$

$$= c_{\mathrm{o}}\left(1 + \frac{3AL}{7R}\right) \quad [17.28.64b]$$

The duration time is determined as the difference between the arrival times of the shock wave and the sound wave and at the radius R_1 of the burnt cloud it is

$$t_+ = R_1\left(\frac{1}{\bar{v}_{\mathrm{fl}}} - \frac{1}{c_{\mathrm{o}}}\right) \quad [17.28.65]$$

where $\bar{v}_{\mathrm{fl}}$ is the average flame speed (m/s).

The velocities of the shock wave and sound wave in the cloud and beyond are shown in Figure 17.76.

Integrating Equation 17.28.64b gives

$$t_+ = R_1\left(\frac{1}{\bar{v}_{\mathrm{fl}}} - \frac{1}{c_{\mathrm{o}}}\right) + \frac{3}{7}A\frac{L}{c_{\mathrm{o}}}\ln\left(\frac{1 + 7R/3AL}{1 + 7R_1/3AL}\right), \quad R > R_1 \quad [17.28.66]$$

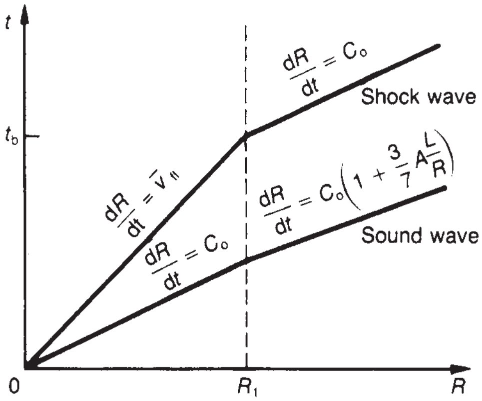

Figure 17.76 *TNO shock wave model for vapour cloud explosions: propagation of flame front and sound wave (Wiekema, 1980) (Courtesy of Elsevier Science Publishers)*

At the cloud boundary ($R = R_1$), Equation 17.28.66 reduces to Equation 17.28.65. The reduced duration time is then

$$\bar{T} = \frac{R_1}{L}\left(\frac{c_o}{\bar{v}_{fl}} - 1\right) + \frac{3}{7}A\ln\left(\frac{1 + 7R/3AL}{1 + 7R_1/3AL}\right), \quad R > R_1 \qquad [17.28.67a]$$

In evaluating Equation 17.28.67 use is made of the relation

$$R_1/L = 0.456 \qquad [17.28.67b]$$

derived from the definitions given in the work.

The following numerical values are assumed in the work:

$$\frac{n_1 T_1}{n_o T_o} = 7$$
$$E_c = 3.5 \times 10^6\ \text{J/m}^3$$

The energy added per unit volume, which is the energy available for shock wave formation, is 6×10^5 and is thus some 17% of the available combustion energy, assuming a stoichiometric mixture. The velocity of sound c_o in air may be taken as 330 m/s.

The method involves selecting an assumed flame speed. The set of flame speeds $\bar{v}_{fl}$ quoted are 40, 80 and 160 m/s, and the corresponding values of the parameter A are 2×10^{-2}, 6×10^{-2} and 15×10^{-2}, respectively.

The reduced overpressure $\bar{P}$ and reduced duration time $\bar{T}$ are both functions of the reduced distance $\bar{P}$, as shown in Figure 17.77.

As an illustration of the method, consider the estimation of the peak overpressure and duration time at a distance P of 500 m for a VCE in a hemispherical cloud of initial radius R_o of 100 m assuming an average flame speed of 80 m/s. Then, from Equation 17.28.56b

$$L = \left[\frac{2}{3}\pi(100)^3 + \frac{3.5 \times 10^6}{10^5}\right]^{1/3}$$
$$= 418\,\text{m}$$

Hence, from Equation 17.28.67a:

$$R_1 = 0.456L$$
$$= 0.456 \times 418$$
$$= 191\,\text{m}$$

From Equation 17.28.58

$$\bar{R} = 500/418$$
$$= 1.2$$

From Equation 17.28.62, taking the value of A corresponding to the average flame speed v_{fl} of 80 m/s,

$$\bar{P} = 6 \times 10^{-2}/1.2$$
$$= 0.05$$

Hence, from Equation 17.28.59 the peak overpressure $(p - p_o)$ for an initial pressure p_o of 10^5 Pa (1 bar) is

$$p - p_o = 0.05 \times 10^5\,\text{Pa} = 0.05\,\text{bar}$$

And from Equation 17.28.67a

$$\bar{T} = 0.456\left(\frac{330}{80} - 1\right) + \frac{3}{7} \times 6 \times 10^{-2}$$
$$\times \ln\left(\frac{1 + (7 \times 1.2)/(3 \times 6 \times 10^{-2})}{1 + (7 \times 0.456)/(3 \times 6 \times 10^{-2})}\right)$$
$$= 1.45$$

Hence, from Equation 17.28.61

$$t_+ = 1.45 \times 418/330$$
$$= 1.83\,\text{s}$$

The model just described is applicable to a deflagration. For the case of detonation in a vapour cloud Wiekema utilizes results obtained by Kogarko, Adushkin and Lyamin (1966), from which he obtains the following relations for the reduced overpressure and reduced duration time:

$$\bar{P} = 0.518\bar{R}^{-1.7}, \quad 0.29 < \bar{R} < 1.088 \qquad [17.28.68a]$$
$$= 0.2177\bar{R}^{-1}, \quad \bar{R} > 1.088 \qquad [17.28.68b]$$
$$\bar{T} = 0.1853\bar{R}^{1/2}, \quad 0.36 < \bar{R} < 12.6 \qquad [17.28.69a]$$
$$= 0.20 + 0.0933\ln(1 + 10.7\bar{R}), \quad \bar{R} > 12.6 \qquad [17.28.69b]$$

Since in the detonation work no results are given for $\bar{T}$ for $\bar{R} > 12.6$, Equation 17.28.69b is based on the deflagration work.

Wiekema then consolidates these two models, for deflagration and detonation in a vapour cloud, into a single VCE model. The reduced overpressure $\bar{P}$ and reduced duration time $\bar{T}$ are shown as functions of the reduced distance $\bar{R}$ in Figure 17.78.

The lines shown in Figure 17.78 are the boundaries of materials of low, medium and high reactivity. Reactivity is essentially sensitivity to flame acceleration. For each class the lower boundary is used unless there is reason to expect a relatively high flame acceleration.

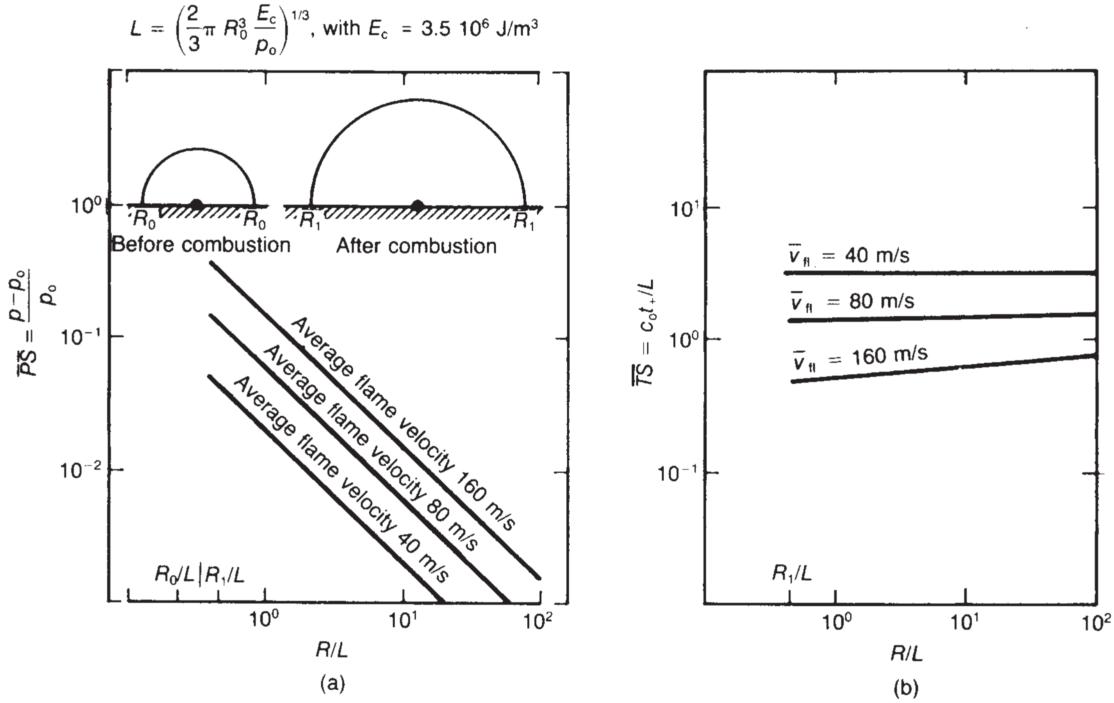

Figure 17.77 *TNO shock wave model for vapour cloud explosions – peak overpressure and duration of the blast wave, as a function of flame speed (Wiekema, 1980): (a) scaled peak overpressure and (b) scaled duration time (Courtesy of Elsevier Science Publishers)*

The reduced overpressure $\bar{P}$ is again inversely proportional to the reduced distance $\bar{R}$, except at the upper boundary for high reactivity materials. Wiekema states that methane is considered as a fuel of low reactivity, ethane and butane as fuels of medium reactivity and hydrogen, ethylene oxide and acetylene as fuels of high reactivity.

17.28.25 TNO correlation model

The second TNO VCE model is the correlation model; this too is described in the Yellow Book. The model allows an estimate to be made of the radius of defined damage circles. It does not give explosion parameters such peak overpressure or duration time.

The model is based on a correlation for VCE incidents of damage effects outside the gas cloud.

The correlation is based on the energy content E of the part of the cloud within the explosive range. This energy is

$$E = M_e \Delta H_c \qquad [17.28.70]$$

where E is the energy content of the part of the cloud within the flammable range (J), M_e is the mass of fuel in the cloud within the flammable range (kg) and ΔH_c is the heat of combustion (J/kg).

If the energy content $E < 5 \times 10^9$, corresponding to approximately 100 kg of hydrocarbon, the cloud is so small that no serious damage would be anticipated, while if $E > 5 \times 10^{12}$ the cloud is so large that no data are available on which to base a correlation. The model is applicable only to clouds with an energy content within those bounds.

The energy actually released is only a fraction η of the energy content E. This fraction, or efficiency, is the product of two separate efficiencies:

$$\eta = \eta_c \eta_m \qquad [17.28.71]$$

where η_c is a yield factor which takes account of the fact that the flammable part of the cloud is not a stoichiometric mixture and η_m is another yield factor which gives the mechanical energy yield of the combustion. The factor η_m is given different values, depending on whether combustion is at constant pressure or constant volume:

Constant pressure combustion $\eta_m = 0.18$
Constant volume combustion $\eta_m = 0.33$

Since combustion of a VCE tends to be associated with a degree of confinement, the constant volume value of η_m (= 0.33) is recommended. The relation for the radius of the damage circles is

$$R(S) = C(S)(\eta E)^{1/3} \qquad [17.28.72]$$

where $C(S)$ is a constant which is a function of the degree of damage S (m/J$^{1/3}$), E is the energy content (J), $R(S)$ is the radius of the damage circle (m) and η is the explosion efficiency.

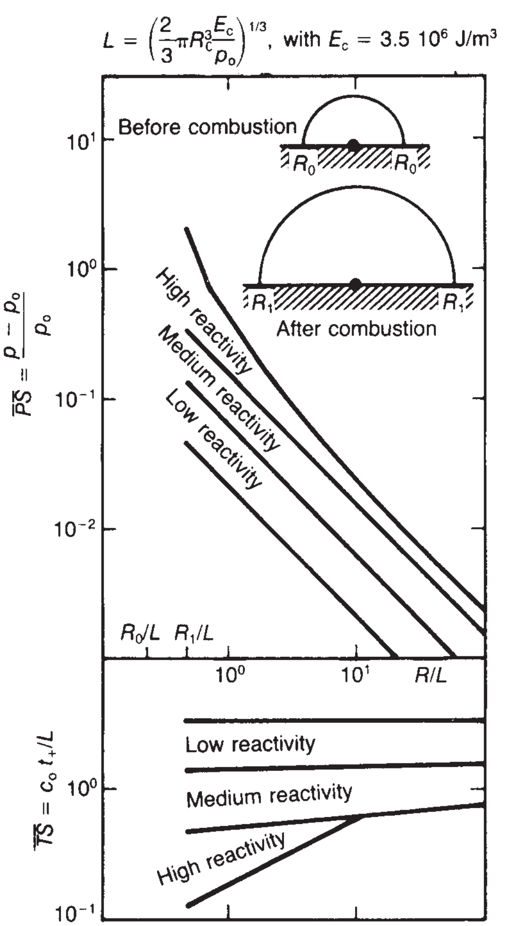

Figure 17.78 TNO shock wave model for vapour cloud explosions – peak overpressure and duration of the blast wave, as a function of fuel reactivity (Wiekema, 1980): (a) scaled peak overpressure and (b) scaled duration time (Courtesy of Elsevier Science Publishers)

The values of the constant C(S) are as follows:

Damage	*C(S)* (m/J$^{1/3}$)
Heavy damage to buildings and to processing equipment	0.03
Repairable damage to buildings and facade damage to dwellings	0.06
Glass damage causing injury	0.15
Glass damage (≈10% of panes)	0.4

17.28.26 van den Berg model (TNO multienergy model)

The third TNO VCE model is the ME model described by van den Berg (1985). This model allows the peak overpressure, peak dynamic pressure and duration time to be estimated.

The starting point for this model is recognition of the role of partial confinement in VCEs. It is assumed in the model that the explosion in those parts of the cloud which are confined is of much higher strength than in those where it is unconfined. The method involves estimating the combustion energy available in the various parts of the cloud and assigning to each part an initial strength.

This initial strength is denoted by a number in the range 1–10, where 1 applies to an explosion of insignificant strength and 10 to a detonation. Confined parts of the cloud are usually assigned a strength greater than 6 or 7.

The peak overpressure, peak dynamic pressure and duration time are estimated using Figure 17.79. For a given part of the cloud the energy of explosion in that part is determined, an initial strength is estimated and the blast parameters are then calculated.

The simplest case is that of a cloud with a single high strength source of reasonable size. The situation is more complex if this high strength source is small or if there are multiple high strength sources. Some judgement is required, therefore, in applying the method.

van den Berg gives as an illustration of the method the estimation of the peak overpressure and duration time of the VCE at Flixborough.

17.28.27 Numerical modelling

An alternative approach to the modelling of VCEs is the use of computational fluid dynamics (CFD) codes. An account of their application is given by the CCPS (1994/15).

The CFD modelling of VCEs is not entirely straightforward. There is a difficulty due to discontinuities, both contact discontinuity between the burned and unburned gases and shock discontinuity. For a blast flow field conventional numerical methods tend to yield inaccurate results.

In order to overcome these problems researchers have resorted to two devices. One is the use of artificial viscosity and the other the use of flux-corrected transport (FCT). The former was introduced by von Neumann and Richtmyer (1950) and the latter is described by Boris (1976) and Boris and Book (1976).

Both Eulerian and Langrangean formulations are used. The difference between these in their application to gas dispersion is touched on in Chapter 15 and discussed in standard texts (e.g. Meteorological Office, 1972).

Many workers have used the artificial viscosity method with the gas dynamics in Lagrangean form. They include Fishburn (1976), van den Berg (1984) and van Wingerden (1984 CEC EUR 9541 EN/II).

The use of artificial viscosity tends, however, to introduce some inaccuracy. Other workers have therefore used the FCT method with Eulerian gas dynamics. Amongst these are van den Berg (1980), with the BLAST code, and Guirao, Bach and Lee (1979) and H. Phillips (1980).

This work on numerical simulation of VCEs has produced a number of significant results. One concerns the fraction of the heat of combustion which is converted into blast energy, or mechanical work done on the surrounding gas/air, in other words, the yield factor of the explosion. In the work of Fishburn (1976) this fraction was found to be 38%. Guiraio, Bach and Lee (1979) performed a study in which they compared a volumetric fuel–air explosion and a fuel–air detonation, and confirmed the finding of Oppenheim *et al.* (1977) that the difference in the fraction of energy converted to blast is small.

Strehlow *et al.* (1979) made an extensive numerical study of the properties of a blast wave for constant velocity

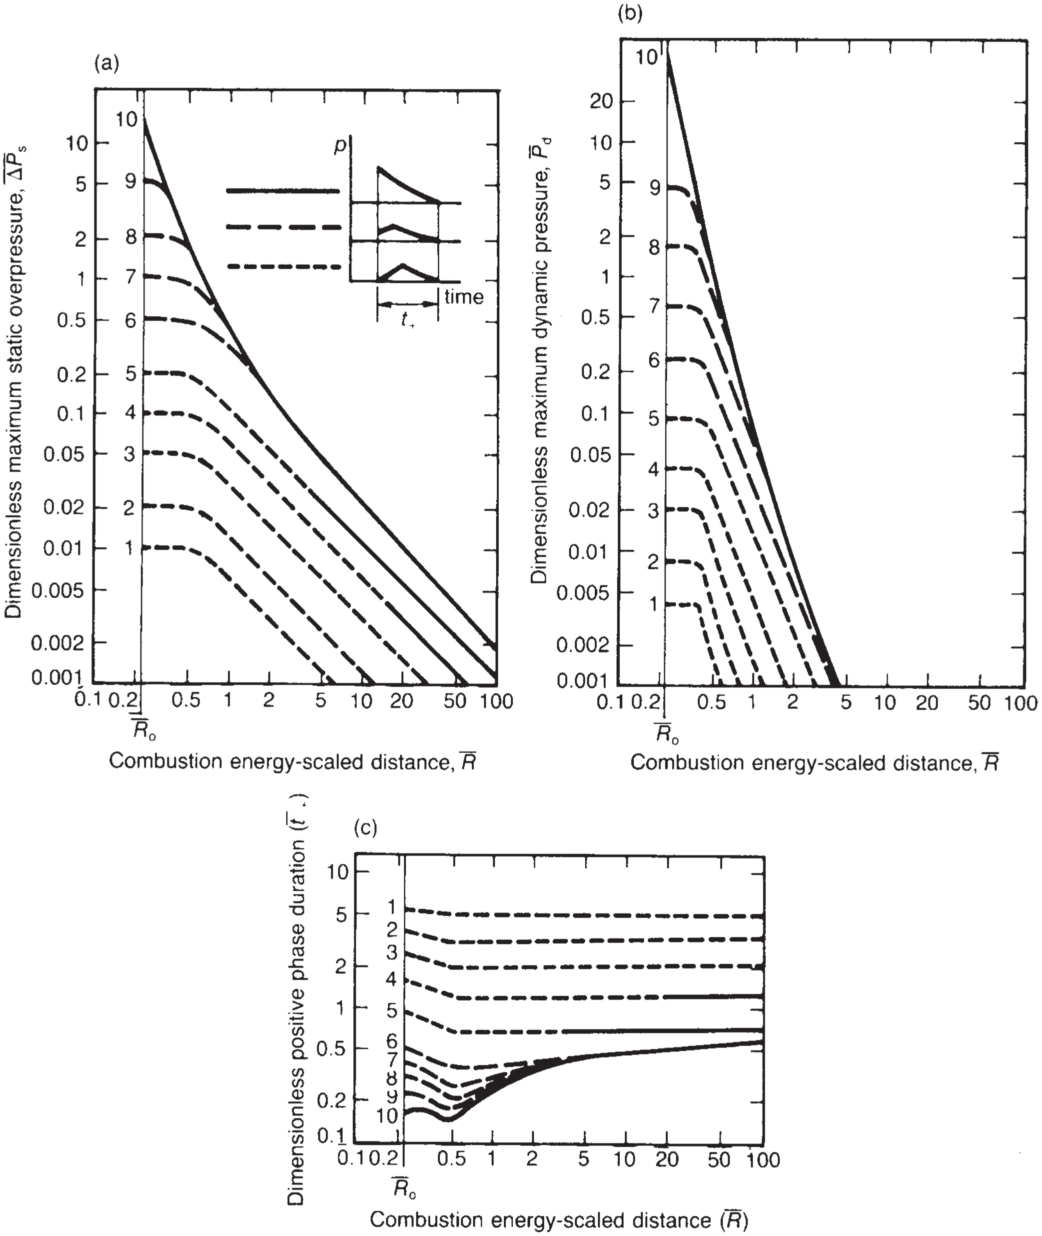

Figure 17.79 *TNO multienergy model for vapour cloud explosions (van den Berg, 1980): (a) peak overpressure; (b) dynamic pressure; and (c) duration.* C_o, *ambient velocity of sound; E, combustion energy;* P_d, *dynamic pressure;* P_o, *ambient pressure;* R_o, *fuel-air charge radius;* t_+, *duration time;* $\bar{P}_d$, P_d/P_o; $\Delta\bar{P}_s$, $\Delta P_s/P_o$; $\bar{R}$, $R(P_o/E)^{1/3}$. $\bar{t}_+$, $t_+C_o(P_o/E)^{1/3}$ *(Courtesy of Elsevier Science Publishers)*

flames over a wide range of flame speeds in spherical symmetry. They found that the calculated blast effects from the simulation, using as the constant flame speed the highest value observed, did not exceed the observed blast effects. This work was the basis of the Baker–Strehlow model, as already described.

The basic approach in this work has been to treat combustion as a fixed addition of energy at the particular flame speed. This does less than justice to the interaction of flow, combustion and turbulence and the associated positive feedback which occurs. The work of Hjertager (1982) advanced the art with a more fundamental treatment of transient compressible turbulent flow with reaction. It has given rise to two major CFD codes, FLACS and EXSIM.

An illustrative example of the use of the EXSIM code is given in Appendix F of the CCPS *Fire and Explosion Model Guidelines* (1994/15). The problem considered is combustion of a vapour cloud released amongst items of equipment on a plant in the open. The results include pressure vs time and flame speed vs distance profiles and contours of gas concentration, overpressure and wind velocity broadly similar to those shown in Plate 28.

Other codes include REAGAS, described by van den Berg (1989), Auto REAGAS, described by van den Berg (1995) and CLICHE, described by Catlin (1990).

17.28.28 Hydrogen explosions

Vapour clouds of hydrogen are somewhat unusual and need separate treatment. An account of hydrogen VCEs has been given by Bulkley and Jacobs (1966).

These authors describe a number of incidents in which hydrogen–air explosions have occurred. Of particular importance is an explosion which took place during the intentional release of hydrogen from Los Alamos Scientific Laboratory at Jackass Flats, Nevada, in 1964 and which has been described by Reider, Otway and Knight (1965). The incident was recorded by high speed photography. The discharge rate had been at a peak of 430,000 lb/h but had been cut back to 125,000 lb/h when spontaneous ignition occurred. The resulting explosion was estimated to have caused a pressure wave of 0.5 psi at buildings less than 200 ft way. From the photographs it was estimated that the cloud of hydrogen–air mixture which took part in the explosion was 30 ft in diameter and 150 ft high and contained 200 lb of hydrogen and that the flame speed reached 100 ft/s. The flame speed was thus considerably above the normal burning velocity but had not reached detonation velocity.

On the assumption that one-fifth of the heat released is converted to blast energy, Bulkley and Jacobs calculate that 1 lb of hydrogen can give a blast effect equivalent to 5 lb of TNT, provided detonation occurs.

They state, however, that if a detonation does not occur, then the results from the Jackass Flats incident indicate that the distances for a particular blast intensity calculated using this TNT equivalent are overestimated by a factor of about 4.

Hydrogen is frequently vented to the atmosphere. Bulkley and Jacobs present results of calculations on the flow rates which might give rise to 10 lb of hydrogen in the flammable range. They estimate that the detonation of 10 lb of hydrogen could cause severe structural damage at about 150 ft and moderate structural damage at about 300 ft. Assuming that the exit velocity is of the order of 1000 ft/s, calculations for free jets indicate that the inventory of hydrogen in the flammable range would be equivalent to 2–8 s of flow and that therefore the hydrogen flow should not exceed 4000–18,000 lb/h if excessive damage is to be avoided. The account of the Jackass Flats explosion by Reider, Otway and Knight mentions that the hydrogen is normally flared off if the release flow exceeds 3600 lb/h.

Emergency releases of hydrogen-rich streams of 50,000–150,000 lb/h are not uncommon.

Many releases are not pure hydrogen, but also contain hydrocarbons. The addition of hydrocarbons narrows the flammable range and reduces the burning velocity. It may also increase the volume of flammable mixture necessary for detonation. On the other hand, it also increases the molecular weight, which means that the jet maintains its integrity longer, so that the volume of flammable mixture is greater, and it increases the energy per unit volume. The overall result is uncertain, but Bulkley and Jacobs suggest that it is prudent to assume that a hydrogen-rich stream has the same hazard potential as one of pure hydrogen.

The authors discuss hydrogen venting, and suggest that emergency venting flows be reviewed and that if high vent flows may occur they should either be released directly to the atmosphere via multiple vents or should be flared.

Other incidents described include two disasters with hydrogen-filled dirigible airships. These are the disaster of the R-38 at Hull in 1921, in which there was an explosion, and that of the LZ-19, the Hindenbttrg, at Lakehurst, New Jersey, in 1937, in which the hydrogen burned with no overpressure. The fatalities in these two accidents were 44 and 36, respectively.

A method of estimating the peak overpressure from hydrogen explosions has been given by Hawksley (1986 LPB 68). The method is applicable to a typical, relatively small release. The two scenarios considered are a jet and a buoyant plume. The mass of fuel in the vapour cloud is determined using modifications of the equations given by J.G. Marshall (1980). The peak overpressure is then obtained from the TNT equivalent model using an explosion yield of 4%.

Hydrogen explosions are also discussed by V.C. Marshall (1987), who deals particularly with hydrogen-filled airships. He gives data showing the ultimate fate of some 129 airships. Of these, 41 (33.5%) caught fire or were set on fire by enemy action, 20 (15%) in flight and 21 (16%) in their sheds, whilst three (2.5%) exploded in flight.

17.28.29 Methane and LNG combustion

Large quantities of methane are handled as LNG, and the behaviour of methane and LNG vapour clouds is therefore of particular interest.

There is now considerable evidence that vapour clouds of methane at normal temperatures burn, but do not readily explode. Many experiments have been done in which attempts have been made to initiate explosions in methane clouds, but in which no explosion occurred.

The occurrence of VCEs involving methane has been reviewed by V.C. Marshall (1987). He cites expert opinion to the effect that there has been no case of an unconfined VCE with natural gas, but also the account given by Gugan (1979) of an explosion involving methane at Raunheim, West Germany, in 1966.

It may be noted that in the *First Canvey Report* (HSE, 1978b) it was conservatively assumed that a vapour cloud of LNG might explode.

17.28.30 Explosion yield limit

As already stated, in VCE work the fraction of the energy of combustion which is converted to blast energy is frequently expressed as a TNT equivalent.

The generally quoted limit for this fraction is about 40%. This is the value given, for example, by the CCPS (1994/15), which also refers to numerical simulation work in which the highest fraction obtained was 38%, as described above.

In his work on VCEs, Gugan (1979) gave equations and listed incidents for which the TNT equivalent was cited as above 50%. Ale and Bruning (1980) took issue with this on the basis that it violated the law of thermodynamics governing the conversion of energy into mechanical work. The matter was further considered by H. Phillips (1981b).

The difficulty appears to lie in the use of the TNT equivalent. In an investigation of an explosion incident the equivalent mass of TNT is obtained by examining the damage effects. It does not follow, however, that for a given level of damage the explosion energies in a TNT explosion and a VCE are the same. A TNT explosion involves a very high drop in overpressure in the near field and a shorter impulse. In other words, the energy released in a TNT explosion may be less effective in causing damage than that in a VCE.

Further, there are uncertainties in the peak overpressure for a TNT explosion and in the correlation of damage effect with peak overpressure. Phillips states that differences in blast correlations can introduce a factor of as much as an order of magnitude.

A VCE may therefore have an apparent TNT equivalent greater than 40% even if the actual fraction of the energy of combustion converted to blast energy does not exceed that value.

17.28.31 CCPS method

The *CCPS Fire and Explosion Guidelines* (1994/15) include a set of methods for VCEs. Both TNT equivalent and fuel–air models are given. For the TNT equivalent method use is made of Equation 17.28.6. The sample problem utilizes an energy of explosion of TNT of 4650 kJ/kg and a yield of 0.03. The fuel–air models used are the Baker–Strehlow model, the Wiekema expanding piston model and the van den Berg ME model.

The *Guidelines* give two sample problems, one a hazard assessment of a VCE at a storage site and the other an assessment of the overpressure at Flixborough. To each of these they apply both the TNT equivalent model and the ME model.

17.28.32 Plant design

The VCE hazard may be mitigated by plant design. Two aspects which have been considered particularly are limitation of the size of potential releases and the layout of plant to deal with the effects of any explosion.

For some plants handling flammable liquids the avoidance of large-bore pipes which could, if ruptured, give a large release has been a specific design objective.

In plant layout, suitable separation distances may be used to decrease the likelihood of unacceptable damage, while buildings such as control rooms which may be affected can be suitably designed. The effect of a possible VCE in a works may be explored by assuming the explosion of vapour clouds of different sizes and degrees of drift and constructing diagrams showing the areas affected by blast, or ‘petal diagrams’. A petal diagram given by Kletz (1977J) is shown in Figure 17.80. Guidelines on plant layout for VCE hazard are given in Chapter 10.

17.29 Boiling Liquid Expanding Vapour Explosions

Another of the most serious hazards in the process industries is the BLEVE. Generally, this occurs when a pressure vessel containing a flammable liquid is exposed to fire so that the metal loses strength and ruptures.

Accounts of BLEVEs have been given by Kletz (1977J), Reid (1979), A.F. Roberts (1981/82, 1982), Manas (1984), Pietersen (1985), Skandia International (1985), Blything and Reeves (1988 SRD R488), Selway (1988 SRD R492), D.M. Johnson and Pritchard (1991) and the CCPS (1994/15).

When a vessel containing liquid under pressure is exposed to fire, the liquid heats up and the vapour pressure rises, increasing the pressure in the vessel. When this pressure reaches the set pressure of the pressure relief valve, the valve operates. The liquid level in the vessel falls as the vapour is released to the atmosphere. The liquid is effective in cooling that part of the vessel wall which is in contact with it, but the vapour is not. The proportion of the vessel wall which has the benefit of liquid cooling falls as the liquid vaporizes. After a time, metal which is not cooled by liquid becomes exposed to the fire; the metal becomes hot and weakens and may then rupture. This can occur even though the pressure relief valve is operating correctly. A pressure vessel is designed to withstand the relief valve set pressure, but only at the design temperature conditions. If the metal has its temperature raised, it may lose strength sufficiently to rupture.

Most BLEVEs involve a pressure storage vessel, rail tank car or road tanker containing a flammable liquid, typically a liquefied flammable gas, which becomes exposed to a fire or flame, and in due course ruptures, often giving a fireball. Another common situation which gives rise to a BLEVE is a derailment. The development of the BLEVE is illustrated in Figure 17.81. A pressure relief valve on one tank car operates, the release ignites and the flame plays on another tank car. The liquid in this vessel heats up, the pressure rises and the relief valve operates, the release being ignited by the flame playing on the vessel. For a time the metal of this vessel is kept cool by liquid in contact with it, but the level falls as the liquid is vaporized, metal cooled only by vapour is exposed, becomes hot, weakens and ruptures. A large fraction of the flammable liquefied gas released, vaporizes and forms a burning vapour cloud, often a fireball.

A BLEVE of a vessel containing a flammable liquid gives rise to the following effects: (1) blast wave, (2) fragments, and (3) fireball.

Following Flixborough much attention was focused on VCEs. It was pointed out by Kletz (1977J) that BLEVEs can cause as many casualties as VCEs and that by comparison they were being relatively neglected. This view has been amply justified by the subsequent record.

Selected references on BLEVEs are given in Table 17.36.

17.29.1 BLEVE incidents

Compilations of BLEVE incidents are less numerous and comprehensive than those for VCEs. The principal lists are those of Pietersen (1985), Skandia International (1985) and Selway (1988 SRD R492). Incident data are also available from the MHIDAS databank of the SRD.

Some principal BLEVE incidents are given in Table 17.37. Other incidents are listed in Table A1.2.

The BLEVE at Feyzin on 1966 has received particular attention (Case History A38). In this incident an operator draining water from the bottom of a propane sphere lost control. A vapour cloud formed, ignited and flashed back to the vessel. The pressure in the vessel rose and the relief valve lifted, but the metal of the vessel lost strength and some 90 min after ignition the vessel burst. The death toll was 18. Plate 32 shows one of the fire engulfed spheres.

A remarkably similar event took place at the Duque de Caxais refinery at Rio de Janeiro in 1972 (Case History A61).

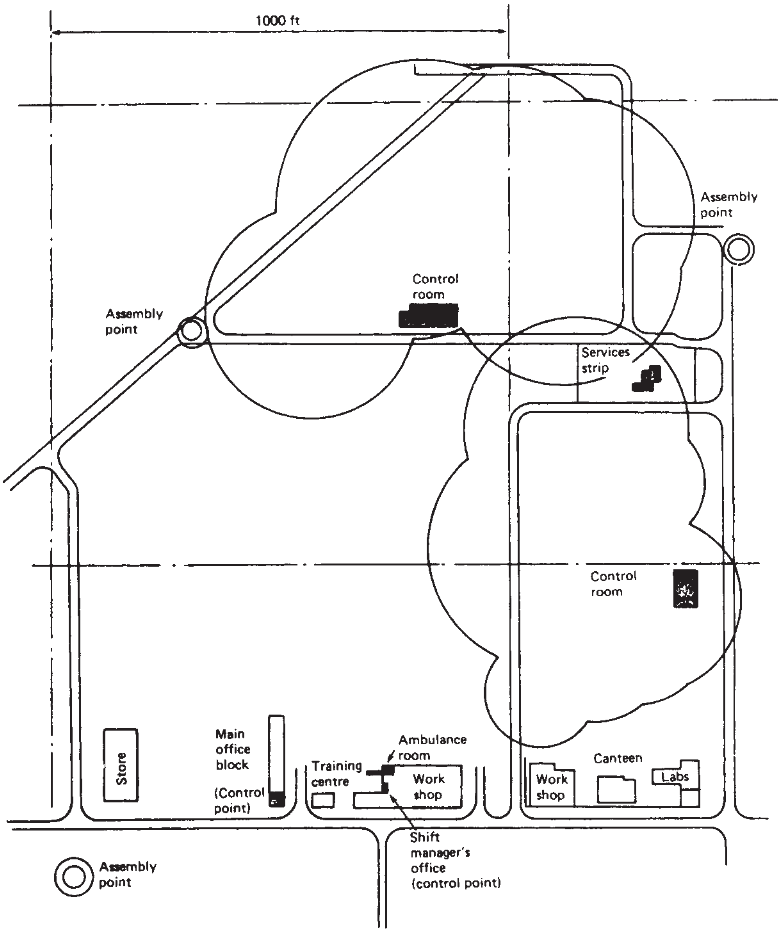

Figure 17.80 Petal diagram showing areas affected by possible vapour cloud explosions (Kletz, 1977J) (Courtesy of the Institution of Chemical Engineers)

Again an operator lost control of a draining operation on an LPG sphere, a vapour cloud formed, ignited and flashed back to the sphere, engulfing it in fire, so that after about 15–20 min it suffered a BLEVE.

In these incidents the release at, and BLEVE of, the vessel was the initial event. There have also been instances where a release from one storage vessel has led to a fire which has caused BLEVE of an adjacent one. Such was the case at Montreal, Quebec, in 1957, when overfilling of a butane sphere caused a release which led to a pool fire (Case History A25).

In 1978 at Texas City, Texas, overfilling of an LPG sphere led to a fire which caused the BLEVE of an adjacent sphere.

In other cases BLEVEs have occurred due to engulfment in a vapour cloud fire. Such a fire occurred at Port Newark, New Jersey, in 1951 and led to the destruction of over 70 bullet tanks, many by BLEVE (Case History A19).

Engulfment in a vapour cloud fire was also the cause of destruction, largely by BLEVE, of four storage spheres and 48 cylindrical vessels holding LPG at Mexico City, Mexico, in 1984. Some 500 people were killed. This incident, shown in Plate 35, is described in Appendix 4.

BLEVEs also occur in transport, typically when flammable material is released and ignited following an accident, so that a transport tank becomes engulfed in fire. They have occurred particularly on rail tank cars, often when a jet flame from the relief valve on one tank has played on another.

A derailment of nine rail tank cars at Crescent City, Illinois, in 1970 caused a release of propane which led to a fire and caused a succession of tank car BLEVEs (Case History A50).

The BLEVEs were accompanied by large fireballs and missiles, including rocketing tanks. One of the fireballs is shown in Plate 33.

Other rail tank car BLEVEs include those at Laurel, Mississippi, in 1969 (Case History A44), Houston, Texas, in 1971 (Case History A53), Kingman, Arizona, in 1973 (Case History A63), Oneonta, New York, and West St. Paul, Minnesota, in 1974, Des Moines, Iowa, in 1975, Belt,

17.29.2 The BLEVE event

An account of the origin of the term 'BLEVE' is given by the CCPS (1994/15), which states that the term was introduced by workers at the FMRC. An early account of the phenomenon was that of Walls (1979) at the National Fire Protection Agency (NFPA). A review of events which can lead to a BLEVE has been given by Prugh (1991), who gives the term a fairly wide interpretation and lists the following: (1) fire exposure, (2) mechanical damage, (3) overfilling, (4) runaway reaction, (5) overheating, (6) vapour space explosion, and (8) mechanical failure.

The essential features of a BLEVE are that (1) the vessel fails, (2) the failure results in flash-off of vapour from the superheated liquid, and, if the liquid is flammable, (3) the vapour ignites and forms a fireball.

The accompanying effects are (1) blast, (2) fragments, and, for flammable liquids, (3) a fireball.

The BLEVE creates an overpressure. The phenomena associated with this are (1) the expansion of the vapour, (2) the flash vaporization of the liquid, and, for flammable

liquids, (3) the combustion of the vapour. These events are not completely simultaneous, but have been measured as separate effects.

A BLEVE usually generates missiles. These may be fragments created by the rupture event and also the body of the vessel itself. The pressure at the instant of burst is high and the reaction force is often large enough to cause the main part of the vessel to rocket.

A BLEVE resulting from the fire engulfment of a vessel containing a flammable liquid also gives rise to a fireball.

Although most BLEVEs of interest here involve a liquid which is flammable, this is not a necessary feature of a BLEVE. The rupture of a vessel containing superheated water can constitute a BLEVE. Likewise, although engulfment in fire is the common cause of BLEVE, it too is not a necessary feature. Any rupture of a vessel containing a superheated liquid may be termed a BLEVE.

It is possible, therefore, though not common, for a BLEVE event not caused by an engulfing fire to provide the source for a large vapour release, leading to a flash fire or VCE.

17.29.3 Experimental studies

As described in Chapter 16, there have been a number of experimental studies of fireballs. The BLEVE event as a whole has not been so well served.

C. Anderson *et al.* (1975) describe work at the Association of American Railroads (AAR) on fire engulfment of a 125 m^3 rail tank car which suffered a BLEVE.

Experimental work on BLEVEs has been described by Hardee and Lee (1975), who did tests involving 420 kg of propane and modelled the processes of bursting and mixing with air.

Tests on vessel bursts directed to the same end are given by Maurer *et al.* (1977), but these authors also report measurements of the overpressure associated with the burst, as described in Chapter 15.

Work in the same series is that described by Giesbrecht *et al.* (1980), who used 450 kg of propylene and modelled the bursting, mixing and combustion processes.

Work at the Bundesansalt fur Materialpriifung (BAM) on fire engulfed vessels containing liquid propane, described by Schulz-Forberg (1984), Droste and Schoen (1988) and Schoen, Probst and Droste (1989), involved tests on 4.84 m^3 tanks with generation of fireball and fragments.

Further larger scale experiments have been performed at British Gas by D.M. Johnson and Pritchard (1991). Their base case was a 5.66 m^3 vessel containing 2 te of butane at a pressure of 15 barg. They performed five tests, with the base case and with the following four variations: (1) lower mass, (2) lower pressure, (3) different vapour/liquid ratio, and (4) using propane. Vessel failure was effected by explosive charges and ignition was by propane lances.

The purpose of this BG work was to investigate the overpressure and thermal radiation. With regard to overpressure, the authors state that the vapour expansion and flash vaporization tended to merge. The overpressure from vapour expansion agreed well with predictions for overpressure from a bursting vessel. The overpressure from flash vaporization was substantially less than that predicted, apparently because the liquid temperature was below that required to give homogeneous nucleation, or superheat limit.

The overpressure from the combustion came somewhat later and had a much longer duration, of the order of 100–300 ms. The overpressure trace which the authors give shows the maxima of the two overpressure pulses to be comparable. These traces show the overpressures measured at 150 m from the vessels to have been of the order of 4 mbar. The authors state, however, that the combustion overpressure was often greater.

With regard to the fireball, this showed in some tests an appreciable degree of asymmetry. For the mass of fuel in the fireball, the authors quote the limit of 35% theoretical flash vaporization above which flash-off of the whole contents is often assumed. The theoretical flash in their work was over 45% and complete flash-off was assumed. This was supported by the visual records, which showed only small amounts of liquid fuel burning on the ground.

The fireball diameter and duration were broadly as predicted by models such as that of A.F. Roberts (1981/82). Except in one test the height of the centre of the grounded fireball was between 0.8 and 1.35 times the equivalent maximum diameter, which compares with the suggestion by Moorhouse and Pritchard (1982) that it be taken as the maximum diameter.

For the thermal radiation from the fireball, the surface emissive power was somewhat higher than the values commonly quoted, with peak values up to 500 kW/m^2 and the remainder in the range 250–350 kW/m^2.

The CCPS (1994/15) describes one of the BAM and one of the British Gas tests and states that the liquid temperature exceeded the superheat limit in the former but not in the latter.

Melham, Croce and Abraham (1993) describe a series of BLEVE tests carried out by the NFPA in conjunction with the production of a successor to its earlier film 'BLEVE', entitled 'Bleve Update'. The purpose of the tests was to establish a database of experiments and to obtain film of BLEVE events. There were six tests, two each with a simulated pool fire, an impinging gas jet flame and an impinging liquid jet flame. The vessels tested were 1.89 m^3 propane tanks. In these tests peak overpressures up to 37 kPa were measured at a distance of 15 m from the tanks.

17.29.4 Empirical features

It is also helpful to consider some features of BLEVEs from an empirical viewpoint. Those discussed here are (1) the time to BLEVE, (2) the mode of rupture, (3) the blast effects, (4) the fireball, (5) the missiles, and (6) the release of flammable fluids. Time to BLEVE is treated in the following subsection and the other items here.

With regard to the mode of rupture, cylindrical tanks usually rupture longitudinally, though some rupture circumferentially. The latter particularly tend to take off like rockets and may travel long distances. This was true of some of the cylindrical tanks at Mexico City. Spheres often explode, but in some cases may simply split at the top as occurred both at Feyzin and Mexico City.

The pressure at the instant of rupture must approximate to that in the vessel. Generally, therefore, it will be appreciably greater than that at the centre of a VCE, which is commonly estimated to have a maximum overpressure of about 1 bar. Thus, in a BLEVE the overpressure at the vessel at the instant of rupture may be an order of magnitude higher than that at the centre of a VCE. The blast wave from a BLEVE can cause damage. At Feyzin the blast wave caused extensive though minor damage in a village 500 m away and broke some windows at a distance of 3 km.

The flammable vapour released forms a fireball. The fireball can be large and it can rise to an appreciable height. Fireball diameters at Mexico City are estimated from film records to have been of the order of 200 or 300 m with a duration time of some 20 s. The fireball at Crescent City rose to a considerable height, as shown in Figure A1.4 (see Appendix 1).

At Mexico City there was also a fire column which resembled a huge flare rather than a fireball and which film records show to have lasted 90 s.

The maximum distances at which injury due to heat radiation has been reported are 300 m at Feyzin and 400 m at Mexico City, while the maximum distance at which death has been reported is 300 m at Kingman.

Survivals have been reported at distances comparable with the estimated radius of the fireball. At Belt the reported fireball diameter was 1000 ft. The calculated diameter is 540 ft, based on the 80 te of flammable material believed to have been involved, though there is some doubt on this quantity. Firemen within 200 ft survived (Kletz 1981n). Further details of survival at this distance and of fireballs are given by Crawley (1982).

BLEVEs tend to generate massive missiles, including the main part of the vessel. Missiles from BLEVEs are considered in more detail in Section 17.34, but a brief mention is made here. At Feyzin the sphere BLEVE generated five large fragments, of which three each had a mass of over 100 te and were thrown distances of 150–350 m. One piece knocked over another sphere which itself in due course underwent a BLEVE.

The BLEVEs which occurred in the vapour cloud fires at Port Newark in 1951, Texas City in 1978 and Mexico City in 1984 all generated large missiles. At Port Newark one large tank section about 17 m long was hurled over half a mile and demolished a petrol filling station. At Mexico City the spheres generated 25 major fragments which travelled 100–590 m, whilst one bullet tank was propelled 1200 m. This latter appears to be the maximum distance travelled by a BLEVE missile.

The liquid in the vessel does not necessarily vaporize completely. At Tewkesbury, Massachusetts, in 1972 some 35% of the propane flashed off, the remaining liquid being scattered in all directions.

BLEVEs do not generally give rise to VCEs. But they may scatter flammable liquid spray which gives a spray fire and/or falls on people and property, rendering them more flammable and liable to ignition. Hot missiles may also cause fires.

17.29.5 Time to BLEVE

The time between the occurrence of an engulfing or torch fire and BLEVE is of significance not just for the general characterization of BLEVEs but for the design of fire systems to protect against them and for fire fighting.

For the sphere at Feyzin in 1966 the time between ignition of the leak and vessel rupture was about an hour and a half. This time to BLEVE is much longer than in most other incidents.

More commonly, for storage vessels the time to BLEVE has been of the order of 5–30 min. A period of 3–10 min was observed for some vessels at Montreal, McKittrick and Mexico City. A time of some 30 min was observed for other vessels at these three incidents.

Hazard assessments of storage vessels in respect of BLEVE have been made by Blything and Reeves (1988 SRD R488) and Selway (1988 SRD R492). Blything and Reeves studied a horizontal cylindrical storage vessel holding butane, with a nominal capacity of 100 te and actually holding 85 te, being thus 75% full. They considered scenarios involving (1) partial fire engulfment and (2) jet flame impingement, and obtained time to BLEVE estimates of between 4 and 48 min.

Selway describes an equivalent study for a 2000 m^3 storage sphere containing some 1000 te of LPG when full. For scenarios of total fire engulfment, partial fire engulfment and jet flame impingement he obtained times to BLEVE of 7–11, 25–38 and 5.5–7 min, respectively. These times are a function of the degree of fill. A vessel which is empty has a much shorter time, whereas the difference in times between a vessel which is half full and one which is full is small. Thus, for example, for the partial engulfment case, the times to BLEVE given for the states virtually empty, half full and full are 25, 36 and 38 min, respectively.

Times to BLEVE for tanks in transport accidents, particularly rail tank cars, have also been mainly in the range 5–30 min.

17.29.6 Vessel burst pressure

The explosion energy released in BLEVE is a function of the initial pressure.

The various different scenarios for vessel burst pressure have been discussed in Section 17.27, where a distinction was made between the following causes: (1) operating overpressure, (2) mechanical failure, and (3) fire engulfment.

17.29.7 Liquid superheat limit

The energy of the explosion which is part of the BLEVE event depends on the conditions in the vessel. In particular, under certain conditions, explosive flashing of the superheated liquid can occur, giving a large release of energy.

The explanation of what happens which has received most acceptance is the liquid superheat limit theory of Reid (1976, 1979, 1980). If a liquid has a sufficient degree of superheat and the pressure on it is suddenly removed, microscopic vapour bubbles form and a large fraction flashes off within milliseconds.

The degree of superheat necessary for this effect to occur is determined by the homogeneous nucleation temperature, or superheat limit temperature. There are a number of correlations for this, which differ according to the equation of state used. Using van der Waals's equation of state, Opshoor (1974) obtained

$$T_{sl} = 0.84\, T_c \qquad [17.29.1]$$

whilst using the Redlich–Kwong equation of state Reid (1976) obtained

$$T_{sl} = 0.895\, T_c \qquad [17.29.2]$$

where T_c is the critical temperature (K) and T_{sl} the superheat limit temperature (K).

Reid also confirmed that for a wide range of industrial substances the coefficient in Equation 17.29.2 lies within the range 0.89–0.90.

Reid studied particularly the superheat limit temperature of propane, for which the value generally quoted is 53°C. The values given by Equations 17.29.1 and 17.29.2 are 38 and 58°C, respectively.

Data on the liquid superheat limit temperature are given by Lide (1994). Where it is necessary to predict it, use is generally made of Equation 17.29.2.

Other mechanisms to explain explosive flashing have been suggested. Board *et al.* (1975) apply the superheat limit concept in conjunction with that of atomization of the liquid by shock waves at the vapour–liquid interface, whilst Venart (1990a) combines the concept with the effect of the depressurization–repressurization cycles associated with the operation of a pressure relief valve.

If the degree of superheat is not sufficient to promote explosive flashing, the energy release in a BLEVE is that due to the pressure energy in the vapour space, which is generally an order of magnitude less.

The superheat limit model of a BLEVE is discussed further in Section 17.29.9.

17.29.8 Modelling of BLEVEs

There are several different approaches to the modelling of BLEVEs. They include (1) the superheated liquid explosion model, (2) the cloud formation model, and (3) the bursting vessel model.

The modelling of a BLEVE is closely related to the modelling of a fireball, as described in Chapter 16.

17.29.9 Superheated liquid explosion model

The superheated liquid explosion model is that of Reid, which has been outlined in Section 17.29.7. Reid suggests that this theory may explain the behaviour of the liquid at the moment of BLEVE.

The application of the theory to a BLEVE may be explained by considering the specific case of the depressurization of a vessel containing propane. The vapour pressure and superheat limit lines for propane are given in Figure 17.82. The superheat limit is the limit to which propane may be heated before spontaneous nucleation occurs,

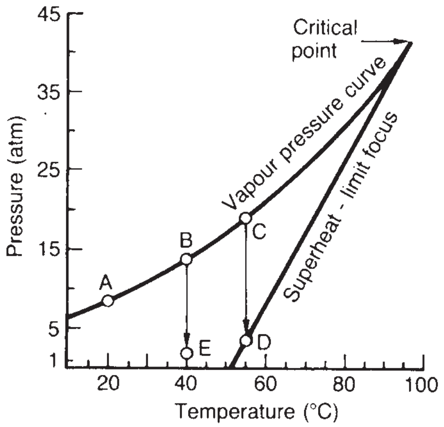

Figure 17.82 *Vapour pressure and superheat curves for propane (R.C. Reid, 1997) (Courtesy of Science)*

giving a vapour explosion. Prior to the accident the propane is at an absolute pressure of 8–9 atm and ambient temperature at point A on the graph. In the accident conditions the liquid is heated up by the fire on the vessel. The behaviour of the liquid then depends on the temperature which it has reached when rupture and sudden depressurization occur. If depressurization occurs when the temperature is that corresponding to point B, the pressure will fall to atmospheric pressure at point E. There will be violent boiling but no vapour explosion, since the superheat limit line has not been reached. If depressurization occurs at point C with fall in pressure to point D, the superheat limit line is reached at about 3.3 atm, and a vapour explosion could occur. The superheat limit temperature at atmospheric pressure is thus a limit below which a superheated liquid explosion will not occur. For propane this is 53°C.

In support of this hypothesis Reid quotes experiments by C. Anderson *et al.* (1974) and Hess, Hoffman and Stoeckel (1974) and a number of industrial accidents as being consistent with the hypothesis.

The theory has implications for prevention of superheated liquid explosions under these conditions. Such an explosion will not occur if depressurization occurs at a pressure corresponding to a temperature below the superheat limit temperature. The pressure relief valve may be set to operate below this pressure and thus to protect against the explosion. Another possible measure is to seed the liquid with solid particles to assist nucleation, but experimental work on these lines has not been encouraging. The measures described are addressed specifically to the mitigation of the problem of superheated liquid explosions and will not prevent explosion from other causes such as the pressure of the vapour in the vessel.

17.29.10 Cloud formation models

Models for vapour cloud formation following depressurization have been given by Hardee and Lee (1975), Maurer *et al.* (1977) and Giesbrecht *et al.* (1980) and have been compared by A.F. Roberts (1982). The first model is based on conservation of momentum with the momentum created by the liquid release appearing explicitly as a function of the initial conditions; the second model is based on turbulent diffusion and the initial conditions do not appear explicitly. Both models give similar predictions of cloud growth for releases of the order of 100 kg and have been verified experimentally at this level, but diverge for larger releases. Roberts bases his treatment on the model of Hardee and Lee.

A model by Martinsen and Marx (1999) makes use of experiments by Johnson *et al.* (1990) to predict time-varying cloud development and buoyant lift-off.

17.29.11 Bursting vessel model

The overpressure created by a BLEVE is complex, since, as discussed above, it is in principle caused by three distinct phenomena.

The aspect where the most progress appears to have been made is in estimating the overpressure associated with the expansion of the vapour. It is suggested by W.E. Baker *et al.* (1983) that as a first approximation the blast wave from a vessel which undergoes BLEVE may be estimated by applying to the vapour space in the vessel the method, described in Section 17.27, for the bursting of a vessel filled with gas.

This approach appears to give reasonable predictions, as now described.

In order to apply this latter method it is necessary first to determine the pressure at which the vessel will burst. The following formula is quoted by Selway (1988 SRD R492) as that used in the ENGULF code for the burst pressure of a sphere:

$$P_{\mathrm{b}} = 2\sigma_{\mathrm{y}} \ln R\left(1 - \frac{\sigma_{\mathrm{y}}}{\sigma_{\mathrm{u}}}\right) \qquad [17.29.3]$$

with

$$R = r_{\mathrm{o}}/r_{\mathrm{i}} \qquad [17.29.4]$$

where P_{b} is the burst pressure, r is the vessel radius, R is the radius ratio, σ_{u} is the ultimate tensile strength, σ_{y} is the yield strength and the subscripts i and o denote inner and outer, respectively.

Pietersen (1985) has applied the method of W.E. Baker *et al.* (1983, p. 149), based on the Erode equation, for the energy in, and overpressure generated by the bursting of, a gas filled vessel to obtain the overpressure caused by the vapour expansion phase of a BLEVE, utilizing the volume of the vapour space and taking as 40% the fraction of the pressure energy which enters the blast wave. He obtains the following peak overpressures (bar) for vessels with a bursting pressure of 13.4 bar and different vapour space volumes:

Distance (m)	*Vapour space volume* (m^3)			
	20	100	800	1200
10	0.44	1.0	2.3	2.6
50	0.04	0.08	0.23	0.29
100	0.018	0.033	0.09	0.10
200	0.0075	0.012	0.033	0.04

Some experimental confirmation is provided by the finding of D.M. Johnson and Pritchard (1991) that the overpressures predicted using a model based on that for the bursting of a gas filled vessel were in reasonable agreement with those measured in their tests for the vapour expansion phase.

17.29.12 BLEVE method

An integrated BLEVE model should comprise models for the main effects of (1) blast, (2) fragments, and (3) fireball. Treatments covering these aspects are given in Sections 17.27 and 17.34 and Chapter 16, respectively. The model may also include a model for fire engulfment, which is treated in Chapter 16.

17.29.13 CCPS method

The CCPS *Fire and Explosion Model Guidelines* (1994/15) give a method for the treatment of the various effects of a BLEVE. The treatment covers (1) blast, (2) fragments, and (3) fireball.

For the blast the *Guidelines* method utilizes the CCPS vessel burst model, essentially that of W.E. Baker *et al.* (1975), given in Section 17.27.

The energy of explosion for use in this model is obtained by first determining whether the liquid temperature is greater than the superheat limit. Then, if the superheat limit temperature is not exceeded, use is made of the Erode equation, whilst if it is, use is made of the method for flashing liquid given in Section 17.4.6. The fraction flashing off is taken as the equilibrium value yielded by the isentropic expansion.

For the fragments the *Guidelines* use the CCPS fragments model given in Section 17.33.

For the fireball the *Guidelines* use the CCPS fireball model given in Chapter 16.

The *Guidelines* devote a chapter to worked examples of BLEVE calculations. These include a problem on a fireball from a propane tank truck; problems on blast from a propane storage vessel, from a propane tank truck and at Mexico City and problems on fragments from overpressure of a gas filled pressure vessel and from fire engulfment of a propane storage vessel.

17.29.14 Energy release and overpressure

The foregoing models provide the background for the estimation of the energy release and blast overpressure in a BLEVE. The two principal sources of energy are the compressed vapour in the vapour space and the superheated liquid as it undergoes flashing. The estimation of the energy release from these two sources has been discussed in Section 17.4. The superheat limit temperature model provides guidance on the extent to which liquid flashing is a significant contributor. A further discussion of the energy release in a BLEVE is given by Prugh (1991).

Given an estimate of the energy release, the overpressure from a BLEVE may be estimated using the methods outlined in Section 17.27.

It has been suggested by Venart *et al.* (1993) that in certain circumstances there may occur an event in which the energy release and explosion overpressure are much higher than in a regular BLEVE. This is discussed in Section 17.29.15.

17.29.15 Boiling liquid collapsing bubble explosions

The interaction between homogeneous nucleation and the vessel itself has been further investigated by Venart and co-workers (Venart, 1990a; Venart *et al.*, 1993), who have developed the concept of the boiling liquid collapsing bubble explosion (BLCBE).

The BLCBE has three aspects, involving the behaviour of (1) the liquid, (2) a crack in the vessel wall, and (3) the liquid–vessel system. If the vessel wall in the vapour space is subject to heating by a flame, a crack may develop. The behaviour of this crack then depends on the degree of fill. If the fill is high, the crack may be arrested, still in the vapour space section of the wall, by plastic blunting. If the fill is lower, there may be sufficient energy in the vapour to cause the crack to propagate plastically to the cold metal, where it can then propagate elastically without restraint and with only minimal energy requirement.

This second case, with the lower fill, corresponds to the regular BLEVE. The first case has the potential for a much greater release of physical energy associated with homogeneous nucleation. If the fill is high, one of two effects may occur: (1) a massive two-phase jet or (2) a violent vessel failure with total loss of containment caused by a homogeneously nucleated liquid.

It is this second type of event in a vessel with high fill which constitutes a BLCBE. It occurs with a liquid homogeneous in temperature and depressurizing. The sequence of events is envisaged to be typically as follows. The liquid is depressurized, say by operation of the pressure relief valve, and due to this becomes nucleated. When the crack occurs, there is an almost instantaneous swell of low-void liquid which chokes in the crack. There is a rapid repressurization of the vessel contents. The resultant liquid shock pressures are very high (1–3 kbar). The crack propagates elastically through the now cooled wall of the vapour space and on to the wall of the liquid space. The vessel fails and the highly compressed two-phase contents are again depressurized. Expansion of the high pressure vapour bubbles shatters the liquid and results in ejection of the whole of the superheated liquid as a fine aerosol. If flammable, this aerosol may then be ignited.

Venart *et al.* (1993) describe tests in which prenucleated R112 and R123 were used and events of the type just described were observed, with destruction of the vessel in times as short as about 200 μs. They give details of the pressure effects in the vessel, including measurement of the rapid pressure transient below the liquid in excess of the static pressure in the vessel and an estimate of the instantaneous overpressure at the crack. The vessel static pressure was some 790 kPa (100 psig), the average excess pressure 490 kPa (70 psi) and the estimated overpressure at the crack itself some 62 bar (900 psig). These authors also give estimates of the diameter of the bubbles (1–3 mm), the diameter of the resultant aerosol droplets (100 μm) and the evaporation time of the droplets (40 ms). They state that there were significant blast overpressures.

These effects were obtained with a liquid temperature more than 50°C below the superheat limit temperature.

Venart *et al.* suggest that all three types of event described (regular BLEVE, two-phase jet and BLCBE) occurred at Mexico City.

They draw attention to the fact that a BLCBE may be caused by a leak, and discuss the implications of this for the leak-before-break philosophy.

17.30 Explosions in Process Plant

Some of the principal types of explosion which occur on process plant have already been described. These are (1) explosions in chemical reactors, (2) explosions of high pressure gases inside plant, (3) explosions of flammable gas–air mixtures inside plant and in buildings, (4) VCEs, and (5) BLEVEs.

In addition, there are certain types of explosion which may occur in particular processes, operations or equipment.

Some of these have already been mentioned, such as explosions in driers, centrifuges and vaporizers, and in oxygen and chlorine plants.

Other explosion hazards include (1) aerosol explosions, (2) crankcase explosions, (3) superheated liquid explosions, (4) air system explosions, and (5) molten metal–water explosions. These various types of explosion are now discussed.

17.30.1 Explosions of aerosols

Under the conditions of an accident, a cloud of finely divided drops of flammable liquid in air, in the form of a mist or spray, may be produced which has many of the characteristics of a flammable gas–air mixture and which can burn or explode.

The combustion of such aerosols has been discussed in Chapter 16, which includes treatment of flame propagation, minimum ignition energy and burning velocity. Here, consideration is given to the extent to which combustion of such clouds has the propensity to generate overpressure, and, more specifically, to undergo detonation.

As described in Chapter 16, if the droplet size of the cloud is sufficiently small, the lower flammability limit, minimum ignition energy and burning velocity are essentially the same as those of a vapour–air mixture of the same concentration, measured in mass per unit volume.

The problem of crankcase explosions, described below, indicates that confined hydrocarbon mists can undergo explosions.

The detonation of aerosols has been discussed by Nettleton (1977b, 1987). The information available is rather limited. It has been shown that some aerosols of hydrocarbons are detonable under confined conditions. The work has been done using hydrocarbon–oxygen mixtures and there is little on mixtures with air. Information is also lacking on detonability limits, as distinct from the flammability limits, which are treated in Chapter 16.

When detonation occurs in an aerosol the detonation waves cause disintegration of the droplets. It is known that it is not necessary for the fuel to be present in extremely finely divided form for detonation to occur.

It is known also that with an aerosol the reaction zone is wider than in a homogenous mixture with consequent effects on peak pressure and duration time.

A particular type of aerosol explosion is the ‘smoke explosion’. An account is given by Croft (1980/81). In this case the flammable aerosol cloud is formed by smouldering combustion in a confined space such that low volatility, flammable aerosol is released. The aerosol cloud is liable to ignite suddenly. This type of explosion is therefore a particular hazard to fire fighters. One such incident occurred in a warehouse fire at Chatham dockyard involved smouldering mattresses, and two men were killed. The phenomenon is sometimes known as a ‘Chatham mattress’ fire.

17.30.2 Heavy aerosol explosions

The work of Burgoyne and co-investigators on the combustion of flammable mists and spray, described in Chapter 16, was undertaken in large part in relation to the problem of mist explosions in crankcases. This has been investigated by Burgoyne, Newitt and Thomas (1954) and Burgoyne and Newitt (1955).

Heavy aerosol explosions are relatively rare, but a marine crankcase explosion in 1947, which claimed 28 lives, showed that a serious hazard existed and led to the initiation of research. Leaks at hydraulic fluids have also caused explosions.

The suspension of oil in air in an engine crankcase during normal running is a mechanical spray with some condensed mist from the lubricated parts which are at temperatures above the average in the crankcase. If there is serious overheating, however, condensed mist formation is accelerated, a condition often referred to as ‘smoke’.

Measures which may be taken to avoid a crankcase explosion are ventilation to keep the atmosphere below the lower flammability limit, or injection of inert gas to suppress flammability, and explosion relief. The design of the latter requires a knowledge of the burning velocity.

As described earlier, the work on condensed oil mists demonstrated that these have flammability characteristics similar to those of the mixture given by the same amount of substance wholly in vapour form at the somewhat higher temperature necessary for vaporization. The lower flammability limit was 0.049 g/l. Flammability was suppressed when the air contained 28.3% of carbon dioxide.

It is now usual to fit crankcases with explosion relief devices.

17.30.3 Superheated liquid explosions: explosions in plant

A liquid may become superheated in various ways. It may be heated while under hydrostatic pressure or it may be heated in a boiling regime which favours superheating. The superheat energy may then be released.

Normally, superheat is released without great violence by the generation of nucleated bubbles.This occurs, for example, in normal heat transfer to a boiling liquid.

In some cases the release of vapour is rather more violent. A layer of water at the bottom of the tank of hot oil, for example, may become superheated so that there is a sudden evolution of vapour.

It has been suggested by R. King (1975a–c, 1976a,b, 1977, 1990) that such an occurrence may have contributed to the Flixborough disaster. A temporary 20 in. pipe was installed between reactor Nos. 4 and 6. Reactor No. 4 was fitted with an agitator, but this had not been in use for some time. It is possible that in the absence of agitation a layer of water may have built up in the bottom of the reactor and, on being heated up during start-up, may have caused a sudden evolution of vapour sufficient to rupture the pipe assembly. During a tank fire, the hydrocarbon layer in the tank can conduct heat to a water layer below. When the water layer heats above its boiling point, it can suddenly boil and displace hot burning hydrocarbon.

Another type of superheat explosion can occur when a refrigerated liquid hydrocarbon mixture such as LNG is poured on to water. This type of explosion is considered in Section 17.29.7.

17.30.4 Air system explosions

Explosions in compressed air system have been reported over the years in coal mines and, more recently, in the process industries also. An explosion in a compressed air line in Germany in 1963 killed 19 people.

Accounts of the explosion hazard in compressed air systems have been given by Mallow (1964a,b), Fowle (1973) and Burgoyne and Craven (1973).

Characteristically, a compressed air system explosion occurs on the air line from a reciprocating compressor with oil lubricated cylinders. Often the compressor has a record of faulty operation and high outlet temperature prior to the explosion. Carbonaceous residues are frequently found just downstream of the compressor outlet.

Explosions in compressed air systems are essentially oil mist explosions. The thickness of the oil film capable of giving a flammable mist is given by Burgoyne and Craven as follows:

$$t = \frac{CDP}{4\rho} \qquad [17.30.1]$$

where C is the concentration of oil mist in air necessary to produce an explosive mixture at atmospheric pressure (g/m^3), ρ is the density of the oil (g/m^3), D is the diameter of the pipe (m), P is the absolute pressure (atm) and t is the thickness of the oil film (m). The minimum value of C is the lower flammability limit, which for hydrocarbons in general is about 49 g/m^3, but work by Loison (1952) indicates that the practical value is about 138 g/m^3, which is about 2.8 times the theoretical value.

If this oil film is dispersed into an oil mist by some primary shock or explosion, the conditions are created for a more powerful secondary explosion. High outlet temperatures (>250°C) of the compressed air can vaporize and ignite the oil. Sudden release of high pressure can cause simultaneous mist formation and ignition. Carbonaceous residues can undergo self-heating and give ignition.

It should be emphasized that fires are more common than explosions in compressed air systems, but the fire creates an explosion hazard.

The oil film explosion which occurs in a compressed air line with a thin film of flammable oil is somewhat unique. Typically, during a detonation in the line the air line is ruptured at intervals over its length. The problem has been discussed by Burgoyne and Craven.

A number of oil film explosions have occurred in the compressed air starter systems of large diesel engines. In these cases, the explosion generally appears to have been initiated by the diesel engine rather than by the air compressor.

There are a number of measures which can be taken to prevent air system explosions. One is to use oils which are non-flammable or have reduced flammability. The oils available and the problems associated with their use are discussed by Burgoyne and Craven.

It is usually suggested that the risk of explosion can be reduced if high oil usage is avoided. This is not a complete answer, however, as explosions have occurred in systems where oil usage was not abnormally high.

The deposition of oil can be minimized by the design of the air compressor. The air velocity in the outlet pipe should be high, although a velocity which might cause vibration should be avoided. The air flow in the aftercooler should be downwards so that it is in the same direction as the oil film flow. There should be drain points so that oil can be removed from the system.

In operating the compressor, particular attention should be paid to the air outlet temperature. Various authors have suggested outlet temperature maximum limits in the region of 140–150°C.

In Germany the maximum air outlet temperature of air compressors is determined by law. The maximum temperature was set at 160°C in 1934, but explosions continued to occur. In 1963 it was reduced to 140°C.

It has been suggested by Burgoyne and Craven, however, that for pressures above 10 atm this may still not be the safe working temperature. They recommend a maximum normal working temperature of 145°C for a final stage outlet pressure of 10 atm gauge, but one of 124°C for a pressure of 100 atm gauge, with automatic cut-off temperatures 10°C higher in both cases. A more detailed table of values is given by these authors.

It is also important for there to be a high standard of maintenance both of the air compressor and also of the rest of the air system.

Other detailed precautions are described by the authors quoted.

17.30.5 Molten metal–water explosions

A violent explosion can occur if water comes into contact with molten metal. This hazard is of particular concern in the nuclear and metallurgical industries, but may sometimes occur in the process industries.

Molten metal–water explosions can occur either where water is added to molten metal or where molten metal is added to water.

There are a number of theories of molten metal–water explosions, including theories of superheat not unlike those described in Section 17.29.7, but the phenomenon is not well understood.

An investigation of molten metal–water explosions with special reference to continuous casting is given in *A Study of the Causes of Molten Metal and Water Explosions* by the HSE (1977/18). This report describes the various theories of such explosions.

A molten–metal water explosion was the cause of the Scunthorpe disaster in 1975 in which a large leak of water from the cooling water pipe ran down into a torpedo ladle of molten iron (Case History A78).

17.30.6 Superheated liquid explosions: explosions on water

As mentioned above, one form of superheated liquid explosion is that occurring inside plants. Another is that which can occur when a refrigerated liquefied hydrocarbon is spilled onto water.

Accounts of this type of explosion have been given by Katz and co-workers (Katz and Sliepcevich, 1971; Katz, 1972), R.P. Anderson and Armstrong (1972, 1974), Enger and Hartman (1972a,b) and Reid, Drake and co-workers (Drake, Jeje and Reid, 1975; Reid, 1976, 1978; Drake and Reid, 1977; Reid and Smith, 1978).

Attention was drawn to the potential for such an explosion during work on the hazards associated with the transport of LNG and involving its spillage onto water at the Bureau of Mines (BM) (Burgess, Murphy and Zabetakis, 1970 BM S 4105; Burgess, Biordi and Murphy, 1972 BM PMSRC 4177). In the 56th test of an otherwise uneventful series, a sharp explosion destroyed the experimental water tank. Later, a similar but larger explosion was experienced when 0.25 m^3 of LNG was spilled on a pond in the open.

Explosions of this kind are variously known as physical vapour explosions, flameless vapour explosions, or simply vapour explosions, and as rapid phase transition (RPT) explosions.

A theory to explain such explosions is given by Reid (1976). The explosion is a form of superheated liquid explosion and is governed by the superheat limit temperature. An explosion of this kind can occur in a BLEVE, and the phenomenon is considered as an aspect of BLEVE in

Section 17.29. As stated there, Reid's expression for the superheat limit temperature (SLT) is

$$T_{\mathrm{sl}} = 0.895\ T_{\mathrm{c}} \qquad [17.30.2]$$

where T_{c} is the critical temperature (K) and T_{sl} is the superheat limit temperature (K). If a liquid is heated above its SLT, rapid vapour bubble nucleation occurs followed by an explosive evolution of vapour.

According to this theory, spillage of a cold liquid onto a hotter one can result in a superheat limit explosion. As the BM work indicates, this occurs only in a few of cases.

The limiting conditions for occurrence of an SLT are discussed by Reid with reference to those for propane. The SLT of propane is 326 K (53°C). The range of water temperatures within which vapour explosions of propane of any violence occur is 326–344 K. Below 326 K the water temperature is less than the SLT of propane whilst above 344 K the phenomenon appears to be suppressed by the film boiling regime.

For small temperature differences the heat transfer regime is nucleate boiling, but as the temperature difference increases film boiling takes over. The heat transfer in this latter regime is reduced so that the cold liquid then has only a thin film above the SLT. Limited to this thin film, the violence of the SLT explosion is much less.

Thus, although liquefied gases such as ethane and methane have lower SLTs, they do not in their pure form give vapour explosions.

The same applies to LNG which is essentially pure methane. However, it is found that if an LNG contains a sufficient proportion of higher hydrocarbons a vapour explosion can occur. A vapour explosion is thus a credible event.

The proportion of higher hydrocarbons in an LNG which would not undergo a vapour explosion may be increased by ageing or by differential vaporization of the methane to the point where it would.

The initial vapour explosion may be followed by a more violent one; the primary explosion may result in further contacting of the cold and hot liquids due to the pressure wave and to droplet formation.

Several groups of workers have reported research on the industrial aspect of the hazard from such explosions. In addition to the BM work they include R.P. Anderson and Armstrong (1972, 1974) and Enger and Hartman (1972a,b).

Enger and Hartman consider particularly the situation where LNG is subject to depletion of the methane content to the point where a vapour explosion is possible. They point out that in these circumstances the weathering is likely to be uneven so that in any given instant an explosion would occur only at part of the interface.

These workers estimate the mechanical energy release as some 0.5 cal/m^2 of interface area.

The consensus view which appears to have emerged is that such vapour explosions are not a prime cause of concern.

17.31 Effects of Explosions

An explosion may give rise to the following effects: (1) blast damage, (2) thermal effects, (3) missile damage, (4) ground shock, (5) crater, and (6) injury.

Not all these effects are given by every explosion. An aerial blast, for example, tends not to form a crater.

Many of the data on the effects of explosions come, not surprisingly, from studies of military and industrial explosives, but an increasing amount of information is available from the investigation of process plant explosions.

Information on the effects of explosions has been given in *Explosions, Their Anatomy and Destructiveness* (C.S. Robinson, 1944), *Structural Defence* (Christopherson, 1946), the *Textbook of Air Armaments* (Ministry of Supply, 1952), *The Effects of Nuclear Weapons* (Glasstone, 1962; Glasstone and Dolan, 1980), *Hazards of Chemical Rockets and Propellants* (Qensen, 1972), *Workbook for Predicting Pressure Waves and Fragment Effects of Exploding Propellant Tanks and Gas Storage Vessels* (W.E. Baker *et al.*, 1975), *Handbook for Estimating the Effects of Accidental Explosions in Propellant Handling Systems* (W.E. Baker *et al.*, 1978), *Explosion Hazard and Evaluation* (W.E. Baker *et al.*, 1983), *Methods for the Determination of Possible Damage to People and Objects Resulting from Releases of Hazardous Materials* (the *Green Book*) (CPD, 1992b) and by Jarrett (1968), Brasie and Simpson (1968), V.J. Clancey (1972b), Eisenberg, Lynch and Breeding (1975) and Gilbert, Lees and Scilly (1994a–i).

Selected references on the effects of explosions are given in Table 17.38.

17.31.1 Blast damage

One of the principal effects of an explosion is the creation of a blast wave, and much of the energy of the explosion is expended on this.

A description of blast effects must take into account both the nature of the blast wave and the damage caused by the blast to structures. The energy entering the blast wave was considered in Section 17.4 and the characteristics of the blast wave in Section 17.25 and its damage effects are described in Sections 17.32 and 17.33.

17.31.2 Missile damage

Another principal effect of an explosion is the generation of missiles, and this takes up most of the energy not transmitted to the blast wave.

A description of missile damage involves both the generation and flight of missiles and the damage caused by missiles to structures. The energy imparted to missiles was considered in Section 17.4 and the generation and flight of missiles and the damage done by them is described in Sections 17.34 and 17.35.

17.31.3 Thermal effects

The combustion process involved in a chemical explosion can give rise to intense local heat radiation, which may cause damage or injury.

Information on the effects of thermal radiation in explosions, mostly derived from nuclear explosions, was given in Chapter 16.

17.31.4 Ground shock

In industrial explosions ground shock effects are usually small and less than those due to blast and assessment of such effects is generally not undertaken.

The effects of ground shock may, however, furnish useful information in accident investigation. An account of ground shock in this context has been given by V.J. Clancey (1972b).

The ground shock produced by an explosion may be regarded as a sinusoidal disturbance and may be characterized by its frequency and amplitude and thus also by its maximum velocity and maximum acceleration:

$$V_{\max} = 2\pi f A \qquad [17.31.1]$$

$$a_{\max} = 4\pi^2 f^2 A \qquad [17.31.2]$$

where a is the acceleration, A is the amplitude, f is the frequency, V is the velocity and the subscript 'max' denotes the maximum value.

For a charge exploded at the ground surface the ground shock depends mainly on the quantity of explosive and the nature of the ground.

An equation widely used to determine the amplitude of ground shock is

$$A = 0.001\frac{KE^{1/2}}{d} \qquad [17.31.3]$$

where A is the amplitude (in.), d is the distance (ft), E is the mass of explosive (lb) and K is a constant. The constant K depends on the nature of the ground. It may be taken as 100 for hard rocks and 300 for clay.

In order to avoid damage to a building owned by others, the amplitude should be limited to a value of 0.008 in. for an average structure or 0.003 in. for a delicate one. The persons responsible for the blast hazard may, however, opt to take the risk of some damage to their own building and allow an amplitude of 0.016 in.

For comparison, an amplitude of 0.001 in. is detectable by someone who is on the lookout for a tremor and one of 0.003 in. may be produced by heavy traffic nearby.

The frequency of the ground shock may be as low as 3–5 Hz in soft or loose soil and as high as 30–100 Hz in rock.

The damage done by ground shock to normal houses has been correlated by Langefors and Kihlstrom (1963) in terms of the quantity

$$\phi = \frac{Q}{R^{3/2}} \qquad [17.31.4]$$

where Q is the mass of explosive (kg) and R is the distance (m).

Some data on damage to normal houses caused by ground shock are given by Langefors and Kihlstrom for hard rock, and further derived data are given by Clancey for soft rock, as shown in Table 17.39. The relationshipis not valid for distances less than 2–3 times the depth at which the explosion takes place. The values given are for damage to normal houses built on the rock in which the explosion occurs. For concrete structures the f value needed to give the same degree of damage is 2–4 times greater.

***Table 17.39** Some data on damage to normal houses by ground shock*

$Q/R^{3/2}$		Damage to normal houses
Hard rock ($kg/m^{3/2}$)	*Soft rock* ($kg/m^{3/2}$)	
0.008	0.02	Fall of plaster, no cracking
0.06	0.25	Insignificant cracking (threshold value)
0.12	0.50	Cracking
0.25	1.0	Major cracking

Sources: Hard rock: Langefors and Kihlstrom (1963). Soft rock: C lancey (1972b).

Data in this table from *Rock Blasting* by U. Langefors and B. Kihlstrom, 1963, are reproduced with permission of the authors and of the publishers, Almqvist & Wiksell Forlags.

For an explosion at or near the surface, damage by blast will extend to a much greater distance than damage by ground shock.

17.31.5 Crater

A condensed phase explosion tends to give rise to a crater. For industrial explosions this effect is not usually assessed beforehand, but may provide information useful in accident investigation.

Accounts of cratering are given by C.S. Robinson (1944) and V.J. Clancey (1972b, 1977d).

The factors which affect the crater produced by an explosion are the position of the charge relative to the ground surface, the nature of the ground and the type and quantity of explosive. A charge exploded at the ground surface gives a wider and shallower crater than one exploded just beneath the surface.

The crater is larger in rock than in soft sand. In the latter there is very little shock transmission; in the former, however, the initial shock propagates and produces cracks as the pressure wave passes. The expanding gases enter the cracks and accelerate the fragmented rock.

It may be noted that understanding of the effects of the nature of the soil on crater size has developed over the years and the effects just outlined differ from those described by Robinson.

A high brisance explosive generally gives a large crater, and a low brisance explosive a small one or none at all. VCEs tend not to give craters; there was no crater at Flixborough.

An equation for crater size which applies to the explosion of dynamite, a high brisance explosive, at the ground surface on average soil is the Olsen formula

$$V = 0.4Q^{8/7} \qquad [17.31.5]$$

where Q is the mass of explosive (lb) and V is the volume of the crater (ft^3).

Robinson gives the experimental data on crater size shown in Table 17.40. The third case is the explosion at Oppau in 1921 (Case History A5). The corresponding crater volumes calculated from Equation 17.31.5 are 3200 and 75,000,000 ft^3, respectively. Thus, the low brisance ammonium nitrate gave a crater size considerably smaller than

Table 17.40 *Crater dimensions (after C.S. Robinson, 1944)*

Explosive		*Crater dimension*		
Type	*Charge* (lb)	*Diameter* (ft)	*Height* (ft)	*Volume* (ft^3)
Dynamite	50	6	2	30
Dynamite	2,400	31	9	3,200
Ammonium nitrate	9,000,000	400	90	10,000,000

that calculated by the equation derived for the high brisance explosive.

An equation relating the diameter of a crater to its volume has been given by V.C. Marshall (1987). He obtains from Robinson's figures the relation

$$D = 3\frac{V^{0.5}}{h} \qquad [17.31.6]$$

where D is the diameter of the crater (m), h is its depth (m) and V is its volume (m^3). Then, utilizing the rule-of-thumb attributed by Robinson to Olsen that the height of the crater is on average half its diameter ($h = D/2$), he gives

$$D = 6V^{0.25} \qquad [17.31.7]$$

Assuming that crater volume is proportional to the cube of the radius, Equation 17.31.5 is broadly consistent with the other main relation used to describe crater dimensions

$$r \propto W^{1/3} \qquad [17.31.8]$$

where r is the radius of the crater and W the mass of explosive.

As mentioned in Section 17.3, there is a reasonably good correlation between the crater radius and the mean detonation distance for ground surface explosions, so that relation 17.31.8 is similar to Equations 17.3.5 and 17.3.6.

Cratering can occur even without an explosion. The V-2 rockets, which had very high kinetic energy, were capable of giving a large crater even when not armed.

17.31.6 Injury

The effects of an explosion on people include injury caused by (1) blast, (2) missiles, (3) thermal effects, and (4) toxic effects. These injury effects are described in Sections 17.38 and 17.39.

17.32 Explosion Damage to Structures

17.32.1 Air blast loading

The general nature of the air blast from an explosion has been discussed in Section 17.25, where the blast characteristics were described essentially in terms of an ideal condensed phase explosion such as that of TNT, while the differences in the blast between a condensed phase explosion and a VCE were considered in Sections 17.26 and 17.28.

The loading of structures by air blast is described by Glasstone (1962) and Glasstone and Dolan (1980). In general, the effective pressure p_e on a given face of a structure is the sum of the overpressure p and the drag pressure p_d:

$$p_e(t) = p(t) + p_d(t) \qquad [17.32.1]$$

The drag pressure p_d is a function of the dynamic pressure q:

$$p_d(t) = C_D q(t) \qquad [17.32.2]$$

where C_D is the drag coefficient. Glasstone and Dolan treat various structures, including (1) a closed, box-like structure, (2) a partially open, box-like structure, (3) an open frame structure, (4) a cylindrical structure, and (5) an arched structure.

For the case of a closed, box-like structure, it is possible to determine (1) the average front face loading, (2) the average side and top loading, (3) the average back face loading, and (4) the net horizontal loading.

If a blast wave reaches the structure and its incidence on the front face is normal, the overpressure p_f at that face rises very rapidly to the peak reflected overpressure p_r^o. As the wave moves around the structure, the front face pressure falls rapidly to the stagnation pressure p_s at the stagnation time t_s,

$$p_f = p_s = p(t_s) + p_d(t_s) \qquad [17.32.3a]$$

$$= p(t_s) + q(t_s) \qquad [17.32.3b]$$

since for this face C_D is unity. The stagnation time is

$$t_s = 3S/U \qquad [17.32.4]$$

where S is the distance through which pressure relief is obtained and U is the shock velocity. S is the height H or the half-breadth $B/2$, whichever is smaller. Thereafter, the front face pressure falls:

$$p_f = p(t) + q(t) \qquad [17.32.5]$$

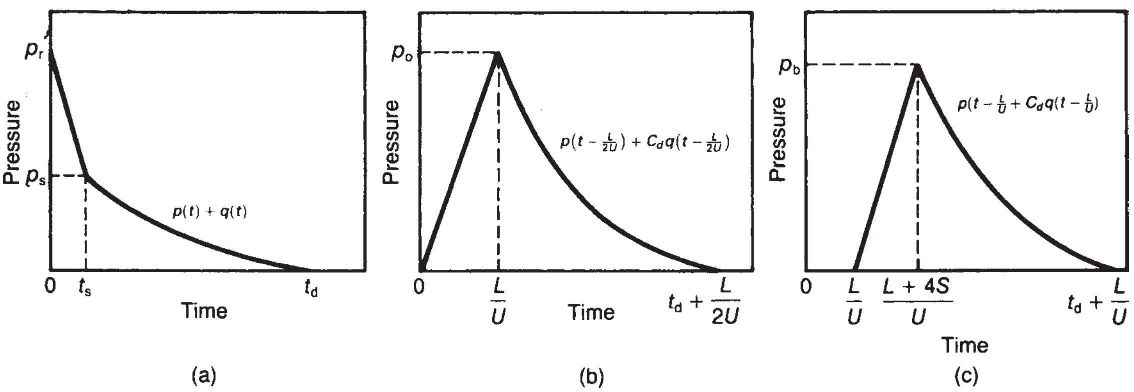
The front face pressure is shown in Figure 17.83(a).

The average side face and top pressure is obtained from Equations 17.32.1 and 17.32.2 as follows. The side face is fully loaded when $t = L/U$, where L is the structure length, and at this time the pressure reaches a maximum value p_o corresponding to that at $t = L/2U$. Thereafter the average pressure is that corresponding to $t - L/2U$, until it falls to zero at $t = t_d + L/2U$. The drag coefficient is approximately -0.4. The average side face and top pressure is shown in Figure 17.83(b).

The average back face pressure is obtained from Equations 17.32.1 and 17.32.2 as follows. The shock front reaches the back face at time $t = L/U$, but it requires an additional time of $4S/U$ for the average pressure to build up to the maximum value p_b corresponding to that at $t = (L + 4S)/U$. Thereafter, the average pressure is that corresponding to $t-L/U$, until it falls to zero at $t = t_d + L/U$. The drag coefficient is approximately -0.3. The average back face pressure is shown in Figure 17.83(c).

The net horizontal loading is the front face loading less the back face loading. This is shown in Figure 17.84.

The response of the walls depends primarily on the loadings on the individual faces, while the response of the frame depends on the net loading. For the shock strengths



(a) (b) (c)

Figure 17.83 *Blast loading of structures – average pressure loading on a closed cuboid structure (Glasstone and Dolan, 1980): (a) average front face loading; (b) average side and top loading; and (c) average back face loading (Courtesy of Castle House Publications)*

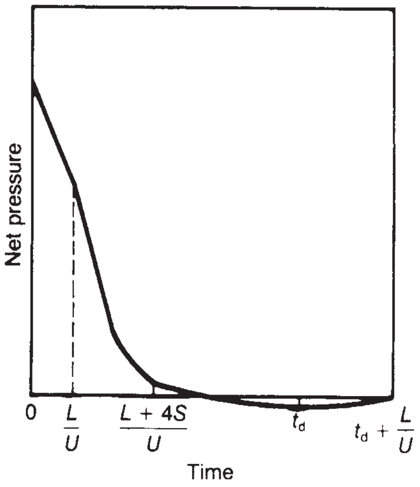


Figure 17.84 *Blast loading of structures – net pressure loading on a closed cuboid structure (Glasstone and Dolan, 1980): net horizontal loading (Courtesy of Castle House Publications)*

of interest here the values required for the drag coefficient C_D are those applicable to the subsonic range. Some values of the drag coefficient are given in Table 17.41.

17.32.2 Diffraction and drag loading

In the air blast loading of structures a distinction is made between diffraction loading and drag loading. Diffraction loading is determined primarily by the peak overpressure, drag loading by the dynamic, and hence the drag, pressure.

There are two types of diffraction loading. One is that due to the pressure differential between the front and back faces. Except for long structures this load is short-lived. The other loading is that due to the pressure differential between the inside and outside of the building. This approximates a static load and is more prolonged. With diffraction loading the damage potential is a function of the peak overpressure and the duration.

Table 17.41 *Drag coefficients (W.E. Baker et al., 1983 after Hoener, 1958)*

Shape	*Sketch*	C_D
Right circular cylinder (long rod), side-on		1.20
Sphere		0.47
Rod, end-on		0.82
Disc, face-on		1.17
Cube, face-on		1.05
Cube, edge-on		0.80
Long rectangular member, face-on		2.05
Long rectangular member, edge-on		1.55
Narrow strip, face-on		1.98

Drag loading is due to the drag pressure on the structure.

The loading is a function both of the air blast and the structure. A given structure may display diffraction-or-drag-type behaviour, depending on the duration. A short duration tends to load by diffraction, a long one by drag.

For a closed structure the duration of diffraction loading is approximately the time for the wave to pass from front to back, which is a relatively short period. Drag loading exists for the whole duration of the positive phase and for a short time thereafter. This is a long period compared with that of diffraction loading.

Certain types of structure are more prone to damage by diffraction, others by drag. Diffraction-type targets tend to be closed or semi-closed structures such as buildings with small window areas and storage tanks. Drag-type targets tend to be tall, thin objects such as telegraph poles and lamp posts. Buildings with large window areas may also constitute drag-type targets.

Drag loading is relatively more important for explosions which give long duration times, such as nuclear explosions, than for those giving short duration times, such as TNT.

17.32.3 Structure response

A typical load-displacement diagram is illustrated in Figure 17.85(a) and other related diagrams are shown in Figures 17.85(b)–(d).

The response of a structure is usually modelled by treating it as a lumped system. The simplest model is the one-mass model. The one-mass system is illustrated in Figure 17.86(a). The general equation of motion is

$$m\frac{d^2x}{dt^2} + c\frac{dx}{dt} + R(x) = F(t) \qquad [17.32.6]$$

where c is the damping factor, F is the applied force, m is the mass, R is the restoring force, t is the time and x is the displacement. It is usual to assume zero damping. Hence, Equation 17.32.6 becomes

$$m\frac{d^2x}{dt^2} + R(x) = F(t) \qquad [17.32.7]$$

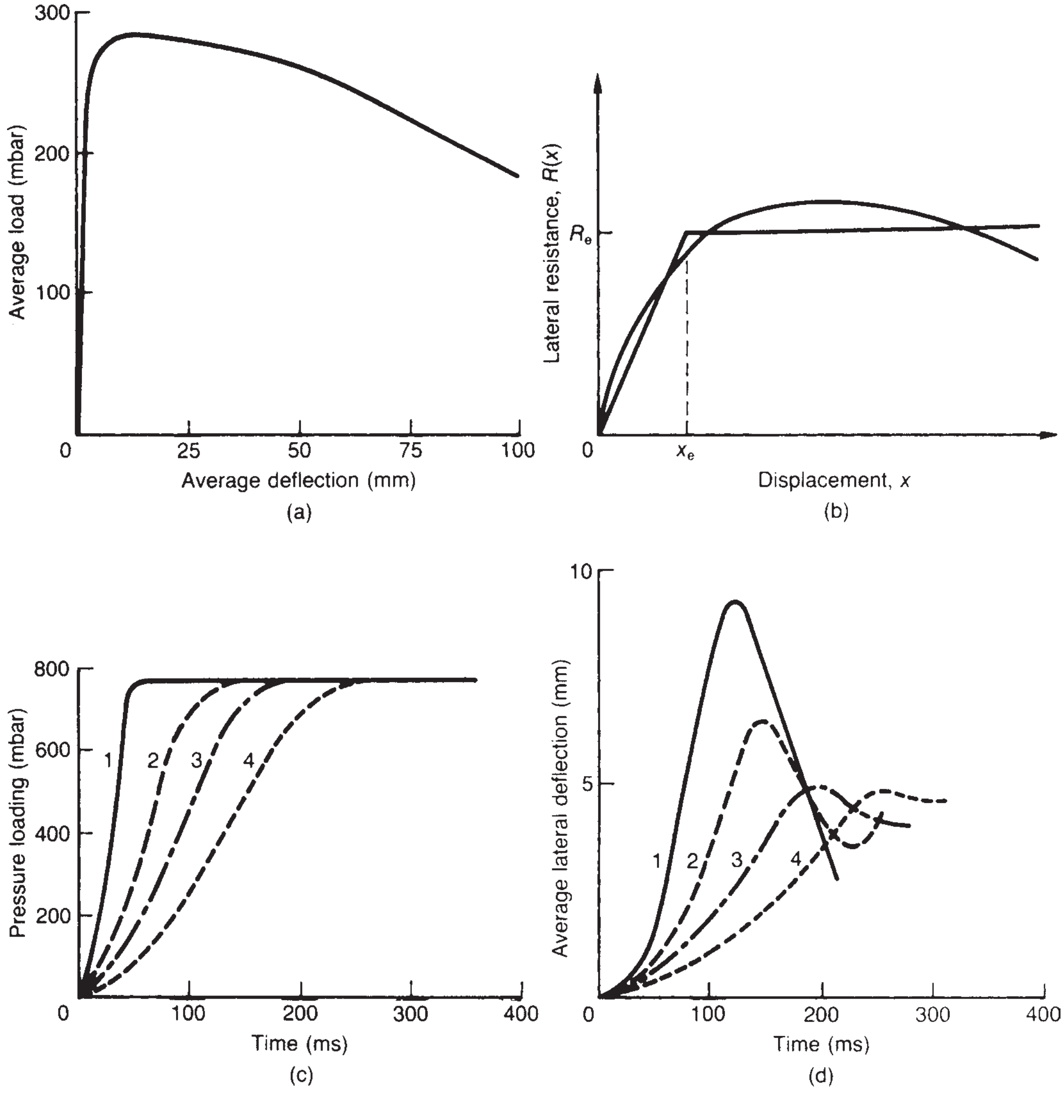

Figure 17.85 *Blast loading of structures: load–displacement and related diagrams: (a) load–displacement diagram; (b) resistance–displacement diagram; (c) load–time diagram; and (d) displacement–time diagram. 1–4, rise times*

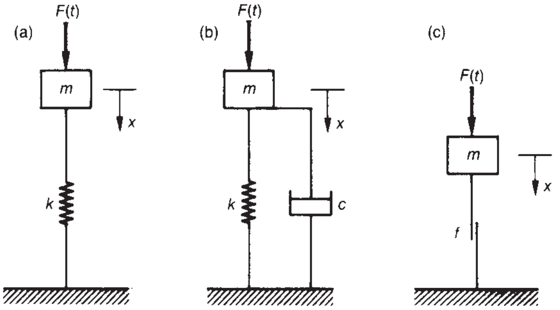

Figure 17.86 *Blast loading of structures – one-mass representation of a structure: (a) undamped elastic spring system (linear oscillator); (b) damped elastic spring system (viscous damping); and (c) rigid-plastic system (Coulomb friction)*

For a system in the elastic regime the retarding force R is proportional to the displacement x. Hence, Equation 17.32.6 becomes

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+c\frac{\mathrm{d}x}{\mathrm{d}t}+kx=F(t) \tag{17.32.8}$$

Or neglecting damping, as illustrated in Figure 17.86(b)

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+kx=F(t) \tag{17.32.9}$$

where k is the elastic constant.

For a system in the plastic regime the retarding force is the Coulomb friction, or retarding, force f. Hence, as illustrated in Figure 17.86(c), Equation 17.32.9 becomes

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+f=F(t) \tag{17.32.10}$$

In this case motion occurs only if $F>f$.

Considering first the one-mass vibrator, shown in Figure 17.86(a), the equation of motion may be written as

$$r^2\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+2\zeta\tau\frac{\mathrm{d}x}{\mathrm{d}t}+x=F^* \tag{17.32.11a}$$

$$\frac{1}{\omega_\mathrm{n}^2}\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+\frac{2\zeta}{\omega_\mathrm{n}}\frac{\mathrm{d}x}{\mathrm{d}t}+x=F^* \tag{17.32.11b}$$

with

$$F^*=F/k \tag{17.32.12}$$

$$\tau=\left(\frac{m}{k}\right)^{1/2} \tag{17.32.13}$$

$$\omega_\mathrm{n}=\left(\frac{k}{m}\right)^{1/2} \tag{17.32.14}$$

$$\zeta=\left(\frac{c^2}{4mk}\right)^{1/2} \tag{17.32.15}$$

where ζ is the damping factor, τ the natural period and ω_n the natural frequency.

If there is no damping, the one-mass vibrator becomes an elastic oscillator, as shown in Figure 17.86(b). The behaviour of the elastic oscillator gives important insight into the response of structures. If the system is subject to an applied force which decays exponentially such that

$$F(t)=F\exp(-t/T) \tag{17.32.16}$$

where T is the time constant of the decay of the force, Equation 17.32.9 becomes

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+kx=F\exp(-t/T) \tag{17.32.17}$$

The general solution of Equation 17.32.17 is

$$\frac{x}{F/k}=f(\omega_\mathrm{n}t,\ \omega_\mathrm{n}T) \tag{17.32.18}$$

and the solution x_m for maximum values of x is

$$\frac{x_\mathrm{m}}{F/k}=f(w_\mathrm{n}T) \tag{17.32.19}$$

where $x_\mathrm{m}/(F/k)$ is the amplification factor and $\omega_\mathrm{n}T$ the duration ratio. The relation between these two quantities is given in the oscillator diagram shown in Figure 17.87. The asymptotes of the curve given in Figure 17.87 are

$$\frac{x_\mathrm{m}}{F/k}=\left(\frac{k}{m}\right)^{1/2}T=\omega_\mathrm{n}T,\quad \omega_\mathrm{n}T<0.4\quad \text{impulsive loading} \tag{17.32.20a}$$

$$=2\,\omega_\mathrm{n}T>40\quad \text{quasi-static loading} \tag{17.32.20b}$$

$$=f(\omega_\mathrm{n}T)\quad 0.4<\omega_\mathrm{n}T<40\quad \text{dynamic loading} \tag{17.32.20c}$$

In sketching the curve it is also helpful to note that at the value of $\omega_\mathrm{n}T$ where the asymptotes intersect the value of $x_\mathrm{m}/(F/k)$ on the actual curve is approximately half that at the point of intersection. Then, in the impulsive loading domain

$$x_\mathrm{m}\propto FT=I \tag{17.32.21}$$

where I is the impulse, whilst in the quasi-static loading domain

$$x_\mathrm{m}=2F/k \tag{17.32.22}$$

Equation 17.32.22 means that the dynamic displacement, or deflection, is twice the static displacement. This dynamic load factor of 2 is widely used in structural engineering. It is also of interest to consider the corresponding energy relations. For impulsive loading the maximum strain energy may be equated with the initial kinetic energy. The initial velocity is

$$\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)_{t=0}=\frac{I}{m} \tag{17.32.23}$$

and the initial kinetic energy E_ko is

$$E_\mathrm{ko}=\frac{m}{2}\left(\frac{I}{m}\right)^2=\frac{I^2}{2m} \tag{17.32.24}$$

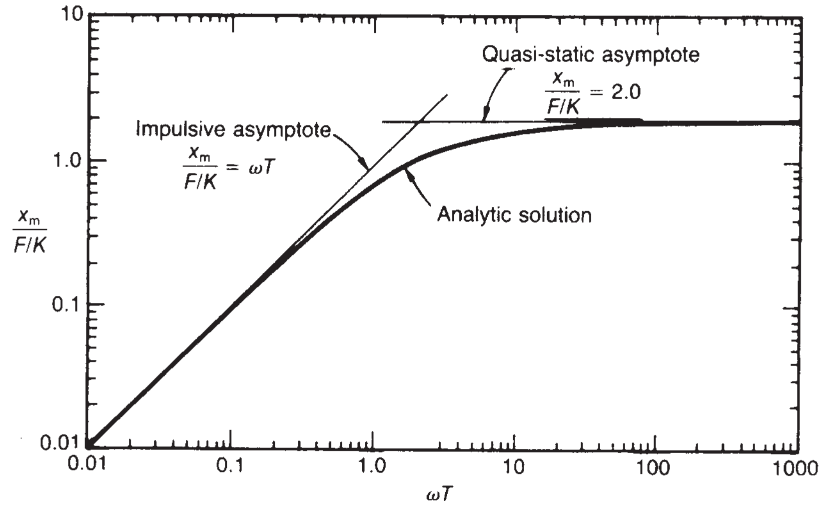

Figure 17.87 *Blast loading of structures response of an elastic structure: (after W.E. Baker et al., 1983) (Courtesy of Elsevier Science Publishers)*

The maximum strain energy E_{sm} is

$$E_{\mathrm{sm}} = 1/2\,kx_{\mathrm{m}}^2 \qquad [17.32.25]$$

Equating the two energies to obtain the asymptote

$$\frac{I}{(km)^{1/2}x_{\mathrm{m}}} = 1 \qquad [17.32.26]$$

Similarly, for quasi-static loading the maximum strain energy may be equated with the maximum work W_{m}. The latter is

$$W_{\mathrm{m}} = Fx_{\mathrm{m}} \qquad [17.32.27]$$

Equating the two energies

$$\frac{2F}{kx_{\mathrm{m}}} = 1 \qquad [17.32.28]$$

as in Equation 17.32.22.

These relationships may be represented graphically in the form of a force–impulse, or F–I, diagram, as illustrated in Figure 17.88, which shows again the three domains of impulsive loading and quasi-static loading separated by dynamic loading.

The force–impulse diagram is readily converted to a pressure–impulse, or P–I diagram, as described below.

A similar treatment may be applied to the plastic regime. In this case the maximum strain energy is

$$E_{\mathrm{sm}} = fx_{\mathrm{m}} \qquad [17.32.29]$$

Equating energies as before gives

$$\frac{F}{f} = 1 \qquad [17.32.30]$$

$$\frac{I}{(2mfx_{\mathrm{m}})^{1/2}} = 1 \qquad [17.32.31]$$

There are also more complex multiple-mass models of structural response.

An account of the practical application of these concepts to the buildings typical of chemical plants has been given by Whitney, Barker and Spivey (1992). The work included investigations of the structural damage in a number of plant accidents and covered peak reflected overpressures of 0.1–15 psi and duration of 5–100 ms. The authors distinguish three types of blast load: impulsive, quasi-static and dynamic. They classify the loads as low, moderate and high, defined in terms of the combination of peak overpressure and duration. They then tabulate for each load class the typical damage to frames, purlins, girts and joists, metal decking and windows, and they indicate the level of protection afforded by the structure and make recommendations for design.

The response of buildings to blast is generally analysed using a static load of long duration. The authors state that the metal frame buildings common in chemical plant tend to have greater impulsive and dynamic resistance than the static analysis indicates. It is quite common for plant buildings to experience a dynamic response in which the duration of the load is close to the natural period of the structure. The conventional plant buildings which perform best are those which allow plastic response without failure. The thrust of the design recommendations is to enhance this plastic behaviour.

17.32.4 Structure parameters

Some parameters which govern the structure response are (1) the natural period, (2) the elastic limit, (3) the ductility ratio, and (4) the resistance function.

The elastic behaviour of a structure may be described in terms of the following parameters:

$$T_{\mathrm{n}} = 1/f_{\mathrm{n}} \qquad [17.32.32]$$

$$= 2\pi/\omega_{\mathrm{n}} \qquad [17.32.33]$$

$$= 2\pi(m/k)^{1/2} \qquad [17.32.34]$$

where f_{n} is the natural cyclic frequency, T_{n} the natural period and ω_{n} the natural frequency.

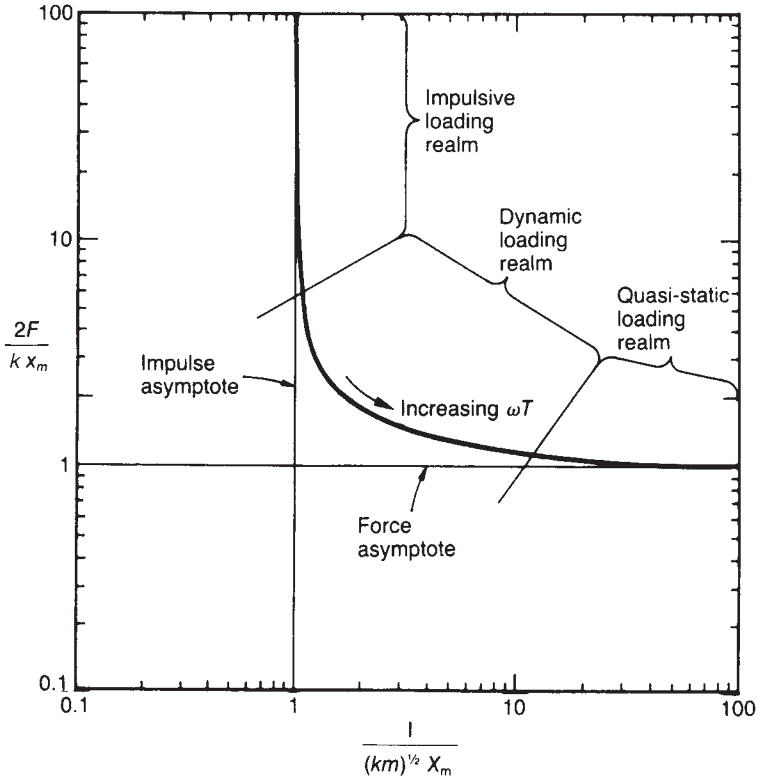

Figure 17.88 *Blast loading of structures: force–impulse (F–I) diagram of a structure (Strehlow and Baker, 1976) (Reprinted from R.A. Strehlow and W.E. Baker, Progress in Energy and combustion Science, 2, 27, © 1976, with permission from Pergamon Press)*

Equation 17.32.34 may be used to determine the elastic constant from the natural period, and vice versa. Some typical values of the natural period given by R.J. Harris (1983) are brick walls 20–40 s, concrete walls 10–15 s concrete floors 10–30 s.

A table of equations for the determination of the natural period is given by W.E. Baker *et al.* (1983). The following empirical equation is given by Kinney (1962) for the estimation of the natural period of a reasonably modern building:

$$T = 0.05\frac{H}{B^{1/2}} \qquad [17.32.35]$$

where B is the breadth of the building (ft), H is its height (ft) and T is its natural period (s). The natural frequencies of buildings is given for a number of common building types in the TNO *Green Book* (1989).

The extent of elastic behaviour is determined by the elastic limit, which is essentially the limit for a static load. Information on the elastic limit is available for most materials of interest. For structural response, where the time of application of the load may be very short, the relevant limit may be the dynamic elastic limit. Some approximate data on the elastic limit for structural materials have been given by Kinney (1962). According to these data the ratio of the dynamic to the static resistance for structural steel is about 1.58 up to a time to yield of 5.5 ms and that for reinforced concrete is about 1.38 up to a time to yield of 10 ms. For both materials the ratio falls to about 1.15 at a time to yield of 100 ms.

Kinney states that the time to reach the maximum elastic displacement, or time to yield t_e, has been investigated using the equation of motion, and may be approximately represented by the relation

$$t_e = \frac{T}{4}\left(\frac{p_m}{r_e}\right)^{-1/2} \qquad [17.32.36]$$

where p_m is the blast pressure (N/m^2), r_e is the maximum elastic resistance per unit area (N/m^2), t_e is the time to yield (s) and T is the natural period (s).

The ductility ratio p, is the ratio of the total sustainable deformation to the elastic deformation:

$$\mu = \frac{x_f}{x_e} \qquad [17.32.37]$$

where x_e is the displacement at the elastic limit and x_f is that at the failure limit. A material with a low ductility ratio is brittle, one with a high ratio ductile.

The behaviour of a structure under load is given by the load-displacement curve, which was illustrated in Figure 17.85(a). If this curve is treated as a resistance-displacement curve, the resistance function R may be obtained from it by approximating the curve by two straight lines, as shown in Figure 17.85(b). At the maximum elastic displacement x_e there is a maximum elastic resistance R_e, or yield resistance.

17.32.5 Component failure

The behaviour of a structural component may be illustrated by considering that of a brick wall. Work on the response of load-bearing brick structures to gas explosions has been described by Astbury *et al.* (1970), and their report contains an appendix by Paterson and Rowe (1970) on experimental work on the dynamic loading of brick panels.

Figure 17.89 shows the load-displacement diagram for brick panels of varying thickness. There is a rise to a maximum load F_m with a given central deflection x_m. The load decays to zero at a failure deflection x_f. These three parameters are functions of the bricks, the mortar, the panel thickness, the aspect ratio and the edge-fixing conditions. The failure deflection x_f is usually somewhat more than the panel thickness. From other work the ratio of central to average deflection is taken as 1:0.44.

From experimental work several simple rules have been derived for scaling load-deflection curves. It is found that if the linear dimensions of a panel are altered by a uniform scaling factor, the lateral strength remains constant. It is also found that the strength is proportional to the square of the thickness. Further, comparing a square with a rectangle comprising two such squares, it is found that the strength of the latter is half that of the former, that for intermediate values of the aspect ratio it is possible to interpolate and that for greater values the strength remains constant at the value for the rectangle.

Although the elasticity of brickwork is very limited, for rapidly applied loads the dynamic strength is somewhat greater than the static strength. In other words, there is some increase in maximum deflection with increase in rate of pressure rise. This is illustrated for a 9 in. brick wall in Figure 17.90.

There is a marked increase in dynamic deflection as the failure loading is approached. This is illustrated for a 4.5 in. brick wall in Figure 17.91, which shows that at explosions with maximum pressure P_m of 4 $\mathrm{lb_f/in.^2}$ the deflection is slight, but that at a pressure of 4.2 $\mathrm{lb_f/in.^2}$ there is a large deflection, failure finally occurring at 5.1 $\mathrm{lb_f/in.^2}$.

Some information is available on the failure pressures of building components. Tables are given by Astbury *et al.* (1970) and R.J. Harris (1983).

17.32.6 Overpressure damage data

Structural damage caused by blast waves from explosions has traditionally been correlated in terms of the peak overpressure of the explosion. There are available a large

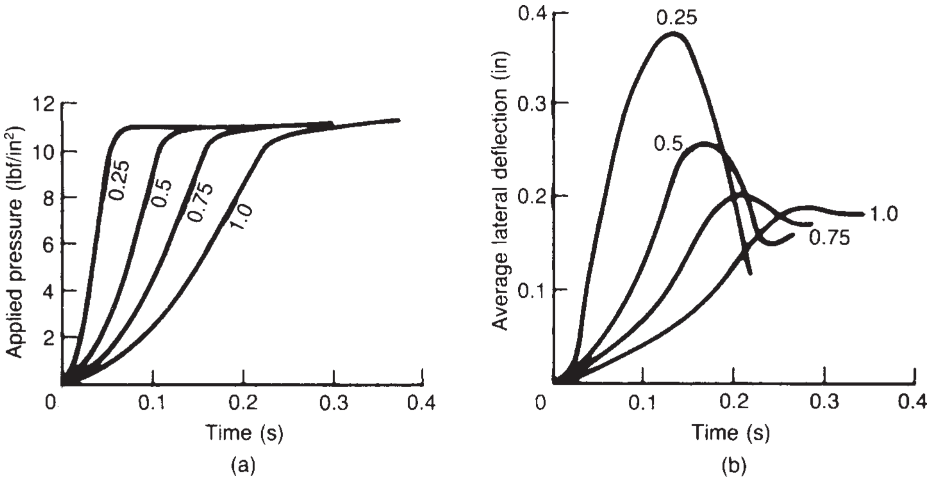

Figure 17.90 *Blast loading of structures–effect of rapidly applied loads on a 9 in. brick wall (after Astbury et al., 1970): (a) applied load and (b) average lateral deflection. Curve parameters on both figures are fractions of longest rise time 200* ms *(Courtesy of the British Ceramics Research Association)*

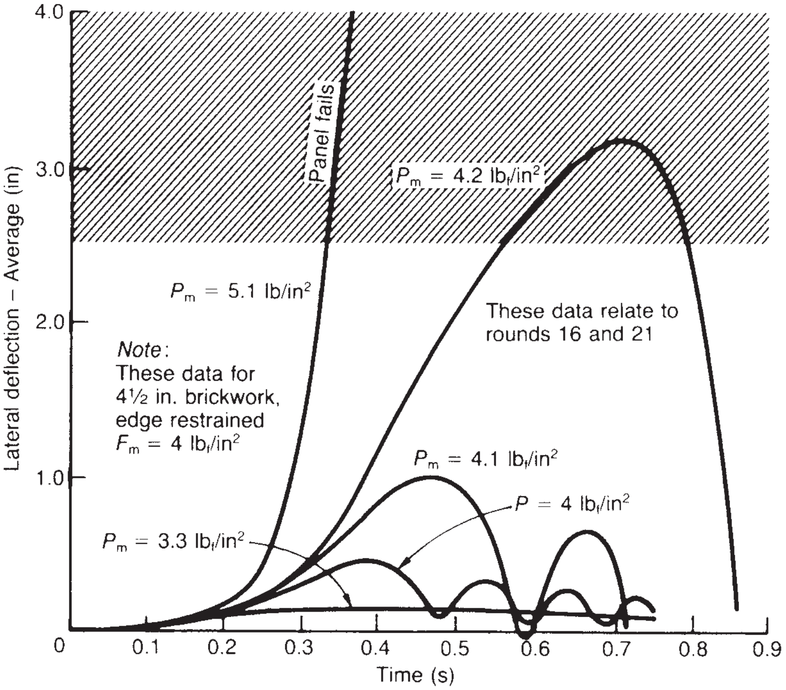

***Figure 17.91** Blast loading of structure: effect of rapidly applied loads on a 4.5 in. brick wall as failure loading is approached (after Astbury et al., 1970). F_m ultimate strength; P_m maximum explosion pressure (Courtesy of the British Ceramics Research Association)*

number of tables and graphs giving damage levels in terms of the peak overpressure.

The applicability of such data is greater for quasi-static loading than it is for impulsive loading. In the latter regime this approach is liable to result in considerable overestimate of the damage.

Thus, W.E. Baker *et al.* (1983) recommend against the use of simple overpressure damage data. Preferred methods are the use of pressure–impulse, or P–I, diagrams and distance–charge, or R–W correlations.

However, useable data in these alternative forms are often not available. In addition, some refinement of the overpressure approach has been effected. It still appears worthwhile, therefore, to consider first this approach.

A survey of damage effects caused by accidental explosions has been made by C.S. Robinson (1944), who also gives graphs of the limits of serious damage, minor damage, glass breakage and missile flight vs charge for both barricaded and unbarricaded installations. The data given by Robinson for unbarricaded installations are plotted in Figure 17.92.

A large amount of information on blast damage is given by Glasstone (1962) and Glasstone and Dolan (1980). These include buildings of various kinds, gas works, oil storage tanks, LPG installations, electrical transmission systems, gas, water and sewage systems and vehicles and ships. These data are based mainly on blasts caused at Hiroshima and Nagasaki by the explosion of a nuclear bomb of approximately 20,000 t TNT equivalent over each city in 1945 and by tests conducted at the Nevada Test Site, supplemented by data from accidental explosions.

Some of the damage effects described by Glasstone are as follows. In the Texas City explosion in 1947, oil storage tanks were severely damaged out to the overpressure region of 3–4 psi.

In the Nevada tests in 1955 a complete 18,000 US gal bulk storage plant containing propane with pump, compressor, piping, valves and fittings, and with a cylinder filling building, was located at the point where the overpressure was 5 psi. The building was demolished and the filling line was broken at the point where it entered the building, but otherwise the installation received only superficial damage.

In the Nagasaki explosion in 1945 the water supply system suffered extensive damage, so that it became virtually impossible to extinguish fires. Breakage of pipes occurred almost entirely in or at the entrance to buildings and structures rather than underground. The exception was a 12 in. cast iron water main 3 ft below ground which did break, but this was in a filled area where the ground was irregular. There appeared to have been little effect on underground gas mains.

Glasstone gives a large amount of data on levels of damage to both diffraction- and drag-type structures, including a number of tables and nomograms. In particular, the data shown in Table 17.42 have been widely quoted. The data given in Table 17.42(A) are from an original table of Glasstone. Those given in Table 17.42(B) are quoted together with the data from section A by Brasie and

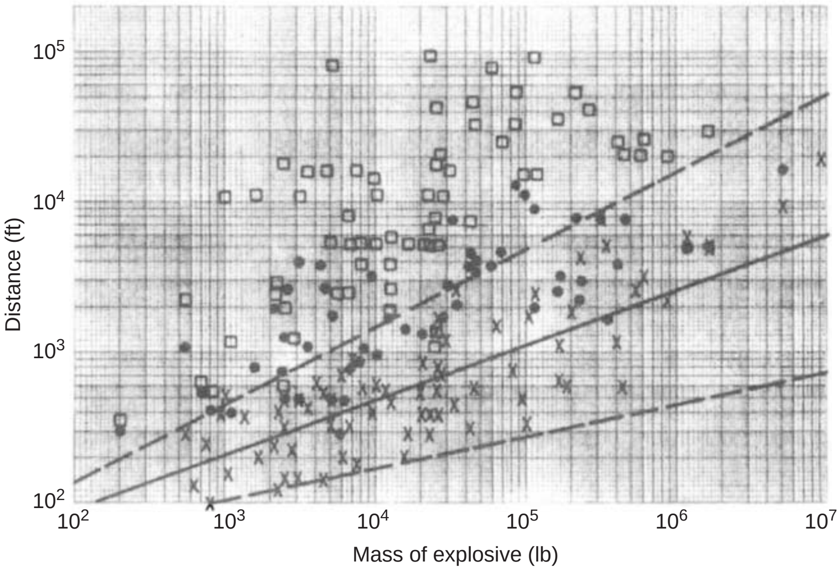

Figure 17.92 *Damage effects of explosions: limits of serious damage, missile flight and glass damage for accidental explosions for unbarricaded installations (after C.S. Robinson, 1944): x, severe damage; ●, missile flight; □, glass breakage. The full and broken lines give, respectively, the average and the outer limits for serious damage (Reproduced with permission from Explosions: their Anatomy and Destructiveness by C.S. Robinson, © 1944, McGraw-Hill Book Company)*

Table 17.42 *Some damage effects produced by a blast wave – 1 (after Glasstone, 1962; Brasie and Simpson, 1968)*

Structural element	*Failure*	*Peak side-on overpressure (approximate)* (psi)
A Original data of Glasstone[a]		
Glass windows, large and small	Shattering usually occasionally frame failure	0.5–1.0
Corrugated asbestos siding	Shattering	1.0–2.0
corrugated steel or asbestos panelling	Connection failure followed by buckling	1.0–2.0
Brick wall panel, 8 or 12 in. thick, not reinforced	Shearing and flexure failures	3.0–10.0 (7–8)
Wood siding panels, standard house construction	Usually failure occurs at the main connections, allowing a whole panel to be blown in	1.0–2.0
Concrete or cinder-block wall panels, 8 or 12 in. thick, not reinforced	Shattering of wall	1.5–5.5 (2–3)
B Additional data of Brasie and Simpson[b]		
Self-framing steel panel building	Collapse	3–4
Oil storage tanks	Rupture	3–4
Wooden utility poles	Snapping failure	5
Loaded rail cars	Overturning	7

[a] Glasstone and Dolan (1980), table 5.145. in parentheses are from Brasie and Simpson (1968).
[b] Brasie Simpson (1968), table 3.

Simpson (1968), and are possibly taken from the text of Glasstone. The table given by Brasie and Simpson has frequently been quoted.

Another damage table is that given by V.J. Clancey (1972b) in the context of accident investigation and reproduced in Table 17.43.

Commenting on these tables, Scilly and High (1986) state that both the tables of Brasie and Simpson and that of Clancey are largely derived from the nuclear weapons data and theoretical analyses in Glasstone together with some additional data for condensed phase explosives from Robinson.

Table 17.43 *Some damage effects produced by a blast wave – 2 (after V.J. Clancey, 1972b)*

	Peak side-on overpressure	
	(psi)	(kPa[a])
Annoying noise (137 dB), if of low frequency (1–15Hz)	0.02	
Occasional breaking of large glass windows already under strain	0.03	0.2
Loud noise (143 dB); sonic boom glass failure	0.04	
Breakage of windows, small, under strain	0.1	0.7
Typical pressure for glass failure	0.15	1.0
'Safe distance' (probability 0.95 no serious damage beyond this value)	0.3	2.0
Missile limit		
Some damage to house ceiling; 10% window glass broken		
Limited minor structural damage	0.4	2.8
Large and small windows usually shattered; occasional damage to window frames	0.5–1.0	3.5–6.9
Minor damage to house structures	0.7	4.8
Partial demolition of houses, made uninhabitable	1.0	6.9
Corrugated asbestos shattered	1–2	6.9–13.8
Corrugated steel or aluminium panels, fatenings fail, followed by buckling		
Wood panels (standard housing), fastening fail, panels blown in		
Steel frame of clad building slightly distorted	1.3	9.0
Partial collapse of walls and roofs of houses	2	13.8
Concrete or cinder block walls, not reinforced, shattered	2–3	13.8–20.7
Lower limit of serious structural damage	2.3	15.9
50% destruction of brickwork of house	2.5	17.3
Heavy machines (3000 lb) in industrial building suffer little damage	3	20.7
Steel frame building distorted and pulled away from foundations		
Frameless, self-framing steel panel building demolished	3–4	20.7–27.6
Rupture of oil storage tanks		
Cladding of light industrial buildings ruptured	4	27.6
Wooden utilities poles (telegraph, etc.) snapped	5	34.5
Tall hydraulic press (40,000 lb) in building slightly damaged		
Nearly complete destruction of houses	5–7	34.5–48.3
Loaded train wagons overturned	7	48.3
Brick panels, 8–12 in. thick, not reinforced, fail by shearing or flexure	7–8	48.3–55.2
Loaded train boxcars completely demolished	9	62.1
Probable total destruction of buildings	10	69.0
Heavy (7000 lb) machine tools moved and badly damaged		
Very heavy (12,000 lb) machine tools survived		
Limit of crater lip	300	2000

[a] These SI values are given by Gugan (1979).

A damage classification which is widely quoted is that by Stephens (1970), who defines the following categories:

Zone	*Damage level*	*Peak side-on overpressure* (kPa)
A	Total destruction	>83
B	Severe damage	>35
C	Moderate damage	>17
D	Light damage	<3.5

The damage levels typical of these zones are such that in A the building may be damaged beyond economical repair, in B it suffers partial collapse and/or failure of some structural members, in C it is still usable but structural repairs are required and in D damage includes broken windows, light cracks in walls and damage to wall panels and roofs.

Fugelso, Weiner and Schiffman have described damage to frame structures from an explosion equivalent of 5001 TNT equivalent. The following data have been quoted in the vulnerability model by Eisenberg, Lynch and Breeding (1975) from this work:

Structural damage (%)	*Peak overpressure*	
	(psi)	(N/m^2)
1 (threshold)	0.9	6,200
50	3.0	20,700
99	5.0	34,500

They derive from these data a probit equation relating structural damage to peak overpressure:

$$Y = -23.8 + 2.92 \ln p^{o} \qquad [17.32.38]$$

where p^{o} is the peak overpressure (N/m^2) and Y is the probit.

In further development of the vulnerability model, Rausch, Eisenberg and Lynch (1977) have dealt with the disintegration of walls and the resultant flying debris. Rausch, Tsao and Rowley (1977) review explosion damage to various types of structure, including frame structures, low office blocks and warehouses. They also give data from Pickering and Bockholt (1971) on explosion damage to process storage such as floating roof tanks, vertical pressure vessels and spherical tanks. The damage levels are quoted at 20% (structural damage) and 99% (total destruction):

Damage level (%)	*Peak overpressure*	
	(psi)	(N/m^2)
Steel floating roof petroleum tank		
20	3.5	24,132
99	20.0	137,895
Vertical cylindrical steel pressure vessel		
20	12.0	82,737
99	14.0	96,527
Spherical steel petroleum tank		
20	8.0	55,158
99	16.0	110,316

A description of the effects of the overpressure in the Flixborough explosion has been given by Sadee, Samuels and O'Brien (1976–77). Among the installations at Flixborough were some storage tanks which were situated about 250 m from the epicentre of the explosion and were severely damaged. It is estimated in the *First Canvey Report* (HSE, 1978b) that, assuming an explosion equivalent to 20–30 t of TNT, the tanks would have been subjected to an overpressure of about 0.1 bar. This overpressure for tank failure is used in the report.

A further account of overpressure damage to various items of plant and transport equipment is given in the study by Gugan (1979).

There is a considerable amount of other data on the effect of air blast on buildings. An overpressure of 1 psi is sufficient to cause partial demolition, whilst one of 10 psi usually causes total destruction.

Table 17.44 is another damage table, given by Scilly and High (1986) for use in estimating damage for explosions with yields in the range 1–100 te TNT equivalent. The preferred approach of these authors is use of R–W or P–I methods, but the table is given for use where data in those forms are not available. The provision of separate data for explosions of different sizes makes some allowance for factors other than overpressure.

A further damage table is given by the CCPS (1994/15).

17.32.7 R-W correlations

An approach to the correlation of structural damage from blast waves now increasingly preferred is the use of a distance–charge, or R–W, correlation. Discussions of the use of the R–W method are given by W.E. Baker *et al.* (1983) and Scffly and High (1986).

The R–W method was effectively used by C.S. Robinson (1944) in his correlation of damage effects. He gives various limits of damage for the explosion of a 100,000 lb charge of high explosive. Some of these are shown in Table 17.45 together with the equivalent scaled distance $R/W^{1/3}$.

Extensive work on the correlation of structural damage to buildings has been done by the Explosives Storage and Transport Committee (ESTC) in the United Kingdom. The aim of the work was the setting of safety distances for the

Table 17.44 *Some damage effects produced by a blast wave – 3 (Scilly and High, 1986) (Courtesy of Societe de Chimie Industrielle; reproduced with permission)*

Structural element	*Failure mode*	*Peak side-on overpressure*[a] *(approximate)* (psi) *at different explosive charge*		
		1 te	10 te	100 te
Window frames	5% broken	0.15	0.1	0.1
	50% broken	0.36	0.24	0.21
	90% broken	0.9	0.6	0.54
Houses	Tiles displaced	0.64	0.42	0.38
	Doors and window frames	1.3	0.86	0.77
	Frames may be blown in			
	Category D damage	0.71	0.44	0.42
	Category Ca damage	1.8	1.15	1.10
	Category Cb damage	4.0	2.4	2.3
	Category B damage	11.5	5.2	5.0
	Category A damage	26.5	11.5	11.0
Telegraph poles	Snapped	52	26	24
Large trees	Destroyed	57	26	24
Primary missiles	Limit of travel	0.2	0.14	0.12
Rail wagons	Limit of derailment	26.5	11.5	11.0
	Bodywork crushed	20	8.7	8.4
	Damaged but easily repairable	11.5	5.7	5.5
	Superficial damage	4.6	2.6	2.5
Railway line	Limit of destruction	205	97	93

[a] All distances (and equivalent overpressures) are measured to the furthest point of the structure from the explosion source.

storage of explosives. The work has been described by Jarrett (1968).

The classification of housing damage used by Jarrett is shown in Table 17.46(B). Jarrett gives the following equation for the determination of the average circle radius for each damage category:

$$R = \frac{kW^{1/3}}{[1 + (7000/W)^2]^{1/6}} \qquad [17.32.39a]$$

where R is the average circle radius for the specified damage category (ft) and W is the mass of explosive in TNT equivalents (lb). The constant k has the values shown in Table 17.47(A). An alternative formulation is to express the circle radius in terms of the RB value, or ratio of the radius to the radius PB for the B damage category, and these ratios also are given in Table 17.47(A). In SI units, Equation 17.32.39a becomes

$$R = \frac{kW^{1/3}}{[1 + (3175/W)^2]^{1/6}} \qquad [17.32.39b]$$

where R is the distance (m) and W is the mass of explosive (kg). The corresponding values of k are given in Table 17.47(B).

The average circle radii define idealized circles for which for a particular damage category the area of houses which suffer that damage outside the circle is balanced by the area of those which do not suffer such damage inside the circle. Definitions of housing damage circles are considered further in Section 17.33.

The use of the R–W method for the correlation of blast damage from VCEs in the TNO correlation model has been described in Section 17.28.

Table 17.45 *Some limits of the effects of the explosion (charge weight 100,000 lb) of a high explosive charge (after C.S. Robinson, 1944)*

Effect	*Limit of effect* (ft)	*Scaled distance* $R/W^{1/3}$ ($\mathrm{ft/lb^{1/3}}$)
Minor damage, inner zone	1,000	21.5
Average serious damage	1,180	25.4
Earthquake damage, normal ground	2,100	45.2
Average missile flight	5,000	108
Minor damage outer zone	10,000	215
Average glass breakage limit	100,000	2150

17.32.8 P–I diagrams

The other preferred approach to the correlation of blast damage is the use of the pressure–impulse, or P–I, diagram.

Table 17.46 *Housing damage categories*

A	**Wartime damage categories (Ministry of Home Security, 1945)**
A	Complete demolition
B	Partial demolition – houses not repairable and will need to be demolished
C	Houses so badly damaged as to be uninhabitable, but are repairable
D	Houses not so badly damaged as to be uninhabitable, but sufficiently so as to cause appreciable discomfort or inconvenience
	Beyond D damage area, there will be considerable amount of minor damage to roof coverings, odd windows, etc.
B	**Jarrett damage categories (Jarrett, 1968)**
A	Almost complete demolition
B	50–75% external brickwork destroyed or rendered unsafe and requiring demolition
Cb	Houawa uninhabitable – partial or total collapse of roof, partial demolition of one to two external walls, severe damage to load-bearing partitions requiring replacement
Ca	Not exceeding minor structural damage, and partitions and joining wrenched from fittings
D	Remaining inhabitable after repair – some damage to ceilings and tiling, more than 10% window panes broken
C	**Damage categories given by Scilly and High (1986)**
A	House completely demolished, i.e. with over 75% of the external brickwork demolished
B	Houses so badly damaged that they are beyond repair and must be demolished when opportunity arises. Property is included in this category if 50–75% of the external brickwork is destroyed, or in the case of less severe destruction the remaining walls have gaping cracks rendering them unsafe
Cb	Houses which are rendered uninhabitable by serious damage, and need repairs so extensive that they must be postponed until after the war. Examples of damage resulting in such conditions include partial or total collapse of roof structures, partial demolition of one or two external walls up to 25% of the whole, and severe damage to load-bearing partitions necessitating demolition and replacement
Ca	Houses that are rendered uninhabitable, but can be repaired reasonably quickly under wartime conditions, the damage sustained not exceeding minor structural damage, and partitions and joinery wrenched from fixings
D	Houses requiring repairs to remedy serious inconveniences, but remaining habitable. Houses in this category may have sustained damage to ceilings and tilings, battens and roof coverings, and minor fragmentation effects on walls and window glazing. Cases in which the only damage amounts to broken glass in less than 10% of the windows are not included

Table 17.47 Constants and RB distances for the Jarrett equation

Damage category	*Constant, k*	*RB ratio*
A Eauation constants (British units) and RB ratios (Jarrett, 1968)		
A	9.5	0.675
B	14	1
Cb	24	1.74
Ca	70	5
D	140	10
B Equation constants (SI units) and RB ratios (after Jarrett, 1968)		
A	3.8	0.675
B	5.6	1
Cb	9.6	1.74
Ca	28	5
D	56	10
C Equation constants (SI units) and RB ratios (Gilbert, Lees and Scilly, 1994c)		
A	4.8	0.675
B	7.1	1.00
Cb	12.4	1.74
Ca	21.3	3.0
D	42.6	6.0

A P–I diagram given by W.E. Baker *et al.* (1983) for some of the Jarrett damage categories is shown in Figure 17.93. This diagram is considered further in Section 17.33.

The use of the P–I diagram method is inhibited by the fact that there are few P–I diagrams available in the literature.

17.32.9 Window damage

The shattering of glass is an important blast damage effect, since flying glass can cause severe injury. It is considered in Section 17.40.

17.33 Explosion Damage to Housing

Explosion damage to housing is usually expressed in the form of distance-charge, or R–W, relations or of pressure–impulse, or P–I, relations. In the description just given of these two methods the application considered is housing damage.

The ESTC, or Jarrett, equation (Equation 17.32.39a) has for some decades held the field as the principal method of determining housing damage, but within the last decade several proposals have been made for the modification of this basic R–W correlation or its associated P–I diagram, including the work of Scilly and High (1986) and Gilbert, Lees and Scilly (1994b,c).

Before considering this more recent work it is appropriate to consider the background to the Jarrett equation.

17.33.1 Housing damage categories

During the Second World War it became the practice in the United Kingdom to assign air raid housing damage to the categories A, B, Cb, Ca and D.

There are several definitions of these categories, as shown in Table 17.46. Table 17.46(A) gives the definitions used in report S104, one of the wartime reports of the Ministry of Home Security (1945). A slightly different set of definitions is given in the paper by Jarrett (1968) describing explosives safety distances as shown in Table 17.46(B). Table 17.46(C) from Scilly and High (1986), contains further amplification of the definitions.

Some wartime reports use an undifferentiated C damage category to describe Cb damage.

17.33.2 Philip equation

In an analysis of wartime damage the following equation was derived in a Ministry of Works report REN 558 by Philip (1945) for the distance PB lor B category damage. In the original British units the equation is

$$R_B = \frac{14W^{1/3}}{[1 + (7000/W)^2]^{1/6}} \qquad [17.33.1a]$$

where R is the distance (ft) and W is the mass of explosive (lb). In SI units this equation is

$$R_B = \frac{5.6W^{1/3}}{[1 + (3175/W)^2]^{1/6}} \qquad [17.33.1b]$$

where R is the distance (m) and W is the mass of explosive (kg). The mass of explosive is quoted as the TNT equivalent. This equation was adopted as a standard.

Gilbert, Lees and Scilly (1994c) have reviewed the basis of Equation 17.33.1a as described by Philip (1945). They conclude that although she referred to the mass of explosive in several weapons and incidents in terms of the TNT equivalent, she appears to have used in the equation a mass of explosive W which is the actual mass of explosive and to have based the equation on data for SC bombs, all of which had the same charge/weight ratio, so that strictly speaking the equation is applicable only to this family of weapons. For other weapons she gives a set of calibration constants, or correction factors.

Equation 17.33.1a was effectively endorsed in a report to the ESTC by Healy (1959), who applied it to a large number of incidents.

17.33.3 Jarrett equation

The paper by Jarrett (1968), already mentioned, was the first open publication of, and gave wider currency to, Equation 17.33.1a. He also gave explicit constants for the A, Cb, Ca and D damage categories. In British units, Jarrett's equation is

$$R = \frac{kW^{1/3}}{[1 + (7000/W)^2]^{1/6}} \qquad [17.33.2a]$$

where R is the distance (ft) and W is the mass of explosive (lb). In SI units this equation is

$$R = \frac{kW^{1/3}}{[1 + (3175/W)^2]^{1/6}} \qquad [17.33.2b]$$

where R is the distance (m) and W is the mass of explosive (kg). Equation 17.33.2a is frequently referred to as the

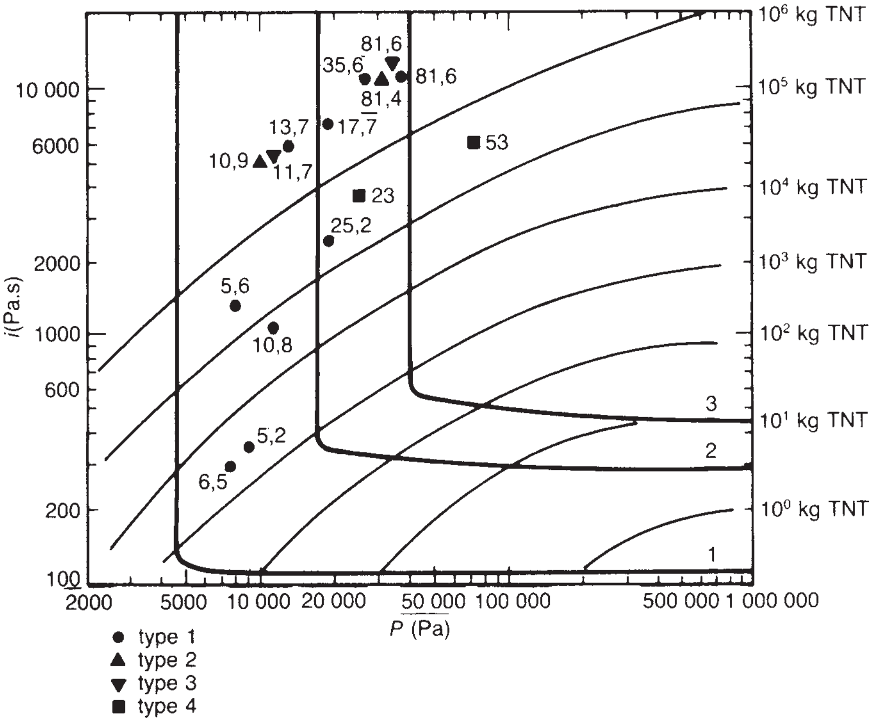

Figure 17.93 *Damage effects of explosions: P–I diagram for housing damage – 1 (after W.E. Baker et al., 1983; Merck, Weerheijm and Verhagen, 1993). Curves are those given by the first set of authors and are as follows: curve 1, threshold for minor structural damage; curve 2, threshold for major structural damage; and curve 3, threshold for partial demolition. Experimental points are those given by the second set of authors and refer to the percentage damage (expressed as building costs) for house types 1–4: type 1, two-floor wooden house; type 2, two-floor masonry house; type 3, single-floor wooden house; and type 4, two-floor masonry house*

Jarrett equation. The values of the constant k given in British units by Jarrett and the SI equivalents are given in Table 17.47 (A) and (B) respectively. The RB ratios are also given.

Equation 17.33.2a was given by Jarrett in a paper on explosives safety distances. He states that his equation is derived from an analysis by the ESTC of 24 well-documented explosions and from the study of records of explosions dating from 1871 and from the experience of enemy bombing in the United Kingdom. He also mentions another examination by the ESTC of 110 reports of accidental explosions. He further states that the quantity of explosive involved ranged from 300 lb to 5.3 million lb, and the types of explosive included dynamite, TNT, Torpex and guncotton. However, Jarrett seemingly overlooked the fact that Equation 17.33.1a was derived for the specific case of SC bombs. The effect of this is that Equation 17.33.2a purports to apply to weapons in general but does not in fact allow for the effect of the weapon casing on the blast potential.

With regard to the constants quoted by Jarrett, these appear to derive from the paper by Healy. Copies of this paper contain hand-written notes suggesting values of the constants for all the damage categories (A–D). For A, B and Cb damage these values are those of Philip. The latter does not, however, give values for Ca and D damage. The values for Ca and D damage of $R_B = 5$ and $R_B = 10$, respectively, quoted by Jarrett, are evidently taken from the hand-written notes in Healy's paper. In the text of this paper, however, these R_B values refer to window breakage rather than housing damage.

Summarizing, the Jarrett equation – Equation 17.33.2a – is in effect the Philip equation – Equation 17.33.1a – as endorsed by Healy, but with extensions to other damage categories as just described.

17.33.4 Housing damage circles

The radius used in Equation 17.33.2 is the average circle radius (ACR) for the damage category. It is defined as the radius of the circle such that the number of houses inside the circle which do not suffer the defined degree of damage is balanced by the number outside which do; this radius is denoted here as $R_{100/0}$. Use is sometimes made of another radius, R_{50}, the radius at which there is a 50% probability of a defined degree of damage. Conceptually, these two radii are quite distinct. In practice, they will often have similar numerical values. They converge where the intensity of the physical phenomenon decays rapidly and where its effect on the target passes through a narrow zone from 0 to 100% effect. A quantitative treatment has been given by Lees, Poblete and Simpson (1986).

It is convenient to mention at this point another method of expressing housing damage. This is the use of the following relation to obtain from the observed values of R_A, R_B and R_C an average value $\bar{R}_\mathrm{B}$:

$$\bar{R}_\mathrm{B} = \frac{1}{3}\left(\frac{R_\mathrm{A}}{0.675} + \frac{R_\mathrm{B}}{1.0} + \frac{R_\mathrm{C}}{1.74}\right) \qquad [17.33.3]$$

17.33.5 Model of Gilbert, Lees and Scilly

A revision of the Jarrett equation has been undertaken by Gilbert, Lees and Scilly (1994b,c), based on analysis of the original wartime documents for damage from bombs, V-1 flying bombs and V-2 rockets.

These authors first analyse the effective charge of the various weapons used, allowing for the particular explosive filling and for the effect of the casing. They then analyse the damage done by each type of weapon.

From this analysis they conclude that for B category damage the value of the constant *k* to be used in Equation 17.33.2b in SI units should be 7.1 instead of 5.6. They also give revised values of the constant for the other damage categories, as shown in Table 17.47(C).

It may be noted that whereas the *k* values for A, B and Cb category damage are somewhat higher than those given by Jarrett, the values for Ca and D damage are less. The KB values for A, B and Cb damage are the same but those for Ca and D damage are less. These latter values agree with those proposed by Scilly and High (1986) in an earlier critique.

The model of Gilbert, Lees and Scilly is therefore Equation 17.33.2b with the constants given in Table 17.47(C). In terms of the R_B distance this equation is

$$R_\mathrm{B} = \frac{7.1W^{1/3}}{[1 + (3175/W)^2]^{1/6}} \qquad [17.33.4]$$

where R is the distance (m) and W is the mass of explosive (kg).

Some characteristics of the revised equation are illustrated in Table 17.48.

17.33.6 P–I diagrams

The housing damage correlations just given are R–W correlations. As described above, it is also possible to correlate housing damage in terms of a P–I diagram.

The P–I diagram for housing damage based on the Jarrett equation given by W.E. Baker *et al.* (1983) has been given above as Figure 17.93. This diagram is reproduced in the *Green Book*.

This same diagram has been quoted by Mercx, Weerheijm and Verhagen (1991), who have plotted on it data from experimental tests detailed by Glasstone and Dolan (1980). These data also are shown in Figure 17.93. The figure shows iso-damage curves for B, Cb and Ca category damage.

The corresponding P–I diagram given by Gilbert, Scilly and Lees, constructed from the data in Table 17.48, is shown in Figure 17.94. The figure shows iso-damage curves for A, B and Cb category damage.

In Figure 17.94, the influence of the two variables, peak overpressure and impulse, may be examined by moving orthogonally from a curve for a category of less severe damage to that for the next most severe category. The iso-damage curves have peak overpressure and impulse asymptotes. On the right-hand side of the diagram, in the region of lower charge weights, the curves exhibit impulse symptotes. In moving orthogonally from a lower damage to a higher damage curve, there is an increase in impulse but not in overpressure. In other words, in this region an increase in damage occurs due to an increase in impulse. By contrast, in the top left region of the diagram, that of higher charge weights, the curves exhibit overpressure asymptotes. In moving orthogonally from a lower damage to a

Effective charge (kg)	R_B *distance* (m)	*Scaled distance* (m/kg$^{1/3}$)	*Peak overpressure* (Pa)	*Impulse* (Pa s)
100	10.4	2.24	2.19×10^5	606
200	16.5	2.82	1.32×10^5	609
500	30.3	3.82	0.717×10^5	614
1,000	47.6	4.76	0.473×10^5	623
2,000	72.5	5.76	0.340×10^5	650
5,000	115	6.71	0.266×10^5	759
10,000	151	6.99	0.250×10^5	917
20,000	192	7.07	0.245×10^5	1140

[a] Revised equation for housing damage: some characteristics of damage circle equation for B damage.

higher damage curve, there is an increase in overpressure but not in impulse. In other words, in this region an increase in damage occurs due to an increase in overpressure. Transition occurs in the region where the charge weights are between 2000 and 5000 kg.

Thus, for many charge weights of interest both peak overpressure and impulse are relevant. For this reason housing damage is correlated by Gilbert, Lees and Scilly directly in terms of charge weight rather than in terms of overpressure.

For the same reason they take the scaled distance appropriate to housing damage as

$$z' = \frac{R}{W^{1/3}[1 + (3175/W)^2]^{1/6}} \qquad [17.33.5]$$

where z' is a modified scaled distance (m/kg$^{1/3}$).

17.34 Explosion Damage by Missiles

If the explosion occurs in a closed system, fragments of the containment may form missiles. In addition, objects may also be turned into missiles by the blast.

Accounts of missiles are given in *Explosions, Their Anatomy and Destructiveness* (C.S. Robinson, 1944), *Structural Defence* (Christopherson, 1946), the *Textbook of Air Armaments* (Ministry of Supply, 1952) and *Explosion Hazards and Evaluation* (W.E. Baker *et al*,. 1983) and by V.J. Clancey (1972b), Jensen (1972), W.E. Baker *et al.* (1975, 1978), Holden and Reeves (1985) and Pietersen (1985).

Brown (1985) reviewed studies on blast and fragmentation of pressurized vessels.

Much of the early work on missiles relates to artillery and other projectiles. Basic work in the field is described by Didion (I860), Helie (1884), Petry (1910) and Cranz and Becker (1921). Further work by the military on ballistics includes that of Gurney (1943, 1946). Other data derive from civil defence work such as that of Christopherson (1946).

Studies have also been made of missiles from the bursting of gas filled vessels in relation to aerospace systems and nuclear power plants. These include work by D.E. Taylor and Price (1971), Pittman (1972a,b, 1976), Bessey (1974), Bessey and Kulesz (1976), W.E. Baker *et al.* (1975, 1978) and Garrison (1975).

A significant source of large missiles in process plant incidents is BLEVEs. Studies of the missiles from such sources have been described by Holden and Reeves (1985) and Pietersen (1985).

17.34.1 Some incidents involving missiles

The generation, size and range of missiles, and the damage which they can cause, have already been discussed to some extent above, mainly in relation to BLEVEs.

Table 17.49 gives some major incidents which involved either escalation by missiles or near misses.

17.34.2 Sources, types and generation of missiles

Missiles are generally classified as primary and secondary. Primary missiles are those resulting from the bursting of a containment so that energy is imparted to the fragments which become missiles. Secondary missiles occur due to the passage of a blast wave which imparts energy to objects in its path, turning them into missiles. Missiles from the bursting of a wall due to an internal explosion are treated here as primary missiles.

Accounts of the source, types and generation of primary missiles include those of Ardron, Baum and Lee (1977), J.H. Bowen (1980), Munday (1980), Porter (1980), Tulacz and Smith (1980) and W.E. Baker *et al.* (1983).

As far as concerns primary missiles from plant, three cases are commonly distinguished: case 1, bursting of a vessel into a large number of relatively small fragments; case 2, separation and rocketing of a vessel or vessel end; case 3, ejection of a single item.

17.34.3 Vessel burst pressure

The explosion energy imparted to fragments in a vessel burst is a function of the initial pressure. The various different scenarios for vessel burst pressure have been discussed in Sections 17.27 and 17.29.

17.34.4 Number and size of missiles

The number of missiles formed in an explosion involving rupture of a containment varies widely. At one extreme is the bursting of a weapon such as high explosive shell or grenade which normally gives a large number of fragments. Large numbers of missiles are also produced by fragmentation of a gas filled pressure vessel. At the other extreme is the ejection of a single item such as a valve component due to failure in a high pressure system.

Of particular interest here is rupture of a pressure vessel. This may involve either brittle or ductile fracture. The differences between these two modes of failure are discussed by Tulacz and Smith (1980). In general, failure is more likely to be ductile. Ductile failure does not usually produce missiles, but if it does they are likely to be small in number but may have potential to do severe damage. It is brittle fracture which is most likely to produce failures in which quite a large number of fragments are generated.

Failure of a vessel may occur under normal pressure loading due to an existing defect or to weakening or it may occur under abnormal pressure such as excessive gas pressure or hydrostatic pressure due to liquid expansion or explosion pressure due to combustion or reaction runaway.

In a cylindrical vessel the initiating crack is typically in the axial direction, but there is a tendency for this crack to turn and propagate circumferentially.

As already stated, for rupture of a gas filled vessel, two main modes are distinguished: (1) bursting into a large number of fragments and (2) separation into two parts. In the former case it is a common assumption that the fragments all have the same mass.

If more refined information is available, it may be correlated as a fragment mass distribution. Methods of correlation are discussed in Section 17.36.

There is some limited information available on the number of fragments formed in the bursting of pressure vessels. W.E. Baker *et al.* (1978) have compiled data on the number and size distribution of fragments for 25 accidental bursts as shown in Table 17.50. The corresponding fragment mass distributions for some of the event groups are shown in Figure 17.95.

Another such compilation is that of Scilly and Crowther (1992). This work is described in Section 17.34.21.

For BLEVEs, Schulz-Forberg, Droste and Charlett (1984) have described tests on fire engulfed vessels, one output from which is plots of the fall of fragments.

Table 17.49 *Some incidents involving escalation, or near misses, by missiles*

Marrietta, OH, 1962
Benzene vapours from a 6 in. relief valve on a phenol plant ignited and an explosion occurred. Flying debris ruptured pipework, releasing flammable liquids.

Louisville, KY, 1965
A compressor circulating gaseous monovinylacetylene exploded. Fragments from the explosion, together with jet flames and transmission through piping, led to a series of further explosions.

Feyzin, France, 1966
A refinery storage sphere suffered a BLEVE, throwing pieces of steel up to 100 tons some three quarters of a mile. One fragment cut the legs from under an adjacent sphere, toppling it and breaking its 8 in. connecting pipe. Another landed on a pipeway and severed 40 lines.

Texas City, TX, 1969
A 100 ft high refinery column disintegrated, apparently due to detonation of vinyl acetylene. Pieces were distributed uniformly over a radius of 1500 ft. One section weighing some 800 lb travelled 3000 ft.

Romeoville, IL, 1977
Roof fragments from an exploding cone roof tank in a refinery struck a covered floating roof tank and a floating roof tank, both of which ignited.

Abqaiq, Saudi Arabia, 1978
Jetting effects of gas escaping from a pipeline threw a 22 ft pipe section 400 ft, where it struck the vapour space of a storage spheroid and released further flammable vapour.

Texas City, TX, 1978
Rupture of a refinery storage sphere due to overpressure led to a large vapour cloud fire. This set off a series of BLEVEs which generated numerous missiles, causing further vessel failures. In addition the original sphere, two further spheres, five horizontal bullets and four vertical bullets were destroyed.

Bantry Bay, Eire, 1979
Explosions on an oil tanker at the jetty generated numerous missiles. One fragment weighing 1000 Il was found at the foot of a large crude oil storage tank 1800 ft from the ship.

Linden, NJ, 1979
A vapour cloud entered an unused control room. When the cloud exploded, debris from this building severed pipes, releasing more hydrocarbons.

Ponce, Puerto Rico, 1979
A 13 ft diameter dimerizer vessel suffered massive failure. The 15 ton steel end travelled 1900 ft and struck an adjacent paraxylene plant, setting it on fire.

Mexico City, Mexico, 1984
See Appendix 4.

Romeoville, IL, 1984
A massive failure occurred of a 55 ft high ×8 ft diameter refinery absorption column. Most of the vessel was propelled 3500 ft where it struck and toppled a 138 kV power transmssion tower. Later in the incident, a piece of a vessel which had suffered a BLEVE travelled 500 ft. shearing off pipes.

Pascagoula, MS, 1986
Fragments, from an explosion in the area of a batch still, punctured two atmospheric storage tanks and a pressure storage vessel, releasing flammable material.

Grangemouth, UK, 1987
Overpressure of a low pressure separator due to gas 'breakthrough' caused the 30 ft high times 10 ft diameter vessel to disintegrate. One piece weighing 3 tons was thrown 3300 ft.

Torrance,CA, 1987
A propane treater vessel failed and rocketed into a central pipe rack, cutting several pipes, including the refinery flare lines.

Antwerp, Belgium, 1989
An explosion on an ethylene oxide distillation column caused a large fire and generated missiles which caused extensive damage throughout the plant

***Table 17.50** Behaviour of fragments in some vessel explosions – 1 (W.E. Baker et al., 1978)*

Event group	*No. of events*	*Material*	*Source energy* (J)	*Vessel details*		*No. of fragments*
				Shape	*Mass* (kg)	
1	4	Propane, anhydrous ammonia	$1.49–5.95 \times 10^5$	Rail tank car	25,542–83,900	14
2	9	LPG	3814–3921	Rail tank car	25,464	28
3	1	Air	5.2×10^{11}	Cylinder pipe and spheres	145,842	35
4	2	LPG, propylene	550	Semitrailer (cylinder)	6,343–7,840	31
5	3	Argon	$244–1133 \times 10^{10}$	Sphere	48.3–187	14
6	1	Propane	24.8	Cylinder	512	11

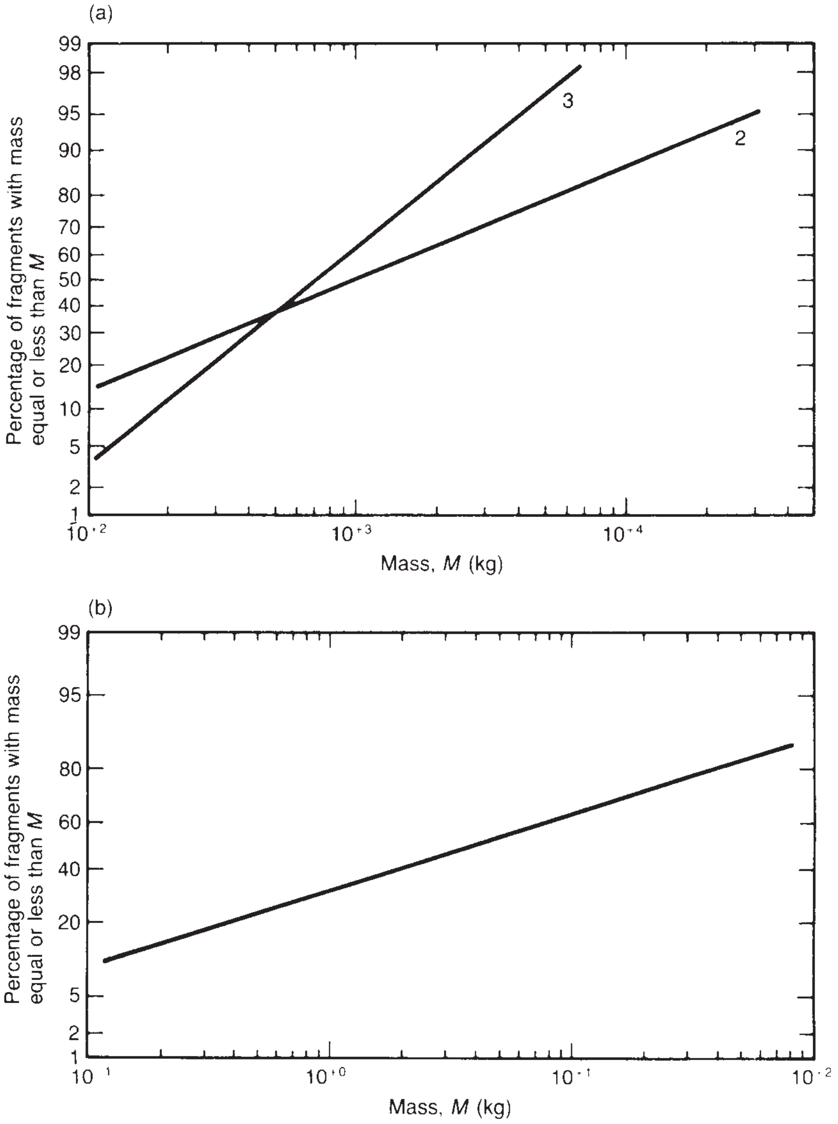

***Figure 17.95** Missile effects of explosions – fragment mass distribution from some accidental events (W.E. Baker et al., 1978): (a) event groups 2 and 3 and (b) event group 6*

A specific study of fragments from BLEVEs has been made by Holden and Reeves (1985). For non-fire events they found that there were three events which gave one fragment, one giving two fragments, one giving three fragments, two giving four fragments and one giving seven fragments. Further information is given in Section 17.34.19.

17.34.5 Initial velocity of missiles

There are a number of different approaches to the estimation of the initial velocity of a missile. They include consideration of (1) the force or pressure on the missile, (2) the transfer of momentum to the missile, and (3) the transfer of energy to the missile.

The force acting on a missile depends on the scenario. Considering first the rupture of a pressure vessel containing gas, the overpressure may occur due to a slow application of pressure or due to an explosion which gives a very high rate of pressure rise. The bursting of the vessel gives rise to a shock wave. In principle, there are two forces which act to accelerate the fragments from the vessel. One is the differential between the gas pressure and the ambient pressure. The other is the dynamic pressure, or wind. In practice, as described below, the pressure differential acts only for a very short time, and the acceleration of the fragments is due essentially to the dynamic pressure.

Another scenario is the rupture of a partition wall by an explosion. Again, the forces acting on the fragments from the wall are the pressure differential between the front face of the wall and the ambient pressure and the dynamic pressure. In principle, if the pressure incident on the wall is that of a rapidly rising blast wave and the wall configuration is such that the pressure differential across it persists until the wall ruptures, the relevant pressure is the reflected pressure. If, on the other hand, the pressure on the wall rises relatively slowly, the pressure differential is simply that between that pressure and the ambient pressure. In practice, in either case, the pressure differential again usually acts only for a very short time and the acceleration of the fragments is due mainly to the dynamic pressure.

Another approach for the bursting of a gas filled vessel is to estimate the fraction of the available energy which is converted into the kinetic energy of the fragments. This approach echoes that used in the treatment of fragments from weapons.

For the ejection of an item such as a valve spindle by a high pressure jet of fluid, an approach based on conservation of momentum is convenient.

Some of the methods for the estimation of missile acceleration and initial velocity are now considered.

17.34.6 Initial velocity of missiles: fragmentation of a gas filled vessel

For missile acceleration and initial velocity, the first case considered (case 1) is that of the bursting of a gas filled vessel into a large number of fragments. Accounts of this include those of C.V. Moore (1967), D.E. Taylor and Price (1971), Ardron, Baum and Lee (1977), Munday (1980) and Baum (1984, 1987). Experimental work is described by Glass (1960) and Pittman (1972a,b).

An account of the initial velocity of fragments from vessels has been given by Ardron, Baum and Lee (1977). They distinguish two main fundamental treatments, one based on the stored energy and the other on fluid mechanics. The models of C.V. Moore (1967) and Munday (1980), given in Sections 17.34.7 and 17.34.8, respectively, exemplify these two approaches. Another family of methods, also based on fluid mechanics, has developed from a model of D.E. Taylor and Price (1971), who studied the rocketing of the two hemispheres from the symmetrical rupture of a sphere. This work was developed by Bessey (1974), Bessey *et al.* (1976) and W.E. Baker *et al.* (1978), who extended it, respectively, to cases of spheres giving more than two equal fragments, cylinders giving multiple equal fragments and both spheres and cylinders giving multiple unequal fragments.

This work has indicated that the fraction of the energy of explosion which translates to kinetic energy of the fragments is relatively low. A more realistic model of this energy has been developed by Baum (1984), as described in Section 17.34.9.

A variant of the problem of the bursting of a gas filled vessel is the rupture of a pipe. Since the pipe is usually part of a pressure system to which it is connected, it is much less easy in this case to define the relevant available fluid energy.

17.34.7 Initial velocity of missiles: Moore model

In the stored energy, or energy partition, method the initial kinetic energy, and velocity, of the fragments is obtained from the energy stored in the vessel. This method has been used by C.V. Moore (1967). The stored energy is obtained by methods such as those given in Section 17.4. Then

$$\frac{M_v u_i^2}{2} = E_f M_f \qquad [17.34.1]$$

where E_f is the energy stored in the vessel per unit mass of fluid, M_f is the mass of fluid stored, M_v is the mass of the vessel itself and u_i is the initial velocity of the fragment. Then

$$u_i = (2E_f M_f / M_v)^{1/2} \qquad [17.34.2]$$

The assumption underlying Equation 17.34.1 is that all the fragments have the same velocity. Some support for this is given in the observations of Glass (1960) and Pittman (1972a) that when a vessel breaks into many pieces, fragments moving in different directions attain comparable terminal velocities.

Moore has also given for the initial velocity of fragments from vessels semi-empirical formulae which are extensions of the well-known formula of Gurney (1946) for the initial velocity of fragments from a cased explosive. His formula is

$$u_i = 1.1(E_f K)^{1/2} \qquad [17.34.3]$$

with

$$K = \frac{M_f}{M_v(1 + 3M_f/5M_v)} \quad \text{sphere} \qquad [17.34.4]$$

or

$$K = \frac{M_f}{M_v(1 + M_f/2M_v)} \quad \text{cylinder} \qquad [17.34.5]$$

where K is a geometric factor.

Ardron, Baum and Lee have compared the predictions of Equations 17.34.2 and 17.34.3 with experimental results for the bursting of a sphere containing superheated water. For this case, Equations 17.34.2 and 17.34.3 overestimate the measured fragment velocities by factors of 5 and 4, respectively. In other words, in this case only about 3% of the fluid energy is imparted to the fragments.

The relations for the available energy of fluid filled vessels given in Section 17.4 yield results which show that the available energy of a gas filled vessel exceeds by an order of magnitude that of a similar liquid filled vessel. Hence, the above result for the water filled vessel is not unexpected. However, Ardon, Baum and Lee also report that even for a gas filled vessel agreement between the measured velocities and the predictions of Equation 17.34.2 was only slightly better than for the water filled case. It would seem, as the authors suggest, that Equation 17.34.2 should be regarded as giving an upper bound on the initial velocity.

17.34.8 Initial velocity of missiles: Munday model

An alternative approach based on the fluid mechanics of the shock wave has been described by Munday (1980). In this model the process of acceleration is envisaged as occurring in the following way. When the vessel ruptures, there is a phase in which the fragment is accelerated by the pressure differential between the gas and the surrounding air, but the duration of this phase is very short, being related to the time for a sound wave to traverse the fragment. Thus, the fragment is surrounded by moving gas before an appreciable increase in velocity has occurred.

The acceleration is caused by the dynamic pressure, or wind. The equation of motion of the fragment may be written as

$$m\frac{\mathrm{d}u}{\mathrm{d}t} = C_{\mathrm{D}}A\rho_{\mathrm{g}}(u_{\mathrm{g}} - u)^2 \qquad [17.34.6]$$

where A is the mean presented area of the fragment, C_{D} is the drag coefficient, m is the mass of the fragment, u is the velocity of the fragment, u_{g} is the velocity of the surrounding gas and ρ_{g} is the density of that gas.

The velocity of the surrounding gas is related to that of the shock front. This latter velocity is determined using an empirical model. The velocity of the surrounding gas is then obtained assuming that it falls linearly from that at the shock front to 0 at a distance halfway between the shock front and the centre of the vessel.

Methods are available for the characterization of the shock front in the bursting of a vessel. Brinkley and Kirkwood (1961) have given a theoretical model. Ardron, Baum and Lee (1977) have plotted the experimental results on bursting of gas filled vessels of Larsen and Olson (1957) and Pittman (1972a) to show the extent to which they fit a TNT equivalent model; the fit is fair with considerable scatter.

17.34.9 Initial velocity of missiles: explosion energy

Expressions for the energy of explosion in a vessel burst are given in Section 17.4. The two principal relations are the Erode equation (Equation 17.4.29) and the Baker equation (Equation 17.4.31).

However, it is apparent from the foregoing that only a fraction of the energy of explosion appears as kinetic energy of the fragments. This has long been appreciated. Various estimates of this fraction are available in the literature. Those given in the *High Pressure Safety Code* have been quoted in Section 17.4. Another value given by Porter (1980) is some 5–10%.

The above problem has been addressed by Baum (1984), who takes as his starting point the Baker equation (Equation 17.4.31), written in the form

$$E_{\mathrm{k}} = k\frac{P_1 V_1}{\gamma_1 - 1} \qquad [17.34.7]$$

with

$$k = 1 - \left(\frac{P_{\mathrm{o}}}{P_1}\right)^{(\gamma-1)/\gamma} \qquad [17.34.8]$$

where E_{k} is the explosion energy imparted to the fragments and k is a parameter. Baum then treats k as a constant to be evaluated. From experimental data reported in the literature he found the value of k to vary between 0.2 and 0.5. On this basis the CCPS (1994/15) proposes that for rough initial calculations a value of $k = 0.2$ be used.

As stated, the foregoing applies to a vessel filled with an ideal gas. As described in Section 17.4, if this is not the case, the energy of explosion is affected. If the fluid is not an ideal gas but is instead a non-ideal gas, vapour or flashing liquid, the energy of explosion should be obtained from thermodynamic data using the method given in Section 17.4.

The CCPS refers to work by Wiederman (1986a,b) on cases involving non-ideal gases and vapour and vapour–liquid systems. In general, the effect of gas non-ideality is to reduce somewhat the initial velocity of the fragments. In some limited tests, the effect of a flashing liquid was found to cause some increase in fragment velocity compared with an ideal gas fill. For this case the CCPS quotes the fraction of the energy of explosion, estimated from thermodynamic data, which translated to kinetic energy of fragments as some 20%

17.34.10 Initial velocity of missiles: separation and rocketing of a gas filled vessel

The second case (case 2) is that of the separation of a gas filled vessel into two parts and the rocketing of one or both of these.

The two parts which separate may be two equal halves such as the two hemispheres of a spherical vessel or two unequal ones such as the end and body of a cylindrical vessel. In either case the rapid discharge of fluid results in a strong reaction force on the separating parts of the vessel.

Models for this situation have been given by D.E. Taylor and Price (1971) and Tulacz and Smith (1980).

The model of Tulacz and Smith (1980) is a single equation for conservation of momentum. The authors give the following illustration of the results obtained. For an autoclave of volume 0.238 m^3 and mass 3131 kg at a pressure of 41.38 bara, from which the head, with area 0.114 m^2 and mass 598 kg, blows off the initial discharge produces a rapid initial acceleration but the velocity attained is only 12 m/s.

17.34.11 Initial velocity of missiles: model of Baker *et al.*

As already mentioned, another method of estimating the initial velocity of fragments from a vessel burst has been developed by W.E. Baker *et al.* (1975, 1978), and is described

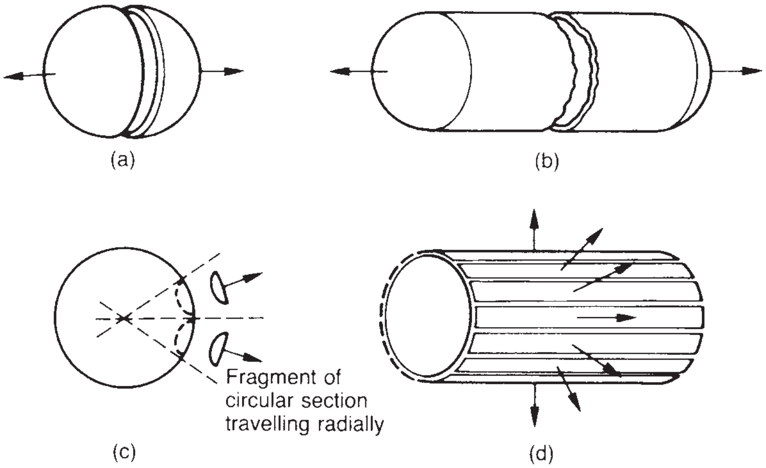

***Figure 17.96** Missile effects of explosions – generation of missiles from vessels (W.E. Baker et al., 1983): (a) sphere bursting into two equal fragments; (b) cylinder bursting into two equal fragments; (c) sphere bursting into n equal fragments; and (d) cylinder bursting into n equal strip fragments (Courtesy of Elsevier Science Publishers)*

by W.E. Baker *et al.* (1983). The method covers spherical and cylindrical vessels breaking into two equal fragments or into n equal fragments as shown in Figure 17.96. The velocities are obtained from a parametric study based on the equations of motion of the fragments, solved using a computer code. The results are correlated in terms of a dimensionless pressure P defined as

$$\bar{P} = \frac{(p - p_o)V_o}{M_c a_g} \qquad [17.34.9]$$

and a dimensionless initial velocity $\bar{u}_i$

$$\bar{u}_i = \frac{u_i}{K a_g} \qquad [17.34.10]$$

with

$$a_g = (\gamma R_m T)^{1/2} \qquad [17.34.11]$$

where a_g is the velocity of sound in the gas, M_c is the mass of the vessel, p is the pressure in the vessel, p_o is atmospheric pressure, R_m is the mass basis gas constant, T is the absolute temperature of the gas, u_i is the initial velocity of the fragment, V_o is the volume of the vessel, V is the ratio of the gas specific heats and K is a constant.

For equal-sized fragments, K is unity. The correlation obtained is shown in Figure 17.97(a).

These authors also give a method of estimating the initial velocity of a fragment from a cylindrical vessel with a length/diameter, or L/D, ratio of 10 breaking into two unequal parts. For this case the constant K is determined using Figure 17.97(b). The initial velocity is then obtained as before from Figure 17.97(a) with this value of K and taking n as 2.

The CCPS (1994/15) draws attention to some apparent discrepancies which cast doubt on the factor K.

17.34.12 Initial velocity of missiles: Baum model

Another method for the initial velocity of fragments from a vessel burst is that of Baum (1987), who gives a set of empirical correlations. He treat the following cases: (1) end cap breaking from a cylindrical vessel, (2) cylindrical vessel breaking into two parts in a plane perpendicular to its axis, (3) disintegration of a spherical or cylindrical vessel into multiple fragments, and (4) a single small fragment ejected from a vessel. The first three of these are considered here, and the last in the next section.

The relations given by Baum utilize a parameter F which is defined as

$$F = \frac{(P_1 - P_o)r}{m a_o^2} \qquad \text{large no. of fragments} \qquad [17.34.12]$$

$$F = \frac{(P_1 - P_o)Ar}{m_f a_o^2} \qquad \text{small no. of fragments} \qquad [17.34.13]$$

where a_o is the speed of sound, A is the area of the detached portion of the vessel wall, m is the mass per unit area of the vessel wall, m_f is the mass of the fragment, P_o is the atmospheric pressure, P_1 is the absolute initial pressure in the vessel and r is the radius of the vessel.

The correlations for the three cases referred to are then

$$u_i = 2 a_o F^{0.5} \qquad [17.34.14]$$

$$u_i = 2.18\, a_o [F(L/r)^{1/2}]^{2/3} \qquad [17.34.15]$$

$$u_i = 0.88\, a_o F^{0.55} \qquad [17.34.16]$$

where L is the length of the cylinder. In Equation 17.34.15 F is obtained using $A = \pi r^2$.

17.34.13 Initial velocity of missiles: ejection of a plant fitting

The third case considered here (case 3) is the ejection of a fitting such as a valve stem by a high pressure jet of gas.

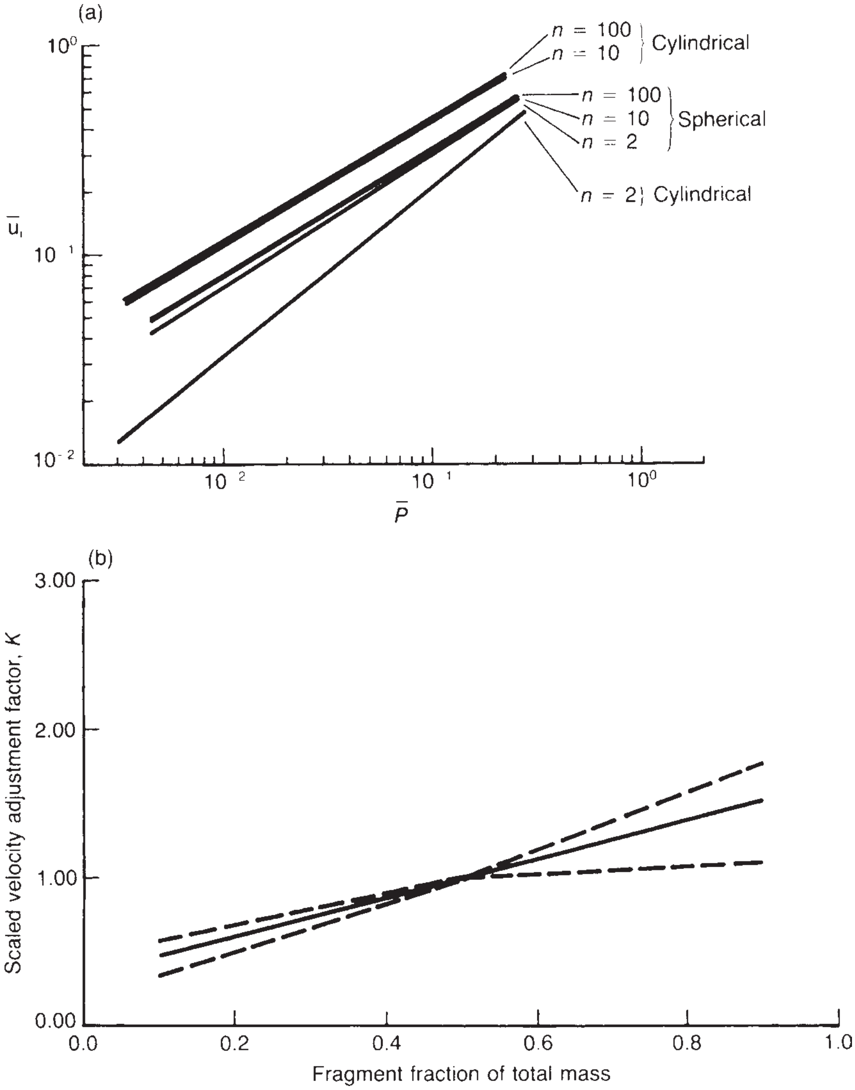

***Figure 17.97** Missile effects of explosions – initial velocity of fragments from a bursting vessel (W.E. Baker et al., 1983): (a) initial velocity correlation and (b) velocity adjustment factor for unequal masses (Courtesy of Elsevier Science Publishers)*

This is a relatively well-defined situation, and modelling based on fluid mechanics is appropriate. Models have been developed by a number of workers, including Cottrell and Savolainen (1965), Gwaltney (1968) and Ardron, Baum and Lee (1977).

The usual approach is based on momentum transfer. The momentum of the jet is assumed to be transferred to the missile and the residual momentum of the jet is neglected.

Gwaltney (1968) has given a number of simple analytical methods for particular cases of ejection of fittings by a jet of gas.

Ejection of a small fragment from a cylindrical vessel is one of the cases treated by Baum as described in the previous section. For this case he gives

$$u_i = 2a_o\left(\frac{F_S}{r}\right)^{0.38} \qquad s < 0.3r;\ \gamma = 1.4;\ 20 < P_1/P_o < 300 \qquad [17.34.17]$$

where s is the dimension of the fragment.

17.34.14 Initial velocity of missiles: comparison of methods

The comparison of methods made by Ardron, Baum and Lee (1977) has already been mentioned. Another more recent comparative study is that of Baum (1984). This is discussed and extended by the CCPS (1994/15).

The following are some of the findings of the CCPS comparative study.

In comparing models, use is made of the scaled energy, which is defined as

$$E = \left(\frac{2E_{\mathrm{ex}}}{Ma_{\mathrm{o}}^2}\right)^{1/2} \qquad [17.34.18]$$

where E is the scaled energy, E_{ex} is the energy released in the explosion and M is the mass of the vessel.

An upper limit to the initial velocity of the fragments is set by the case of a hypothetical massless fragment for which the velocity is the maximum velocity of the expanding gas, or peak contact surface velocity. This velocity is a function of the pressure ratio P_1/P_{o}.

Differences between models tend to become significant for small values of the scaled energy.

The Moore model, which is based on high explosion energies, whilst tending to give an upper limit value, nevertheless compares quite favourably with other models for both low and high energies.

In the lower energy range the CCPS discusses the relative merits of the models of Baum and Baker *et al.* For certain specific comparisons Baum's model yielded higher velocities for spheres but lower ones for cylinders.

17.34.15 Angle of departure of missiles

In order to determine the flight of a missile it is necessary also to have information on the angle of departure. The extent to which this is known depends on the particular case. For ejection of a fitting, the direction of the gas jet and, hence, the angle of departure of the fitting is usually defined. Likewise, this will generally be so for the two parts in the separation and rocketing of a gas filled vessel.

The angles of departure in the case of the bursting of a gas filled vessel into a large number of fragments are less well defined. The common assumption is that the fragments are projected uniformly in all directions. Alternatively, the more conservative approach may be adopted in which the spatial density of the fragment is assumed to be greater in the direction of the vulnerable targets.

For some methods the results for an individual fragment can be sensitive to the angle of departure. The CCPS (1994/15) report this to be the case for the model of rocketing fragments.

17.34.16 Shape and air resistance of missiles

The behaviour of the fragment in flight depends on its shape. Some fragments are chunky, with dimensions similar along the three main axes, while others are less symmetrical, with dissimilar lengths along these axes.

A fragment in flight is acted on by a lift force normal to the trajectory and a drag force along the trajectory. These forces are defined in Equations 17.34.47 and 17.34.48 below in terms of a lift coefficient C_{L} and a drag coefficient C_{D}.

In ballistic terms a fragment may be characterized as a drag-type fragment if it is chunky so that for any orientation $C_{\mathrm{D}} \gg C_{\mathrm{L}}$ and as a lifting type fragment if it is such that for some orientation $C_{\mathrm{L}} \geq C_{\mathrm{D}}$.

The force resisting the flight of the missile is a function of its velocity, but the relationship is not a simple one. The velocity range of interest for projectiles is termed the ballistic range. At very low velocities, below the ballistic range, the resistance is proportional to the velocity. At ballistic but subsonic velocities the resistance is proportional to the square of the velocity. At supersonic velocities the resistance is a complex function.

17.34.17 Flight of missiles

The flight of a projectile is a standard problem in mechanics and is treated in texts on this topic (e.g. Synge and Griffiths, 1960; R.C. Smith and Smith, 1968; B. Brown, 1969).

Three cases are considered here: case 1, no air resistance, case 2, air resistance proportional to the velocity and case 3, air resistance proportional to the square of the velocity. The first case is not realistic and results in gross overestimates of velocity and range, but provides a useful illustration of the general approach. The third case is realistic for ballistic velocities in the subsonic range.

Considering first the flight of a projectile in the absence of air resistance (case 1), the equations of motion are

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} = 0 \qquad [17.34.19]$$

$$\frac{\mathrm{d}^2y}{\mathrm{d}t^2} + g = 0 \qquad [17.34.20]$$

where g is the acceleration due to gravity, t is the time and x and y are the distances in the horizontal and vertical directions, respectively.

Since there is no horizontal component of acceleration, in the x direction, both at $t = 0$ and subsequently

$$\frac{\mathrm{d}x}{\mathrm{d}t} = u_{\mathrm{i}} \cos \alpha \qquad [17.34.21]$$

where u is the velocity along the line of flight, α is the angle of departure and the subscript i denotes initial. Integrating with initial conditions $t = 0$, $x = 0$

$$x = u_{\mathrm{i}}(\cos \alpha)t \qquad [17.34.22]$$

In the y direction, at $t = 0$

$$\frac{\mathrm{d}y}{\mathrm{d}t} = u_{\mathrm{i}} \sin \alpha \qquad [17.34.23]$$

Integrating Equation 17.34.20 with initial conditions $t = 0$, $\mathrm{d}y/\mathrm{d}t = \mathrm{u_i} \sin\alpha$

$$\frac{\mathrm{d}y}{\mathrm{d}t} = u_{\mathrm{i}}(\sin \alpha) - gt \qquad [17.34.24]$$

Integrating again with initial conditions $t = 0$, $y = 0$

$$y = u_{\mathrm{i}}(\sin \alpha)t - \frac{1}{2}gt^2 \qquad [17.34.25]$$

For t from Equation 17.34.22

$$t = \frac{x}{u_{\mathrm{i}} \cos \alpha} \qquad [17.34.26]$$

For the relation between x and y, eliminating t from Equations 17.34.22 and 17.34.25

$$y = x \tan \alpha - \frac{gx^2}{u_i^2 \cos^2 \alpha} \qquad [17.34.27]$$

For the distance travelled, or range, setting $y = 0$ in Equation 17.34.27

$$x = \frac{2u_i^2 \cos \alpha \sin \alpha}{g} \qquad [17.34.28]$$

For the velocity u

$$u = \left[\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2 + \left(\frac{\mathrm{d}y}{\mathrm{d}t}\right)^2\right]^{1/2} \qquad [17.34.29]$$

Then, from Equations 17.34.21, 17.34.24 and

$$u = \left[u_\mathrm{i}^2 - 2u_\mathrm{i}(\sin \alpha)gt + g^2t^2\right]^{1/2} \qquad [17.34.30]$$

For the angle of approach to earth, or angle of return, β noting that

$$\tan \beta = \frac{\mathrm{d}y}{\mathrm{d}x} = \frac{\mathrm{d}y}{\mathrm{d}t}\frac{\mathrm{d}t}{\mathrm{d}x} \qquad [17.34.31]$$

from Equations 17.34.21 and 17.34.24

$$\tan \beta = \tan \alpha - \frac{gt}{u_\mathrm{i} \cos \alpha} \qquad [17.34.32]$$

For the time of return to earth from Equation 17.34.25 with $y = 0$

$$t_\mathrm{r} = \frac{2u_\mathrm{i} \sin \alpha}{g} \qquad [17.34.33]$$

Note that return to earth distance is the horizontal velocity times the time in flight.

The maximum range, which occurs at a projection angle of 45°, is

$$x_\mathrm{r} = t_\mathrm{r} u_\mathrm{i} \cos \alpha \qquad [17.34.34]$$

For the angle of approach β at the point of return to earth, or angle of return, from Equations 17.34.32 and 17.34.34 $\tan \beta = -\tan \alpha$. For the velocity at return to earth from Equations 17.34.30 and 17.34.34 $u = u_\mathrm{i}$.

For a projectile subject to a resistance k proportional to the velocity (case 2), the equations of motion are

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + k\frac{\mathrm{d}x}{\mathrm{d}r} = 0 \qquad [17.34.35]$$

$$\frac{\mathrm{d}^2y}{\mathrm{d}t^2} + k\frac{\mathrm{d}y}{\mathrm{d}t} + g = 0 \qquad [17.34.36]$$

Following an approach similar to that for the first model, it can be shown that

$$\frac{\mathrm{d}x}{\mathrm{d}t} = u_\mathrm{i} \cos \alpha \exp(-kt) \qquad [17.34.37]$$

$$\frac{\mathrm{d}y}{\mathrm{d}t} = \frac{1}{k}(ku_\mathrm{i} \sin \alpha + g)\exp(-kt) - \frac{g}{k} \qquad [17.34.38]$$

$$x = \frac{u_\mathrm{i} \cos \alpha}{k}[1 - \exp(-kt)] \qquad [17.34.39]$$

$$y = \left(\frac{u_\mathrm{i}}{k}\sin \alpha + \frac{g}{k}\right)[1 - \exp(-kt)] - \frac{gt}{k} \qquad [17.34.40]$$

For a projectile subject to a resistance proportional to the square of the velocity (case 3), the equations of motion are

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + k\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2 = 0 \qquad [17.34.41]$$

$$\frac{\mathrm{d}^2y}{\mathrm{d}t^2} + k\left(\frac{\mathrm{d}y}{\mathrm{d}t}\right)^2 + g = 0 \qquad [17.34.42]$$

Beyond this point, the attempt to apply to cases 2 and 3 the treatment used for case 1 becomes increasingly intractable.

However, there is an alternative approach which for case 3 yields much simpler results. This involves working in terms not of the velocity u along the flight path but of the velocity v relative to the ground. The relation between the two initial velocities is

$$v_\mathrm{i} = u_\mathrm{i} \cos \alpha \qquad [17.34.43]$$

The relevant equation of motion is

$$\frac{\mathrm{d}v}{\mathrm{d}x} + kv = 0 \qquad [17.34.44]$$

which is obtained from Equation 17.34.41 utilizing $\mathrm{d}x/\mathrm{d}t = v$. Integrating with initial conditions

$$\begin{aligned} &x = 0, \quad v = v_\mathrm{i} \\ &v = v_\mathrm{i} \quad \exp(-kx) \end{aligned} \qquad [17.34.45]$$

An empirical formula which allows for air drag quoted by V.J. Clancey (1972b) is

$$v = v_\mathrm{i} \exp(-kc_\mathrm{d}x/m^{1/3}) \qquad [17.34.46]$$

with

$k = 0.002$ velocity supersonic
$= 0.0014$ velocity subsonic

where c_d is the drag coefficient, v is the velocity of the projectile (ft/s), v_i is the initial velocity of the projectile (ft/s),

m is the mass of the projectile (oz), x is the distance travelled by the projectile (ft) and k is a constant. The drag coefficient c_d is a function of fragment shape but is generally approximately 1.5–2.

Equation 17.34.46 is of the same form as Equation 17.34.45. It also appears to be related to the equations for the flight of fragments from exploding weapons given by Christopherson and quoted in Section 17.36.

17.34.18 Range of missiles

The range of a missile in the absence of air drag is given by Equation 17.34.28 and the maximum value of that range for an angle of departure of 45° by Equation 17.34.34.

However, these relations greatly overstate the actual ranges obtained. For example, using the initial velocities from TNT charges given by V.J. Clancey (1972b) as quoted in Section 17.36, ranges of 5×10^5 ft and upwards are obtained. Therefore, it is clearly necessary to take air drag into account.

Clancey also gives a relation for the maximum horizontal range of fragments from a cased charge of TNT on the ground surface as shown in Figure 17.98. The correlation is based on experimental determination with TNT in lightweight containers. Most of the fragments do not travel the maximum distance, but fall at distances between 0.3 and 0.8 of the maximum.

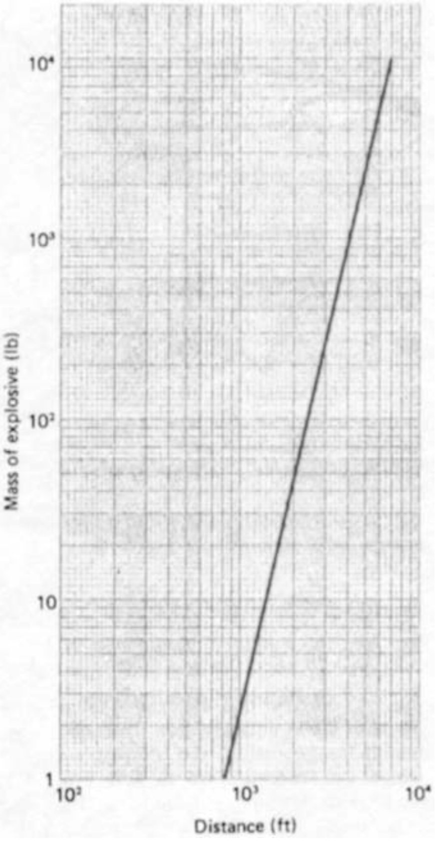

Figure 17.98 Missile effects of explosions: maximum horizontal range of fragments from a cased charge of TNT on the ground surface (V.J. Clancey, 1972b)

The probability that there would be at least one fragment which travels the maximum distance increases with the number of fragments and is therefore greater for a large explosion.

As stated above, a fragment in flight is acted on by a lift force, which is normal to the trajectory and opposes gravity, and a drag force, which is along the trajectory. These forces are

$$F_L = C_L A_L \frac{\rho u^2}{2} \qquad [17.34.47]$$

$$F_D = C_D A_D \frac{\rho u^2}{2} \qquad [17.34.48]$$

where A_D is the drag area, A_L is the lift area, C_D is the drag coefficient, C_L is the lift coefficient, F_D is the drag force, F_L is the lift force, u is the velocity of the fragment and ρ is the density of air.

A fundamental approach to the estimation of fragment range has been developed by W.E. Baker *et al.* (1975, 1978) and is described by W.E. Baker *et al.* (1983). The range is obtained by solving the equations of motion for acceleration of the fragment in the horizontal and vertical directions, utilizing for the drag and lift forces Equations 17.34.47 and 17.34.48. The results are correlated in terms of the dimensionless $\bar{u}_i$,velocity defined as

$$\bar{u}_i = \frac{C_D A_D \rho_o u_o^2}{Mg} \qquad [17.34.49]$$

and the dimensionless range $\bar{R}$

$$\bar{R} = \frac{C_D A_D \rho_o R}{M} \qquad [17.34.50]$$

and the lift/drag ratio

$$= \frac{C_L A_L}{C_D A_D} \qquad [17.34.51]$$

where g is the acceleration due to gravity, M is the mass of the fragment, R is its range, u_o is its initial velocity and ρ_o is the density of air. The treatment is based on the assumption that the fragment is spinning and applies to fragment velocities up to Mach 1 or about 340 m/s. The equations were solved using the computer code FRISB.

The correlation obtained is shown in Figure 17.99. For values of the lift/drag ratio not given, interpolation can be used, but it becomes inaccurate on the steep portions of the curve.

Many fragments from explosions are chunky and have a lift coefficient C_L, and hence a lift/drag ratio, of 0. Other fragments may be pieces of plate for which the lift/drag ratio is more complex. A method of estimating the lift/drag ratio for these latter is given in appendix E of W.E. Baker et al. (1983).

Data on missile flight are available in many descriptions of accidental explosions. Jacobs *et al.* (1973) state that in the explosion at the American Oil Company refinery at Whiting, Indiana (Case History A22):

> The vessel fragments were scattered for several hundred feet away from the unit site. One 60-t piece landed on a tank of gasoline, smashing it severely and igniting and scattering its contents.

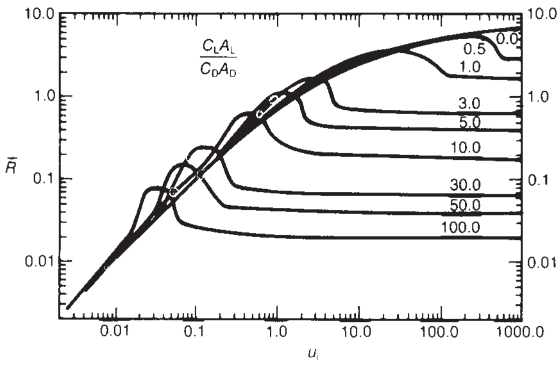

Figure 17.99 *Missile effects of explosions: distance travelled by missiles (W.E. Baker et al., 1983) (Courtesy of Elsevier Science Publishers)*

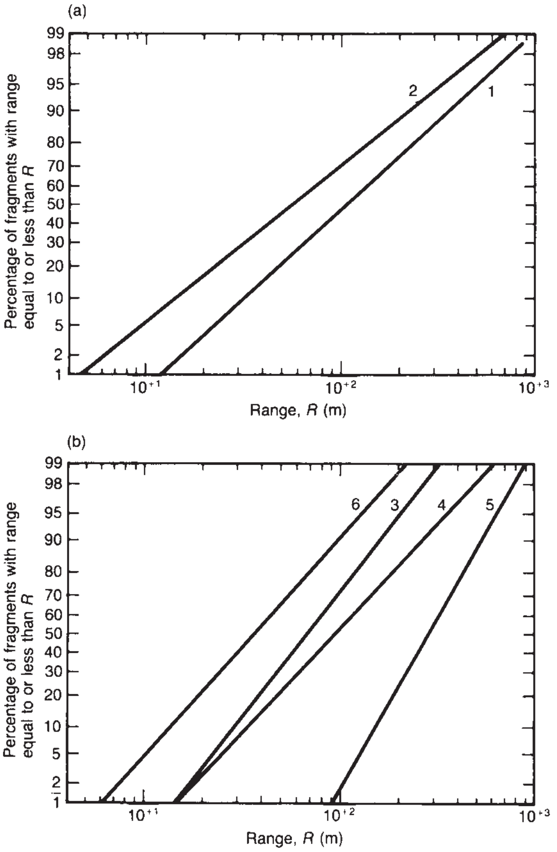

Figure 17.100 *Missile effects of explosions: fragment range distribution from some accidental event (W.E. Baker et al., 1978): (a) event groups 1 and 2 and (b) events groups 3–6*

The investigation of the explosion at the Dow Chemical Company's works at King's Lynn by the HSE (1977b) gives a map of the fragments from the explosion (Case History A81). In one ship explosion investigated by V.J. Clancey (1976b) a deck cover of 400 t was thrown 100 ft.

The study of accidental explosions by W.E. Baker *et al.* (1978) referred to in Section 17.34.4 and tabulated in Table 17.50 also yielded data on fragment range. The graphs of fragment range for the different event groups are shown in Figure 17.100.

An absorber column exploded from a hydrogen-rich fuel and air mixture that skattered 16 large fragments. The energy of the explosion was evaluated by three alternative methods by Woodward and Ketchum (2001). Fragment range analysis, using Figure 17.99, gave 30–83 kg TNT equivalence. Modelling the fuel combustion energy gave 78–96 kg TNT equivalence. Window breakage analyses gave 37 kg TNT equivalence.

17.34.19 Missiles from BLEVEs

A particular type of explosion which is prone to generate missiles is the BLEVE. A study of missiles from BLEVEs has been described by Holden and Reeves (1985).

Much of the information obtained in the work relates to vessels used in transport, but no reason was seen why it should not apply to fixed plant also. A distinction is made between cylindrical and spherical vessels, which are treated separately. For cylindrical vessels information was obtained on (1) probability of fragment generation, (2) number of fragments, (3) range of fragments, and (4) direction of fragments, and for spherical vessels on the last three features.

For cylindrical vessels there were 113 events involving fire on which sufficient information was available and of these 89 involved fragment generation. The probability of fragment generation was estimated from this as 0.8.

The number of fragments generated by a cylindrical vessel was obtained for 27 events involving LPG vessels and ranged from one to four. The number of events generating one, two, three and four fragments were 8, 7, 10 and 4, respectively. This excluded a fire engulfment test at White Sands reported by C. Anderson and Morris (1974), in which 10 fragments were generated and which appears to be anomalous in comparison with the accident data.

The range of fragments was taken as the ultimate end point after landing and travelling across the ground, through structures, etc. The range for fragments from LPG vessels is shown in Figure 17.101. Figure 17.101(a) gives the range for all events together with a comparison with data from an earlier study by W.E. Baker *et al.* (1978). Figure 17.101(b) shows the effect of vessel size and Figure 17.101(c) the difference between end tub fragments and other fragments. There is a clear tendency for fragments from vessels with a capacity <90m^3 and for end tubs to travel further. Figure 17.101(d) gives the range for fragments from spherical vessels. A further graph is given for the range of fragments from vessels containing ammonia, ethylene oxide and vinyl chloride.

The authors comment that the ranges found tend to be much less than those obtained from theoretical estimates of maximum range using the corresponding launch angle, which can exceed 3 km to first ground impact, that launch angle is important, and that their empirical data include implicit allowance for factors such as launch angle, inventory, etc.

With regard to direction of fragments from cylindrical vessels, for some 11 incidents involving 15 vessels,

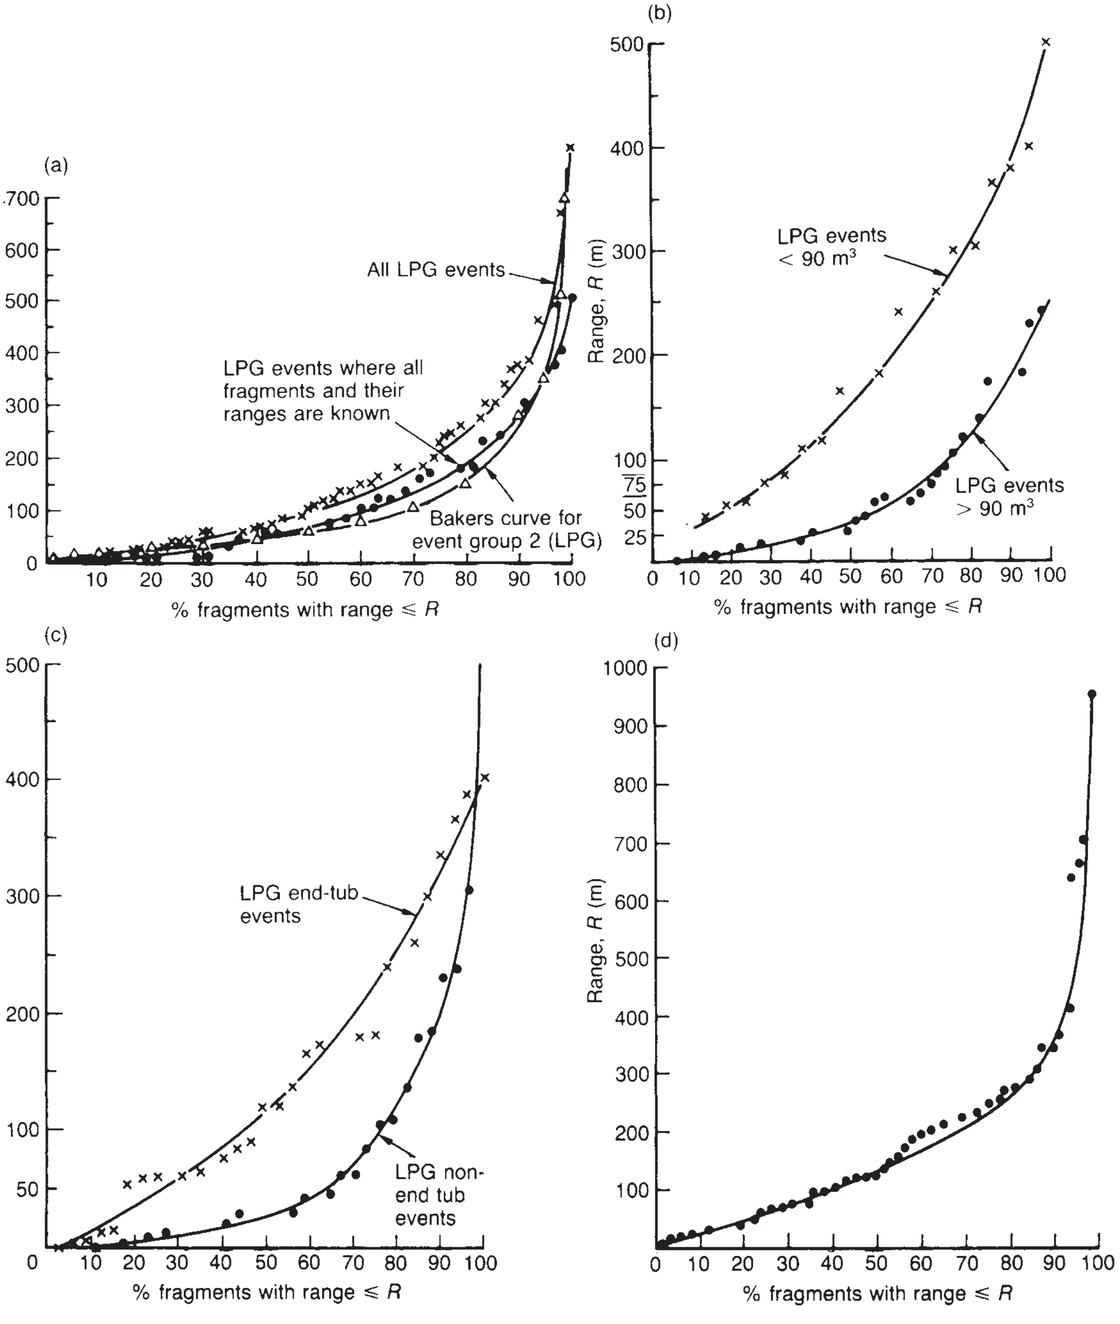

Figure 17.101 *Missile effects of explosions: distance travelled by missiles from bursting of LPG vessels (Holden and Reeves, 1985): (a) all events; (b) effect of vessel size; (c) end tub and other fragments and (d) spherical vessels (BLEVEs) (Courtesy of the Institution of Chemical Engineers)*

mainly LPG, about half the fragments were projected into about a third of the total area, in arcs of 30° to either side of the vessel front and rear axial directions. The correlation given for LPG vessel fragments is shown in Figure 17.102.

For spherical vessels the sample of events was only seven. The number of fragments generated in these vents was 3, 4, 5, 5, 6, 16 and 19, giving an average of 8.3 fragments per event. This number is appreciably higher than for cylindrical vessels.

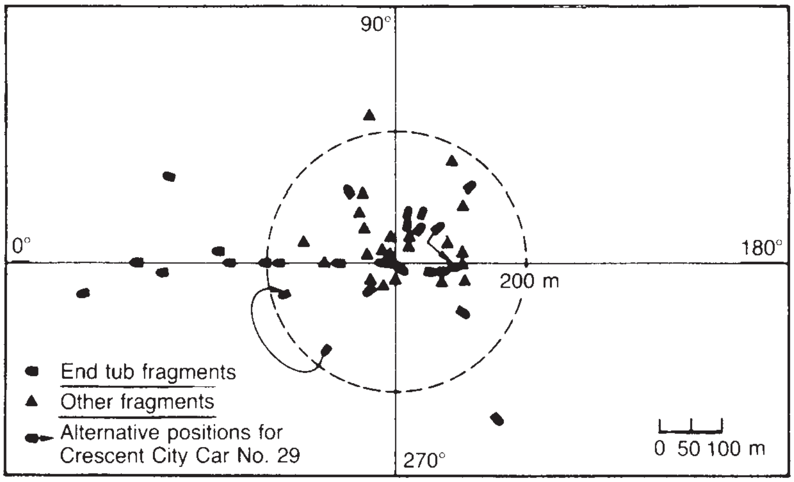

Figure 17.102 *Missile effects of explosions: direction of travel of missiles bursting of LPG vessels (Holden and Reeves, 1985) (Courtesy of the Institution of Chemical Engineers)*

Figure 17.101(d) shows that the range of the fragments from spherical vessels is marginally higher than for cylindrical vessels.

Fragments from spherical vessels tend to be projected in a non-uniform distribution of directions. Taking the favoured direction in each incident and treating this as an arbitrary 0° and then overlaying the plots for the individual incidents to give an overall plot divided into 30° sectors, it was found that a fragment is 17 times more likely to be projected in the favoured direction than in the least favoured.

The authors describe a number of incidents where fragments from BLEVEs have caused damage or injury. At Crescent City a propane rail tank car exploded, generating two main fragments, one of which punctured the head of another such tank and the other sheared the housing and valves off a third tank (Case History A50).

Similarly, at Laurel a fragment from the BLEVE of a tank car pierced another propane tank car (Case History A44). Escalation may also occur by disablement of other equipment. At Laurel a fragment from one of the rail tank cars hit a pumphouse and cut an 8 in. water main, reducing the fire water pressure. At Puebla, Mexico, in 1977 a fragment from the BLEVE of a vinyl chloride storage sphere hit the main site water tank and carried it across the perimeter fence (Case History A87). At Texas City in 1978 a fragment from the BLEVE of an LPG sphere travelled 210 m and hit the site fire water tank.

Fragments from BLEVEs are also a cause of injury. In the LPG road tanker BLEVE at Deer Lake, Pennsylvania, in 1959 it was a rocketing fragment which was responsible for most of the 11 dead and 10 injured. These bystanders were at a distance of more than 200 m and beyond the range of thermal hazard in that case. At West St. Paul, Minnesota, in 1974 fragments from the BLEVE of an LPG storage vessel were held responsible for the deaths of three fire fighters and a bystander.

A further study of missiles from BLEVEs is that of Pietersen (1985), who investigated the disaster at Mexico City, Mexico, in 1984, described in Appendix 4. For 44 cylindrical bullet tanks he found that 4 were still on their supports and a further 11 still in their original bund, and that of the remaining 29, the distribution of bullets and end tubs was as follows:

Distance (m)	*No. of fragments from bullets*	*No. of fragments from end tubs*
<100	17	3
100–200	4	4
200–300	3	3
300–400	2	2
400–700	1	1
700–1000	1	1
1000–1200	1	1
Total	29	15

For the spheres, 25 major fragments were collected lying as follows: six within 100 m, six between 100 and 200 m, seven between 200 and 300 m, one between 300 and 400 m, three between 400 and 500 m, one between 500 and 590 m and one at 590 m.

Pietersen discusses the mechanism of rocketing of part of a cylindrical bullet. He takes as the energy transferred to the missiles 60% of the total available energy of a gas filled vessel as given by the Erode equation and then utilizes a relation equivalent to Equation 17.34.1. On this basis he obtains for the larger vessels on the site

Vessel volume (m^3)	*Vessel mass* (kg)	*Initial velocity of missile* (m/s)
270	70	149
1600	215	206
2400	300	214

which gives maximum velocities of about 150 m/s for cylinders and 200 m/s for spheres. He also quotes a velocity of 60 m/s for the vapour of the LPG in the cylinder undergoing flash vaporization. He states that calculations based on these figures indicate that without lift the maximum range of the fragment is of the order of 360 m, though the figure is not very accurate. It is sufficient to show, however, that lift must play a significant role.

17.34.20 CCPS method

The CCPS *Fire and Explosion Model Guidelines* (1994/15) include as part of the treatment for BLEVEs a method for fragments.

The method used for the estimation of the energy of explosion used has been described in Section 17.27.

For the number of fragments the value of the scaled energy given by Equation 17.34.18 is used to discriminate between the case where the fragments are few and that where they are numerous. The region where the scaled energy lies between 0.1 and 0.4 is one where the number of fragments generated tends to be small.

Use is also made of Baker's event groups as described in Section 17.34.4. An event group is selected which approximates the case in hand, and the event group data are then used to obtain an estimate of the expected number of fragments and of their mass distribution.

For the initial velocity of the fragments three methods are given. Method 1 is to obtain the energy of explosion using the methods given in Section 17.34.9 and to apply to it a factor of 0.2 to obtain the kinetic energy available to the fragments and then to assume this is distributed equally among the fragments as in Equation 17.34.1. Method 2 is that of Baker *et al.* outlined in Section 17.34.11. Method 3 is that of Moore, which is given here as Equation 17.34.3. The choice of method to use is governed by the scaled energy relation 17.34.18.

For the range distribution of the fragments use is made of the method of Baker *et al.* which is described in Section 17.34.18.

Ranges may also be estimated using the event group data.

17.34.21 Missile damage method of Scilly and Crowther

A method for assessment of the risk of missile impact on a process plant site has been described by Scilly and Crowther (1992).

These authors give data on the fragments generated in eight incidents, as shown in Table 17.51.

The method which they describe involves for a given target estimation of the following features: (1) the number of fragments, (2) the range distribution, (3) the mass distribution, (4) the orientation factor, (5) the effective range interval, and (6) the probability of a strike.

They illustrate the method by reference to the case of a distillation column 50 m high, 2.4 m in diameter and 12.5 mm thick subject to a sudden pressure increase due to a rapid decomposition.

In general, the number N of fragments depends on a variety of factors, including the vessel size and shape, the material of construction, the operating temperature and the rate of pressure rise. The authors obtain the estimate of the number of fragments N by inspection of Table 17.51. For their illustrative example they take N as 35.

As already described, the distribution of fragments may exhibit directionality. The authors suggest there is some justification for allowing for this by the use of a correction factor of 2, applied to N.

For the distribution of the ranges of the fragments, they utilize not the fragment with maximum range $R_{\max}$ but that with the next farthest range, or penultimate range, R_{pen}, arguing that the latter is more meaningful. The range distribution is found to be log-normal, and is fitted by the authors using a probit equation. They give the following tentative relations:

$$R_{\text{med}} = 2.8P_{\text{v}} \qquad [17.34.52]$$

$$R_{\text{pen}} = 4.1R_{\text{med}} \qquad [17.34.53]$$

where P_{v} is the vessel pressure (barg), R_{med} is the median range (m) and R_{pen} is the range of the penultimate fragment (m). A probit equation for the probability P of a fragment falling at a range R may then be constructed from the pair of points ($P = 0.5$, R_{med}) and ($P = N_{\text{pen}}/N$, R_{pen}), where $N_{\text{pen}} = N - 1$.

Given that for vessels of size exceeding 20 m^3 the great majority of fragments will have energy sufficient to penetrate steel containments, which are unlikely to have a wall thickness greater than 15 mm, the distribution of mass is much less important. However, for the case where it is desired to estimate the mass distribution for vessels of such size, the authors propose that the median mass of the fragments be taken as that of the vessel divided by 73 and that the slope of the associated probit equation be taken as 1.5.

The orientation factor F_{or} is

$$F_{\text{or}} \approx \frac{W}{2\pi R} \qquad [17.34.54]$$

where R is the range of the fragment (m) and W is the combined width of the target and the fragment (m). The width of a fragment is taken in the illustrative example as 4 m.

The target is vulnerable to any fragment falling between a minimum range R and a maximum range $R + L$, where L may be termed the effective range interval. For a target consisting of a sphere supported on legs the authors derive by geometry for fragments directed, respectively, at the midpoint and at the edge of the sphere

$$L = (H - r + r\ \sec\theta)\ \tan\theta + r \quad \text{sphere midpoint} \qquad [17.34.55]$$

$$= (H - r)\tan\theta + r \quad \text{sphere edge} \qquad [17.34.56]$$

where H is the height of the top of the sphere (m), L is the effective range interval (m), r is the radius of the sphere (m) and θ is the angle of descent (°). For the angle of descent the authors suggest 45° as a conservative value. They use 60° in their illustrative example.

The probability P_{ri} that a fragment falls within the effective range interval L is then determined from the probit equation for the range distribution by taking the difference between the probabilities of a fragment reaching $R + L$ and of one reaching R.

The probability of a strike P_{st} is then

$$P_{\text{st}} = F_{\text{or}}NP_{\text{ri}} \qquad [17.34.57]$$

As already stated, the authors effectively take as unity the probability of puncture of the target given a strike.

For an explosion in the vessel used to illustrate the method, described above, and for a target consisting of a

[a] Incidents are as follows: 1a and 1b, separator and reactor respectively, at Whiting, Indiana, 1957 – fuel/air combustion probably leading to detonation; 2, Ponca City, 1959 – probable fuel/air combustion; 3, Doe Run, 1962 – probable liquid phase polymerization and gas phase decomposition of ethylene oxide; 4, Texas City, 1969 – liquid phase decomposition of vinyl acetylene; 5, Grangemouth, 1987 – breakthrough of high pressure (155 bar) gas; 6, Antwerp, 1987 – decomposition of ethylene oxide during distillation; 7, Wendstone Chemicals, 1988 – liquid phase decomposition of *o*-nitrobenzaldehyde containing nitrate esters.

[b] Distillation column had a volume of 200 m^3, but only the central section of volume 53 m^3 disintegrated.

[c] Authors suggest that this value is understand and that it should be at least 43 barg.

sphere 12 m in diameter supported on 3 m legs at 150 m distance from the exploding vessel, the authors obtain a calculated burst pressure $P_v = 45$ barg, a number of fragments $N = 35$, a range of fall between 150 and 199 m, the range probit $Y = -1.44 + 3.066 \log_{10} R$, a probability that a fragment falls within the effective range interval of 0.14, an orientation factor $F_{or} = 0.016$, and a probability of strike $P_{st} = 0.08$.

17.34.22 Flying glass

Glass fragments from the breaking of windows are significant for injury of personnel. This effect is considered in Section 17.40.

17.34.23 Falling masonry and glass

Another form of missile which is relevant particularly to an explosion in a built-up area is falling masonry and glass.

A model for this hazard is included in the set of submodels in the model for a condensed phase explosion in a built-up area given by Gilbert, Lees and Scilly (1994h). A person in the street near a building is vulnerable to falling masonry and glass. The extent of the hazard from these two sources will vary. The relative importance of falling glass may be expected to rise where the buildings in question are large city skyscrapers.

Casualties occurred from falling masonry in air raids, but the interpretation of such data needs to take account of the fact that in many cases the weapons exploded inside buildings.

The model tentatively proposed by Gilbert, Lees and Scilly (1994h) for the estimation of the risk from falling masonry and glass is as follows. The approach used is to designate a band of specified width on the pavement beside the building and to assume that persons in this band do not survive. The width of the band is intended to allow both for the density and size distribution of falling debris within a wider band and for the probability of a fatality given a hit. The default value used for the width of the band is 1 m. This value is for use where the height of the building does not exceed 15 m.

17.34.24 Crater ejecta

Some explosions create a crater and in this case fragments are ejected. Craters have been treated in Section 17.31. The account here is confined to the crater ejecta.

A treatment of the fragments from cratering has been given by Richmond and Fletcher (1971). These authors base their work on data given by Henny and Carlson (1968) for crater ejecta from explosions in rock and in soil. The charges were half buried in the ground. The missiles considered are those with a mass exceeding 0.5 lb.

For the maximum range of fragments Richmond and Fletcher give the following equations:

$$R_{\max} = 70\mathrm{W}^{0.4} \quad \text{rock} \qquad [17.34.58a]$$

$$= 30\mathrm{W}^{0.4} \quad \text{soil} \qquad [17.34.58b]$$

where R is the range (ft) and W is the mass of explosive (lb) (of TNT equivalent) and the subscript max denotes maximum.

The probability P of being struck by one or more such missiles is

$$P = 1 - \exp(-a/A) \qquad [17.34.59]$$

where a is the projected area of the body (ft^2) and A is the specific area, or surface hemispherical area per missile (ft^2/missile). The projected area a is taken as 6.2 ft^2.

The authors deal primarily with fragments from cratering in rock and consider particularly the conditions for 50 and 1% probability of being struck. The fragment specific areas at these levels of probability are 9 and 600 ft^2/fragment, respectively.

For cratering of rock the authors give a graph showing curves for the 50 and 1% probability of being hit as a function of mass of explosive and distance, but give no guidance on obtaining other values. However, their data may be correlated approximately by the following relations:

$$\mathrm{A} = \frac{A_h}{n_e} \qquad [17.34.60]$$

with

$$n_e = \phi_n nm \qquad [17.34.61]$$

$$\phi_n = 1, \quad R < 200 \qquad [17.34.62]$$

$$\phi_n = 3.46 - 0.466 \ln R, \quad 200 \leq R \leq 900 \qquad [17.34.63]$$

where A_h is the area of the hemisphere on the surface of which the human target is standing (ft^2), m is the mass of explosive (tons), n is the near field number of missiles per ton of explosive (missiles/t), n_e is the number of missiles at distance R (missiles/t), R is the distance (ft) and ϕ_n is a correction factor which allows for the reduction in the number of missiles with distance. The value of n is 230 missiles/t.

The authors state that the average mass of the missiles is well above 0.5 lb and argue that the probability of serious injury given a hit is likely to be high.

The application of this work to the cratering caused by an explosive load in a street has been discussed by Gilbert, Lees and Scilly (1994h). From an analysis of the crater in the Peterborough explosion (HSE, 1990c), which involved an explosive load equivalent to some 800 kg of TNT on a vehicle in a built-up area, they conclude that it is probably not necessary to make any correction for the height of the load above ground or for the nature of the ground, but suggest that some correction seems appropriate for the fact that in the experimental work described the charges were half buried and suggest a reduction in the near field number n of fragments from 230 to 150 missiles/t.

17.34.25 Impact effects

There are available a number of empirical equations for estimating the penetration of fragments in various types of target. However, it is pointed out by W.G. High (1980) that most of these relations are for fragments from high energy density sources, where the sources of interest in process plant, such as high pressure vessels, are of relatively low energy density.

It is convenient to quote first some of the empirical equations for determining fragment penetration given in the *High Pressure Safety Code* by E.G. Cox and Saville (1975),* which may be regarded as a coherent set selected by the authors for plant design purposes. Other individual

formulae for penetration into reinforced concrete and into steel plate are given in Sections 17.34.26 and 17.34.27.

A treatment of the impact of missiles on pipework is given in Section 17.35.

The equations quoted in the *High Pressure Safety Code* assume penetration normal to the surface. They are valid for projectile velocities not exceeding 1000 m/s, above which there is often a quite different mechanism in which target and projectile are melted by the impact energy.

For penetration by small fragments, the depth of penetration is given by the relation

$$t = Km^{n_1} V^{n_2} \qquad [17.34.64]$$

where m is the mass of the fragment (kg), t is the thickness of the barricade needed just to stop the fragment (m), V is the velocity of the fragment (m/s), K is a constant and n_1 and n_2 are indices. The values of the constant K and the indices n_1 and n_2 for different target materials are:

	K	n_1	n_2
Concrete (crushing strength 35 MN/m^2	18×10^{-6}	0.4	1.5
Brickwork	23×10^{-6}	0.4	1.5
Mild steel	6×10^{-5}	0.33	1.0

Equation 17.34.64 is valid for compact blunt steel fragments such as solid cylinders with the length equal to the diameter with a mass of not more than 1 kg.

For penetration by larger fragments the depth of penetration may be calculated from

$$t = \frac{Cm}{A}\log_{10}(1 + 5 \times 10^{-5} V^2) \qquad [17.34.65]$$

where A is the presented area of the fragment (m^2) and C is a constant. The constant C has the following values:

	C
Concrete (unreinforced, crushing strength 15 MN/m^2)	10×10^{-4}
Concrete (1.4% reinforcement, crushing strength 40 MN/m^2)	3.5×10^{-4}
Brickwork	25×10^{-4}
Mild steel	0.5×10^{-4}
Alloy steel	0.3×10^{-4}

Equation 17.34.65 applies for large blunt fragments with a mass exceeding 1 kg.

For penetration by rod shaped missiles for concrete

$$t = 2 \times 10^{-7}\,\frac{mV^{1.5}}{d^{1.8}} \qquad [17.34.66]$$

and for mild steel plate

$$t = \left(0.33 \times 10^{-9}\,\frac{mV^2}{d^3}\right)^{1/1.41} \qquad [17.34.67]$$

where d is the diameter of the fragment (m).

Fragments of irregular shape, such as are usually produced by the bursting of a pressure vessel, have much lower penetrating power, often only half, than compact blunt fragments, while pointed projectiles have appreciably more.

Further relations for impact of fragments on various types of target have been given by W.E. Baker *et al.* (1983). They consider the following targets: (1) thin metal plates and sheets, (2) roofing materials, and (3) reinforced concrete. For the latter the treatment includes steel pipe, utility pole and rod missiles.

The impact relations given by these authors are correlated in terms of a non-dimensional projectile velocity, a non-dimensional target deflection and non-dimensional target thickness.

As the size of the projectile increases, the response of the target becomes more significant. Work by R.P. Kennedy (1976) has shown that the target response may be modelled by assuming it to be subject to a rectangular pulse forcing function. With this assumption it is then possible to apply conventional structural response techniques.

Another aspect of fragment impact on concrete targets is spalling and scabbing, and correlations are available for the threshold and for depth attained.

17.34.26 Impact effects: penetration of reinforced concrete

There has been a considerable amount of work on the penetration of reinforced concrete by missiles. Accounts are given by Chelapati, Kennedy and Wall (1972), R.P. Kennedy (1976), Barr *et al.* (1980), Porter (1980) and Tulacz and Smith (1980).

Some principal correlations are those of Petry (1910), the Army Corps of Engineers (ACE), the Ballistics Research Laboratory (BRL) and the National Defense Research Committee (NDRC) (1946). These correlations are given by Tulacz and Smith (1980).

Of these models, the modified NDRC correlation (NDRC, 1946) particularly appears to have found widespread acceptance. It is applicable to a flat-faced cylindrical missile. The equation is given in SI units by Barr *et al.* (1980) as follows:

$$G(x/d) = 2.74 \times 10^{-5}(\rho d^{0.2}/\sigma_c^{0.5})\mu^{1.8} \qquad [17.34.68]$$

with

$$G(x/d) = (x/2d)^2, \qquad x/d \le 2 \qquad [17.34.69]$$

$$G(x/d) = (x/d) - 1, \quad x/d > 2 \qquad [17.34.70]$$

$$\rho = m/d^3 \qquad [17.34.71]$$

where d is the diameter of the missile (m), ρ is its calibre density (kg/m^3), m is its mass (kg), μ is its velocity (m/s), x is the penetration depth (m) and σ_c is the compressive strength of concrete (Pa). The limits of applicability of Equation 17.34.68 are discussed by Gwaltney (1968) and Tulacz and Smith (1980).

Equation 17.34.68 is a penetration correlation. NDRC has also developed perforation formulae for use in conjunction with this equation. These are

$$\frac{e}{d} = 3.19\frac{x}{d} - 0.718\left(\frac{x}{d}\right)^2, \quad \frac{e}{d} < 3 \qquad [17.34.72]$$

$$\frac{e}{d} = 1.32 + 1.24\frac{x}{d}, \quad 3 \leq \frac{e}{d} \leq 18 \qquad [17.34.73]$$

where e is the perforation thickness (m). This is the thickness of target which the missile will just perforate. Another model for penetration by a flat-nosed cylinder, again based on extensive testing, is the Commissariat à 1'Energie Atomique/Electricite de France (CEA/EDF) formula, described by Berriaud *et al.* (1978) and discussed by Barr *et al.* (1980):

$$\mu_p^2 = 1.7\sigma_c \rho^{1/3}\left(\frac{de^2}{m}\right)^{1/3} \qquad [17.34.74]$$

where μ_p is the perforation velocity (m/s) and p is the density of the concrete (kg/m^3); the other symbols are as defined above.

The limits of applicability of Equation 17.34.74 are discussed by Berriaud and Barr *et al.*

A three-dimensional computer code, CRASH, for the investigation of impact effects on various types of target, including reinforced concrete and steel plate, has been described by Hopkirk, Lympany and Marti (1980).

17.34.27 Impact effects: penetration of steel plate

There has also been a good deal of work on the penetration by missiles of steel plate. Accounts are given by Neilson (1980) and Tulacz and Smith (1980).

Some principal correlations are those of Christopherson (1946), Stanford Research Institute (SRI), the Ballistics Research Laboratory (BRL) and the NDRC.

Of these models, that of SRI, described by R.W. White and Botsford (1963), appears to have found wide acceptance. It is given in SI units by Neilson as

$$\frac{E_c}{d} = \frac{S_u}{10.29}(42.7h^2 + wh) \qquad [17.34.75]$$

where d is the diameter of the missile (m), E_c is its critical impact energy (J), h is the thickness of the target panel (m), S_u is the ultimate tensile strength of the panel (Pa) and w is the width of the panel (m).

Equation 17.34.75 was derived originally for relatively long missiles striking thin panels (<7 mm thick). The limits of applicability and behaviour of the equation are discussed by Neilson and by Tulacz and Smith.

The latter also give the BRL and NDRC formulae and discuss the comparative behaviour of the three models.

Mention has already been made of the general impact computer code CRASH, which can be used for steel plates. Neilson also describes the use for this purpose of the codes EURDYN and CADROS.

17.34.28 Impact effects: impact on a storage sphere

A treatment of the impact of a fragment from a BLEVE on a storage sphere has been given by Pietersen (1985). The method involves calculating (1) the force at the point of impact to deform the sphere up to the yield point, and the corresponding energy E_y, and (2) the energy E_r to deform the sphere in the plastic region between yield and rupture. Utilizing relations given by Roark and Young (1975) and taking the impact area as five times the vessel wall thickness, these two energies are found to be $E_y = 7$ kJ and $E_r = 64$ kJ. Assuming that plastic deformation of the impacting fragment uses up an amount of energy equal to that used in the sphere itself the total energy required for rupture is 135 kJ. From simple kinetic energy considerations, for a fragment of mass 20 te (1/10th of a sphere) the velocity required to effect rupture is then 3.7 m/s and for one of 2 te (1/100th of a sphere) it is 11.6 m/s. This calculation indicates that the velocities to cause rupture are well below the initial velocities of fragments from a sphere undergoing BLEVE, which have been discussed above, and therefore that rupture of a sphere close by is to be expected.

17.34.29 Barricade design

In some cases use is made of barricades around a potential source of explosion. Barricades are utilized particularly in work with explosives, but may also be used around other potential explosion sources such as high pressure equipment. There is also considerable interest in barricades in the nuclear industry.

Accounts of the design of barricades include those given in the *High Pressure Safety Code* by E.G. Cox and Saville (1975) and by Loving (1957), W.G. High (1967) and C.V. Moore (1967).

The essential first step in design of a barricade is to determine the failures against which protection is required. In other words, it is necessary to start with hazard identification.

In barricade design, provision of protection against an explosion of flammable gas is generally treated as a special case. Excluding this, the design resolves into provision of a barricade which offers resistance to (1) blast and (2) fragments. Broadly, design against blast is often based on an equivalent static pressure approach and design against fragments on fragment penetration correlations.

Design methods for barricades to protect against vessel rupture are discussed in the *High Pressure Safety Code*. It is relatively easy to provide a barricade for vessels with energy contents in the range 10^3–10^5J, but it becomes progressively more difficult as the energy content rises, and for energy contents capable of giving a shock wave of 50×10^6 to 100×10^6 J it is usually impractical.

The preferred method is a closed cubicle. For protection against blast using the equivalent static pressure method the *Code* gives the relevant pressure as

$$P = 7.6[(E \times 10^{-6})/V]^{0.72}, \quad P < 70 \qquad [17.34.76]$$

where E is the shock wave energy (J), P is the equivalent static pressure (bar) and V is the volume of the enclosure (m^3). Equation 17.34.76 is applicable where the ratio of the maximum to the minimum dimension of the enclosure does not exceed 2.

Cylindrical cubicles can be designed as thin-walled pressure vessels. Small cubicles can be made of angle iron and steel plate. Large cubicles should be of reinforced concrete. Since the shock wave has positive and negative phases, reinforcement is required on both inner and outer faces.

Some transmission of the shock wave occurs through the walls of the cubicle. This creates the hazard that persons outside may be injured by eardrum rupture. The Code gives the following method of estimating this. The impulse incident on an isolated wall is given as

$$I = 0.008E^{1/3}(R/E^{1/3})^{-1/2}, \quad 0.004 < (R/E^{1/3}) < 0.2 \qquad [17.34.77]$$

where I is the impulse per unit area (N s/m^2) and R is the distance (m). Also for an isolated wall the initial velocity of the wall, assumed unconstrained, is

$$u = I/m \qquad [17.34.78]$$

where m is the mass of the wall per unit area and u is the velocity (m/s). For the wall of a cubicle the impulse is taken as three times the value given by Equation 17.34.77 and the initial velocity of the wall is then that given by Equation 17.34.78.

If the value of the initial velocity u so calculated is less than 10 m/s, the shock wave generated outside should be too small to cause eardrum rupture.

If the plant in the cubicle contains flammables or toxics an opening may be necessary to allow dispersion of small leaks by ventilation. The *Code* states that the design of a vented cubicle is essentially the same as that for a closed cubicle.

With a vented cubicle, however, the escaping shock wave will tend to cause overpressure similar to that which would exist if there was no cubicle and the explosion was in the open. The *Code* gives the following equation for the estimation of the peak incident overpressure:

$$P = 8.45 \times 10^{-5}(E^{1/3}R)^{2.3} - 0.16(R/E^{1/3}) + 0.06, \quad 0.004 < (R/E^{1/3}) < 0.2 \qquad [17.34.79]$$

where P is the peak incident overpressure (bar).

The cubicle should also withstand the fragments generated. Since the distances are usually short, such a fragment will tend to be at its initial velocity. Much of the work on fragment penetration, described above, has been done to assist with barricade design.

Safety walls may be used instead of a cubicle. For a safety wall the impulse from the blast wave is as given by Equation 17.34.77 without application of the factor of 3 and the initial velocity as given by Equation 17.34.78. There will, however, be diffraction of the shock wave around the wall which is difficult to estimate.

The thickness of the barricade should be such as to enable it to withstand both shock wave and fragment penetration.

The barricade may be required to survive the simultaneous assault of the shock wave and of fragments. This problem is discussed in the *Code* and also by Moore.

Information on viewing ports for cubicles is given by Moore (1967).

17.34.30 Plant design

The hazard from missiles has not generally been a major factor in plant design, but rather more attention is now paid to it.

Design of plant for the hazard of missiles may focus on the source or on the target. On the whole it makes more sense to concentrate on the source, since the probability that a given plant item will be the target of a missile, even if a missile-generating explosion occurs, is very low.

Attention should be paid in design to features such as doors, vents and other fixtures on plant which may become missiles and measures should be taken to minimize this.

Where a serious missile hazard exists, use may be made of barricades and safety walls as described above.

17.35 Explosion Damage to Plant by Missiles

The treatment just given of missile impact effects constitutes a rather general account, with emphasis on penetration of concrete walls and steel plates. This is now supplemented by consideration of a particular problem, taken as representative for missile impacts on plant, that of damage to pipework.

The account given draws particularly on evidence given to the Piper Alpha Inquiry by A.C. Palmer (1989), which considered the mechanisms of, and potential for, damage to a 4 in. high pressure gas condensate line in B Module from fragments from the firewall between B and C Modules set in motion by an explosion in C Module.

17.35.1 Fragment velocity and energy

The velocity and energy of fragments has been considered in the previous section. Essentially, a fragment is accelerated by a force which will vary with the circumstances. The point which is relevant here is that in a large proportion of cases, the principal force causing acceleration is that due to the dynamic pressure, or wind. The acceleration of the fragment up to its maximum velocity then requires a finite distance, which may be several metres. This fact can be significant if the target is close to the source of the fragments.

17.35.2 Distribution of energy

Only a part of the kinetic energy of the fragment is transferred to the target and is available to cause damage. Some of the energy goes into the deformation, and possible disintegration, of the fragment itself. The distribution of energy between the fragment and the target depends on their relative stiffness and is highly variable. If the fragment is more readily deformed than the target, it absorbs more energy than it transmits.

The relative stiffness is itself a function of the velocity of impact. If the impact velocity is low, the relative stiffness is governed by the overall deformation of the two objects, whilst if it is high deformation may be localized and the energy distribution may alter.

The energy transferred to the target is itself divided into that energy which causes local damage and that which causes the whole target to respond. This latter energy is taken into account in some treatments but not in others.

17.35.3 Impact effects

Before considering damage caused by the fragment, it is appropriate to mention several effects associated with the impact of a high velocity object on a steel target.

Accounts of impact and its effects include *Impact by Goldsmith* (1960) and *Impact Strength of Materials* by W. Johnson (1972).

The impact effects of principal interest here are those which bear on the effective force exerted, the effective strength of the material and the nature of the target response.

The force exerted by a rapidly applied load is twice that of a slowly applied load. Thus, consider, as an approximate treatment, a vertical rod with a disc at the bottom and with an annular weight around the rod of the same radius as the disc and of mass m. Let this weight be suddenly applied from effectively zero height, to the disc so that it produces in the rod an extension x. Then, by energy balance the force F exerted on the disc is

$$mgx = \frac{1}{2}Fx$$

Hence

$$F = 2mg$$

This is twice the force exerted by a static load for which $F = mg$.

If a load is applied very rapidly to a steel object so that the strain rate is high, there is an increase in the effective strength of the material. This may be expressed as the ratio of the yield stress to the static yield stress, the ratio increasing with the strain rate. From the work of N. Jones (1983) this dynamic strength factor is of the order of 2 at a strain rate of 10^2 and 3 at one of 10^3.

The nature of the impact also affects the response of the target and the mode of deformation. If the load is applied slowly, quasi-static failure modes apply, whilst if it is applied very rapidly, dynamic failure modes come into play. Further, if the velocity of impact is very high, the effect may be intense, but localized.

The rapidity of loading at which these different effects come into play varies with the effect.

17.35.4 Modes of damage

Some modes of damage to pipework are exemplified by those considered in relation to the 4 in. condensate line mentioned. This pipe passed through the firewall from C Module into B Module, took a 90° bend and ran parallel to the wall, then took another 90° bend and ran away from the wall, into the main oil line. The pipe was understood to have had an outside diameter of 114 mm and a wall thickness of 11.1 mm (revised from an initial value of 8.6 mm) and to have been operating at a pressure of about 62 bar. In the analysis the steel was treated as having a yield stress of 260 N/mm^2, an elastic modulus of 210 N/mm^2, a Poisson ratio of 0.3 and a density of 7850 kg/m^3.

The modes of damage considered by Palmer are listed in Table 17.52.

Table 17.52 *Estimated minimum energy or velocity requirements for failure of the 4 in, condensate line on Piper Alpha (after A.C. Palmer, 1989)*

17.35.5 Models for damage

In general, the energy absorbed, or work done, during deformation caused by a slowly applied load is obtained from the relation

$$U = \frac{1}{2}FS \quad [17.35.1]$$

with

$$\delta = le \quad [17.35.2]$$

where e is the strain, F is the force applied (N), l is the length of pipe stretched (m), U is the energy absorbed (J) and δ is the resultant elongation (m). As shown above, for a load applied rapidly, as in impact, the force is twice the static force.

Considering first the failure modes for a load applied relatively slowly, the tensile failure mode involves failure of a section of the pipe under tension due to application of a load which causes the ultimate tensile stress to be exceeded. For this mode, the model for energy absorbed, or work done, is given by Equation 17.35.1 using the impact force value.

For bending, two regimes were considered: elastic bending and plastic bending. When a pipe is bent, it first responds elastically and then starts to yield. Once yielding has begun, an increasing proportion of the cross-section deforms plastically, in compression on one side of the pipe and in tension on the other. The pipe cross-section becomes oval and then a buckle forms on the compression side. For this mode, the model for energy absorbed, which is that applicable to the plastic regime, the energy absorption in the elastic regime being negligible, is essentially

$$U = \phi\theta \quad [17.35.3]$$

where θ is the angle of the bend (rad) and ϕ is the plastic moment (Nm).

For shear, the limiting shear force depends on the details of the loading. One approach is to assume that the distribution of the shear stress is similar to that in a circular tube acting as a beam. An estimate may then be made of the energy for the shear displacement of one pipe wall thickness.

For cutting, two distinct modes are considered: cutting to leak and cutting off. The first involves cutting through to the extent that a leak occurs and the second cutting to the extent of a complete guillotine break. For this mode, the model used for energy absorbed is that of Lu (1989). This model is based on measurement of the energy absorbed when a sharp rigid wedge is pushed through a flat steel plate. This energy is

$$\frac{U}{\sigma_y t^3} = 3\frac{L}{t}, \quad \frac{L}{t}\text{small} \qquad [17.35.4]$$

$$= 2.5\left(\frac{L}{t}\right)^{1.3}, \quad 5 < \frac{L}{t} < 100 \qquad [17.35.5]$$

where L is the length of the cut (m), t is the thickness (m) and σ_y is the yield stress (N/m^2). The length of the cut is taken for cutting to leak as part of the circumference and for cutting off as the whole circumference.

For denting, again two modes are considered: denting by a concentrated force and denting by an edge. These evidently correspond to denting by a blunt and by a sharp-edged object, respectively. For the first mode, in which the load is assumed to be a radial force applied over a circular area of the pipe, the model for energy absorption used is that of A.J. Morris and Calladine (1971). The force for plastic collapse is determined and the energy absorbed is obtained from this force and the depth of the dent, using Equation 17.35.1.

For the second mode of denting, in which the load is assumed to be applied by a sharp-edged object at right angles to the pipe, the model for energy absorption used is that of Wierzbicki and Myung Sung Su (1986).

Moving on to the failure modes for a load applied very rapidly, these modes occur only if at impact the fragment has a certain minimum velocity as well as the requisite minimum energy. For these modes, therefore, Table 17.52 gives minimum values for both velocity and energy.

Dynamic tensile failure is caused by the very sudden application of a tensile load. For the minimum velocity, the model used is based on the work of Kolsky (1963) on tensile plastic waves in a bar whose end is suddenly given a velocity v. It applies to the case where the velocity thus imparted exceeds that at which the steel just becomes plastic. The velocity v is related to the strain e_p behind the plastic wave front set up by the impact. If the velocity is high enough for this strain to reach the ultimate tensile strain, failure occurs. The relation between the velocity v and the strain e_p is

$$v = \int_0^{e_p} [\sigma_t(e)/\rho]^{1/2}\, de \qquad [17.35.6]$$

where e is the strain, e_p is the strain behind the plastic wave front, v is the imparted velocity (m/s), ρ is the density of steel (kg/m^3) and σ_t is the tensile stress (N/m^2).

For the minimum energy for dynamic tensile failure, the approach is similar to that for the quasi-static tensile failure described above, except that a factor, taken as 3, is applied to the yield stress to allow for the suddenness of the application of the load, or dynamic effect.

Dynamic puncturing is gouging caused by high velocity impact. For the minimum velocity the model used is based on the velocity required to raise the local compressive stress to the yield point and thus just to enter the plastic regime and is

$$\sigma_c = \rho c v \qquad [17.35.7]$$

where c is the velocity of elastic compression waves in steel (m/s), v is the velocity of impact of the missile (m/s) and σ_c is the compressive stress caused by the impact (N/m).

For the minimum energy for dynamic puncturing, the model used is that of W. Johnson (1972). This model gives the energy required to gouge out a cavity and is

$$U = 3\sigma_y V_c \qquad [17.35.8]$$

where V_c is the volume of the cavity (m^3). The yield stress used here is again enhanced by a factor of 3 to allow for the dynamic effect.

17.36 Explosion of a Cased Explosive

Another event which can give rise to missiles is the explosion of a cased explosive. This is considered in this section. Whilst the discussion has most relevance to an explosion involving munitions, there are features which have wider application.

There is obviously a large volume of work done by the military dealing with the various aspects of this problem. In particular, the accounts given in *Structural Defence* by Christopherson (1946) and in the *Textbook of Air Armaments* (referred to below as the *Textbook*) by the Ministry of Supply (1952) provide a basic starting point, though this needs to be supplemented by more recent work on the specific aspects.

A model for an exploding object which draws on this work has been given by Gilbert, Lees and Scilly (1994f,g), and the account here is based mainly on this.

In addition to the models specifically for fragments from cased explosives described below, further material on missiles is given in Section 17.34.

17.36.1 Exploding object

The exploding object primarily considered is a cased high explosive, typically a shell or bomb. The explosive could be some combination of TNT and RDX. The following treatment, therefore, is in terms of weapons.

17.36.2 Fragment mass distribution

The fragmentation behaviour of a cased explosive varies depending on the nature of the casing. A plain casing will undergo natural fragmentation. An armament such as a shell may be high explosive or shrapnel. In the latter case the casing is designed to give a particular pattern of fragments.

The fragment mass distribution of this latter type of casing is obtained experimentally by conducting an explosion and collecting the fragments formed. In some cases information is also obtained on the fall of the fragments.

Work on fragment mass distribution (FMD) includes that of Mott (1947), Held (1968, 1979, 1990), Grady (1982a,b), C.E. Anderson, Predebon and Karpp (1985), Burman (1989), Helwig, Klee and Hubner (1989) and Jagusch (1989).

An early method of representing the FMD was that of Mott (1947). That described here is the method developed by Held (1968, 1979, 1990). The correlation is

$$M(n) = M_o[1 - \exp(-Bn^{\lambda})] \qquad [17.36.1]$$

where $M(n)$ is the cumulative fragment mass, or overall mass of the fragments of number n, starting with the largest fragment, M_o is the total mass of fragments, n is the number of the nth largest fragment, or cumulative fragment number, and B and λ are constants.

The mass m of the nth fragment is obtained from Equation 17.36.1 by differentiation:

$$m = \frac{\mathrm{d}M(n)}{\mathrm{d}n} = M_o B\lambda n^{\lambda-1} \exp(-Bn^{\lambda}) \quad [17.36.2]$$

Held (1990) gives as an example the fragment mass distribution of the Hispanic Suiza 30 × 170 mm incendiary high explosive projectile. The parameters which he obtains for this weapon are $M_o = 288.7$ g, $B = 0.511$ and $\lambda = 0.7318$.

In some cases an improved fit for higher values of n is obtained by replacing M_o with a modified mass M_{oB} defined as that value which best fits the set of equations

$$M_{oB} = \frac{M(n)}{1 - \exp(-Bn^{\lambda})} \quad [17.36.3]$$

Equation 17.36.1 then becomes

$$M(n) = M_{oB}[1 - \exp(-B_B n^{\lambda_B})] \quad [17.36.4]$$

where B_B and λ_B are constants.

The risk from explosion of a cased explosive depends on the number and size of the fragments. As the number of fragments increases, the risk initially increases but eventually decreases as the fragments become too small to cause injury.

Often it is a stack of weapons which is of interest. Stack effects on FMD are considered in Section 17.36.11.

17.36.3 Projection angle of fragments

Methods exist for the estimation of the angle at which the fragments from a single weapon are projected. Treatments include those of Christopherson (1946), G.I. Taylor (1963a,b) and Karpp and Predebon (1974).

A discussion of the direction in which fragments are projected is given by Christopherson (1946). He states, 'Fragments of the case are, in general, projected normally to the inner surface on which the pressure of the explosive gases acts at the moment of break-up.'

Weapons such as bombs have some curvature along their length, which tends to spread fragmentation over a wider zone. If detonated at one end the casing becomes conical rather than cylindrical, directing fragments away from the initiating end.

A study of the fragmentation of tubular bombs was conducted by G.I. Taylor (1963a,b). He gives the following equation for the angle ϕ formed by the deforming case relative to the direction of the detonation wave:

$$2 \sin \phi = u_o/D \quad [17.36.5]$$

where D is the velocity of detonation (VOD), u_o is the initial velocity of the fragment (VOF) and ϕ is the angle to the axis of the tube at which fragments are projected. ϕ is known as the Taylor angle.

In practice, these models of projection angle appear of limited use in accident modelling, where the appropriate approach depends on the particular case. Considering the plan view, it will be sufficient in many scenarios to assume that for a weapon on its side, fragments of the cylindrical part of the casing are ejected in two broad sectors, whilst for a weapon standing vertically the fragments are ejected in all directions; in both cases the end cap and base can be taken as travelling along the axis of the weapon.

It is also necessary to consider the angle of elevation. In principle, for the case of an exposed person standing vertically, three cases need to be considered, as illustrated in Figure 17.103. In the near field, shown in Figure 17.103(a), the fragments hitting the human target are those projected at low angle α; the fragments approach the target with near normal incidence. In the medium field, shown in Figure 17.103(b), the target is struck by some fragments of low trajectory issuing at angle $\beta \pm \delta_1$ and others of high trajectory issuing at angle $\gamma \pm \delta_2$; in both cases the fragments approach the target obliquely. Finally, at the limit of the fragment range, shown in Figure 17.103(c), these two trajectories combine; again the fragments approach the target obliquely. This is an idealized model. In practice, due to air drag, fragments slowing below a critical velocity will tend to stall.

Frequently weapons are in an ordered stack. Alternatively, in an accident, they may be in a disordered pile. In each case there is an effect on the angle of projection. Stack effects on projection angle are discussed in Section 17.36.11.

17.36.4 Initial velocity of fragments

Methods of determining the initial velocity of the fragments from a weapon include those given in the *Textbook, in Structural Defence* and by Gurney (1943), V.J. Clancey (1972b), Kamlet and Finger (1979) and E. Hirsch (1986).

One approach to the estimation of the initial velocity of fragments is the use of empirical rules. The *Textbook* suggests values for the initial velocities of 4000 ft/s for bomb fragments and 3000 ft/s for shell fragments.

For fragments from the bursting of a cased TNT charge the following empirical values of initial velocity have been given by V.J. Clancey (1972b) in the context of incident investigation:

Thin case	8000 ft/s
Medium case	6000 ft/s
Thick case	2000 ft/s

This approach provides a useful guideline, but as Clancey points out, it assumes that any size charge will propel fragments the same distance, which is not the case – larger explosions tend to project fragments further.

One equation for the initial velocity of the fragments is that given in *Structural Defence* by Christopherson (1946):

$$V_o = \{8.22 \times 10^7[1 - \exp(-0.69E/C)]\}^{1/2} \quad [17.36.6]$$

where C is the mass of the uniform cylindrical case per unit length (lb), E is the mass of charge per unit length (lb) and V_o is the initial velocity (ft/s). Equation 17.36.6 is a generalization of an empirical equation obtained by Payman for small tetryl filled bombs. Christopherson states, 'for a medium case bomb, the initial velocity of fragments will not exceed approximately 7500 ft/s.'

The correlation for initial velocity which appears to be most widely used is that of Gurney (1946). The Gurney model is based on a fundamental energy balance. The sum

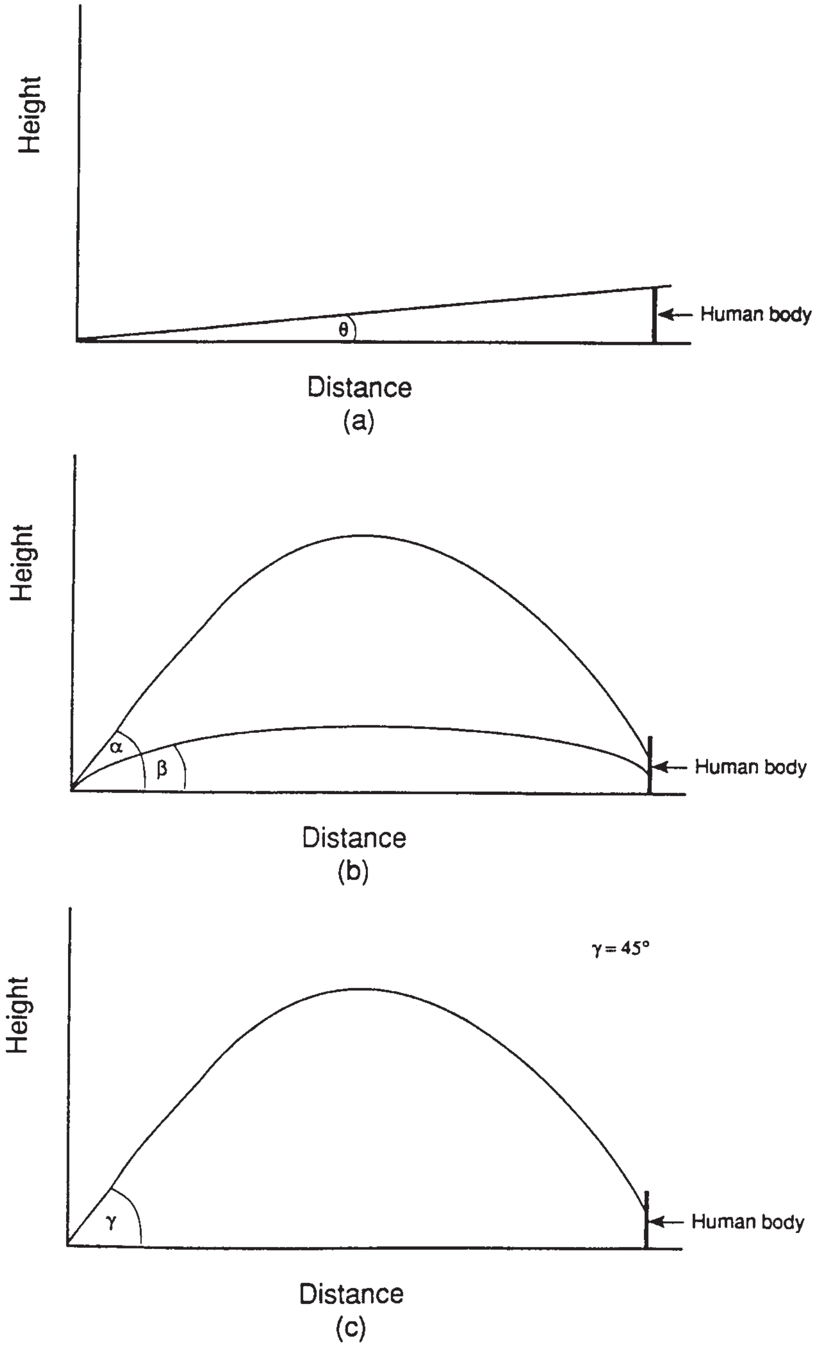

Figure 17.103 *Angle of projection in the vertical plane of missiles from a cased explosive: (a) near field (b) medium field and (c) limit of range (Gilbert, Lees and Scilly, 1994f)*

of the kinetic energy of the fragments and the energy of the expanding explosion products is equated to the internal energy of explosion. It is assumed that all the fragments are projected out at the same velocity and that the velocity of the gaseous explosion products increases from 0 at the centre of the mass of the explosive to a maximum which is also the velocity of the fragments at the moment of break-up of the casing.

The equation given by Gurney for the initial fragment velocity u_o is

$$u_o = C_G\left(\frac{C/M}{1+(C/M)/2}\right)^{1/2} \qquad [17.36.7]$$

with

$$C_G = [2(-\Delta E)]^{1/2} \qquad [17.36.8]$$

where C is the mass of explosive (kg), ΔE is the internal energy of explosion per unit mass of explosive (J/kg), M is the mass of the cylindrical section of the casing, and hence of the sidewall fragments (kg), u_o is the initial fragment velocity (m/s) and C_G is the Gurney constant (m/s). C_G is also commonly known as the Gurney velocity.

The Gurney constant is one of the standard parameters of an explosive. Values for a number of the more common explosives are given by Kinney and Graham (1985).

The use of the Gurney equation to determine the velocity of fragments from an explosion is known as a Gurney analysis. Accounts of such analysis have been given by G.E. Jones, Kennedy and Bertholf (1980) and Kinney and Graham (1985).

Further treatments of the Gurney method have been described by Kamlet and Finger (1979) and E. Hirsch (1986). Kamlet and Finger give for the Gurney constant the following relation:

$$C_G = 0.887\phi^{0.5}\rho_o^{0.4} \qquad [17.36.9]$$

with

$$\phi = NM^{0.5}Q^{0.5} \qquad [17.36.10]$$

where C_G is the Gurney constant (km/s), M is the average molecular weight of the products of explosion, N is the number of moles of gas produced by the explosion, Q is the heat of detonation (cal/g), ρ_o is the explosive loading density (g/cm^3) and ϕ is a parameter. Stack effects on initial velocity are considered in Section 17.36.11.

17.36.5 Flight of fragments

Treatments of the flight and retardation of fragments include those in the *Textbook* and in *Structural Defence* and by Zaker (1971) and Naz (1989). For the retardation of fragments the *Textbook* gives

$$u = u_o \exp(-s/284\,m^{1/3}) \qquad [17.36.11]$$

where m is the mass of the fragment (oz), s is the distance travelled (ft), u is the velocity of the fragment (ft/s) and u_o is its initial velocity (ft/s).

In his account in *Structural Defence*, Christopherson states:

> Immediately after the case has broken up, the shock front expands more rapidly than the case, and thus at this stage the fragments are surrounded by air moving outwards, at a velocity comparable to their own. It is not long, however, before the rapid deceleration of the shock front due to the falling shock-wave pressure allows the fragments to overtake it and pass through it into the zone of undisturbed air beyond. As soon as this happens – and it happens within a few feet of the bomb – the fragments are retarded by a force which is proportional to the square of their velocity, and to the area presented. Under these conditions, it is easy to show that the velocity at a distance x ft from the origin is given by an equation of the form
>
> $$u = u_o \exp(-kxA/m) \qquad [17.36.12]$$
>
> where A is the area of the fragment, u is the velocity of the fragment, u_o is the velocity of the fragment at the commencement of retardation by air drag, m is the mass of the fragment, x is the distance and k is a constant.

It should be noted that Christopherson's statement that the drag force is proportional to the square of the velocity applies to the subsonic regime only.

Christopherson quotes the following relations for the velocity of a fragment in air, based on a generalization of an equation given by Payman for tetryl filled tubes

$$u = u_o \exp(-0.00204xa/m^{1/3}), \quad u \geq u_s \qquad [17.36.13a]$$

$$u = u_o \exp(-0.00137xa/m^{1/3}) \quad u < u_s \qquad [17.36.13b]$$

with

$$a = A_m/Q^{2/3} \qquad [17.36.14]$$

where a is the dimensionless coefficient of area, A_m is the mean area presented by the fragment in flight (ft^2), Q is the fragment volume (ft^3), u is the velocity of the fragment (ft/s), u_o is the initial velocity of the fragment (ft/s), u_s is the velocity of sound (ft/s), m is the mass of the fragment (oz) and x is the distance (ft). The value quoted for the velocity of sound is 1100 ft/s.

For natural fragmentation Christopherson quotes work at the Safety in Mines Research Station to the effect that

$$a = 1.93 + 1.3m \qquad [17.36.15]$$

Christopherson states that for a cube the value of a is 1.5, but that for natural fragments it is higher. He argues that there will be very few fragments for which the term $a/m^{1/3}$ is less than 2. Equation 17.36.15 gives for $a/m^{1/3}$ a minimum value of 3.2 at $m = 0.75$ oz.

A large fragment tends to retain its velocity. Such a fragment will travel some hundreds of feet before its velocity is halved.

The model for fragment flight given by V.J. Clancey (1972b) and quoted in Section 17.34 appears very similar to that of Christopherson.

Another relation for the flight of a fragment from a weapon is that given by Naz (1989):

$$u = u_o \exp\left(-\frac{C_x A_s}{2m}\rho_a x\right) \qquad [17.36.16]$$

where A_s is the effective area of the fragment (m^2), C_x is the drag coefficient, m is the mass of the fragment (kg), u is the velocity of the fragment (m/s), u_o is its initial velocity (m/s), x is the distance (m) and ρ_a is the density of air (kg/m^3). For the effective area A_s Naz gives

$$A_s = (\pi/4)a^2 \quad \text{sphere} \qquad [17.36.17a]$$

$$A_s = (3/2)a^2 \quad \text{cube} \qquad [17.36.17b]$$

where a is the diameter of the sphere or the side of the cube (m).

For the coefficient C_x Naz gives relations from the work of Suterlin (1966), which show the coefficient for spheres, cubes and cylinders as a function of Mach number. He also quotes work by McCleskey (1988a) which shows that there is a considerable scatter in observed values of the coefficient.

17.36.6 Range of fragments

The account of fragment flight given by Christopherson in *Structural Defence* also includes a treatment of the maximum range of a fragment. From Equation 17.36.13a and taking $a/\mathrm{m}^{1/3}$ as 2,

$$u = u_o \exp(-0.00409x) \qquad [17.36.18]$$

Then, from this equation the distance at which the velocity u falls to the velocity of sound u_s is

$$x = [\ln(u_o/u_s)]/0.00409 \qquad [17.36.19]$$

For an initial velocity of 7500 ft/s Christopherson obtains a distance of 475 ft.

Then, noting that $u = \mathrm{d}x/\mathrm{d}t$ and integrating Equation 17.36.18 with respect to time gives

$$x = [\ln(1 + 0.00409u_o t)]/0.00409 \qquad [17.36.20]$$

or

$$t = [\exp(0.00409x) - 1]/(0.00409u_o) \qquad [17.36.21]$$

From Equation 17.36.21 the time for transition to subsonic velocity is only 0.2 s. This is a negligible proportion of the total flight time.

Utilizing Equation 17.36.13b again with a value of the term $a/m^{1/3}$ of 2 and integrating as before, taking the initial velocity now as that of sound gives

$$x = [\ln(1 + 0.00273u_s t)]/0.00273 \qquad [17.36.22]$$

Christopherson obtains a maximum value of the flight time of 330 s, on the basis that the flight time is necessarily less than the flight time to maximum range in the absence of air resistance, which is $V_v/2g$, where V_v is the initial vertical velocity (ft/s), and that the value of this term for maximum range is necessarily less than $V_o/2^{1/2}$. Then, substituting this flight time of 330 s in Equation 17.36.22 gives a travel distance of 2530 ft, which together with the distance of 475 ft travelled in the supersonic range yields for the maximum range of the fragment a total distance of 3005 ft. He compares this with the distance of 1000 yards usually taken as the danger area for a 1000 lb medium capacity (MC) bomb and comments that the latter is certainly on the safe side, though not so grossly as might be expected in view of the crudeness of the method adopted.

There is also available some empirical guidance on the range of fragments from cased explosives. The empirical correlation for the maximum horizontal range of fragments from a cased charge given by V.J. Clancey (1972b) has been described in Section 17.4.

Guidance is also available from relationships for safety distances. A formula of this type is the US safety distance in bomb disposal work. This is given by Kinney and Graham (1985), quoting Lenz (1965), as follows:

$$r = 120W^{1/3} \qquad [17.36.23]$$

where r is the safety distance (m) and W is the mass of explosive (kg). There is a minimum distance of 90 m. However, since this is a safety formula it may be expected to incorporate a safety factor.

17.36.7 Mean presented area of fragments

The mean presented area (MPA) of the fragments is relevant both to their flight and to their injuring power. In the treatment just given, which is concerned with flight, the MPA is given by Equations 17.36.14 and 17.36.15.

17.36.8 Number of fragments hitting target

Following the *Textbook*, the number n of incapacitating fragments is

$$n(x) = \int_0^\infty q(v, x) r(x) \mathrm{d}v \qquad [17.36.24]$$

where n is the number of incapacitating fragments, q is the number of fragments of equivalent velocity v at a distance x, r is the proportion of fragments of equivalent velocity v at a distance x capable of causing incapacitation, v is the velocity of the fragment (ft/s) and x is the distance (ft).

The density of incapacitating fragments over the area of a sphere centred on the exploding object is

$$\frac{N(x)}{A_p} = \frac{n(x)}{4\pi x^2} \qquad [17.36.25]$$

where A_p is the projected area of the exposed person (ft^2) and N is the average number of incapacitating fragments at a distance x. Hence

$$N(x) = \frac{n(x)A_P}{4\pi x^2} \qquad [17.36.26]$$

The value of the projected area A_p does not appear to be given explicitly in the *Textbook*, but a value of 2.8 ft^2 may be inferred.

The probability p of being hit by one or more incapacitating fragments is taken as given by the Poisson distribution and is therefore

$$p = 1 - \exp[-N(x)] \qquad [17.36.27]$$

A vulnerable area A_v may be defined as the equivalent ground area in which probability of incapacitation is unity. This vulnerable area is

$$A_v = \int_0^\infty p(x) x \, \mathrm{d}x \qquad [17.36.28]$$

where A_v is the vulnerable area (ft^2).

The vulnerable area so defined takes no account of any hard cover which may provide protection from the fragments.

The *Textbook* gives as an illustrative example the determination of the fragments from a British 20 lb bomb. The example is described by Gilbert, Lees and Scilly (1994f).

17.36.9 Textbook model

The model of an exploding weapon given in the *Textbook* utilizes the framework relations Equations 17.36.24–17.36.27 together with the following supporting equations. The FMD is obtained from experimental values for the particular weapon. The fragments are evidently assumed to be projected equally in all directions with an initial velocity obtained from the empirical values quoted. The flight and retardation of the fragments are given by Equation 17.36.11. As described in Section 17.42, the *Textbook* also includes an injury model.

17.36.10 Model of Gilbert, Lees and Scilly

In the model of Gilbert, Lees and Scilly (1994f) use is again made of Equations 17.36.24–17.36.27 as the framework, but with a different set of supporting relations. The FMD is based on fitting the experimental values for the weapon to Equation 17.36.1 of Held. The angles of projection in plan and elevation depend on the problem considered and guidance is given on this aspect. For the initial velocity use is made of the Gurney equation (Equation 17.36.7) with the Gurney constant given by Equation 17.36.9 of Kamlet and Finger. The flight and retardation of the fragments is described by Equation 17.36.13 of Christopherson, which covers both sonic and subsonic regimes.

The model is used in conjunction with the model for injury from penetrating fragments given by the authors and described in Section 17.42.

Gilbert, Lees and Scilly (1994g) also describe a computer program EXFRAG which gives for an exploding weapon the probability of defined degrees of injury as a function of distance and give an illustration of the results obtained.

17.36.11 Stack effects

In the foregoing treatment the exploding object is taken as a single weapon. In many situations of practical interest it is likely to be a stack of weapons. There is a potential stack effect on each of the following features: (1) the number of fragments, (2) fragment mass distribution, (3) the projection angle of the fragments, and (4) the initial velocity of the fragments.

There is little published information which can be used to quantify these effects, but the following qualitative comments can be made. In a stack explosion, a significant proportion of the fragments hit other objects within the stack and do not leave the stack. This potentially affects not only the number but also the mass distribution of fragments leaving the stack. The angle of projection of the fragments depends on the nature of the stack, which may be an ordered stack or a disordered pile. The former has to be dealt with on a case by case basis, whilst for the latter the common assumption is that the fragment density is the same in all directions. There may also be stack effects on the initial velocity in so far as fragments may be further accelerated by the hot gases from the explosion.

17.37 Explosion of an Explosive Load

Another situation which it may be necessary to model is the explosion of a load of condensed phase explosives, either uncased or cased. The former might typically be blasting explosives, the latter munitions.

Models for the explosion of a condensed phase explosive, particularly in a built-up area, have been given by Withers and Lees (1991) and Gilbert, Lees and Scilly (1994a–i). The model of the latter is encoded in the program EXMOD, which incorporates the program EXFRAG.

The following account of the modelling of this situation is based on the work described by the latter authors. Using appropriate physical models, it is possible to estimate as a function of distance the intensity of the various physical effects and hence, using the corresponding injury relations, the probability of defined types of injury for defined types of exposure. Then, using a suitable model for the numbers with each type of exposure as a function of distance, an estimate can be made of the numbers suffering each type of injury. Where the explosion occurs not at the start but during the course of an incident, separate estimates can be made for different times into the incident.

17.37.1 Exploding object

The exploding object is envisaged as a load of explosives, typically uncased civil explosives or cased explosives in the form of munitions such as shells, bombs, etc.

17.37.2 Explosion scenario

The elements of the scenario are the events prior to the situation of imminent risk; the explosion itself; the persons at risk; the physical characteristics of the location and the human behaviour prior to the explosion.

The most common scenario for the realization of the hazard is that of engulfment of the explosive load in a fire which lasts long enough to initiate an explosion. This scenario is important not only by virtue of its relative frequency, but also because all the features just mentioned are relevant, which is not the case for every scenario.

The approach to scenario development takes as its starting point the persons at risk, in other words the targets of the explosion. Categories of persons exposed are defined which are intended to be exhaustive over the whole course of the scenario and estimates made of the numbers in each category at the start of the scenario and of the change in these numbers with time until the explosion occurs.

If the explosion is caused by a sudden event such as impact, the start is the explosion itself. If it is caused by a more gradual event such as fire, the start is the occurrence of an event observable either by the vehicle crew or the public.

17.37.3 Explosion effects

The principal effects of a condensed phase explosion such as the explosion of a load of cased explosives on a lorry are:

(1) blast;
(2) fireball;
(3) missiles
    (a) primary fragments,
    (b) secondary missiles;
(3) crater;
(4) building damage.

Primary fragments include those generated by the disintegration of the casing and are also taken to include those from the vehicle. Secondary fragments include fragments from the crater and objects set in motion by the blast wave, not only objects travelling in a more or less horizontal direction, but others such as glass, falling vertically. The blast wave may also cause translation of the human body, causing it to fly through the air or to tumble along the ground, and possibly to impact with some hard object.

There may also be other effects. For example, in some large explosions of explosives in ships at docks, hot fragments have been ejected which then caused secondary fires. These effects are not, however, considered in the model.

17.37.4 Population exposure

These explosion effects act on an exposed population. For this particular type of incident it is necessary to model this population in some detail. The exposure model used covers the population density, the population's disposition indoors and outdoors, the categories of exposure, the incident scenarios and the vulnerabilities of persons in each exposure category in given scenarios.

For exposure a basic distinction is between persons indoors and those outdoors, since this affects vulnerability to the individual injury mechanisms. For example, persons outdoors are more vulnerable to fragments from the casing and those indoors to building collapse.

For each of these groups further distinctions are made based on situation or behaviour. For those indoors the classification used is:

I1 Persons unaware or aware of the incident who go about their normal business
I2 Persons aware of the incident who observe it through a window (or those unaware who happen to be close to a window).

The classification used for those outdoors is:

O1 Persons on foot unaware or aware of the incident who go about their normal business.
O2 Persons occupying vehicles near to the scene.
O3 Persons on foot aware of the incident who have come to the scene as spectators.
O4 Members of the emergency services who have come to the scene.

As stated above, the numbers of persons in each category will in principle change with time, but the scope for such change will depend on the interval between the start of the scenario and the explosion.

At the start of the scenario, there are persons in categories I1, I2, O1 and O2 but, by definition, in no other category. Persons in O1 are essentially pedestrians who are passing by or gathered for some purpose such as an open market.

If the scenario takes a finite time to develop, the numbers in each indoor category may be expected to change. Persons indoors may observe the scene through windows. Alternatively, they may take evasive action against the risk of an explosion, either by moving further away or by changing posture. Some pedestrians may continue about their business, but others will take evasive action, essentially by quitting the scene. Those who by contrast are attracted to the scene are classed as spectators. Likewise, the occupants of vehicles may continue on their journey or may stay near the scene, possibly as spectators, but more probably owing to obstruction of the traffic. In due course, members of the emergency services will arrive. The total number exposed is not assumed to be constant; it may decrease or increase.

The model therefore gives the number of persons exposed in each category at the start of the scenario and over its course. It may be used to obtain an instantaneous picture, or 'snapshot', of these numbers at any time up to the explosion.

17.37.5 Blast

The blast effects for a condensed phase explosive used in the blast submodel are the peak incident overpressure and impulse and the peak dynamic pressure and dynamic pressure impulse, obtained from the relations given in Section 17.26.

Eardrum rupture is a function of peak incident overpressure. Lung injury is a function of peak incident overpressure and, for some postures, of peak dynamic pressure and of impulse. Whole body displacement is a function of peak dynamic pressure and dynamic impulse. The relevant injury relations are given in Section 17.38.

17.37.6 Fireball

The fireball from a condensed phase explosive is described by a submodel different from that for a hydrocarbon fireball. The relevant model is given in Chapter 16. Injury from the fireball occurs due to engulfment in the fireball or thermal radiation from it. It is assumed in the model that a person engulfed in the fireball is killed. The injury relations for thermal radiation are those given in Chapter 16 and are the same as those for injury by radiation from hydrocarbon fireballs or pool fires.

17.37.7 Missiles

The missile submodel treats six types of missile: (1) primary fragments from the casing, if any; (2) fragments from the vehicle; (3) fragments ejected from the crater; (4) secondary missiles set in motion by the blast; (5) falling masonry and glass; and (6) flying glass.

The prime application of these models is to persons outdoors. However, they are also applicable to persons indoors who are near windows; the effect of falling masonry on persons indoors is taken into account in the separate housing damage model given in Section 17.39.

An outline of the model used for fragments from the casing and the vehicle has been given in Section 17.36. The models for crater ejecta and for falling masonry and glass are described in Section 17.34 and that for flying glass in Section 17.40.

No separate model is used for the effects of secondary missiles on persons outdoors; the effect of such missiles indoors is taken into account in the housing damage model.

17.37.8 Building damage

The building damage submodel used is actually a housing damage model.

The housing damage submodel used is the correlation between category of housing damage and mass of explosive as given by the revision by Gilbert, Lees and Scilly (1994c) of the Jarrett equation. This model is described in Section 17.33.

17.37.9 Injury to persons outdoors

The model for explosion injury outdoors is therefore based on four separate broad causes of injury: (1) blast causing eardrum rupture and lung injury, (2) blast causing injury by whole body displacement, or bodily translation, (3) injury from the fireball, and (4) injury from the following types of missile: (4a) primary fragments from the casing, if any, (4b) fragments from the vehicle, (4c) crater ejecta, (4d) falling masonry and glass, and (4e) flying glass. The models for injury from these various causes have just been described. The probability of injury outdoors is estimated by applying each of these submodels in turn.

The model gives the probability of lethal injury for all the injury modes mentioned; in some cases it also gives the probability of sublethal types of injury, e.g. eardrum rupture.

Allowance is made in the model for multiple injury, as described in Chapter 9 and in Section 17.38.

17.37.10 Injury to persons indoors

The model for explosion injury to person indoors is based on the correlation between category of housing damage and probability of injury described in Section 17.39. The latest is the model of Oswald and Baker (2000).

This correlation gives the probability not only of lethal injury but also that of severe injury and light injury.

This model for injury to persons indoors includes injury from flying glass, but, where appropriate, this latter may be accorded separate treatment, using the model for injury from flying glass given in Section 17.40.

17.37.11 Large targets

The model also includes an estimate of the probability that an explosion occurring at random in a built-up area will find a target comprising a large number of people, such as a block of flats or a large store or market. The estimate is based on the size distribution of targets hit by V-2 rockets. From these data the authors give the following estimates of incident size versus probability of occurrence:

Deaths	*Probability*
≥10	0.089
≥33	0.014

It should be borne in mind that the data include a number of cases where there was a direct hit and that the population densities in wartime London were much higher than they are today, by a factor in the range 1.5–2.

17.38 Explosion Injury to Persons Outdoors

For persons in the open there is a large amount of information available on specific explosion injury causes and modes. Accounts are given in *The Effects of Nuclear Weapons* (Glasstone, 1962; Glasstone and Dolan, 1980) and in *Explosion Hazards and Evaluation* (W.E. Baker *et al.*, 1983).

Much of the data on injury from explosions derives from the work of Zuckerman and co-workers in the 1940s, from work on the effects of nuclear weapons described by Glasstone (1962) and Glasstone and Dolan (1980) and from an extensive programme of research at the Lovelace Foundation in the 1960s, 1970s and 1980s, which has been reported by Bowen, Fletcher, Richmond, White and other workers. Some of this latter work is listed in Appendix 28.

A set of correlations of explosion injury is given in the *Green Book*.

The causes of explosion injury to a person in the open include the following: (1) blast, (2) whole body displacement, (3) missiles, (4) thermal effects, and (5) toxic effects.

The modes of explosion injury due to these causes include (1) eardrum rupture, (2) lung haemorrhage, (3) whole body displacement injury, (4) missile injury, (5) burns, and (6) toxic injury.

In the case of outdoor exposure, it is generally possible to apply the injury relations for the individual physical causes, provided that where applicable due allowance is made for the effects of more than one cause.

There are several ways in which injury may be correlated. One is in terms of single values of the injurious physical effect, of which the threshold value and the value for 50% probability of injury are particularly important. Another is a probit equation, which also generally correlates the probability of injury with a single physical effect, typically overpressure. A third is in the form of a P–I diagram.

Data in forms such as threshold and 50% probability values are illustrated by those given in Table 17.53 from the work of Glasstone and of White.

Probit equations have been widely used to express injury relations. The use of probit equations is illustrated by the many correlations of injury given by the Lovelaci Foundation workers which are cast in this form.

The probit equation form is also that used in the vulnerability model described by Eisenberg, Lynch and Breeding (1975). Much of the data on which these relations are based derives from the work of Fugelso, Weiner and Schiffman (1972). These relations have beer quite widely used, mainly for lack of other data, and some are described below, but comparison with the other relations given indicates that they generally predict considerably higher levels of injury than those by other researchers.

Table 17.53 *Some data on the injury effects of explosions: direct blast effects*

Effect	*Effective peak overpressure*[a] (psi)		
	Duration		
	Glasstone[b]	*White*[c]	
	'Long'[b]	3 ms[c]	400 ms
Eardrum rupture			
Threshold	5	5	5
50% (≥20 years old)	15–20	15–20	15–20
50% (≤20 years old)	30–35		
Lung damage			
Threshold	12 (8–15)	37–49	12–15
Severe	25 (20–30)	≥98	≥37
Lethality			
Threshold	40 (30–50)	112–156	37–52
50%	62 (50–75)	156–217	52–72
100%	92 (75–115)	217–302	72–100

[a] This overpressure is described as the maximum effective overpressure. It is stated that this may be one of the three defined overpressure, one of which is the maximum incident overpressure for free-stream exposure if the axis of the subject is parallel to the direction of travel of the blast wave.

[b] Tentative criteria for some injury effects applicable to a fast-rising, long-duration overpressure (after Glasstone, 1962).

[c] Tentative criteria for some injury effects in young adults applicable to fast-rising, short- or long-duration overpressure (after C.S. White, 1968b).

The third form of P–I diagram is illustrated by those given by W.E. Baker *et al.* (1983).

17.38.1 Eardrum rupture

The data for eardrum rupture given by Glasstone (1962) and by C.S. White (1968b) are shown in Table 17.53. Both sets of data apply to rapidly rising overpressure. In general, White distinguishes between short- and long; duration overpressures, but his data for eardrum rupture are identical.

Relations for eardrum rupture are given in the vulnerability model described by Eisenberg, Lynch and Breeding. They quote the following data from Fugelso, Weiner and Schiffman:

Probability of eardrum rupture (%)	*Peak overpressure*	
	(psi)	(N/m^s)
1 (threshold)	2.4	16,500
10	2.8	19,300
50	6.3	43,500
90	12.2	84,000

They derive from these data a probit equation relating eardrum rupture to peak overpressure:

$$Y = -15.6 + 1.93 \ln p^{\mathrm{o}} \qquad [17.38.1]$$

where p^{o} is the peak overpressure (Pa) and Y is the probit.

Eardrum rupture has been discussed by F.G. Hirsch (1968), who reviews the physiology of the ear and injury to it and summarizes the available data on the blast conditions causing rupture.

The ear responds to sound waves, and a blast wave is physically the same phenomenon. For sound waves the ear responds over the frequency range 20–20,000 Hz and at very low energy levels. It is unable, however, to respond faithfully to a pulse with a period of less than 0.3 ms, and the attempt to do so results in a single, large excursion, and it is this which causes rupture. The response is governed by the peak overpressure and the rise time of the overpressure.

Hirsch states that it has been established that there is a direct relation between peak overpressure and eardrum rupture.

He states further that there is evidence that other parameters such as rate of rise and positive and negative duration also have an influence. Rapid rise of overpressure tends to increase the probability of rupture. Hence, data from loading by explosion overpressures is more applicable than data from loading by static pressures.

Zalewski (1906) performed tests in which cadavers were subjected to static pressures. He obtained a mean pressure for rupture of 22.9 psi. Zuckerman and co-workers (Blake *et al.*, 1941) did work on cadavers, but used slow rising overpressures from explosions. They found for 50% probability an overpressure of about 1 atm (14.7 psi). In other studies on air raid casualties they obtained for 50% probability of rupture a lower limit of 15 psi and an upper limit of 50 psi.

G.A. Henry (1945) studied 292 men who had been subjected to a landmine explosion, 52% of whom had suffered eardrum rupture. He estimated the overpressure as 17 psi. Other data reported on eardrum rupture are those of Vadala (1930) for anti-aircraft gun blast and those of Reider (1968) for two industrial explosions. These data have been plotted by Hirsch as shown in Figure 17.104.

Hirsch reviews the data for threshold and 50% probability of eardrum rupture and obtains for a fast rising overpressure, pulse estimates of 5 and 15 psi, respectively.

The probit equation for eardrum rupture obtained from Figure 17.104 is

$$Y = -12.6 + 1.524 \ln p^{\mathrm{o}} \qquad [17.38.2]$$

Equation 17.38.2 is that given for eardrum rupture in the *Green Book*.

On the basis of the data given by Hirsch, W.E. Baker *et al.* (1983) have derived a P–I diagram for eardrum rupture. The lines for the threshold and 50% probability values are horizontal lines and correspond to peak overpressures of 5 and 15 psi, respectively.

17.38.2 Lung injury

Direct blast effects, particularly lung haemorrhage, have been studied by a number of workers, including Zuckerman (1940, 1941), Krohn, Whitteridge and Zuckerman (1942), Glasstone (1962), I.G. Bowen, Fletcher and Richmond (1968), Richmond, Damon *et al.* (1968), C.S. White (1968b) and C.S. White *et al.* (1971).

Early work on direct blast effects was carried out by Zuckerman (1940), who combined experimentation on the exposure of tethered goats to explosions with analysis of air raid casualties. In the experiments he used 70 lb charges, giving an overpressure of about 15 psi at 30 ft with a duration time of about 5 ms. Zuckerman estimated that for a 500 lb bomb the lethal overpressure for man is between 400 and 500 psi (between 27.6 and 34.5 bar).

The data of Glasstone and of White are shown in Table 17.53. These data indicate for long overpressure pulses a 50% lethality at an overpressure of about 60 psi

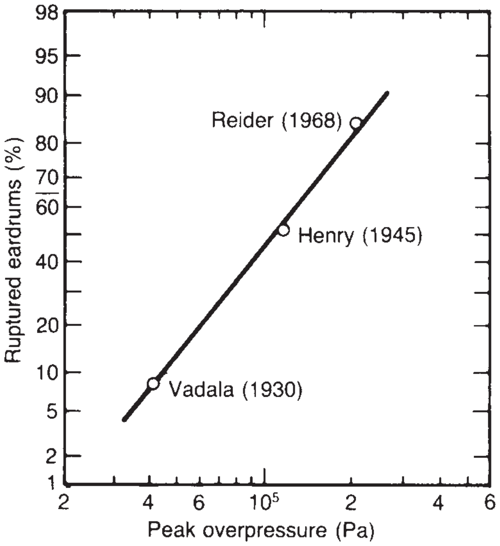

Figure 17.104 *Injury effects of explosions: eardrum rupture (after F.G. Hirsch, 1968) (Courtesy of the New York Academy of Science)*

(4.1 bar), but for short pulses much higher values of overpressure.

Work by Withers and Lees (1991) suggests that the overpressure for 50% lethality increases from about 10 bar for charges of 10 kg TNT to 4 bar for charges of 1000 te TNT.

Relations for death due primarily to lung haemorrhage are given in the vulnerability model by Eisenberg, Lynch and Breeding. They quote the following data from Fugelso, Weiner and Schiffman:

Probability of facility	*Peak overpressure*	
	(psi)	(N/m^2)
1 (threshold)	14.5	100,000
10	17.5	120,000
50	20.5	140,000
90	25.5	175,000
99	29.0	200,000

They derive from these data a probit equation relating death primarily from lung haemorrhage to peak overpressure:

$$Y = -77.1 + 6.91 \ln p^{o} \qquad [17.38.3]$$

Extensive work on direct blast effects was conducted in the 1950s and 1960s at the Lovelace Foundation and has been reported by Bowen, Fletcher, Richmond, White and co-workers (e.g. I.G. Bowen, Fletcher and Richmond, 1968; Richmond, Damon *et al.*, 1968; C.S. White *et al.* 1971).

This work has yielded a large amount of data on blast effects. The effects were studied for a variety of positions of the subject (standing, lying, etc.) and of situations of the subject (free stream, near wall, etc.). It was therefore necessary to correlate the results not only in terms of the peak incident overpressure, but also of various peak reflected overpressures.

J.G. Bowen, Fletcher and Richmond (1968) distinguish between the cases shown in Figure 17.105. Figure 17.105(a) shows the case where the longitudinal axis of the body lies

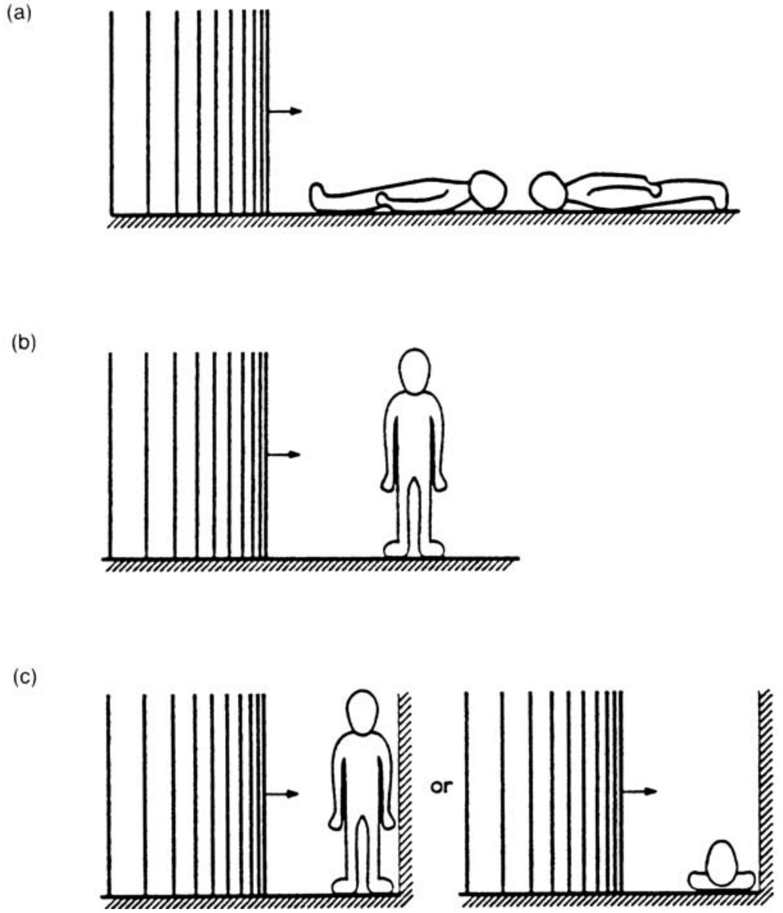

Figure 17.105 *Injury effects of explosions – postures determining lung injury (I.G. Bowen, Fletcher and Richmond, 1968): (a) long axis of body parallel to the direction of the blast wave; (b) long axis of body perpendicular to the direction of the blast wave; (c) thorax near a surface against which the blast wave reflects at normal incidence*

in the direction of the shock wave. For this case the peak applicable overpressure is

$$p_a^o = p^o \quad [17.38.4]$$

where p^o is the peak incident overpressure (Pa) and $p_a{}^o$ is the peak applicable overpressure for lung injury (Pa). In Figure 17.105(b) the longitudinal axis of the body is perpendicular to the shock wave. The peak applicable overpressure is in this case

$$p_a^o = p^o + q^o \quad [17.38.5]$$

where q^o is the peak dynamic pressure (Pa). The dynamic pressure is given by the *Green Book* as $q^o = 5P_s^2/(2p_s + 14 \times 10^5)$ for p_s in p_a. The case where the body is in any arbitrary position in front of a surface on which the shock wave reflects is shown in Figure 17.105 (c). In this case the peak applicable overpressure is

$$p_a^o = p_r^o \quad [17.38.6]$$

where p_r^o is the peak reflected overpressure. Expressions for the peak dynamic pressure and peak reflected overpressure are given in Equations 17.25.5 and 17.25.7, respectively.

One of the correlations for lung injury caused by the peak applicable overpressure is shown in Figure 17.106.

These injury relations have been converted by W.E. Baker *et al.* (1983) to the alternative form of a P–I diagram as shown in Figure 17.107. The definition of the scaled peak applicable overpressure and scaled impulse for use in this figure are

$$\bar{p}_a^o = \frac{p_a^o}{p_a} \quad [17.38.7]$$

$$\bar{i} = \frac{i}{p_a^{1/2} m^{1/3}} \quad [17.38.8]$$

where i is the impulse (Pa s), $\bar{i}$ is the scaled impulse (Pa$^{1/2}$ s/kg$^{1/3}$), m is the mass of the body (kg), p_a is the atmospheric pressure (Pa) and is the scaled peak applicable overpressure. These authors recommend the following values for body mass: babies 5 kg, small children 25 kg, adult women 55 kg and adult men 70 kg. These correlations of Bowen, Fletcher and Richmond and of Baker *et al.* are referred to in the *Green Book*, which gives a P–I diagram broadly similar to Figure 17.107 together with the following associated probit equation:

$$Y = 5 - 5.74 \ln S \quad [17.38.9]$$

with

$$S = \frac{4.2}{\bar{p}_a^o} + \frac{1.3}{\bar{i}} \quad [17.38.10]$$

where S is a 'damage number' and Y the probit for fatal injury.

17.38.3 Whole body displacement

Another blast effect is bodily translation, or whole body displacement. Accounts of whole body displacement are given by Glasstone (1962), Clemedson, Hellstrom and Lindgren (1968), C.S. White (1968b, 1971), Richmond and Fletcher (1971), W.E. Baker *et al.* (1983), Hadjipavlou and Carr-Hill (1986) and in the *Green Book*.

The data of Glasstone (1962), Clemedson, Hellstrom and Lindgren (1968), C.S. White (1968b, 1971) and Richmond and Fletcher (1971) are shown in Table 17.54.

The treatment for body translation in the vulnerability model by Eisenberg, Lynch and Breeding is somewhat complex. They derive a probit equation relating lethality for body translation to impulse:

$$Y = -46.1 + 4.82 \ln J \quad [17.38.11]$$

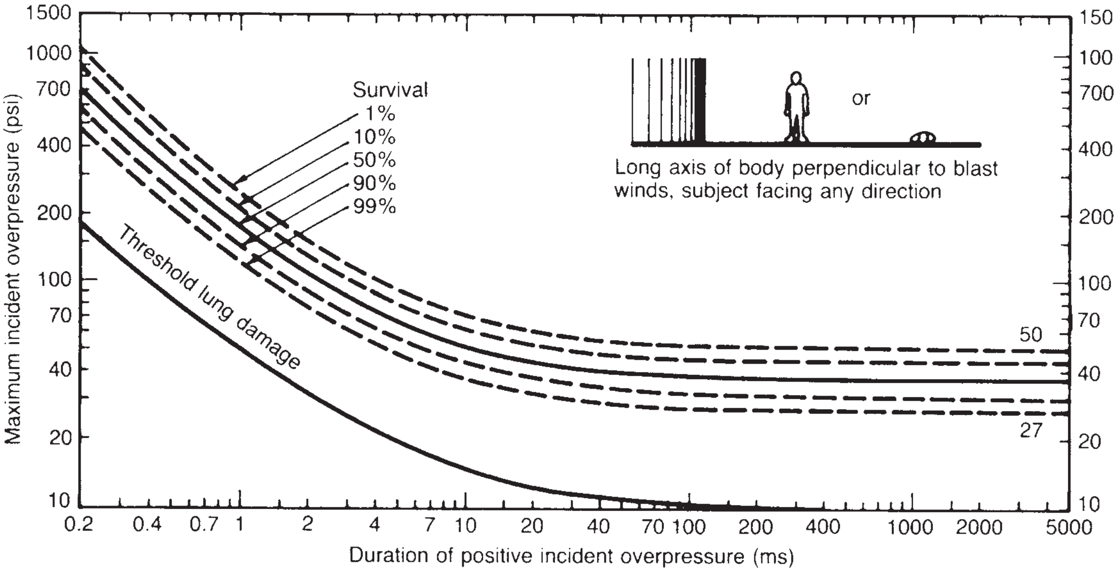

Figure 17.106 *Injury of explosions: lung injury – 1 (I.G. Bowen, Fletcher and Richmond, 1968). Survival curves for a 70 kg man in a free-stream situation with the long axis of the body perpendicular to the direction of the blast wave*

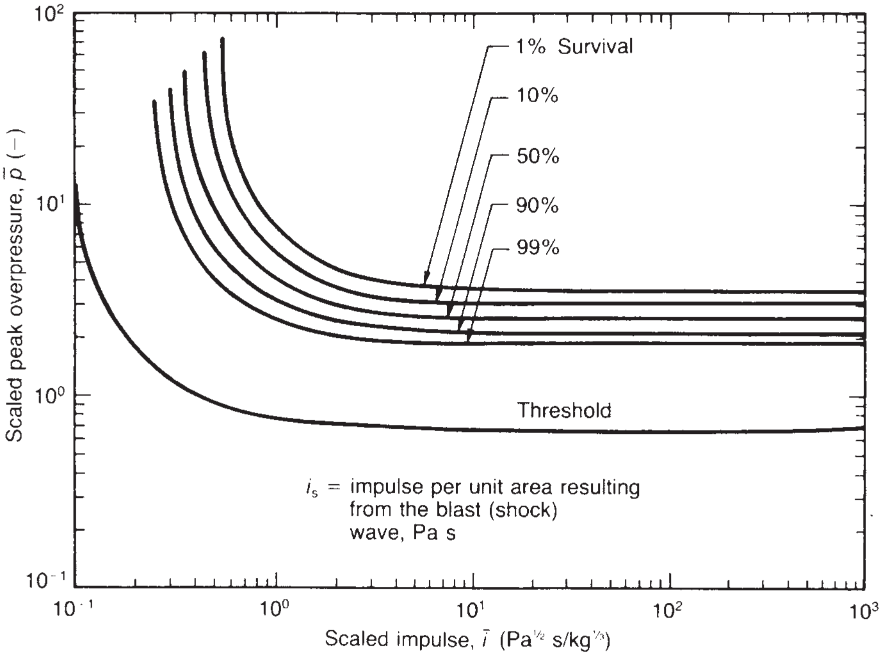

Figure 17.107 *Injury effects of explosions: lung injury – 2 (W.E. Baker et al., 1983). P–I diagram for survival applicable to all three standard postures and to different body weights (see text) (Reproduced by permission of Elsevier Science Publishers)*

with

$$J = \int_0^{t_d} p(t)\,dt \qquad [17.38.12]$$

where J is the impulse (Pa s), p is the incident overpressure (Pa) and t_d is the duration time (s). They also derive a probit equation relating serious injury for body translation to impulse:

$$Y = -39.1 + 4.45 \ln J \qquad [17.38.13]$$

A fundamental treatment of whole body displacement of a person standing involves consideration of the following effects: (1) displacement from the upright to the prone posture, (2) bodily translation followed by impact of the skull, (3) bodily translation followed by impact of the whole, body and (4) tumbling across open terrain, or decelerative tumbling. In the first three cases, injury is due mainly to impact, whilst in the fourth flailing of the limbs is a significant contributor.

Considering these effects in turn, the treatment of displacement from upright is broadly as follows. It is first necessary to consider the force acting on the body. An account of the force acting on structures and objects of different configurations is given in Section 17.32. If the human body is treated like an element in an open structure, the relevant force is that due to the dynamic pressure. Then the force acting on the body initially is

$$F = C_D q^o A \qquad [17.38.14]$$

where A is the projected area of the body (m^2), C_D is the drag coefficient and F is the force acting on the body (N). The dynamic pressure decays from the peak dynamic pressure to 0 over the period of the dynamic pressure duration t_q. Assuming that the shape of the dynamic pressure impulse i_q can be approximated by a triangle,

$$i_q = \tfrac{1}{2} q^o t_q \qquad [17.38.15]$$

where i_q is the dynamic pressure impulse (Pa s) and t_q is the dynamic pressure duration (s). Neglecting deceleration, the velocity u attained by a body of mass m due to this impulse is given by

$$mu = \frac{F t_q}{2} \qquad [17.38.16]$$

where m is the mass of the body (kg) and u is the velocity imparted to the body (m/s).

Relations for the peak dynamic pressure and dynamic pressure impulse are given in Section 17.25. These in combination with the equations just given allow the velocity imparted to the body to be estimated.

A more refined model for bodily translation is given by Hadjipavlou and Carr-Hill (1986), which they term the 'centre-of-mass' model. This model is

$$\frac{d^2x}{dt^2} = \alpha L(t) - F(t) \qquad [17.38.17]$$

Table 17.54 *Some data on the injury effects of explosions: whole body displacement*

A Data in terms of body velocity (Glasstone, 1962)

	Impact velocity	
	(ft/s)	(m/s)
Standing stiff legged impact		
Mostly 'safe'		
No significant effect	<8	<2.44
Severe discomfort	8–10	2.44–3.05
Injury:		
Threshold	10–12	305–3.7
Fracture threshold (heels, feet, legs)	13–16	4.0–4.9
Seated impact		
Mostly 'safe'		
No significant effect	<8	<2.44
Serve discomfort	8–14	2.44–4.3
Injury:		
Threshold	15–26	4.6–7.9
Skull fractures[a]		
Mostly 'safe'	10	3.0
Threshold	13	4.0
50%	18	5.5
Near 100%	23	7.0
Total body impact[b]		
Mostly 'safe'	0	3.0
Lethality threshold	21	6.4
Lethality 50%	54	16.5
Lethality near 100%	138	42

B Data in terms of dynamic impulse (Richmond and Fletcher, 1971)

	Dynamic pressure impulse (psi ms)	*Peak horizontal body velocity*	
		(ft/s)	(m/s)
No personnel blowdown	1.25	0.3	0.092
50% personnel blowdown	8.3	2.0	0.61
1% serious injury from being blown down[c]	54	13	4.0

[a] Data quoted by Clemedson, Hellstrom and Lindgren (1968); C.S.White (1968b, 1971).

[b] Earlier data were given by C.S.White (1968b). The values given here are later, revised values given by C.S.White (1971).

[c] Serious injury such as bone fracture or rupture of internal organs could occur from impact with the ground; high probability of minor injuries such as bruises and lacerations.

with

$$\frac{\mathrm{d}x}{\mathrm{d}t} = u \qquad [17.38.18]$$

$$\alpha = \frac{AC_{\mathrm{D}}}{m} \qquad [17.38.19]$$

$$L(t) = P_{\mathrm{e}}(t) \qquad [17.38.20]$$

where A is the projected area of the body (ft^2), C_{D} is the drag coefficient, F is the deceleration due to friction (ft/s^2), L is the loading on the body (lb$_{\mathrm{f}}$), m is the mass of the body (lb), P_{e} is the effective pressure on the body (lb$_{\mathrm{f}}$/ft^2), t is the time (s), u is the velocity of the body (ft/s), x is the distance travelled by the body (ft) and α is the acceleration coefficient (ft^2/lb).

The authors use for the loading an effective pressure which includes an overpressure as well as a dynamic pressure term. They give values of the acceleration coefficient α for a number of postures. That for a person standing with the body square on to the blast wave is 0.052 ft^2/lb. Then from Equation 17.38.19 for a body area A of 8.9 ft^2 and mass m of 165 lb, the corresponding value of the drag coefficient C_{D} is about 1.0. They quote for the deceleration of the body the following equation of E.R. Fletcher and Bowen (1968):

$$F(t) = 8.9u(t)^{0.383} \qquad [17.38.21]$$

This centre-of-mass model may be rewritten as

$$m\frac{\mathrm{d}u}{\mathrm{d}t} + m\phi_{\mathrm{fr}}(t) = L(t) \qquad [17.38.22]$$

where L is the loading (N), m is the mass of the body (kg), t is the time (s), u is the velocity of displacement (m/s) and ϕ_{fr} is the deceleration due to friction (m/s^2). If the load is taken as due only to the dynamic pressure

$$L(t) = C_D q(t) \qquad [17.38.23]$$

The deceleration term is obtained, with suitable change of units, from Equation 17.38.21.

Hadjipavlou and Carr-Hill give an extensive treatment of the velocity attained by a body subject to a blast wave.

The injury effects arising from whole body displacement may then be determined from the data given in Table 17.54.

Several authors have given probit equations for such injury effects. For lethal injury due to body translation with impact of the skull on a hard surface the following equation is given by Hadjipavlou and Carr-Hill (1986) based on the data of Gurdjian, Webster and Lissner (1949):

$$Y = -6.04 + 7.11 \ln u \qquad [17.38.24]$$

where u is the velocity of the body (m/s). For lethal injury due to body translation with impact of the whole body on a hard surface, R.K. Jones, Richmond and Fletcher (1969) give

$$Y = -2.14 + 2.54 \ln u \qquad [17.38.25]$$

E.R. Fletcher, Yelverton *et al.* (1975) also give an equation for serious injury due to impact on a hard surface:

$$Y = 0.82 + 2.697 \ln u \qquad [17.38.26]$$

The basis of this equation is unclear, but it is suggested by Hadjipavlou and Carr-Hill that it appears to be based on Equation 17.38.25 of Jones, Richmond and Fletcher with a reduction in the severity of the effect considered and a corresponding reduction in velocity.

A treatment of injury by whole body displacement is given by W.E. Baker *et al.* (1983) utilizing P–I diagrams.

The *Green Book* gives the following equations for lethal injury due to body displacement followed by impact with a hard surface. For skull impact

$$Y = 5 - 8.49 \ln S \qquad [17.38.27]$$

with

$$S = \frac{2.43 \times 10^3}{p^o} + \frac{4 \times 10^8}{p^o i}, \quad p^o < 4 \times 10^5 \qquad [17.38.28]$$

where i is the overpressure impulse (Pa s), p° is the peak incident overpressure (Pa) and S is an injury factor. For whole body impact

$$Y = 5 - 2.44 \ln S \qquad [17.38.29]$$

with

$$S = \frac{7.38 \times 10^3}{p^o} + \frac{1.3 \times 10^9}{p^o i} \quad p^o < 4 \times 10^5 \qquad [17.38.30]$$

The *Green Book* also gives the corresponding P–I diagrams.

Turning to decelerative tumbling, Glasstone (1962) describes experimental work in which cadavers of several animal species, including sheep and goats, were dropped from the back of a vehicle travelling at speeds of between 10 and 60 mph (4.5 to 27 m/s). All the animals assumed a rolling posture along their long axis regardless of initial orientation. One conclusion of this work was that a person tumbling over a smooth surface might survive even if the initial velocity were high provided head injury and flailing of the limbs were avoided. Another was that injury is likely to result not so much from the initial impact of the blast wave as from impact of the body with a hard object in its path.

Glasstone gives a graph for 50% casualties in decelerative tumbling over (a) open terrain and (b) terrain with structures for a 1 kt explosion. Casualties of 50% occur at 550 ft (168 m) and 680 ft (207 m), respectively. He also proposes the scaling law

$$d = d_r W^{0.4} \qquad [17.38.31]$$

where d is the distance for 50% casualties (ft), d_r is the distance for 50% casualties for a 1 kt TNT explosion (ft) and W is the mass of TNT (te). Equation 17.38.31 gives for this size of explosion a 50% probability of casualty at 222 and 274 m for open terrain and terrain with structures, respectively.

E.R. Fletcher and Bowen (1968) have given for the decay of velocity in decelerative tumbling Equation 17.38.21 above.

An alternative treatment is that described by W.E. Baker *et al.* (1983). The work of W.E. Baker *et al.* (1975) is used to predict the translation velocity of the human body, the correlation being in the form of a P–I diagram with translational velocity as the parameter. Use is then made of data on the relation between level of injury and impact velocity given by Clemedson, Hellstrom and Lindgren (1968) and by C.S. White (1968b, 1971) as shown in Table 17.54. The authors state that there is some debate as to whether skull fracture or whole body injury is more important. They therefore present data for both injury modes.

17.38.4 Flying glass

Blast generates missiles, the main type of missiles considered in treatments of blast injury being fragments of flying glass. The injury caused by flying glass is considered in Section 17.40.

17.38.5 Thermal and toxic effects

An explosion, like a fire, gives rise to thermal and toxic effects. These effects have been dealt with in Chapter 16 on fire and are not considered further here.

17.38.6 Distribution of injury modes

The correlations just given may be used to obtain an estimate of the relative probabilities of injury in the different modes, or injury mode distribution. The distribution of injury modes for both outdoor and indoor exposure is considered in Section 17.39.

17.38.7 Combination of injury effects

In some cases there are finite probabilities of injury in more than one injury mode and/or injury by more than one item within a given mode. For example, a person may be exposed to injury by blast and by missiles. He or she may also be exposed to injury by several items within one mode such as multiple fragments or different toxic gases.

The problem of multiple injuries and of double counting of injuries, including injuries from explosions, is discussed in Chapter 9.

17.39 Explosion Injury to Persons Indoors

For persons indoors, information on the specific explosion injury causes and modes applicable to persons in the open has some limited use, but for the most part it is necessary to rely on the correlation of injury with damage to structures, principally housing. Accounts of the latter are given in the *Green Book* and by Withers and Lees (1991), Gilbert, Scilly and Lees (1994h) and Oswald and Baker (2000).

The causes of explosion injury to a person indoors include those causing injury to a person in the open, namely, (1) blast, (2) whole body displacement, (3) missiles, (4) thermal effects, and (5) toxic effects but, in addition, (6) falling masonry and (7) asphyxiating dust.

There are also certain differences between the outdoor and indoor situations which modify the effect of some of these causes. Indoors the distances which the body can travel before impact are short and there are many more objects which can become missiles, including walls and windows.

The modes of explosion injury due to these causes include, for the causes common to outdoors and indoors, (1) eardrum rupture, (2) lung haemorrhage, (3) whole body displacement injury, (4) missiles injury, (5) burns, and (6) toxic injury and, for those specific to indoors, (7) crushing and (8) asphyxiation.

A large proportion of indoor casualties are due to the two causes specific to the indoor situation, falling masonry and asphyxiating dust, and a large proportion of the casualties are therefore in the two injury modes of crushing and asphyxiation. Injury due to these two causes, and in these two modes, is difficult to model by any means other than by correlation with structural damage.

17.39.1 Models based on housing damage

Hence, for the indoor situation the prime approach to estimation of injury is by correlation with structural damage. This may be complemented to some degree by appropriate application of the outdoor injury correlations.

It is convenient here to base the treatment on damage to, and injury to persons in, housing, followed by some limited discussion of the treatment for other structures.

Withers and Lees (1991) have analysed various events which have caused housing damage and associated fatalities, including tornadoes, earthquakes, air raids and chemical and gas explosions. They utilize two categories of injury. Primary injuries are those due to blast effects other than housing damage such as lung haemorrhage, whole body displacement, etc., and secondary injuries those due to housing damage such as falling masonry and asphyxiating dust. They define an additional category of housing damage U, uninhabitable, which is intermediate between the Cb and Ca damage categories. By reference to the original Jarrett equation, Equation 17.33.2, for which in British units the values of the constant k are 24 for Cb damage and 70 for Ca damage, they give a value of 33 for U damage. They estimate the number of fatalities by determining the area within the U damage circle and then taking a fatality rate of 0.1 persons per house, based on an occupancy of 2.5 persons/house. Some results given by their model for an explosion of TNT occurring at random and without warning in a built-up area are:

Mass of explosive (te)	*Primary fatalities*	*Secondary fatalities*	*Total fatalities*
10^{-2}	0.07	0.009	0.079
10^{-1}	0.45	0.19	0.62
1	2.46	3.9	6.2
10	11.3	33	44
100	80.4	186	263

Gilbert, Lees and Scilly (1994h) give a model for several different degrees of injury which they define as follows: K, killed; SI, serious hospital casualty; LI, slight hospital casualty and U, no injury requiring hospital treatment. They also define the following probabilities of injury: P(K) probability of fatal injury, P(K + SI) probability of fatal or serious injury and P(K + SI + LI) probability of fatal, serious or light injury. Further, they subdivide the A housing damage category into two further categories, Ab and Aa, where Ab corresponds to complete demolition and Aa almost complete demolition. Then, to obtain the numbers with each degree of injury they utilize their revised Jarrett equation, Equation 17.33.2 again, but with the revised values of the constant k, to determine the housing damage and the correlation given in Table 17.55 for injury as a function of housing damage. The latter is based on data giving the probabilities of injury in 12 V-2 rocket incidents.

Figure 17.108 shows the number of casualties predicted by the model of Gilbert, Lees and Scilly for the explosion of a charge of TNT located at random on a built-up area with a population density of 4000 persons/km^2.

By comparison with a load on a road vehicle, for which in most instances the road and its verges provide a degree of separation, the figures overestimate the casualties.

Oswald and Baker (2000) have developed a more general simplified vulnerability model primarily for industrial buildings that predicts the percentage of building occupants with serious, life-threatening injuries. Acta (2001) has developed a similar simplified model that predicts building damage and percentages of occupants with serious and fatal injuries in blast-loaded industrial buildings. W.S. Atkins has developed a more detailed model that

***Table 17.55** Injury as a function of housing damage for a condensed phase explosion occurring at random and without warning in a built-up area (Gilbert, Lees and Scilly, 1994h)*

Housing damage category	*Probability of injury*		
	P(K)	P(K + SI)	P(K + SI + LI)
Aa	0.96	1.0	1.0
Ab	0.57	0.66	0.82
A	0.62	0.71	0.84
B	0.086	0.15	0.38
Cb	0.009	0.043	0.13
Ca	0	0.002	0.006
D	0	0	0

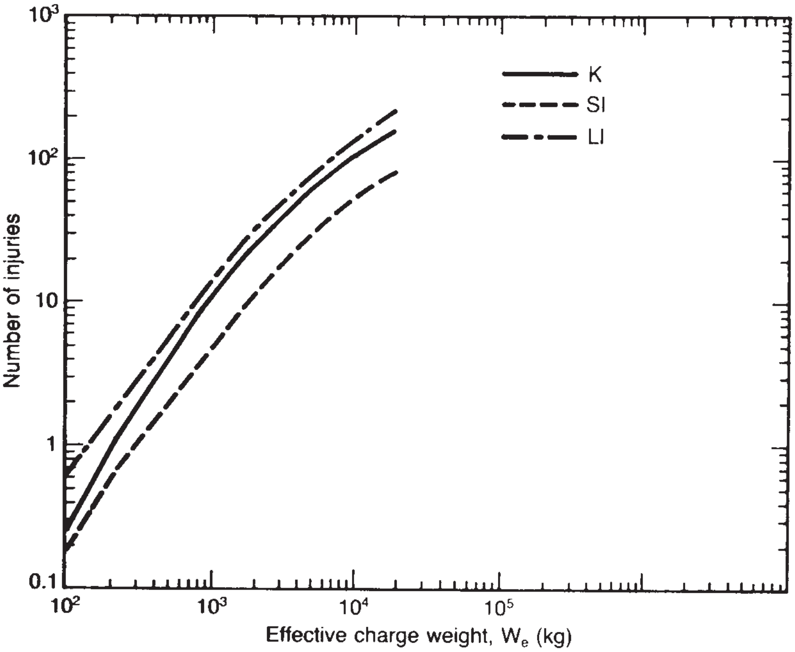

Figure 17.108 *Injury effects of explosions: number of injuries from explosion of a condensed phase explosive in a built-up area (Gilbert, Lees and Scilly, 1994h). Total injuries indoors and outdoors. Charge located in area at random. Population density 4000 persons/km^2. K, killed; SI, seriously injured; LI, lightly injured*

predicts the percentage of fatalities among occupants of blast-loaded buildings (HSE, 1997), including typical industrial buildings in the United Kingdom. This report was critiqued using available injury data in a subsequent HSE publication (HSE, 1998). Oswald (2003) also presents an overview of available injury data on occupants of blast-loaded buildings including some recent terrorist bombing events.

The treatment of injury due to building damage in the *Green Book* refers to building collapse and is based primarily on information relating injury to building collapse in earthquakes. It refers to the work of Blume (1971), who estimates that building collapse in an earthquake results in the death of 50% of the occupants, and to that of the US Department of Commerce (1973), which gives for these circumstances an estimate of 20% dead and 80% injured. The authors of the *Green Book* conclude from these and other data that building collapse in an earthquake causes between 20 and 50% dead and adopt the same figures for explosions. Building collapse is not defined, at least not at this point in the text.

It may be noted that the estimates of the *Green Book* and of the model of Gilbert, Scilly and Lees become consistent if building collapse is taken as a degree of housing damage somewhat more severe than A category but much less severe than B category damage.

17.39.2 Injury inside other structures

Information on the casualty rate in Britain in the Second World War was expressed in terms of standardized casualty rates. One such was the Standardized killed and hospitalized casualty rate (SKHCR). The following data are given in the *Textbook* for all weapons used in air raids:

	In open	*In dwellings*	*In other buildings*	*In shelters*	*All exposures*
SKHCR	18.85	5.31	5.45	1.94	5.07
Ratio	3.55	1.00	1.03	0.37	0.95

where the ratio is that of the SKHCR in question to the SKHCR for dwellings.

17.39.3 Distribution of injury modes

There is available some information on the distribution of injury modes from explosions for persons outdoors and indoors.

There are available a number of accounts of the casualties from explosions, both military and industrial. Descriptions of the casualties admitted to individual hospitals in the Emergency Medical Services (EMS) system for handling air raid casualties have been given by Payne (1941) for bomber raids and by R.C. Bell (1944) for V-1 flying bomb raids.

Bell gives an analysis of 259 flying bomb casualties. The breakdown of injuries is shown in Table 17.56. Some of the casualties had more than one type of injury so that the total number of entries is greater than 259. Theatre treatment was required in 83 cases.

Although these air raid data provide an indication of the injury modes, there are inevitable biases. They usually exclude casualties who died on the spot, including those who died from asphyxiation by fumes and dusts.

More detailed information is given in the *Textbook*. Table 17.57 gives a breakdown of injuries to persons outdoors and persons indoors and overall, by cause in section A and by mode in section B. The data in Table 17.57 show that a large proportion of injuries indoors were caused by falling debris and asphyxiating dust.

Table 17.56 *Distribution of injuries in casualties requiring surgery*[a] *admitted to a London hospital during the V-1 flying bomb raids (after R.C. Bell, 1944) (Courtesy of the British Medical Journal)*

	Cases		*Deaths*	
	No.	*%*	*No.*	*%*
Glass	100	47.4	1	6.3
Bomb splinters	24	11.4	3	18.7
Masonry	52	24.6	9	56.2
Blast	26	12.3	2	12.5
Burns	9	4.3	1	6.3
Total surgical	211			

[a] There were 259 casualities admitted,but some are classified in more than one category, so that there were 211 surgical cases.

A study of 81 chemical and gas accidents has been described by Settles (1968). Of these, 44 involved fire and explosion, 23 fire only and 14 a detonation reaction. Settles states:

> The 14 accidents in which detonating forces were present resulted in injuries to 35 persons and 34 fatalities. It appears from information available that only one of these 34 deaths resulted from blast overpressures that are associated with a detonating reaction. However, this one fatality was not the result of blast damage to human tissue. Rather, the blast pressure caused this individual to be propelled as a projectile. The other 33 persons who died in these 14 accidents were located at points where the density of flying fragments and in some cases, the lethal searing of radiant heat, were so great that their deaths were certain, even though there were no blast effects.

17.39.4 Models based on injury modes

An alternative approach to models based on housing damage is to try to estimate the overall probability of injury from the individual modes. Correlations for injury to persons outdoors which may be relevant here are those for lung haemorrhage, whole body displacement injury, missile injury, including that from flying glass, and thermal and toxic injury. However, models are lacking for two of the principal modes, crushing and asphyxiation. This makes it difficult to construct a satisfactory model of indoor injury in this way.

Table 17.57 *Causes and modes of injury (proportion, %) by bombs in Second World War air raids (Ministry of Supply, 1952)*

A Injury causes[a]

	In dwellings			*Outdoors*			*All exposures*		
	Fatal	*Hospitalizing*	*Total*	*Fatal*	*Hospitalizing*	*Total*	*Fatal*	*Hospitalizing*	*Total*
Bomb fragments	14.1	4.7	9.1	38.5	32.8	34.9	19.7	13.7	16.3
Burns	2.7	1.2	1.9	4.4	1.1	2.4	3.8	1.5	2.5
Blast	2.4	0.2	1.3	1.3	0.2	0.6	1.8	0.2	0.9
Flying glass	0.2	10.6	5.8	0	2.7	1.7	0.4	6.2	3.7
Flying debris	16.3	19.5	18.0	17.6	32.6	26.9	16.0	24.2	20.6
Falling debris	46.1	45.4	45.7	10.9	7.3	8.7	36.0	34.5	35.2
Falls, etc.	5.8	11.7	8.9	13.5	19.0	16.9	9.5	13.8	11.9
Other/unknown	12.3	6.6	9.2	13.8	4.2	7.9	12.9	5.8	8.9
Total injuries	439	498	937	160	261	421	850	1,117	1,967
Total casualties	353	303	656	122	159	281	680	684	1,364

B Injury modes

	In dwellings		*Outdoors*		*All exposures*	
	Fatal	*Non-fatal*	*Fatal*	*Non-fatal*	*Fatal*	*Non-fatal*
Asphyxia	21	–	4	–	17	–
Gross injuries[a]	20	1.5	17.5	1.6	18	1
Penetrating injuries	9	24	22	47	11	30
Fractures	19	50	28.5	38	23	47.2
Crush injuries	14	1.6	9	0.8	12	1
Bruises/abrasions	–	8	–	4	–	4.4
Eye injuries	–	5	–	2	–	5
Other/unknown	17	9	19	8.2	19	11
Total injuries	439	196	158	126	850	483
Total casualties	353	122	122	77	680	306

[a] Gross injuries include cases where the victim was blown to bits.

17.39.5 Models based on total injury

The foregoing account has given information on individual modes of injury. Studies have also been done to assist in the determination of total injury by all modes.

Rausch, Eisenberg and Lynch (1977) have described studies in support of the vulnerability model in which an attempt has been made to assess total injury. They deal in particular with the disintegration of walls and the resultant flying debris, other flying objects and bodily translation. They also refer in particular to work by Longinow *et al.* (1973) and Fricke (1975) on injury from nuclear explosions and from low yield nuclear explosions, respectively. These authors have studied total injury by all the principal modes for people in the open and indoors in various types of building. The work on low yield explosions is of particular relevance and although the work was classified some information was released.

The estimates of the overpressures associated with 50% probability of fatality for people outdoors and indoors for such low yield explosions are shown in Figure 17.109. The yields are for nuclear weapons and should be divided by 2 obtain the TNT equivalent. Figure 17.109(a) shows the basic injury mode curves from which the other graphs are derived. Figure 17.109(b) shows the curves for injury to persons outdoors in the open and outdoors in a built-up area and Figure 17.109(c) to persons indoors in housing. Figure 17.109(d) shows the curves for all situations. There is one curve for injury by all modes to persons outdoors in the open and one for injury by all modes to persons outdoors in a built-up area or indoors in housing. The figures also gives curves for 50% probability of burdening injury. For persons subject to injury by glass fragments, however, the peak overpressures for 50% probability of fatality and burdening injury are taken as 11 and 1 psi, respectively.

17.40 Explosion Injury from Flying Glass

The shattering of window glass is an important blast damage effect, since flying glass can cause severe injury.

17.40.1 Experimental studies

There have been a number of experimental studies of the behaviour of, and injury by, flying glass and also studies of glass breakage following accidental explosions and of injury by flying glass in accidents and air raids.

Experiments on the breaking of glass windows by internal gas explosions have been described by Mainstone (1971 BRE CP 26/71) and M.R. Marshall, Harris and Moppett (1977).

The Eskimo series of trials, which involved the breaking of windows using large external charges of TNT, have been described by E.R. Fletcher, Richmond and Jones (1973) and E.R. Fletcher, Richmond and Richmond (1974). In Eskimo II the charge was 12.6 te and in Eskimo III 159 te.

Window breakage is among the damage effects of the explosion of 5001 TNT equivalent referred to by Fugelso, Weiner and Schiffman (1972).

There are also a number of accounts of the extent of window breakage following accidental explosions. Window breakage is one of the explosion effects analysed by C.S. Robinson (1944). Healy (1959) deals with window breakage in air raids.

The window breakage resulting from a large accidental explosion at Medina, San Antonio, Texas in 1963 has been described by Reed and co-workers (Q.W. Reed *et al.* 1968; J.W. Reed, 1980, 1992). The explosion involved 111, 500 lb of high explosive, equivalent to 145, 000 lb of TNT.

A review of window breakage is given by D.K. Pritchard (1981).

17.40.2 Flying glass models

A model for the behaviour of flying glass should cover the following features: (1) breaking pressure, (2) fragment characteristics, (3) velocity of fragments, (4) spatial density, and (5) distance travelled by fragments. These features are now considered in turn.

17.40.3 Breaking pressure

The pressure at which windows break is generally quoted in terms of the peak side-on overpressure.

The force acting on the window is that of the peak reflected pressure. For a window directly facing the source of the explosion, the peak reflected pressure is some two times the peak side-on overpressure. For random orientation of windows J.W. Reed (1992) estimates an average reflection factor not of 2 but of 1.32.

The strength of window glass is very variable. It is not uncommon for an explosion to cause isolated window breakages at very considerable distances, and correspondingly low overpressures, while bangs from supersonic aircraft sometimes break windows at overpressures much less than those usually regarded as necessary to cause damage. Such instances, however, rarely cause injury.

Estimates of the peak side-on overpressure which causes window breakage have been given by a number of authors. Brasie and Simpson (1968) quote for the breaking pressure of glass windows a typical pressure of 1 kPa (0.145 psi). They also refer to breakage at low pressures of 0.2 kPa (0.029 psi) by sonic boom. Iverson (1968) gives the range of breaking pressures as 1–10 kPa (0.145–1.45 psi).

Some information on window breakage has already been given in Figure 17.92 and in Tables 17.43–17.44. Robinson's data show that for large explosions glass breakage can occur at great distances, of the order of 20 miles. The average glass breakage limit given in Table 17.44 is estimated by Brasie and Simpson (1968) to correspond to an overpressure of 0.006 psi, and they suggest that this is unrealistically low for estimation purposes.

Healy (1959) correlates window breakage in terms of the RB distance, and gives the following estimates:

RB distance	*Window breakage (%)*
5	90
10	50
20	5

These same estimates are given by Scilly and High (1986).

Glasstone (1962) gives the peak overpressure for window breakage as 0.5–1.0 psi (0.34–0.068 bar), as shown in Table 17.43, but without defining the proportion of windows broken.

Fugelso, Weiner and Schiffman (1972) give for the 5001 TNT equivalent explosion described above data on glass breakage also. These data have been analysed by Eisenberg, Lynch and Breeding (1975). The threshold or 1% level of glass breakage was 0.25 psi. They assume that the threshold level of structural damage corresponds

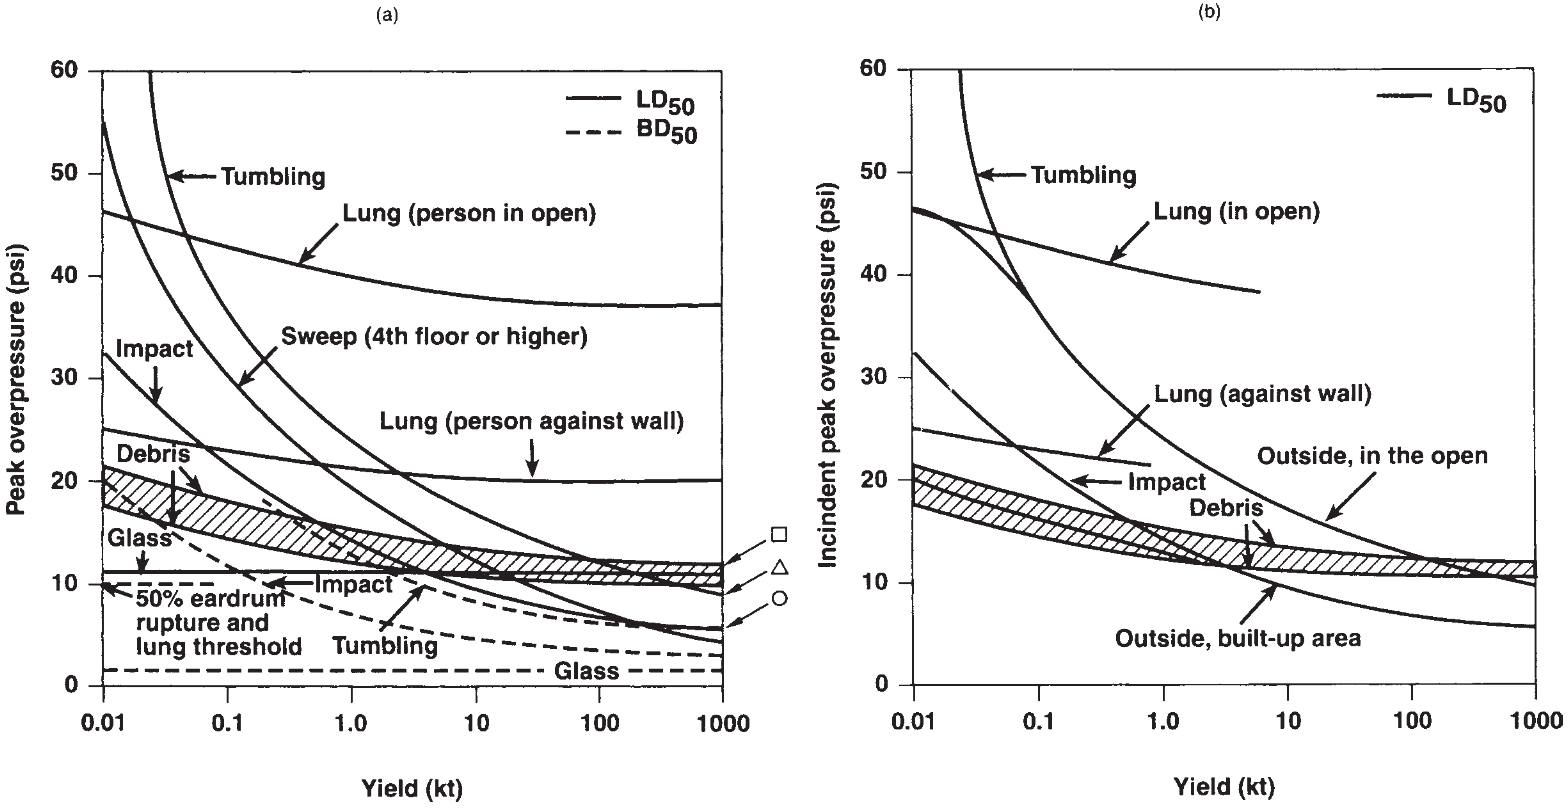

Figure 17.109 *Continued*

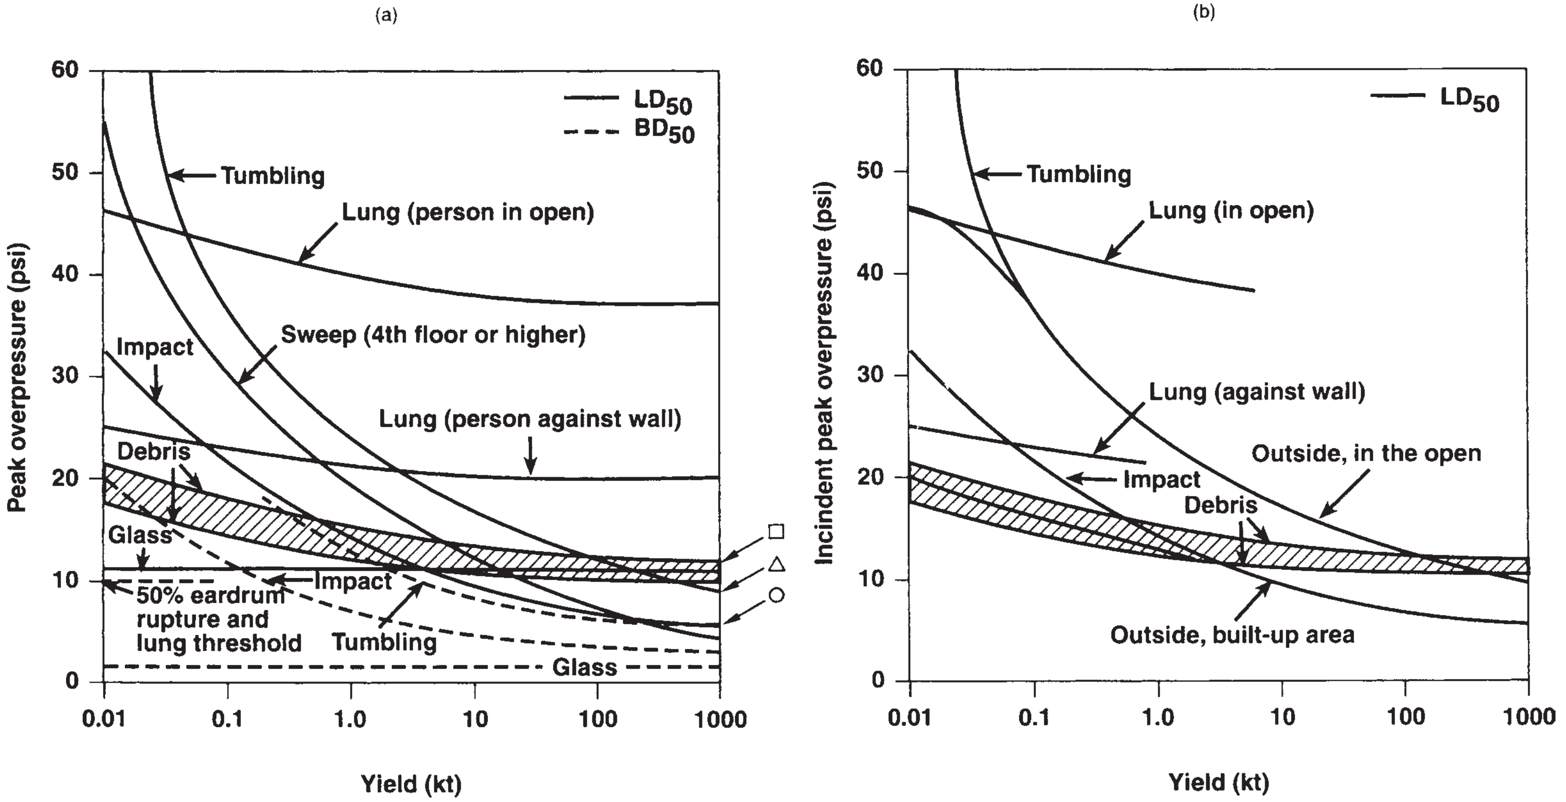

Figure 17.109 *Injury effects of explosions: lethal effects of low yield nuclear explosions (see text) (Fricke, 1975) BD$_{50}$, LD$_{50}$, load for 50% probability of burdening, lethal injury, respectively. (a): ○, LD$_{50}$ for first three floors of buildings with weak walls, brick buildings and residences. △, LD$_{50}$ for basements of wood-frame and brick-veneer residences; basements of steel and reinforced concrete framed buildings with flat plate ground floor. □, LD$_{50}$ for first three floors of building with 'strong walls'; basements and sub-basements of steel and reinforced concrete framed building having flat slab or slab and beam ground floor construction. (d): 1, home basements; basements and sub-basements of multi-storey buildings; first three floors of strong-walled multi-storey buildings. 2, outside, in the open. 3, outside, built-up area; residence, above ground; first three floors of weak-walled multi-storey buildings. 4, fourth or higher floors of multi-storey buildings. 5, outside, in the open. 6, outside, built-up area; residences, above ground; multi-storey buildings, above ground. 7, basements*

to the 90% level for glass breakage and thus obtain the following data:

Glass breakage	*Peak overpressure* (%)	
	(psi)	(N/m^2)
1 (threshold)	0.25	1700
90	0.9	6200

They derive from these data a probit equation relating glass breakage to peak overpressure:

$$Y = -18.1 + 2.79 \ln p^{\mathrm{o}} \qquad [17.40.1]$$

where p° is the peak incident overpressure (Pa) and Y is the probit.

In the Eskimo trials described by E.R. Fletcher, Richmond and Jones (1973) and E.R. Fletcher, Richmond and Richmond (1974), the thickness of the panes tested ranged from 0.08 to 0.128 in. (from 2 to 3.25 mm) and from 0.203 to 0.264 in. (from 5.16 to 6.7 mm). All the windows were positioned directly facing the blast wave and the peak effective overpressure was taken as the peak reflected pressure, or twice the peak incident overpressure. Although the duration times in Eskimo II were significantly shorter than in Eskimo III, this did not significantly alter the breaking pressure, indicating that for such large explosions at least the breaking pressure is essentially independent of duration. Some results from these trials are as follows:

Window size	*Breaking pressure*			
(m)	*Eskimo II*		*Eskimo III*	
	(Pa)	(psi)	(Pa)	(psi)
1.14 × 1.14	4830	0.70	4830	0.70
0.86 × 1.22	5930	0.86	5860	0.85

Window breakage in the Medina explosion has been analysed by Reed and co-workers (Q.W. Reed *et al.*, 1968; J.W. Reed, 1980, 1992). The typical window is given by J.W. Reed (1992) as single-strength glass 2 ft × 2 ft × 2 mm thick. He gives a graph showing the probability of breaking vs the peak incident overpressure. Gilbert, Lees and Scilly (1994h) found that the relationship is a log-normal one, and give the following probit equation for breaking of a 'Reed' window:

$$Y = -4.77 + 1.09 \ln p^{\mathrm{o}} \qquad [17.40.2]$$

where p° is the peak effective overpressure (Pa) and Y is the probit. These authors also give the following relation for the determination of the peak effective overpressure for other windows for use in the above equation:

$$p_{\mathrm{e}}^{\mathrm{o}} = \left(\frac{A/0.372}{t/0.002}\right) p^{\mathrm{o}} \qquad [17.40.3]$$

where A is the area of the pane (m^2), p° is the peak incident overpressure (Pa), p_{e}° is the peak effective overpressure for use in Equation 17.40.2 (Pa) and t is the thickness of the glass (m).

As already mentioned, experimental work on window breakage from internal gas explosions has been described by Mainstone (1971 BRE CP 26/71). Figure 17.110 shows the pressure for breakage for sheet glass panes of various thicknesses.

W.E. Baker *et al.* (1983) suggest that these data of Mainstone be treated as the quasi-static regime asymptote values.

Further experimental work on window breakage in internal gas explosions has been done by M.R. Marshall, Harris and Moppett (1977). Results from this work are given in Figure 17.111(a)–(d), showing breaking pressure as a function of glass thickness and window area.

These workers also investigated the behaviour of Georgian wired glass and glass treated with shatter resistant film, with the results shown in Figure 17.111.

Gilbert (1994) has analysed the results of Marshall, Harris and Moppett for plain glass windows as follows:

Window thickness (mm)	*Window size* (m × m)	*Pane area* (m^2)	*Breaking pressure*		*Ratio of thickness to area* (1/m)
			Range (kPa)	*Average* (kPa)	
5	1.0 × 1.0	1.03	6.2–7.6	6.9	0.00471
	1.0 × 0.5	0.515	8.3–11.7	10.0	0.0189
	0.48 × 0.48	0.233	15.2–20.7	18.0	0.0921
3	1.0 × 1.0	1.03	3.5–5.2	4.35	0.00283
	1.0 × 0.5	0.515	6.9–8.3	7.6	0.0113
	0.48 × 0.48	0.233	10.3–12.4	11.35	0.0553
4 (32 oz)	1.0 × 1.0	1.03	4.8	4.8	0.00377

and derives from them the relation

$$p_{\mathrm{br}}^{*} = 132\frac{t}{A} + 5.43 \qquad [17.40.4]$$

where p_{br}^{*} is the breaking pressure (kPa) and t is the thickness of the pane (m).

The overpressures necessary to cause window breakage have been reviewed in the *Second Report* of the ACMH (Harvey, 1979b). The report quotes for a typical dwelling house window of 24 oz glass of area 1 m^2 the work of Marshall, Harris and Moppett, indicating that a peak overpressure between about 0.03 and 0.05 bar is needed to break it. It concludes that for typical dwelling house windows the peak overpressures at which 50 and 90% window breakage is likely to occur are 0.016 and 0.038 bar, respectively, but emphasizes that the breaking pressure is a function of a large number of variables.

17.40.4 Fragment characteristics

I.G. Bowen *et al.* (1963b), cited by Hadjipavlou and Carr-Hill (1986), have given correlations for the mass and initial velocity of fragments from window breakage, though it is unclear under what conditions. They found that the mass distribution was log-normal and gave the following probit equation:

$$Y = 5.97 + 0.86 \ln m \qquad [17.40.5]$$

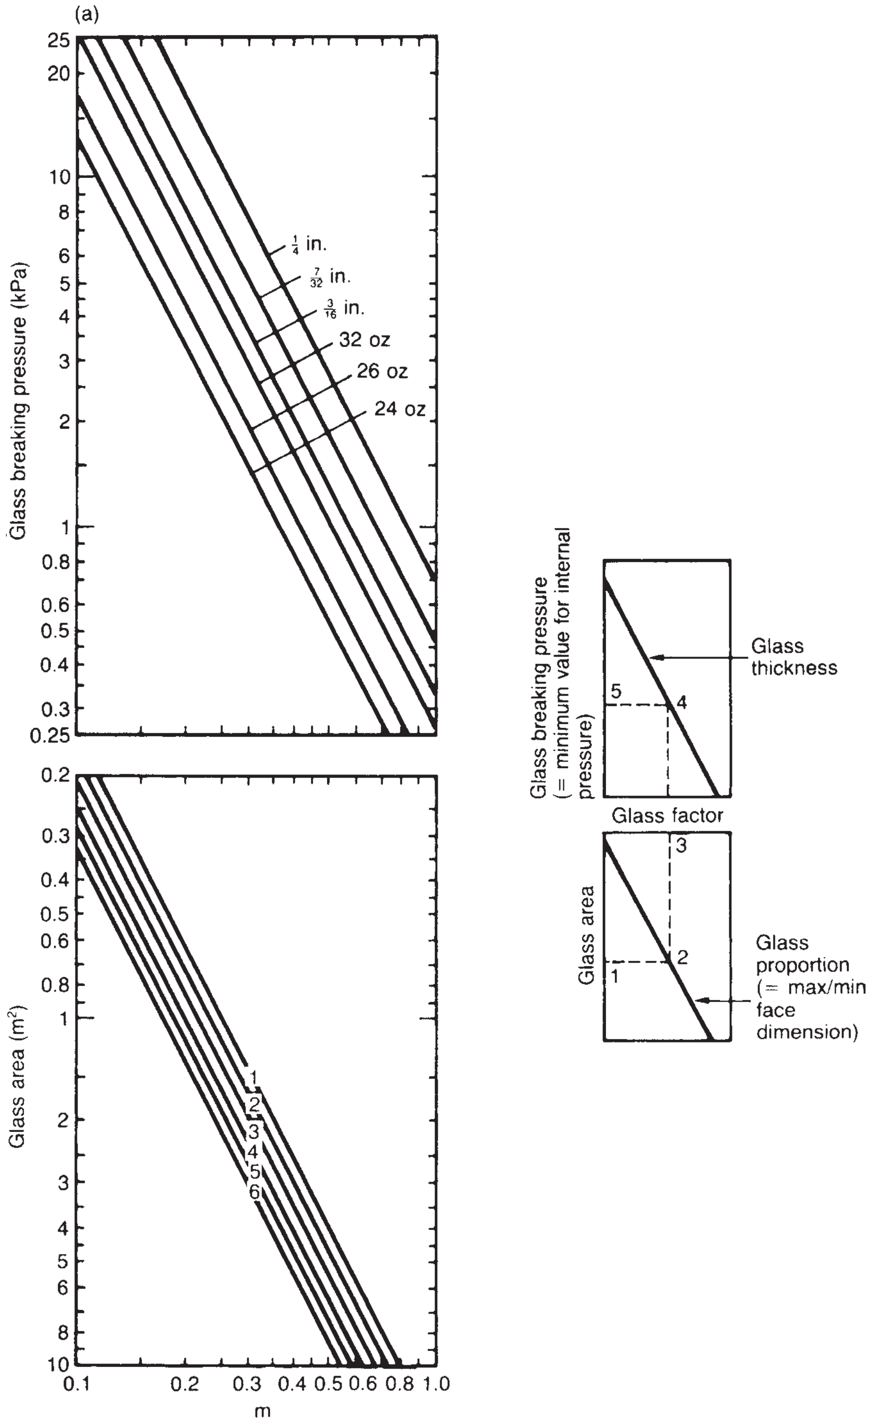

Figure 17.110 *Window breakage and flying glass from an internal gas explosion – breaking pressure of sheet glass panes (Mainstone, 1971): (a) sheet glass panes; and (b) plate glass panes (Courtesy of the Building Research Establishment)*

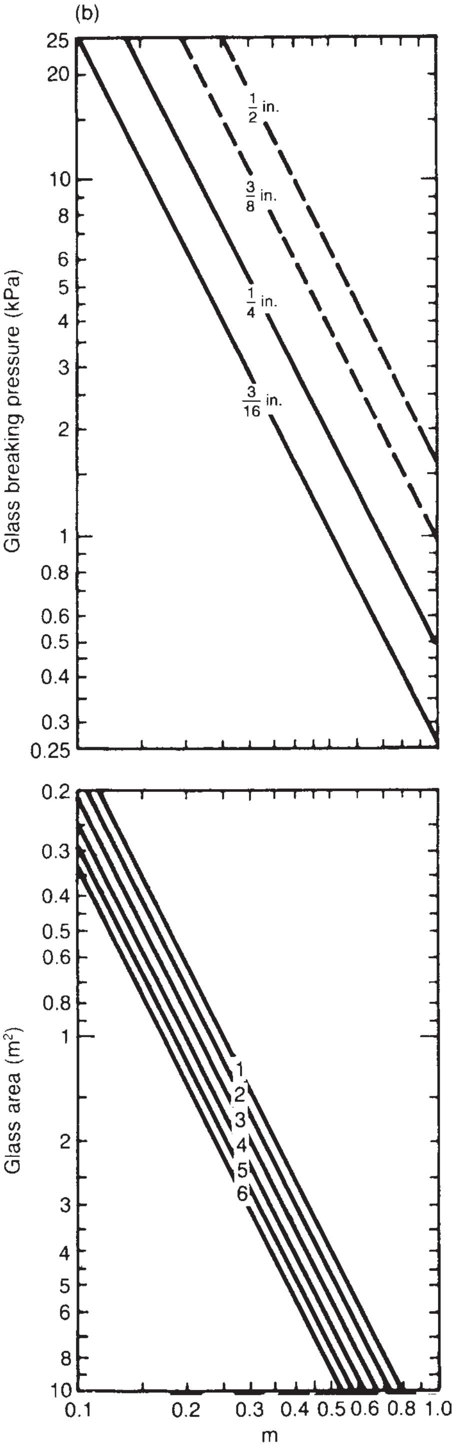

Figure 17.110 *Continued*

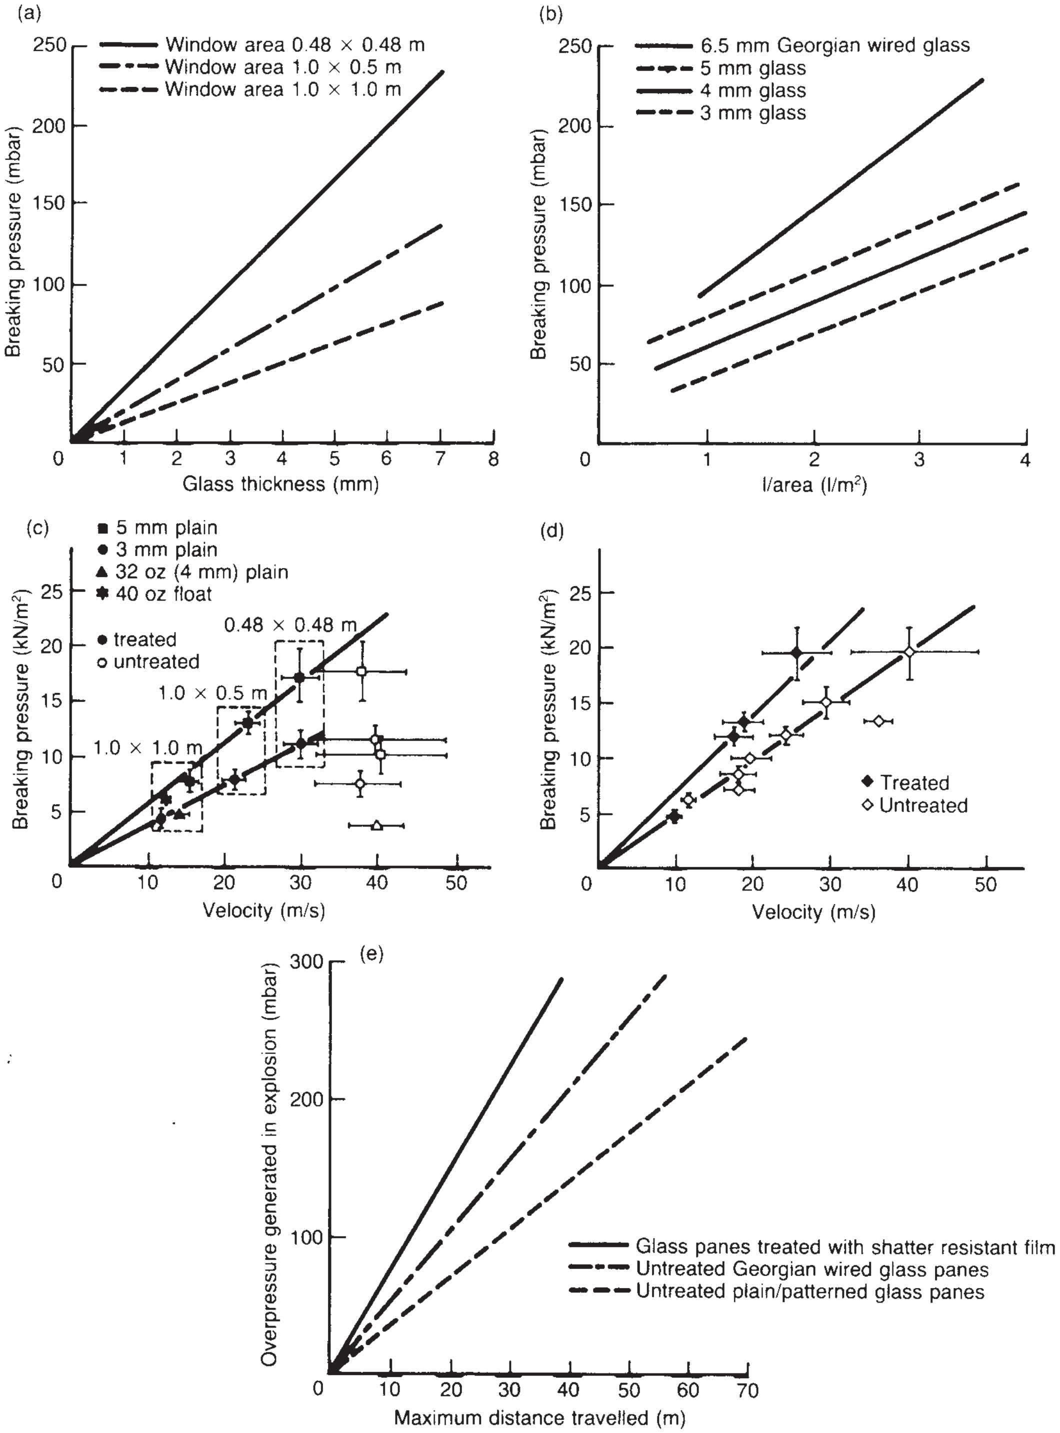

Figure 17.111 *Window breakage and flying glass – breaking pressure of windows and characteristics of flying (M.R. Marshall, Harris and Moppett, 1977): (a) breaking pressure as function of glass thickness; (b) breaking pressure as function of window area; (c) velocity of glass fragments, plain glass; (d) velocity of glass fragments, Georgian wired glass; and (e) distance traveled by glass fragments (Courtesy of the Institution of Chemical Engineers)*

where m is the mass of the fragment (g) and Y is the probit. The median value of the mass ($Y = 5$) is thus 0.324 g.

E.R. Fletcher, Richmond and Richmond (1974) characterize glass fragments in terms of the mean mass m_{50} and mean frontal area A_{50}. Their expression for the latter, in the form given by E.R. Fletcher, Richmond and Yelverton (1980), is

$$\ln A^*_{50} = 4.2643 - (12.5 + 0.003\,43 p^{\mathrm{o}}_{\mathrm{e}*}{}^2)^{1/2} \qquad [17.40.6]$$

where A^*_{50} is the mean frontal area (cm^2) and $p^{\circ}_{\mathrm{e}}*$ the peak effective overpressure (kPa).

The mean mass m_{50} may be then obtained as

$$m_{50} = A_{50}\rho_{\mathrm{gl}}t \qquad [17.40.7]$$

where A_{50} is the mean frontal area of the fragment (m^2), m_{50} is the mean mass of the fragment (kg), t is the thickness of the fragment (m) and ρ_{gl} is the density of glass (kg/m^3).

This mean frontal area is not necessarily the mean presented area (MPA) on impact. This latter depends on the behaviour of the fragment during flight. Consider a fragment of rectangular cross-section and uniform thickness with a length : width ratio of 2 : 1. If the length of the long side is l and the thickness is t, the width is 1/2 and the area A_{50} is $l^2/2$. For a fragment approaching a target square on there are three possible MPAs: $l^2/2$, lt and $lt/2$. Taking the second of these, or the intermediate case, the MPA is then

$$A_{\mathrm{mp}} = (2A_{50})^{1/2}t \qquad [17.40.8]$$

where A_{mp} is the MPA of the fragment on impact (m^2) l is the length of the fragment (m) and t is the thickness of the fragment (m).

A further treatment of fragment characteristics is given in Section 17.40.6.

17.40.5 Velocity of fragments

A treatment of the velocity of glass fragments is given by Glasstone (1962). He gives a correlation in terms of the geometric mean velocity V'_{50}, or antilogarithm of the mean of the logarithms of the velocities. He uses a scaled geometric mean velocity $\bar{V}'_{50}$, which allows for the thickness of the glass and which is defined as

$$\bar{V}'_{50} = \frac{V'_{50}}{0.83 + 0.019(t' - 0.03)^{-0.93}} \qquad [17.40.9]$$

where t' is the pane thickness (in.), V_{50} is the geometric mean velocity (ft/s) and $\bar{V}_{50}$ is the scaled geometric mean velocity (ft/s). The correlation relates the scaled geometric mean velocity to the peak effective overpressure applicable to conventional explosions of 15–500 t. Glasstone states that the correlation is based on experiments with various types of glass ranging from 0.25 in. thick plate glass, through various standard thicknesses of single- and double-strength glass, to non-standard glass panes 0.064 in. thick. This correlation may be represented as

$$\ln \bar{V}'_{50} = 3.746 + 0.546 \ln p'^{\mathrm{o}}_{\mathrm{e}} \qquad [17.40.10]$$

where p'° is the peak effective overpressure (kPa).

In the work described earlier, I.G. Bowen *et al.* (1963b) found that the velocities of fragments from window breakage had a log-normal distribution, and gave the probit relation

$$Y = -11.7 + 4.41 \ln u \qquad [17.40.11]$$

where u is the velocity of the fragment (m/s). The median value of the fragment mass was 0.324 g and the median value of the velocity from Equation 17.40.11 is 44 m/s.

A correlation of the initial velocity in the Eskimo trials is given by E.R. Fletcher, Richmond and Richmond (1974). Their expressions for the latter, in the form given by E.R. Fletcher, Richmond and Yelverton (1980), are as follows. A scaled velocity $\bar{V}_{50}$ is defined as

$$\bar{V}_{50} = \left(\frac{V_{50}}{0.833 + 0.04465(t^* - 0.0762)^{-0.928}}\right) \qquad [17.40.12]$$

where t^* is the thickness of the pane (cm), V_{50} is the geometric mean velocity (m/s) and $\bar{V}_{50}$ is the scaled geometric mean velocity (m/s). The correlation is

$$\ln \bar{V}_{50} = 1.5241 + 0.547 \ln p^{\mathrm{o}}_{\mathrm{e}}* \qquad [17.40.13]$$

where $p^{\circ}_{\mathrm{e}}*$ is the peak effective pressure (kPa).

E.R. Fletcher, Richmond and Yelverton (1980) also give data on average impact velocity of fragments from which the following relation may be inferred:

$$\ln u = 1.5241 + 0.55 \ln p^{\mathrm{o}}_{\mathrm{e}}* \qquad [17.40.14]$$

where $p^{\mathrm{o}}_{\mathrm{e}}*$ is the peak effective overpressure (kPa) and V is the average velocity (m/s).

For an internal gas explosion the velocity of fragments from a breaking window is given by M.R. Marshall, Harris and Moppett (1977) in the work described earlier, as shown in Figure 17.111 (c). The velocity concerned is the average velocity over the first 6 m of travel. The mean values of the velocities in Figure 17.111(c) are in the range 35–40 m/s.

These data have been analysed by Gilbert, Lees and Scilly (1994h). The data for untreated unwired windows show wide scatter, but from those for wired glass there appears to be a factor of about 1.38 between the velocities from untreated and treated windows. Applying this same factor to the velocities from treated, unwired windows gives for untreated, unwired windows

$$u = 11.57\frac{p^*_{\mathrm{br}}}{0.001t} \qquad [17.40.15]$$

where p^*_{br} is the breaking pressure (kPa), t is the thickness of the glass (m) and u is the average velocity of the fragments (m/s).

17.40.6 Velocity of fragments: method of Baker *et al.*

W.E. Baker *et al.* (1983) give the following treatment for the velocity of fragments from breaking windows based on the work of E.R. Fletcher, Richmond and Jones (1973, 1976). An effective peak overpressure P_{e} is defined, which for windows side-on or back-on to the blast wave is equivalent to the peak incident overpressure P_{s} and for those face-on, to the peak reflected overpressure P_{r}.

The latter may be obtained as follows:

$$\bar{P}_{\mathrm{r}} = 2\bar{P}_{\mathrm{s}} + \frac{(\gamma+1)\bar{P}_{\mathrm{s}}^2}{(\gamma-1)\bar{P}_{\mathrm{s}} + 2\gamma'} \quad \bar{P}_{\mathrm{s}} \leq 3.5 \qquad [17.40.16]$$

with

$$\bar{P}_{\mathrm{s}} = P_{\mathrm{s}}/P_{\mathrm{o}} \qquad [17.40.17]$$

$$\bar{P}_{\mathrm{r}} = P_{\mathrm{r}}/P_{\mathrm{o}} \qquad [17.40.18]$$

where P_{o} is atmospheric pressure (Pa), P_{e} is the peak effective overpressure (Pa), $\bar{P}_{\mathrm{r}}$ is the peak reflected overpressure (Pa), $\bar{P}_{\mathrm{r}}$ is the dimensionless peak reflected overpressure, $\bar{P}_{\mathrm{s}}$ is the peak side-on overpressure (Pa), and $\bar{P}_{\mathrm{s}}$ is the dimensionless peak side-on overpressure. For $\bar{P}_{\mathrm{s}} > 3.5$ the authors give an alternative equation (their Equation 3.5).

On the assumption that all the fragments are square, the mass of a fragment is

$$M = y^2 t \rho_{\mathrm{gl}} = A t \rho_{\mathrm{gl}} \qquad [17.40.19]$$

where M is the mass of the fragment (kg), t is the thickness of the glass (m), y is the length of the square edge (m) and ρ_{gl} is the density of glass (kg/m^3). The density of glass may be taken as 2471 kg/m^3.

The geometric mean frontal area A'_{50} of the fragments is given by the equation

$$A'_{50} = 6.45 \times 10^{-4} \exp\{2.4 - [12.5 + (5.86 \times 10^{-5} P_{\mathrm{e}})^2]^{1/2}\} \\ \times 0 < P_{\mathrm{e}} < 96{,}500 \qquad [17.40.20]$$

where A$'_{50}$ is the geometric mean frontal area (m^2).

If all the fragments travel with the flat face forward, the presented area A of the fragments is

$$A = A'_{50} \qquad [17.40.21]$$

while if all fragments travel edge forward

$$A = t{A'_{50}}^{1/2} \qquad [17.40.22]$$

where A is the presented area of the fragment (m^2).

The ratio A/M for these two cases is, respectively

$$\frac{A}{M} = \frac{1}{t\rho_{\mathrm{gl}}} \qquad [17.40.23]$$

and

$$\frac{A}{M} = \frac{1}{\rho_{\mathrm{gl}} {A'_{50}}^{1/2}} \qquad [17.40.24]$$

The lower value of A/M given by these two alternative equations is selected.

The geometric mean velocity V_{50} of the fragments is given in SI units by the equation

$$V_{50} = [0.2539 + (1.86 \times 10^{-4})(t - 7.62 \times 10^{-4})^{-0.928}] \\ \times (0.344 P_{\mathrm{e}}^{0.547}) 690 < P_{\mathrm{e}} < 689{,}000; t \geq 7.62 \times 10^{-4} \qquad [17.40.25]$$

where V_{50} is the geometric mean velocity (m/s).

17.40.7 Spatial density of fragments

A correlation for the spatial density of glass fragments from window breakage based on the Eskimo trials is given by E.R. Fletcher, Richmond and Richmond (1974). Their expression for the latter, in the form given by E.R. Fletcher, Richmond and Yelverton (1980), is as follows. A scaled spatial density $\bar{\rho}'_{\mathrm{sd}}$ is defined as

$$\bar{\rho}'_{\mathrm{sd}} = \frac{\rho_{\mathrm{sa}}}{4.91 \exp(-5.0121) + 22.28} \qquad [17.40.26]$$

and gives the correlation

$$\ln \bar{\rho}'_{\mathrm{sd}} = 3.1037 + 0.058\,57 p_{\mathrm{e}}^{\circ} * \qquad [17.40.27]$$

where $p_{\mathrm{e}}^{\circ}*$ is the peak effective overpressure (kPa), ρ_{sd} is the spatial density (fragments/m^2) and t is the glass thickness (cm).

17.40.8 Range of fragments

For an internal gas explosion the distance travelled by fragments from a breaking window is given by M.R. Marshall, Harris and Moppett (1977) in the work already described, as shown in Figure 17.111(e).

17.40.9 Injury relations

Glasstone (1962) gives the data on injury effects caused by glass fragments of different impact velocities shown in Table 17.58.

Methods for the estimation of serious injury from flying glass have been given in the vulnerability model by Eisenberg, Lynch and Breeding (1975) and by W.E. Baker *et al.* (1983). These are described in Sections 17.40.10 and 17.40.11, respectively.

Hadjipavlou and Carr-Hill (1986) have analysed data from animal experiments and have proposed the following probit equations for laceration and for penetration:

$$Y = -12.23 + 0.83 \ln mu' \quad \text{laceration} \qquad [17.40.28]$$

$$Y = -8.35 + 0.61 \ln mu' \quad \text{penetration} \qquad [17.40.29]$$

***Table 17.58** Some data on injury effects caused by glass fragments (after Glasstone, 1962)*

A Penetration of abdomen wall: impact velocity

Mass of glass fragment (g)	*Probability of penetration* (%)		
	1	50	99
0.1	235	410	730
0.5	160	275	485
1.0	140	245	430
10.0	115	180	355

B Injury from penetrating 10 g fragments

Effect	*Impact velocity* (ft/s)
Skin laceration	
Threshold	50
Serious wounds	
Threshold	100
50%	180
Nearly 100%	300

where m is the mass of the fragment (g) and u' is its velocity (ft/s).

A method of determining the probability of fatality for a person standing behind a window is given in the *Green Book* and is described in Section 17.40.12.

Gilbert, Lees and Scilly (1994f) have given a model for fatal and non-fatal injury by any potentially penetrating fragment. This is applicable to flying glass, as described in Section 17.42.

17.40.10 Injury relations: vulnerability model method

The treatment of injury by flying glass in the vulnerability model described by Eisenberg, Lynch and Breeding is as follows. The impact velocity of a missile V_i is related to the impulse J by the equation

$$MV_i = C_D AJ \qquad [17.40.30]$$

where A is the presented area of the missile (m^2), C_D is the drag coefficient, J is the impulse (Pa s), M is the mass of the missile (kg) and V_i is the impact velocity (m/s). The value of the drag coefficient C_D is taken as unity.

For injury from flying glass they consider a 10 g fragment and quote the data given in the second and third columns of the following table, which are derived from information given by the Department of the Army (1969):

Injury	*Peak overpressure* (psi)	*Impact velocity* (m/s)	*Impulse*	
			(psi ms)	(Pa s)
Skin laceration				
Threshold	1–2	15	74.2	512
Serious wound				
Threshold	2–3	30	148.4	1024
50%	4–5	55	272.1	1877
Near 100%	7–8	90	445.3	3071

They derive from this the impulse values given in columns four and five of the above table and hence a probit equation relating serious injury from missiles, particularly glass, to impulse:

$$Y = -27.1 + 4.26 \ln J \qquad [17.40.31]$$

It is assumed in the application of Equation 17.40.31 that all personnel not inside buildings who are in the region traversed by a blast wave of sufficient strength suffer injury from missiles. The density of flying fragments and the target area presented by people are not factors affecting the probability of injury in this analysis. Thus, the equation overestimates by a considerable factor the extent of injury by flying fragments. This particular probit equation, therefore, should be regarded as representing an upper bound.

17.40.11 Injury relations: method of Baker *et al.*

The treatment for injury by glass fragments given by W.E. Baker *et al.* (1983) is based on the work of Sperrazza and Kokinakis (1967, 1968), but is essentially similar. For the fragment velocity they use the correlations obtained by Fletcher and co-workers and described in Section 17.40.6.

Sperrazzo and Kokinakis carried out experiments on the perforation of the skin of animals. Baker *et al.* give a straight-line graph of the results of this and other work, including that quoted by Glasstone, to which they fit with the relation

$$V_{50} = 22.30 + 1247.1\frac{A}{M}, \quad \frac{A}{M} < 0.09;\ M \le 0.015 \qquad [17.40.32]$$

where A is the presented area of the fragment (m^2), M is its mass (kg) and V_{50} is the velocity for 50% probability of perforation (m/s).

It is assumed by Sperrazzo and Kokinakis that if a fragment perforates the skin, its residual velocity will be sufficient to do severe injury. Baker *et al.* suggest that this assumption incorporates a margin of safety.

17.40.12 Injury relations: *Green Book* method

The *Green Book* gives a probit equation for fatality due to impact of glass fragments on the head of a person standing 1.75 m behind the window pane. The equation is

$$Y = 2.67 + \ln\left(\frac{f_{dl}P^{\circ}}{P_{st}}\right) \qquad [17.40.33]$$

where f_{dl} is the dynamic load factor, P° is the peak incident overpressure (Pa) and P_{st} is the static strength of the pane (Pa).

The basis of this equation is tests in which the peak reflected pressure was twice the dynamic failure load P_{df} of the panes and in which the probability of fracture of the skull was estimated as 94%. Then, for these conditions $P_{df} = P_{st}/f_{dl}$ and $P^{\circ} = 2P_{st}/f_{dl}$. Hence, $P^{\circ}/(P_{st}/f_{dl}) = 2$. It was assumed that for 1% lethality $P^{\circ}/(P_{st}/f_{dl}) = 1$. The probit equation is derived from these two values.

The static strength of the pane is obtained from the relations

$$f_t = \frac{2 \times 10^6}{A^{0.18}d^{0.7}} \qquad [17.40.34]$$

and

$$f_t = 0.225 P_{st}\frac{a^2}{d^2} \qquad [17.40.35]$$

where a is the smaller of the two dimensions of the pane (m), A is the area of the pane (m^2), d is the thickness of the pane (m) and f_t is the tensile strength of the pane (Pa).

Thus, a window $1.5 \times 1.0 \times 0.005$ m has a tensile strength $f_t = 75.9 \times 10^6$ Pa and a static strength $P_{st} = 8.43 \times 10^3$ Pa.

The dynamic load factor f_{dl} is a function of the ratio t_d/T of the duration time t_d to the natural period of vibration T. It has a value less than 1 for a short duration ($t_d \ll T$) and of 2 for a long duration ($t_d \gg T$).

17.40.13 Flying glass: model of Gilbert, Lees and Scilly

Gilbert, Lees and Scilly (1994f) have given a model for the probability of incurring various degrees of injury due to impact of a potentially penetrating fragment. This model is described in Section 17.42. It is applicable to injury by fragments from window breakage.

In another paper, Gilbert, Lees and Scilly (1994h) have used this model in combination with some of the relations given above to provide an integrated treatment for the estimation of injury from flying glass. The model is applicable to the explosion of a condensed phase explosive external to the building.

The approach used in this integrated model is as follows. The characteristics of the window typical of the scenario considered are determined. Following Reed, the average peak reflected overpressure is taken as 1.32 times the peak incident overpressure. From Equation 17.40.3 the peak incident overpressure to produce an equivalent load on a 'Reed' window is estimated. Using Equation 17.40.2, the probability of window breakage is estimated. Given that the window is broken, Equations 17.40.6, 17.40.7, 17.40.14 and 17.40.27 are used to obtain the mean frontal area, mass, velocity and spatial density of the fragments. Then, using the fragment injury model of the authors, the probability of fatal and non-fatal injury is determined.

17.40.14 Flying glass hazard

The question of injury from flying glass is considered in the *Second Report* of the ACMH (Harvey, 1979b). The report is particularly concerned with the risks from a VCE.

In general, much of the concern about possible injury from flying glass relates to injury to people indoors. The shattering of glass as a result of an explosion has occurred at distances up to 20 miles. In such cases, however, the energy of the fragments is very low. The evidence appears to indicate that there are surprisingly few injuries to people from glass fragments even in buildings where most of the windows have been shattered by blast.

The report describes first the historical record. A large number of windows were broken in the VCEs both at Flixborough and at Beek. At Beek there were 2508 cases of damage outside the factory and these were almost entirely glass breakage (Case History A75). One person was injured by glass.

The report refers to the experimental work M.R. Marshall, Harris and Moppett (1977) on the breakage of glass windows by explosions inside buildings. In this work the peak overpressure was in the range 0.03–0.25 bar (0.44–3.6 psi). The fragment velocities measured were high, being of the order of 40 m/s, and varied relatively little. The report argues, however, that these results are not applicable to the very different conditions of explosions outside buildings.

This latter situation is then considered. It is estimated in the report that the overpressures required to effect 50 and 90% breakage of windows are about 0.016 bar (0.23 psi) and 0.038 bar (0.46 psi), respectively. A breakage of 50% implies a non-breakage of 50% of the windows, which suggests that the fragment velocity is likely to be low.

The report quotes experimental work in the United States in which windows 1/8 in. (3.17 mm) and 1/4 in. (6.35 mm) thick were mounted at various distances from large masses of TNT so that overpressures of 0.3 psi (0.02 bar), 0.5 psi (0.035 bar) and 0.6 psi (0.04 bar) with a duration time of 250 ms were applied to them, and fragment masses and velocities were determined. Separate experiments were conducted to find the probability that such fragments would penetrate bare skin, or clothed skin, or 1 cm of soft tissue. Only one fragment, out of 90, from the thicker windows broken at the highest pressure was found to have a 10% probability of penetrating 1 cm. No other fragment had even 1% probability of this degree of penetration.

It is concluded in the report that there is ample justification for regarding as negligible the risk of injury from flying fragments of window glass for an explosion which gives a peak overpressure outside the building of 0.6 psi (0.04 bar) or less.

17.41 Explosion Injury from Penetrating Fragments

One of the principal modes of injury from an explosion is wounding by penetrating fragments. In this section the information available on the wounding and incapacitating power of fragments is reviewed and several criteria and models for injury by a penetrating fragment are given. A further model for such injury by Gilbert, Lees and Scilly (1994f) is described in the next section.

This problem is of particular interest to the military, and much of the data are from military sources. These include the *Textbook* and the work of Gurney (1944), Dunn and Sterne (1952) and Beyer (1962). The work of the Stockholm International Peace Research Institute (SIPRI) (1978) is also relevant.

17.41.1 Definition of injury

The degree of injury of prime interest to the military is incapacitation, and much of the information available on injury by penetrating fragments relates to this. An account of the incapacitating power of weapons has been given in a review by SIPRI (1978).

This review emphasizes that the interpretation of incapacitating power is not straightforward. The military interest is in the ability of a projectile to cause rapid incapacitation, in other words its stopping power. Stopping power, however, is not synonymous with wounding power.

Work in the United States during and after the Second World War showed that immediate incapacitation is obtained only by severe injury to parts of the spinal column or brain. It is harder to achieve than fatal or severe injury, which results from injury to major organs or blood vessels.

Dunn and Sterne (1952) carried out experiments in which projectiles were fired at goats. They found that the probability of incapacitation was much less than for ultimate fatal or severe injury. SIPRI summarize their work to the effect that even for the most effective projectile the probability of fatal or severe injury is three to four times greater than the probability of immediate incapacitation.

The main sources of data on the injuring power of fragments refer to incapacitation, but in order to be able to utilize them it is necessary to be able to interpret incapacitation and to relate it to fatal and severe injury.

The meaning of incapacitation is discussed in the *Textbook*. It states:

> Despite the shortcomings of the available information, it is safe to conclude, from the data that have been summarized here, that any penetrating splinter wounds of the head, neck and trunk are highly dangerous, and that almost any wound may be regarded as incapacitating (which for convenience may be defined as a wound necessitating medical attention), provided that the missile concerned gets through the skin into the underlying tissues. In the case of limbs, single splinter wounds are not as dangerous, and the relative number of hits by small

splinters which would prove incapacitating is clearly smaller.

The Textbook then discusses wounds by small splinters, treating separately the head and neck, the thorax and abdomen, and the limbs. The criteria used for incapacitating wounds are:

Head: perforation of the skull;
Thorax and abdomen: perforation of trunk;
Limbs: penetration to half-depth and hitting central supporting bone.

The *Textbook* states that a rough estimate of the proportion of the total projected area of the body which represents the vital organs, where a battle injury due to a small missile would result in almost certain death, is roughly 10–15%.

The most vulnerable parts of the body are the head and neck and the thorax and abdomen. These account for some 39% of the projected area of the body.

17.41.2 Causative factor

There are two basic types of relation which are used for the damaging, or injuring, power of a fragment, or projectile. One is the relation for kinetic energy

$$E = mu^2/2 \qquad [17.41.1]$$

where E is the kinetic energy (J), m is the mass of the fragment (kg) and u is the velocity (m/s). This equation also may be written in the alternative form

$$um^{0.5} = \text{constant} \qquad [17.41.2]$$

or more generally

$$um^{c} = \text{constant} \qquad [17.41.3]$$

where c is an index.

It is now recognized that the mean presented area (MPA) of the fragment is also relevant. This is discussed in Section 17.42.

17.41.3 Incapacitation criteria

At the turn of the last century the German army adopted a projectile kinetic energy of 78 J (58 ft lb) as incapacitating to military personnel. This is also the value which has traditionally been used in Britain and the United States.

Other criterion values quoted by SIPRI are the French, Swiss and Russian values of 39, 62 and 235 J, respectively.

According to Beyer (1962) this type of criterion has proved a better indicator of incapacitating power than measures such as penetration into solid objects such as pine boards.

The 78 J criterion has been discussed by Gurney (1944), who states that it is valid for fragments in the range 50 mg to 30 g.

More sophisticated criteria have since been developed for weapons design, based on actual casualty data and taking into account the different areas of the body hit.

A computer code for the estimation of incapacitation by bullets, COMPUTER MAN, has been developed by the US Army. In this code the human body is divided into small sections ($5 \times 5 \times 25$ mm) with the tissue type within the each section specified. The model is then utilized in conjunction with information on the impact points of bullets, their ballistic properties, etc., to obtain a ranking on a relative incapacitation index (RII).

A commercial computer code, WBD2, is also available, developed by Timberwolf Consulting Services (1991), which embodies a wound ballistics simulation model.

An interpretation of the 78 J incapacitation criterion has been given by Gilbert, Lees and Scilly (1994f), who conclude that in terms of the *Textbook* incapacitation model, described below, the criterion corresponds approximately to a 90% probability of incapacitation.

17.41.4 *Textbook* model

A model for the incapacitating power of a penetrating fragment is given in the *Textbook*. The basic relation used is the penetration equation

$$P = ku^b m^c \qquad [17.41.4]$$

where m is the mass of the fragment (mg), P is the penetration (ft) and u is the velocity (ft/s), k is a constant and b and c are indices. It follows from Equation 17.41.4 that for a given incapacitating power

$$u^b m^c = \text{constant} \qquad [17.41.5]$$

or

$$v = u(m/m_{\mathrm{r}})^{c/b} \qquad [17.41.6]$$

where m_{r} is the mass of a reference fragment (mg) and v is the equivalent velocity (ft/s). The values given for b and c are 1 and 0.4, respectively.

A standard fragment is defined for which the value of m_{r} is 52 mg. The *Textbook* gives probit relations for incapacitation by 52 mg fragments of different shapes. The relations are formulated in terms of velocity as the causative factor. The probability of incapacitation by a fragment of given mass and velocity is then obtained by determining the equivalent velocity from Equation 17.41.6 and using this value in the probit relations.

It may be noted that this standard fragment size of 52 mg is small but that a large proportion of the fragments are of this size or below. However, some doubt must attach to extrapolation of the correlation to much larger fragment sizes.

This model applies to a soldier wearing the full complement of land service clothing and equipment, including a helmet.

The *Textbook* model has been cast in convenient form by Gilbert, Lees and Scilly (1994f). For a 52 mg cuboid fragment the probit relation in terms of the velocity u is

$$Y = -8.25 + 1.96 \ln u \qquad [17.41.7]$$

where u is the velocity of the fragment (m/s).

As just indicated, Equation 17.41.7 is specific to a 52 mg fragment. Generalizing for other fragments, by using the causative factor $um^{0.4}$ used in the *Textbook*, these authors obtain

$$Y = -0.51 + 1.96 \ln(um^{0.4}) \qquad [17.41.8]$$

where m is the mass of the fragment (kg).

Gilbert, Lees and Scilly have also adapted the *Textbook* model to the estimation of fatal and serious injuries (K + SI). This is based on equating a 10% probability of incapacitation to a 30% probability of fatal or serious injury, whilst retaining the slope of the probit equation. The equation obtained is

$$Y = 0.24 + 1.96 \ln(um^{0.4}) \qquad [17.41.9]$$

17.42 Explosion Injury from Penetrating Fragments: Model of Gilbert, Lees and Scilly

A model for injury from fragments and missiles generated by an explosion has been given by Gilbert, Lees and Scilly (1994f,g). The model is applicable to the assessment of injury caused by impact of any missile which has the potential to penetrate the skin; it is not intended for the assessment of impact by blunt objects. It was developed primarily with reference to the hazard of fragments from the casing of munitions.

17.42.1 Classification of injury

The injury classification used is:

K	Injury which is fatal, either immediately or in hospital.
S	Injury which is serious, involving perforation of the skin, and which necessitates medical attention, implying hospitalization.
M	Injury which is generally not serious, involving perforation of skin, but which deserves medical attention.
T	Injury which is trivial, possibly penetrating the skin but not perforating it, or no injury at all.

A serious injury is defined more specifically as one involving the following:

Head and neck: perforation of the skull;
Thorax: penetration of the 'vulnerable area';
Abdomen: penetration of the 'vulnerable area';
Limbs: penetration of the 'vulnerable area'.

The abdomen is taken to mean the abdomen proper and that part of the thorax which is not protected by bone, whilst the thorax is taken as that part of the chest which is so protected.

17.42.2 Probability of injury

The following probabilities are defined:

$P(H)$	probability of hit by fragment;
$P(H_i)$	probability of hit by fragment in body region i;
$P(K)$	probability of fatal injury;
$P(K_i)$	probability of fatal injury in body region i;
$P(S)$	probability of serious injury;
$P(S_i)$	probability of serious injury in body region i;
$P(P_{vul,i})$	probability of penetration of vulnerable area of body region i, equal to probability of fatal or serious injury in that region;
$P(P_{skin})$	probability of perforation of skin;
$P(P_{skull})$	probability of perforation of skull;
$P(P_{thor})$	probability of penetration of vulnerable area of thorax;
$P(P_{abd})$	probability of penetration of vulnerable area of abdomen;
$P(P_{limb})$	probability of penetration of vulnerable area of limb.

Use is also made of the subscripts lwlimb and uplimb to denote lower and upper limbs, respectively. The last four probabilities are conditional probabilities, as defined below.

It is assumed that if the body is hit at all by a fragment, the effect is classified using one of the four categories. The trivial injury category covers the cases where the injury is trivial or where no injury is sustained, so that the sum of the probabilities of injury in these four categories is always unity.

The probability of a hit on body region *i* is

$$P(H_i) = A_i/A \qquad [17.42.1]$$

where A is the total MPA of the body and A_i is the MPA attributable to region i.

The probability of perforation of the skin is a function of fragment mass, projected area and velocity. It is assumed that perforation of the skin by a fragment will result in fatality, serious injury or medium injury (K, S or M).

The probability of penetration to a vulnerable area in a particular region i of the body is

$$P(P_{vul,i}) = P(P_{vul,i}|P_{skin})P(P_{skin}) \qquad [17.42.2]$$

Specifically, for each region considered,

$$\begin{aligned} P(P_{vul,i}|P_{skin}) &= P(P_{skull}) \quad \text{head and neck} && [17.42.3]\\ &= P(P_{thor}) \quad \text{thorax} && [17.42.4]\\ &= P(P_{abd}) \quad \text{abdomen} && [17.42.5]\\ &= P(P_{limb}) \quad \text{limb} && [17.42.6] \end{aligned}$$

Then, for the head and neck

$$p(P_{vul,i}) = P(P_{skull})\ P(P_{skin}) \qquad [17.42.7]$$

for the thorax

$$P(P_{vul,i}) = P(1P_{thor})P(P_{skin}) \qquad [17.42.8]$$

for the abdomen

$$P(P_{vul,i}) = P(P_{abd})P(P_{skin}) \qquad [17.42.9]$$

and for the limbs

$$P(P_{vul,i}) = P(P_{limb})P(P_{skin}) \qquad [17.42.10]$$

In this model, the probability of fatal or serious injury (K or S) in body region i is defined by $P(P_{vul,\,i})$. The probability of fatal injury is

$$P(K_i) = P(K_i|P_{vul,i})P(_{vul,i}) \qquad [17.42.11]$$

The probability of serious injury in body region i is then

$$P(S_i) = P(P_{vul,i}) - P(K_i) \qquad [17.42.12]$$

The overall probability of fatal injury is

$$P(K) = \sum P(K_i) \qquad [17.42.13]$$

and that of serious injury is

$$P(\mathrm{S}) = \sum P(\mathrm{S_i}) \qquad [17.42.14]$$

The overall probability of trivial or no injury is

$$P(\mathrm{T}) = 1 - P(\mathrm{P_{skin}}) \qquad [17.42.15]$$

and that of medium injury is simply the residue

$$P(\mathrm{M}) = 1 - [P(\mathrm{K}) + P(\mathrm{S}) + P(\mathrm{T})] \qquad [17.42.16]$$

The probabilities which need to be estimated for this model are therefore for the perforation of the skin $P(\mathrm{P_{skin}})$ and the following probabilities for each body region i: $P(P_{\mathrm{vul,i}}|P_{\mathrm{skin}})$ and $P(K|P_{\mathrm{vul,i}})$.

17.42.3 Causative factor

Traditionally the criterion for military incapacitation has been expressed in terms of a kinetic energy. Later it became recognized that the presented area of the fragment was also relevant.

It has become usual to work, therefore, in terms of the following causative factor X:

$$X = mu^2/A \qquad [17.42.17]$$

where A is the projected area of the fragment (m^2), m is its mass (kg), u is its velocity (m/s) and X is the causative factor (J/m^2).

17.42.4 Perforation of skin

A distinction is made between skin penetration, or epidermis perforation, and skin perforation, or full-depth perforation.

The problem of skin perforation is relatively complex. In a review of work on this topic Di Maio (1981) makes a distinction between experiments carried out on samples of skin with, and without, subcutaneous tissue attached. Skin seems to be more resistant to fragment penetration when it is *in situ*, with underlying muscle and fat still attached.

Some information on the properties of the skin is provided by Mehta and Wong (1967). Experimental work on skin perforation using unattached skin has been described by Grundfest *et al.* (1945) and Sperrazza and Kokinakis (1968). Accounts of experiments on attached skin have been given by Journee (1907), Mattoo, Wani and Askegar (1974) and Di Maio *et al.* (1982). A review of work on penetrating trauma has been given by Neades and Rudolph (1983) as part of an attempt to improve on the widely used criterion for incapacitation of 78 J.

The model adopted by Gilbert, Lees and Scilly is that of J.H. Lewis *et al.* (1987). These latter authors give an empirical formula for the probability of complete skin perforation (full-thickness skin laceration) which is said to apply to both primary and secondary fragments (debris).

Experiments were performed using goat skin to simulate human tissue. This approach follows the work of Sperraza and Kokinakis (1968), who found no significant difference between goat and human skin in this respect.

The results were correlated using the logistic equation

$$P(\mathrm{P_{skin}}) = \frac{1}{1 + \exp[-a + bmu^2/A)]} \qquad [17.42.18]$$

where A is the projected area of the fragment (cm^2), m is its mass (g), u is its velocity (m/s) and a and b are constants.

Values of the constants given for bare skin and for two-layer and six-layer uniforms are:

Target	*Constant*	
	a	*b*
Bare skin	−28.42	2.94
Two-layer uniform	−49.47	4.62
Six-layer uniform	−50.63	4.51

The corresponding probit equation for bare skin is

$$Y = -20.5 + 1.54\ln(mu^2/A) \quad \text{bare skin} \qquad [17.42.19]$$

where A is the projected area of the fragment (m^2), m is its mass (kg) and u is its velocity (m/s).

Analysis by the authors of the data for skin *in situ* indicated that there is strong evidence to support the adoption of the following thresholds for skin penetration and skin perforation:

$$mu^2/A = 3 \times 10^5\ \mathrm{J/m^2} \quad \text{skin penetration}$$
$$= 3.6 \times 10^5\ \mathrm{J/m^2} \quad \text{skin perforation}$$

On the basis of these findings a revision was made to the correlation of J.H. Lewis *et al.* (1987). The threshold was taken to be equivalent to a probability of 1%. The probit equation of Lewis *et al.* given in Equation 17.42.19 was revised by adjusting the intercept but retaining the slope. The result for bare skin is

$$Y(\mathrm{P_{skin}}) = -17.0 + 1.54\ln(mu^2/A) \qquad [17.42.20]$$

The model assumes that on perforation of the skin there is a reduction in the causative factor (mu^2/A) of 360,000 J/m^2, the threshold value for skin perforation. The residual energy is then available for further penetration of the body region in question.

17.42.5 Penetration to vulnerable areas

Head and neck

Information on penetration of the skull by fragments is given in the *Textbook*. A series of 54 shots were made using eight fresh skull caps obtained at autopsy at velocities in the range 280–960 m/s. The data given are for penetration by a 53 mg fragment, and are shown in Table 17.59(A). It is recommended in the *Textbook* that the crude data for the normal velocity be increased by 10% to allow for experimental error and this adjustment is shown in the second column of the table. The probit equation obtained from Table 17.59(A) is

$$Y(\mathrm{P_{skull}}) = -40.5 + 3.03\ln(mu^2/\mathrm{A}) \qquad [17.42.21]$$

Thorax

An essentially similar treatment is available for penetration of the sternum, the information again deriving from the *Textbook*. A series of 56 shots were made using 13 fresh sterna obtained at autopsy at velocities in the range

Lower limb	0.55	0.22	0.77	1.65	0.467

[a] *Source*: *Textbook of Air Armament* (Ministry of Supply, 1952): table C1. Data for a 3/32 in. sphere, of mass 53 mg.
[b] Adjusted as explained in text.

153–530 m/s. The data given are for penetration by a 53 mg fragment and are shown in Table 17.59(B). It is recommended in the *Textbook* that the crude data for the normal velocity be increased by 10% to allow for experimental error, and this adjustment is shown in the second column of the table.

The vulnerability of the thorax, given penetration of the skin, is obtained in the model from the vulnerability to perforation of the sternum. A fraction, say two thirds, of the thorax may be considered to be protected by the sternum or other bones. The remaining one third is treated as unprotected and is lumped with the abdomen. This redistribution is effected by adjusting the values of the MPA A used for these two parts of the body.

Then, applying to the thorax the probit equation obtained for the sternum from Table 17.59(B)

$$Y(P_{\mathrm{thor}}) = -7.37 + 0.948 \ln(mu^2/A) \qquad [17.42.22]$$

Abdomen
Data given below indicate that 84% of the injuries to the abdomen result in death or serious injury. This value is taken as the probability $P(\mathrm{P_{abd}})$ of penetration to a vulnerable area given perforation of the skin.

Limbs
The vulnerable parts of the limbs are bones and vessels and nerves outside the bone area. The *Textbook* gives the MPA of these vulnerable areas and the probability $P(\mathrm{P_{limb}})$ is then simply the ratio of the vulnerable area of the limb to its total MPA. The data are shown in Table 17.59(C).

17.42.6 Fatal injury

All parts of the body
An approximate estimate of the probability of fatality given fatal or serious injury may be obtained from the data on civilian air raid casualties given in the *Textbook* and shown in Table 17.60(A). This table gives the overall probability of fatality as 0.26, which may be compared with the value of 0.27 given in the *Textbook* for ‘all regions’.

It should be noted that the probability given in this table is the probability of fatality given a hit, not the probability of fatality given penetration to a vulnerable area.

The *Textbook* also gives information on British military casualties in the First World War as given in Table 17.60(B). These data have been used in relation to fatal injuries of the trunk, as described below.

Head and neck
Further information on fatal injuries arising from penetration of the skull is given by A. Palmer (1962). He gives data on the mass distribution of flak fragments in 30 cases recovered from fatal and non-fatal fracture wounds to the skull. The proportion of the cases which were fatal is 77%. On this basis the probability of fatality given perforation of the skull $P(\mathrm{K|P_{vul,skull}})$ is taken as 0.8.

Thorax and abdomen
For fatal injuries involving the thorax and abdomen use has been made of data given in the *Textbook* on military casualties in the First World War shown in Table 17.60(B). The effect of an injury to the trunk tends to be serious. From the data in the table the probability $\mathrm{P(K|P_{vul,thor})}$ of fatal injury given penetration to the vulnerable area for the

Table 17.60 *Fatal injury by a fragment penetrating to a vulnerable area*

Lower limb	3.9	44.4	51.7	48.3	0.081

[a] *Source: Textbook of Air Armament* (Ministry of Supply, 1952). Section A: table 3; section B: table 2.

thorax is taken as 0.75 and similarly for the probability $P(\mathrm{K}|\mathrm{P_{vul,abd}})$.

Limbs

Palmer also gives information on fatal injuries arising from penetration of vulnerable parts of limbs. He gives data on the mass distribution of flak fragments recovered from fatal and non-fatal extremity fracture wounds. The proportion of the cases which were fatal for the upper limb is 5.9% and for the lower limb 15.4%.

An alternative approach is to utilize the Second World War data given in Table 17.59(C) and Table 17.60(A). From these tables it may be inferred that for the upper limb

$$P(\mathrm{K}|\mathrm{P_{vul,uplimb}}) = 0.07/0.467$$
$$= 0.15$$

and for the lower limb

$$P(\mathrm{K}|\mathrm{P_{vul,lwlimb}}) = 0.14/0.406$$
$$= 0.345$$

17.42.7 Effect of advances in medicine

Surveys of battle casualties generally conclude that rapid first aid, medical treatment and modern surgery can greatly reduce mortality from wounds to the extremities, or limbs, although this is of little help in the case of wounds to the head. This is supported by statistics which show that US battle deaths from extremity wounds were reduced from about 13% of all deaths in the Second World War to 7.4% in Vietnam.

The probability of fatality given penetration to a vulnerable part of a limb $\mathrm{P(K|P_{vul,\ limb})}$ during the Second World War is therefore reduced in the model to half its crude estimated value by taking credit for medical advances.

No other credit for medical advances is taken in the model.

17.42.8 Effect of clothing

Clothing may in principle affect the probability of skin perforation. The work of French and Callender (1962) indicates that although exhibiting a finite threshold velocity for perforation, light clothing is much less resistant than skin. It is assumed in the model that the type of clothing worn by civilians offers very little protection against missiles and hence bare skin criteria are used.

17.42.9 Injury model

The model of injury by fragments may be summarized as follows. The adjusted values of proportion $\mathrm{A_i}/A$ of MPA assigned to body region i are:

Body region	A_i/A
Head and neck	0.12
Thorax	0.11
Abdomen	0.16
Upper limb	0.22
Lower limb	0.39

$P(P_{\mathrm{skin}})$ Equation 17.42.20 for bare skin.

Following skin perforation, X is reduced by 360,000 J/m^2 to account for the energy expended:

$P(\mathrm{P_{skull}})$ Equation 17.42.21;
$P(\mathrm{P_{thor}})$ Equation 17.42.22;
$P(\mathrm{P_{abd}}) = 0.84$;
$P(\mathrm{P_{lwlimb}}) = 0.467$ from Table 17.59 (C);
$P(\mathrm{P_{uplimb}}) = 0.467$ from Table 17.59 (C);
$P(\mathrm{K}|\mathrm{P_{skull}}) = 0.8$;
$P(\mathrm{K}|\mathrm{P_{thor}}) = 0.75$;
$P(\mathrm{K}|\mathrm{P_{abd}}) = 0.75$;
$P(\mathrm{K_{uplimb}}|\mathrm{P_{vul,uplimb}}) = 0.15$;
$P(\mathrm{K_{lwlimb}}|\mathrm{P_{vul,lwlimb}}) = 0.345$.

If allowance is made for medical advances since the Second World War, the last two values become 0.07 and 0.15, respectively.

17.43 Dust Explosions

Another explosion hazard in the process industries is the explosion of flammable dusts. Explosions of dust suspensions have characteristics in common with gas explosions, but there are also some important differences. Fire and explosions can also occur in dust layers. Legal requirements for plant handling flammable dusts are given in the Factories Act 1961, section 31. This section includes the following:

(1) Where, in connection with any grinding, sieving or other process giving rise to dust, there may escape dust of such a character and to such an extent as to be liable to explode on ignition, all practicable steps shall be taken to prevent such an explosion by enclosure of the plant used in the process, and by removal or prevention of accumulation of any dust that may escape in spite of the enclosure, and by exclusion or effective enclosure of possible sources of ignition.

(2) Where there is present in any plant used in any such process as aforesaid dust of such a character and to such an extent as to be liable to explode on ignition, then, unless the plant is so constructed as to withstand the pressure likely to be produced by any such explosion, all practicable steps shall be taken to restrict the spread and effects of such an explosion by the provision, in connection with the plant, of chokes, baffles and vents, or other equally effective appliances.

There are other statutory requirements relating to particular flammable dusts.

Accounts of dust explosions are given in *Dust Explosions in Factories* (HSE, 1970 HSW Bklt 22), *Dust Explosions and Fires* (K.N. Palmer, 1973a), *Explosions* (Bartknecht, 1981a), *Dust Explosions* (Cross and Farrer, 1982), *Dust Explosions* (Field, 1982), *Development and Control of Dust Explosions* (Nagy and Verakis, 1983), *Venting Gas and Dust Explosions* (Lunn, 1984b, 1992), *Dust Explosions* (Bartknecht, 1989), *Dust Explosions in the Process Industries* (Eckhoff, 1991) and by Wilkes (1948), Maisey (1965), H.E. Rose (1970, 1975), K.N. Palmer (1971, 1974a–c, 1975a,b, 1975–76, 1977, 1981a, 1982, 1983, 1990), O'Reilly (1972), Schwab (1986) and Lunn (1989a,b, 1990).

Relevant codes are NFPA 68: 1994 *Explosion Venting* and NFPA 69: 1992 *Explosion Prevention* Systems. In addition, there are a number of codes relevant to particular industries which deal with dusts such as NFPA 61 series (foodstuffs), NFPA 654 (chemicals, dyes, pharmaceuticals and plastics), NFPA 655 (sulphur) and NFPA 651 (aluminium and magnesium).

Selected references on dust explosions are given in Table 17.61 and on dust explosibility in Table 17.62.

17.43.1 Industrial dusts

Many industrial materials are at some stage handled as dusts or powders and many final products are in dust/powder form. Some typical industrial dusts/powders are

(1) wood;
(2) coal;
(3) food (e.g. starch, flour, sugar, cocoa, feedstuffs);
(4) chemicals (e.g. drugs, dyestuffs);
(5) plastics (e.g. urea formaldehyde resin, polyethylene, polystyrene);
(6) metals (e.g. aluminium, magnesium).

Some of the operations in which such dusts are produced are considered in Section 17.49.

Table 17.61 *Selected references on dust explosions*

Dusts may be formed by condensation from vapours of materials which condense to form solids directly or by mechanical size reduction of solid materials. In the former case the particle size tends to be much smaller.

The terms 'dust and powder' tend to be used interchangeably and have no agreed definition. It is desirable, however, to set some limits to the particle size of materials under consideration. BS 2955: 1958 defines as 'powder' material with a particle diameter of less than 1000 μm (16 BS mesh size) and as 'dust' material with a particle diameter of less than 76 μm (200 BS mesh size). K.N. Palmer (1973a) takes a somewhat wider definition and does not exclude from his treatment information on materials with a particle diameter coarser than 1000 μm.

17.43.2 Dust explosions

The hazard of a dust explosion or fire exists wherever flammable dusts are handled. Generally, a dust explosion occurs only if the dust is dispersed in air, but transition from a fire to an explosion can occur, and vice versa. If a burning dust is disturbed, a dust suspension may be formed and ignited. This initial explosion may generate further dust clouds, which in turn explode. On the other hand, burning particles from an explosion may act as the source of ignition for a fire of other flammable materials.

The explosive effect of a dust explosion is caused by the rapid release of heat and the accompanying rapid pressure rise or expansion of the hot gases.

In dust explosions the combustion process is very rapid. The flame speed is high, comparable with that in gas deflagrations. Maximum explosion pressures are often close to the theoretical values calculated assuming no heat loss during the explosion.

It is uncertain whether detonation can occur in dust explosions in industrial plant. The flame speed in dust explosions is high and in some cases has been reported as approaching that found in detonations. Most of the evidence for detonations in dust suspensions relates to coal mine galleries where the explosion was initiated by a strong ignition source. It is not clear whether detonations can develop from weak ignition sources in industrial plant.

As far as explosion protection is concerned, K.N. Palmer (1973a) states:

> It is general practice in considering protection against dust explosions, in industrial plant, to assume that deflagrations rather than detonations occur. This procedure has proved to be satisfactory in practice, which is fortunate, because deflagrations are simpler to deal with than detonations.

The sequence of events in a serious industrial dust explosion is often as follows. A primary explosion occurs in an item of plant. The explosion protection is not adequate to prevent the flame issuing from the plant, due either to rupture of the plant or to poor explosion venting. The air disturbance disperses the dust in the work room and causes a secondary explosion. The quantity of dust in the secondary explosion often exceeds that in the primary one. Moreover, the building in which the secondary explosion occurs may be weaker than the plant itself. The secondary explosion is thus often more destructive than the primary one.

In some cases the primary explosion also occurs in the open and disturbs dust deposits, and this causes a secondary explosion. In other cases the primary explosion occurs in one unit of the plant and the explosion propagates within the plant to other units.

The possibility of a highly destructive secondary explosion makes dust explosions rather unpredictable.

It is characteristic of plant handling dusts that it is generally very weak relative to the stresses exerted by a dust explosion. Frequently, it can withstand pressures of only 7–15 kPa (1–2 psi). This compares with the pressures of up to 1000 kPa (140 psi) which have been reported for dust explosions under the most unfavourable conditions.

Similar considerations apply to buildings containing plants handling dusts. Generally, buildings cannot withstand more than about 7 KN/m^2 (1 $lb_f/in.^2$) pressure.

Some very destructive dust explosions have occurred in multi-storeyed buildings. The failure of walls on a lower floor has led to collapse of floors and walls on higher storeys. A particular hazard in multi-storeyed buildings is vertical bucket elevators handling dust. A bucket elevator may allow an explosion to propagate through many storeys of the building.

The dust explosion problem is aggravated by the increasing size of plants. The damage caused by an explosion in a large volume may be more than proportionately greater than that resulting from a small volume explosion, because the larger unit is frequently relatively weaker.

A particular problem arises where it is desired to use plant designed for a low explosibility dust to handle a high explosibility one. In this case it is essential to check very carefully whether the plant is suitable or needs modification.

17.43.3 Dust explosion incidents

Accounts of dust explosion accidents have been given in *Dust Explosions* (D.J. Price and Brown, 1922), *Report of Important Dust Explosions* (NFPA, 1957/1) and *Dust Explosions in Factories* (HSE, 1970 HSW Blkt 22) and by K.C. Brown and James (1962), Beach (1964), K.N. Palmer (1973a) and Kaufman (1986).

The HSE booklet lists a wide range of industries and operations in which serious dust fires/explosions have occurred. Beach gives a detailed analysis of dust explosions, excluding those in coal mines, in the period 1900–59. He lists 1110 explosions and 648 fatalities.

Some principal dust explosions are given in Table 17.63.

Historically, industries particularly affected by dust explosions have been flour milling, grain storage and coal mining. A classic flour mill explosion was that in a flour mill in Turin in 1785 (Morozzo, 1795). Serious flour mill explosions have occurred in the United Kingdom, including one at Bow, London, in 1965 which killed five people.

An explosion in a starch/corn plant at Cedar Rapids, Iowa, in 1919 killed 43 people and one at a similar plant in Peking, Illinois, in 1924 resulted in 42 deaths.

Grain storage facilities are liable to serious dust explosions. In 1977 a series of dust explosions occurred in a set of grain silos at Westwego, near New Orleans, Louisiana, which killed 35 people (Case History A89). This disaster was thus on the same scale as that of Flixborough.

Many severe dust explosions have also occurred in coal mines, but these are not considered here.

Some statistical data on dust explosions are given by Lunn (1992). In the United Kingdom in the period 1958–67, there were 247 reported explosions with 9 fatalities and 324 non-fatal injuries, and in the period 1962–79 there were 474 explosions reported with 25 fatalities and 633 non-fatal injuries; 10 of the 25 fatalities in this latter period occurred in two incidents.

Lunn also quotes two other surveys. One is by the HSE covering the periods 1979–84 and 1985–88, and gives breakdowns by type of event, dust involved, equipment involved and ignition source. In the total period 1979–88 there were 36 dust fires with injury, 123 fires with no injury, 41 explosions with injury and 95 explosions with no injury. Principal items of equipment involved were mills, grinders, filters, driers, silos/hoppers and ducts with 51 (17%), 47 (16%), 43 (14%), 19 (6%) and 15 (5%) events, respectively; 95 (31%) events were classified in the category 'other'. The second survey is by the Berufsgenossenschaftliches Institut fur Arbeitssicherheit (BIA) and gives breakdowns by plant group, equipment involved and ignition sources.

17.44 Dust Explosibility Characteristics

17.44.1 Dust explosibility parameters

Important explosibility characteristics of dust suspensions are:

(1) explosibility classification;
(2) minimum explosive concentration;
(3) minimum ignition temperature;
(4) minimum ignition energy;
(5) maximum permissible oxygen concentration to prevent ignition;
(6) explosion pressure characteristics
  (a) maximum explosion pressure,
  (b) maximum rate of pressure rise,
  (c) average rate of pressure rise.

An account is given first of the factors which influence dust explosibility, then of the tests used to determine the explosibility parameters and then of the explosibility parameters themselves.

Table 17.63 *Some dust explosion incidents*

17.44.2 Factors influencing dust explosibility

The explosibility of dust suspensions in air is characterized by parameters similar to those which define the flammability of gas–air mixtures as described in Chapter 16, but there are some significant differences.

The explosibility of a dust may be regarded as increasing as the minimum explosible concentration, the minimum ignition temperature and the minimum ignition energy decrease and the burning velocity and maximum rate of pressure rise increase.

The characterization of particles is a complex matter, but general characteristics which affect the behaviour of particles include those of the individual particle itself such as particle composition, density, size, shape, surface properties and moisture content and those of the bulk powder such as bulk density and flow properties.

Some factors which influence dust explosibility are:

(1) chemical composition;
(2) particle size;
(3) moisture content;
(4) oxygen concentration;
(5) inert gas;
(6) admixed inert dust concentration.

Nagy and Verakis (1983) give a large number of plots showing the effect of these factors on the dust explosibility parameters, mainly for particular dusts.

There are certain chemical groups such as COOH, OH, NH_2, NO_2, C≡N, C=N and N=N which tend to be associated with higher dust explosibility and certain others such as Cl, Br and F with lower explosibility.

Dusts of pure metals generally react with air to form metallic oxides. In this case the explosive increase in pressure is due to expansion of the nitrogen of the air caused by the heat release. In some cases metals actually react violently with the nitrogen itself to form a metallic nitride.

Volatile matter in the dust tends to enhance the explosibility, although there is generally little increase for volatile contents below 10%. Coal dust in particular can contain a high proportion of volatile matter.

Interestingly, according to Nagy and Verakis, pure carbon dust does not explode. They speculate that the reaction rate of pure carbon with oxygen is too low. But carbon dust containing 8% volatile matter is explosive.

If the dust contains inert material this reduces its explosibility. This includes coal dust with clay and some polymeric materials that contain inert fillers.

Dust explosibility is strongly affected by particle size. Particle size is usually defined in terms of an equivalent particle diameter. Generally, a dust with a particle diameter greater than 500 μm is unlikely to be responsible for initiation of an explosion, though it may undergo combustion in one already occurring. At the other end of the range, reduction in particle size below about 50–74 μm does not normally result in any significant increase in explosibility. The particle diameter of dusts used in dust explosibility testing normally does not exceed 75 μm.

A dust usually contains a range of particle sizes. A relatively small proportion of fine particles enhances the explosibility of a dust. Moreover, attrition caused by handling the dust tends to generate fine particles.

Figure 17.112 illustrates the effect of particle size on some of the more important dust explosibility parameters. These results are for atomized aluminium, which is a rather extreme case, but nevertheless they illustrate general trends.

Moisture content has a strong effect on dust explosibility, although the effect is generally weak for moisture contents below 10%. At the other end of the range, dust with a moisture content greater than 30% is unlikely to be responsible for initiation of an explosion.

The oxygen concentration in the surrounding atmosphere has a strong effect on dust explosibility, which increases as the oxygen concentration increases. Conversely, the explosibility decreases as the oxygen concentration decreases and the inerts concentration increases.

Dust explosibility is affected by the concentration of any admixed inert dust, although the effect is generally weak for inert dust concentrations below 10–20%.

17.44.3 Dust explosibility tests

The tests which are carried out on dust explosibility vary between countries and a large variety of tests are in use. It is convenient to start with those developed at the Bureau of Mines (BM) in the United States, since these have also been widely used in other countries, including the United Kingdom.

Accounts of the various tests in the Bureau of Mines scheme have been given in a series of reports, in particular that by Dorsett *et al.* (1960 BM RI 5624). A summary has been given by Nagy and Verakis. Some of the apparatus used in these tests is illustrated in Figure 17.113.

Dust explosibility is determined in the Hartmann apparatus, shown in Figure 17.113(a). The Hartmann apparatus is a vertical tube of volume 1.2 l. The dust is dispersed by an air blast. The ignition source is a hot wire or spark igniter. If any flame propagation is observed, the dust is explosible.

Two other types of apparatus which are also used to determine whether a dust is explosible are the horizontal tube apparatus and the inflammator apparatus, shown in Figures 17.113(b) and (c), respectively. In the horizontal tube apparatus, the dust is dispersed by an air blast. The ignition source is a hot coil. In the inflammator apparatus, the dust suspension is injected into the apparatus against a deflector plate and falls onto the ignition source a hot wire or spark igniter. The apparatus is useful for dusts which are not readily dispersed.

The minimum ignition temperature for explosion of a dust suspension is measured in the Godbert–Greenwald furnace, shown in Figure 17.113(d). A dust suspension is injected into a vertical tube held in a constant temperature furnace and the appearance of flame at the open bottom mouth of the furnace is observed.

A separate determination is made of the minimum ignition temperature of a dust layer, which in general differs from that of the dust in suspension. Again, the Godbert–Greenwald furnace is used, but in this case the dust is held in a wire mesh basket 1 in. in diameter and ½ in. deep. Another method which is also used is ignition of the layer on a hot plate.

The minimum ignition energy for explosion of a dust suspension is measured in the Hartmann vertical tube apparatus. The dust is dispersed by an air blast. The ignition source is a capacitor discharge spark igniter. Any propagation of flame is observed.

The maximum oxygen concentration to prevent ignition is measured in the open Hartmann vertical tube using spark ignition and in the Godbert–Greenwald furnace.

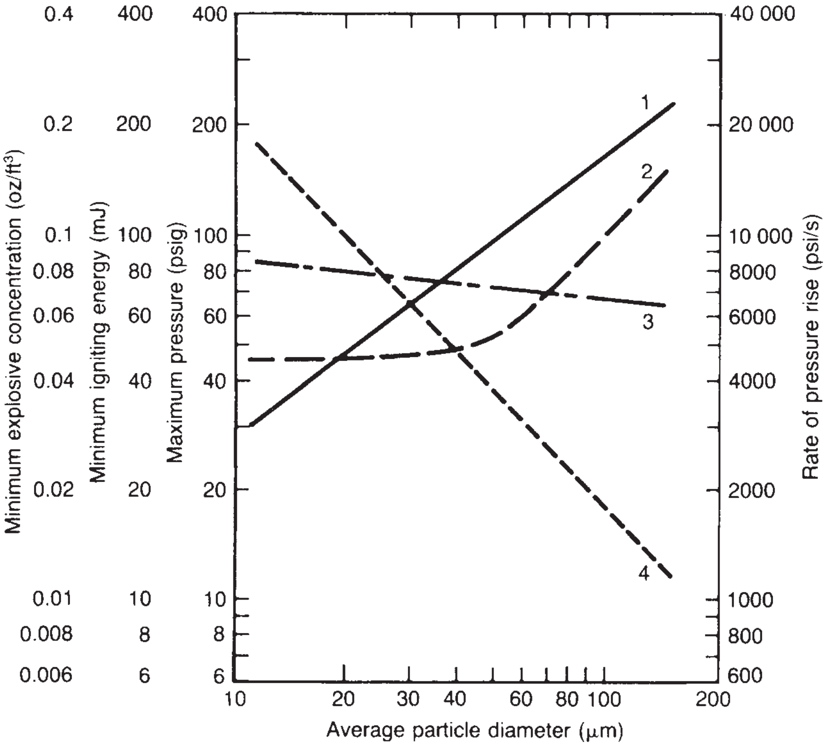

__Figure 17.112__ Dust explosibility characteristics: effect of particle size on some principal parameters for atomized aluminium (Nagy and Verakis, 1983). 1, minimum ignition energy; 2, minimum explosive concentration; 3, maximum explosion pressure; 4, maximum rate of pressure rise

The pressure–time profile is measured in a closed Hartmann vertical tube apparatus, or Hartmann bomb. The explosion pressure characteristics are obtained from this.

The Hartmann test for the pressure–time profile is the subject of ASTM E789-81 1981 Test for Pressure and Rate of Pressure Rise for Dust Explosions in a Closed Vessel (Hartmann test).

In the United Kingdom dust explosibility testing is done at the Fire Research Station (FRS), Borehamwood, and the test scheme covers the explosibility characteristics listed above. These tests have been described by K.N. Palmer (1973a), Raftery (1975 FRS Fire Res. Tech. Pap. 21) and Field (1982).

Dust explosibility classification is performed using the vertical tube, the horizontal tube and the inflammator apparatus. The dust is classed as explosible if a positive result is obtained in any one of the three types of test. The minimum explosive concentration is measured in the vertical tube apparatus, the minimum ignition temperature in a modified form of the Godbert–Greenwald furnace and the minimum ignition energy in a modified form of the vertical tube apparatus.

The maximum permissible oxygen concentration to avoid ignition used to be measured in the Godbert–Greenwald furnace but is now measured in the vertical tube apparatus at ambient temperature. The dust is dispersed by a blast of the reduced oxygen mixture. The ignition source is a hot coil or spark igniter. Any propagation of flame is observed.

The explosion pressure parameters are obtained by measuring the pressure–time profile in a stronger form of the vertical tube apparatus. A typical pressure–time curve, given by K.N. Palmer (1973a), is shown in Figure 17.114. The pressure p_1 is caused by the entry of dispersing air into the vessel. The maximum explosion pressure $p_{\max}$ is normally calculated as

$$p_{\max} = p_2 - p_1 \qquad [17.44.1]$$

An alternative definition is

$$p_{\max} = \frac{p_o}{p_1 + p_o}(p_2 - p_1) \qquad [17.44.2]$$

where $p_{\max}$ is the maximum explosion pressure, p_o is the atmospheric pressure, p_1 is the small initial pressure rise and p_2 is the pressure defined in Figure 17.114.

Since p_1 is usually about 40 kPa, the values of $p_{\max}$ calculated from Equation 17.44.2 differ by about 40% from those calculated from Equation 17.44.1. In using values of maximum explosion pressure given in the literature, care should be taken to check the definition used.

The maximum rate of pressure rise $(\mathrm{d}P/\mathrm{d}t)_{\max}$ is determined from the maximum slope of the pressure rise curve

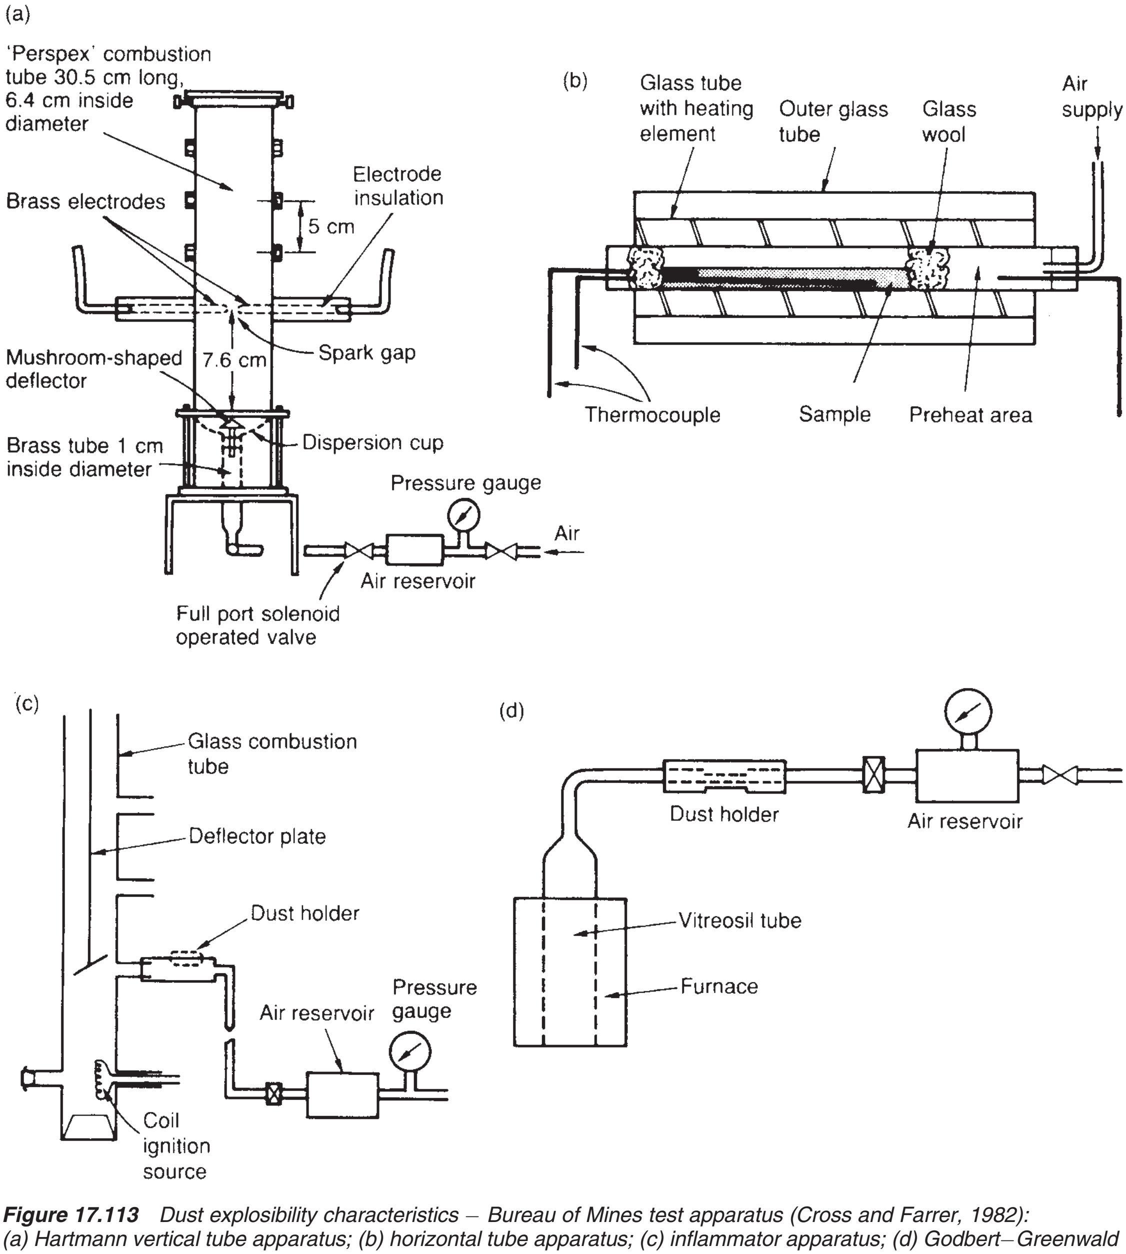

Figure 17.113 *Dust explosibility characteristics – Bureau of Mines test apparatus (Cross and Farrer, 1982): (a) Hartmann vertical tube apparatus; (b) horizontal tube apparatus; (c) inflammator apparatus; (d) Godbert–Greenwald furnace (Courtesy of Plenum Publishing Corporation)*

a/b and the average rate of pressure rise $(\mathrm{d}P/\mathrm{d}t)_{\mathrm{av}}$ is calculated as $(p_2-p_1)/(t_2-t_1)$.

Another important dust explosibility test scheme is that developed in Switzerland by Bartknecht. Accounts are given by Bartknecht (1981a) and Field (1982). Various workers have shown that the Hartmann vertical tube test involves wall effects and gives less than ideal dust dispersion. In this scheme, therefore, basic test for dust explosibility is performed in a 20 l spherical vessel, shown in Figure 17.115. This test is an alternative to the Hartmann vertical tube test in the BM scheme.

In the 20 l sphere test the dust is injected into the sphere from a separate container. The ignition source is located in the centre of the sphere and is usually a chemical igniter with an ignition energy of 10 kJ. A standard time delay is used between injection and ignition.

The 20 l sphere test is used, like the Hartmann vertical tube, for both qualitative and quantitative determinations.

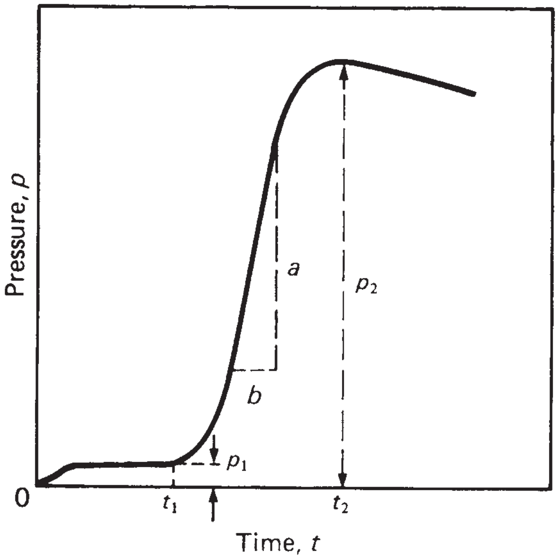

Figure 17.114 *Dust explosibility characteristics: explosion pressure curve in a vertical tube apparatus (K.N. Palmer, 1973a) (Reproduced with permission from Dust Explosions and Fires by K.N. Palmer, 1973, Chapman and Hall)*

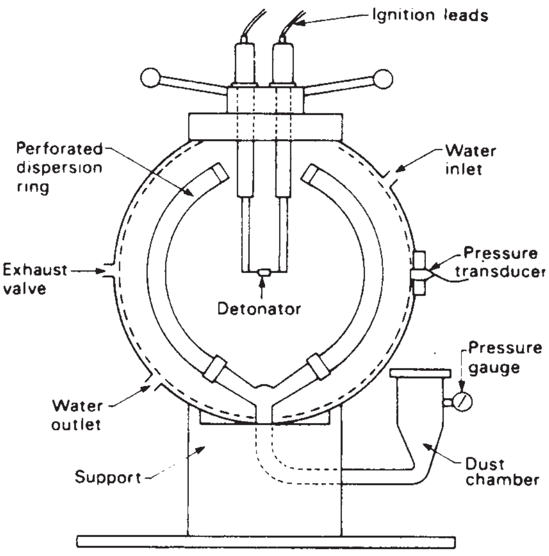

Figure 17.115 *Dust explosibility characteristics: 20 l sphere test apparatus (Field, 1982; reproduced by permission of Elsevier Science Publishers)*

It is used both to determine whether a dust is explosible and to measure the maximum explosion pressure and the maximum rate of pressure rise.

Use is also made of a 1 m^3 sphere as an alternative to the 20 l sphere.

The general approach taken in this scheme is to use these spheres to determine also the other explosibility characteristics. Thus, the spheres are used to determine the minimum explosible concentration and the minimum ignition energy.

The analysis of the results is similar to that used for gas explosions. The cube root law is written in the form

$$\left(\frac{dP}{dt}\right)_{\max} V^{1/3} = K_{\mathrm{st}} \qquad [17.44.3]$$

where K_{st} is the dust explosibility constant (or K_{st} value), P is the absolute pressure, t is the time and V is the volume of the vessel. The K_{st} value is the basis of the dust explosibility classification and is a measure of the maximum rate of pressure rise. It corresponds to the K_G value for gases.

Another dust explosibility test scheme is that developed by Eckhoff at the Christian Michelsen Institute (CMI) in Norway. An account is given by Field (1982). Eckhoff has shown that the minimum ignition energy obtained in a test apparatus depends critically on the ignition source used. He has developed for this test an ignition source with a long duration spark which is a particularly efficient igniter for dusts.

Dust explosibility testing in Germany is performed by the Bundesanstalt fur Materialprufing (BAM). Accounts of the test scheme have been given by Leuschke (1966) and Field (1982). For dust explosibility use has been made of the vertical tube and inflammator types of apparatus, but increasing use is made of the 20 l and 1 m^3 spheres. Other parameters such as minimum explosive concentration and minimum ignition energy are determined in relatively large (~1 m^3) vessels.

Turning to the background, and interpretation, of these various tests, the two main apparatus for dust explosibility testing are the Hartmann vertical tube and the 20 l sphere. The Hartmann tube is liable not to give uniform conditions for dust dispersion and turbulence. Further, it is subject to wall effects. After initial spherical expansion the flame travels as two fronts up and down the tube. These conditions give a lower rate of combustion and of pressure rise. Consequently, the strength of the pressure rise in the Hartmann bomb is less than that in the 20 l sphere.

These problems are largely overcome by the use of a sufficiently large spherical test vessel. The two principal vessels adopted are 20 l and 1 m^3 spheres. It has been shown that the former is close to the critical size below which effects of vessel size occur and above which they do not. This is illustrated in Figure 17.116.

A large amount of the earlier work on dust explosibility was done at the Bureau of Mines using the Hartmann apparatus. Much recent work has been done using the 20 l vessel. Moreover, methods have been developed for dust explosion venting which depend on experimental data for one or other apparatus. It is therefore of some interest to be able to relate the results obtained in one apparatus to those obtained in the other. Unfortunately, the results often do not agree and may even give different rankings.

The problem of relating results for the two methods has been examined by Field and Abrahamsen (1981 BRE N81/81). They conclude that there is no simple relation, although Field (1982) does quote the table given in NFPA 68: 1978 relating the dust class to the maximum rate of pressure rise in the Hartmann apparatus; this relation is given below.

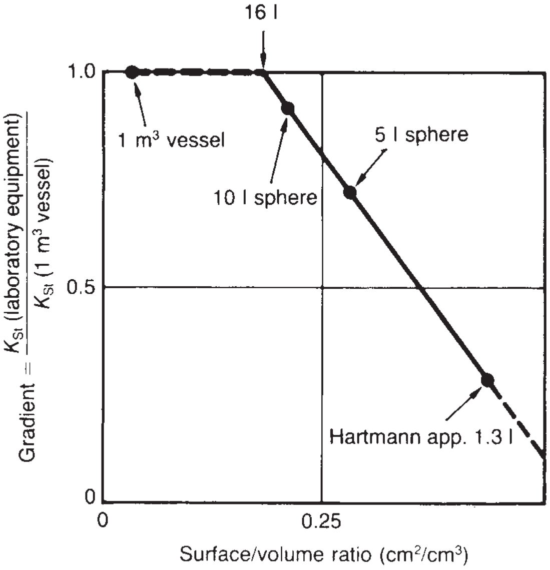

***Figure 17.116** Dust explosibility characteristics: effect of test vessel size on K_{st} value (Bartknecht, 1981a) (Courtesy of Springer-Verlag)*

The furnace apparatus for the determination of the minimum ignition temperature gives a relatively short residence time. Cross and Farrer comment that a lower minimum ignition temperature may be possible if the dust suspension is held at an elevated temperature for a prolonged period.

With regard to the minimum ignition energy, it has gradually become clear that the Hartmann vertical tube has a number of deficiencies. The test appears to overestimate the minimum ignition energy by a factor of between 2 and 5, and is therefore not conservative.

The ignition source in the Hartmann vertical tube test is a capacitive spark igniter. This has two disadvantages. One is that the spark energy tends to be less than the theoretical energy ($\frac{1}{2}CV^2$) due mainly to loss in the transformer. The other is that it is not possible to control the duration of the spark, which is a significant variable.

An alternative igniter is the direct capacitive spark, which uses a circuit without a transformer, and the inductive spark, developed by Eckhoff. Both these igniters give much lower values of the minimum ignition energy than the Hartmann apparatus. Thus, the Hartmann apparatus, the direct capacitance and Eckhoff igniters give the value of the minimum ignition energy of wheat dust as 40, 25 and 7 mJ and that of fine aluminium powder as 1–15, 7.5 and 1 mJ, respectively.

All early data on minimum ignition energy are likely to have been determined using the Hartmann vertical tube test.

The maximum oxygen concentration to prevent ignition was originally measured, as stated above, using the furnace test, but since the operating temperature of the furnace is high and since this concentration is a function of temperature, the values obtained were excessively low. In the United Kingdom the measurement is now made using the vertical tube apparatus at ambient temperature. Typical values of the maximum oxygen concentration obtained using the furnace test are 4–7% compared with 10–15% using the vertical tube test.

17.44.4 Dust explosibility classification

In the United Kingdom the dust explosibility classification used over a number of years is:

Group A: Dusts which ignited and propagated flame in the test apparatus.

Group B: Dusts which did not propagate flame in the test apparatus.

Tests are made using all three types of apparatus described, and the dust is classified as Group A if flame propagation occurs in any one apparatus.

Group A dusts should be regarded as capable of causing a dust explosion. Group B dusts are non-explosible, but can burn.

The classification into Groups A and B applies only to dust dispersions at near atmospheric temperature. At higher temperatures some dusts in Group B may be capable of causing a dust explosion.

This classification system replaced an earlier scheme in which dusts were classified as Class I, II or III. Broadly, class I corresponds to Group A and Classes II and III to Group B.

In the United States the NFPA classification of hazardous materials is Class I for gases and vapours and Class II for dusts. The latter are subdivided into E, metal dusts, F, carbonaceous dusts, and G, flour dusts.

The Bureau of Mines has developed an index of explosibility which ranks dusts relative to Pittsburgh coal. The index of explosibility IE is the product of the explosion severity ES and the ignition sensitivity IS

$$\mathrm{IE} = \mathrm{IS} \times \mathrm{ES} \qquad [17.44.4]$$

with

$$\mathrm{IS} = \frac{(\mathrm{MIT} \times \mathrm{MIE} \times \mathrm{MEC})_{\mathrm{Pc}}}{(\mathrm{MIT} \times \mathrm{MIE} \times \mathrm{MEC})_{\mathrm{sample}}} \qquad [17.44.5]$$

$$\mathrm{ES} = \frac{(\mathrm{MEP} \times \mathrm{MRPR})_{\mathrm{Pc}}}{(\mathrm{MEP} \times \mathrm{MRPR})_{\mathrm{sample}}} \qquad [17.44.6]$$

where MEC is the minimum explosive concentration, MEP is the maximum explosion pressure, MIE is the minimum ignition energy, MIT is the minimum ignition temperature and MRPR is the maximum rate of pressure rise, and the subscripts Pc and sample denote Pittsburgh coal and sample.

The index of explosibility is a relative one, and is to this extent less dependent on the apparatus used, but its determination requires the conduct of the full range of tests.

The K_{st} method has already been described. The actual K_{st} classification, its relationship to Hartmann bomb data and to some typical industrial dusts are given in Table 17.64.

17.44.5 Minimum explosive concentration

A dust suspension in air is usually explosible only within certain concentration limits. The upper concentration limit, however, is ill-defined. The lower limit is known as

Table 17.64 *Dust explosibility characteristics: the K_{st} classification*

A Dust explosion classes

Dust explosion class	K_{st}^{a} (bar m/s)	*Explosion features*
St 0	0	No explosion
St 1	>0–200	Weak
St 2	201–300	Strong
St 3	>300	Very strong

B Relation of K_{st} and Hartman bomb data[b]

$K_{st}{}^{a}$ (bar m/s)	*Hartman bomb*, $(dP/dt)_{max}$ (psi/s)
≤200	≤7300
201–300	7300–22000
>300	>22000

C Typical dusts

Dust explosion class	*Typical dust*
St 0	Non-explosive dust
St 1	Grain dust
St 2	Organic pigment
St 3	Fine metal dust

[a] These figures are for a strong ignition source (10,000 J). For a weak ignition source (10 J) the corresponding figures are given by NFPA 68: 1978 as: 0, >0–100, 101–200 and >200.

[b] NFPA 68: 1978.

the minimum explosive concentration or the lower explosive limit (LEL), the two terms being interchangeable, and the upper as the upper explosive limit (UEL).

It is found empirically that for a large number of dusts the lower explosive limit lies in the range 20–60 g/m^3 and the upper explosive limit in the range 2–6 kg/m^3.

Some progress has been made in the theoretical estimation of the explosive limits for dusts.

The minimum explosive concentration decreases as the particle size decreases and the volatile matter content and oxygen concentration increase and increases as the moisture content and concentration of admixed inert dust increase.

Dust suspensions in industrial plant are often above the upper limit, but it is not generally practical to use this as a design parameter. For design it is the minimum explosible concentration which is of prime interest.

17.44.6 Minimum ignition temperature

The minimum ignition temperature decreases as the particle size decreases and the volatile matter content and oxygen concentration increase and increases as the moisture content and concentration of admixed inert dust increase.

17.44.7 Minimum ignition energy

The minimum ignition energy decreases as the particle size decreases and the volatile matter content and oxygen concentration increase and increases as the moisture content and concentration of admixed inert dust increase.

17.44.8 Maximum permissible oxygen concentration

There appears to be relatively little data on the variation of the maximum oxygen concentration to prevent ignition with the various influencing factors. As already described, the maximum oxygen concentration decreases as temperature increases.

17.44.9 Maximum explosion pressure

The maximum explosion pressure increases as the particle size decreases, but the effect is relatively weak. There does not appear to be much data on the effect of the other influencing factors.

17.44.10 Maximum rate of pressure rise

The maximum rate of pressure rise increases as the particle size decreases and the volatile matter content and oxygen concentration increase and decreases as the moisture content and concentration of admixed inert dust increase.

An investigation of the relationship between the initial and maximum rates of pressure rise in dust explosibility testing using a 1 m^3 vessel has been described by Chathrathi (1994). No such relationship was found.

17.44.11 Burning velocity

Another parameter of interest in relation to dust explosions is the burning velocity. Knowledge of this parameter would allow the use of the large number of methods and models developed for gas explosions and gas explosion venting. The burning velocity is not the subject of standard tests, but some work has been done to estimate burning velocities of dusts.

Maisey (1965) has used an 'equivalent burning velocity' for dust mixtures. His basic approach is to compare the maximum rate of pressure rise for dust mixtures with that obtained for gases with known burning velocity and thus to calibrate the dusts.

Burgoyne (1967a, 1978) has tabulated for gases maximum rates of pressure rise determined in the Hartmann bomb and burning velocities for gases. His data are shown in Table 17.65. These data have then been used by Field (1982) to give the relation between maximum rate of pressure rise in the Hartmann bomb and burning velocity shown in Figure 17.117.

Nagy and Verakis (1983) have given values of the burning velocity of dust mixtures obtained by applying Equation 17.7.77, which gives a relation between the rate of pressure rise and the burning velocity, to the experimental data on the rate of pressure rise of such mixtures determined in work at the Bureau of Mines.

Table 17.65 *Dust explosibility characteristics: relation between maximum rate of pressure rise in Hartmann bomb and burning velocity (after Burgoyne, 1978) (Courtesy of the Society of Chemical Industry)*

Gas	*Maximum rate of pressure rise* (bar/s)	*Maximum burning velocity* (m/s)
Methane	181	0.37
Propane	248	0.46
Ethylene	536	0.70
Hydrogen	1,276	3.35

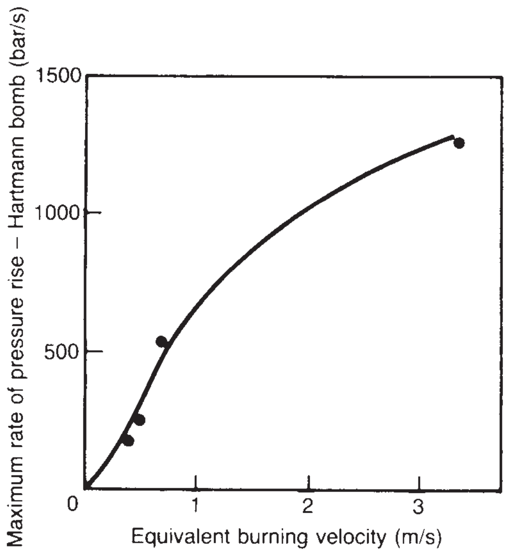

***Figure 17.117** Dust explosibility characteristics: relationship between maximum rate of pressure rise in the Hartmann bomb and burning velocity (Field, 1982; reproduced by permission of Elsevier Science Publishers)*

17.44.12 Minimum ignition temperature of dust layer

The minimum ignition temperature of a dust layer is a function both of the dust and of the thickness of the layer, the ignition temperature decreasing as the thickness of the layer increases.

The two methods of measurement, by furnace and by hot plate, give results which differ by up to about 30°C.

The layer ignition temperature decreases as the particle size decreases and the volatile matter content and oxygen concentration increase.

In Germany, use is made of a maximum permissible surface temperature (MPST) for equipment on which dust may settle. An account of work related to this is given by Hensel *et al.* (1994). The MPST is established by determining the glow temperature of the dust and substracting a safety margin, set at 75°C. The glow temperature is the temperature at which a 5 mm dust layer is ignited in a hot plate test. As indicated, a dust layer thicker than 5 mm may give a lower glow temperature. The authors describe work on models based on constant surface temperature and the alternative of constant surface heat flux, utilizing thermal explosion theory.

17.44.13 Hybrid dust–gas mixtures

If flammable gas is present in addition to the dust, the explosibility of the dust is enhanced. Increase in the concentration of flammable gas results in decrease in the minimum explosive concentration, minimum ignition temperature, minimum ignition energy and increase in the maximum rate of pressure rise.

The presence of flammable gas can therefore render explosive a dust–gas mixture at a dust concentration which is below the normal lower explosive limit for the dust and at a gas concentration below the normal lower explosive limit for the gas. Another important effect is to make explosive a dust with a particle size large enough to keep it normally non-explosive.

For such hybrid dust–gas mixtures Cardillo and Anthony (1978) have applied Le Chatelier's equation in the form

$$\frac{c_{\mathrm{d}}}{l_{\mathrm{d}}}+\frac{c_{\mathrm{g}}}{l_{\mathrm{g}}}=1 \qquad [17.44.7]$$

where c is the concentration (g/m^3) and l is the lower explosive limit (g/m^3) and subscripts d and g denote dust and gas, respectively. They modify this relation empirically to give

$$\frac{c_{\mathrm{d}}}{l_{\mathrm{d}}}+\frac{c_{\mathrm{g}}}{l_{\mathrm{g}}}=0.8 \qquad [17.44.8]$$

An alternative relation has been given by Pellmont (1979) as follows:

$$l_{\mathrm{dh}}=l_{\mathrm{d}}\left(\frac{c_{\mathrm{g}}}{l_{\mathrm{g}}}-1\right)^2 \qquad [17.44.9]$$

where l_{dh} is the lower explosive limit of the dust given the presence of flammable gas.

Where the hybrid mixture rises due to contamination of a dust by solvent, it is convenient to be able to express Equation 17.44.8 in terms of the mass of solvent contaminated dust and of the mass fraction of solvent in that dust. Thus, following Field (1982), Equation 17.44.8 can be rearranged to yield

$$m_{\mathrm{sd}}=\frac{0.8l_{\mathrm{d}}}{1+\phi_{\mathrm{s}}[(l_{\mathrm{d}}/l_{\mathrm{g}})-1]} \qquad [17.44.10]$$

where m_{sd} is the mass concentration of solvent contaminated dust (g/m^3) and ϕ_{s} is the mass fraction of solvent in that dust.

As already mentioned, the presence of flammable gas also affects the other explosibility characteristics. In particular, it affects the maximum rate of pressure rise and hence the K_{st} value. Bartknecht gives data showing the effect of different concentrations of methane and propane on the dust explosion class of polyvinyl chloride dust. Dust of class St 0 changes to classes St 1, 1/2, 2 and 3 at methane concentrations of 1, 3, 5 and 7%, respectively, and to classes 1, 2/3 and 3 at propane concentrations of 0.9, 2.7 and 4.5%, respectively.

For hybrid mixtures the minimum ignition energy is also lower than that of the dust alone.

17.44.14 Dust explosibility data

There are available a number of compilations of dust explosibility data. Most of these data derive either from the work of the Bureau of Mines or from that of Donat and Bartknecht.

The explosibility classification of a number of dusts is given in SHW 830 *Dust Explosions in Factories. Classification List of Dusts That Have Been Tested in the form of a Dust Cloud* by HM Factory Inspectorate (1968).

Compilations of data have been given by Maisey (1965), K.N. Palmer (1973a), Cross and Farrer (1982), Field (1982) and Nagy and Verakis (1983). Field gives two tables, one for data obtained in tests in small scale apparatus and one for data from large apparatus.

Some explosibility properties of selected dusts in air are given in Table 17.66.

The more modern apparatus such as the 20 l vessel tends to yield much higher values for the maximum explosion pressure and the maximum rate of pressure rise. A comparison of values is given by Nagy and Verakis (1983).

An account of current results from dust explosibility testing at the BM, using the 20l vessel and covering a wide and representative range of dusts, has been given by Cashdollar (1994).

17.44.15 Variability of dust explosibility data

Like the data on flammability characteristics, data on dust explosibility exhibit considerable variability. Nagy and Verakis (1983) begin their account with a table of data to emphasize the point. Another set of data illustrating the data variability are those given by Cross and Farrer (1982) on polyethylene.

It may be expected that the considerable progress made in dust explosibility testing has reduced this variability, but it should always be borne in mind, particularly in assessing data for early work.

17.45 Dust Ignition Sources

An account of ignition sources was given in Chapter 16 with particular reference to ignition of gases. The ignition sources for dusts are broadly similar, although there are certain points specific to dusts and dust-handling plant. The account given here is therefore relatively brief.

Discussions of ignition for dusts are given by K.N. Palmer (1973a), Field (1982), Cross and Farrer (1982) and Eckhoff (1991).

Some principal ignition sources for dusts include:

(1) flames and direct heat;
(2) hot work;
(3) incandescent material;
(4) hot surfaces;
(5) electrostatic sparks;
(6) electrical sparks;
(7) friction sparks;
(8) impact sparks;
(9) self-heating;
(10) static electricity;
(11) lightning.

As with gases, it is not easy to compare ignition effects. Different ignition sources are naturally characterized by different quantities such as temperature, energy and power, as reflected in the laboratory tests performed, so that comparison of different ignition sources is difficult. However, in general terms, dusts can be ignited by low energy as well as high energy ignition sources.

Ignition sources which can occur inside the plant are of particular importance. They include incandescent material, hot surfaces, sparks, self-heating and static electricity.

Some account of the control of ignition sources for dusts is given in this section. A further discussion is given in Section 17.46.

17.45.1 Flames and direct heat

Incident statistics show that a large proportion of dust ignitions are caused by flames. A flame is a very effective source of ignition for dust suspensions.

One source of flames is direct fired equipment. This source may be eliminated by the use of indirect heating using hot water or steam. If this course is adopted, the basis of safety should not be negated by any additional means of heating provided as a standby.

17.45.2 Hot work

Another principal ignition source for dusts is hot work such as welding and cutting. Again a welding flame is a very effective source of ignition.

In this case it is frequently a dust layer inside equipment which is ignited. Such a dust layer may have an ignition temperature in the range 100–200°C and is readily ignited by hot work. Incidents occur because this hazard is not appreciated and the dust is not cleaned out of the equipment before work is started.

17.45.3 Incandescent material

Burning dust, or other incandescent material, is another important ignition source. Considerable efforts are made to prevent ignition by burning dust.

Burning dust is an ignition source which can occur inside dust-handling equipment. One consequence of this is that it may travel through the plant. Another is that it may remain undetected.

A direct firing system is one potential source of incandescent particles. In direct-fired driers the air inlet is protected by a fine screen to prevent ingress of such incandescent material.

17.45.4 Hot surfaces

Hot surfaces are another important ignition source. One type of hot surface is equipment with a hot surface such as a steam pipe or electric lamp. Another is overheated moving equipment such as a distressed bearing.

Ignition due to a hot surface is particularly likely to occur with dust layers. As already mentioned, the surface temperature which can cause ignition of a dust layer is frequently no more than 100–200°C. The ignition temperature of a dust layer decreases as the thickness of the layer increases. It is frequently found in investigations of ignition that a dust layer has ignited at an unexpectedly low temperature.

Bowes and Townshend (1962) have applied self-heating theory to the prediction of the temperature at which a dust layer is liable to ignite.

Practical considerations should also be borne in mind. For example, contamination with oil may effect an appreciable reduction in the ignition temperature of a dust layer. Another factor which may lead to a lower ignition temperature is thermal degradation of the material.

The dust itself may contribute to its own ignition. Dust is a poor conductor of heat and a layer of dust on equipment may reduce heat loss to atmosphere and thus cause the surface to be hotter than it would be otherwise. Or again, dust may enter a bearing and cause it to run hot.

Hot surface ignition is a particular problem with driers of various types. A discussion of the problem with different types of drier is given by Field (1982) and detailed guidance is given in the *IChemE Drier Guide* (Reay, 1977; Abbott, 1990). Field summarizes the general recommendations of

Table 17.66 *Some explosibility properties of selected dusts (K.N. Palmer,1973a) (data in this table from Dust Explosions and Fires by K.N. Palmer, are reproduced with permission of the author and of the publishers, Chapman & Hall)*[a]

[a] See text for discussion of higher values of parameters such as maximum explosion pressure and maximum rate of pressure rise obtained in modern test apparatus.

the latter to the effect that inlet temperatures should be at least 50°C below the minimum ignition temperature of the dust suspension and 20°C below that of any dust layer likely to form.

Electric lamps give hot surfaces which may ignite dust suspensions. There are available lamps with special protection for use in dusty atmospheres. Alternatively, areas which may contain dust suspensions, may be illuminated by lamps which are separated on the other side of an armoured glass panel.

A number of incidents have occurred, particularly in silos, involving the use of wander lamps supplied by the mains. These should be avoided and portable battery lamps used instead.

Hot surfaces may also occur as a result of distress in machinery such as pumps and motors. It may be necessary in some cases to monitor features such as bearing temperatures.

17.45.5 Electrostatic sparks

As stated in Chapter 16, there are three main types of spark which may serve as an ignition source: (1) electrostatic sparks, (2) electrical sparks, and (3) friction/impact sparks. The first two involve an electrical discharge, but the difference is that the first is a capacitive or inductive discharge spark and the second a spark from a voltage source.

The standard minimum ignition energy tests use an electrostatic ignition source and are therefore most directly applicable to electrostatic spark ignition, but less so to electrical sparks.

An electrostatic spark may occur due to a discharge from electrical equipment. Protection against such discharges is based on hazardous area classification and the associated safeguarding of electrical equipment. Intrinsically safe equipment is designed so that incendive capacitative or inductive discharges cannot occur.

17.45.6 Electrical sparks

Electrical sparks occur in the normal operation of certain equipment such as switches and relays and may occur in electrical equipment generally as a result of malfunction.

Again, protection against electrical sparks is based on hazardous area classification and safeguarding. In particular, flameproof equipment is used. Where dust is present this equipment should exclude dusts. A distinction may be drawn between equipment which is dust tight and excludes dust entirely and equipment which is dustproof and lets in only an insignificant amount of dust. An account of the two types of equipment is given by Field (1982).

A more detailed discussion of hazardous area classification and of safeguarding of electrical equipment, including equipment for use in dusty conditions, is given in Chapter 16.

17.45.7 Friction sparks

Another important contributor to incidents is frictional sparks associated with rubbing or grinding. These can occur in plant handling dust in several ways. The dust itself may block the equipment and cause overloading, leading to spark generation. Preventive measures include control of dust flow and machine overload trips. Foreign materials such as tramp iron can cause sparks. Removal of such objects can be done by magnetic or pneumatic separation, and is especially desirable if the material is to pass through a mill. Failure of equipment can also give rise to sparks.

17.45.8 Impact sparks

Much concern has centred around the potential of hand tools to create an incendive impact spark, although there is little evidence from incidents of single impact ignition.

There has, however, been a good deal of work done on the potential of hand tools as an ignition source. Most of the work on this has been done on gases and an account is given in Chapter 16.

As described there, the incendive potential of an impact such as that of a metal tool on a metal surface arises from the heating of that surface. In other words, the ignition source is not the spark itself but the heated surface. The problem is the transfer of the heat from the metal surface to the dust.

Experimental work on impact ignition of dusts has been performed by Morse (n.d.), Brown (1941 BM 1C 7148) and N. Gibson, Lloyd and Perry (1967). The work is summarized by Cross and Farrer (1982) to the effect that dust ignitions have been obtained either if the dust was a sensitive one, such as aluminium, magnesium, zinc or sulphur, or if the thermite reaction occurred, but no ignition of a non-sensitive dust in the absence of the thermite reaction has been obtained.

17.45.9 Self-heating

An account of self-heating was given in Chapter 16, where the general features and quantitative aspects where discussed. Consideration here is limited to a few basic points.

Self-heating, or spontaneous combustion, is another significant ignition source.

There are a wide variety of reactions which can give rise to self-heating. They include not only oxidation reactions but reactions with water or wood. For many reactions the reaction rate accelerates with temperature, according to the Arrhenius equation. But there are also autocatalytic reactions which may accelerate due to production of a catalyst or removal of an inhibitor. Induction times may be long and the self-heating may be slow to start but may then proceed undetected for a long period. Account should also be taken of the effect of contaminants such as oil and of thermal degradation. It follows that the first step is screening of the dust to determine whether it is liable to self-heating.

Control of the temperature of dust in process and in storage is another means of preventing self-heating. One aspect of this is control of hot surfaces, which may arise in normal operation or due to fault conditions.

In general, situations in which there is a large mass of dust stored at a high initial temperature tend to present the greatest hazard. Dust in a pile has a high surface area and sufficient air circulation, both of which favour self-heating.

Measures should be taken to avoid unintended accumulation of deposits of dust which could undergo self-heating.

A situation which has frequently led to trouble is the discharge of hot dust from a drier into a hopper. It may be necessary to cool the dust prior to storage. Another measure which is sometimes used is to recirculate dust from storage through a cooling system.

Another precaution which is taken is the monitoring of the temperature of dust in storage.

17.45.10 Static electricity

Static electricity is a further significant ignition source for dusts. This too has been treated in Chapter 16 so that again consideration here is limited to a few basics. A more detailed discussion is given by Cross and Farrer (1982).

In general terms, the static charge on dusts is a function of the work done on them. Hence, the charge tends to be a stronger function of the process than of the material. This is illustrated by the data on charges for different dust-handling processes given in Chapter 16. For sieving and pouring the charges are low, but for size reduction they are much higher.

It is not easy to screen for situations where static electricity might present a hazard in dust handling. Laboratory tests for this are not well developed.

There are certain types of dust-handling plant in which static electricity is readily generated. These include mills, conveyor belts and pneumatic conveying systems. The hazard in such equipment should therefore be carefully considered.

As with liquids, static charge can accumulate at the centre of a large storage hopper; it may then be discharged by an earthed probe. But there is also a hazard unique to dusts, that of sliding of highly charged material towards an earthed container wall.

Plastic surfaces such as those used in chutes may give rise to sparks. Bags used for transporting dusts can also create sparks. A detailed discussion of these is given by Cross and Farrer.

An operation which has resulted in a number of incidents is the pouring of powder from a polyethylene bag into a flammable solvent.

The human body can carry a charge sufficient to make it a potential ignition source. In the manual handling of dusts, the hazard of static electricity from the human body becomes significant if the dust has a minimum ignition energy less than 25 mJ.

As far as the human body is concerned, the main precaution is the use of conducting footwear or antistatic footwear and conductive flooring.

If the minimum ignition energy is less than 10 mJ, it is advisable to provide antistatic flooring and to use antistatic clothing and footwear.

Factors which tend to reduce the hazard of dust explosions from static electricity are the relatively high minimum ignition energy of dusts and the tendency of dusts to give corona discharge.

Measures to counter static electricity include modification of the processing conditions and of the plant. The reduction of static electricity by controlling the atmosphere at a higher relative humidity is particularly relevant to handling dusts.

In storage bins use may be made of earthed wire meshes on the wall and of earthed rods in the bulk powder. These do, however, have the disadvantage that if they lose their connection to earth, they may aggravate the situation. Another measure which is particularly relevant to storage bins is the use of passive dischargers on the material entering.

17.45.11 Ignition incidents

Some information on ignition sources in dust explosion incidents is given in Table 17.67. Apart from the usual problem of consistency of classification, the data show that different studies tend to highlight different ignition sources. For example, the proportion of incidents attributed to welding and cutting in the three sections of the table is 10, 3 and 24.3%, respectively.

Another important point which is illustrated particularly by Table 17.67(C) is the multiplicity of situations which can give rise to ignition. This reinforces the point often made that it is prudent to assume that the necessary attempt to eliminate all ignition sources may not be completely successful.

Further statistical data on ignition sources for dust explosions are given by Lunn (1992), as mentioned in Section 17.43. The HSE survey for 1979–88 gives the principal ignition sources as friction/mechanical failure, overheating/spontaneous heating, flames/flaming material, tramp material and welding/cutting, with 56 (18%), 51 (17%), 44 (15%), 21 (7%) and 20 (7%) events, respectively; 83 (27%) events were classified in the category ‘unknown’. In the BIA survey, the main ignition sources were mechanical sparks, smouldering clumps, mechanical heating and electrostatic discharge, with 26.1, 11.3, 8.9 and 8.7% events, respectively; 16% of events were classified in the category ‘unknown’.

17.46 Dust Explosion Prevention

As for flammable gases, control of dust explosions may be approached by way of prevention or protection.

Accounts of dust explosion prevention include those given in *Dust Explosions in Factories* (HSE, 1970 HSW Bklt 22) (the HSE *Dust Explosion Guide*), *Guide to Dust Explosion Prevention and Protection. Part 2: Ignition Prevention, Containment, Inerting, Suppression and Isolation* by Schofield and Abbott for the IChemE (1988/30) (the IChemE *Dust Explosion Protection Guide*), EPA FS 6022: 1989 *Explosible Dusts: Control of Explosions*, FS 6023: 1989 *Explosible Dusts: Elimination of Ignition Sources* and NFPA 69: 1992 *Explosion Prevention Systems* and by K.N. Palmer (1973a), Bartknecht (1981a, 1989) and Eckhoff (1991).

There are several approaches to the prevention of dust explosions. They include (1) use of a dust-free process, (2) avoidance of flammable dust suspensions, (3) elimination of sources of ignition, and (4) inerting.

17.46.1 Dust-free processes

A fundamental solution to the dust explosion problem is to use a dust-free process. In particular, it may be possible to process the materials wet rather than dry, so that dust suspensions do not occur at all. This approach is in effect an application of the principle of inherently safer design. Where it is applicable, it is one of the most satisfactory methods.

17.46.2 Dust control

If flammable dust has to be handled dry, it is generally not possible to prevent the occurrence of dust concentrations above the lower explosive concentration in some parts of the plant. Nevertheless, much can be done to minimize the volume of any dust clouds formed and to reduce the probability of formation.

Where dust suspensions may occur, large volumes should be avoided as far as practicable. Often it may be appropriate to have several smaller volumes rather than one large one. Overdesign of a unit, such as a hopper, should be avoided so that it does not operate empty all the time.

Situations should be avoided which encourage dust cloud formation such as the free fall of dust from a height into a hopper.

Table 17.67 Ignition sources for dust explosions

A Ignition sources for primary dust explosion[a]

Ignition source	*Proportion* (%)
Welding and cutting	10

[a] After Spiegelman (1981).

[b] K.N. Palmer (1891a) after Jacobsen (1981). Original sources: NFPA (1957) for all dusts; Verkade and Chiotti (1987b) for grain elevator and mills.

[c] After Cross and Farrer (1982). Original source: Department of Agriculture (1980).

Dust should be removed from suspension at as early a stage as process considerations permit. Thus, if dust has to be removed from a gas stream, it is better to do this as soon as practicable as the gas leaves the plant rather than to transfer it down long ducts to a central cleaning point.

Buildings which contain plant handling flammable dusts should be designed to minimize the accumulation of dust deposits and to facilitate cleaning.

Avoidance of dust suspensions depends as much on operation as on design. Dusts should not be allowed to accumulate at the gas cleaning plant, but should be removed regularly in accordance with the design. Buildings which have plant handling dust should be cleaned to prevent accumulation of dust deposits.

It should be borne in mind that even if a dust suspension within the explosive range is not present in normal operation, it may be so during start-up, shut-down or fault conditions.

17.46.3 Control of ignition sources

Measures should be taken to eliminate ignition sources which could give rise to a dust explosion.

Control of ignition sources needs to be addressed both in the design and operation of the plant. Measures which can be taken in design include the location or elimination of direct firing and the avoidance of situations where static electricity can give rise to incendive sparks.

Measures to ensure close control of operations is particularly necessary for activities such as welding and cutting. Training to ensure that personnel understand the reasons for the precautions is an integral part of this.

Good housekeeping, and particularly avoidance of accumulation of dust deposits, has a role to play which is especially important in plants handling dusts.

Hazardous area classification provides a formal framework for the control of ignition sources. An account of hazardous area classification, including that for areas where combustible dusts may occur, was given in Chapter 16. Two points made there merit repetition. First, although hazardous area classification was originally concerned primarily with ignition by electrical sources, it has developed into a comprehensive system for the control of all ignition sources which might ignite a release outside the plant. Second, the effectiveness of hazardous area classification depends as much on operation as on design.

However, hazardous area classification is concerned essentially with releases from plant rather than with ignition within plant. Dusts particularly are prone to ignition from ignition sources within the plant. It is necessary, therefore, to complement the measures taken by hazardous area classification with other measures to eliminate in-plant ignition sources.

Maintenance of equipment to minimize the fault conditions which could constitute ignition sources is another significant aspect of control of ignition sources not only outside but inside equipment.

The IChemE *Guide* gives detailed measures for the control of ignition sources covering the following operations/equipment: (1) size reduction, (2) pneumatic conveying, (3) screw conveyors, (4) drag link and mass conveyors, (5) belt conveyors, (6) bucket elevators, (7) storage bins and silos, and (8) dust filters.

It is generally imprudent, however, to assume that an ignition source will not occur.

17.46.4 Inerting

The suspension of a flammable dust in air may be rendered non-explosive by the addition of inert gas.

Guidance on inerting of dust-handling plant is given in the NFPA 69 and the IChemE *Guide*.

The main gases used for inerting of dust-handling plant are nitrogen, carbon dioxide, flue gas and inert gas from a generator. The IChemE *Guide* gives guidance on the factors governing selection of a suitable gas.

One factor is any hazards associated with the use of the gas. One such hazard is reaction with the dust: carbon dioxide can react violently with aluminium dust, and nitrogen can react at high temperature with magnesium dust. Carbon dioxide can also generate static electricity, as described in Chapter 16.

Other relevant factors are the availability and cost of supply.

In using inerting, complete replacement of oxygen by inert gas may be uneconomic. An alternative approach in such cases is to keep the oxygen content well below the maximum permissible oxygen concentration to prevent ignition. This concentration is obtained using the test referred to earlier.

The IChemE *Guide* also cites certain rules-of-thumb relating the maximum permissible oxygen concentration for carbon dioxide C_o and that for nitrogen N_o:

$$N_o = C_o - 2$$

or

$$N_o = 1.3C_o - 6.3$$

These rules are attributed to Germany and NFPA 69: 1978, respectively.

The maximum permissible oxygen concentrations to prevent ignition which are reported in the literature are normally measured at ambient temperature. If it is proposed to use inerting for dust at high temperatures (say >100°C), the maximum permissible oxygen concentration to prevent ignition should be determined by tests. Likewise tests are called for if there is a hybrid vapour–dust mixture.

With regard to the safety margin to be employed, the IChemE *Guide* suggests a minimum margin of 2%. Thus, if the maximum permissible oxygen concentration to prevent ignition is 11%, the oxygen concentration should be kept below 9%. It also recommends a larger margin where there are large plant volumes, extended hot surfaces or high explosibility dusts (St 3).

There will be a certain out-leak of inert gas from the plant and a certain in-leak of air, and this needs to be taken into account, by design measures to minimize these leaks and by monitoring the oxygen concentration.

Often the plant is totally enclosed and dust is added and removed through valves which give only a small loss of inert gas. Inert gas is supplied to make up these losses. Where the inert gas is recycled through the plant, it is important to avoid the accumulation in the gas of fine particles which are not removed by gas cleaning equipment and which constitute a much increased hazard if ignition occurs.

Careful design and testing of the plant is necessary to ensure that the concentration of oxygen is below the maximum permissible oxygen concentration throughout. Dead spots where there is no gas circulation should be eliminated, and low pressure points where air could leak in should be checked. Usually it is necessary to distribute the inert gas to a number of different points on the plant.

The inert gas demand is liable to vary due to causes such as material flows in the plant, materials withdrawal, temperature changes and leaks. The supply of inert gas should be sufficient to meet peak demands. It should also be reliable.

The gas should be free of moisture, rust and noxious gases. There should be controls to ensure a balanced supply to the different parts of the plant. There should be non-return valves to prevent the entry of dust into the inert gas system. It is usual to provide means of cleaning inert gas leaving the plant.

There should be continuous monitoring of the oxygen content of the gas in the plant and a trip system to shut the plant down if the concentration rises towards a hazardous level. Since the gas contains dust, there may be problems in the measurement of the oxygen level.

The inerting solution is particularly useful in handling dusts of very high explosibility ($K_{st} > 600$ bar/s).

Inerting is not necessarily effective in eliminating dust fires.

The IChemE *Guide* gives examples of the application of inerting to grinding and spray drying operations.

It is also possible with dust suspensions to use inert dust to effect inerting. This method is utilized in certain specialized applications, of which the principal example is coal mining. Thus, in the United Kingdom, limestone dust is used on the floor of mine roadways to prevent a coal dust explosion propagating. The use of inert diluent dusts is discussed in the IChemE *Guide*. The proportions of inert dust quoted as necessary to provide effective inerting are high, generally more than 60%.

Inerting may be used in combination with dust explosion suppression or venting. This is an approach which may be considered where complete elimination of combustion by inerting is judged uneconomic. In such circumstances the effect of partial inerting is to reduce the strength of the explosion to be handled by the suppression or venting system.

17.47 Dust Explosion Protection

Accounts of dust explosion protection include those given in FS 6015: 1974 *Explosible Dusts, Flammable Liquids and Gases: Explosion Suppression*, the HSE *Dust Explosion Guide* (1970 HSW Bklt 22), *Explosions* (Bartknecht, 1981a), the *IChemE Dust Explosion Protection Guide* (1988/30), *Dust Explosions* (Bartknecht, 1989), EPA FS 6022: 1989 *Explosible Dusts: Control of Explosions, Dust Explosions in the Process Industries* (Eckhoff, 1991) and NFPA 69: 1992 *Explosion Prevention Systems* and by KN. Palmer (1973a), P.E. Moore (1979b, 1981, 1982b, 1984, 1986, 1990), J. Singh (1979a), Maisey (1980), Kirby (1985a), Kirby and Siwek (1986), P.E. Moore and Bartknecht (1986), Chatrathi (1992b,c) and P.E. Moore and Cooper (1993).

A relevant standard is BS 6713: 1986 *Explosion Protection Systems*.

Methods of protection against dust explosions include (1) explosion containment, (2) explosion isolation, (3) explosion suppression, and (4) explosion venting. The first three methods are considered in this section and the fourth in the following section.

17.47.1 Explosion containment

The first option for dealing with a dust explosion is total containment.

A general discussion of pressure containment as opposed to pressure relief has been given by Wilday (1991), as described in Chapter 12. Accounts of the containment method for dust explosions include those given in the IChemE *Guide* and by Bartknecht (1981a), Kirby (1985) and Kirby and Siwek (1986).

In some ways containment is an attractive option, since it is an essentially passive method and avoids the problem of relief disposal. It is not usually practicable, however, to design the whole of a dust-handling plant so that it can withstand the pressures generated by dust explosions. This is particularly the case with large plants. Normally, it is preferable to use some other method of protection. Containment may be practicable, however, on small scale units and on particular equipments. Thus, a grinding mill, for example, may be made strong enough to withstand a dust explosion.

The maximum explosion pressure for most flammable gases and dusts is given by Bartknecht (1981a) as about 7 barg. The IChemE *Guide* quotes for dusts the range 7–10 barg.

The static pressure is not, however, the sole criterion. The rate of pressure rise in a dust explosion is high, and the vessel must be able to withstand this dynamic loading.

The IChemE *Guide* distinguishes two basic options for containment: ‘pressure resistance’ and ‘pressure shock resistance’. In the first the vessel is designed to withstand the explosion without deformation, whilst in the second some deformation is allowed provided the explosion is contained. If using this latter method an explosion occurs which is sufficiently severe, it may not be possible to reuse the vessel, but experience shows that generally the vessels are reusable, presumably because the explosions are not especially severe.

The use of containment raises the issue of its coverage within pressure vessel codes. Companies using the technique have tended to develop their own codes. In the United Kingdom the matter has been considered by the BSI Pressure Vessel Technical Committee (PVTC) (BSI, 1986). The IChemE *Guide* summarizes its findings to the effect that a vessel designed to BS 5500 should have sufficient reserve of strength to withstand quite rapid rates of pressure rise up to the design pressure on a one-off basis.

There are a number of engineering issues involved in the use of pressure vessels for containment of dust explosions. They include pressure piling and modes of failure, including brittle fracture. Such design is therefore a specialist matter.

One basic principle is to use rotational symmetry and to avoid large flat surfaces and angular parts.

In designing to contain a dust explosion, particular attention should be paid to the points at which dust is fed or withdrawn from the plant and to connections between units.

An alternative to full containment is partial containment. This involves the use of a stronger vessel combined with explosion relief.

17.47.2 Explosion isolation

Another option for dealing with a dust explosion is isolation.

The three basic methods of isolation are (1) automatic isolation, (2) automatic explosion suppression, and (3) material chokes.

Taking these in turn, automatic isolation is applied to a pipe and involves the use of a quick acting shut-off valve. The general arrangement is similar to that used for flammable gases, as described in Section 17.11.

Details of this type of explosion isolation are given in the IChemE *Guide*. Detection of the explosion is by means of pressure and/or optical sensors. The former are usually preferred, since an optical detector can be blinded. On the other hand, a pressure sensor may not detect a weak pressure wave. A common threshold pressure setting is 0.1 bar.

Typically, the quick acting isolation valve is located about 5–10 m along the pipe from the detectors and has a closure time of some 25 ms.

Bartknecht (1981a) states that rapid action barrier devices can be used to protect against explosions of dust and hybrid dust–gas mixtures, but that for dusts, rapid action slide valves are preferable to rapid action valves with moving parts in the cross-section of the pipe.

The second type of isolation is automatic explosion suppression applied to a pipe. Again the general arrangement is similar to that used for flammable gases, as described in Section 17.11.

The explosion is detected by instrumentation similar to that just described for automatic isolation. The suppressant barrier is located some 5–10 m from the detectors.

Quick acting valves operate most effectively on pipes up to about 0.5 m in diameter. Suppressant barriers have been found effective in pipes up to 2.5 m in diameter.

With both techniques the pipe should be designed to withstand the local pressure, given in the *Guide* as up to 10 barg.

The third type of isolation is the use of a material choke. This is applicable where it is necessary to have a flow of dust between units. A treatment of this method is given in the HSE *Dust Explosion Guide*.

Two commonly used types are rotary valves and worm conveyors, as shown in Figure 17.118. A variety of other types are illustrated in FS 6022.

A rotary valve, which is installed vertically and is driven by a motor, is generally designed to act as a dust explosion choke even in the absence of a head of dust above it.

There have not been many tests of the effectiveness of rotary valves as dust explosion chokes. It has been found, however, in one test, with an explosion above the valve, that the explosion was transmitted by the valve unless arrangements were made to trip the motor within 0.5 s of the detection of the explosion.

If a rotary valve is installed on the inlet of a hopper, there should be arrangements to prevent it from continuing to turn if the hopper becomes overfilled, since this could cause ignition by overheating the dust or overloading the motor.

A worm conveyor, which may be installed horizontally, vertically or inclined and is driven by a motor, is an alternative type of dust explosion choke. One turn of the helix is removed to prevent the choke emptying if the feed is interrupted. If the conveyor is mounted horizontally, a baffle plate is also necessary.

The motor on a worm conveyor is rather liable to be overloaded and should be provided with an overload trip. A worm conveyor is not suitable for dusts which flow less freely when heated.

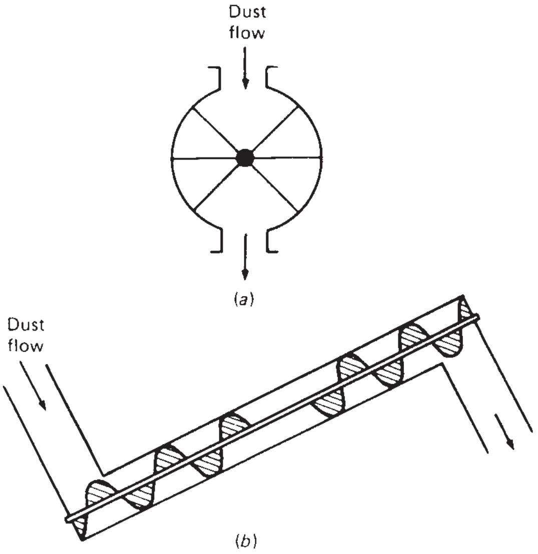

Figure 17.118 *Chokes for the isolation of sections of dust-handling plant: (a) rotary valve and (b) worm conveyor*

Again there have been few tests on the effectiveness of worm conveyors. Since the residence time in a worm conveyor is much longer than that in a rotary valve, the former may be expected to be more effective as a dust explosion choke, but smouldering dust could still pass through unless the motor is tripped.

The choke should prevent the passage of the dust explosion and of any burning material. There should be arrangements to trip the motor. Depending on the application it may be appropriate to provide inerting or suppression.

17.47.3 Explosion suppression

Explosion suppression is the third option. Its application to explosion isolation in a pipe has been described above. Here, consideration is given to its use against explosion in vessels.

Accounts of explosion suppression include those given in FS 6015 and the IChemE *Guide* and by P.E. Moore (1979b, 1981, 1982b, 1984, 1986, 1990), Bartknecht (1981a), P.E. Moore and Bartknecht (1986), Chatrathi (1992) and P.E. Moore and Cooper (1993).

Also relevant is BS 6713: 1986 *Explosion Protection Systems. Part 4: Method for Determination of Efficacy of Explosion Protection Systems*.

The general principle is similar to that for suppression of explosions of flammable gases, described in Section 17.11. Most published work on explosion suppression refers, however, to dusts, and a fuller account is given at this point.

Design of an explosion suppression system is based on the maximum rate of pressure rise in the explosion. This parameter has been discussed in detail in Section 17.44. It may be characterized in terms of the dust St class. In applying the basic data, account should be taken of the features of the particular application, in the light of knowledge of the factors which influence the violence of such an explosion. These include the initial pressure and turbulence and the vessel aspect ratio.

Explosion suppression requires the use of a control system, which has several functions. These are (1) to detect the explosion and inject suppressant, (2) to shut-down the plant, and (3) to prevent restart of the plant unless it is safe to do so.

Detection of the explosion is generally by means of a pressure sensor. Detectors are available which are robust to most materials, to condensation and corrosion, and to shock. In some cases use is made of two detectors oriented in different planes. Activation occurs when the pressure reaches its threshold value, typically of the order of 0.05 bar. In some systems use is also made of the rate of pressure rise.

The mechanisms of suppression of the explosion are (1) quenching, (2) free radical scavenging, (3) wetting, and (4) inerting. Of these the principal mechanism is quenching, or abstraction of heat. The contribution of free radical scavenging is specific to the particular explosion reaction. Wetting of unburned particles is applicable to liquid suppressants. There is also some inerting effect.

The principal suppressants used are halons, dry powders and water. The general characteristics of these have been outlined in Chapter 16. The halons used are principally Halon 1011 (chlorobromomethane), which is effective but toxic, and the less toxic Halons 1211 and 1301. The dry powder most widely used is ammonium phosphate based.

With regard to dry powder, the point has been made earlier that its effectiveness depends on complete extinction of the flame in the initial discharge. Reignition, whether due to incomplete extinction or to hot surfaces, is therefore a potential problem characteristic of this type of suppressant.

Another issue in the selection of suppressants is contamination. With halons the problem is minimal, but with dry powders it can be significant. Water may constitute a contaminant in some cases.

The IChemE *Guide* gives guidance on selection of suppressants. The use of halons is mainly confined to dust class St 1, whilst dry powders are used for both St 1 and St 2. Water is used for hydrophilic St 1 and St 2 dusts.

The effectiveness of suppression depends in large measure on the injection system. The requirement on this is that it be capable of injecting a large quantity of suppressant in a very short time and with adequate reach to all parts of the space protected. An injection system should be capable of a high mass discharge rate, a high discharge velocity and hence good 'throw' and good angular coverage.

The response time of the sensor to the explosion depends on the size of the vessel. The explosion will propagate at the speed of sound, giving a delay, or equalization time, of the order of 4 ms/m distance between the ignition source and the detector. The response of the suppression system is very rapid. The time taken for the suppressant to reach the flame depends on the discharge velocity, which initially is of the order of 40 m/s.

Two injection devices are in common use. One is a hemispherical suppressor with chemical detonator installed inside the vessel. This type is used with a liquid suppressant, usually halon. It has a limited throw, about 2.5 m, and contains only a small quantity of suppressant. The time to complete discharge is about 10–30 ms. It is suitable for protection of smaller vessels.

The other injection device is the high discharge rate (HDR) bottle, installed on the outside of the vessel and pressurized with nitrogen at 20–100 bar. This type is much more versatile, being able to handle most common suppressants and available in capacities from 0.003 to 0.1 m^3. The time to complete discharge is about 100 ms.

The size of vessel which can be protected by suppression is limited by the factors described. Over the years various figures have been quoted for the limiting size. The figure given in FS 6016: 1974 was 115 m^3. That quoted in the IChemE *Guide* is 1000 m^3. Relevant work is described by P.E. Moore (1986).

An effective suppression system requires rapid detection, rapid injection and an adequate quantity of suppressant. The IChemE *Guide* gives a number of graphs of the course of failed suppressions which illustrate these points.

Extinction of the flame is not, however, the only requirement of the suppression system. Its other function in respect of the explosion itself is to limit the pressure developed. Factors affecting this pressure are the dust St class and the detection and injection times.

One measure which may be taken to limit the pressure is the use of multiple injection points.

BS 6713: Part 4 gives the criteria to be applied in determining the safe operating regime of an explosion suppression system.

Various applications of explosion suppression are described in the IChemE *Guide*, which treats (1) mills, (2) bunkers, (3) mixers, (4) elevators, and (5) spray driers.

17.48 Dust Explosion Venting

The use of explosion venting is generally an effective and economic method of providing protection against dust explosions, and is the method normally considered.

Dust explosion venting is dealt with in most of the publications referred to at the start of Section 17.43, and particularly in *Dust Explosions in Factories* (HSE, 1970 HSW Bklt 22), *Dust Explosions and Fires* (K.N. Palmer, 1973a), *Dust Explosions* (Field, 1982), *Development and Control of Dust Explosions* (Nagy and Verakis, 1983) and *Dust Explosions in the Process Industries* (Eckhoff, 1991).

The set of monographs on gas and dust explosions published by the IChemE includes the following on dust explosion venting: *A User Guide to Dust and Fume Control* by C.R. Smith (1981) with a second edition by D.M. Muir (1985) and a revised second edition by Lunn (1992a) and *Guide to Dust Explosion Prevention and Protection* (the IChemE *Dust Explosion Protection Guide*), in three parts: Part 1, *Venting* by Schofleld (1984) with a second edition by Lunn (1992b) (the IChemE *Dust Explosion Venting Guide*); Part 2, *Ignition Prevention, Containment, Inerting, Suppression and Isolation* by Schofield and Abbott (1988) and Part 3, *Venting of Weak Explosions and the Effect of Vent Ducts* by Lunn (1988).

Further guidance is given in NFPA 68: 1994. Much of the literature refers to the earlier 1974 edition (reaffirmed 1978).

Venting is suitable only if there is a safe discharge for the material vented. Preferably the plant should be in the open. If it is in a building, it should be possible to effect a discharge through a short duct. Any such duct will have an effect on the maximum vented pressure and the whole problem should therefore be considered at an early stage of the design.

The venting solution is not appropriate if the plant contains toxic dusts, or other associated toxic substances, which cannot be vented to atmosphere, or is awkwardly sited so that safe discharge is not possible.

17.48.1 Dust explosion venting of vessels

The venting of gas explosions was dealt with in Section 17.12. For dust explosion venting, the general approach and some of the methods are similar, but there are also some important differences.

A dust explosion can occur only if the dust is dispersed. It follows, therefore, that one of the conditions for a dust explosion is a degree of turbulence. A gas explosion on the other hand may occur with a gas mixture which is initially quiescent.

Another difference is that the dust cloud tends not to be uniform, although a high degree of turbulence tends to promote uniformity.

The comments made in Section 17.12 concerning the definitions and units used in explosion venting of gases apply equally to dust explosion venting. The definitions and units used here are summarized in the Notation.

17.48.2 Factors influencing dust explosions

An account of the factors which affect dust explosibility was given in Section 17.44. There are in addition other factors which influence the strength of an explosion of a dust of given explosibility.

The maximum explosion pressure and maximum rate of pressure rise are affected by a number of factors. These are discussed by Cross and Farrer (1982), Field (1982) and Nagy and Verakis (1983). They include

(1) vessel size and shape;
(2) dust concentration;
(3) initial pressure;
(4) initial temperature;
(5) initial turbulence;
(6) ignition source;

and the presence of

(7) flammable gas;
(8) inert gas or dust.

The maximum explosion pressure is essentially independent of vessel size provided heat effects are disregarded.

Experimental measurements of maximum explosion pressure tend to show considerable scatter. Data given by Nagy and Verakis show scatter with most points lying within the ±15% band.

For elongated vessels the heat loss tends to be more significant and the maximum explosion pressure less.

The maximum rate of pressure rise is affected by vessel size and shape. Equation 17.7.48 shows that the maximum rate of pressure rise follows the cube root law and is inversely proportional to $V^{1/3}$. Equation 17.7.75 shows that it is proportional to the surface area/volume ratio S/V.

The dust concentration with the highest explosibility, as measured by the characteristics described earlier such as minimum ignition temperature, minimum ignition energy and maximum rate of pressure rise, tends to be several times greater than the stoichiometric concentration. This contrasts with gas mixtures where the most explosive concentration is usually close to, though not at, the stoichiometric value. The effect of dust concentration is illustrated in Figure 17.119.

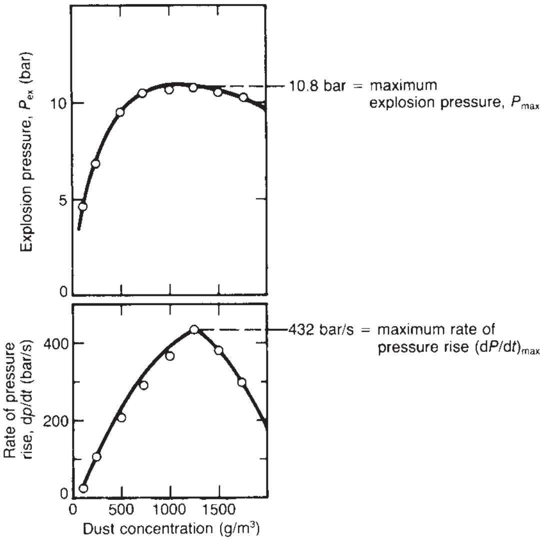

Figure 17.119 *Dust explosion pressure: effect of dust concentration (Bartknecht, 1981a) (Courtesy of Springer-Verlag)*

There is surprisingly little information on the effect of initial pressure. One reason may be that most plant handling dusts operates close to atmospheric pressure. The account of the effect of this parameter given by Nagy and Verakis is in fact relative to gas explosions. According to Field, whereas in a gas explosion the maximum explosion pressure is proportional to the initial pressure, the effect is less for dust explosions. However, data given by Bartknecht for starch dust show maximum explosion pressure proportional to initial pressure for initial pressures up to 2 bara. The same data set shows that the maximum rate of pressure rise is also proportional to initial pressure for the same range of initial pressures.

The initial temperature may have several effects. These include reduction of the mass of air available for combustion and reduction of the moisture content of the dust. The net effect of an increase in initial temperature may therefore be to reduce rather than increase the maximum explosion pressure. An increase in initial temperature does, however, increase the maximum rate of pressure rise through its effect on the combustion rate, and also through any reduction in moisture content.

As already indicated, it is difficult to envisage a dust explosion without a degree of initial turbulence. Turbulence tends, however, to be non-uniform and difficult to measure or quantify. In general terms, an increase in initial turbulence will have only a weak effect on the maximum explosion pressure, but a strong effect on the maximum rate of pressure rise. Situations associated with high turbulence include grinding operations.

The effect of the ignition source on the strength of the explosion is complex and depends essentially on the nature as well as the strength of the ignition source. This aspect was discussed in Section 17.44. In brief, some experiments have shown that similar K_{st} values are obtained for ignition by condenser discharge with an ignition energy in the range 0.005–8 J and by chemical detonator with an ignition energy of 10,000 J.

The effects of the presence of flammable gas and/or inert gas or inert dust have already been described in discussing dust explosibility.

17.48.3 Experimental studies

There have been a number of experimental studies of dust explosion venting of vessels. Some of the principal studies are listed in Table 17.68.

Early work on dust explosion relief was done at the Bureau of Mines by Hartmann, Cooper and Jacobsen (1950 BM RI 4725) using corn starch and by Hartmann and Nagy (1957) using cellulose acetate. According to Nagy and Verakis (1983), the Bureau of Mines has performed some 10,000 experiments on vented explosions. The principal enclosures used were 0.32, 1, 64 and 216 ft^3 in size, the first being cylindrical, the second cubical and the others rectangular galleries.

Schwab and Othmer (1964) carried out experiments using plastics and metallic stearate dusts.

Donat (1971b) has carried out experiments in 1 and 30 m^3 vessels on coal, organic pigment, dextrin and aluminium dusts.

Bartknecht (1981a) has described experiments, including those of Donat, in a 20 l sphere and a/m^3 sphere on a number of parameters for a wide variety of dusts.

The HSE has carried out experiments on a 20 l sphere and an 18.5 m^3 cylindrical vessel to investigate a number of features of venting, including extension of the K_{st} method (Lunn, Brookes and Nicol, 1988) and the effect of vent ducts (Lunn, Crowhurst and Hey, 1988).

Experimental studies of dust explosion relief of silos have been performed by Eckhoff and co-workers (e.g. Eckhoff *et al.*, 1982, 1984; Eckhoff and Fuhre, 1983; Eckhoff, Fuhre and Pedersen, 1986, 1987) and Radant (1982), as described below.

17.48.4 Empirical methods

In contrast to the situation with gas explosion venting there is a lack of empirical methods which do not rely on experimental data. This is not surprising in view of the difficulty of characterizing dust explosibility other than by test data and the complexity of dust explosions.

17.48.5 Scaling methods

The empirical approach used for dust explosions is the use of scaling laws validated over a wide range of experimental conditions.

The three scaling methods used are similar to those used for gas explosion venting: the vent ratio method, the vent coefficient method and the K_{st} method.

In dust explosion venting, the traditional approach has been to express the venting requirement as a vent area per unit volume of space protection, the vent ratio approach. This contrasts with the approach which has developed in gas explosion venting where the venting requirement is generally expressed as a vent area per unit cross-sectional area of space protected, the vent coefficient approach.

17.48.6 Vent ratio method

The vent ratio f is defined as for gas explosions as

$$f = A_v/V \qquad [17.48.1]$$

where A_v is the vent area, f is the vent ratio and V is the volume of the enclosure.

As already mentioned, a common method of characterizing the vent area required is to plot the reduced explosion pressure as a function of vent ratio. Such a plot for dusts given by Hartmann, Cooper and Jacobsen for data covering a range of volumes from 1 to 216 ft^3 is shown in Figure 17.120. Numerous other plots for dusts are given by Lunn.

Recommended values of the vent ratio have been given by various sources. Table 17.69 gives some values which have been available for some time, but which are also quoted by Lunn. Table 17.69(A) gives values recommended for volumes up to 1000 ft^3 by K.N. Palmer (1973a) on the

Table 17.68 *Dust explosion venting: some experimental studies*

Investigators	*Vessel or enclosure type*	*Volume*	*Dust*
Hartmann, Cooper and Jacobsen (BM 1950 RI 4275)	Galleries	1, 64, 216 ft^3	Corn starch
Hartmann and Nagy (1957)	Gallery	1 ft^3	Cellulose acetate
Schwab and Othmer (1964)	Cylindrical chamber	0.0461 ft^3	Plastics dusts, metallic stearate dusts
Donat (1971b)	Sphere	1 m^3	Coal dust, dextrin, organic pigment, aluminium dust
Eckhoff and Fuhre (1983)	Silo	500 m^3	
Eckhoff, Fuhre and Pedersen (1986, 1987); Eckhoff *et al.* (1988)	Silo	236 m^3	Maize starch
Radant (1982)	Silo	20 m^3	
Nagy and Verakis (1983)[a]	Galleries	0.32, 1, 64, 216 ft^3	Various[b]

[a] Account based essentially on earlier work at the Bureau of Mines.

[b] Dusts tested comprised some 19 dusts including atomized aluminium, cellulose acetate, chromium dust, coal dust, cornstarch, magnesium dust, wheat starch, several plastics dusts and several flours. Not all of these were tested in each chamber.

basis of the Hartmann bomb maximum rate of pressure rise values. Table 17.69(B) gives values recommended by NFPA 68: 1978 without reference to dust explosibility measurements.

Palmer states that dusts with a very high maximum rate of pressure rise (say >12,000 $lb_f in.^2$ s) should be treated with particular caution. For these, venting may not be sufficient or even appropriate.

17.48.7 Vent coefficient method

The vent coefficient K is likewise defined as for gas explosions:

$$K = A_c/A_v \qquad [17.48.2]$$

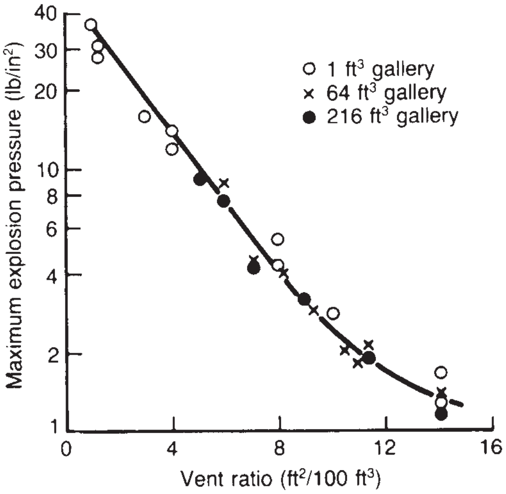

Figure 17.120 *Dust explosion venting: effect of vent ratio on reduced explosion pressure (Hartmann, Cooper and Jacobsen, 1950 BM PI 4725)*

with

$$A_c = L_1 L_2 \qquad [17.48.3]$$

where A_c is the area of the smallest cross-section of the enclosure, K is the vent coefficient and L_1 and L_2 are the two smallest dimensions of the enclosure.

N. Gibson and Harris (1976) have shown that a vent coefficient $K = 3$ gives good agreement with Donat's data for organic pigment and for St 2 dust. Their results have been given in Figure 17.24.

17.48.8 K_{st} method

The K_{st} method developed by Bartknecht is based on the cube root law given in Equation 17.44.3. The cube root law in terms of the maximum rate of pressure rise is

$$\left(\frac{dP}{dt}\right)_{max} V^{1/3} = K_{st} \qquad [17.48.4]$$

and in terms of the rate of pressure rise with venting

$$\left(\frac{dP}{dt}\right)_{Pred} V^{1/3} = K_{st} \qquad [17.48.5]$$

Thus, for the same reduced pressure the vent ratio f also follows the cube root law:

$$fV^{1/3} = \text{constant} \qquad [17.48.6]$$

Bartknecht gives a set of nomographs for the vent area A_v where

$$A_v = f(V, K_{st}, P_{stat}, P_{red}) \qquad [17.48.7]$$

where P_{red} is the reduced pressure and P_{stat} the vent opening pressure.

Table 17.69 *Dust explosion venting: vent ratio recommendations*

A Smaller volumes (≤1000 ft^3) (K.N. Palmer, 1973a)

Maximum rate of pressure rise in Hartman bomb, (dP/dt)$_{max}$ ($lb_f/in.^2$ s)	*Vent ratio* (ft^2/ft^3)
<5000	1/20
5000–10,000	1/15
>10,000	1/10

B Large volumes (NFPA 68: 1978; Lumm 1984b)

Volume (ft^3)	*Other details*	*Vent ratio* (ft^2/ft^3)
1000–25,000	–[a]	1/30–1/50
>25,000	Small fraction obstructed, and	
	Heavy reinforced concrete construction	1/80
	Light reinforced concrete construction	1/60–1/80
	Lightweight construction	1/50–1/60
	Large fraction obstructed	1/10–1/50

[a] An attempt should be made to predict the location of the ignition source and the volume of the dust suspension.

The derivation of these nomographs has been described by Lunn, Brookes and Nicol (1988). The equation from which the nomographs are derived is that of Heinrich, derived in Section 17.48.13.

$$A_{\mathrm{v}} = \frac{V^{2/3} V_{\mathrm{L}}^{1/3} (\mathrm{d}P_{\mathrm{ex}}/\mathrm{d}t)_{\mathrm{P_{red}},V_{\mathrm{L}}}}{C_{\mathrm{d}} (2RT/M)^{1/2} P_{\mathrm{red}}^{1/2} (P_{\mathrm{red}} - P_{\mathrm{a}})^{1/2}} \qquad [17.48.8]$$

where C_d is the coefficient of discharge, M is the molecular weight of the vented gas, P_a is the atmospheric pressure, P_{red} is the reduced pressure, $(\mathrm{d}P_{ex}/\mathrm{d}t)_{P_{red}}$, V_L is the maximum rate of pressure rise in the test vessel, R is the universal gas constant, T is the absolute temperature of the vented gas, V is the volume of the vessel and V_L is the volume of the test vessel. The derivation of this equation is given below.

Bartknecht has given the correlations for dust explosion venting in nomograph form. His nomograph method is that adopted in VDI 3673: 1979 *The Pressure Relief of Dust Explosions*, NFPA 68 and the IChemE *Dust Explosion Venting Guide*.

The nomographs were adopted in NFPA 68: 1988, are given in the 1998 edition of NFPA 68 and are shown in Figure 17.121. The nomographs are for a high energy (10,000 J) ignition source, and there is a separate nomograph for each value of the vent opening pressure P_{stat}. The three values of P_{stat} are 0.1, 0.2 and 0.5 barg and that of P_{red} is 0.2–2.0 barg.

NFPA 68: 1978 gave two separate sets of nomographs, for strong (high energy) and weak (low energy) ignition sources. Only the first set is given in the later editions.

The nomographs apply to dusts with $K_{st} < 300$ bar m/s and with maximum explosion pressure P_{max} up to 10 barg and to dusts with $K_{st} > 300$ bar m/s and with P_{max} up to 12 barg.

The nomographs are valid within a limited range of conditions. Their use is not recommended for $V > 1000$ m^3, $K_{st} < 50$ bar m/s and the values of P_{stat} and P_{red} just stated.

The vent area given by the nomographs for both gases and dusts in a vessel of volume 1 m^3 was given in Figure 17.22.

Bartknecht distinguishes between small and large vessels, defining the latter as $V > 30$ m^3. He states that the nomographs tend to oversize the vent area for large volumes.

An equation equivalent to the Bartknecht nomographs shown in Figures 17.121(a)–(c) has been given by Simpson (1986) and is quoted in NFPA 68: 1994. It is

$$A_{\mathrm{v}} = aV^{2/3} K_{\mathrm{st}}^{b} P_{\mathrm{red}}^{c} \qquad [17.48.9]$$

with

$$a = 0.000571 \exp(2P_{\mathrm{stat}}) \qquad [17.48.10a]$$

$$b = 0.978 \exp(-0.105P_{\mathrm{stat}}) \qquad [17.48.10b]$$

$$c = -0.687 \exp(0.226P_{\mathrm{stat}}) \qquad [17.48.10c]$$

where the units are as follows: A_v (m^2), K_{st} (bar m/s), P_{red} (bar), P_{stat} (barg) and V (m^3). The range of validity of the equation is

$$1 \leq V \leq 1000; \quad 50 \leq K_{\mathrm{st}} \leq 600;$$
$$0.1 \leq P_{\mathrm{stat}} \leq 0.5; P_{\mathrm{stat}} + 0.1 \leq P_{\mathrm{red}} \leq 2$$

Figures 17.121(a)–(c) are given in terms of the K_{st} value. NFPA 68: 1994 also provides nomographs in terms of the K_{st} value. For the latter it gives the following equation, attributed to Schwab:

$$\log A_{\mathrm{v}} + C = a \log \mathrm{V} + \frac{b}{P_{\mathrm{red}}^{d}} \qquad [17.48.11]$$

with the following values of the constants:

P_{stat} (barg)	C			a	b	d
	St 1	*St 2*	*St 3*			
0.1	1.88854	1.69846	1.50821	0.67005	0.96027	0.2119
0.2	1.93133	1.71583	1.50115	0.67191	1.03112	0.3
0.5	1.94357	1.69627	1.50473	0.65925	1.20083	0.3916

where the units are A_v (m^2), P_{red} (barg), P_{stat} (barg) and V (m^3).

Extension and extrapolation of the nomographs is discussed in NFPA 68: 1994.

The Bartknecht nomographs have been extended by Lunn, Brookes and Nicol (1988). The extrapolation is based on Equation 17.48.8. This equation does not include P_{stat} explicitly. But the experiments of Donat give values of $(\mathrm{d}P_{ex}/\mathrm{d}t)_{P_{red}}\ V_L$ for the three values of P_{stat}. The authors plot $(\mathrm{d}P_{ex}/\mathrm{d}t)_{P_{red}}$, V_L vs $(\mathrm{d}P/\mathrm{d}t)_{P_{red}}$, V_L for the three P_{stat} values. Then, applying the cube root law (Equation 17.44.3) and taking $V_L = 1$ m^3 yields

$$\left(\frac{\mathrm{d}P_{\mathrm{ex}}}{\mathrm{d}t}\right)_{P_{\mathrm{red}},V_{\mathrm{L}}} = BK_{\mathrm{st}} \qquad [17.48.12]$$

The values of B are 0.283, 0.333 and 0.5 for values of P_{stat} 1.1, 1.2 and 1.5 bara, respectively. They take B as a function of P_{stat} so that the effect of P_{stat} enters Equation 17.48.8 via the term $(\mathrm{d}P_{ex}/\mathrm{d}t)_{P_{red}}$, V_L:

The extended nomographs given by these authors are shown in Figure 17.122. The nomographs show extension down to $K_{st} = 10$ bar m/s, $P_{stat} \leq 1.1$ bara and $P_{red} = 1.02$ bara. The authors recommend that for $1.05 < P_{red} < 1.2$ the lower limit of P_{stat} be taken as $P_{stat} \leq [1 + (P_{red} - 1)/2]$.

The nomographs have been validated by tests with low K_{st} dusts in a 18.5 m^3 vessel. Like the original nomographs they incorporate a safety factor. However, where the K_{st} value is low, it is important that it be determined accurately and that in using the nomograph the next highest value of K_{st} be used. The detailed limitations of the extended nomographs are discussed by the authors.

The IChemE *Dust Explosion Protection Guide* Part 3 gives detailed guidance on the application of venting to weak explosions and on the effect of vent ducts. It contains a large number of graphs for the estimation of the reduced explosion pressure in vent ducts which are straight (Appendix 1) or have a single, sharp 45° bend (Appendix 2) or a single sharp 90° bend (Appendix 3).

The 2002 edition of NFPA 68 does not offer nomographs, but rather plots of the following equation for vent area and dust explosions:

$$A_{\mathrm{v}} = (8.535 \times 10^{-5})(1 + 1.75P_{\mathrm{stat}})K_{\mathrm{st}}V^{0.75}\left(\frac{1-R}{R}\right)^{1/2} \qquad [17.48.13]$$

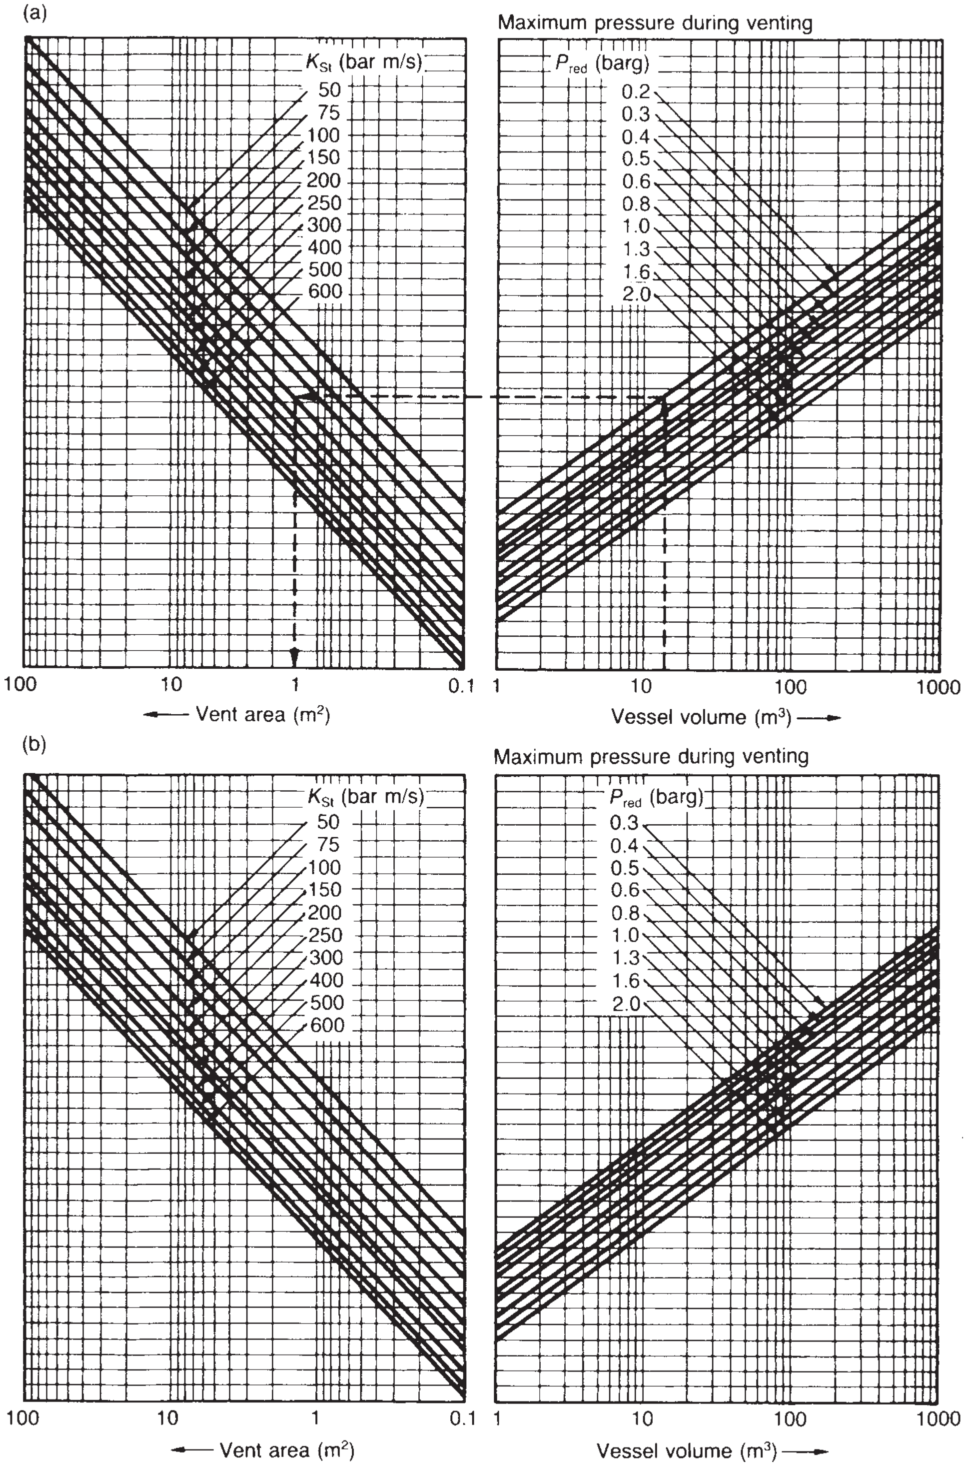

Figure 17.121 *Continued*

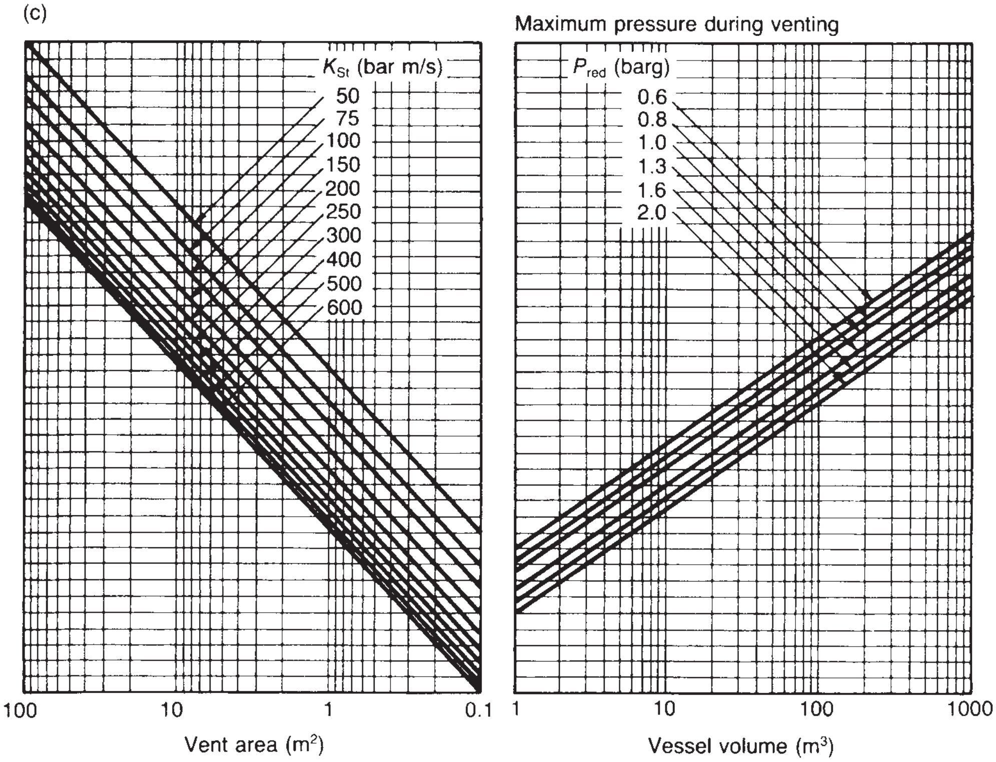

Figure 17.121 *Dust explosion venting: nomographs for vent area for high energy ignition source (NFPA 68: 1994). (a) P_{stat} = 0.1 barg; (b) P_{stat} = 0.2 barg; and (c) P_{stat} = 0.5 barg; see text for details and note to figure 17.25 (Reprinted with permission from NFPA 68 Deflagration Venting, © 1994, National Protection Association, Quincy, MA 02269)*

where A_v = vent area (m^2), P_{stat} = static burst pressure of the vent (bar), K_{st} = deflagration index (bar m/s), V = volume of room (m^3), $R = P_{red}/P_{max}$, P_{red} = reduced pressure after venting (bar) and P_{max} = maximum pressure of a deflagration (bar).

For L/D values greater than 2 and less than 6, the vent area, A_v, calculated by Equation 17.48.13 is increased by adding the area ΔA as calculated from:

$$\Delta A = 1.56A_v\left[\frac{1}{P_{red}} - \frac{1}{P_{max}}\right]^{0.65}\log\left[\frac{L}{D} - 1\right] \qquad [17.48.14]$$

where L = longest dimensions of enclosure (m), $D = 2(A^*/\pi)^{1/2}$ and A^* = cross-sectional area normal to the longitudinal axis of the space (m^2).

The 2002 edition of NFPA 68 also treats partial volume explosions that apply when dust concentrations in some process equipment and buildings are inherently limited to only a fraction of the enclosure volume. When the volume fill fractions, X_r, can be determined, the minimum required vent area is calculated from the following equation:

$$A_v = A_{vo}X_r^{-1/3}\left[\frac{X_r - R}{1 - R}\right]^{1/2} \qquad [17.48.15]$$

where A_{vo} = vent area for full volume deflagrations determined from Equations 17.48.13 and 17.48.14, and the other terms are as used in these equations.

17.48.9 Schwab and Othmer method

Schwab and Othmer (1964) presented an empirical correlation of experimental tests performed using a Hartmann bomb type of apparatus of volume 1.3 l. The dusts tested included powders of polymers and metal stearates. They expressed their results in the form

$$P_{red} = \frac{P_{max}}{10^{Sf}} \qquad [17.48.16]$$

where f is the vent ratio, P_{red} is the reduced pressure and S is a constant.

For the rates of pressure rise, Schwab and Othmer gave the equations

$$\left(\frac{dP}{dt}\right)_{max} = \frac{5500}{10^{2.443K}} \qquad [17.48.17a]$$

$$\left(\frac{dP}{dt}\right)_{av} = \frac{2700}{10^{2.443K}} \qquad [17.48.17b]$$

where $(dP/dt)_{max}$ and $(dP/dt)_{av}$ are the maximum and average rates of pressure rise (psi/s), respectively. These equations are equivalent to

$$\left(\frac{dP}{dt}\right)_{max} = \frac{k_{max}}{10^{Kf}} \qquad [17.48.18a]$$

$$\left(\frac{dP}{dt}\right)_{av} = \frac{k_{av}}{10^{Kf}} \qquad [17.48.18b]$$

where k_{av} and k_{max} are constants.

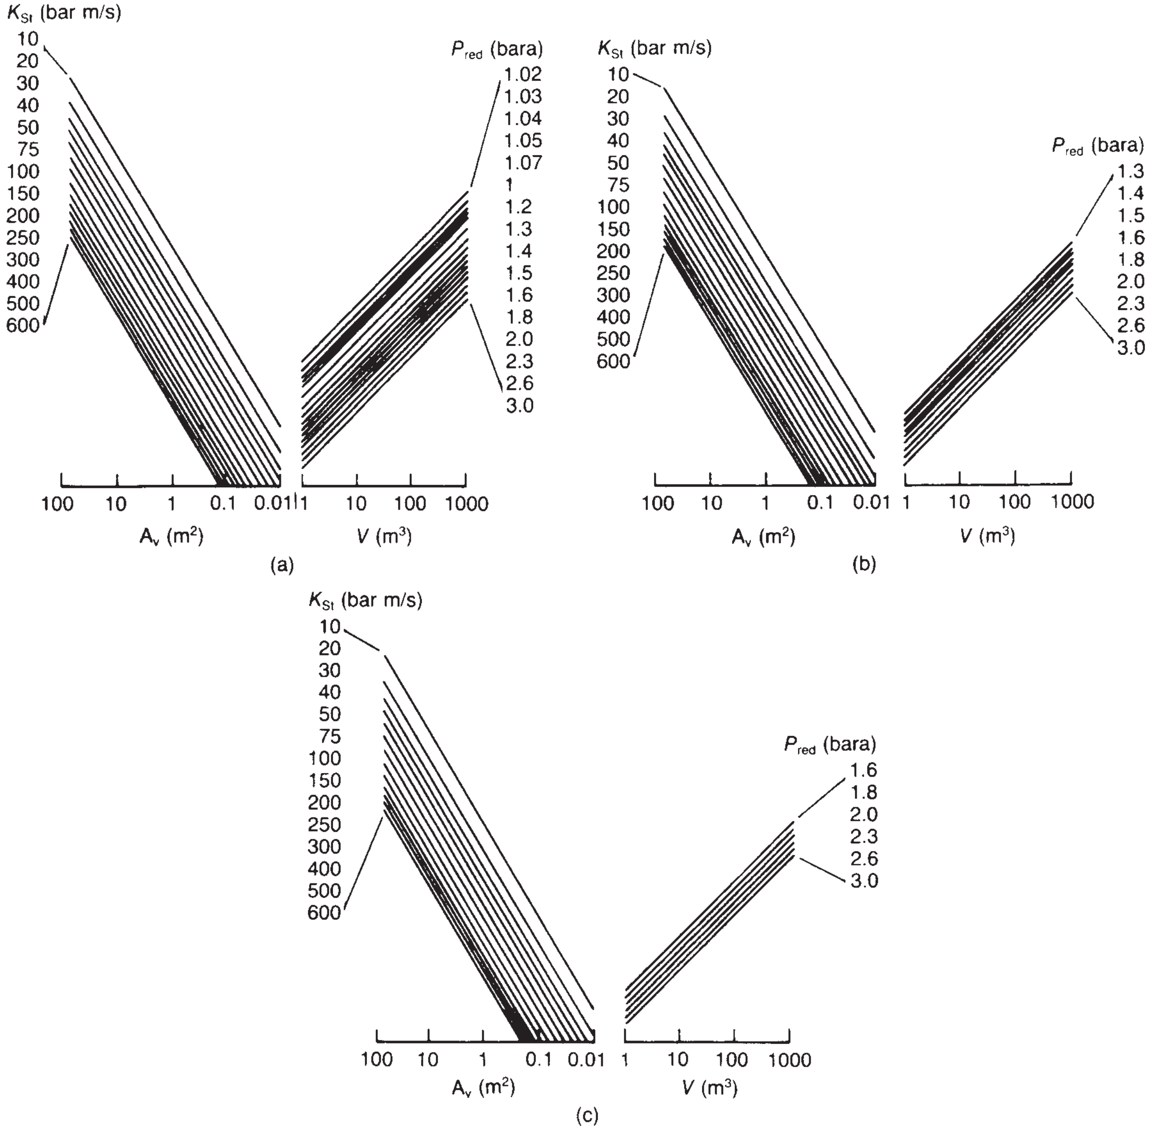

Figure 17.122 *Dust explosion venting: nomographs for vent area extended to lower reduced pressure (Lunn, Brookes and Nicol, 1988): (a) $P_{stat} \leq 1.1$ bara; (b) $P_{stat} = 1.2$ bara; and (c) $P_{stat} = 1.5$ bara (Courtesy of Butterworth-Heinemann)*

The authors give a nomograph for the determination of the vent ratio f. This is shown in Figure 17.123.

17.48.10 Runes method

The method of Runes was described in Section 17.12.

The Runes equation is

$$A_{\mathrm{v}} = C\frac{A_{\mathrm{c}}}{(\Delta P)^{1/2}} \qquad [17.48.19]$$

where ΔP is the explosion overpressure and C is the Runes constant.

NFPA 68: 1978 gives values of the Runes constant C in metric units as 6.8 for organic dusts and 10.5 for high flame speed metal dusts. These compare with values of 6.8 for propane and 10.5 for ethylene.

NFPA 68: 1994 gives a relationship similar to Equation 17.48.16 and containing a constant C. It is described in

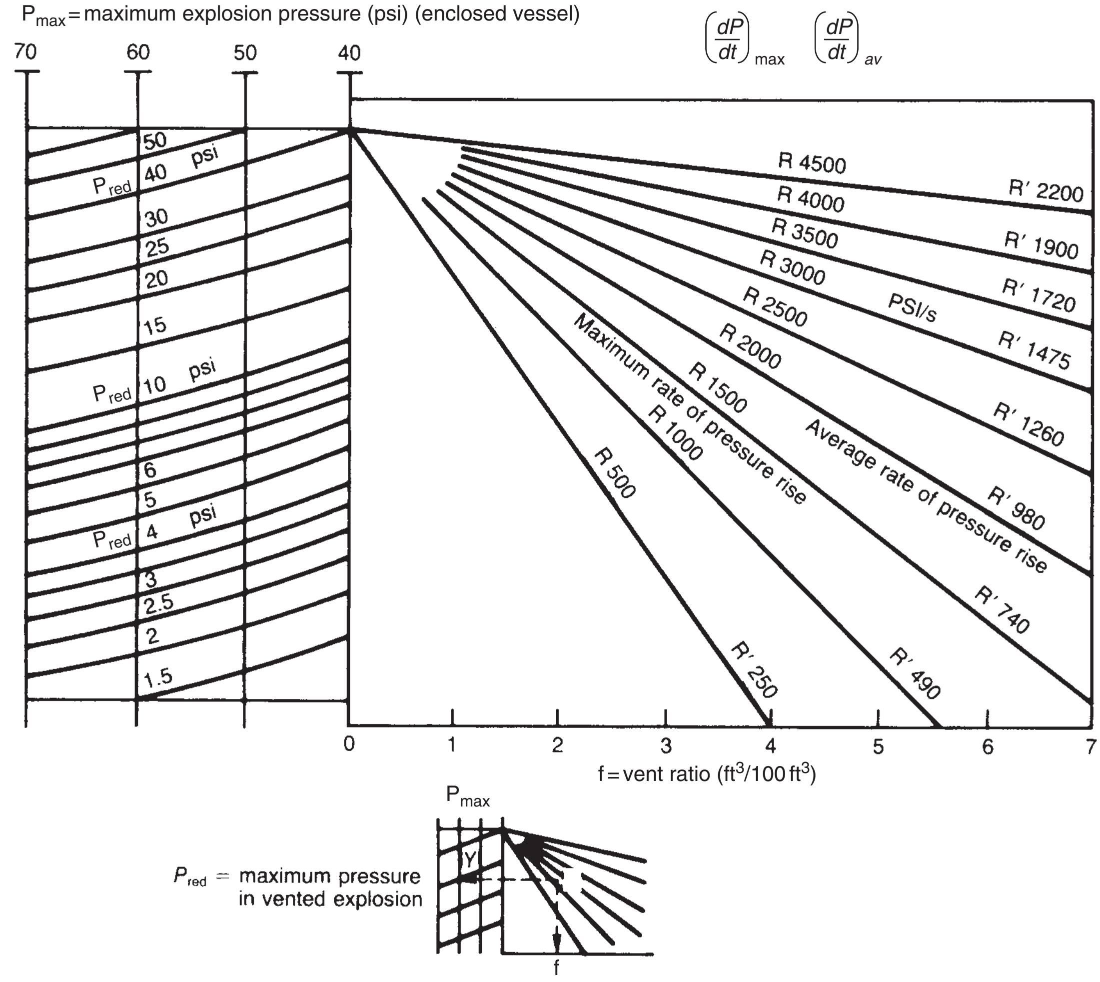

Figure 17.123 Dust explosion venting: Schwab and Othmer nomograph for vent area (Lunn, 1984b; after Schwab and Othmer, 1964) (Courtesy of the Institution of Chemical Engineers)

Section 17.14. The code gives the following value of C for dusts:

Dust class	C (bar$^{1/2}$)
St 1	0.026
St 2	0.030
St 3	0.051

17.48.11 Critique of empirical methods

A review of experimental studies comparing the predictions of empirical methods with experimental results is given by Lunn.

Comparison of the empirical correlations for gas explosion venting of Cubbage and Simmonds, Rasbash, Decker, Dragosavic, Cubbage and Marshall and of Runes with the experimental work of Hartmann, Cooper and Jacobsen and of Donat gave generally poor agreement. The Schwab and Othmer method gave excellent agreement with the results of Hartmann, Cooper and Jacob.

The methods considered by Lunn are primarily the vent ratio, vent coefficient and K_{st} methods and the methods of Heinrich and Rust. He gives a set of graphs comparing the predictions given by these methods with the results of Donat for 1 and 30 m^3 spheres. One of these graphs is shown in Figure 17.124. The vent coefficient and vent ratio methods were assessed by scaling up the results on the smaller vessel to the larger vessel, so that predictions were available only for the 30 m^3 vessel. The vent ratio method consistently overestimated the explosion pressure. The vent coefficient method gave closer agreement, but tended to underestimate the explosion pressure. Predictions for the K_{st} method were made for both sizes of vessel. For the 1 m vessel the low ignition energy source nomographs gave good predictions for dusts in classes St 1–3. For the 30 m^3

vessel the low ignition energy source nomographs again gave reasonable agreement, but always tended to underestimate the explosion pressure, sometimes substantially.

Overall, Lunn recommends the use of the K_{st} method. It generally tends to overestimate the vent area and will normally give adequately sized vent areas. He points out, however, that the method can give underestimates, as shown by the work of Eckhoff on silos.

Lunn also states that if reliable Hartman bomb data are available, the Schwab and Othmer method yields good results.

17.48.12 Modelling of dust explosion venting

In principle methods developed in the modelling of gas explosion venting given in Section 17.12 may be used for dust explosion venting also, but in practice there are difficulties. These arise mainly because the models involve the use of the burning velocity and a turbulence factor which are difficult to specify for dust explosions. Therefore, models for dust explosion venting tend to be constructed so that they can incorporate experimentally measured parameters.

17.48.13 Heinrich method

One of the first methods to use this approach was that of Heinrich (1966, 1974). The method is discussed by Matsuda and Naito (1975), Lunn (1984b) and Nicol (1988).

Heinrich made the assumption that the condition for effective relief is

$$\left(\frac{\mathrm{d}P}{\mathrm{d}t}\right)_{P_{\mathrm{red},V}} = \left(\frac{\mathrm{d}P_{\mathrm{ex}}}{\mathrm{d}t}\right)_{P_{\mathrm{red},V}} \qquad [17.48.20]$$

where P is the absolute pressure, P_{ex} is the pressure due to the explosion, t is the time and the subscripts P_{red} and V refer to venting at reduced pressure and in volume V, respectively. The right-hand side of Equation 17.48.20 represents the rate of pressure increase due to the explosion, and the left-hand side represents the rate of pressure decrease due to venting. The terms are equal at $\mathrm{d}P/\mathrm{d}t = 0$ and $P = P_{red}$, where P_{red} is the absolute reduced pressure.

The rate of pressure rise in the actual vessel is related to that in a test vessel by use of the cube root law

$$\left(\frac{\mathrm{d}P_{\mathrm{ex}}}{\mathrm{d}t}\right)_{P_{\mathrm{red}},V} V^{1/3} = \left(\frac{\mathrm{d}P_{\mathrm{ex}}}{\mathrm{d}t}\right)_{P_{\mathrm{red}},V_{\mathrm{L}}} V_{\mathrm{L}}^{1/3} \qquad [17.48.21]$$

where V is the volume of the actual vessel, V_L is the volume of the test vessel and the subscript V_L refers to the test vessel volume.

The volume rate of generation of burned gas is

$$\frac{V}{P}\frac{\mathrm{d}P}{\mathrm{d}t} \qquad [17.48.22]$$

and the mass rate is

$$\frac{V_\rho}{P}\frac{\mathrm{d}P}{\mathrm{d}t} \qquad [17.48.23]$$

where ρ is the density of the burned mixture.

The mass velocity of vent outflow for the isothermal case is given by Equation 17.12.62. Then, equating the mass rate of generation of burned gas given by Equation 17.48.23 to the mass vent outflow obtained from Equation 17.12.62 and utilizing Equation 17.48.21 gives for the vent area

$$A_{\mathrm{v}} = \frac{V^{2/3}V_{\mathrm{L}}^{1/3}(\mathrm{d}P_{\mathrm{ex}}/\mathrm{d}t)_{P_{\mathrm{red}},V_{\mathrm{L}}}}{C_{\mathrm{d}}(2RT/M)^{1/2}P_{\mathrm{red}}^{1/2}(P_{\mathrm{red}} - P_{\mathrm{a}})^{1/2}} \qquad [17.48.24]$$

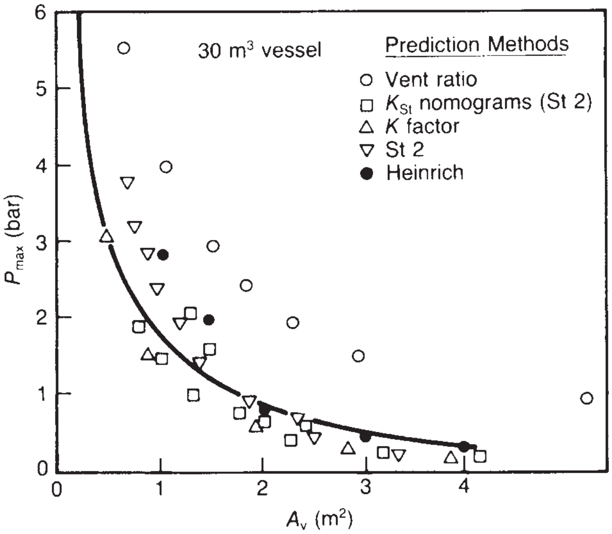

Figure 17.124 Dust explosion venting: comparison of selected methods of vent area prediction with experimental results of Donat (Lunn, 1984b). The curve is Donat's experimental results for organic pigment in a 30 m³ vessel (Courtesy of the Institution of Chemical Engineers)

where P_a is the atmospheric pressure. From this equation the pressures are evidently absolute pressures.

A corresponding equation may be derived for the adiabatic case using Equation 17.12.55.

The method requires the specification of a suitable value of $(\mathrm{d}P_{\mathrm{ex}}/\mathrm{d}t)_{P_{\mathrm{red}}}, V_{\mathrm{L}}$ for use in Equation 17.48.24. In general, this term is a function of the maximum rate of pressure rise:

$$\left(\frac{\mathrm{d}P_{\mathrm{ex}}}{\mathrm{d}t}\right)_{P_{\mathrm{red}},V_{\mathrm{L}}} = K_{\mathrm{f}}\left(\frac{\mathrm{d}P_{\mathrm{ex}}}{\mathrm{d}t}\right)_{\max,V_{\mathrm{L}}} \qquad [17.48.25]$$

where K_{f} is a constant. The values of K_{f} recommended for use in Equation 17.48.25 are given in Table 17.70.

The nomograph due to Heinrich for the estimation of vent areas is shown in Figure 17.125.

As stated earlier, the Bartknecht nomograph method draws on this work.

17.48.14 Palmer method

The method given by K.N. Palmer (1974c) takes as its starting point experimental measurements on the maximum closed explosion pressure and rate of pressure rise for the dust mixture. He considers two cases: a low pressure case where the venting pressure is close to atmospheric and a high pressure case.

For the low pressure case the venting pressure is close to atmospheric:

$$P/P_{\mathrm{o}} \approx 1 \qquad [17.48.26]$$

where P_{o} is atmospheric pressure. For this case Palmer uses Equation 17.12.63 for the mass velocity G_{v} of vent outflow. Then, utilizing relation 17.48.26

$$G_{\mathrm{v}} \approx C_{\mathrm{d}}[2P_{\mathrm{o}}\rho_{\mathrm{o}}\ln(P/P_{\mathrm{o}})]^{1/2} \qquad [17.48.27]$$

where C_{d} is the coefficient of discharge and ρ_{o} is the density of the gas at atmospheric pressure. From these equations the pressures are evidently absolute pressures. In the closed vessel at the point where the rate of production of burned gas is at a maximum, the rate of pressure rise is $(\mathrm{d}P/\mathrm{d}t)_{\max}$, the corresponding pressure is P_{c} and the rate of volume production is

$$\frac{V}{P_{\mathrm{c}}}\left(\frac{\mathrm{d}P}{\mathrm{d}t}\right)_{\max} = \frac{\mathrm{d}V}{\mathrm{d}t} \qquad [17.48.28]$$

Table 17.70 *Dust explosion venting: the Heinrich K parameter*

Vent opening pressure (bar)	*Maximum rate of pressure rise in closed vessel,* $(\mathrm{d}P_{\mathrm{ex}}/\mathrm{d}t)_{\max}, V_{\mathrm{L}}$ (bar/s)	K_{f}
1.15	1000	0.5
	2000	1.0
1.6–1.8	1000	0.5
	1000–2000	0.67
	2000	1.0

He takes account of the fact that with venting, combustion conditions approximate to constant pressure rather than constant volume. By introducing the ratio of specific heats γ, then writing

$$\rho = \rho_{\mathrm{o}}P/P_{\mathrm{o}} \qquad [17.48.29]$$

the maximum mass rate of production is

$$\frac{PV\rho_{\mathrm{o}}}{P_{\mathrm{o}}\gamma P_{\mathrm{c}}}\left(\frac{\mathrm{d}P}{\mathrm{d}t}\right)_{\max} = \frac{\mathrm{d}m}{\mathrm{d}t} = \frac{s\,\mathrm{d}V}{\mathrm{d}t} \qquad [17.48.30]$$

Then, equating this rate of mass rate of production with the mass vent outflow given in Equation 17.48.27 and utilizing the relation

$$\rho = \rho_{\mathrm{c}}P_{\mathrm{a}}/P_{\mathrm{c}} \qquad [17.48.31]$$

and the empirical relation

$$P_{\mathrm{c}} = 0.6P_{\max} \qquad [17.48.32]$$

gives

$$P - P_{\mathrm{o}} = \frac{2.3P_{\mathrm{o}}\rho_{\mathrm{c}}}{C_{\mathrm{d}}^2\gamma^2P_{\max}^3}\left(\frac{V}{A_{\mathrm{v}}}\right)^2\left(\frac{\mathrm{d}P}{\mathrm{d}t}\right)_{\max}^2 \qquad [17.48.33]$$

where A_{v} is the vent area and the subscript c refers to the point at which the maximum rate of pressure rise occurs. Palmer defines the density ρ_{o} as the density of the unburned gas at P_{o} and as that of the combustion products ρ_{c} at P_{c}. Equation 17.48.33 is the equation for the low pressure case.

For the high pressure case the mass velocity of venting is given by Equation 17.12.55. Then, utilizing relation 17.48.26 and rearranging,

$$G_{\mathrm{v}} = C_{\mathrm{d}}\left[\frac{\rho_{\mathrm{o}}\gamma}{P_{\mathrm{o}}}\left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/(\gamma-1)}\right]^{1/2}P \qquad [17.48.34]$$

$$= KP \qquad [17.48.35]$$

with

$$K = C_{\mathrm{d}}\left[\frac{\rho_{\mathrm{o}}\gamma}{P_{\mathrm{o}}}\left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/(\gamma-1)}\right]^{1/2} \qquad [17.48.36]$$

Also for this case the author takes the mean mass flux of venting as

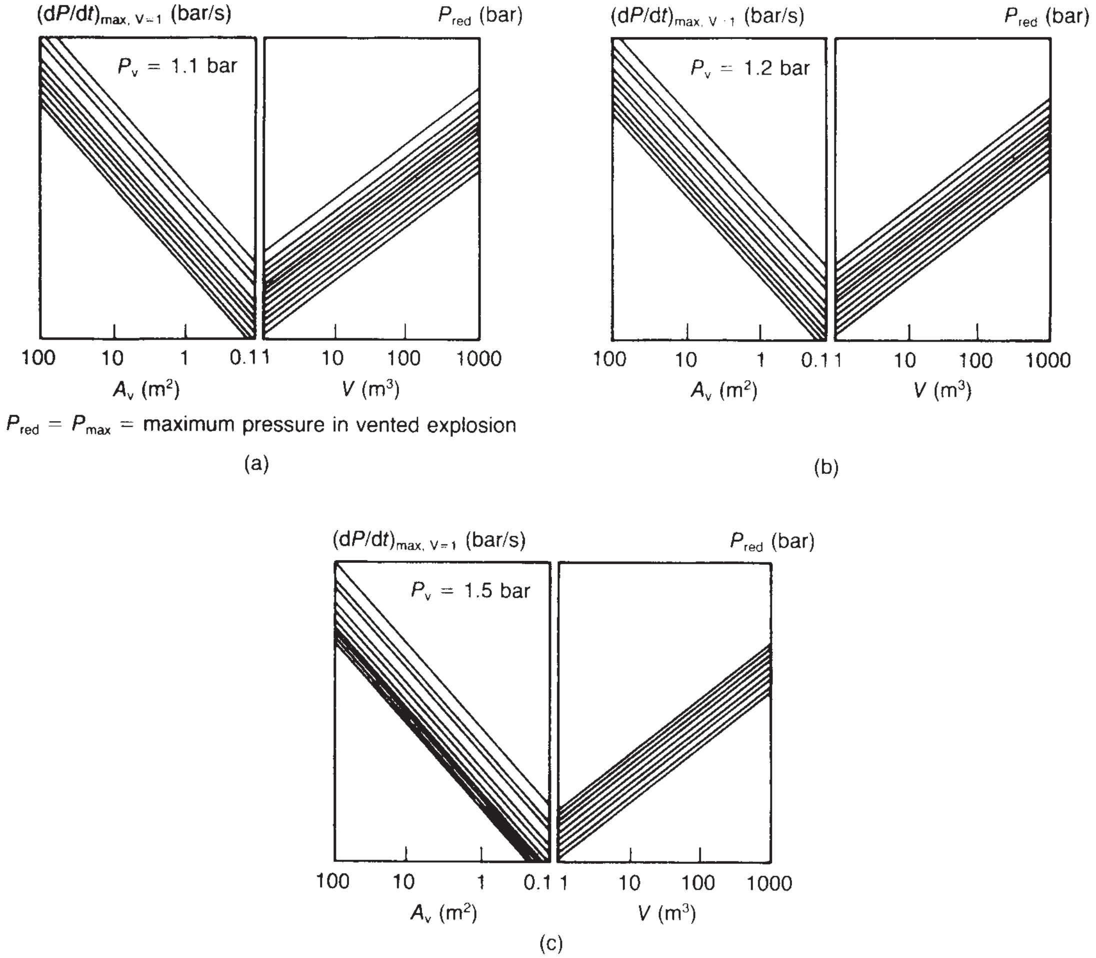
$$G_{\mathrm{v,av}} = \frac{K}{2}(P - P_{\mathrm{o}}) \qquad [17.48.37]$$

The duration of the explosion in the closed vessel, from ignition to maximum pressure, is

$$\frac{P_{\max} - P_{\mathrm{o}}}{(\mathrm{d}P/\mathrm{d}t)_{\mathrm{av}}} \qquad [17.48.38]$$

where $P_{\max}$ is the maximum unvented explosion pressure and the subscript av denotes average. Then, from Equations 17.48.37 and 17.48.38 the total mass vented is

$$\frac{KA_{\mathrm{v}}}{2}\frac{(P - P_{\mathrm{o}})(P_{\max} - P_{\mathrm{o}})}{(\mathrm{d}P/\mathrm{d}t)_{\mathrm{av}}} \qquad [17.48.39]$$



$P_{red} = P_{max}$ = maximum pressure in vented explosion

Figure 17.125 *Dust explosion venting: Heinrich nomographs for vent area (Lunn, 1984b; after Heinrich, 1974) (Courtesy of the Institution of Chemical Engineers)*

The total mass originally present was $V\rho_c$. Hence, the fraction of the mass remaining is

$$1 - \frac{KA_v}{2}\frac{(P - P_o)(P_{max} - P_o)}{V\rho_c(dP/dt)_{av}} \qquad [17.48.40]$$

Utilizing the empirical relation

$$\left(\frac{dP}{dt}\right)_{av} = 0.4\left(\frac{dP}{dt}\right)_{max} \qquad [17.48.41]$$

Equation 17.48.40 gives for the fraction of mass remaining

$$1 - KA_v\frac{(P - P_o)(P_{max} - P_o)}{0.8V\rho_c(dP/dt)_{max}} \qquad [17.48.42a]$$

$$= \frac{P}{P_{max}} \qquad [17.48.42b]$$

At P_{max}

$$P \gg P_o \qquad [17.48.43]$$

So Equations 17.48.42 become

$$\frac{1}{P - P_o} = \frac{1}{P_{max} - P_o} + \frac{KA_vP_{max}}{0.8V\rho_c(dP/dt)_{max}} \qquad [17.48.44]$$

Equation 17.48.44 is the equation for the high pressure case.

17.48.15 Rust method

Another method described in Section 17.12 is that of Rust (1979). This method was in fact derived originally for the venting of dust explosions in low-strength plants. For a dust mixture initially at atmospheric pressure

$$P = \frac{K_Dt^3}{V} \qquad [17.48.45]$$

with

$$K_{\mathrm{D}} = \frac{4}{3}\pi u^3 P_{\max} \qquad [17.48.46]$$

where K_{D} is an explosion parameter, P is the absolute pressure, t is the time, u is the velocity of the flame front, V is the volume of the vessel and the subscript max denotes maximum. Then, as before, the vent area is

$$A_{\mathrm{v}} = \frac{kF(P_{\max}V)^{2/3}K_{\mathrm{D}}^{1/3}}{P_{\mathrm{red}}^{1/2}} \qquad [17.48.47]$$

where P_{red} is the reduced pressure (gauge) and k is a constant. The value of k is given in Section 17.12.

The parameter K_{D} may be determined from the pressure rise in tests. Thus, differentiating Equation 17.48.48 gives

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{3K_{\mathrm{D}}t^2}{V} \qquad [17.48.48]$$

17.48.16 Nagy and Verakis method

The model given by Nagy and Verakis (1983), described in Section 17.12, is applicable to dust explosions. Using the notation given in Section 17.12, for explosion venting of a cylinder with an open vent, with ignition at the closed end, with subsonic flow and with venting of burned gas

$$\frac{P_{\mathrm{red}}}{(P_{\mathrm{red}} - P_{\mathrm{o}})^{1/2}} = \frac{RT_{\mathrm{u}}k_{\mathrm{v1}}P_{\mathrm{o}}L(A_{\mathrm{v}}/V)}{T_{\mathrm{b}}^{1/2}\alpha S_{\mathrm{u}}(P_{\mathrm{m}} - P_{\mathrm{o}})} \qquad [17.48.49]$$

The left-hand side term in Equation 17.48.49 is termed the pressure coefficient. For dust explosions it may be measured directly.

For venting with an initially closed vent, Equation 17.48.49 becomes

$$\frac{P_{\mathrm{red}} + P_{\mathrm{v}}}{(P_{\mathrm{red}} - P_{\mathrm{o}})^{1/2}} = \frac{RT_{\mathrm{u}}k_{\mathrm{v1}}P_{\mathrm{o}}L(A_{\mathrm{v}}/V)}{T_{\mathrm{b}}^{1/2}\alpha S_{\mathrm{u}}(P_{\mathrm{m}} - P_{\mathrm{o}})} \qquad [17.48.50]$$

where ΔP_{v} is the vent overpressure at which the vent opens ($\mathrm{lb_f/in.^2}$).

17.48.17 Elongated vessels

There is relatively little information available on the dust explosion venting of elongated vessels. Most treatments are either for compact vessels or for pipes.

17.48.18 Critique of available methods

The methods available for the estimation of the vent area for a given reduced explosion pressure have been reviewed by Lunn (1984b). Of the empirical methods, his preferred methods are the K_{st} nomograph method and, where suitable data are available, the Schwab and Othmer method.

The theoretical methods all rely more or less heavily on experimental data. Lunn finds that the Heinrich method gives upper limits of the reduced pressure for St 1 and 2 dusts, but should not be used for St 3 dusts. The Palmer method gives good predictions for St 1 and 2 dusts, but tends to underestimate the reduced pressure for St 3 dusts in larger vessels. The Rust method is better for St 1 dusts than for St 2 and 3 dusts, and can be highly inaccurate in some cases. The Pittsburgh method requires information on the burning velocity and turbulence factor which are generally not available and is of limited application.

For silos Lunn states that the only available method is that given in VDI 3673, which tends to overestimate the vent area. He suggests that the Rust method may also be used for quiescent conditions.

In his later treatment, Lunn (1992) concentrates on the Bartknecht nomograph, the vent ratio and venting coefficient, or K factor, methods.

17.48.19 Venting of low-strength plants

The maximum safe pressure for many plants handling dusts is 15 kPa (2 $\mathrm{lb_f/in.^2}$), and this maximum pressure is used in some of the design methods. Dust-handling plants are often constructed, however, in thin metal sheet which is unable to withstand pressures of more than 7 kPa (1 $\mathrm{lb_f/in.^2}$), even if the large flat sections of plant are provided with additional stiffening.

There is some difference of practice between the United Kingdom and the United states on the one hand and continental Europe on the other. Plant in the latter tends to be designed to a somewhat higher pressure rating.

Several authors have addressed the problem of dust explosion venting for low-strength plant. The method given by Rust (1979) is explicitly intended for this application. The worked example given by Rust is for a filter with a maximum allowable pressure of 23.9 kPa (3.47 psi).

The lowest reduced pressure for which the Bartknecht nomographs apply is 0.2 barg, but, as already described, Lunn, Brookes and Nicol (1988) have extended the nomograph method down to reduced pressures of 0.05 barg, or even less.

17.48.20 Venting phenomena

If the vent is an open one, venting will result in the emergence of a flame. With a dust the flame tends to be considerably larger than with a gas. This is illustrated by the series of photographs given by Bartknecht (1981a) for gas and dust explosion venting.

If the vent has a duct, there is the potential of unburned dust to undergo combustion, possibly resulting in overpressure in the duct.

17.48.21 Vent design and details

In general terms, the design of vents for dust explosion venting and the details of the vents are similar to those used for gas explosion venting. Details are given in NFPA 68: 2002.

17.48.22 Vent ducting effects and design

As described in Section 17.12, the vent duct can have a marked effect on the maximum pressure in a vented explosion.

Figure 17.126 given by Bartknecht (1981a) shows the effect of dust class, dust concentration and duct length on the reduced pressure in a 2 $\mathrm{m^3}$ vessel with a vent area of 0.13 $\mathrm{m^3}$.

The general recommendations given by Bartknecht for vent ducts apply to gases and dusts. The vent duct should be straight, as short as practicable and preferably cylindrical. It should have the same pressure rating as the vessel. Since detonations may develop in pipes of 10–30 m in length, the vent duct should be limited to 10 m. Reaction forces should be allowed for.

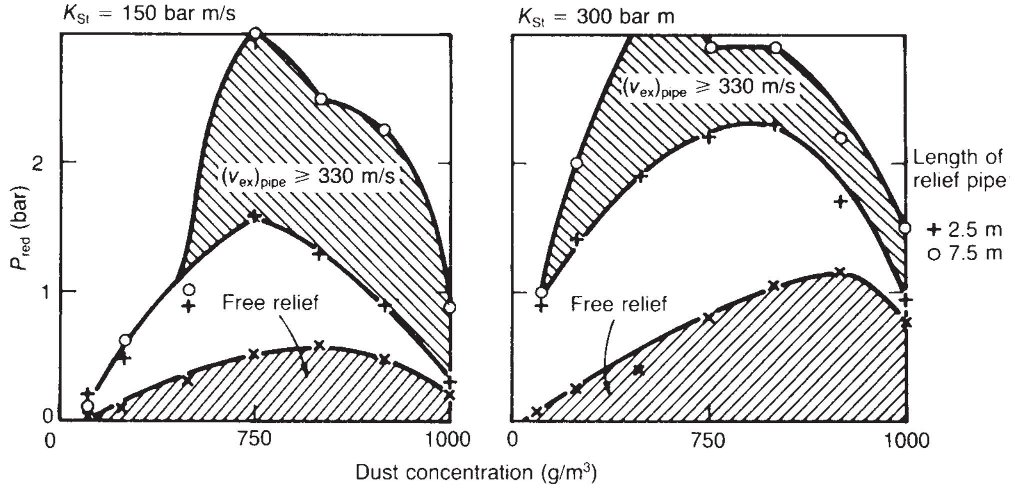


Figure 17.126 *Dust explosion venting: effect of dust explosibility and concentration and of length of duct on reduced pressure (Bartknecht, 1981a). Vessel volume 2 m^3, vent area 0.13 m^2 (Courtesy of Springer-Verlag)*

A graph to determine the maximum allowable length of smooth, straight pipe or vessel which is closed at one end and vented at the other which is applicable to propane and to dusts is given in NFPA 69: 1994 and has been given as Figure 17.36. If the *L*/*D* ratio is greater than that shown, there is a risk of detonation. There are separate curves for dusts with $K_{st} \leq 200$ and $K_{st} > 200$ bar m/s.

There are available several correlations to assist in allowing for the effect of the vent duct. Figure 17.127 given by Bartknecht (1981a) gives the relationship between the reduced pressure with the duct and that without the duct. There are two lines, the parameter being the duct length. Figure 17.128 gives a further correlation for the same relationship, but in this case the parameter is the gas velocity. Both correlations were given in NFPA 68: 1988, but only the first is retained in NFPA 68: 1994.

The correction given in the NFPA 69: 2002 edition for ducts of lengths 2–6 m (10–20 ft) is:

$$P'_{\mathrm{red}} = 0.172(P_{\mathrm{red}})^{1.936}$$

where P'_{red} is the reduced pressure resulting with a vent duct (bar or psi).

Figure 17.129, also given in NFPA 68: 1994, shows the maximum explosion pressure developed in deflagration of dust in a smooth, straight pipe open at one end with an initial flow velocity of less than 2 m/s.

17.48.23 Safe discharge

Explosion venting gives rise to three effects: a pressure wave and discharges of flame and unburned material. It is essential that all three effects be handled safely.

The discharge of unburned dust can be particularly strong and can result in a large flame. With dusts the problem of the toxicity of the vented material can be particularly severe.

17.48.24 Dust explosion venting of ducts and pipes

The gas explosion venting of ducts and pipes was considered in Section 17.13. There is relatively little guidance available on dust explosion venting of ducts and pipes.

Early work by K.C. Brown (1951) on elevator casings showed a general similarity between gas explosions and dust explosions and the value of vents near the point of ignition.

In his discussion of explosion venting of pipes, Bartknecht (1981a) states explicitly that the course of gas and dust explosions in pipes is similar and that his recommendations for explosion venting apply to all combustible materials.

Lunn (1984b) recommends that in the absence of specific information for dusts the guidelines for gas explosion venting be used.

Dust-carrying pipelines will generally require multiple vents. NFPA 68: 1988, 1994 and 2002 gives guidance on the spacing of vents. This is shown in Figures 17.38 and 17.39, which apply to propane and dusts.

The treatment given in the IChemE *Dust Explosion Venting Guide* is based on these graphs.

17.48.25 Dust explosion venting of buildings

The strength of buildings is discussed in Section 17.8. A pressure of 7 kPa (1 psi) is often quoted as sufficient to destroy a typical brick building.

Methods for the explosion venting of buildings are discussed in Section 17.14. The two principal methods for the gas explosion venting of buildings are those of Rasbash and of Runes. The Runes method is that most often mentioned for the dust explosion venting of buildings and is that given for that purpose in NFPA 68: 1978. The use of the Runes equation for the explosion venting of buildings was described in Section 17.14 and the values of the Runes constant *C* for dusts were given in Section 17.48.10.

17.49 Dust-handling Plants

Operations in which dusts are generated or handled include

(1) size reduction;
(2) conveying
    (a) manual,
    (b) mechanical,

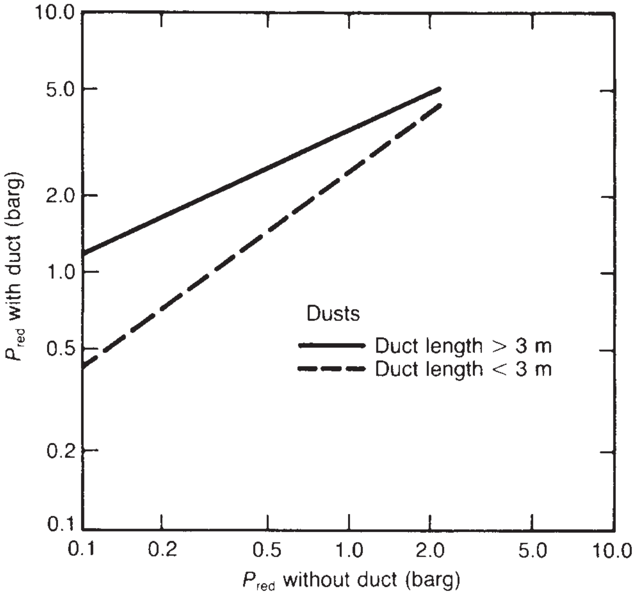

Figure 17.127 *Dust explosion venting: effect of length of vent duct on reduced pressure (NFPA 68: 1994). See text for details and note to Figure 17.25 (reprinted with permission from NFPA 68 Deflagration Venting, © 1994, National Fire Protection Association, Quincy, MA 02269)*

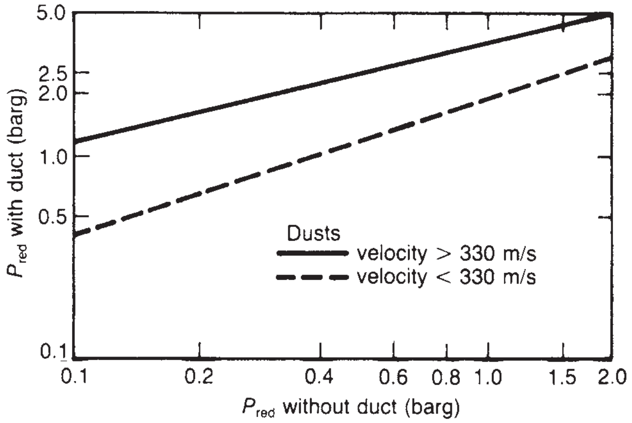

Figure 17.128 *Dust explosion venting: effect of velocity in vent duct on reduced pressure (NFPA 68: 1988). See text for details and note to Figure 17.25 (reprinted with permission from NFPA 68 Deflagration Venting, © 1988, National Fire Protection Association, Quincy, MA 02269)*

  (c) pneumatic;
(3) separation
  (a) settling chambers,
  (b) cyclones,
  (c) filters,
  (d) scrubbers,
  (e) electrostatic precipitators;
(4) driers
  (a) tray driers,
  (b) rotary driers,
  (c) fluidized bed driers,
  (d) pneumatic driers,
  (e) spray driers;
(5) screening and classifying;
(6) mixing and blending;
(7) storage;
(8) packing;
(9) fired heaters.

In many cases, there is a choice of different methods of carrying out a particular operation. The hazard of a dust explosion should be a factor in selecting a suitable method.

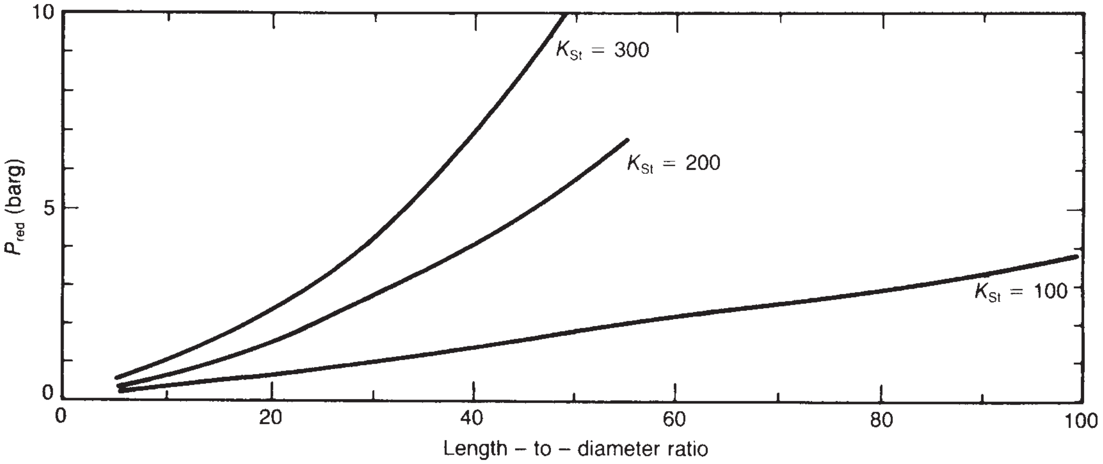

***Figure 17.129** Dust explosion venting: reduced explosion pressure in deflagration of dust/air mixture in a smooth, straight pipe or duct closed at one end (NPFA 68: 1994). See text for details and note to Figure 17.25 (reprinted with permission from NFPA 68 Deflagration Venting, © 1994, National Fire Protection Association, Quincy, MA 02269)*

All plants handling flammable dusts should have a combination of sufficient strength and explosion protection to withstand a dust explosion safely.

Some other basic principles in the design and operation of dust-handling plants are (1) minimization of space filled by dust suspensions, (2) maintenance of design operating conditions, (3) minimization of mechanical failure and overheating, (4) precautions against static electricity and (5) precautions against passage of burning dust.

Some particular types of dust-handling plants, namely, grinding mills, conveyors, dust separators, driers and storages, are considered below.

Operations involving screening and classifying or mixing and blending tend to create dust suspensions. Plants for such operations should be enclosed and preferably run under a slight vacuum. Precautions should be taken against static electricity and explosion protection should be provided.

Where dusts such as pulverized coal are used as fuels for fired heaters or furnaces, an explosive dust suspension is burned under controlled conditions. As with other fuels the principal hazard is loss of ignition followed by reignition and explosion.

Accounts of the safe design of dust-handling plants are given by K.N. Palmer (1973a), Bartknecht (1981a) and Field (1982).

17.49.1 Grinding mills

There is a large variety of size reduction equipment from jaw crushers to micronizers. In equipment which produces powders or dusts by size reduction, there is inevitably a real possibility of a dust explosion. The dust concentrations in a mill may be in the explosive range and the grinding elements in the mill, or possibly foreign bodies, may act as sources of ignition.

There are various steps which can be taken to minimize the dust explosion hazard in a mill. The free volume should be kept low so as to avoid a large volume of dust of explosible concentration. Large free volumes can occur if the mill is oversized or the feed to the mill is too low.

Overloading of or blockage in the mill can cause it to run hot and give ignition. The motor should be protected with an overload trip.

In general, mills are relatively robust. Even the larger mills with a volume of some tens of cubic metres can be designed to withstand pressures up to 350 kPa (50 $lb_f/in.^2$). However, explosion relief should be provided if necessary.

Bartknecht (1981a) gives three designs for complete grinding mill systems, with inerting, explosion suppression and explosion venting.

17.49.2 Conveyors

Dust may be conveyed by manual methods or by mechanical or pneumatic conveyors.

Applications of manual dust handling are restricted largely to operations such as bagging up of dust products or removal of unwanted dusts in limited quantities. There should be good local ventilation at places where dust may be generated such as bagging points and there should be a high standard of housekeeping on the plant.

Methods of mechanical conveying include screw and drag-link conveyors, belt conveyors and bucket elevators. A screw conveyor has minimal free volume and is an effective conveyor for dusts. So also is a drag-link conveyor, although the return leg contains free space which usually requires explosion protection. A belt conveyor is suitable for dusts only if enclosed. The free volume within the enclosure is likely to be larger than for a drag-link conveyor and the hazard correspondingly greater. If a belt conveyor is used, the enclosure should have explosion protection.

All mechanical conveying methods involve the risk of overheating due to mechanical failure, and appropriate steps should be taken in design and operation to minimize this hazard. In addition, belt conveyors are particularly liable to generate static electricity, and suitable safeguards should be provided.

17.49.3 Bucket elevators

The use of a bucket elevator to convey dust involves severe hazards unless there are suitable safeguards. There have been a number of explosions in bucket elevators and, as already mentioned, one of the few pieces of work on dust explosions in ducting is the work of K.C. Brown (1951) on elevator casings. Precautions for bucket elevators are discussed by K.N. Palmer (1973a) and Field (1982).

A bucket elevator tends to have a dust suspension virtually continuously, particularly at the boot and the head. The ignition source for an explosion is commonly a slipping belt or impact of the buckets on the casing.

Features of design to minimize the hazard include the provision of separate delivery and return legs, making the casing dust tight and able to contain fire, provision of isolation chokes at both ends and location of the elevator outside the building.

Explosion suppression may often be a suitable option, particularly if the elevator is inside a building. For explosion venting, Field recommends a vent ratio of $\frac{1}{6}$ m^2/m^3 with vents at the boot and head and, if the elevator is longer than 6 m, vents at intervals along it.

17.49.4 Pneumatic conveying

There are two basic systems for pneumatic conveying described by K.N. Palmer (1973a). These are (1) low volume/high pressure air and (2) high volume/low pressure air. The high pressure system uses relatively strong piping. It may be possible, therefore, to design it to withstand a dust explosion. There may be a risk, however, of erosion and consequent thinning of the pipe wall. The low pressure system utilizes weaker pipework and usually requires additional explosion protection such as vents.

Field (1982) states that in most pneumatic conveying systems the dust concentration is normally operated well above the upper explosive limit, though this may not apply at start-up and shut-down, and that the pipework is of a sufficient rating to withstand the full explosion pressure. The application of explosion protection is therefore mainly to the plant connected to the conveying system.

Precautions against ignition by static electricity or burning dust are particularly important in pneumatic conveying systems.

Further aspects of dust explosion hazards in pneumatic conveying systems are described by Palmer and Field.

17.49.5 Dust separators

In selecting a method of separation of a dust from a gas an important factor as far as dust explosions are concerned is the free volume. A settling chamber tends to involve a rather large free volume and usually is not a very desirable method.

Two of the main types of dust separator are dust filters and cyclones, which are considered below.

For both types of separator, precautions against ignition by static electricity or burning dust are especially important.

An alternative type of separator, in which the dust explosion hazard is much reduced, is the wet scrubber. Thus,in the United kingdom the use of wet scrubbers has been a statutory requirement in the grinding of magnesium. Wet scrubbers are used mainly to remove unwanted materials.

High efficiency cleaning of gases is often effected by an electrostatic precipitator. Although the inlet concentration of dust is normally below the explosive limit, mechanical rapping of the electrodes can create an explosive dust concentration. Electrostatic precipitators are not generally very suitable for removal of flammable dusts.

17.49.6 Dust filters

A widely used separation device is the bag filter. Such filters may be fitted after a cyclone or on their own. An explosive concentration of dust is liable to arise in bag filters which are cleaned by mechanical shaking and occurs during the cleaning operation. Again the ignition source may be dust ignited elsewhere.

Precautions for dust filters are discussed by K.N. Palmer (1973a), Bartknecht (1981a) and Field (1982).

Explosion suppression is an option which may have merit for a dust filter. For explosion venting, Field indicates that the volume on which the venting is based should be the free volume, or total volume less the volume of the filter bag assembly. Where the filter is lightly constructed, he states that the vent ratio method is suitable for smaller volumes ($<30\ m^3$), but that the vent coefficient method is preferable for larger volumes, whilst where the filter is able to withstand a reduced explosion pressure of 0.2 barg, the regular K_{st} nomograph method is suitable. He also says that there is evidence that the nomograph method may overestimate the vent area, absorption of heat by the filter bags being a possible factor in this. The location of the vent is important in the case of dust filters. For the filter configuration which he considers, vents on the top tend to be less effective probably due to the obstacle-induced turbulence as flame propagates through the filter assembly. His recommendation is for vents located near the bottom of the rear side.

Bartknecht gives an account with detailed design of several filters.

17.49.7 Cyclones

Another common means of separation is the cyclone. Explosions in plant handling dusts occur not infrequently at a cyclone. Often the source of ignition is not at the cyclone itself but dust ignited elsewhere in the plant.

Precautions for dust cyclones are discussed by K.N. Palmer (1973a), Bartknecht (1981a) and Field (1982).

In a cyclone there is a concentration gradient of dust with a very low concentration at the wall. At some intermediate point the dust concentration is in the explosive range. This unique pattern of dust concentration could mean that the usual correlations for dust explosion venting may be less applicable. On the other hand, the explosion pressure in a cyclone may well rise due to ignition elsewhere in the plant and in this case the normal dust pattern in the cyclone may be disturbed.

For cyclones with the product offtake connected to other plant as in a spray drier system, Bartknecht recommends an isolation choke on product offtake.

Explosion suppression is an option which can be considered for cyclones. For explosion venting, Field refers to work by K.N. Palmer (1974b) and Tonkin and Berlemont (1972 FRS Fire Res. Note 942) showing that the vent ratio method tends to overestimate the vent area. Cyclones are often of too light a construction for the regular K_{st} nomograph method to be applicable. The vent is most effective if located on the top of the cyclone.

17.49.8 Driers

There are a large number of different types of drier, but there are certain common hazards. These types include

(1) tray driers, (2) rotary driers, (3) fluidized bed driers,(4) pneumatic driers, and (5) spray driers.

Precautions for driers are discussed by K.N. Palmer (1973a), Bartknecht (1981a) and Field (1982). The IChemE *Drier Guide* also gives detailed guidance.

In many driers, the liquid driven off is itself a flammable vapour and constitutes an explosion hazard. The main method of prevention is to use ventilation to keep the vapour concentration well below its lower flammability limit.

Direct firing of driers creates a strong ignition source and for this reason indirect heating is often used instead.

Other hazards in driers arise if the plant is not operated according to design conditions. Thus, if the feed rate is low, the material may become overheated and may ignite. Overheating may also occur if material from a previous batch is exposed to hot air on start-up. Similar hazardous conditions can arise in shut-down or emergency situations. The control of drier operating conditions is therefore particularly important.

The hot product from a drier is another hazard. It may be necessary to cool it before storage if self-heating is to be avoided.

17.49.9 Fluidized bed driers

Fluidized bed driers may be batch or continuous. According to Bartknecht, incidents in such driers have mainly been with hybrid dust–gas mixtures.

The explosion suppression option is more difficult to apply to fluidized bed driers, because it is hampered by the high air velocities. Nevertheless, Bartknecht gives an account of its application.

For explosion venting, Field states that any of the three main methods, vent ratio, vent coefficient or regular K_{st} nomograph, may be used. He gives details of the optimum vent location.

Bartknecht gives an account with detailed design of several fluidized bed driers, including explosion suppression and explosion venting. Figure 17.130 shows one of his graphs for explosion venting, illustrating the effect of locating the explosion relief on the clean side of the dust filters.

17.49.10 Spray driers

In spray driers the dust concentration is usually calculated to be below the lower explosive limit, but air currents may create higher concentrations. Deposits of dried product may build up and may undergo thermal degradation or become contaminated with oil so that the ignition temperature is lowered. Ignition may occur if the air inlet temperature is too high or if part of the high speed atomizer breaks off and causes an incendive spark.

Precautions for spray driers are discussed by Bartknecht (1981a) and Field (1982).

These precautions include ensuring that the air inlet temperature is below the decomposition temperature of the product and that the product does not form layers which may undergo thermal degradation.

The atomizer should be regularly serviced. Other precautions against its acting as an ignition source are to monitor its vibration and the bearing temperature as well as the power consumption of its motor.

Inerting, explosion suppression and explosion venting are all options which may be used with spray driers.

Field states that if flammable solvents are present, the only suitable option is inerting. Explosion suppression is a suitable option for smaller volumes but he does not recommend it for larger ones. For explosion venting, he states that any of the three main methods, vent ratio, vent coefficient

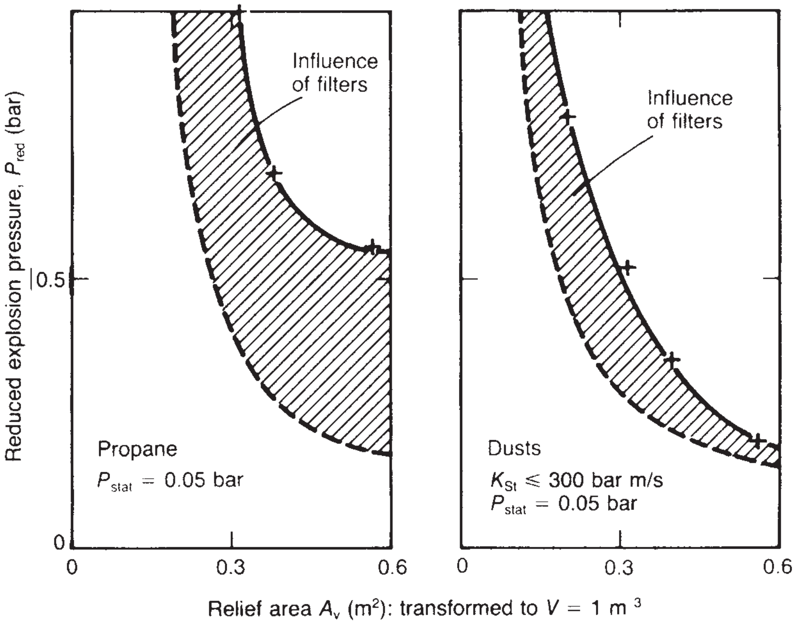

Figure 17.130 *Dust explosion venting: vent area requirement for a fluid bed driver (Bartknecht, 1981a) (Courtesy of Springer-Verlag)*

or regular K_{st} nomograph, may be used, although the vent ratio method overestimates the vent area for large volumes.

Bartknecht gives detailed designs for three complete spray drier systems, based on inerting, explosion suppression and explosion venting.

In the particular design which he considers for the second of these options, explosion suppression is used in the drier and the cyclones and an extinguishing barrier in the pipe between the drier and the cyclones. All three are activated independently, and activation of any one causes shutdown. He states that design of an explosion suppression system for a volume $>100\,m^3$ is a specialist matter.

In the design based on explosion venting, he considers first driers with $H/D < 5$. He states that for dusts a vent area may be used which is less than that given by the K_{st} nomograph method, since this tends to oversize the vent area for larger volumes. Moreover, the drier will never be full of an explosive dust suspension. For driers processing material with flammable solvents and thus containing hybrid dust–gas mixtures the nomograph for propane should be used, but the design is a specialist matter. For driers with $H/D > 5$ the vent area should be the whole roof.

For explosion venting, Bartknecht uses rapid action valves for isolation between the drier and the air heater and between the drier and the cyclones, and a rotary choke valve at the product offtake. Likewise, he gives isolation arrangements for the explosion suppression case.

He also emphasizes that in the event of an explosion there should be automatic shut-down and water sprinklers should be available to deal with the resultant dust fire.

17.49.11 Silos

As already described, a number of the principal dust explosions have occurred in silos. In a silo it is virtually inevitable that a dust suspension will exist in at least part of the space.

Precautions for silos are discussed by Bartknecht (1981a), Field (1982) and Eckhoff (1991).

A silo should be provided with feed arrangements which minimize the formation of dust suspensions. A silo may be filled by letting the dust fall from the roof or by introducing it down a vertical feeder duct so that it flows sideways onto the existing dust pile, the latter minimizing dust cloud formation.

The explosion suppression option is applicable to silos. Field states that it can be used effectively for volumes up to $60\,m^3$, but that beyond this careful consideration needs to be given to the dust explosibility and to the ability of the suppressant to fill the volume rapidly.

For explosion venting, Field states that the vent coefficient and regular K_{st} nomograph methods are applicable, but that the vent ratio method overestimates the vent area, and that none of the methods works well for H/D ratios greater than 3–5.

The explosion venting of silos has been considered in detail by Bartknecht. He treats it as an example of an elongated vessel and applies to it the principles which govern the venting of a pipe at one end. As with that case, the vent needs to be along the axis and to utilize the whole cross-sectional area of the end, which in this instance is the roof.

Bartknecht considers in particular the allowable height of the silo. This is essentially governed by two principles. One is that the cross-sectional area defines the maximum volume which can be vented and the other is that the maximum volume should be limited to $1000\,m^3$. Figures 17.131 and 17.132 illustrate the limits on the allowable height of a silo based on these principles.

17.49.12 Grain elevators

Other storages which have been the site of some of the main dust explosions are grain elevators. In consequence, there have been a number of studies of grain elevator explosions and of the precautions which should be taken.

In many incidents, poor standards of training, housekeeping and maintenance appear to have been major contributors.

The ignition sources identified in grain elevator explosions were given in Section 17.45.

Two of the principal components of grain elevators are the silos and the bucket elevator, both of which have just been discussed. Another main component is the horizontal conveyor, which conveys grain from the receiving point to the boot of the bucket elevator and from the offtakes of the silos to the loading point.

17.50 Dust Fires

It is convenient to deal at this point with dust fires. An account of dust fires is given by K.N. Palmer (1973a).

Dust fires occur in dust deposits and are of two types – laming and smouldering fires.

The type of fire that is produced by a particular dust is not predictable and can only be determined by experiment, but some general guidelines can be given. A flame can be sustained only if sufficient volatile matter is evolved from the dust. If the dust is able to smoulder, the volatiles may be produced by this smouldering, otherwise they must be generated by the flame itself.

Characteristics of the dust which particularly affect this combustion process are volatile content, melting point and particle size.

The flame may spread across the surface of the dust or may burn down from the surface into the dust layer. If the flame is able to release sufficient volatiles, it may travel quite rapidly across the surface. Otherwise, its propagation over the surface is determined by the smouldering rate. Smouldering combustion may continue into the dust layer with the flame burning on the surface.

If the particle size of the dust is sufficiently large, the flame may propagate through the dust layer. In this case combustion is likely to be rather rapid.

On the other hand, a large particle size tends to give a low smouldering rate. In the limit the particle size may be too great for smouldering to persist.

Another feature which favours rapid combustion is an air flow caused by ventilation or by convection currents, including those arising from the combustion process itself.

If a smouldering fire starts below the surface of the dust and works its way up, it may burst into flame and spread more rapidly when it reaches the surface.

Smouldering rates are commonly determined by measuring the rate of travel of smouldering combustion along a 'dust' train of stated dimensions. Typical smouldering rates for dusts are about 5 cm/h for wood and about 20 cm/h for coal with a bed depth of 1 cm. An extreme value is given by magnesium dust with a smouldering rate of 14 m/h.

There is a minimum depth of dust layer for sustained smouldering. Minimum depths typically range from approximately 2 mm upwards.

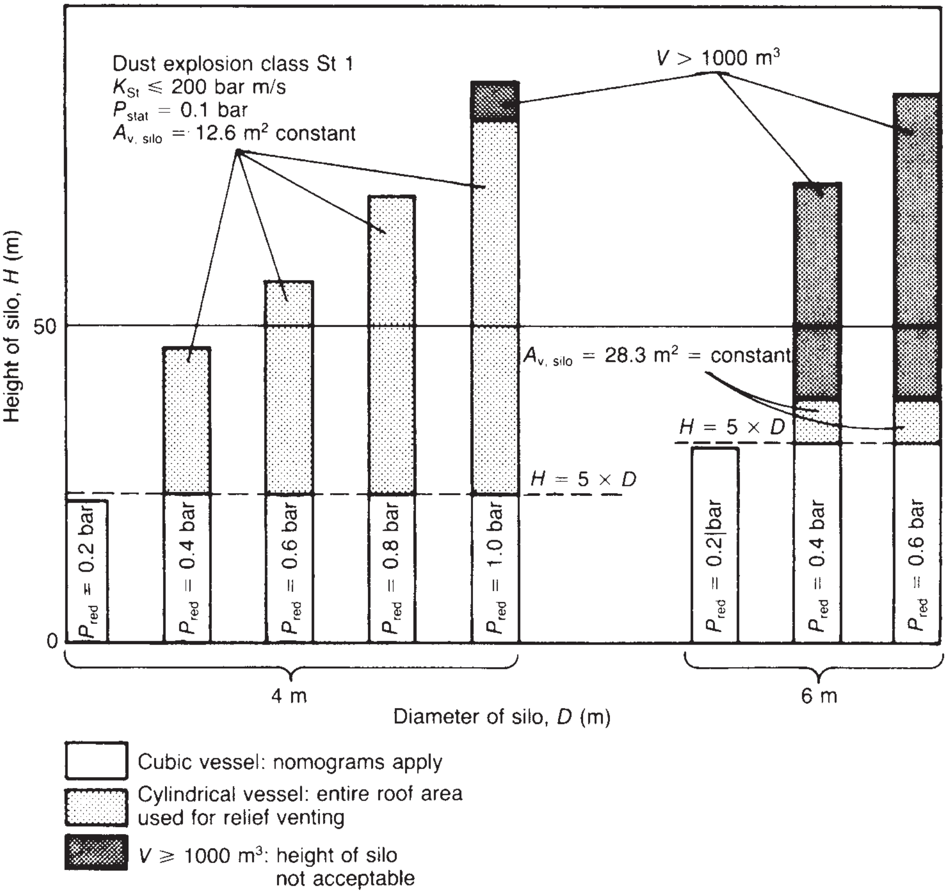

Figure 17.131 *Dust explosion venting: allowable height of a silo – 1 (Bartknecht, 1981a). The figure is based on the use of Bartknecht nomographs (Courtesy of Springer-Verlag)*

Detection of dust fires is difficult. There are no special types of detector for dust fires. The effects given by smouldering are usually weak and difficult to detect with the sensors normally used in automatic fire protection systems. It may be appropriate, however, to monitor the temperature in the interior of large dust piles with thermocouples.

A dust deposit can undergo smouldering for a long period. It is not unknown for large dust piles to smoulder for a matter of years. Both air access and heat loss are restricted so that combustion is very slow, but is sustained. Such smouldering may not give rise to readily detectable effects. In particular, there may be no smoke or smell from the burning.

This delay between ignition and outbreak of flaming can create hazards. Fire may break out unexpectedly in a factory shut-down overnight or at the weekend, or the cargo of a ship may be discovered to be on fire when it is being unloaded.

Hazards of dust fires include those of a dust explosion resulting from the formation and ignition of a dust suspension, of the ignition of other flammables and of the evolution of toxic combustion products.

In general, dust deposits around the factory should be minimized by good housekeeping. As already indicated, the dust layer does not need to be very thick to sustain smouldering.

Extinction of the dust fire may be effected by letting the fire burn itself out, by applying extinguishing agents or by starving the fire of oxygen.

Whichever approach is used, however, it is essential to avoid disturbing the dust in such a way as to allow a suspension to form and ignite.

Water is the usual extinguishing agent and is suitable unless it reacts with the dust or electrical equipment is involved. The water should not be applied, however, as a high pressure jet, which could raise a dust cloud, but as a low pressure spray which simply dampens the dust deposit. The penetration of this water into the dust layer can be assisted by the addition of about 2% of a wetting agent such as a detergent.

The use of fire fighting foam generally offers little advantage over water. Foam has the additional capability of cutting off air to the fire, but this is unlikely to have much effect in a slow smouldering combustion which requires very

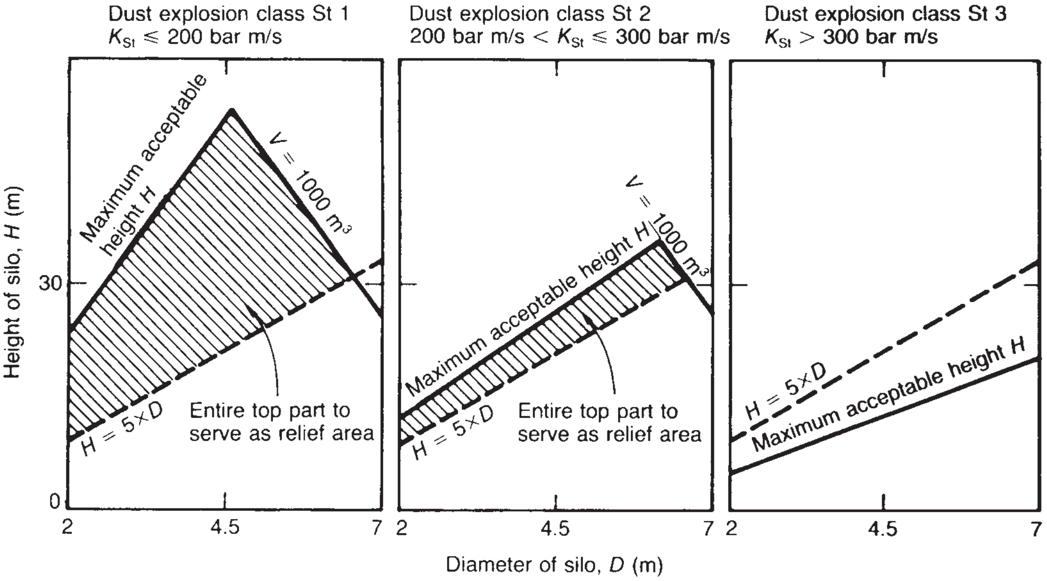

Figure 17.132 Dust explosion venting: allowable height of silo – 2 (Bartknecht, 1981a). The figure is based on the use of Bartknecht nomographs, P_{stat} = 0.1 bar; P_{red} = 0.4 bar (Courtesy of Springer-Verlag)

little air anyway. Since the foam is largely water, it should not be used in applications where water is unsuitable.

The other non-gaseous fire fighting agents are of limited application. Dry powder is appropriate if the dust is one which reacts with water, as do some metal dusts. Vaporizing liquids are appropriate if electrical equipment is involved, but should not be used on reactive metal dusts.

Inert gases may be used as extinguishing agents and can be effective if the dust is held in a relatively gas tight container such as a hopper or a ship's hold. It is necessary, however, not only to cut off the supply of oxygen, but also to effect sufficient cooling to prevent reignition when the air supply is restored. Thus, the inerting may need to be maintained for a long period.

In some situations, however, the fire cannot be extinguished sufficiently rapidly by fire extinguishing agents alone. A smouldering fire in a ship's hold, for example, could immobilize the whole ship. In such cases it may be necessary to dig the material out. This involves a number of hazards and suitable precautions should be taken against them. The operations should be conducted in such a way as not to raise a dust cloud. The atmosphere should be monitored and any necessary breathing equipment worn. The danger of subsidence of the dust due to the creation of burnt-out hollows beneath the surface should be allowed for.

In other instances a more gradual extinction of the fire is acceptable. This might be the case, for example, with a fire smouldering inside a tip. The methods used in such situations are generally based on excluding air and include covering the heap with a layer of non-combustible such as earth or pumping a limestone slurry into fissures in the heap. A hazard in the first method is subsidence due to hollows, and in the second, movement in the tip due to the slurry. Alternatively, but generally as a last resort, the heap may be dug out.

17.51 Explosion Hazard

The types of explosion typical of the process industries are those described above. The hazard of a large industrial explosion may be assessed by consideration of assumed scenarios using appropriate hazard and effects models or of the historical record of explosions and their effects.

17.51.1 Historical experience

A large proportion of the major accidents which have occurred in the process industries have involved explosions. In particular, explosions account for the preponderance of cases where there has been substantial loss of life.

A classification of process industries explosions has been given in Section 17.1. The main headings are (1) physical explosions, (2) condensed phase explosions, (3) VCEs, (4) BLEVEs, (5) confined explosions with reaction, (6) vapour escape into, and explosions in, buildings and (7) dust explosions. Some principal condensed phase explosions have been listed in Table 17.24, VCEs in Table 17.30, BLEVEs in Table 17.37 and dust explosion in Table 17.63. A fuller listing of all types of explosion with references is given in Table A1.2. The statistical features have been given in Chapter 2 and Section 17.1.

The process industries have suffered major explosions in virtually all the categories of the classification in Section 17.1. Considering these in turn, and starting with physical explosions, these may occur as (1) a mechanical failure, (2) overpressure, (3) underpressure, (4) overtemperature or (5) undertemperature of the system. The essential distinction is that in the first case the failure occurs whilst the process conditions are within the design envelope, so that the failure is due to a mechanical defect, and in the other cases it occurs because the process conditions have been taken outside the design envelope.

A failure of a pressure system due to mechanical defects occurred in 1984 at a refinery at Romeoville, Illinois, where a 55 ft high × 8 ft diameter absorption column suffered massive failure such that most of the 201 vessels rocketed about 3500 ft and struck and toppled a 138 kV power transmission tower (Case History A111).

Overpressure of a pressure system is exemplified by the explosion at Grangemouth in Britain in 1987 when gas 'breakthrough' caused the disintegration of a 30 ft high × 10 ft diameter low pressure separator (Case History A116). One 3 t missile from this explosion travelled 3300 ft.

Condensed phase explosions in the process industries include explosions of (1) high explosives, (2) ammonium nitrate, (3) organic peroxides, and (4) sodium chlorate. An account of condensed phase explosions has been given in Section 17.26.

With regard to high explosives, the explosion of the munitions ship Mont Blanc at Halifax, Nova Scotia, in 1917 destroyed a large part of the town and killed 1963 people (Case History A3). An explosion of TNT at a munitions factory in Silvertown, London, in 1917 caused 69 deaths (Case History A4).

Many of the large explosions in the early years of the chemical industry involved ammonium nitrate (AN). The AN explosion at Oppau, Germany, in 1921 destroyed hundreds of houses and killed 561 people (Case History A5).

The explosions at Texas City in 1947 occurred in two ships, the Grandcamp and the High Flyer, both of which were carrying AN (Case History A16). They damaged thousands of buildings, hurled missiles several miles and killed 552 people.

Major explosions involving organic peroxides occurred at Tonawanda, New York, in 1953 and at Los Angeles in 1974 (Case History A72).

Two warehouse fires in Britain, at Renfrew in 1977 and Salford in 1982, resulted in large sodium chlorate explosions (Case History A85).

In recent years, the most destructive explosions in the process industries have tended to be VCEs or BLEVEs.

Some of the principal VCEs have been described in Section 17.28. They include those at the Ludwigshafen works in 1953 and 1958, the refinery at Lake Charles in 1967, the refinery at Pernis in 1968, a pipeline at Port Hudson in 1970, a rail tank car at East St Louis in 1972, the works at Flixborough in 1974, the rail tank car at Decatur in 1974, a petrochemical plant at Beek in 1975 and a petrochemical plant at Pasadena in 1989. Flixborough and Pasadena are described in Appendices 2 and 6, respectively, and the other incidents in Appendix 1, as referenced in Section 17.28.

Some of the principal BLEVEs have been described in Section 17.29. Major incidents in which the BLEVE occurred due to release from the vessel involved or a similar, adjacent vessel include those at a storage in Montreal in 1957, the refinery at Feyzin in 1966, a rail tank car at Crescent City in 1970, a refinery in Rio de Janeiro in 1972 and a storage at Texas City in 1978. Those at Feyzin, Crescent City and Rio are described in Appendix 1, as referenced in Section 17.29.

In other instances, BLEVEs have occurred as a result of engulfment in a major vapour cloud fire. Incidents where this was the case include those at the storage in Port Newark in 1951 (Case History A19) and at Mexico City in 1984 (Appendix 4).

Turning to confined explosions with reaction, these include (1) explosions involving vapour combustion, (2) reactor explosions and (3) other explosions involving liquid phase reactions. In the first category is the detonation in a 127 ft high × 22.5 ft diameter reactor at Whiting 1955 (Case History A22). The vessel disintegrated, hurling one 60 te fragment onto a tank farm 1200 ft away and causing two deaths.

There have been a large number of reactor explosions, usually incurring a medium level of casualties and loss. One of the more serious occurred at Geismar in 1976, when a large polygylcol ether reactor exploded, throwing the reactor head 1400 ft (Case History A80).

Liquid phase reactions occurring in other equipment have also led to major incidents. One such occurred at Doe Run in 1962, when backflow of ammonia from a reactor into an ethylene oxide feed tank resulted in a severe explosion (Case History A31).

Incidents of vapour escapes into, and explosions in, buildings (VEEBs) are exemplified by those at St Paul in 1951 and Attleboro in 1964 (Case History A33). In the first an escape of LPG at a loading terminal caused an explosion which killed 14 people. In the second a massive leak of vinyl chloride from a reactor into the building resulted in an explosion which led to seven deaths.

The explosion on Piper Alpha, which occurred in a partially confined module, might also be regarded as falling in this category (Appendix 19).

Finally, there have also been a number of serious dust explosions inside (1) plant and (2) buildings. An explosion inside a grain silo at Westwego in 1977 resulted in 36 deaths (Case History A89).

Most, though not all, of the incidents just described are in the M&M Large Loss List. Details of casualties and loss are given in Table A1.2.

17.51.2 Mortality index for explosions

The relation between the size of an explosion and the number of people killed has been investigated by V.C. Marshall (1977b), who has developed a mortality index (deaths/t) for explosions.

Data on the relation between the size of the explosion and the number of fatalities, and on the mortality index, are plotted in Figure 17.133. The solid squares which do not have a specific reference are accidental explosions. The full line is the best fit for these accidental explosions.

Mortality data on the number of casualties by shell explosions are available from the First World War. According to one account, the belligerents used 2.23×10^6 t of high explosive in 1.39×10^9 shells and caused 10^7 casualties. The latter figure includes wounded as well as dead, and the deaths are estimated at 2.4×10^6. Thus, on average a shell contained 1.6 kg of explosive. Allowing for 10% dud shells, the fatalities per shell are approximately 0.0019, which gives a mortality index of 1.2.

The Second World War data for conventional bombing give mortality indices between 0.96 for Germany and 3.40 for Japan. This is no doubt influenced by factors such as population density, construction of houses and degree of shelter.

The mortality indices for the nuclear bombs at Hiroshima and Nagasaki are 2.05 and 1.0, respectively. The bombs were assumed to have a nominal yield each of 20, 000 t of TNT.

The mortality indices of the Halifax explosion in 1917 and the Oppau explosion in 1921 are 0.64 and 0.25, respectively.

For accidental explosions the data used are the data given by C.S. Robinson (1944) and some unpublished data

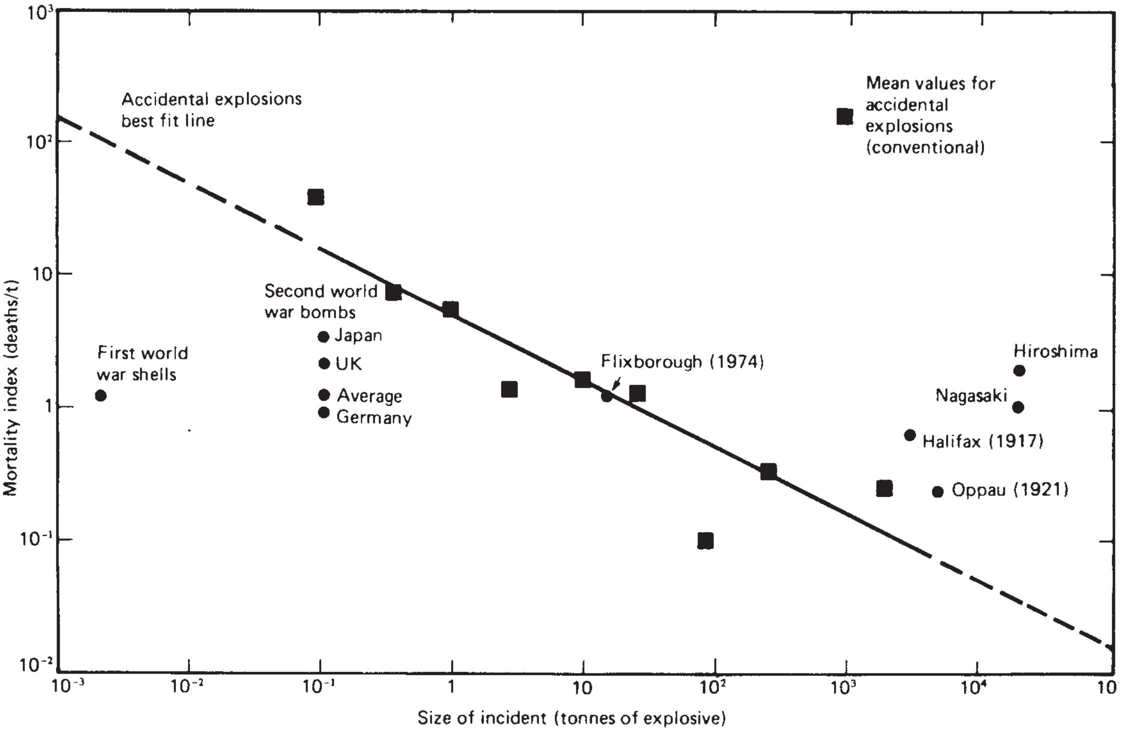

Figure 17.133 *Mortality index for explosions (after V.C. Marshall, 1977b) (Courtesy of the Institution of Chemical Engineers)*

by Healy (1965), and they have been grouped by Marshall in size intervals.

As Figure 17.133 shows, the mortality index decreases as the size of the explosion increases. The line has a slope of about −0.5. This differs somewhat from the slope suggested by theoretical considerations. From the blast scaling laws the radius r at which a given blast intensity occurs is related to the mass of explosive W by the relation

$$r \propto W^{1/3} \qquad [17.51.1]$$

The number of fatalities f is proportional to the area:

$$f \propto r^2 \propto W^{2/3} \qquad [17.51.2]$$

The mortality index MI is the ratio of the number of fatalities to the mass of explosive:

$$\mathrm{MI} \propto \frac{f}{W} \propto W^{-1/3} \qquad [17.51.3]$$

Marshall suggests that a possible explanation is that small explosions which do not kill people tend not to be well reported, which has the effect of exaggerating the mortality index for small explosions. VCEs are also considered by Marshall, as shown in Table 17.71. Since for such explosions the TNT equivalent is generally unknown, the mortality index in this case is based on the mass of vapour involved.

Other aspects of historical experience with explosions are discussed in Sections 17.28–17.30 and 17.31–17.34.

17.51.3 Hazard assessment

Hazard assessment of explosion on process plants tends to be rather more varied than that of fire. As stated in Section 17.1, explosions in the process industries include (1) physical explosions, (2) condensed phase explosions, (3) VCEs, (4) BLEVEs, (5) confined explosions with reaction, (6) vapour escape into, and explosions in, buildings, and (7) dust explosions. The extent to which these different types of explosion are represented in the hazard assessment literature varies.

In principle, a hazard assessment involves formulation of a scenario and a full assessment of the frequency and consequences of the event. An assessment which is confined either to the estimation of the frequency of the event or to the modelling of the consequences is a partial one. Hazard assessments may be generic or may relate to a specific situation.

The scenario which has received most attention is the release and ignition of a vapour cloud, which may result either in a vapour cloud fire or a VCE. Thus, the hazard assessment of VCEs involves the development of a set of scenarios for explosion, by release and ignition, and of the associated event trees; the estimation of the frequency/probability of the initial events and of the events in the branches of the event trees from a mixture of historical data and synthesis of values, often using fault trees, and the modelling of the outcome events in the event tree, including both physical events and damage/injury.

Up to the point of damage and injury, the assessment of a VCE involves essentially the same set of models as those

Table 17.71 *Some data on the relation between size of flammable release and number of fatalities (after V.C. Marshall, 1977b) (Courtesy of the Institution of Chemical Engineers)*

Date	*Location*	*Chemical*	*Material released*		*Nature of incidents*	*Fatalities*	*Mortality index* (deaths/t)

[a] Date quoted in the original paper have been corrected (F.P.L.).

used for the modelling of vapour cloud fires, as described in Chapter 16. If the event gives an overpressure, it is a VCE, otherwise it is a vapour cloud fire.

A hazard assessment of the kind just described constitutes a full hazard assessment. The types of explosion which are most fully represented are high explosives and ammonium nitrate explosions, VCEs and BLEVEs.

Overviews of generic process plant explosion scenarios have been given for LPG by Rasbash (1979/80) and Crocker and Napier (1988a) and for LNG by Napier and Roopchand (1986).

Some principal types of model used for hazard assessment of explosions on process plants are those for (1) condensed phase explosions, (2) explosions of vessels, (3) VCEs, (4) BLEVEs and (5) dust explosions.

An early, essentially generic, hazard assessment of explosion is that given in the vulnerability model by Eisenberg, Lynch and Breeding (1975), who studied the area affected by a flammable vapour cloud and the lethality of a VCE in such a cloud. The events of principal interest which they consider are marine spillage of 20,750, 83 and 0.8 te of LNG on water with drifting of the vapour cloud towards populated areas. Their treatment of these scenarios is described in Chapter 16. For explosion injury they utilize their own probit equations described in Section 17.38. The populations at risk are defined in terms of the cell model already described. Some results obtained have been given in Chapter 16.

The *First Canvey Report* (HSE, 1978b) included assessments of the hazard at the specific installations at Canvey from an explosion of ammonium nitrate; a VCE from the British Gas LNG storage and VCEs from several LPG storages.

These assessments were refined in the second report. An account of this work is given in Appendix 7.

The *Rijnmond Report* (Rijnmond Public Authority, 1982) gives specific hazard assessments for storages of acrylonitrile, propylene and LNG. It considers VCEs and BLEVEs. An account of this work is given in Appendix 8.

The *Transport Hazard Report* of the Advisory Committee on Dangerous Substances (ACDS) (1991) gives hazard assessments for the transport of hazardous substances in ports, by road and by rail which are applicable to transport nationwide, although based in some cases on generalization from a sample of specific situations. The hazards covered include explosion of high explosives and of ammonium nitrate and VCEs and BLEVEs from LPG and flammable liquids.

For physical explosions, hazard assessments have been mainly treatments of the frequency of explosion without modelling of the consequences. Studies of this type on specific plant have been described for overpressure of a storage tank by gas breakthrough by Kletz and Lawley (1982), overheating of a distillation column by Lawley and Kletz (1975) and undertemperature of a pipeline by Lawley (1980).

For condensed phase explosions, the hazard assessments of explosions of high explosives are represented by those in the ACDS study and of ammonium nitrate explosions by those in the Canvey Reports and the ACDS study. These are for specific situations, although in the ACDS study the results are then generalized.

For VCEs and BLEVEs, there are a number of hazard assessments which cover these events. They include a generic study of storage installations by Considine, Grint and Holden (1982) and studies of specific installations by Panthony and Smith (1982) and Ramsay, Sylvester-Evans and English (1982).

There are also generic assessments of the frequency of BLEVEs by Drysdale and David (1979/80), Blything and Reeves (1988 SRD R488) and Selway (1988 SRD R492).

For confined explosions with reaction, hazard assessment of explosions involving vapour combustion include the estimations of explosion frequency for an ethylene oxide reactor system by R.M. Stewart (1971) and for a hydrocarbon sweetening plant by Kletz (1972a) and of explosion involving liquid phase reactors by Roy, Rose and Parvin (1984).

Vapour escapes into, and explosions in, buildings and dust explosions are not well represented in the hazard assessment literature.

17.52 Hazard Range of Explosions

The estimation of the hazard range of an explosion depends on the type of explosion considered.

The two main types of explosion of interest here are condensed phase explosions such as those of TNT, together with explosions which can be characterized in terms of TNT equivalent, and VCEs.

17.52.1 Condensed phase explosions

The blast wave from a condensed phase explosion is characterized by the peak side-on overpressure and the impulse.

The variation of peak overpressure of a condensed phase explosion with distance is given by the scaling law and values of the overpressure may be obtained from graphs such as those given in Section 17.26. Thus

$$p^{\mathrm{o}} = f(z) \qquad [17.52.1]$$

with

$$z = \frac{r}{W^{1/3}} \qquad [17.52.2]$$

where p° is the peak overpressure, r is the distance, W is the mass of explosive and z is the scaled distance. Over a limited range the curve of p° vs z may be approximated by a straight line so that

$$\frac{(\rho^{\mathrm{o}})r}{p^{\mathrm{o}}} = \left(\frac{r_{\mathrm{r}}}{r}\right)^{n} \qquad [17.52.3]$$

where n is an index and subscript r is reference value. From the Baker curve for the overpressure range 1.0 – 0.1 bar the index n is approximately 1.7. A similar approach may be used for the determination of the impulse.

The effects of the explosion may then be determined from the overpressure and impulse utilizing the methods given in Sections 17.31 – 17.35.

For housing damage, the variation of the degree of damage, or damage category, with distance may be obtained from the revision by Gilbert, Lees and Scilly of the Jarrett equation; this revision is given by Equation 17.33.2b with revised values of the constant k.

The graph given by C.S. Robinson (1944) and reproduced as Figure 17.92 summarizes in convenient form the range of many of the principal damage effects.

17.52.2 Vapour cloud explosions

For a VCE, it is necessary to take into account the movement of the cloud, which is likely then to be the dominant factor.

The variation of cloud size with distance may be estimated from gas dispersion relations given in Chapter 15. An account is given there of the method of Considine and Grint (1985) which allows an estimate to be made of the size of the cloud for an LPG release.

Considine and Grint have also given for LPG methods for estimating the hazard range for fires and explosions. For a VCE they use the ACMH method based on the TNT equivalent. They give for the overpressure the relations

$$p^{\mathrm{o}} = 138\left(\frac{I^{1/3}}{r_{\mathrm{c}}}\right)^{1.558} \qquad r < r_{\mathrm{c}};\ \ 0.05 < p^{\mathrm{o}} < 1 \qquad [17.52.4a]$$

$$p^{\mathrm{o}} = 138\left(\frac{I^{1/3}}{r}\right)^{1.558} \qquad r > r_{\mathrm{c}};\ \ 0.05 < p^{\mathrm{o}} < 1 \qquad [17.52.4b]$$

where I is the mass of vapour in the cloud (te), p° is the peak overpressure (bar) and r_{c} is the radius of the cloud (m).

These authors quote from the *First Canvey Report* the estimates of 50 and 1% fatalities at overpressures of 0.36 and 0.18 bar, respectively. Within the cloud, 100% fatalities are assumed.

For a quasi-instantaneous release, the cloud range R and the cloud radius r_{c} vary with time. The mass m of vapour in the cloud may be taken as the total mass released. The cloud is flammable, however, only whilst its concentration is within the flammable range.

For a quasi-continuous release, the approach taken is to treat the plume as if it were fully established. In this case the cloud is non-circular and the following relation is given for the equivalent value of cloud radius r_{c}:

$$r_{\mathrm{c}} = \left(\frac{1.2k^{*}R_{\mathrm{LFL}}^{5/3}}{\pi}\right)^{1/2} \qquad [17.52.5]$$

where R_{LFL} is the distance to the LFL (m) and k^* is a constant defining crosswind range. This constant is described in Chapter 15.

The TNT equivalent method for a VCE is obsolescent. More modern methods, particularly the TNO and Baker Strenlow methods, are available, as described in Section 17.28, and may be preferred. However, the method of determining the cloud size may still be found useful.

In reality, for a VCE the peak overpressure is inversely proportional to the distance, and this is reflected in the more modern models. An illustration is the decay of the peak overpressure with distance shown in Figure 17.79(a).

17.53 Notation

Ma	Mach number
Re	Reynolds number
g	acceleration due to gravity
t	time
T	absolute temperature
γ	ratio of gas specific heats

Superscripts

$\dot{}$	time derivative
$\ddot{}$	second time derivative

Subscript

max	maximum

Note:
(a) Some of these variables have different local definitions, for example: t (thickness of glass), T (time constant, natural period),
(b) The symbol R generally denotes the universal gas constant but is also used for distance, range. It is therefore not defined globally for the chapter.

Section 17.2

Subsections 17.2.3–17.2.9

a	velocity of sound
$\bar{c}_v$	mean specific heat at constant volume
D	velocity of shock wave
d_c	critical tube diameter (mm for detonatation)
D_H	ratio of E_c^* for a fuel to that of acetylene
e	specific internal energy
E_c	critical (minimum) energy for initiating spherical detonation
E_c^*	minimum value of E_c
Δe	specific internal energy change
h	specific enthalpy
i	impulse
L_i	induction zone length
L_c	length of cell
Ma	Mach number
p	absolute pressure
p_{pl}	plateau pressure
p_v	pressure of constant volume combustion
q	energy addition per unit mass
S	width of cell
T	temperature
T_i	induction time
u	velocity
v	specific volume
V_1	velocity of gas entering shock wave
w	particle velocity
α	angle defined in Figure 17.1(d)
ξ	fractional completion of reaction
Δ	induction length for detonation
ρ	density

Subscripts

CJ	Chapman–Jouguet condition
s	shock wave
1	entering shock wave
2	leaving shock wave
Q_L, Q_U	fuel mole frequency to stoichiometric mole frequency at lower and upper limits for detonation

Subsection 17.2.10

a_o	velocity of sound in burned gas
d	diameter of tube
k_n	Bessel function derivative
p	pitch of spin
γ_o	ratio of specific heats of detonation products
λ	wavelength of spin

Subsections 17.2.11 and 17.2.12

a_o	velocity of sound in mixture
d_c	critical diameter for transmission of detonation
E_c	critical energy for initiation of spherical detonation
L_c	length of detonation cell
L_i	length of induction zone
n	constant
S	width of detonation cell
Δ	induction length
τ_i	induction time
ϕ	fuel–air ratio

Subscripts

1	lower limit
st	stoichiometric
u	upper limit

Subsection 17.2.13

c	velocity of sound
d_c	critical diameter for transmission of detonation
D_h	detonation hazard parameter
E_c	critical energy
E_c^*	minimum critical energy
p	absolute pressure
u	particle velocity
λ	stoichiometric ratio

Subscript

D	detonation state

Subsections 17.2.15–17.2.17

c	velocity of sound in uncompressed gas
d	diameter of tube

d_c	critical diameter for transmission of detonation
d_{min}	minimum diameter of vapour cloud to support detonation
g_f	acceleration of flame
L_c	length of detonation cell
S_u	maximum fundamental burning velocity
X_d	run-up distance
X_f	distance from origin of flame to its position at time when shock first forms
X_s	distance from origin to position at which shock is produced
β	ratio of velocity of flow just ahead of flame to that of flame
γ	ratio of specific heats of reactant
ϵ	expansion ratio
θ_{cr}	critical angle for transition to regular reflection
θ_w	angle between shock wave traveling horizontally and a surface

Equations 17.2.56–17.2.57

A_t	area of truncation
d	diameter of nozzle
D_{CJ}	C–J velocity
E_c	critical energy
L_c	length of detonation cell
p	pressure of planar detonation
S	width of detonation cell
t_c	time at which heads of expansio fan cross axis of symmetry
u_{CJ}	gas velocity behind C–J front
W	work done

Subscripts

c	critical
CJ	C–J
o	actual

Section 17.3

Subsection 17.3.2

p°	peak overpressure
r	distance
r_c	radius of crater
r_{50}	distance at which there is 50% chance of sympathetic detonation, mean detonation distance
R	radius of damage circle
W	mass of explosive
z	scaled distance

Subsection 17.3.3

k	constant
R	distance (ft)
W	mass of explosive (lb)

Subsection 17.3.4

Equation 17.3.8

k	constant
n	index
R	distance
W	mass of explosive

Equations 17.3.9–17.3.11

R	distance (ft)
W	mass of explosive (lb)

Subsection 17.3.5

B	blast effect
B^*	blast effect required for certainty of detonation
j	site counter
k	constant
n_1, n_2	indices
p	probability of further detonation
p'	parameter defined by Equation 17.3.15
$P(j)$	probability that j sites are involved in detonation
r	distance
T	threshold of p' below which no propagation occurs
W	mass of explosive

Section 17.4

A	Helmholtz free energy
E	internal energy
F	Gibbs free energy
H	enthalpy
ΔH_c	heat of combustion
ΔH_{cl}	heat of combustion with initial reactant as liquid
ΔH_{clw}	heat of combustion with final water product as liquid
ΔH_{cv}	heat of combustion with initial reactant as vapour
ΔH_{cvw}	heat of combustion with final water product as vapour
ΔH_v	latent heat of vaporization
ΔH_{vw}	latent heat of vaporization of water
n	number of moles
P	absolute pressure
R	universal gas constant
S	entropy
T	absolute temperature
V	volume
W	work
γ	ratio of gas specific heats

Superscript

o	standard state

m	final
o	initial
u	unburned
1	closed end side
2	vent end side

Subsection 17.12.26

$\bar{A}$	dimensionless vent area
A_f	area of flame front (m^2)
A_s	surface area of sphere (m^2)
A_v	vent area (m^2)
A_x	cross-sectional area of cylinder (m^2)
k	constant
n	index
ΔP_m	maximum pressure rise (atm)
r_c	radius of cylinder (m)
r_s	radius of sphere (m)
$\bar{S}_o$	dimensionless burning velocity at initial conditions
T_f	adiabatic flame temperature (K)
ρ	density of gas (kg/m^3)

Subscripts

b	burned
o	initial
u	unburned

Subsection 17.12.27

A_v	vent area
B	dimensionless burning number
C_d	coefficient of discharge
G_v	vent mass velocity
m	mass
P	absolute pressure
P_a	atmospheric pressure
P_f	absolute final pressure of vented explosion, reduced pressure
P_{max}	absolute maximum pressure of unvented explosion
P_o	absolute initial pressure
P_{set}	absolute vent opening pressure
r_b	radius of burned gas
S_u	burning velocity
V	volume of vessel
Z	dimensionless burned volume
λ	dimensionless vent opening pressure
ρ	density of gas
ϕ	turbulence correction factor

Subscripts

b	banned
e	outflow
o	initial
u	unburned

Section 17.12.28

As Section 17.7.5

Subsection 17.12.32

A_v	vent area
F_r	force due to back reaction
P_{red}	reduced pressure (gauge)
u	velocity of fluid
ρ	density of fluid

Subsection 17.12.36

a	acceleration of vent panel
A	area of vent panel
C	parameter defined by Equation 17.12.163
D	'density' of vent panel
E	parameter defined by Equation 17.12.165
F	force on vent panel
g	acceleration due to gravity
K	parameter defined by Equation 17.12.100
L	length of vent panel
M	mass of vent panel
P	pressure (gauge)
P_v	vent opening pressure (gauge)
s	distance travelled by vent panel
S	distance defined by Equation 17.12.158
t_v	time of start of venting
v	velocity of vent panel
w	vent inertia
W	width of vent panel
θ	angle of rotation of vent panel

Section 17.13

A_v/V	vent ratio
D	diameter of duct (ft)
k_1–k_4	constants
K	vent coefficient
K_{st}	dust K_{st} value
L	length of duct (ft)
L_1	distance between relief openings (ft)
L_{1max}	maximum distance between relief openings (ft)

L_2	distance between relief openings for gas other than propane (ft)
P	maximum pressure (lbf/in.^{2})
P_1	maximum pressure resulting from explosion of propane (lbf/in.^{2})
P_2	maximum pressure for gas other than propane (lb$_f$/in.^{2})
S_u	maximum fundamental burning velocity for gas other than propane (ft/s)

Equations 17.3.5–17.13.6

L	maximum distance between vents
P_{red}	reduced pressure
S	maximum fundamental burning velocity

Subscripts

p	propane
x	gas other than propane

Section 17.14

Subsection 17.14.4

A_c	smallest cross-sectional area of building space (m^2)
A_v	total area of combustion vents (m^2)
f	turbulence factor
K	venting ratio
P_I	back pressure due to inertia of vent (gauge) (kPa)
P_{red}	maximum pressure reached during venting, reduced pressure (gauge) (kPa)
P_v	pressure with building space at which vent opens (gauge) (kPa)
S_u	maximum fundamental burning velocity (m/s)
V	volume of enclosure (m^3)
w	vent inertia (kg/m^2)

Subsection 17.14.5

Equations 17.14.1–17.14.6

A_v	vent area (ft^2)
C	Runes constant ((lb$_f$/in.^{2})$^{1/2}$)
E	expansion ratio
L_1, L_2	two smallest dimensions of building (ft)
ΔP	vented explosion overpressure (lb$_f$/in.^{2})
u_f	flame speed (ft/s)
ρ	density of gas (Ib/ft^3)

Equation 17.4.7

A_v	building vent area (m^2)
C	constant
L_1, L_2	two smallest dimensions of building (m)
P	maximum internal building pressure (kPa)

Subsection 17.14.6

a	constant
A_s	area of side of enclosure (m^2)
A_v	vent area (m^2)
K	venting ratio
P_m	maximum pressure reached during venting (mbar)
P_v	pressure at which vent opens (mbar)
P_1	first peak pressure (mbar)
P_2	second peak pressure (mbar)
S_u	burning velocity (m/s)
V	volume of enclosure (m^3)
w	vent inertia (kg/m^2)

Subsection 17.14.7

A_s	internal surface area of enclosure (m^2)
A_v	vent area (m^2)
C	venting constant (bar$^{1/2}$)
P_{red}	maximum pressure which can be withstood by weakest structural element not intended to fail (bar)

Subsection 17.14.8

f	turbulence factor
k_1, k_2	constants
K_1	vent coefficient for compartment 1
K_2	vent coefficient for compartment 2
K_{12}	vent coefficient between compartments 1 and 2
$(Kw)_{2av}$	average value of Kw for compartment 2
P_1	vented explosion pressure of compartment 1 (mbar)
P_2	vented explosion pressure of compartment 2 (mbar)
S_u	maximum fundamental burning velocity (m/s)
V_1	volume of compartment 1 (m^3)
V_2	volume of compartment 2 (m^3)

Subsections 17.16–17.19

A	vent area (m^2)
A_o	vent area for zero overpressure (m^2)
C	specific heat of reaction mass (kJ/kg)
D	diameter of vent line (m)
D_o	diameter of vent line in bench-scale apparatus (m)
F	flow correction factor for vent line
G	mass velocity (kg/m^2/s)
G_o	mass velocity in bench-scale apparatus (kg/m^2/s)
h	specific enthalpy (kJ/kg)
h_{fg}	latent heat of vaporization (kJ/kg)
ΔH_r	heat of reaction (kJ/kg)
ΔH_v	latent heat of vaporization (kJ/kg)
k	constant
K	discharge coefficient
L	length of vent line (m)
m	mass in vessel (kg)
m_o	initial mass in vessel (kg)
N	non-equilibrium parameter defined by Equation 17.18.2
P	absolute pressure (Pa)
ΔP	overpressure (Pa)
P_a	atmospheric pressure (Pa)
P_g	absolute partial pressure of gas (Pa)
P_o	absolute stagnation pressure (Pa)
P_s	absolute set pressure (Pa)
P_v	absolute partial pressure of vapour (Pa)
q	heat release rate per unit mass (kW/kg)
Q	heat release or input rate (kW)

Q_g	volumetric gas evolution rate (m^3/s)
Q_v	volumetric vapour evolution rate (m^3/s)
r	rate of reaction (kg/m^3/s)
t	time (s)
Δt	time interval (s)
Δt_p	emptying time (s)
Δt_v	venting time (s)
T	absolute temperature (K)
T_o	absolute stagnation temperature (K)
ΔT	temperature rise (°C)
$(dT/dt)_s$	self-heat rate at set pressure (°C/s)
u	specific internal energy (kJ/kg)
v	specific volume (m^3/kg)
V	volume of vessel (m^3)
W	mass flow (kg/s)
x	mass fraction of vapour, or quality
α	void fraction
β	parameter defined by Equation 17.16.10
μ	viscosity
ρ	density (kg/m^3)
τ_t	turnaround time for temperature (s)
ω	critical flow scaling parameter

Subscripts

a	atmospheric
d	at disengagement
ERM	equilibrium rate model
f	liquid
fg	liquid–vapour transition
g	gas or vapour
l	liquid
L	laminar
m	peak pressure
o	initial
s	set point
T	turbulent
v	vapour

Equation 17.16.6

Δt	time interval to maximum allowable pressure (s)
ΔT	temperature difference at equilibrium between initial pressure and maximum allowable pressure (°C)

Equation 17.16.8

ΔT	temperature rise corresponding to overpressure ΔP (°C)

Equations 17.18.2–17.18.3

ΔP	total available pressure drop (Pa)

Equation 17.18.7

ΔT	temperature rise corresponding to overpressure ΔP (°C)

Equation 17.19.1

ρ	density of reaction mass (kg/m^3)

Equations 17.19.5 and 17.19.7

α_d	void fraction at disengagement
α_o	initial void fraction

Equations 17.19.7 and 17.19.8

Δt_v	time to temperature turnaround (s)

Equation 17.19.12

Q_g	peak volumetric gas evaluation rate
Q_v	peak volumetric vapour evaluation rate

Subsection 17.19.10

Δt_A	measured adiabatic rise time (s)
Δt_E	measured vessel emptying time (s)

Subscripts

LS	large scale
T	test

Section 17.20

A	vent area
A_0	vent area for zero overpressure
C	specific heat of liquid at constant volume
C_{pf}	specific heat of liquid at constant pressure
C_{pg}	specific heat of gas at constant pressure
C_{vf}	specific heat of liquid at constant volume
e	base of natural logarithms
G	mass velocity of vent flow
h	specific enthalpy
h_{fg}	latent heat of vaporization
m	mass of material in vessel
m_o	initial mass of material in vessel
P	absolute pressure
q	heat release rate per unit mass
Q	heat generation or input rate
Q_T	total heat input
R	universal gas constant
V	volume of vessel
u	specific internal energy
v	specific volume
W	mass flow from vessel
x	mass fraction of vapour, or quality
ρ	density

Subscripts

f	liquid
fg	liquid–vapour transition
g	vapour
i	phase i
m	peak pressure or temperature
o	initial
s	relief set pressure
1	vent inlet

Section 17.21

As Section 17.20, plus

Q_g	volumetric gas generation rate at temperature and pressure in reactor during relief
ΔT	difference in saturation temperature between set pressure (as redefined) and maximum allowable pressure
α	void fraction
α_d	void fraction at disengagement
α_o	initial void fraction

Subscript

m	mean value between set pressure (as redefined) and maximum allowable pressure

Section 17.22

C	drag coefficient
d	particle diameter (m)
g	acceleration due to gravity (m/s^2)
k	constant
u	vapour velocity (m/s)
u_d	dropout velocity (m/s)
μ	viscosity of gas (cP)
ρ_l	density of liquid (kg/m^3)
ρ_v	density of vapour (kg/m^3)

Section 17.24

a	radius of vent
A	vent area
F	flow reduction factor
g	acceleration due to gravity
h	height
h_{fg}	latent heat of vaporization
ΔP	pressure drop through vent system
P_s	set pressure
Q_T	total heat input to tank
Q_v	energy release rate
s	radius of hemisphere
u	velocity of vapour through vent
u_E	entrainment velocity
u_o	velocity up vent
u_s	velocity across hemispherical surface
u_{scr}	critical velocity across hemispherical surface
ρ_g	density of vapour
ρ_l	density of liquid
σ	surface tension

Equation 17.24.8

R_m	mass basis gas constant

Section 17.25

c_o	velocity of sound in air
i_p	positive phase overpressure impulse, impulse
i_q	dynamic pressure impulse
i_s	scaled impulse
p	overpressure
p_a	absolute ambient pressure (ahead of shock front)
p°	peak overpressure
p_r°	peak reflected overpressure
p_s	scaled pressure
q	dynamic pressure
q°	peak dynamic pressure
r	distance
t_a	arrival time
t_d	duration of positive phase, duration tin
t_q	dynamic pressure duration time
u	particle velocity
U	shock velocity
W	mass of explosive
z	scaled distance
α	decay parameter
γ	ratio of specific heats of air
λ	yield factor
ρ	density of air (behind shock front)
τ	scaled time
τ_a	scaled arrival time
τ_d	scaled duration time

Subscripts

o	reference value

Equation 17.25.5

i_q	dynamic pressure impulse (psi/ms)
R	distance (ft)
W	mass of explosive (lb)

Section 17.26

i_p	impulse (Pas)
i_s	scaled impulse (Pas/kg$^{1/3}$)
p°	peak overpressure (Pa)
p_a	atmospheric pressure (Pa)
p_s	scaled peak overpressure
t_a	arrival time (s)
t_d	duration time (s)
W	mass of explosive (kg)
z	scaled distance (m/kg$^{1/3}$)
τ_a	scaled arrival time (s/kg$^{1/3}$)
τ_d	scaled duration time (s/kg$^{1/3}$)

Equations 17.26.1 and 17.26.2

a, b	constants
c_i	constants
i_p	impulse (kPa ms)
p°	peak side-on overpressure (kPa)
t_a	arrival time (ms)
t_d	duration time (ms)
U	variable defined by Equation 17.26.1
z	scaled distance (m/kg$^{1/3}$)
ϕ	parameter defined by Equation 17.26.2

Equations 17.26.3–17.26.5

i_p	impulse (bar/ms)
p_s	scaled peak overpressure
t_d	duration time (ms)
W	mass of explosive (kg)
z	scaled distance (m/kg$^{1/3}$)

Equations 17.26.6–17.26.8

a_o	speed of sound in gas (m/s)
E_{ex}	explosion energy (J)
i_s	side-on impulse (Pas)
$\bar{I}$	scaled side-on impulse
p°	absolute pressure of ambient air (Pa)
p_s	absolute peak side-on overpressure (Pa)
$\bar{P}_s$	scaled peak side-on overpressure
r	distance (m)
$\bar{R}$	scaled distance

Section 17.27

a	speed of sound (m/s)
a_o	speed of sound in air (m/s)
a_1	speed of sound in compressed gas (m/s)
p_o	absolute pressure of ambient air (Pa)
p_1	absolute initial pressure of gas (Pa)
p_s	absolute peak side-on pressure (Pa)
$\bar{P}_{so}$	scaled peak side-on overpressure at R_0
r_o	effective radius of equivalent hemisphere (m)

$\bar{R}_o$	scaled distance
V_1	volume of gas-filled vessel (m^3)
γ_0	ratio of specific heats of air
γ_1	ratio of specific heats of compressed gas

Subscripts

0	ambient air
1	compressed gas in vessel

Section 17.28

R	gas constant

Subsection 17.28.5

$\Delta A/A$	relative increase in flame surface area
A_f	disturbed flame surface area
A_o	undisturbed flame surface area
n	number of obstacles
p	pitch
r	radius of flame front
r_o	radius for flame front at entry to obstacles
S	burning velocity
S_L	laminar burning velocity
V_f	flame front velocity
V_{f1}	flame front velocity after one obstacle
V_{fn}	flame front velocity after n obstacles
V_{fo}	flame front velocity at entry to obstacles
V_L	base value of flame front velocity
α	multiplier
ρ	gas density

Subscripts

b	burned
u	unburned

Subsection 17.28.10

E_{TNT}	energy of explosion of TNT (kJ/kg)
ΔH_c	heat of combustion of hydrocarbon (kJ/kg)
W	mass of hydrocarbon (kg)
W_{TNT}	equivalent mass of TNT (kg)
α	yield factor

Subsection 17.28.12

E_{gas}	heat of combustion of hydrocarbon (MJ/kg)
E_{TNT}	energy of explosion of TNT (MJ/kg)
M_{gas}	mass of gas (in confined/congested region) (te)
M_{TNT}	mass of TNT (te)
R	distance (m)
V	volume of gas (in confined/congested region) (m)
α	yield factor

Subsection 17.28.16

a_o	speed of sound
M_f	flame Mach number
M_p	piston Mach number
p	absolute pressure
$\bar{p}$	dimensionless overpressure
p_o	ambient pressure
r	radial distance
u	velocity
α	expansion ratio
ρ_o	density of ambient gas
ϕ	velocity potential

Subsection 17.28.17

a_a	velocity of sound
A_f	effective frontal area of flame
H	height of cloud
$\dot{m}$	rate of mass addition
$\ddot{m}$	rate of change of mass addition rate
M_f	flame Mach number
M_{su}	Mach number in unburned gas
p	absolute pressure
$\bar{p}$	dimensionless overpressure
p_o	ambient pressure
$\hat{q}$	dimensionless rate of energy addition
r	characteristic radius of source region
r_f	radius of flame
r_{obs}	distance of observer from centre of cloud
S_b	flame speed
S_u	effective burning velocity
u_f	velocity of flame front
$\ddot{V}$	rate of volume addition
V_b	specific volume of burned gas
V_u	specific volume of unburned gas
α	expansion ratio
p_0	initial density of gas

Subscript

su	unburned gas

Subsection 17.28.18

a	speed of sound
F	parameter defined by Equation 17.28.3
r	radial distance
r_s	radial distance of leading shock
u	particle velocity
U_s	velocity of leading shock
X	parameter defined by Equation 17.28.3
Z	parameter defined by Equation 17.28.3

Subsection 17.28.19

a_o	speed of sound
K	parameter defined by Equation 17.28.47b
p	parameter defined by Equation 17.28.45
p_i	absolute pressure in region *i*
r	flame radius
R	shock radius
R_o	initial value of shock radius
s	parameter defined by Equation 17.28.45b
S	flame speed
T_i	absolute temperature in region *i*
V	velocity
x	parameter defined by Equation 17.28.46
y	parameter defined by Equation 17.28.46b
θ	parameter defined by Equation 17.28.47
ρ_i	density in region *i*

τ	dimensionless time defined by Equation 17.28.47c

Subscripts

0	undisturbed gas
1	shocked gas (shell)
2	burnt gas (core)

Subsection 17.28.21

a	velocity of sound in normal atmosphere
E	energy
E_e	explosive energy release
E_o	total energy release
E_u	vapour cloud energy release
ΔH_c	heat of combustion
m	mass of fuel in cloud
M	molecular weight of vapour
p	pressure
p_c	pressure at centre of explosion
r	distance from centre of blast symmetry
R	distance from centre of explosion
t_o	time of termination of rapid energy release
V	volume
ϵ	stoichiometric ratio
η	explosion efficiency
v	flame speed

Subsection 17.28.22

M_{su}	Mach number with coordinates relative to gases moving ahead of flame front
M_w	Mach number with fixed coordinates

Subsection 17.28.23

A	constant
c_o	local velocity of sound (m/s)
E_c	energy of combustion per unit volume (J/m^3)
E_o	energy added to unburned gas during combustion process (J)
L	characteristic length (m)
n	number of mols
p	absolute pressure (Pa)
$\overline{PS}$	reduced overpressure
R	distance (m)
$\bar{R}$	reduced distance
R_g	universal gas constant (J/mol K)
R_0	radius of initial cloud (m)
R_1	radius of burned cloud
t_+	duration time (s)
$\bar{t}$	reduced time
t_b	time at which explosion process is complete (s)
T	absolute temperature (K)
$\overline{TS}$	reduced duration time
U_{SW}	velocity of shock wave (m/s)
$\bar{u}_{fl}$	average flame speed (m/s)
V	volume (m^3)
γ	ratio of specific heats of air
λ	parameter defined by Equation 17.28.57

Subscripts

0	initial
1	final

Subsection 17.28.24

$C(S)$	parameter (m/J$^{1/3}$)
E	energy content of part of cloud within flammable range (J)
ΔH_c	heat of combustion (J/kg)
M_e	mass of fuel in cloud within flammable range (kg)
$R(S)$	radius of damage circle (m)
S	degree of damage
η	fraction of energy released, explosion efficiency
η_c	yield factor relating to stoichiometry
η_m	yield factor relating to mechanical energy

Section 17.29

Subsection 17.29.7

T_c	absolute critical temperature (K)
T_{sl}	absolute superheat limit temperature (K)

Subsection 17.29.11

P_b	burst pressure
r	vessel radius
R	radius ratio
σ_u	ultimate tensile strength
σ_y	yield strength

Subscripts

i	inner
o	outer

Section 17.30

Subsection 17.30.4

C	mass of oil mist in air necessary to produce explosive mixture at atmospheric pressure (g/m^3)
d	density of oil (g/m^3)
D	diameter of pipe (m)
P	absolute pressure (atm)
t	thickness of oil film (m)

Subsection 17.30.6

As Section 17.29.7

Section 17.31

Subsection 17.31.4

Equations 17.31.1 and 17.31.2

a	acceleration
A	amplitude
f	frequency
V	velocity

Equation 17.31.3

A	amplitude (in.)
d	distance (ft)

E	mass of explosive (lb)
K	constant

Equation 17.31.4

Q	mass of explosive (kg)
R	distance (m)
ϕ	ϕ value

Subsection 17.31.5

D	diameter of crater (m)
h	depth of crater (m)
Q	mass of explosive (kg)
V	volume of crater (m^3)

Equation 17.31.8

r	radius of crater
W	mass of explosive

Section 17.32

Subsection 17.32.1

B	breadth of structure
C_D	drag coefficient
H	height of structure
L	length of structure
p	overpressure
p_a	maximum value of average side and top pressure
p_b	maximum value of average back face pressure
p_d	drag pressure
p_e	effective pressure
p_f	overpressure at front face
p_r°	peak reflected overpressure
p_s	stagnation pressure
q	dynamic pressure
S	distance through which pressure relief is obtained
t	time
t_s	stagnation time
U	shock velocity

Subsections 17.32.2 and 17.32.3

c	damping factor
E_{ko}	initial kinetic energy
E_{sm}	maximum strain energy
f	Coulomb friction force
f_n	natural cyclic frequency
F	applied force
F^*	parameter defined by Equation 17.32.12
I	impulse
k	elastic constant
m	mass of system
R	restoring force
T	time constant for force decay
T_n	natural period
W_m	maximum work
x	displacement
x_m	maximum displacement
ζ	damping factor
τ	natural period
ω_n	natural frequency

Subsection 17.32.4

R	resistance function
R_e	maximum elastic resistance

Equations 17.32.32–17.32.34

f_n	natural cyclic frequency
k	elastic constant
m	mass of system
T_n	natural period
ω_n	natural frequency

Equation 17.32.35

B	breadth of building (ft)
H	height of building (ft)
T	natural period of building (s)

Equation 17.32.36

p_m	blast pressure (N/m^2)
r_e	maximum elastic resistance per unit area (N/m^2)
t_e	time to yield (s)
T	natural period (s)

Equation 17.32.37

x_e	displacement at elastic limit
x_f	displacement at failure
μ	ductility ratio

Subsection 17.32.5

F_m	maximum load
P_m	maximum pressure
x_e	displacement at elastic limit
x_f	displacement at failure
x_m	central deflection

Subsection 17.32.6

p°	peak overpressure (N/m^2)
Y	probit

Equation 17.32.39a

k	constant
R	average circle radius for specified damage category (ft)
W	mass of explosive (lb)

Equation 17.32.39b

k	constant
R	average circle radius for specified damage category (m)
W	mass of explosive (kg)

Section 17.33

Subsection 17.33.2

Equation 17.33.1a

R_B	distance for B category damage (ft)
W	mass of explosive (lb)

Equation 17.33.1b

R_B	distance for B category damage (m)
W	mass of explosive (kg)

Subsection 17.33.3

Equation 17.33.2a – as Equation 17.33.1a,
Equation 17.33.2b – as Equation 17.33.1b

Subsection 17.33.4

R_A	average circle radius for A category damage
R_B	average circle radius for B category damage
$\bar{R}_B$	average circle radius defined by Equation 17.33.3
R_C	average circle radius for C category damage

Subsection 17.33.5

Equation 17.33.4 – as Equation 17.33.1b

Subsection 17.33.6

I	impulse
P	pressure

Equation 17.33.5 – as Equation 17.33.1b plus

z'	modified scaled distance (m/kg$^{1/3}$)

Section 17.34

Subsection 17.34.7

E_f	energy stored in vessel per unit mass of fluid
K	geometric factor
M_f	mass of fluid stored
M_v	mass of vessel
u	velocity of fragment

Subscript

i	initial

Subsection 17.34.8

A	mean presented area of fragment
C_D	drag coefficient
m	mass of fragment
t	time
u	velocity of fragment
u_g	velocity of surrounding gas
ρ_g	density of surrounding gas

Subsection 17.34.9

As Section 17.4.5 plus

E_k	explosion energy imparted to fragments
k	parameter defined by Equation 17.34.8

Subsection 17.34.11

a_g	velocity of sound in gas
K	constant
M_c	mass of vessel
p	pressure in vessel
p_o	atmospheric pressure
R_m	mass basis gas constant
T	absolute temperature of gas
u	velocity of fragment
V_0	volume of vessel
γ	ratio of gas specific heats

Subsections 17.34.12 and 17.34.13

a_o	speed of sound
A	area of detached portion of vessel wall
F	parameter defined by Equations 17.34.12 and 17.34.13
L	length of cylinder
m	mass per unit area of vessel wall
m_f	mass of fragment
P_o	atmospheric pressure
P_1	absolute initial pressure in vessel
r	radius of vessel
s	dimension of fragment
u	velocity of fragment
$\bar{u}$	dimensionless velocity of fragment

Subscript

i	initial

Subsection 17.34.14

a_o	speed of sound in gas at failure
$\bar{E}$	scaled energy
E_{ex}	energy released in explosion
M	mass of vessel
P	atmospheric pressure
P_1	absolute initial pressure in vessel

Subsection 17.34.16

C_D	drag coefficient
C_L	lift coefficient

Subsection 17.34.17

g	acceleration due to gravity
k	constant
u	velocity along line of flight
v	velocity relative to ground
x	distance in horizontal direction
y	distance in vertical direction
α	angle of departure
β	angle of return

Subscript

i	initial

Equation 17.34.46

c_d	drag coefficient
k	constant
v	velocity of projectile (ft/s)
m	mass of projectile (oz)
x	distance travelled by projectile (ft)

Subscript

i	initial

Subsection 17.34.18

A_D	drag area
A_L	lift area
C_D	drag coefficient
C_L	lift coefficient
F_D	drag force
F_L	lift force
g	acceleration due to gravity
M	mass of fragment
R	range of fragment
$\bar{R}$	dimensionless range
u	velocity of fragment
$\bar{u}$	dimensionless velocity of fragment
u_o	initial velocity of fragment

ρ	density of air
ρ_o	initial density of air

Subsection 17.34.21

F_{or}	orientation factor
H	height of top of sphere (m)
L	effective range interval (m)
N	number of fragments
N_{pen}	$= N - 1$
P	probability
P_{ri}	probability that fragment falls within effective range interval L
P_{st}	probability of a strike
P_v	vessel pressure (barg)
r	radius of sphere (m)
R	range (m)
R_{med}	median range (m)
R_{pen}	range of penultimate fragment (m)
W	combined width of target and fragment (m)
Y	probit
θ	angle of descent (°)

Subsection 17.34.24

a	projected area of body (ft^2)
A	area per missile (ft^2/missile)
A_h	area of hemisphere on surface of which human target is standing (ft^2)
m	mass of explosive (ton)
n	near field number of missiles per ton of explosive (missiles/ton)
n_e	number of missiles at distance R
P	probability of being struck by missile
R	distance (ft)
W	mass of explosive (lb)
ϕ_o	correction factor

Subsection 17.34.25

A	presented area of fragment (m^2)
C	constant
d	diameter of fragment (m)
K	constant
m	mass of fragment (kg)
n_1, n_2	indices
t	thickness of barricade to just stop fragment (m)
u	velocity of fragment (m/s)

Subsection 17.34.26

d	diameter of missile (m)
D	calibre density of missile (kg/m^3)
e	perforation thickness (m)
G	parameter defined by Equations 17.34.68–17.34.70
m	mass of missile (kg)
V	velocity of missile (m/s)
V_p	perforation velocity (m/s)
x	penetration depth (m)
ρ	density of concrete (kg/m^3)
σ_c	compressive strength of concrete (Pa)

Subsection 17.34.27

d	diameter of missile (m)
E_c	critical impact energy of missile G)
h	thickness of target panel (m)
S_u	ultimate tensile strength of panel (Pa)
w	width of panel (m)

Subsection 17.34.28

E_r	energy to deform sphere in plastic region between yield and rupture (kJ)
E_v	energy to deform sphere up to yield point (kJ)

Subsection 17.34.29

E	shock wave energy (J)
P	equivalent static pressure (bar)
R	distance (m)

Equation 17.34.76

V	volume of enclosure (m^3)

Equations 17.34.77 and 17.34.78

I	impulse per unit area ($N/s/m^2$)
m	mass of wall per unit area (kg/m^2)
V	velocity (m/s)

Equation 17.34.79

P	peak incident overpressure (bar)

Section 17.35

Subsection 17.35.3

F	force on disc
g	acceleration due to gravity
m	mass of disc
x	extension

Subsection 17.35.5

e	strain
U	energy adsorbed (G)
ρ	density of steel (kg/m^3)
σ_y	yield stress (N/m^2)

Equations 17.35.1–17.35.3

F	applied force (N)
l	length of pipe stretched (m)
U	energy absorbed G)
δ	elongation (m)
θ	angle of bend (rad)
ϕ	plastic moment (N/m)

Equations 17.35.4 and 17.35.5

L	length of cut (m)
t	thickness (m)

Equation 17.35.6

e_p	strain behind plastic wave front
v	imparted velocity (m/s)
σ_g	tensile stress (N/m^2)

Equation 17.35.7

c	velocity of elastic compression wave in steel (m/s)
v	velocity of impact of missile (m/s)
σ_c	compressive stress caused by impact (N/m^2)

Equation 17.35.8

V_c	volume of cavity (m^3)

Section 17.36

Subsection 17.36.2

B, B_B	constants
m	mass of nth fragment
$M(n)$	cumulative mass of fragments
M_o	total mass of fragments
M_{oB}	modified total mass of fragments
n	number of nth largest fragment
λ, λ_B	constants

Subsection 17.36.3

D	velocity of detonation
u_o	initial velocity of fragments
ϕ	angle beween initial trajectory of fragment and axis of tube, Taylor angle

Subsection 17.36.4

Equation 17.36.6

C	mass of cylindrical case per unit length (lb)
E	mass of charge per unit length (lb)
V_o	initial velocity of fragments (ft/s)

Equations 17.36.7 and 17.36.8

C	mass of explosive (kg)
C_G	Gurney velocity, Gurney constant (m/s)
ΔE	internal energy per unit mass of explosive (J/kg)
M	mass of cylindrical section of casing (kg)
u_o	initial velocity of fragments (m/s)

Equations 17.36.9 and 17.36.10

C_G	Gurney velocity (km/s)
M	average molecular weight of products of explosion
N	number of moles of gas produced by explosion
Q	heat of detonation (cal/g)
ρ_o	explosive loading density (g/cm^3)
ϕ	parameter defined by Equation 17.36.10

Subsection 17.36.5

Equation 17.36.11

m	mass of fragment (oz)
s	distance travelled (ft)
u	velocity of fragment (ft/s)
u_o	velocity of fragment at commencement of air drag (ft/s)
u_s	velocity of sound (ft/s)

Equation 17.36.12

A	area of fragment
k	constant
u	velocity of fragment
u_o	velocity of fragment at commencement of air drag
m	mass of fragment
x	distance

Equations 17.36.13–17.36.15

A	coefficient of area
A_m	mean area presented by fragment in flight (ft^2)
Q	fragment volume (ft^3)
u	velocity of fragment (ft/s)
u_o	velocity of fragment at commencement of air drag (ft/s)
u_s	velocity of sound (ft/s)
w	mass of fragment (oz)
x	distance (ft)

Equations 17.36.16 and 17.36.17

a	diameter of sphere or side of cube (m)
A_s	effective area of fragment (m^2)
C_α	drag coefficient
m	mass of fragment (kg)
u	velocity of fragment (m/s)
u_o	initial velocity of fragment (m/s)
x	distance (m)
ρ_a	density of air (kg/m^3)

Equation 17.36.23

r	safety distance (m)
W	mass of explosive (kg)

Subsection 17.36.8

A_p	projected area of exposed person (ft^2)
A_v	vulnerable area (ft^2)
n	number of incapacitating fragments
N	average number of incapacitating fragments at distance x
p	probability of being hit by one or more incapacitating fragments
q	number of fragments of equivalent velocity v at distance x
r	proportion of fragments of equivalent velocity v at distance x capable of causing incapacitation
u	velocity of fragment (ft/s)
x	distance (ft)

Section 17.38

C_D	drag coefficient
i	impuse (Pas)
$\bar{i}$	scaled impulse ($Pa^{1/2}s/kg^{1/3}$)
m	mass of body (kg)
p°	peak incident overpressure (Pa)
p_a	atmospheric pressure (Pa)
p_a^o	peak applicable overpressure for lung injury (Pa)
$\bar{p}_a^\circ$	scaled peak applicable overpressure for lung injury
p_r°	peak reflected overpressure (Pa)
q	dynamic pressure (Pa)
q^o	peak dynamic pressure (Pa)
Y	probit

Equations 17.38.9 and 17.38.10

S	damage number

Equations 17.38.11 and 17.38.13

J	impulse (Pa s)

p	incident overpressure (Pa)
t_d	duration time (s)

Equations 17.38.13–17.38.16

A	projected area of body (m^2)
F	force acting on body (N)
i_q	dynamic pressure impulse (Pas)
t_q	dynamic pressure duration (s)
V	velocity imparted to body (m/s)

Equations 17.38.17–17.38.21

A	projected area of body (ft^2)
F	deceleration due to friction (ft/s^2)
L	loading on body (lbf)
M	mass of body (ln)
P_e	effective pressure on body (lb$_f$/in.^{2})
t	time (s)
u	velocity of body (ft/s)
x	distance travelled by body (ft)
α	acceleration coefficient (ft^2/lb)

Equations 17.38.22 and 17.38.23

L	loading (N)
m	mass of body (kg)
t	time (s)
u	velocity of displacement (m/s)
ϕ_r	deceleration due to friction (m/s^2)

Equations 17.38.24–17.38.30

S	injury factor

Equation 17.38.31a

d	distance for 50% casualties (ft)
d_r	distance for 50% casualties for 1 kt explosion (ft)
W	yield of a nuclear explosion (kiloton)

Equation 17.38.31b

d	distance for 50% casualties (m)
d_r	distance for 50% casualties for a 1 kte explosion (m)
W	mass of explosive (te)

Section 17.40

Subsections 17.40.3–17.40.5

A	area of pane (m^2)
A_p	presented area of fragment (m^2)
A_{mp}	mean presented area of fragment (m^2)
A_{50}	mean frontal area of fragment (m^2)
l	length of long side of fragment (m)
m_{so}	mean mass of fragment (kg)
p^*_{br}	breaking pressure (kPa)
p°	peak incident overpressure (Pa)
p°_e	peak effective overpressure (Pa)
t	thickness of glass, fragment (m)
u	velocity of fragment (m/s)
u'	velocity of fragment (ft/s)
Y	probit
ρ_{gl}	density of glass (kg/m^3)

Superscripts

50	geometric mean
¯ (overbar)	scaled

Equations 17.40.5 and 17.40.6

A^*_{50}	mean frontal area fragment (cm^2)
m	mass of fragment (g)
$p^{\circ *}_e$	peak effective overpressure (kPa)

Equation 17.40.8

A_{mp}	mean presented area of fragment on impact (m^2)
t	thickness of glass, fragment (cm)

Equations 17.40.9 and 17.40.10

$p^{\circ\prime}_e$	peak effective overpressure (psi)
t'	thickness of pane (in.)
V'_{50}	geometric mean velocity of fragment (ft/s)
$\bar{V}'_{50}$	scaled geometric mean velocity of fragment (ft/s)

Equations 17.40.12 and 17.40.13

t^*	thickness of pane (cm)
$\bar{V}_{50}$	scaled geometric mean velocity of fragment (m/s)

Equation 17.40.14

$p^{\circ *}_e$	peak effective overpressure (kPa)
u	average velocity of fragments (m/s)

Equation 17.40.15

t	thickness of glass, fragment (m)
u	average velocity of fragments (m/s)
P^*_{br}	breaking pressure (kPa)

Subsection 17.40.6

A	presented area of fragment (m^2)
A'_{50}	geometric mean frontal area of fragment (m^2)
M	mass of fragment (kg)
P_e	peak effective overpressure (Pa)
P_o	atmospheric pressure (Pa)
P_r	peak reflected overpressure (Pa)
$\bar{P}_s$	dimensionless peak reflected overpressure
P_s	peak side-on overpressure (Pa)
$\bar{P}_s$	dimensionless peak side-on overpressure
t	thickness of pane, fragment (m)
u_{50}	geometric mean velocity of fragment (m/s)
y	length of square edge of fragment (m)
ρ_{gl}	density of glass (kg/m^3)

Subsection 17.40.7

$p^{\circ *}_e$	peak effective overpressure (kPa)
ρ_{sd}	spatial density of fragments (fragments/m^2)
$\bar{\rho}'_{sd}$	scaled spatial density of fragments
t	glass thickness (cm)

Subsection 17.40.9

m	mass of fragment (g)
u'	velocity of fragment (ft/s)
Y	probit

Subsection 17.40.10

A	presented area of missile (m^2)
C_D	drag coefficient
J	impulse (Pa s)
M	mass of missile (kg)
u_i	impact velocity (m/s)
Y	probit

Subsection 17.40.11

A	presented area of fragment (m^2)
M	mass of fragment (kg)
u_{50}	velocity for 50% probability of perforation (m/s)

Subsection 17.40.12

a	smaller of two dimensions of pane (m)
A	area of pane (m^2)
d	thickness of pane (m)
f_{dl}	dynamic load factor
f_t	tensile strength of pane (Pa)
P°	peak incident overpressure (Pa)
P_{df}	dynamic failure load (Pa)
P_{st}	static strength of pane (Pa)
t_d	duration time (s)
T	natural period of vibration (s)

Section 17.41

Subsection 17.41.24

c	index
E	kinetic energy (J)
m	mass of fragment (kg)
u	velocity of fragment (m/s)

Subsection 17.41.4

b, c	indices
k	constant
m	mass of fragment (mg)
m_r	mass of reference fragment (mg)
P	penetration (ft)
u	velocity of fragment (ft/s)

i	body region counter

Subsection 17.42.2

A	total mean presented area of body
A_i	mean presented area of body attributable to region i

Subsection 17.42.3

A	projected area of fragment (m^2)
m	mass of fragment (kg)
u	velocity of fragment (m/s)
X	causative factor (G/m^2)

Subsections 17.42.4 and 17.42.5

Equation 17.42.18:

a, b	constants
A	projected area of fragment (cm^2)
m	mass of fragment (g)
u	velocity of fragment (m/s)

Equations 17.42.19 – 17.42.22

A	projected area of fragment (m^2)
m	mass of fragment (kg)
u	velocity of fragment (m/s)

Section 17.44

c	concentration (g/m^3)
ES	explosion severity
IE	index of explosibility
IS	ignition sensitivity
K_G	gas explosibility constant, K_G value
K_{st}	dust explosibility constant, K_{st} value
l	lower explosive limit (g/m^3)
m_{sd}	mass concentration of solvent-contaminated dust (g/m^3)
MEC	minimum explosive concentration
MEP	maximum explosion pressure
MIE	minimum ignition energy
MIT	minimum ignition temperature
MRPR	maximum rate of pressure rise
P	absolute pressure
p_{max}	maximum explosion pressure
p_o	atmospheric pressure
p_1	small initial pressure rise
p_2	pressure defined in Figure 17.114
V	volume of vessel (m^3)
ϕ_s	mass fraction of solvent in solvent-contaminated dust

Subscripts

d	dust
dh	dust in presence of flammable gas, hybrid
g	gas
Pc	Pittsburgh coal
sample	sample

Section 17.46

C_o	maximum permissible oxygen concentration for carbon dioxide inerting
N_o	maximum permissible oxygen concentration for nitrogen inerting

Section 17.48

Toxic Release

Contents

The third of the major hazards, after fire and explosion, is a release of a toxic chemical. The hazard presented by a toxic substance depends on the conditions of exposure and on the chemical itself. It ranges from a sudden brief exposure at high concentration to prolonged exposure at low concentrations over a working lifetime.

Both these situations present serious hazards. A very large release of a toxic chemical such as chlorine under the most unfavourable conditions is usually regarded as having a disaster potential greater than that of fire or explosion. However, a large toxic release is a much less frequent occurrence than a large fire or explosion.

The First Report of the ACMH (Harvey, 1976) states:

> With toxic materials, the sudden release of very large quantities could conceivably cause even larger numbers of casualties than a flammable escape. In theory such a release could, in certain weather conditions, produce lethal concentrations in places 20 miles from the point of release but the actual number of casualties (if any) would depend on the population density in the path of the cloud and the effectiveness of the emergency arrangements that might include evacuation.

In a quite different way the long-term toxic effects of exposure at even low concentrations of certain chemicals over a working lifetime can also affect large numbers of people.

The aspects of the problem considered here are the general effects of toxic substances, the limit values set for these, the effects of particular toxic chemicals and the assessment and control of the hazard of toxic releases. The treatment here is complemented by the account of occupational health given in Chapter 25.

Reference was made in Chapter 3 to the establishment by the Government of the Advisory Committees on Dangerous Substances (ACDS) and on Toxic Substances (ACTS) to advise the Health and Safety Commission (HSC). The terms of reference of both committees include toxic substances.

It cannot be too strongly emphasized that the assessment of the effect of toxic chemicals is a medical matter and that it is essential that the engineer seek expert advice on medical aspects such as interpretation of limit values and assessment of long-term effects.

Selected references on toxicology and toxic chemicals and on toxic release are given in Tables 18.1 and 18.2, respectively.

18.1 Toxic Effects

The treatment of toxic effects given here deals both with acute and chronic effects, but it is necessarily a brief one. Sources of information on the toxicity of chemicals are given in Section 18.3, and for carcinogens, in Section 18.7.

The effects of toxic substances are described in treatments of occupational diseases such as *Occupational Diseases and Industrial Medicine* (R.T. Johnson and Miller, 1960), *Diseases of Occupations* (Hunter, 1975), *National Occupational Exposure Survey* (NIOSH, 1974–/3), *Occupational Diseases – A Guide to Their Recognition* (NIOSH, 1977/4), *A Guide to Work-relatedness of Disease* (NIOSH/5, 1979), *Recognition of Health Hazards in Industry* (Burgess, 1981 ACGIH/5), *Chemical Exposure and Disease* by Sherman (1988 ACGIH/16) and Work Related Lung Disease Surveillance Report (NIOSH, 1991/20).

Toxicity testing

WHO (EHC 6); Goldberg (1974); Christopher (1978); Dewey (1978); M. Sherwood (1978); Smythe (1978); Anon. (1982a); Kolber *et al.* (1983); Patrick (1983); Rodricks and Tardiff (1984a); Walters and Jameson (1984); Anon. (1986a); ten Berge, Zwart and Appelman (1986); Kletz (1987e); ten Berge and Zwart (1989)

Epidemiology

Acheson (1967, 1979); J.P. Fox, Hall and Elvaback (1970); Lowe and Kostrzewski (1973); Tsuchiya, Okubo and Ischizu (1975); Alderson (1976); Duncan (1977, 1979); Wynder and Gori (1977); Registrar General (1978); Harrington (1979, 1980a); Lawther (1979); Monson (1980); Acheson and Gardner (1981); A.J. Fox (1981); Ryan (1981); Clary, Gibson and Waritz (1983); Leese and Jones (1983); Neal and Gibson (1984); CONCAWE (1991, 91/53); ACGIH (1992/79)

Toxic load-response

Bryan and Shimkin (1945); B.C. King (1949); J.M. Brown (1976); Liddell, McDonald and Thomas (1977); Hewitt (1978); M.W. Anderson, Hoel and Kaplan (1980); Krewski and van Ryzin (1981); Hoel, Kaplan and Anderson (1983); C.C. Brown (1984); Ride (1984b); Snyder (1984); Anon. (19861); ten Berge, Zwart and Appelman (1986); Zwart *et al.* (1988)

Toxicokinetic modelling

Dominguez (1933); E. Nelson (1961); J.G. Wagner (1975); Tuey (1980); Muller and Barton (1987)

Human and animal physiology
Oilman *et al.* (1948); Farris and Griffiths (1949); Specter (1956b); R.T.Williams (1959); Oser (1965); Altaian and Dittmer (1961, 1968, 1971, 1974); Weibel (1963); Munro (1969); Zenz (1975); Mitruka and Rawnsley (1977); Parke and Smith (1977); J.B.West (1977); Altaian and Katz (1979); Waldron (1979, 1989); Harrington and Waldron (1980); Schroter and Lever (1980); Waldron and Harrington (1980); Ganony (1983); Lindberg, Dolata and Merke (1987)

Statistical interpretation
Trevan (1927); Bliss (1934, 1935, 1952, 1957); Bliss and Cattell (1943); Finney (1971)

Animal models, extrapolation between species
Freirech *et al.* (1966); Rail (1970); S.B. Baker, Tripod and Jacob (1970); Hushon and Ghovanlou (1980); Paddle (1980); Purchase (1980); Oser (1981); Task Force of Past Presidents of the Society of Toxicology (1982); C.C. Brown (1984); Menzel and Smolko (1984); N. Nelson (1984); Rousseaux (1987)

Toxic risk assessment
NAS/NRC (1973b); Zeller (1979); Ruschena (1980); US Congress, OTA (1981); Totter (1982); Rodricks and Tardiff (1984b); Bridges (1985); Clayson, Krewski and Munro (1985)

Toxics control policy
Anon. (1981k); Pittom (1978); Relio (1978); C.R. Pearson (1982); Barnard (1984); Corn and Corn (1984); Deisler (1984a,b); Gough (1984); Karrh (1984); Lowrance (1984); Neal and Gibson (1984); Rijkels (1984); Rodricks and Tardiff (1984); Doull (1987); Rodricks and Taylor (1989); Cote and Wells (1991); Fairhurst and Turner (1993)

Process design and handling
Halley (1965); Prugh (1967); J.R. Hughes (1970); Constance (1971a); Gage (1972); Schaper (1973); Kusnetz (1974); Wirth (1975); J.T. Carter (1976, 1980); Garner (1976); Weissbach (1976); Toca (1977); Payne (1978); S.D. Green (1980); IBC (1982/27); Cralley and Cralley (1983); First (1983); Kusnetz and Phillips (1983); Kusnetz and Lynch (1984); Carson and Mumford (1986 LPB 67); Anon. (1989 LPB 86, p. 19); Jackson (1989 LPB 87); Desai and Buonicore (1990); Grossel (1990a); Doerr and Hessian (1991); Chadha and Parmele (1993)

Workplace exposure, environmental control, exposure monitoring; analytical methods (*see* Table 25.1)

Toxics detection and alarm
D. Doyle (1971); ACGIH (1972); Eckstrom (1973); Blears and Coventry (1974); Johanson (1974, 1976); Visanuvinol and Slater (1974); Dailey (1976); Thain (1976); Lichtenberg and McKerlie (1979); Warncke (1977); Ricci (1979a); Ellgehausen (1980); Cullis and Firth (1981); Rooney (1986); J.M. Rogers (1988); Thompson, Sekula and Whitson (1992)

Hygiene standards, threshold limit values, occupational exposure limits
ACGIH (n.d./l-3, 1992/78, 80); Elkins (1939); Bowditch *et al.* (1940); Anon. (1962a); Associated Octel Co. (1972 Bull. 24); ASTM (1973 DS 48); Levinson (1975); Ferguson (1976); HSE (1976 TDN2/73, 1993, EH 64, EH 65/4, EH 65/6, 1994 EH 40); Henschler (1979); Lauwerys (1983); IBC (1984/56); CIA (1985 PA23); P. Lewis (1985a, 1986a,b); Skinner (1985); AIHA (1987/12); Anon (1990h); ILO (1991/2); Weisburger (1994)
MAKWerte: Henschler (1979); Deutsche Forschungsgemeinschaft (1982); German Commission for Investigation of Health Hazards in the Workplace (1994)
Emergency exposure limits': Zielhuis (1970); Siccama (1973); CPD (1974); Balemans (1975); Eisenberg, Lynch and Breeding (1975); AIHA (1988–/13); ECIETOC (1991); Rusch (1993)
HSE limit system: Fairhurst and Turner (1993)
Dow Chemical Exposure Index: RA Smith and Miller (1988); Dow Chemical Co. (1994a)

Odour
(ASTM 164, 1973 DS 48); Leonardos, Kendall and Barnard (1969); Turk (1969); ASTM (1973 DS 48); Turk, Johnston and Moulton (1974); Cheremisinoff and Young (1975); Fazzalari (1978); Eugen (1982); Polak (1983); Lynskey (1984 LPB 60); J.C. Stevens, Cain and Weinstein (1987); AIHA (1989/17); CCPS (1989/4); R.M. Turner and Fairhurst (1989a); MacFarlane and Ewing (1990); ACDS (1991); de Weger, Pietersen and Reuzel (1991); CPD (1992b)

Toxicity of chemicals
Browning (n.d.a.b, 1965); HSE (Appendix 28 inc. Toxicology of Substances, MS, TON and TR series, SIR 21); MCA (1952–, SD series, 1972/21); Merck (1889); Flury and Zernick (1931); Brookes (1948); Patty (1948–); Sax (1957–); Matheson Co. 18.1.1 Modes of exposure

Toxic chemicals enter the body in three ways: (1) inhalation, (2) ingestion and (3) external contact. Generally, gases, vapours, fumes and dusts are inhaled and liquids and solids are ingested. Entry may also occur through the intact skin or the mucous linings of the eyes, mouth, throat and urinary tract.

18.1.2 Effects of exposure

Exposure to some chemicals results in temporary or permanent damage to organs of the body, that is, poisoning. There is a wide variety of types of damage caused by toxic substances.

The effects of exposure to toxic chemicals may be acute or chronic. Acute effects result from a single exposure to a high concentration of the chemical; chronic effects result from exposure to low concentrations, perhaps over a large part of a working lifetime. With the latter type of exposure the effects may be latent and may show themselves only after many years. It is also possible for the effects of a single exposure to a high concentration to be latent.

A toxic chemical may induce a graded or a quantum response. A graded response refers to the symptoms shown by an individual, which become progressively more severe as the dose in increased. Exposure to carbon monoxide, for example, results in a set of symptoms of increasing severity. The graded responses for this and other gases are shown in Table 18.3.

A quantum response, on the other hand, refers to the effect of a toxic chemical on a population, in which some individuals suffer the defined injury and others do not. A person either has or does not have mesothelioma from crocidolite (‘blue’) asbestos. In this case it is the proportion of cases in the population that rises with an increasing dose level.

The effects of acute exposure to toxic chemicals include:

(1) irritation –
  (a) respiratory,
  (b) skin,
  (c) eyes;
(3) narcosis;
(4) asphyxiation –
  (a) simple,
  (b) chemical;
(2) systemic damage.

Inhalation of some substances (e.g. chlorine) causes respiratory irritation. This irritation can serve as a warning. There are some chemicals, however, which reach a toxic level before they cause appreciable irritation and thus give no warning.

Some substances (e.g. hydrocarbon vapours) have narcotic effects so that the person’s responses are affected and he may become exposed to an accident. With certain chemicals (e.g. toluene diisocyanate) the effect is that the person becomes euphoric and oblivious of danger so that he is liable to perform hazardous acts.

Gases which act as simple asphyxiants (e.g. nitrogen and helium) merely displace oxygen in the atmosphere so that the concentration falls below that needed to maintain consciousness. But there are also chemical asphyxiants (e.g. carbon monoxide and hydrogen cyanide) that have a specific blocking action and prevent a sufficient supply of oxygen from reaching the tissues.

The effects of chronic exposure to toxic chemicals tend to be induction of injury or disease. One of the most important of these diseases is cancer. Some chemicals induce cancer. In addition to these carcinogens there also mutagens, which induce gene changes, and teratogens, which induce birth defects.

Some chemicals are much more liable than others to accumulate in the body over the long term. Such bioaccumulative chemicals are particularly harmful.

Different toxic chemicals affect different sites in the body. The effect of such chemicals depends on the target organ.

It will be apparent, therefore, that it is difficult to express the toxicity of different chemicals in terms of a common equivalent. Use is sometimes made of the term ‘chlorine equivalent’. This is discussed in the First Report of the ACMH, which makes the following observations:

> Toxicity depends on a number of factors and no simple hard and fast rules can be laid down. The mode of action depends not only on the nature of the chemical but upon the dose received and the time scale of exposure. Strictly speaking the term ‘chlorine equivalent’ can be given relevance only in connection with slow, corrosive irritant chemicals having similar solubility in inhalation. Chemicals such as sulphur dioxide, ammonia, acrolein

Table 18.3 *Effects of different concentrations of some toxic gases*

Gas	*Concentration* (ppm)	*Reference*[a]
Ammonia		
TLV[c]	25	ACGIH
Concentration detectable by odour	20	Matheson
Concentration causing severe irritation of throat, nasal passages and upper nasal tract	400	Matheson
Concentration causing severe eye irritation	700	Matheson
Concentration causing coughing, bronchial spasms, possibly fatal for exposure of less than 30 min	1700	Matheson
Concentration causing oedema, strangulation, asphyxia, fatal almost immediately	5000	Matheson
Carbon monoxide	(%v/v)	
TLV	0.005 (50 ppm)	ACGIH
Concentration inhale for 1 h without appreciable effect	0.04–0.05	Matheson
Concentration causing a just appreciable effect for exposure of 1 h	0.06–0.07	Matheson
Concentration causing unpleasant symptoms but not dangerous for exposure of 1 h	0.1–0.12	Matheson
Concentration dangerous for exposure of 1 h	0.15–0.2	Matheson
Concentration fatal for exposure of less than 1 h	0.4	Matheson
Chlorine		
TLV	1	ACGIH
Minimum concentration detectable by odour	1	*Chlorine Code*
	3.5	Matheson
Maximum concentration inhalable for 1 h without damage	4	Matheson
Minimum concentration causing throat irritation	15	Matheson
Minimum concentration causing coughing	30	Matheson
Concentration dangerous for exposure of 30 min	40–60	Matheson
Concentration probably fatal after a few deep breaths	1000	Matheson
Hydrogen sulfide		
TLV	10	ACGIH
Concentration causing slight symptoms after exposure of several hours	70–150	Matheson
Maximum concentration inhalable for 1 h without serious effects	170–300	Matheson
Concentration dangerous for exposure of 0.5–1 h	400–700	Matheson
Phosgene		
TLV	0.1	ACGIH
Minimum concentration detectable by odour	0.5–2	*Phosgene Code*
	5.6	Matheson
Maximum concentration for exposure of 15 min	1	*Phosgene Code*
Minimum concentration affecting throat	3.1	Matheson
Concentration probably fatal for exposure of 30 min	5	Matheson
Concentration dangerous for exposure of 0.5–1 h	25	Matheson
Concentration rapidly fatal for short [b] exposure	50	*Phosgene Code*
Concentration capable of causing lung injury in 2 mm	167	Matheson

[a] ACGIH–Threshold Limit Values for 1976 (HSE, 1977 EH 15).
Matheson–*Matheson Gas Data Book* (Matheson Company, 1961).
Chlorine Code–Code of Practice for Chemicals with Major Hazards: Chlorine (BCISC, 1975/1).
Phosgene Code–Code of Practice for Chemicals with Major Hazards: Phosgene (CISHC, 1975/3).
[b] Presumably several minutes; this code defines 15 min as a prolonged exposure.
[c] TLV, threshold limit value.

and nitrogen dioxide are all irritant yet have such different sites of action and variable effects as to make even an approximate calculation of a 'chlorine equivalent' difficult. The problem becomes even more difficult when one considers the potential toxicity of chemicals such as carbon monoxide that are not predominantly irritant. Mechanisms of toxicity are almost as varied as the classes of chemical that could be released.

18.2 Toxic Substances

Some factors relevant to toxic substances include:

(1) generation of the substance;
(2) toxic concentrations;
(3) effects of exposure;
(4) detectability by odour;

(5) precautions in handling;
(6) leak detection;
(7) first aid.

Most toxic substances that present a hazard in the chemical industry are chemicals that are deliberately produced, but some are generated as by-products by accident. Carbon monoxide and carbon dioxide are generated by combustion processes either in the process itself or in fires. Nitrogen oxides may be given off in welding. Ultratoxics may arise from side reactions.

The number of chemicals used in industry is very large and grows each year. Various figures have been quoted for the number of chemicals involved. According to Langley (1978) in the decade prior to 1978 approximately 4 million new chemicals had been identified, although at least 75% of these had been cited only once in the literature. Of more practical relevance is the estimate of the UK Chemical Information Centre (UKCIS), also quoted by Langley, that there are some 20,000–30,000 chemicals manufactured in quantities greater than 1 te per annum.

For the number of new chemicals coming into use each year in the United Kingdom at this level of output, Langley gives an estimate of some 300–400. For the United States the annual number of new chemicals has been estimated as about twice this value.

The problems posed by toxic chemicals have generally been perceived primarily in terms of noxious effects resulting from chronic exposure to chemicals that possess a degree of toxicity which has not been appreciated. More recently, there has been increased concern over the threat of large scale acute poisoning from the accidental release of toxic chemicals.

Early instances of the discovery of the noxious properties of substances include those of radium, phosphorus, lead, asbestos and naphthylamines. More recent examples include: polychlorinated biphenyls (PCBs), vinyl chloride and benzene. Even if the toxicity of a particular substance has been established, instances of exposure may still occur.

Some examples of the discovery of toxic effects or of instances of exposure to a substance with known toxic effects that have made impact in the United Kingdom have been given by Pittom (1978) and include:

1965	Bladder cancer from antioxidants (rubber industry)
1972	Lead poisoning (Avonmouth, Isle of Dogs)
1974	Angiosarcoma from vinyl chloride (polyvinyl chloride (PVC) plants)
1975	Asbestos related diseases (Hebden Bridge)
1976	TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) (Seveso)

The dates refer to the years when publicity was at its height.

It is necessary, therefore, to take measures to ensure that the long-term, or chronic, toxic hazard is kept under good control. Of particular importance is the control of exposure to carcinogens. One of the principal means of control is the establishment of exposure limits, or hygiene standards. Over the years these limit values have tended to be reduced, and in some cases the reductions have been dramatic. For example, in the United States the limits for asbestos were reduced over the period 1938–83 as follows (Corn and Corn, 1984): 1938, 30 fibres/cm^3; 1970, 12 fibres/cm^3; 1971, 2 fibres/cm^3; and 1983, 0.5 fibres/cm^3.

There have also been occasional large releases of toxic chemicals of which the escape of methyl isocyanate at Bhopal in 1984 was much the worst. Good control of the acute toxic hazard posed by a large release is equally important.

18.3 Toxicity Assessment

18.3.1 Toxicity data

Comprehensive accounts of occupational health risks involving toxic hazards are given in a number of texts, including the following: Toxicity of Industrial Metals (Browning, n.d.a), Toxicity of Industrial Organic Chemicals (Browning, n.d.b), Industrial Hygiene and Toxicology (Patty, 1948–), with its later edition *Patty's Industrial Hygiene and Toxicology* (Clayton and Clayton, 1991 ACGIH/73); Dangerous Properties of Industrial Materials (Sax 1957–), with its later edition-*Salt's Dangerous Properties of Industrial Materials* (Lewis, 1992 ACGIH/89); *Toxicity and Metabolism of Solvents* (Browning, 1965); *Toxicology of Drugs and Chemicals* (Deichmann and Gerarde, 1969); *Hazards in the Chemical Laboratory* (G.D. Muir, 1971–); *Registry of Toxic Effects of Chemical Substances* 1981–82 (Tatken and Lewis, 1984); *Rapid Guide to Hazardous Chemicals in the Workplace* (Sax and Lewis, 1986), with its later edition (Lewis, 1990 ACGIH/49); *Toxicology: the Basic Science of Poisons* (Casarett and Doull, 1975), with its later edition (Amdur, Doull and Klaassen, 1991, ACGIH/54); *Chemical Hazards in the Workplace* (Scott, 1989 ACGIH/29); *Neurotoxicity Handbook* (Singer, 1990 ACGIH/46); *Chemical Hazards of the Workplace* (Hathaway *et al.*, 1991 ACGIH/55); *Hazardous Chemicals Desk Reference* (Lewis, 1991, ACGIH/60); and *Handbook of Toxic and Hazardous Chemicals and Carcinogens* (Sittig, 1991/ACGIH/59).

The American Conference of Government Industrial Hygienists (ACGIH) and the American Industrial Hygiene Association (AIHA) issue a number of publications on exposure limits for toxic chemicals. These are considered in Section 18.5.

The National Institute for Occupational Safety and Health (NIOSH) issues Criteria Documents for a large number of chemicals and also several other series: *Occupational Hazard Assessments, Joint Occupational Health Recommendations and Special Hazard Reviews*. Other publications include *Occupational Health Guidelines for Chemical Hazards* (NIOSH, 1981/6) and *Pocket Guide to Chemical Hazards* (NIOSH 1990/18). The Occupational Safety and Health Administration (OSHA) also issues the Chemical Information Manual (OSHA, 1991/1).

Chemical Safety Data Sheets on toxic chemicals were formerly issued by the Manufacturing Chemists Association (MCA), but many of these have been withdrawn.

Information on toxicity is given in a number of publications by the Health and Safety Executive (HSE). EH 40/94 *Occupational Exposure Limits 1994* (HSE, 1994) is supported by EH/64 *Occupational Exposure Limits: Criteria Document Summaries* (HSE, 1992). Series relevant to toxicity are the Environmental Hygiene (EH) series, the Medical (MS) series and the Toxicity Review (TR) series.

There are a number of databases for the toxicity of chemicals, many of which are available on computer. They include the following:

CHRIS	Chemical Hazard Response Information System (US Coast Guard)
OHMTADS	Oil and Hazardous Materials Technical Assistance Data System (Environmental Protection Agency (EPA))

RTECS	Registry of Toxic Effects of Chemical Substances (NIOSH)
TOXLINE	National Library of Medicine toxic substances database
HSELINE	HSE toxic substances database

An account of these and other systems is given in Chapter 29.

There is a good deal of guidance available on the handling of individual toxic substances. An early compilation was the Gas Data Book (Matheson Company, 1961). This deals with toxic concentrations, symptoms of exposure, precautions in handling and first aid.

Much relevant information is given in materials safety data sheets (MSDSs), which are described in Chapter 8. There are a number of MSDS compilations. They include Compilation of Safety Data Sheets for Research and Industrial Chemicals (Keith and Walters, 1985–), Chemical Safety Data Sheets (Walsh, 1988, vol. 1; A. Allen, 1988, vols 2–5; Kluwer Publishers, 1992) and Croner's Substances Hazardous to Health (Kellard, 1993).

Other guidance is given in codes such as Codes of Practice for Chemicals with Major Hazards by the Chemical Industries Association (CIA) and in the EH series of the HSE.

The toxicity of chemicals is a field in which, at present, the situation changes particularly rapidly and the importance of seeking the most up-to-date information cannot be too strongly emphasized.

18.3.2 Toxicity testing

Information on toxicity is often incomplete or non-existent. This is not surprising, since the number of chemicals used in industry is so large. Therefore, in some cases it is necessary to conduct tests in order to obtain information on toxicity. Toxicity testing is now a well-established activity which is conducted to ensure safety not only in the manufacture of chemicals but also in the use of food, drugs and cosmetics. General accounts are given by Hemsworth (1974), J.T. Carter (1976) and Neal and Gibson (1984).

Methods that are used to assess toxicity include (1) micro-organism tests and (2) animal experiments. The object of toxicity testing is to obtain quantitative information on toxic effects. The simple classification of substances as 'toxic' or 'non-toxic' is of little value.

Toxicity testing is expensive. According to C.R. Pearson (1982) the cost of the Base Set of tests required under the EEC Sixth Amendment to the Dangerous Substances Directive is £25,000–50,000. Detailed information on cost of specific tests for the United States is given by A.S. West (1986). He also estimates the costs of the EEC Premanufacturing Data Set of tests and of the Level 1 and Level 2 sets as $100,000, $500,000 and several million dollars, respectively.

The assessment of toxicity is a matter for experts. There are a number of organizations which specialize in toxicity testing and assessment, as described below.

18.3.3 Micro-organism tests

Accounts of micro-organism tests are given in In Vitro Toxicity Testing of Environmental Agents (Kolber *et al.* 1983) and by Neal and Gibson (1984). Studies of the effects of chemicals on micro-organisms are used for screening chemicals, particularly for possible carcinogenic, mutagenic or teratogenic effects. Developments in this area include, in particular, the tests used by Ames and co-workers (Ames, 1971).

18.3.4 Animal experiments

The other main type of test is experimentation on animals. This allows the use of the normal techniques of controlled experimentation. Although some earlier work made use of other animals such as monkeys, dogs, cats and rabbits, the animals now almost universally used are mice and rats.

The testing is done according to a strict protocol. The animal is given a fixed dose of chemical or is exposed to a gas of a given concentration for a fixed time and its health is then monitored for a defined observation period. Pathological investigation may also be performed. For certain types of test, such as those on inhalation toxicity, the observation period may be 10–14 days. For other types, such as those on carcinogens, it may extend to 2 or 3 years.

For many tests the objective is to determine the dose or concentration which is lethal to 50% of the animals. This is the lethal dose LD_{50} for an orally administered substance and the lethal concentration LD_{50} for an inhaled gas (see Section 18.11). In the latter case the period of exposure must also be defined. Frequently there is a legislative requirement for the determination of the LD_{50} as an index of toxicity. The corresponding index of aquatic toxicity is the median tolerance limit $TL_m x$, which is the concentration lethal to 50% of the test species for an exposure period of x hours.

There are various problems in the use of animal experiments. The first of these is the ethical problem. For this reason there are increasing pressures to limit such experiments to those for which high priority can be established.

Animal experiments are also both expensive and time-consuming. As already mentioned, experiments on the long-term effects of exposure to low concentrations of chemicals may involve extensive observation periods.

In order to obtain statistically valid results it is necessary to use quite large numbers of animals. This is a problem in almost all instances, but particularly so where the level of risk which is of interest is low. There is then the further problem of interpreting the results obtained and extrapolating them from other species to man.

18.3.5 Epidemiology

Another approach to the assessment of toxicity is epidemiology. Epidemiological studies are based on comparisons of disease or abnormality between the group under study and a control group. This approach is applicable to situations where a number of people have been exposed, often, though not always, over a period of years.

Accounts of epidemiology are given in Medical Record Linkage (Acheson, 1967), *Epidemiology and Disease* (Q.P. Fox, Hall and Elvaback, 1970), *An Introduction to Epidemiology* (Alderson, 1976), *Guide for the Management, Analysis and Interpretation of Occupational Mortality Data* (NIOSH, 1990/19), *Exposure Assessment for Epidemiology and Hazard Control* (Rappaport and Smith, 1991 ACGIH/56), and by Harrington (1980a) and Neal and Gibson (1984).

There have been a number of important epidemiological investigations of toxic substances, including those of radium, β-naphthylamine, lead, asbestos and vinyl chloride.

Epidemiological studies have the great drawback that, by their nature, they yield information on the existence of a toxic effect only after people have fallen victim to it. This drawback is most serious where the effects are latent rather than acute, because in this case even the initiation of control measures cannot prevent disease, due to the backlog of previous exposure. This problem of lag has become much more important as the rate at which new substances are introduced has increased. Despite this, epidemiology is an important tool for toxicity assessment, as evidenced by the number of chemicals that have been identified as noxious by this means.

There are certain methodological problems in the epidemiological approach. One is the difficulty of determining the degree of exposure. In some cases, for example, the best estimate which investigators have been able to make of the level of exposure has been the threshold limit value current in the period concerned. Another difficulty is in defining the control group.

In practice, where a positive correlation is obtained between exposure and disease, this tends to be in cases in which a relatively small number of people have been exposed to quite high concentrations. Conversely, cases where a large number of people have been exposed to low concentrations tend to yield negative results.

The epidemiological approach has certain limitations. It is relatively easy to show a correlation between an agent and a disease, but it may only be possible to establish a causal relation by experiments that cannot normally be justified. Another is that, whereas a rare disease can be detected as a relative excess of the disease among small numbers of people, the demonstration of a common disease as a relative excess requires the investigation of a large population.

The epidemiological method may be modified by investigating not only overt manifestations of the disease but also pre-disease phenomena such as those revealed by urine tests or radiography.

18.3.6 Toxic load

The correlation of toxicity data requires the definition of the toxic load. This is the independent variable in terms of which toxic injury is expressed. Toxic load is thus a form of injury factor.

In the case of an orally administered dose, the toxic load L is simply the dose d:

$$L = d \qquad [18.3.1]$$

In the case of an inhaled gas the toxic load is, in general, some function of concentration c and the time t:

$$L = f(c, t) \qquad [18.3.2]$$

This function may simply be the product

$$L = ct \qquad [18.3.3]$$

but it may alternatively be of the form

$$L = ct^{\mathrm{m}} \qquad [18.3.4]$$

For acute inhalation toxicity of irritant gases the value of m for animals tends to be less than unity and is often of the order of 0.5 (Doe and Milburn, 1983).

18.3.7 Toxic load-response relation

Given the form of the toxic load, a correlation may be sought between the toxic load and the proportion of the population suffering a defined degree of injury. This correlation is the toxic load-response relation. This term is preferred here to the more usual dose-response relation, since toxic load is a more general term than dose.

A distribution that is widely used to correlate data for toxic injury, as for injury of other kinds, is the log-normal distribution. Associated with the log-normal distribution is the probit equation.

A particular problem arises at low levels of toxic load, because the precise relationship between toxic load and the proportion affected is a critical issue in setting exposure limits. Figure 18.1 illustrates two possible relations. With the linear relation A there is no lower limit below which there is no noxious effect, whereas with the sigmoidal relation B, there may be said to be a 'threshold' below which the effect of the toxic load is negligible.

It is frequently difficult to distinguish between these two types of curve and to establish whether there is or is not a threshold. This is the case particularly where the numbers of workers involved are small and the conditions of exposure are variable.

There are relatively few toxic load-response relations established for toxic substances. Apart from those for tobacco, alcohol and certain drugs, Acheson and Gardner (1981) recognize for cancer only two such relations: one for chrysotile asbestos and one for ionizing radiation. The former is that given in the work of Liddell, McDonald and Thomas (1977) in a study of the effect of chrysotile asbestos dust on some 11,000 workers in Quebec, which gives a linear relation passing close to the origin and is interpreted by these authors as indicating no safe threshold.

Further discussions of the toxic-load response are given by C.C. Brown (1984) and Snyder (1984). The latter describes different ways of plotting the load-response curve and gives a number of such curves obtained in animal experiments.

Various equations have been developed for the toxic load-response relations at low levels of toxic load, and statistical methods have been applied to obtain fits to the data. There are deficiencies, however, in a purely statistical approach and it may be more fruitful to support such work with exploration of the toxicokinetics. An example of work on these lines is that of Gehring, Watanabe and Park (1979), who studied the load-response relation for vinyl chloride by modelling the metabolism of the chemical in the body and examining different empirical equations for this relation in the light of the model. A further treatment of the relation

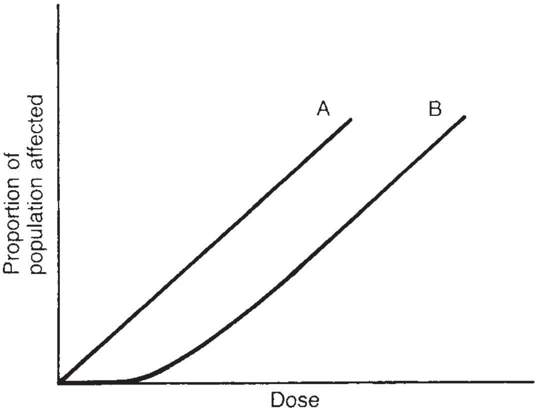

Figure 18.1 *Some idealized load-response relations for quantum response*

between load-response curve and toxicokinetic modelling is given by C.C. Brown (1984).

18.3.8 Toxicokinetic modelling

The unsteady-state modelling of the effects of chemicals in the body is widely practised by pharmacologists, who have developed a number of pharmacokinetic models. The typical model is for a drug which is taken in a single dose. Accounts of such models include those given for E. Nelson (1961), Casarett and Doull (1975), Tuey (1980), Rogers, Specter and Trounce (1981) and Albert (1985).

One of the simplest models is the one-compartment model with finite rate elimination, which is illustrated in Figure 18.2. For this model the two cases commonly treated are the impulse and the step response, the first corresponding to the instantaneous introduction of the chemical and the second to the constant input of the chemical into the body, the prior concentration being zero in both cases. For the first case

$$\frac{dX}{dt} = -k_e X \qquad [18.3.5]$$

with

$$X(0) = D_0 \qquad [18.3.6]$$

where D_0 is the dose of the chemical, k_e is the elimination constant and X is the mass of chemical in the body. For the second case

$$\frac{dX}{dt} = D - k_e X \qquad [18.3.7]$$

where D is the dose rate. The concentration C is given by

$$C = X/V_d \qquad [18.3.8]$$

where V_d is the apparent volume of distribution of the chemical in the body. The chemical is distributed between the bloodstream and other body matter, both aqueous and non-aqueous, and the total effective capacity constitutes the apparent volume of distribution. For elimination after an instantaneous input of the chemical

$$C = C(0)\exp(-k_e t) \qquad [18.3.9]$$

From Equation 18.3.5 the half-life $t_{1/2}$ of the chemical in the body is $0.693/k_e$. Some typical half-lives of drugs in the body, as given by Albert (1985), are aspirin 0.3 h, morphine 3 h, quinidine 6 h, diazepam 50 h and phenobarbital 86 h.

The model describes the variation of concentration with time of the chemical in the body and is based on the assumption that the body has a mechanism for elimination of the chemical. Elimination occurs by metabolism or secretion.

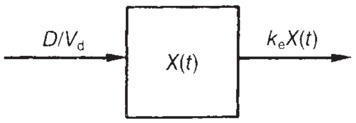

Figure 18.2 *One compartment model of a toxic chemical in the human body*

Similar models may be used to explore toxic effects, and are then termed toxicokinetic models. Toxicokinetic models provide valuable guidance on the interpretation of empirical results, both in applying the results of animal experiments to man and in assessing the shape of the toxic load-response curve at low toxic loads.

18.3.9 Statistical interpretation

Statistical methods have an important part to play in the design and interpretation of animal experiments, in the interpretation of toxic load-response data and in estimating the parameters of correlations.

Accounts of the application of statistics to these problems are given in *The Statistics of Bioassay* (Bliss, 1952) and *Probit Analysis* (Finney, 1971).

For obvious reasons the number of animals, which can be used in gas toxicity experiments has to be kept as low as possible and the statistical interpretation of the results is therefore crucial. It has been shown by Trevan (1927) that for a particular dose–mortality determination the confidence level depends on the number of animals and on the mortality. He applied the binomial expansion

$$(p + q)^N = 1 \qquad [18.3.10]$$

where p and q are the probabilities of death and survival, respectively, and N is the number of animals in the experiment. Then for the distribution

$$\text{Mean} = Np$$

$$\text{Standard deviation } \sigma = (pqN)^{1/2}$$

$$\text{Confidence limits} = Np + z\sigma$$

where z is the number of standard deviations corresponding to the confidence level.

Applying Trevan's method with a 95% confidence level, the results given in Table 18.4 and Figure 18.3 are obtained. It can be seen that for experiments with small numbers of animals the confidence limits for 50% mortality are wide and those for other mortalities such as 25% (or 75%) and 10% (or 90%) they are even wider.

Thus for a given confidence level it is necessary to use more animals to determine an LC_{10} or LC_{90} than an LC_{50}

Table 18.4 *Expected numbers of deaths in experimental animals (Withers and Lees, 1985a; after Trevan, 1972) (Courtesy of Elsevier Science Publishers)*

Mortality (%)	*N*	σ	$z\sigma$	*Np*	*Range*
50	10	1.581	3.099	5	2–8
	20	2.236	4.383	10	6–14
	30	2.739	5.368	15	10–20
	40	3.162	6.198	20	14–26
	50	3.536	6.931	25	18–32
	60	3.873	7.591	30	22–38
	70	4.183	8.199	35	27–43
	80	4.472	8.765	40	31–49
	100	5.000	9.800	50	40–60
25	30	2.372	4.649	7.5	3–12
	100	4.330	8.487	25	17–33
10	30	1.643	3.220	3	0–6
	100	3.000	5.880	10	4–16

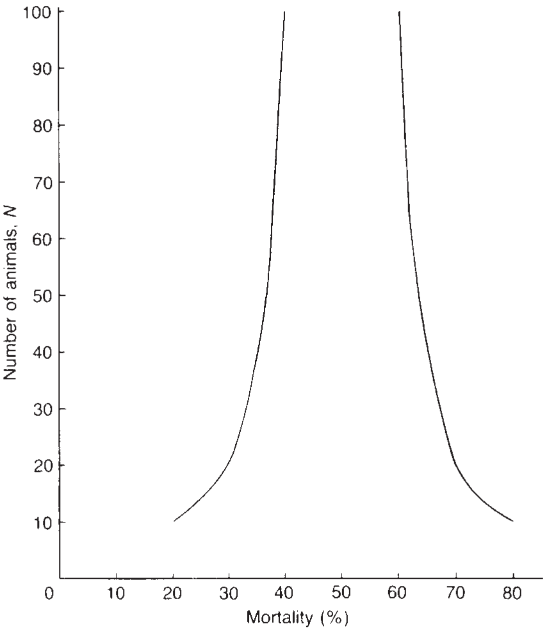

Figure 18.3 *Expected numbers of deaths in experimental animals (Withers and Lees, 1985a; after Treven, 1927) (Courtesy of Elsevier Science Publishers)*

(see Section 18.11). Alternatively, and this is the more usual case experimentally, for a given number of animals the confidence in the LC_{10} and LC_{90} values is less than that in the LC_{50}.

A method widely used for determining the lethal toxicity parameters and confidence limits in a study where groups of animals are exposed to different concentrations for a fixed period is that of Litchfield and Wilcoxson (1949). The method requires information on the numbers of animals and the numbers of concentrations and yields the LC_{50}, the LC_{16} and the LC_{84} and the confidence limits.

18.3.10 Extrapolation between species

The application to man of results from experiments on animals is an area of considerable difficulty and uncertainty. With many substances different species exhibit similar reactions and extrapolation to man may be made. But there are also many examples of different reactions to the same chemical in different species. For example, penicillin causes lethal haemorrhage enteritis in guinea pigs, but is used medically in man, while β-napthylamine, which is carcinogenic to man, does not cause bladder cancer in rats.

Accounts of the principles underlying the extrapolation of empirical results between species are given in *Detoxification Mechanisms* (R.T. Williams, 1959), *Hawk's Physiological Chemistry* (Oser, 1965), *Mammalian Protein Metabolism* (Munro, 1969) and *Drug Metabolism: From Microbe to Man* (Parke and Smith, 1977) and by Freireich *et al.* (1966), S.B. Baker, Tripod and Jacob (1970), Rail (1970), F.J. Miller, Menzel and Coffin (1978), Paddle (1980), Purchase (1980), Oser (1981), Menzel and Smolko (1984) and ten Berge and Zwart (1989).

One general principle is that the toxic effect is likely to be similar only if the target organ is the same in the two species. Another general principle is that what matters is the quantity of the toxin which reaches the target organ, rather than simply the quantity which enters the body. These two principles are applicable in the interpretation of the chronic effects of chemicals such as carcinogens.

The extent to which extrapolation can be made between two species is illustrated by the data given by Purchase (1980). He examined data on 250 chemicals tested for carcinogenicity on rats and mice and found the following results:

126 chemicals positive for cancer in rats; 87% positive for mice also
119 chemicals negative for cancer in rats; 82% negative for mice also
130 chemicals positive for cancer in mice; 84% positive for rats also
115 chemicals negative for cancer in mice: 85% negative for rats also

A widely used rule-of-thumb in toxicology is that if consistent results are obtained for three animal species, they may be treated, with caution, as applicable to humans.

For the inhalation toxicity of irritant gases, the target organ is the respiratory system and the quantity of toxic gas reaching the organ is relatively well defined. In this case the specific loads of toxic gas on the respiratory system of each species may be compared.

18.3.11 Toxic risk assessment

The information obtained from toxicity assessments of the kind just described may be used to make a toxic risk assessment for a particular chemical or plant. There are two rather different kinds of toxic risk assessment. One is the risk assessment undertaken by the regulatory agency in order to determine the precautions to be taken and to set the hygiene limits. The other is that carried out by a manufacturer in order to define the requirements for plant design and operation.

Accounts of toxic risk assessment are given in *Risk Assessment in the Federal Government: Managing the Process* (NAS/NRC, 1983), *Assessment and Management of Chemical Risks* (Rodricks and Tardiff, 1984a), *Toxicological Risk Assessment* (Clayson, Krewski and Munro, 1985), *The Risk Assessment of Environmental Hazards* (Paustenbach, 1989 ACGIH/37) and by Bridges (1985).

The National Academy of Sciences (NAS) report considers toxic risk assessment as involving four stages: (1) hazard identification, (2) dose-response assessment, (3) exposure assessment and (4) risk characterization.

Some of the problems of dose-response, or toxic load-response, assessment have already been considered. Clearly the existence or otherwise of a threshold value below which any noxious effect is negligible is a key issue. The definition of the level of exposure to be expected is also difficult but important. Once the risks have been assessed, they may be evaluated using suitable risk criteria.

In the United States, toxic risk assessment has been used in the setting of hygiene standards. Thus for inorganic arsenic, the OSHA estimated, using a linear dose-response model, that for 1000 workers over a working lifetime there would be 8 excess deaths at a level of 10 mg/m^3, 40 at 50 mg/m^3 and 400 at 500 mg/m^3, and on the basis of this assessment reduced the hygiene standard from 500 to 10 mg/m^3.

In justifying this decision, the OSHA stated

> The level of risk from working a lifetime of exposure at 10 mg/m^3 is estimated at approximately 8 excess lung cancer deaths per 1000 employees. OSHA believes that this level of risk does not appear to be insignificant. It is below risk levels in high-risk occupations but it is above risk levels in occupations with average levels of risk.

18.3.12 Relevant organizations

There are a rather large number of organizations involved in the assessment of toxic hazards, as regulatory bodies, research institutes, industrial groupings and so on. Some of these are listed in Table 18.5. Brief accounts of the function and activities of many of these organizations are given by Deisler (1984b), as shown in the table.

18.4 Control of Toxic Hazard: Regulatory Controls

There is a worldwide trend towards much stricter regulatory control of toxic chemicals. Elements of such control include determination of the properties of the substances, limitation of emissions to the atmosphere, setting of limits for airborne concentrations, monitoring and control of airborne concentrations, monitoring of health of workers and assessment of risk to workers. The legislation in the European Commission, the United Kingdom and the United States on toxic chemicals has been outlined in Chapter 3. This section gives further details.

18.4.1 Control strategies

The control of the chronic toxic hazard needs to be based on a coherent strategy. The outline of such a strategy is given by Lowrance (1984), in a review which is concerned specifically with carcinogens, but which is of wider applicability. He argues that there is need for a framework that allows different risks to be compared and that the approach taken should be more explicit.

18.4.2 Regulatory controls in Europe

In the European Commission, the Sixth Amendment to the Dangerous Substances Directive (79/831/EEC) creates requirements for the notification and testing of new chemicals. Existing chemicals are listed in the European Core Inventory of Existing Substances (ECOIN) and the European Inventory Existing of Commercial Chemical Substances (EINECS).

For new chemicals a manufacturer is required to submit a premarketing notification (PMN). The information required covers the chemical and its chemical and physical properties, the health effects, the ecological effects, the production volume and major uses, and the storage, transport and ultimate disposal. The level of manufacture that attracts notification is 1 te per annum. Intermediates for use only on site and polymers are excluded from the notification requirements. The inventory of chemicals is a static one. A manufacturer of a chemical must notify a new chemical that is not on the list, even if this has already been done by another manufacturer.

The information required on the properties of the chemical was originally defined in the Base Set given in the Sixth Amendment and subsequently specified in the minimum premarketing data (MPD) set shown in Table 18.6.

For chemicals to be manufactured in quantities larger than 1 te per annum further tests are required. The trigger levels are:

The Level 1 and Level 2 sets comprise further toxicology and ecotoxicology tests.

Accounts of the Sixth Amendment have been given by Langley (1978), C.R. Pearson (1982) and A.S. West (1986). An account by Rijkels (1984) on the control of carcinogens in Europe gives additional background. Further directives cover exposure to toxic chemicals (89/677/EEC) and carcinogens (90/394/EEC).

18.4.3 Regulatory controls in the United Kingdom

In the United Kingdom, the control of toxic substances has been primarily through the Health and Safety at Work etc. Act 1974 (HSWA) with the HSE as the enforcing authority. In particular, these arrangements have applied to control of toxic substances in the workplace and to hygiene standards.

The EC Sixth Amendment is implemented by the Notification of New Substances Regulations 1982. The requirements are essentially as described in the previous section.

Exotoxicity data	
Fish acute toxicity	Degradation (biotic and abiotic)
Daphnia toxicity	

An account of the background to these regulations has been given by C.R. Pearson (1982).

The Control of Substances Hazardous to Health Regulations 1988 (COSHH) creates a comprehensive system of controls. HSE guidance is given in an associated ACOP L5 Control of Substances Hazardous to Health and Control of Carcinogenic Substances (HSE, 1988). The occupational exposure limits (OELs) are given in EH 40/94 *Occupational Exposure Limits 1994* (HSE, 1994). The COSHH Regulations cover carcinogens and dusts. HSE guidance on carcinogens is given in the ACOP L5, as just described.

There are also regulations dealing with certain specific substances. They include the Lead at Work Regulations 1980 and the Control of Asbestos Regulations (CAWR) 1987. These are described below. More detailed accounts of the COSHH Regulations and the CAWR are given in Chapter 25.

The control of plants with major inventories of toxic chemical is exercised under the Control of Major Accident Hazards (CIMAH), Regulations 1984 as described in Chapters 3 and 4.

Requirements for the reporting of toxic releases are given in the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1985 (RIDDOR), as described in Chapter 3.

18.4.4 Regulatory controls in the United States

In the United States, the OSHA has responsibility for the control of toxic substances in the workplace. It promulgates and enforces hygiene standards under the Occupational Safety and Health Act 1970. The OSHA may adopt by administrative action any health and safety standards in federal legislation or in codes or guidelines produced by consensus groups. It has in fact adopted various American National Standards Institute (ANSI) standards and many ACGIH threshold limit values (TLVs).

The OHSA issues Permanent Health Standards. The list of standards, as of 1983, is shown in Table 18.7.

The Toxic Substances Control Act (TSCA) 1976 provides a framework for the control of toxic chemicals in manufacture and transport. The enforcing authority is the EPA, which has extensive duties and powers under the act. The TSCA has been described in a series of papers by A.S. West (1979, 1982, 1986).

The TSCA lays down requirements for the notification of new chemicals, and is in this respect the equivalent of the EC Sixth Amendment, but it also contains requirements for existing chemicals. Some principal sections of the TSCA are listed in Table 18.8. Existing chemicals are listed in the TSCA Chemical Substance Inventory (EPA, Office of Toxic Substances, 1979, 1982).

For new chemicals a manufacturer is required under Section 5 to submit a premanufacture notice (PMN). The information required covers the chemical, the health effects, the exposure of workers, the major uses and production

Table 18.7 *OSHA Permanent Health Standards 1983*[a]

	8(a) Reporting on existing chemical substances
	8(e) Notice of substantial risks

volumes, the by-products and the ultimate disposal of the main product and by-products. There is no requirement for a base set of toxicity data, but an assessment is required of the health risk.

Notification is attracted at any level of manufacture. Intermediates used only on site are included, as are polymers, with some exceptions, but chemicals in research and development are excluded. Once a chemical has been notified by a single manufacturer, it is added to the TSCA Inventory, which is therefore a dynamic inventory.

While the TSCA is broadly similar to the Sixth Amendment, there are some important differences. The TSCA covers existing as well as new chemicals and it has no threshold level for notification, but there is no requirement for a base set of toxicity data and the inventory of chemicals is dynamic. Detailed comparisons are given by Doyal and Epstein (1983) and A.S. West (1986).

Under Section 4 of the TSCA the EPA is both empowered and required to initiate toxicity testing of existing chemicals. Recommendations for such testing are made by the Interagency Testing Committee (ITC), which issues periodic lists. The EPA is required to initiate testing or show cause why it has not done so, and it also issues periodic lists of chemicals for priority testing.

The factors which the EPA is required to take into account in regulating a chemical and in establishing a rule for testing a chemical are specified in Section 6 of the TSCA and are listed in Table 18.9, Sections A and B, respectively.

There have been a number of important legal cases that have influenced the control of toxic chemicals in the United States. The Delaney Amendment to the Federal Food, Drug and Cosmetic Act in 1958 banned the deliberate addition to food of any additive that is carcinogenic as determined from animal experiments or human response. This absolute requirement was subsequently modified on appeal to the effect that the Food and Drug Administration (FDA) was not required to bar containers in which very small amounts of a carcinogen, actually acrylonitrile monomer, were liable to migrate into the food.

In 1977, the OSHA promulgated an Emergency Temporary Standard for benzene, followed by a permanent rule, after an epidemiological study that seemed to show that benzene was more toxic than previously supposed. In the Benzene Case (Industrial Union Department vs American Petroleum Institute) in 1980, the Supreme Court set aside the benzene standard and ruled that the OSHA could not adopt a standard unless it finds both that there is a significant risk and that the standard will significantly reduce that risk.

The Formaldehyde Case (Gulf South Insulation vs United States Consumer Product Safety Commission) in 1983 involved a ban by the Consumer Product Safety Commission (CPSC) on urea formaldehyde foam insulation in homes and schools. The case centred on the interpretation of epidemiological data. The court took the view that the methodology and data used in extrapolating to low exposure levels were unsatisfactory and did not meet the substantial evidence criterion.

The control of major chemical hazards is exercised through Title III of the Superfund Amendments and Reauthorization Act (SARA) 1988, enforced by the EPA, as described in Chapters 3 and 4. SARA Title III, Section 6, requires the EPA to create a toxic chemicals inventory, the toxic release inventory (TRI).

These and other developments in the control of toxic chemicals in the United States may be followed through the references given in Table A1.4.

18.5 Hygiene Standards

There are two main types of toxic limit. For exposure over a working lifetime there are hygiene standards in the form of OELs, whilst for emergency exposure there are emergency exposure limits. Occupational hygiene standards are considered in this section and in Section 18.7, and emergency exposure limits are considered in Section 18.10.

Three principal sets of occupational hygiene standards are the TLVs used in the United States, the OELs used in the United Kingdom and the MAK-Werte used in Germany.

18.5.1 US threshold limit value system

A set of threshold limit values (TLVs) is published in the United States by the ACGIH. The TLV system is widely used, not only in the United States but also in many other countries.

The US TLVs are given in the *Threshold Limit Values and Biological Exposure Indices 1992–1993* (ACGIH, 1992/80). Other related documents are the *Guide to Occupational Exposure Values* – 1992 (ACGIH, 1992/78), which also gives the German MAK-Werte; *Documentation of Threshold Limit Values and Biological Exposure Indices* (ACGIH/3); and *Documentation for the Biological Exposure Indices* (ACGIH/1).

There are a number of critiques of the TLV system, including that by Doyal and Epstein (1983).

18.5.2 Former UK TLV system

As far as concerns the limits for workplace exposure to toxic chemicals in the United Kingdom, for many years use was made of a modified version of the US TLV system. This replaced an earlier system based on maximum allowable concentrations (MACs). In 1980, the United Kingdom moved to a system of OELs. The latter system is described in the following section.

Since the TLV system has now been superseded, it is not appropriate to give a detailed description here. On the other hand, the TLV system is referred to frequently in the literature and is still in widespread use in many countries. The general nature of the system is indicated by the following information taken from EH 15 TLVs for 1976 (HSE, 1977).

In order to avoid misuse, the nature and limitations of TLVs need be appreciated. Some principal features are:

(1) a TLV is not a sharp dividing line between 'safe' and hazardous concentrations;

Table 18.9 *Factors to be considered by EPA under the Toxic Substances Control Act 1976 in regulating and in establishing a rule for testing a chemical*

A Regulation of a chemical

1 Effects on health and magnitude of exposure of human beings
2 Effects on the environment and magnitude of exposure of the environment
3 Benefits of various uses and the availability of substitutes for each use
4 Reasonably ascertainable economic consequences of regulation after consideration of the effect on the national economy, small business, technological innovation, the environment and public health

B Rule for testing a chemical

1 The relative costs of the various test protocols and methodologies
2 The reasonably foreseeable availability of facilities and personnel to perform such tests

Health and environmental effects for which standards for development for test data may be prescribed include:

1 Carcinogenesis
2 Mutagenesis
3 Teratogenesis
4 Behaviour disorders
5 Cumulative or synergistic effects
6 Any other effect related to unreasonable risk of injury to health or the environment

Characteristics for which standards may be prescribed include:

1 Persistence
2 Acute toxicity
3 Subacute toxicity
4 Chronic toxicity
5 Any other characteristic which may present such a risk

(2) the absence of a substance from the list does not mean that it is necessarily safe;
(3) the best practice is to keep the concentration of a substance in the atmosphere to a minimum, regardless of whether it is known to present a hazard and whatever the value of the TLV;
(4) the application of a TLV to a particular case is a specialist matter.

There are three categories of TLV: (1) threshold limit value, time-weighted average (TLV-TWA); (2) threshold limit value short-term exposure limit (TLV-STEL) and (3) threshold limit value-ceiling (TLV-C).

The TLV-TWA is the time-weighted average (TWA) concentration for a normal 8-h workday or 40-h workweek to which nearly all workers may be repeatedly exposed, day after day, without adverse effect. Excursions above the limit are allowed, provided they are compensated by other excursions below the limit. There is also a limit on the maximum concentration. In some cases it may be permissible to use the average concentration over a workweek rather than over a workday.

The TLV-STEL is the maximum concentration to which workers can be exposed for a period of 15 min continuously without suffering from (1) intolerable irritation, (2) chronic or irreversible tissue change, or (3) narcosis of sufficient degree to increase accident proneness, impair self-rescue or materially reduce work efficiency, provided that no more than four excursions per day are permitted, with at least 60 min between exposure periods, and provided that the daily TLV-TWA is not exceeded.

The TLV-C is the concentration that should not be exceeded even instantaneously. Substances that are given a TLV-C are those that are predominantly fast-acting and require a limit related to this aspect.

The TLVs on the list are expressed in two units: ppm (parts of gas or vapour per million parts of contaminated air at 25°C and 760 mmHg) and mg/m^3 (milligrams of substance per cubic metre of air). For particulate materials the unit is mppcf (millions of particles per cubic foot of air).

TLVs are based on the best available information from industrial experience and from experimental studies of humans and animals and, where possible, from all three. The basis of the values thus varies. In some cases it is freedom from irritation, narcosis or other stress, in others it is the absence of effects impairing health.

The limits based on physical irritation should be regarded as equally binding as those based on health impairment, since there is increasing evidence that irritation can initiate or promote impairment.

There is a wide variation in the susceptibility of individuals to low levels of airborne contaminants. A small proportion may be seriously affected.

The nature and amount of information on which a TLV is based varies widely and the degree of confidence that can be placed in a particular TLV is therefore variable.

TLVs are intended for use in industrial hygiene and their interpretation is a specialist matter. They should not be used or adapted for other purposes, in particular not (1) as a relative index of toxicity, (2) for air pollution work or (3) for the assessment of toxic hazard from a continuous, uninterrupted exposure. They should also not be used as proof or disproof of an existing disease or physical condition or in countries where working conditions differ substantially from those in the United States.

The use of a TLV implies that there must be a system for monitoring the concentration of the substance in the air and that the measurements must be, if not continuous, at least frequent enough for the purpose.

In addition to giving TLVs, EH15 also deals with the following:

(1) skin effects;
(2) mineral dusts;
(3) nuisance particulates;
(4) simple asphyxiants;
(5) carcinogens.

18.5.3 Other OSHA limits

There are a number of other limit values. Some that are used by the OSHA include:

STEL Short-term exposure limit: maximum exposure concentration for a period of exposure less than a workshift.
MAC Maximum acceptable ceiling: maximum exposure concentration regardless of period of exposure.
PEL Permissible exposure limit: applied variously to the TLV, STEL or MAC.
AL Action level: one-half the PEL; the concentration below which additional measurements of the same exposure will probably not exceed the PEL.

18.5.4 MAK-Werte limit system

The German system of hygiene standards is the MAK-Werte system. As stated above, values of the MAK-Werte are included in *Guide to Occupational Exposure Values – 1992* (ACGIH, 1992/78). The MAK-Werte and also the Technische Richtskonzentrazionen (TRK) systems are described by Rijkels (1984).

18.5.5 International exposure limits

An international set of OELs are the *Occupational Exposure Limits for Airborne Toxic Substances*, published by the International Labour office (ILO, 1991/2).

As already mentioned, many countries use the US TLV system, with or without modifications. An account of the limits adopted is given in *Occupational Exposure Limits – Worldwide* (Cook, 1987, AIHA/12).

18.6 Hygiene Standards: Occupational Exposure Limits

The system of OELs now used in the United Kingdom is described, as stated above, in EH 40/94 *Occupational Exposure Limits* 1994 (HSE, 1994). Two sets of limits are used. These are (1) the maximum exposure limits (MELs) and (2) the occupational exposure standards (OESs). The difference between these two types of limit is that, whereas an OES is set at a level at which there is no indication of risk to health, for an MEL a residual risk may exist.

These OELs are to be viewed in the context of the regulations governing occupational health, specifically the COSHH Regulations 1988 and the accompanying Approved Code of Practice ACOP L5 Control of Substances Hazardous to Health and Control of Carcinogenic Substances (HSE, 1988). These regulations are discussed in detail in Chapter 25, the discussion here being confined to the OELs themselves.

18.6.1 Maximum exposure limits

A MEL is the maximum concentration, averaged over a reference period, to which an employee may be exposed by inhalation in any circumstances. MELs are listed in Schedule 1 of the COSHH Regulations 1988 and also in EH 40/94, which also give the reference periods.

There are two reference periods, a long-term period and a short-term period. The long-term period is an 8-h TWA period. The short-term period given in EH 40/94 is 15 min. This is a recent change from a previous value of 10 min. Selected values of the MEL from EH 40/94 are given in Table 18.10, Section A.

18.6.2 Occupational exposure standards

As already stated, an OES is a concentration at which there is no indication of risk to health. OESs are listed in EH 40/94, which is referred to in the COSHH Regulations as the list of Approved OESs. The reference periods are the same as for the MELs, the long-term one being an 8-h TWA and the short-term one being 15 min. Selected values of the OES from EH 40/94 are given in Table 18.10, Section B.

18.6.3 Occupational exposure limit system

Maximum exposure limits and OESs are set by the HSC on the recommendations of the ACTS, following assessment by the Working Group on the Assessment of Toxic Chemicals (WATCH).

A substance is assigned an OES if it meets all three of the following criteria:

Criterion 1: the available scientific evidence allows for the identification, with reasonable certainty, of a concentration averaged over a reference period, at which there is no indication that the substance is likely to be injurious to employees if they are exposed by inhalation day after day to that concentration; and
Criterion 2: exposure to concentrations higher than that derived under criterion 1 and which could reasonably occur in practice, are unlikely to produce serious shorter long-term effects on health over the period of time it might reasonably take to identify and remedy the cause of excessive exposure; and
Criterion 3: the available evidence indicates that compliance with the OES, as derived under criterion 1, is reasonably practicable.

A substance is assigned an MEL if it meets either of the following criteria:

Criterion 4: the available evidence on the substance does not satisfy criterion 1 and/or 2 for an OES and exposure to the substance has, or is liable to have, serious health implications for workers; or
Criterion 5: socio-economic factors indicate that although the substance meets criteria 1 and 2 for an OES, a numerically higher value is necessary if the controls associated with certain uses are to be regarded as reasonably practicable.

The setting of an OES proceeds, in principle, by identifying the critical health effect, determining a no observable adverse effect level (NOAEL) and determining a limit. Generally the data available are from animal experiments, and judgement has to be exercised with respect to confidence levels and extrapolations.

A substance is assigned an MEL only if there are serious health implications for workers, which may be serious effects for a small number of workers or less serious effects for a large number. Most substances to which MELs have

[a] Sk, can be absorbed through the skin.
[b] Sen, capable of causing respiratory sensitization. The identified substances are those which: (1) are assigned the risk phrase R42: 'may cause sensitization by inhalation' in Part IA1 of the Approved List; (2) are listed under the Social Security Act 1975 or Schedule 2 of the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1985 in connection with prescribed or reportable diseases, respectively.
[c] Vinyl chloride is also subject to an overriding MEL of 3 ppm, as described in EH 40.
[d] Ethane-1,2-diol.
[e] Propan-2-ol.
[f] Liquefied petroleum gas.
[g] Proposed change for 1995 is a long-term OES of 0.02 ppm (0.08 mg/m3) and a short-term OES of 0.06 ppm (0.25 mg/m^3).

been assigned are carcinogens or chemicals for which no threshold of effect can be identified and for which there is doubt about the seriousness of exposure.

In setting OESs account is taken of the indicative limit values given in EC Directive 91/332/EEC.

Synopses of the data used in setting limits are given in EH 64 *Occupational Exposure Limits: Criteria Document Summaries* (HSE, 1992), which is updated annually.

The units of measurement for OELs are as follows: for gases and vapours in air, either ppm or mg/m^3; for airborne particles (fume, dust, etc.), mg/m^3; and for fibres, either mg/m^3 or fibres/ml. For dusts, limits are given as 'total inhalable' fraction unless specified as 'respirable' fraction.

The treatment of substances assigned an MEL under the COSHH Regulations, specifically Regulation 7(4), differs from that of those assigned an OES.

The lists of OESs and MELs are updated annually in EH 40. This publication also includes a table of new or revised entries in the list and a table showing substances which are under review.

18.6.4 Long- and short-term exposure limits

The basic OEL is the long-term, 8-h TWA limit, which is intended to control effects caused by prolonged or accumulated exposure. Where a substance has effects which occur after only a brief exposure, a short-term, usually 15-min, limit is applied. Some substances have only a long-term limit, others have both a long-term and a short-term limit, and others again have only a short-term limit. Where a substance is governed by both types of limit, the short-term limit restricts the extent of any excursion above the average concentration during longer exposures. Where there is no short-term limit, EH 40 recommends that short-term excursions should not exceed three times the long-term limit. For some substances the effects of a brief exposure may be critical, and for these a short-term limit is used; a separate long-term limit is considered unnecessary and the short-term limit is applied throughout the shift. The period to which the limits apply are termed the reference periods, the periods being, as stated, 8 h and 15 min for long- and short-term limits, respectively.

18.6.5 Application of occupational exposure limits

An MEL is a maximum limit. The long-term, 8-h limit attracts requirements for monitoring under the COSHH Regulations, unless an assessment shows such monitoring to be unnecessary. The Regulations also require that the exposure of personnel be kept as far below this level as reasonably practicable. The short-term, 15-min, MEL should never be exceeded.

Control to or below an OES can always be regarded as adequate under the COSHH Regulations. However, it is still incumbent on the occupier to follow good occupational hygiene practice and it is prudent to reduce exposure below the OES to allow for concentration fluctuations in the workplace. There are certain circumstances in which control may still be deemed adequate even if an OES is exceeded; these are described in Chapter 25.

18.6.6 Limitations of occupational exposure limits

Occupational exposure limits are intended to be used for normal working conditions in factories and other workplaces. Their application is not to be extended to other situations, and specifically they should not be used as limits either for emergencies or for pollution.

18.6.7 Mixed exposures

The majority of OELs are for individual substances, although a few relate to complex mixtures such as white spirit. In some situations workers are exposed to a mixture of substances. In some instances, an OEL for a mixture may be already established. In this case it can be used, but should it not be extrapolated to situations where the concentrations are different.

For mixtures, three different situations are recognized: (1) synergistic substances, where the presence of one substance causes another to produce a much greater toxic effect; (2) additive substances, where the effects of the substances are additive and (3) individual substances, where there are no known or likely synergistic or additive effects.

Synergistic effects may arise because one substance enhances the toxicity of another, or because it potentiates the other, causing it to act in a qualitatively different way. Where effects are additive, EH 40 gives the following formula for the overall OEL:

$$L = \sum_{i=1}^{n} \frac{C_i}{L_i} \quad L<1 \tag{18.6.1}$$

where C_i is the TWA of the ith component, L_i its OEL and L the overall OEL. Where effects are individual, it is sufficient to comply with each OEL separately.

It will be apparent that in many situations involving mixtures expert advice is required.

18.6.8 Skin effects

For certain substances there exists the hazard of absorption through the skin as well as by inhalation. EH 40 uses the skin notation 'Sk' against the substance in the lists. For these substances special precautions should be taken to prevent skin contact.

18.6.9 Sensitizer effects

Certain substances act as sensitizers in that they may cause sensitization of the respiratory tract if inhaled or of the skin if contact occurs. Respiratory sensitizers can cause asthma and other conditions, skin sensitizers cause allergic contact dermatitis. Individuals exposed may react even to minute amounts of the sensitizing substances. EH 40 uses the sensitizer notation 'Sen' against substances in the lists that are in certain defined categories and which have been identified as respiratory sensitizers. For these substances particular care should be taken to minimize airborne concentrations and to prevent their spread to other areas.

18.6.10 Asphyxiants

Some gases and vapours act as simple asphyxiants. They are hazardous insofar as they may reduce the oxygen content in the workplace. They include acetylene, argon, ethane, ethylene, helium, hydrogen, nitrogen, propane and propylene. Many of these substances are colourless and odourless and are thus not readily detected.

As the list just given shows, many asphyxiants are also flammable, and the concentration at which they present a fire or explosion hazard (the lower flammability limit) is generally lower than that at which they cause asphyxiation. It may be noted that many hydrocarbons are not classed as simple asphyxiants, but have an OEL value. Butane is one example.

Asphyxiants do not rank as substances hazardous to health for the purposes of the COSHH Regulations.

18.6.11 Carcinogens

As described earlier, some carcinogenic substances are prohibited. Other substances that have or may have carcinogenic potential are listed in Appendix 9 of EH 40/ 94 and are assigned the 'Risk phrase' 'R45; may cause cancer' in the current edition of the *Authorised and Approved*

List: Information Approved for the Classification, Packaging and Labelling of Dangerous Substances for Supply and Conveyance by Road (the Approved List).

Some substances listed in EH 40/94, Appendix 9, and assigned the 'Risk phrase' are given an MEL. They include acrylonitrile, benzene, ethylene oxide and vinyl chloride. Other substances are simply listed in the appendix.

Guidance on carcinogens under the COSHH Regulations is given in the second of the two ACOPs in L5 Control of Substances Hazardous to Health and Control of Carcinogenic Substances (HSE, 1988).

18.6.12 Dusts

For dusts a distinction is made between 'total inhalable dust' and 'respirable dust'. The former approximates to the fraction of the airborne material that enters the mouth and nose during breathing and is therefore available for deposition in the respiratory tract. The latter refers to the fraction that penetrates to the gas exchange region of the lung. Details are given in MDHS 14 *General Method for the Gravimetric Determination of Respirable and Total Inhalable* Dust (HSE, 1989). Some dusts are assigned an OEL. EH 40/94 gives OELs for a number of dusts, including grain dust and silica (crystalline), which have an MEL, and emery, graphite, limestone, silica (amorphous) and starch, which have an OES. Dust of crystalline silica, or quartz, is of particular importance as the cause of silicosis and attracts a low OEL. It has a long-term MEL for the respirable dust of 0.4 mg/m^3.

The former TLV system used in the United Kingdom identified some dusts as toxic and assigned a TLV, but treated other dusts as nuisance dusts, which were not considered toxic, although they could be unpleasant to breathe and could cause irritation by abrasive action.

In the current system there are dusts that do not attract an OEL. EH 40/94 states that in the absence of a specific limit and of any indication for the need for a lower limit, exposure should be controlled below 10 mg/m^3 for an 8-h TWA. A concentration at this level or above is to be taken as a 'substantial concentration' for the purposes of Regulation 2 of the COSHH Regulations and as rendering the dust a substance hazardous to health under those regulations.

18.6.13 Asbestos

Asbestos is controlled by the CAWR 1987. It is considered in Section 18.8.

18.6.14 Lead

Lead is controlled by the Control of Lead at Work Regulations 1980, which is complemented by COP2 Control of Lead at Work (HSE, 1985). The lead-in-air standards given in this ACOP, and in EH 40/94, are as follows. The 8-h TWA (as Pb) is 0.15 mg/m^3 for lead and lead compounds other than tetraethyl lead, and 0.10 mg/m^3 for tetraethyl lead.

18.6.15 Working conditions

In applying OELs regard should be had to working conditions that may impose additional stress and may enhance toxic effects. These include exposure to high temperature, high humidity or UV radiation.

18.7 Carcinogens

18.7.1 Cancer risk

There are a number of accounts of the contribution of cancer to mortality. They include *The Causes of Cancer* (Doll and Peto, 1981) and other treatments by Doll (1979), Peto (1979), A.E.M. (McLean 1979) and (Higginson 1984).

As infectious diseases have declined as a cause of death, the proportion of deaths attributable to cancer has tended to rise. Cancer is now a major cause of death. In developing countries it accounts for some 20% or more of deaths. This is also the case for the United Kingdom and the United States. The numbers of people who die of cancer are therefore large. In 1980, in England and Wales, the number of deaths from cancer was 130,000 and the proportion 22%. In 1977, cancer caused 382,000 deaths in the United States.

The factors that cause cancer are physical, biological and cultural as well as chemical. Two of the principal factors are cultural. One of these is smoking, which is perhaps the most generally accepted major cause of cancer. There is also strong evidence that diet is another major cause. Estimates of the proportions of avoidable cancers given by Higginson and Muir (1979) in a case study done in England are given in Table 18.11, together with figures quoted by Doll and Peto (1981) in a study done in the United States.

The trend in cancer mortality has been reviewed by Doll (1979), who found that over the 40-year period 1931–35 to 1971–75, for 26 sites in the male body and 28 sites in the female body, the age standardized mortality at 45–64 years of age showed less than 1% variation at 25 sites, a progressive decrease of more than 1% at 16 sites and a progressive increase of more than 1% at 13 sites. He concludes that where increases in cancer rates have occurred this is due mainly to personal and dietary habits rather than to exposure to chemicals.

The proportion of cancer deaths that are attributable to occupational exposure, that includes exposure to chemicals at work, is estimated by many authorities as about 5%. In this respect the estimates given in Table 18.12 are typical. A review of these estimates has been given by Corn and Corn (1984).

This view is strongly disputed by certain workers, who believe that the contribution of chemicals, in the workplace, in food and in the environment, is underestimated by 'establishment' workers, and they represent a 'radical' view. Statements of this viewpoint are given in *The Politics of Cancer* (S.S. Epstein, 1978) and *Cancer In Britain. The Politics of Prevention* (Doyal and Epstein, 1983). It is argued by these workers that exposure to chemicals may account for some 40% of cancer deaths.

Table 18.11 *Estimates of the proportion of avoidable cancers[a] (after Higginson and Muir, 1979)*

Feature	Proportion of avoidable deaths (%)	
	Male	Female
Tobacco	30	7
Alcohol	5	3
Life-style	30	63
Occupation	6	2
Iatrogenic	1	1
Geophysical	11	11
Congential	2	2
Unknown	15	11

[a] Figures given by Doll and Peto (1981) for the United States include the following proportions for both sexes: tobacco 30%; alcohol 3%; life-style 42%; infection 10%; and occupation 4%.

Table 18.12 *Estimates of cancer deaths attributable to occupational exposure (after US Congress, Office of Technology Assessment, 1981)*

	Preferred estimate (%)	*Period to which estimate applies*	*Reference*
Male incidence, USA	4	1976	Wynder and Gori (1977)
Female incidence, USA	2	1976	
Male cancer, England	6	1968–72	Higginson and Muir (1979)
Female cancer, England	2	1968–72	
Male mortality, USA	6.8	1977	Doll and Peto (1981)
Female mortality, USA	1.2	1977	

These critics (e.g. S.S. Epstein, 1978) argue that there is a tendency to estimate the proportion of cancers attributable to chemicals as the residue remaining after estimates have been made of those attributable to other causes and that this approach is unsound. On the other hand, it is argued (e.g. Peto, 1980) against these critics that they tend to make their estimates of potential cancer mortality from a particular chemical by combining the numbers exposed to any level of the chemical with the risk attributable to persons exposed to very high levels.

The authors of the *Health and Safety Statistics* 1990–91 (HSE, 1992b) discuss the number of premature deaths from cancer. On the basis of the work of Doll and Peto it might be estimated that about 4% of cancers are work-related, which would give some 5000 premature deaths. A death from cancer might be avoided by the removal of any one of a number of contributing factors, of which workplace exposure is only one. The only hard statistics given are that there were some 78 cases of awards for occupational cancer other than mesothelioma (from asbestos).

18.7.2 Regulatory controls in Europe

The Sixth Amendment to the EC Directive on Dangerous Substances (79/831/EEC) creates controls on the introduction of new chemicals and thus of potential carcinogens. There is, in addition, a specific Directive that deals with carcinogens (90/394/EEC).

There is also an ILO Convention on Carcinogenic Substances and Agents. An account of the European arrangements for the regulation of carcinogens is given by Rijkels (1984).

18.7.3 Regulatory controls in the United Kingdom

The Carcinogenic Substances Regulations 1967 prohibit the use of certain human carcinogens and the Carcinogenic Substances (Prohibition of Importation) Order 1967 prohibit their importation.

As stated earlier, the COSHH Regulations 1988 cover carcinogens. HSE guidance is given in the associated ACOP L5 Control of Substances Hazardous to Health and Control of Carcinogenic Substances (HSE, 1988). The OELS are given in EH 40/94 *Occupational Exposure Limits 1994* (HSE, 1994). Carcinogens are one of the categories of substance given in the MEL list.

The control of one particular important carcinogen, asbestos, is effected through the CAWR 1987.

18.7.4 Regulatory controls in the United States

In the United States the framework legislation for the control of carcinogens, as for other toxic chemicals, is the Occupational Safety and Health Act 1970 administered by OSHA, but other legislation of particular relevance is the TSCA 1976 administered by the EPA. The control of carcinogens in the workplace is effected through the system of standards set by the OSHA.

The standards that may now be adopted are constrained by the results of the Benzene Case and the Formaldehyde Case, described above. Between 1977 and 1980, the OSHA attempted in the document *Identification, Classification and Regulation of Occupational Carcinogens* (OSHA, 1977) to set a generic standard for carcinogens. The Benzene Case increased the difficulty of creating such a standard and a generic standard was not adopted.

18.7.5 Carcinogenic chemicals

Some information on the toxicity of carcinogens is given in works on the toxicity of chemicals in general, of which carcinogenic chemicals are a subset, but there are also a number of specific treatments. Accounts of carcinogenic substances are given in *Cancer Causing Chemicals* (Sax, 1981), *Carcinogenically Active Chemicals: A Reference Guide* (Lewis, 1991 ACGIH/53) and *Handbook of Toxic and Hazardous Chemicals and Carcinogens* (Sittig, 1991 ACGIH/59).

The identification of chemicals that are carcinogenic is one of the main tasks of the International Agency for Research on Cancer (IARC). By 1979 the IARC (1979a) had identified 16 chemicals and industrial processes, as well as soot and vinyl chloride, for which there is sufficient epidemiological evidence to indicate a link between exposure and excess cancer in man. It has also identified a further 18 chemicals which the epidemiological evidence indicates as being probable human carcinogens.

According to Corn and Corn (1984), there are some 350 chemicals that are suspected of being human carcinogens. A list of carcinogens regulated by the OSHA for airborne concentrations in 1980 is given in Table 18.13.

18.7.6 Benzene

Benzene is an important chemical in the petroleum and petrochemical industries and the numbers of people who have been exposed to it in some degree is large. For many years it was regarded as not particularly toxic. The attitude to exposure both in industry and in laboratories was relatively relaxed. More recently the long-term effects of benzene on the blood and bone marrow and its carcinogenic properties have been better appreciated and the hygiene limits have been greatly reduced.

Reviews of toxicity are given in Criteria Document Publ. 74–137 *Benzene* (NIOSH, 1974), *TR 4 Toxicity Review: Benzene* (HSE, 1982), *Benzene: Occupational and Environmental Hazards* (Mehlman, 1989 ACGIH/28) and EH 64

Soots, tars, and mineral oils
Vinyl chloride[a]

[a] Permanent standards promulgated after Administrative Procedures Act rule-making.
[b] From the ANSI list.

Occupational Exposure Limits: Criteria Document Summaries (HSE, 1992).

The development of controls on benzene is described by Thorpe (1978a,b) and by Barnard (1984). The following extracts from a table by Thorpe (1978a) illustrate the tightening of exposure standards in the United States:

Year	*Limit* (ppm)	*Standard*
1946	100	ACGIH TLV
1947	50	ACGIH TLV
1957	25	ACGIH TILV-TWA
1963	25	ACGIH TLV-C
1969	10	ANSI TLV-TWA, with ceiling of 25 ppm
1976	1	OSHA (proposed) with 5 ppm excursion

The HSE paper reviews the toxicity of benzene and micro-organism tests, animal experiments and epidemiological data. Benzene affects the formation of blood cells in bone marrow. It may reduce the number of red cells, white cells or platelets, or all three. It may cause anaemia or leukaemia.

Although in all three types of toxicity investigation there are many studies that have given negative results, some have demonstrated injurious effects. Carcinogenic, mutagenic and teratogenic effects have all been demonstrated for benzene in animal experiments. The review describes a number of epidemiological studies of workers exposed to benzene. A study by Infante *et al.* (1977a,b) of 748 workers on rubber film in Ohio found a significant increase in leukaemia. The authors quote low levels of exposure, below 15 ppm in most cases, but have apparently subsequently accepted that the levels may have been 100 ppm or more. Another study in which a significant increase in leukaemia was found is that by Pagnotto, Elkins and Brugsch (1979) on 549 workers at a Dow Chemical plant in the United States with very low exposures, about 2 ppm, but the workers concerned had a varied history of exposure to chemicals and there was no significant increase in leukaemia among other workers exposed to higher concentrations. Other studies that either are inconclusive or have shown no significant increase in leukaemia include those by Thorpe (1974) on 38,000 workers exposed to petroleum products, and Rushton and Alderson (1981) on 35,000 oil refinery workers.

The HSE review concludes that there is considerable evidence that exposure to high concentrations of benzene may eventually cause leukaemia, but that there is no conclusive evidence of leukaemia in workers exposed to lower concentrations. The only work reviewed in which there was an increase in leukaemia among workers exposed to less than 100 ppm was the Dow Chemical study just described. Increasing awareness of the toxicity of benzene has led to a progressive reduction in the hygiene limits. This is illustrated by the data given earlier. There has also been a corresponding tightening of the regulatory controls. As described above, in the United States this led to the attempt by the OSHA to introduce a very low benzene standard and the rejection of this by the courts in the Benzene Case. In the United Kingdom benzene has a long-term MEL of 5 ppm.

18.7.7 Vinyl chloride

Vinyl chloride monomer (VCM) is manufactured on a large scale and polymerized to give PVC, which is one of the most common plastics. It has a boiling point of −13°C and therefore is a gas at ambient temperatures.

Accounts of the toxicity of vinyl chloride are given in Criteria Document Publ. 78–205 (NIOSH, 1978), EH 64 *Occupational Exposure Limits: Criteria Document Summaries* (HSE, 1992), and in the other references quoted below.

Until the mid-1970s, vinyl chloride was regarded as a mild narcotic less harmful than chloroform. The ACGIH TLV was 500 ppm and the UK TLV was 200 ppm (HSE, 1972 TON 2/72).

It was also well known that vinyl chloride could give rise to acro-osteolysis, which involves deterioration of the bones, particularly the fingers, and certain other conditions. These diseases have been found mainly in PVC workers in circumstances where the exposure may well have been at concentrations appreciably above 1000 ppm. However, in 1974 it was found, that vinyl chloride is a carcinogen.

Accounts of the development of the vinyl chloride problem are given in the *Annual Report of HM Chief Inspector of Factories 1974* (HMFI, 1974) and by Atherley (1978), Doyal and Epstein (1983) and Corn and Corn (1984).

Indications of the carcinogenicity of vinyl chloride were given by animal experiments conducted by Viola (1970), but the first widespread impact was made by a report from a BE Goodrich plant in the United States that three cases of a rare liver cancer, angiosarcoma, had been discovered and were probably associated with exposure to high levels of vinyl chloride. The men concerned had been autoclave cleaners in plant polymerizing vinyl chloride to PVC. The average time for the condition to develop after first exposure was 19 years.

It is noteworthy that the cancer associated with vinyl chloride is a rare one. The discovery of a carcinogenic effect could have been much more difficult if the cancer had been of a type that also has other causes, such as the lung cancer that can be caused by cigarette smoking. It is probably fair to say that this discovery has had as great an impact in the area of chronic toxic exposure as the Flixborough disaster has had in the area of fire and explosion.

By the end of 1974, some 25 cases of angiosarcoma in workers exposed to vinyl chloride had been established worldwide. These were mostly in the United States and mostly in one company.

In the United States, the OSHA reduced the standard from 500 ppm to an interim standard of 50 ppm and then to a TLV of 1 ppm and a maximum of 5 ppm. It was envisaged, however, that it might be necessary to rely on the extensive use of respirators to meet these levels of exposure.

In the United Kingdom, the HSE issued Vinyl Chloride Code of Practice for Health Precautions (HSE, 1975b), which gave as an interim standard a TLV of 25 ppm and a maximum of 50 ppm.

Guidance to industrial users of the monomer was given in *Vinyl Chloride Monomer. Advisory Notes for PVC Processors* (BCISC, 1974/14). Notes on best practicable means for PVC polymer plants were given in the *Annual Report on Alkali, etc. Works 1974*. The publication *Vinyl Chloride and You* was issued to workers.

The monitoring of very low concentrations of vinyl chloride requires sensitive analytical methods. In the 1970s, there was intense activity in this area. Methods of analysis were described in The *Determination of Vinyl Chloride – A Plant Manual* (CIA, 1975/7).

Various other countries adopted very low standards for vinyl chloride. The United Kingdom approach was based on the argument that it is preferable to devote effort to reducing the concentration of vinyl chloride in the atmosphere by improved engineering than to rely on respirators, which may well not be used.

The reduction of concentrations of vinyl chloride to very low levels is a difficult engineering problem. Early experience was that it was more difficult to eliminate occasional peaks over 50 ppm than to achieve the TWA of 25 ppm.

A survey of the atmospheric concentrations of vinyl chloride at plants in the United Kingdom was made in 1974 by the CIA (quoted by McKinnon, 1974). The survey established that the approximate exposure levels in the plant atmosphere were:

	Explosure level (ppm)
Plants polymerizing VCM to PVC	50
Plants producing VCM	5
Plants fabricating PVC	0–5

The survey obtained the following figures for the weekly average gas concentration in the seven polymerization plants in the United Kingdom:

Plant	*Weekly average concentration* (ppm)
A	25
B	10
C	10
D	25
E	20
F	40
G	30

The CIA stated that the ultimate for most existing plants is 10 ppm and that entirely new plants with the most modern techniques might achieve 5 ppm.

Accounts are also available of measures taken at that time to reduce exposure at plants in the United States and elsewhere (e.g. Chementator, 1975 Apr. 14, 33; Jul. 7, 34; 1977, Jan. 3, 37). Indications were that the achievement of low levels of exposure did not prove as difficult as was sometimes anticipated (e.g. Meade and Press, 1977).

Information on plant emissions of vinyl chloride has been given by Sittig (1978), who quotes vent and fugitive emission rates. The development of controls on vinyl chloride in the United States may be followed through the references given in Table A1.4.

In the United Kingdom vinyl chloride has a long-term MEL of 7 ppm with an overriding annual MEL of 3 ppm.

18.7.8 Acrylonitrile

In 1977, several animal and epidemiological studies were published which showed carcinogenic effects from acrylonitrile. One of these was an epidemiological study by Dupont on 470 workers in an acrylic fibre plant in South Carolina, which showed the incidence of excess cancers.

As described by Karrh (1984), the company made its data, interpretation and recommendations available to the OSHA that accepted these and based a standard on them. The standard set by the OSHA was 2 ppm. This case is therefore an interesting example of co-operation between industry and the regulatory authorities. The author adds that, to his knowledge, this is the only OSHA health standard which has not been the subject of litigation.

In the United Kingdom, the practicality of the 2 ppm standard was a matter of some debate, but by 1981 this level was accepted, as described by Doyal and Epstein (1983). Acrylonitrile now has a long-term MEL of 2 ppm.

18.7.9 Other substances

Other substances with carcinogenic potential include *bis*(-chloromethyl) ether (BCME), formaldehyde, inorganic arsenic and asbestos.

For BCME the toxicity and development of controls are described Doyal and Epstein (1983) and by Kusnetz and Lynch (1984).

Chloromethyl ether (CME) is manufactured by reacting formaldehyde and hydrogen chloride. BCME is an intermediate and a contaminant in the CME. BCME has long been known to be a highly toxic irritant gas, but awareness of its carcinogenic properties dates from various epidemiological and animal studies done in the 1960s and 1970s. In 1982, the ACGIH classified BCME as a carcinogen. In the UK BCME has a long-term MEL of 0.001 ppm.

For formaldehyde a review of toxicity is given in TR2 *Toxicity Review: Formaldehyde* (HSE, 1981). The toxicity and the development of controls on formaldehyde are described by Neal and Gibson (1974), Doyal and Epstein (1983), Barnard (1984), and Gough (1984).

Formaldehyde has been shown to be carcinogenic to rodents, but there is disagreement among experts on the extent of its human carcinogenicity. In the Formaldehyde Case the CPSC used some of the animal experiments and interpretations in support of its ban on urea formaldehyde insulation, but its assessment was not accepted by the court. Following a further expert review under the aegis of the National Center of Toxicological Research (NCTR), the OSHA decided not to alter its standard for formaldehyde. In the United Kingdom, formaldehyde has long- and short-term MELs that are both 2 ppm.

For inorganic arsenic the toxicity and development of controls are described by Lowrance (1984), Neal and Gibson (1984) and Sagan and Whipple (1984). There is epidemiological evidence of the human carcinogenicity of inorganic arsenic (OSHA, 1983). In 1983, on the basis of this evidence, the OSHA adopted a standard of 10 $\mu g/m^3$. As described above, the reasoning given by the OSHA in support of this standard, though not necessarily the numerical values, is commended by Lowrance (1984) as a model. In the United Kingdom, inorganic arsenic has a long-term MEL of 0.1 mg/m^3.

Asbestos is a carcinogenic dust and is considered in Section 18.8.

18.8 Dusts

There are many industrial chemicals that are used in powder form and can give rise to dust in the atmosphere. Dust may also be generated by the attrition of materials.

Dusts are covered by the OEL system, and OELs for dusts have been described in Section 18.6.

Some dusts are not classified as having any specific toxic effect, but can cause irritation. Excessive quantities of such dust are unpleasant to inhale, can deposit in the eyes and ears, and can injure the skin or mucous membranes by chemical or mechanical action or through the cleaning procedures necessary to remove them.

Other dusts can cause injurious effects. One such dust is silica in the crystalline, or quartz, form. A well-known example is the silica dust produced in coal mining, which causes pneumoconiosis, a progressive fibrosis of the lung tissue.

Fibrosis can also be caused by asbestos dust. In addition, this dust is a carcinogen. Asbestos is considered in more detail below.

Metal dusts that are sufficiently fine can enter the lungs and give rise to the toxic symptoms associated with the parent metal.

Other dusts which are themselves non-fibrogenic may produce an allergic response in the lungs that leads eventually to fibrosis. Such conditions are ‘farmer’s lung’ and byssinosis, an asthmatic condition prevalent in the cotton industry. Process workers involved with enzyme washing powders have experienced similar asthmatic conditions.

The control of dust in the workplace is considered in Chapter 25.

18.8.1 Asbestos

‘Asbestos’ is a generic term that is applied to a number of naturally occurring, hydrated mineral silicates. More than 90% of the world production of asbestos is as is chrysotile (‘white’) asbestos. Virtually all the rest is amosite (‘brown’) and crocidolite (‘blue’) asbestos.

Accounts of the toxicity of asbestos include Criteria Document Publ. 77–169 *Asbestos* (NIOSH, 1977), *Asbestos: Medical and Legal Aspects* (Castleman, 1990 ACGIH/39), EH 64 *Occupational Exposure Limits: Criteria Document Summaries* (HSE, 1992) and the other references quoted below. Other HSE publications on asbestos are given in Chapter 25.

Asbestos has been in widespread use as a material for building products, fireproofing, lagging, brakes, glands and many other purposes. Asbestos dust is generated to some degree in many of these applications, particularly in cutting and demolition operations.

There are two injurious effects caused by asbestos dust, the fibres of which enter the lung. One is asbestosis, a fibrosis of the lung. The other is mesothelioma, a rare cancer of the lung and bowels, of which asbestos is the only known cause.

Evidence of the hazard of asbestos appeared as early as the 1890s. Of the first 17 people employed in an asbestos cloth mill in France, all but one were dead within 5 years. Oliver (1902) describes the preparation and weaving of asbestos as ‘one of the most injurious processes known to man’.

In 1910, the Chief Medical Inspector of Factories, Thomas Legge, described asbestosis. A high incidence of lung cancer among asbestos workers was first recognized in the 1930s and has been the subject of continuing research. The synergistic effect of cigarette smoking, which greatly increases the risk of lung cancer to asbestos workers, was also discovered (Doll, 1955). The specific type of cancer, mesothelioma, was identified in the 1950s (Q.C. Wagner, 1960).

In the United Kingdom, an Act passed in 1931 introduced the first restrictions on the manufacture and use of asbestos. It has become clear, however, that the concentrations of asbestos dust allowed by industry and the Factory Inspectorate were too high. In consequence, numbers of people have been exposed to hazardous concentrations of the dust over long periods.

The problem was dramatically highlighted by the tragedy of the asbestos workers at Acre Mill, Hebden Bridge. The case was investigated by the Parliamentary Commissioner (Ombudsman, 1975–76). It was found that asbestos dust had caused disease not only to workers in the factory but also to members of the public living nearby.

Although all types of asbestos can cause cancer, it is held that crocidolite, or blue asbestos, is the worst offender.

By the late 1960s, growing concern over the asbestos hazard in the United Kingdom led to action. The building industry virtually stopped using blue asbestos in 1968 and the Asbestos Regulations 1969 prohibited the import, though not the use, of this type of asbestos.

The problem of asbestos continued to be a subject of controversy (e.g. Kinnersley, 1976; W.P. Howard, 1976). Criticisms included the failure of industry and government to act earlier, the adequacy of current concentration standards, the particular hazard of blue asbestos, and the effect of ‘casual’ exposures. Obviously the problem is more difficult if it is not confined to blue asbestos and if even occasional exposure can cause cancer.

Most cases of disease from asbestos are associated with exposure over a period of years and often in high dust concentrations, but several cases have been quoted of contraction of the cancer after apparently very short exposure. However, in some of these at least, it has been shown that the exposure, though short, was in fact quite intense.

As a result of continuing concern, in 1976 the Government set up an Advisory Committee on Asbestos (ACA). The asbestos industry also set up its own Asbestos Advisory Committee. In contrast to most of the other chemicals discussed earlier, and in particular to VCM, asbestos is a material widely used by the public. The industry was therefore faced with the problem of allaying the fears of numerous and relatively unsophisticated users.

The Asbestos Regulations 1969 were followed by further legislative requirements. These include The Asbestos

(Licensing) Regulations 1983 and the Asbestos (Prohibition) Regulations 1985.

The CAWR 1987, which revoke the Asbestos Regulations 1969, now provide a comprehensive set of controls on asbestos. The corresponding ACOP is L27 The Control of Asbestos at Work (HSE, 1988).

The CAWR 1987 set control limits for asbestos. These limits are reproduced in EH 10 *Asbestos – Exposure Limits and Measurement of Airborne Dust Concentrations* (HSE, 1990) and in EH 40/94. They are given in Chapter 25 where the CAWR 1987 are discussed in more detail. A more stringent limit is applied for crocidolite or amosite asbestos.

Although there is now much more stringent control of asbestos dust, the backlog of exposure in previous years is likely to claim victims for some time to come. The Health and Safety Statistics 1990–91 (HSE, 1992b) give, for 1990, 882 deaths recorded as due to mesothelioma and another 163 deaths recorded as due to asbestosis (excluding those where mention is made of mesothelioma).

18.8.2 Dust and fume atmospheres

Not infrequently, dusts occur as part of a mixture of dusts, fumes, gases and vapours. This is the situation, for example, in ferrous foundries. A recent review of airborne ferrous foundry particulates (HSE, 1994a) has highlighted the enhanced risk of lung cancer from such atmospheres.

18.9 Metals

The toxic effects of metals and their compounds vary according to whether they are in inorganic or organic form, whether they are in the solid, liquid or vapour phase, whether the valency of the radical is low or high and whether they enter the body via the skin, lungs or alimentary tract.

Some metals that are harmless in the pure state form highly toxic compounds. Nickel carbonyl is highly toxic, although nickel itself is fairly innocuous. The degree of toxicity can vary greatly between inorganic and organic forms. Mercury is particularly toxic in the methyl mercury form.

The wide variety of toxic effects is illustrated by the arsenic compounds. Inorganic arsenic compounds are intensely irritant to the skin and bowel lining and can cause cancer if exposure is prolonged. Organic compounds are likewise intensely irritant, produce blisters and damage the lungs, and have been used as war gases. Hydrogen arsenic, or arsine, is non-irritant, but attacks the red corpuscles of the blood, often with fatal effects.

Hazard arises from the use of metal compounds as industrial chemicals. Another frequent cause of hazard is the presence of such compounds in effluents, both gaseous and liquid, and in solid wastes. Fumes evolved from the cutting, brazing and welding of metals are a further hazard. Such fumes can arise in the electrode arc welding of steel. Fumes that are more toxic may be generated in work on other metals such as lead and cadmium.

The HSE has issued a number of Guidance Notes on metals and their hazards, including notes on cadmium (EH 1), chromium (EH 2), arsenic (EH 8), beryllium (EH 13), mercury (EH 14), antimony (EH 17) and lead (EH 29). There are also notes on the compounds arsine (EH 11), stibine (EH 12) and phosphine (EH 20).

18.9.1 Lead

One of the metals most troublesome in respect of its toxicity is lead. Accounts of the toxicity of lead are given in Criteria Document Publ. 78–158 *Lead, Inorganic* (NIOSH, 1978) and EH 64 *Occupational Exposure Limits: Criteria Document Summaries* (HSE, 1992).

The toxicity of lead and its compounds has been known for a long time, since it was described in detail by Hippocrates. Despite this, lead poisoning continues to be a problem, particularly where cutting and burning operations, which can give rise to fumes from lead or lead paint, are carried out. Fumes are emitted above about 450–500°C. These hazards occur in industries working with lead and in demolition work.

Legislation to control the hazard from lead includes the Lead Smelting and Manufacturing Regulations 1911, the Lead Compounds Manufacture Regulations 1921, and the Lead Paint (Protection against Poisoning) Act 1926 and the Control of Lead at Work Regulations 1980. The associated ACOP is COP 2 Control of Lead at Work (HSE, 1988).

The limits for lead, which is referred to as the ‘lead-in-air standard’, are given in COP 2 and in Appendix 5 of EH 40. They have been given in Section 18.6.

Monitoring of lead in the working environment is dealt with in EH 28 *Control of Lead: Air Sampling Techniques and Strategies* (HSE, 1986).

The *Annual Report of HM Chief Inspector of Factories* 1974 records 36 cases of lead poisoning in that year. Also, 154 employees were removed from lead work because of increased lead absorption. The number of cases of lead poisoning was 82 in 1972 and 59 in 1973. The *Health and Safety Statistics* 1990–91 (HSE, 1992b) do not quote cases of lead poisoning but the statistics given show that in 1990–91 some 258 male workers and 26 female workers were suspended from work due to the levels of lead in their blood.

18.9.2 Mercury

Another highly toxic substance is mercury. This is used on a large scale in the chemical industry in the manufacture of chlorine by the mercury cell process.

Mercury is particularly toxic in the organic form, and especially as methyl mercury. Organic mercury was responsible for the tragedy at Minimata, Japan, where many members of the public were poisoned and deformed by liquid effluent containing mercury.

Mercury vapour from spillage of the metal should also be treated as hazardous.

Industrial use of mercury is dealt with in EH 17 *Mercury – Health and Safety Precautions* (HSE, 1977).

18.10 Emergency Exposure Limits

Limits for occupational exposure are complemented by limits for emergency exposure. A number of types of limit for exposure in an emergency have been defined by various bodies, but it is fair to say that there is no system with a status comparable to that of the TLV or OEL systems.

Some emergency exposure limits, emanating from various bodies, include the following:

EEGL	Emergency exposure guidance level
EEI	Emergency exposure index
EEL	Emergency exposure limit
ERPG	Emergency response planning guideline

IDLH	Immediately dangerous to life and health (limit)
PEEL	Public emergency exposure limit
SPEGL	Short-term Public Emergency Guidance Level

The National Research Council (NRC) Committee on Toxicology has, since the 1940s, submitted to the Department of Defense EEGLs for toxic chemicals. An EEGL is a concentration that is judged acceptable and which will permit exposed individuals to perform specified tasks during emergency conditions lasting from 1 to 24 h. The NRC has also developed SPEGLs. These are acceptable concentrations for exposures of members of the general public. Some early limits were those given in the Guides for Short Term Exposure of the Public to Air Pollutants (NAS/NRC, 1972a, 1973). More recent publications are the Guidance Levels for Emergency and Continuous Exposure to Selected Airborne Contaminants (NAS, 1984–).

A number of EELs were developed in the early 1970s in the Netherlands, as described by the Committee for the Prevention of Disasters (CPD) in the Netherlands (1974) and by Zielhuis (1970), Siccama (1973) and Balemans (1975).

The NIOSH has published a set of IDLH limits. NIOSH data are given in the *Pocket Guide to Chemical Hazards* (NIOSH, 1990/18).

The AIHA publishes a series *Emergency Response Planning Guidelines* (AIHA, 1988–/13). An ERPG is the maximum airborne concentration below which, it is believed, nearly all individuals could be exposed for up to 1 h without experiencing or developing certain defined effects. Three ERPGs are used, the defined effects being as follows:

ERPG-1	Effects other than mild transient adverse health effects or perception of a clearly defined objectionable odour.
ERPG-2	Irreversible or other serious health effects or symptoms that could impair an individual's ability to take protective action.
ERPG-3	Life threatening health effects.

So far some 40 ERPGs have been published. The ERPG-2 is broadly similar to the EEGL.

Another emergency limit is the EEI given in Emergency Exposure Indices for Industrial Chemicals (ECETOC, 1991). Three EEIs are defined, namely EEI-1, EEI-2 and EEI-3, which separate four zones of effect: detection, discomfort, disability, and permanent incapacity/death.

Another limit used is the PEEL. This is a maximum airborne concentration to which a member of the public may be exposed without significant adverse effects.

Critical reviews of emergency exposure limits are given in the QRA Guidelines (CCPS, 1989/4) and by Franklin (1991).

18.10.1 Dow Chemical Exposure Index

There are also indices for acute toxic exposures that are not a simple concentration value, but take account of other parameters also. One such is the Chemical Exposure Index (CEI) developed by the Dow Chemical Company (1994a) and described by R.A. Smith and Miller (1988).

The CEI takes account of (1) toxicity, (2) quantity, (3) distance, (4) molecular weight and (5) process variables, and the index is computed as the product of a set of 'scale factors' which allow for these features. The authors give full details, including proformas and credit factors.

18.11 Gas Toxicity

18.11.1 Industrial gases

Some of the principal toxic gases which are handled in the chemical industry and the toxic effect which each exerts are:

Gas	*Toxic effect*
Ammonia	Irritant
Bromine	Irritant
Chlorine	Irritant
Hydrogen chloride	Irritant
Hydrogen cyanide	Systemic
Hydrogen fluoride	Systemic (fluoride poisoning), irritant
Hydrogen sulfide	Systemic irritant
Phosgene	Irritant
Sulphur dioxide	Irritant

All except one of these gases are irritants. In this context 'irritation' is a technical term: the effect ranges from mild discomfort to death. An irritant gas attacks the respiratory tract and the lungs. The locus of action depends mainly on the solubility of the gas, the more soluble gases attacking the respiratory tract and the less soluble the lungs. The action of irritant gases has been described by Haggard (1924) as follows:

> Ammonia produces intense congestion of the upper respiratory passages and immediate death from laryngeal spasm or oedema; on the other hand phosgene and nitrogen peroxide cause little irritation of the upper respiratory tract but induce pneumonia or lung oedema through their action upon the lung alveoli; chlorine in its action is intermediary between ammonia on the one hand and phosgene and nitrogen peroxide on the other.

Of the irritant gases, ammonia and hydrogen fluoride are miscible with water. Bromine is more soluble than chlorine, which in turn is more soluble than phosgene. As indicated, ammonia and hydrogen fluoride attack the upper respiratory tract. The main action of chlorine is on the lungs, but there is some effect on the respiratory tract. Bromine, being more soluble than chlorine but less soluble than ammonia, attacks both the respiratory tract and the lungs. Phosgene, being less soluble than chlorine, enters deep into the lungs where its action occurs.

Hydrogen sulfide is an irritant gas, but also attacks the nervous system and causes respiratory paralysis. It is oxidized in the blood stream to pharmacologically inert compounds. Hydrogen fluoride is again an irritant gas but also gives rise to fluoride poisoning in the body.

Hydrogen cyanide is the only one of the gases listed which is not an irritant; it causes cyanide poisoning. The most important effect of this is probably the inhibition of cytochrome oxidase, which in turn prevents the utilization of molecular oxygen by the cells. The cyanide is excreted in the urine.

18.11.2 Lethal concentration and load

In general, the injurious effect of the inhalation of a toxic gas is a function of concentration and of time that may be expressed by the relation

$$c^n t^m = \text{Constant} \qquad [18.11.1]$$

where c is the concentration, t is the time, and m and n are indices.

If the exposure time is constant, a lethal concentration LC_i may be defined such that for this exposure time C_i is the concentration that is lethal at the i% level. Widespread use is made of the LC_{50} value and also of other values such as LC_{10}, LC_{05} and LC_{01}.

If the exposure time is not constant, but the injurious effect is proportional to the product ct of the concentration and time ($m = n = 1$), and hence to the dosage D, a lethal dosage LD_i may be defined with

$$D = ct \qquad [18.11.2]$$

If the injurious effect is proportional to some other function ($m \neq n$), it is necessary to use the concept of toxic load L and to define a lethal load LL_i with

$$L = ct^m \qquad [18.11.3]$$

An alternative toxic load, L^* may also be defined

$$L^* = c^n t \qquad [18.11.4]$$

with $m = 1/n$. This second form of the lethal load is that most often used in hazard assessment studies.

In such studies it is usually necessary to estimate mortality for exposures at a number of different combinations of concentration and time and in this case the lethal load function is usually expressed in the form

$$L^* = \sum C^n T \qquad [18.11.5]$$

where C is the concentration (ppm) and T is the time (min). The lethal load function in the form of Equation 18.11.5 has been widely used in hazard assessment.

For the case where $n = 1$ so that the load becomes $L = ct$, it is possible to define the LCt value. In particular, use is made of the LCt_{50}.

The relation between toxic load and mortality is usually a log-normal distribution and may therefore be plotted on log-probability paper. It may also be expressed as a probit equation

$$Y = k_1 + k_2 \ln L^* \qquad [18.11.6]$$

where Y is the probit and k_1, k_2 are constants.

It is a matter of indifference which expression, Equation 18.11.3 or Equation 18.11.4, is used to define the toxic load that causes a specified degree of injury; both give the same numerical results. In principle, it would be possible to distinguish between the two forms if one fitted better than the other the load–mortality distribution generally used, but in fact the distribution almost universally used for intensity–injury relationships in hazard assessment, not just for toxic gases but also for fire and explosion, is the log-normal distribution. With this distribution, if L is log-normally distributed, so is L^*.

Similarly, in the corresponding probit equation use of L^* instead of L is equivalent to multiplying the constant k_2 by m. Thus it is not possible to distinguish between the two forms.

There are, however, other arguments. From the point of view of hazard assessment, in which it is usually necessary to integrate the lethal load function, the definition of load given in Equation 18.11.4, or its discrete form Equation 18.11.5, is the more convenient.

There are also arguments, however, for the alternative form. Here toxicokinetic models appear relevant. For example, a one-compartment model for the body fluid concentration of the toxin with first-order excretion and constant gas concentration is equivalent to a first-order exponential stage with a step input, which gives a concentration rise of the form $[1-\exp(-kt)]$, where k is a constant. It may be significant that this exponential rise may be approximated by a suitably scaled expression in $t^{1/2}$.

18.12 Gas Toxicity: Experimental Determination

The main source of information on the lethal toxicity of gases is experimentation on animals, particularly mice. In a typical study, groups of mice are exposed to different concentrations of gas for a single exposure period and the mortality is determined over a given period of observation after the exposure is over.

For a particular gas, assuming there are any data, there will typically be between one and half a dozen studies quoted in the literature that appear applicable. There may be one or two in which the exposure period has been varied. There may also be one or two studies with other species such as rats, guinea pigs, rabbits, and, in older work mainly, cats and dogs.

The determination of the lethality of a toxic gas by inhalation experiments with animals is a difficult undertaking and is subject to various sources of error. In addition to the concentration of the gas and the exposure time, other important variables are the caging conditions, the breed, sex, age and health of the animals, and their behaviour, including their breathing rate. The animals may not die immediately and it is necessary to observe delayed deaths over a period of time, usually 10 days, and to record both immediate and delayed deaths. A sufficient number of animals needs to be used to obtain results with a high level of confidence, and pathological examinations should be conducted. The toxicity data sought are usually for a given exposure time and comprise the LC_{50} together with suitable values nearer the extremes of mortality such as the LC_{10} and LC_{90}.

18.12.1 Statistical interpretation of experiments

The statistical interpretation of experiments in toxicology was discussed in Section 18.3.

The method of Litchfleld and Wilcoxon (1949) is convenient for the statistical treatment of results on inhalation toxicology. The application of this method to concentration mortality data for dogs exposed to chlorine is given in Section 18.18.

The lethal toxicity estimates required for hazard assessment are essentially the LC_{50}, the slope of the concentration mortality line, which may be expressed in terms of the ratio LC_{90}/LC_{10}, and the toxic load function, which defines the equivalence between concentration and time.

18.12.2 Estimation of lethal toxicity to animals

Usually, if there are any data at all, there will be enough to permit some estimate to be made not only of the LC_{50} but also of the ratio LC_{90}/LC_{10}, but the latter estimate will generally be such as to yield much less confidence in the LC_{10} than in the LC_{50}.

For some gases there may be a single set of experiments on one species, for others several sets on one species and for others again several sets on different species.

In the first case the estimate is straightforward, but where there are several sets of experiments on one species, there may be appreciable differences, say a factor of 2, in the LC_{50} reported by different authors, even though each group of workers reports relatively narrow confidence limits for its results.

In the second case where there are differences in the LC_{50} reported, it is necessary to decide whether to average the results or to select those that appear of highest quality. Each case must be treated on its merits.

The third case, where different species are involved, is discussed below.

In general, the lethal toxicity is a function of concentration and time. Although concentration may sometimes be completely dominant, there tends to be a trade-off between the two, so that at a particular value of the toxic load there is a given degree of lethality.

The experimental data from which to determine the index m in Equation 18.6.3 or n in Equation 18.6.4 are often sparse and in weak agreement. Work by Doe and Milburn gives a value for n of about $\frac{1}{2}$ for many of the irritant gases but about 1 for some other gases.

18.12.3 Extrapolation between species

Extrapolation of results obtained on one particular species to another species is beset with many difficulties, but it is an unavoidable step in the estimation of toxicity. Some accounts of the principles were mentioned in Section 18.3. In relation to inhalation toxicity specifically, reference may also be made to the accounts given by Flury and Zernik (1931) and Wachtel (1941), who worked on the toxicity of war gases, and to the Major Hazards Assessment Panel (MHAP) monographs (MHAP, 1987, 1988, 1993) described below.

The crucial question is whether or not the toxic effects are the same, or at least sufficiently similar, in the two species, thus providing a basis for extrapolation. Other important features are the relative modes and rates of inhalation and the mechanisms and rate of elimination, or metabolism.

In the case of irritant gases the toxic effects in the main laboratory animals and in man appear to be broadly similar, in that gas attacks the respiratory system. The fact that for these gases it is, the respiratory system that is the target means that metabolism is not significant. It is necessary to consider, however, the locus of action for each gas in each species, bearing in mind the solubility of the gas and the anatomy and respiratory behaviour.

18.12.4 Animal physiology

In many cases extrapolation from animals to humans is supported by an argument based on the ratio of physiological quantities such as the minute volume or body weight.

Information on animal physiology is given in *The Rat – Data and Reference Tables for the Albino Rat* (Donaldson, 1924), *The Rat in Laboratory Investigation* (Farris and Griffiths, 1949), *Handbook of Biological Data* (Spector, 1956a), Blood and Other Body Fluids (Altaian and Dittmer, 1961), *Metabolism* (Altaian and Dittmer, 1968), *Respiration and Circulation* (Altaian and Dittmer, 1971), *Biology Data Book* (Altman and Dittmar, 1974), *Clinical, Biochemical and Hematological Reference Values in Normal Experimental Animals* (Mitruka and Rawnsley, 1977) and *Inbred and Genetically Defined Strains of Laboratory Animals. Part 1, Mouse and Rat* (Altman and Katz, 1979).

Data on some of the principal parameters of animal physiology relevant here are given in Table 18.14.

18.12.5 Vulnerable populations

Extrapolation from animals to man is usually done in the first instance for healthy young adults. It may be necessary, however, to allow for vulnerable members of the population.

It is commonly assumed in hazard assessment that a section of the population, including young children and old people, is particularly vulnerable. In the case of toxic gas hazard, those with respiratory disease are also included. However, this is an aspect on which very little work has been done.

It may be preferable to derive separate estimates of the lethal toxicity for the regular and vulnerable populations. This makes it possible to allow for differences in the numbers and composition of the exposed population at different times of day.

18.13 Gas Toxicity: Physiological Factors

18.13.1 Respiration

Any attempt to model the toxic effects of inhaled gases requires some understanding of the respiratory process.

Accounts of the respiratory system, the effects of gases on this system and the absorption of gases into the blood include those given in: standard texts on general physiology, such as *Handbook of Physiology* (Fenn and Rahn, 1964), *Medical Physiology* (Mountcastle, 1974) and *Samson Wrights Applied Physiology* (Keele, Neil and Joels, 1982); texts on the respiratory system, such as The *Morphometry of the Human Lung* (Weibel, 1963), *Ventilation Blood Flow and Gas Exchange* (Q.B. West, 1965), *Human Respiration* (Lippold, 1968), *Physiology of Respiration* (Comroe, 1974), *Lung Function* (Cotes, 1979), *Lung Connective Tissue* (Pickrell, 1981), *Modelling and Control of Breathing* (Whipp and Wiburg, 1983), *Inhalation Studies* (Phalen, 1984) and MS 5 *Lung Function* (HSE, 1977); and in texts on the inhalation of gases, such as *Modeling of Inhalation Exposure to Vapor* (Fiserova-Bergerova, 1983).

The account given here describes in outline the respiratory process and some of the quantitative data and relations in respiratory physiology. This information is the starting point for modelling the effect of toxic gases, both irritant gases that attack the lungs and other gases which enter the blood. The data given are taken mainly from Mountcastle (1974) and apply to a young adult male, unless otherwise stated.

The respiratory system is illustrated in Figure 18.4. Air entering the lung passes through the trachea, then down the bronchioles and through the alveolar duct into the alveolar sac. Interchange between the air and the blood occurs at the surface of the alveoli.

The walls of the capillaries lining the alveoli are extremely thin. The equilibrium partial pressure of a solute gas in the alveoli is effectively the same as that above the blood, neglecting the membrane. Mass transfer between the air and the blood is very rapid.

The volume of air moved in one respiratory cycle is less than the total capacity of the lungs. Moreover, not all the air moved enters the alveolar space, since there is dead space. It is necessary, therefore, to define a number of

Table 18.14 *Some principal physiological parameters of animals, including humans, relevant to respiration (Withers a nd Lees, 1986a) (Courtesy of the Institution of Chemical Engineers)*

A Animals, including man (after Altman and Dittmer, 1974)

	Species				
	Mouse	*Rat*	*Rabbit*	*Dog*	*Man*

Volume of cell fluid (ml/kg body weight)	30	1020

[a] Page number in Mountcastle (1974), unless otherwise noted.

components of lung volume as shown in Figure 18.5. These include:

Tidal volume (TV)	Volume of air entering and leaving the lungs in one natural respiratory cycle.
Inspiratory reserve volume (IRV)	Volume of air additional to the tidal volume that can be inhaled by maximum effort.
Expiratory reserve volume (ERV)	Volume of air additional to tidal volume which can be exhaled by maximum effort.
Residual volume (RV)	Volume of air remaining in lungs after exhalation with maximum effort.
Vital capacity (VC)	Sum of tidal, inspiratory reserve and expiratory reserve volumes.
Inspiratory capacity (IC)	Volume of air which can be inhaled with maximum effort; sum of tidal volume and inspiratory reserve volume.
Functional residual volume (FRV)	Volume of air left in lungs at end of natural exhalation.
Total lung capacity (TLC)	Sum of vital capacity and residual volume. Also sum of inspiratory capacity and functional residual capacity.

Thus

$$\text{TLC} = \text{VC} + \text{RV} = \text{IRV} + \text{TV} + \text{ERV} + \text{RV}$$
$$= \text{IC} + \text{FRC}$$
$$\text{VC} = \text{IRV} + \text{TV} + \text{ERV}$$
$$\text{IC} = \text{IRC} + \text{TV}$$
$$\text{FRC} = \text{ERV} + \text{RV}$$

The tidal volume consists of the alveolar space and the anatomical dead space. Some typical values are:

Tidal volume, $V_T = 500$ ml

Alveolar space, $V_A = 350$ ml

Anatomical dead space, $V_D = 150$ ml

The typical respiration rate at rest is

Respiration rate, $f = 12$ breaths/min

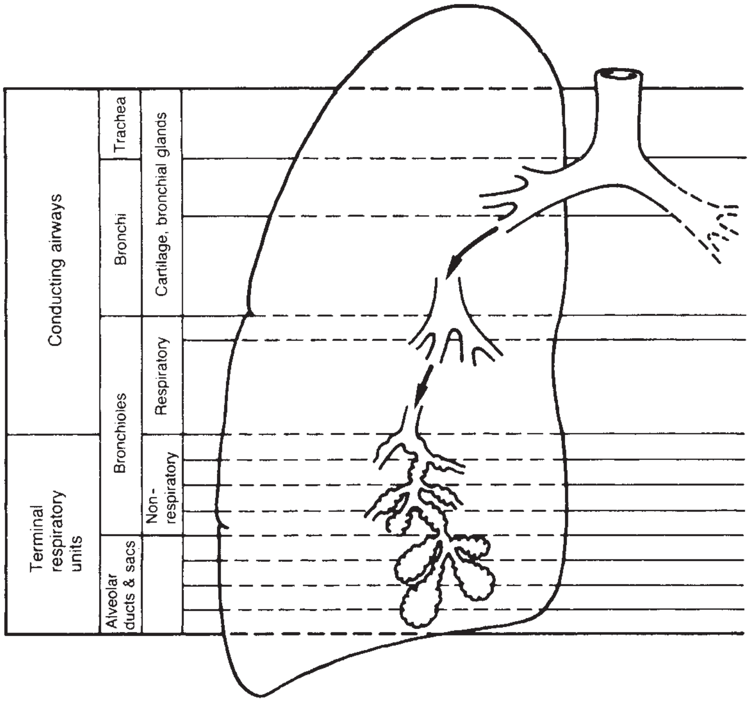

Figure 18.4 The structure of the respiratory tree in the lung (after Weibel, 1973)

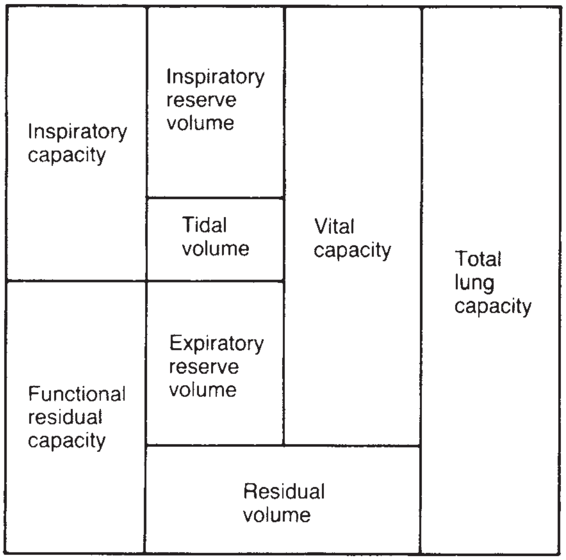

Figure 18.5 Components of lung volume (after Lambertsen, 1974; Cotes, 1979)

The product of the tidal volume and the respiration rate is termed the minute volume, $V_T$and that of the alveolar space and the respiration rate the alveolar ventilation, V_A. Typical values of these two quantities are

$$\text{Minute volume, } V_T = 12 \times 500 = 600\,\text{ml/min}$$

$$\text{Alveolar ventilation, } V_A = 12 \times 350 = 4200\,\text{ml/min}$$

The lungs contain some 3×10^8 alveoli with an alveolar area of about 70 m^2. The thickness of the capillary membrane is about 0.3–2.5 μm. The capillary volume is some 140 ml and the transit time of the blood is some 0.75 s at rest and 0.34 s during exercise.

The flow of blood through the capillaries of the lung depends on the cardiac output, which is a function of the heart rate and the stroke volume. The heart rate is typically 75 strokes/min and the stroke volume some 77 ml, and the cardiac output about 5000 ml/min.

It is the function of the lung to absorb oxygen from the air into the blood and to desorb carbon dioxide from the blood into the air. The measure of the ability of the lung to do this is pulmonary diffusion capacity D_L. The pulmonary diffusion capacity for oxygen is defined by the relation

$$D_{LO2} = \frac{\dot{V}_{O2}}{P_{AO2} - P_{AO2'}} \qquad [18.13.1]$$

where D_{LO2} is the pulmonary diffusion capacity for oxygen (ml/min mmHg), P_{AO2} is the partial pressure of oxygen in the alveolar space (mmHg), $P_{AO2'}$ is the equilibrium partial pressure of oxygen in the alveolar space and above the pulmonary capillaries (mmHg) and V_{O2} the rate of absorption of oxygen (ml/min). The diffusion capacity for carbon dioxide D_{LCO2} is defined in a similar way.

In practice, the principal measured values relate to the diffusion capacity of carbon monoxide D_{LCO}. Carbon monoxide has a very high affinity for haemoglobin, some 210 times that of oxygen, so that the equilibrium partial pressure of carbon monoxide in the alveolar space is very small and may be neglected in estimating the diffusion coefficient.

The diffusion capacity of a gas is proportional to its solubility and inversely proportional to the square root of its molecular weight. The solubilities of oxygen and carbon dioxide at 37°C are for water 2.386 and 56.7 ml gas/100 ml fluid atm and for plasma 2.14 and 51.5 ml gas/100 ml fluid atm, respectively. The diffusion capacity for oxygen D_{LO2} is $1.23 \times D_{LCO}$ and that for carbon dioxide is $24.6 \times D_{LCO}$. The ratio D_{LCO2}/D_{LO2} is 20.

The value of D_{LO2} at rest is about 75 ml/min mmHg.

	Partial pressure of oxygen (mmHg)
Ambient air	158
Tracheal air	149
Alveolar air	100
Exhaled air	116

The partial pressure of the exhaled air is the weighted average of the tracheal and alveolar air. The equilibrium partial pressure of oxygen above arterial blood $P_{O2a'}$ is about 95 mmHg and that above venous blood $P_{O2v'}$ about 40mmHg.

Blood comprises plasma and cells. The volume of plasma is some 45 ml/kg body weight and that of cells some 30 ml/kg body weight. For a man of 70 kg the volume of plasma is therefore about 3150 ml and that of blood about 5250 ml.

Extracellular fluid comprises some 20% and plasma some 5% of body weight. Thus extracellular fluid other than plasma has a volume some 3 times that of the plasma. All but a very small fraction of this extracellular fluid is in diffusion equilibrium. The specific gravity of plasma is 1.026.

Some principal relations for lung volumes, ventilation rates and partial pressures are

$$V_T = V_E = V_A + V_D \qquad [18.13.2]$$

$$\dot{V}_A = V_A f \qquad [18.13.3]$$

$$\dot{V}_E = V_E f \qquad [18.13.4]$$

$$\dot{V}_I = \frac{F_{EN2}}{F_{IN2}} \dot{V}_E \qquad [18.13.5]$$

$$\dot{V}_{O2} = \dot{V}_I F_{IO2} - \dot{V}_E F_{EO2} \qquad [18.13.6]$$

$$F_{EO2} = (F_{IO2} V_D + F_{A02} V_A)/V_E \qquad [18.13.7]$$

$$\dot{V}_{O2} = D_{LO2}(P_{AO2} - P_{AO2'}) \qquad [18.13.8]$$

$$P_{AO2'} \approx P_{O2A'} \qquad [18.13.9]$$

$$P_{O2'} = C_{O2}/H_{O2} \qquad [18.13.10]$$

where C_{O2} is the concentration of oxygen in the liquid phase (ml O_2/ml fluid), D_{LO2} is the pulmonary diffusion capacity for oxygen (ml/min mmHg), F_{AO2} is the concentration of oxygen in alveolar space (ml O_2/ml space), F_{EN2} is the concentration of nitrogen in the exhaled air (ml N_2/ml air), F_{EO2} is the concentration of oxygen in the exhaled air (ml O_2/ml air), F_{IN2} is the concentration of nitrogen in the exhaled air (ml N_2/ml air), F_{IO2} is the concentration of oxygen in the inhaled air (ml O_2/ml air), H_{O2} is Henry's law constant for oxygen (ml O_2/ml fluid (mmHg O_2)), P_{AO2} is the partial pressure of oxygen in the alveolar space (mmHg), $P_{AO2'}$ is the equilibrium partial pressure of oxygen at the capillary membrane (mmHg), $P_{O2'}$ is the equilibrium partial pressure of oxygen (mmHg), $P_{O2a'}$ is the partial pressure of oxygen above arterial blood (mmHg), V_A is the alveolar volume (ml), is the alveolar minute volume (ml/min), V_D is the anatomical dead space (ml), V_E is the volume exhaled (ml), $\dot{V}_E$ is the exhaled minute volume (ml/min), $\dot{V}_I$ is the inhaled minute volume (ml/min), $\dot{V}_{O2}$ is the oxygen consumption minute volume (ml/min), V_T is the tidal volume (ml), and f is the respiration rate (breaths/min).

Some principal physiological parameters in man relevant to respiration have been given in Table 18.14. Further data on the lung in man are summarized in Table 18.15.

18.13.2 Toxicokinetic models

The treatment just given of the respiratory system provides the front-end part for a toxicokinetic model describing the absorption and distribution of the toxin in the body.

Such toxicokinetic models for an inhaled gas may be developed by modelling the absorption of gas in the lung into the bloodstream. The difference between the mass inhaled and that exhaled equals the mass transferred across the membrane of the lung and this in turn equals the mass deposed in the body. Then if the chemical enters the main bloodstream, its concentration in the blood will be a function of the rates of absorption and of elimination. In simple terms, this situation may be modelled as a single exponential stage with a time constant that is a function of the apparent volume of distribution. The equilibrium back pressure of the chemical at the lung surface will depend on the concentration in the blood.

A toxicokinetic model of this general type is applicable where the toxic gas does not attack the respiratory system, but enters into the bloodstream and attacks some other organ in the body. There is, however, a lack of models relevant to hazard assessment.

18.13.3 Irritant gases

Such models are, in any case, less applicable to the important class of irritant gases, which act directly on the surface of the respiratory tract and/or lung rather than by accumulation in the body fluids. In this case the respiratory system acts as a sink for the chemical. This clearly requires a different model but, again, models suitable for hazard assessment are lacking.

18.13.4 Inhalation rates

In most cases the inhalation rate is a dominant factor in the entry of toxic gas into the system. It is therefore of great importance both in modelling the effects of and in extrapolating from experiments on toxic gases.

In applying to man the results of animal experiments on gas toxicity it is necessary to make allowance for the effect of inhalation rate. If the base case for comparison between animals and man is that each has the inhalation rate which is normal at rest, there are two separate allowances, or factors, which need to be applied. The first is between the inhalation rate of the animal at rest and in the experiment, the second between that of man at rest and in the accident conditions envisaged in the hazard assessment. It can be seen from Table 18.14 that there are appreciable differences in the inhalation rates, as related to features such as body weight and lung surface area.

Information on the breathing of animals during exposure is recorded in some experiments, although quantitative data appear to be relatively rare. By contrast, the variation of the inhalation rate of man with different degrees of exercise is well documented. Some data given by Henderson and Haggard (1943) are shown in Table 18.16.

Table 18.15 *Some principal parameters of the lung in man (after Mountcastle, 1974) (Courtesy of CV Mosby Company)*

[a] J.B.West (1965).

18.13.5 Other factors

The respiratory system is not the only organ that is a target for toxic gases. The eyes and the skin may also be affected. Accounts of the eye relevant here are given in Toxicology of the Eye (Grant, 1962) and *Synopsis of Ophthalmology* (Havener, 1971).

18.14 Gas Toxicity: Toxicity Data

Before considering the toxicity of some of the principal industrial gases, attention is drawn to some of the general sources of data on toxicity, particularly toxicity to humans.

Sources of toxicity data have been described in Section 18.3. Some texts which deal particularly with gas toxicity include: *Kompendittm der praktischen Toxikologie* (Kobert, 1912); *Industrial Poisoning* (Rambousek, 1913); *Kurzes Lehrbuch der Arbeits- und Gewerbehygiene* (Lehmann, 1919); *Industrial Poisons in the United States* (Hamilton, 1925); *Lehrbuch der Toxikologie* (Flury and Zanger, 1928), *Noxious Gases* (Henderson and Haggard, 1943); *Industrial Hygiene and Toxicology* (Patty, 1948–), with its later editions (Cralley and Cralley, 1978; Wands, 1981; Clayton and Clayton, 1991 ACGIH/73); *Dangerous Properties of Industrial Materials* (Sax, 1957–), with its later edition (Lewis, 1992 ACGIH/89); *Toxicology of Drugs and Chemicals* (Deichman and Gerarde, 1969); and *Toxicology: the Basic Science of Poisons* (Casarett and Doull, 1975), with its later edition (Amdur, Doull and Klaassen, 1991 ACGIH/54).

At the turn of the century an appreciable amount of research was done in Germany by Lehmann and others on the effects on humans of many gases of industrial interest. This includes work by Lehmann himself (Lehmann, 1886, 1887, 1893, 1899a) and by Matt (1889); there is also later work by Hess (1911), Drescher (1920), Dschang (1928) and Beck (1959).

Table 18.16 *Inhalation rate for various levels of activity for man (after Henderson and Haggard, 1943)*

Activity	*Inhalation rate*[a] (l/min)	*Oxygen consumption rate*[b] (l/min)
Rest in bed, fasting	6	0.240
Sitting	7	0.300
Standing	8[c]	0.360
Walking, 2 mile/h	14	0.650
Walking, 4 mile/h	26	1.200
Slow run	43	2.000
Maximum exertion	65–100	3.000–4.000

[a] Measured at 0°C and 760 mmHg.
[b] Measured at 20°C.
[c] This value is quoted by A. Meyer (1938) and also by Prentiss (1937).

Many of the main industrial gases have also been used in warfare, particularly in the First World War. Accounts of the military use of these gases do not generally provide usable quantitative data, but some give pointers to the effects of the gases on humans that constitute a collateral check on data from animal experiments, which is the main source.

Accounts of the gas warfare are given in *The Poison War* (A.A. Roberts, 1915), *Reports of the Chemical Warfare Medical Committee* (1918–), *Atlas of Gas Poisoning* (MRC, 1918), *The Lethal War Gases* (Underbill, 1920), *Chemical Warfare* (Fries and West, 1921), *History of the Great War, Medical Services, Diseases of the War*, vol. II (Macpherson *et al.*, 1923), *Gas Warfare* (Fischmann, 1924), *Poisoning Warfare Gases* (Gilchrist, 1924), *Fünf Vortrage aus den Jahren 1920–1923* (F. Haber, 1924), *La Guerre Chimique* (Le Wita, 1925), *The Medical Aspects of Chemical Warfare* (Vedder, 1925), *The Medical Department of the United States Army in the World War, vol. 14: Medical Aspects of Gas Warfare* (Ireland, 1926), *Der Gaskampf und die chemischen Kampfstoffen* (J. Meyer, 1926), *History of the War: Military Operations in France and Belgium* (Edmonds and Wynne, 1927), *A Comparative Study of World War Casualties from Gas and Other Weapons* (Gilchrist, 1928), *Manual of Treatment of Gas Casualties* (Anon., 1930), *Schadliche Case* (Flury and Zernik, 1931), *Grun und Gelbkreuz* (Buscher, 1932), *Die wichtigsten Vergiftungen* (Loschke, 1933), *Die Gasschutzfrage* (Zangger, 1932), Gas. The Story of the Special Brigade (Foulkes, 1934), *Leitfaden der Pathologie und Therapie der Kampjgaserkrankungen* (Muntsch, 1935), *Die Tiere im chemischen Krieg* (Richters, 1936b), *Der chemische Kreig* (Hanslian, 1937), *Chemicals in War* (Prentiss, 1937), *Breathe Freely* (Kendall, 1938), *Gaz de Combat* (A. Meyer, 1938), *The War Gases* (Sartori, 1939), *Chemical Warfare* (Wachtel, 1941), *United States Army in World War II: The Technical Services: Chemical Warfare Service* (Brophy, Miles and Cochrane, 1959), *The Problem of Chemical and Biological Warfare, vol. 1: The Rise of CB Weapons* (Q.P. Robinson, 1971) and *The Poisonous Cloud. Chemical Warfare in the First World War* (L.F. Haber, 1986). Other work on war gases is described by L. Hill (1915, 1920), Haldane, Meakins and Priestley (1918a,b, 1918/19), Herringham (1919, 1920), Flury (1921a,b), Haggard (1924), Chlopin (1927–) and Richters (1936b).

Accounts of the physiological and medical aspects of gas poisoning are given in *Respiratory Function of the Blood* (Barcroft, 1925), *Respiration* (Haldane and Priestley, 1935), and *Pulmonary Oedema and Inflammation* (Drinker, 1945).

Some authors have dealt in a single publication with a number of different gases. They include Lehmann (1893, 1899a), Ronzani (1908, 1909), Hess (1911), Zeehuisen (1922), Haggard (1924), Schutze (1927), Walton and Witherspoon (1928), Carpenter, Smyth and Pozzani (1949), Smyth and Carpenter (1949), Zielhuis (1970), Higgins *et al.* (1972), MacEwen and Vernot (1972), Vernot *et al.* (1977) and ten Berge, Zwart and Appelman (1986).

Setterstrom and co-workers (McCallan and Setterstrom, 1940; Thornton and Setterstrom, 1940; Weedon, Hartzell and Setterstrom, 1940) have studied ammonia, chlorine, hydrogen cyanide, hydrogen sulfide and sulfur dioxide.

A somewhat separate area of work that also yields toxicity data is that on the toxicity of combustion products. Accounts of research in this area, notably by Hilado and co-workers and by Hartzell and co-workers, are given in Section 18.22.

An early collection of gas toxicity data for hazard assessment is that given in the Vulnerability model of Eisenberg, Lynch and Breeding (1975), and extended by Perry and Articola (1980). Their work is discussed below. Another collection of data on gas toxicity is that made by Back, Thomas and MacEwen (1972).

8.15 Gas Toxicity: Vulnerability Model

18.15.1 Initial model

As just stated, some of the first correlations for the toxicity of industrial gases relevant to major releases were those given in the vulnerability model by Eisenberg, Lynch and Breeding (1975). These workers analysed data for the toxicity of chlorine and ammonia and obtained probit equations for the lethality of these two gases. For chlorine they found that the line for composite lethality in animals passes through the following points:

Arbitrary units	*Percent affected*
0.54	3
0.59	5
1	50
1.5	90
1.8	97 (extrapolated)

They also refer to the *Guide for Short-Term Exposure for Chlorine* (NAS/NRC, 1973), which describes an exposure of 14–21 ppm for 0.5–1 h as 'dangerous' and one of 34–51 ppm for 1–1.5 h as 'lethal'. They suggest that the terms 'dangerous' and 'lethal' might be interpreted as 5% and 90% lethal.

Eisenberg, Lynch and Breeding quote limit values given in the *Guides for Chlorine* (NAS/NRC, 1973) and ammonia (NAS/NRC, 1972b). At the short-term exposure limit (STEL), there is mild odour, minimal irritation and no health hazard. The STEL values for chlorine and ammonia are:

Time (min)	*Concentration* (ppm)	
	Chlorine	*Ammonia*
10	1	20
30	0.5	10
60	0.5	10

At the public emergency limit (PEL), there is strong odour and some irritation. The PEL values, which are ceilings, not averages, for chlorine and ammonia are:

Time (min)	*Concentration* (ppm)	
	Chlorine	*Ammonia*
10	3	100
30	2	75
60	2	50

In addition, they quote for chlorine the EEL suggested by Zielhuis (1970):

Time (min)	*Concentration* (ppm)
5	7
15	5
30	4
60	3

On the basis of such arguments the authors give for chlorine the following response relations:

Chlorine concentration (ppm)	*Time of exposure*	*Effect*
3	Any	No risk, but some harassment
7	1 h or more	Strong to intolerable irritation, with some risk to highly susceptible individuals
20	Severals hours	50% lethal (their estimate)
33	c.1 h	50% lethal (estimate based on NAS/NRC report)
60	c.10 min	50% lethal (their estimate)

Eisenberg, Lynch and Breeding took the causative factor V in the probit equation for chlorine as

$$V = \sum C_i^n T_i \qquad [18.15.1]$$

where C is the concentration (ppm), T is the time interval (min), and n is an index. From analysis of the data, they obtained a value of $n = 2.75$. The probit equation for chlorine lethality derived by these authors is then

$$Y = -17.1 + 1.69 \ln\left(\sum C_i^{2.75} T_i\right) \qquad [18.15.2]$$

where Y is the probit.

A similar treatment was applied to ammonia. For this gas the authors give the following response relations:

Ammonia concentration (ppm)	*Time of exposure*	*Effect*
20	Any	Odour detected by majority of population
100	Any	Irritation and complaint
500	Any	Strong to intolerable irritation, with some risk to highly susceptible individuals
2500–5000		Fatalities mostly from a few in the first 5 min to 90–100% after 1 h, depending on concentration
>5000		100% fatal. Heavy casualties in 5–10 min, and shorter exposures are unlikely in practice

and derive the following probit equation for ammonia lethality:

$$Y = -30.57 + 1.385 \ln\left(\sum C_i^{2.75} T_i\right) \qquad [18.15.3]$$

The relationships described apply to healthy adults. The population also includes more susceptible individuals such as infants, old people and people with advanced pulmonary/cardiovascular disease. The authors propose for such high risk populations the scaling shown in Table 18.17, which is applied to specific concentrations and exposure times for chlorine and ammonia.

Eisenberg, Lynch and Breeding also consider non-lethal injury from chlorine. They give the following estimated response:

Chlorine concentration (ppm)	*Percent affected*
6	1
10	25
13	50
20	90

In this case the causative factor is taken simply as $V = C$. The probit equation for non-lethal injury from chlorine is then

$$Y = -2.40 + 2.90 \ln C \qquad [18.15.4]$$

Non-lethal injury is here taken to mean hospitalization without or with lasting impairment of health.

The authors discuss the possible long-terms effects of exposure to chlorine. They state:

> The most recent paper seen was Weill *et al.* (1969). They say that their data for subjects seven years after an accidental exposure to chlorine 'are consistent with the prevailing clinical view that significant permanent lung damage does not result from acute exposure to chlorine gas'. Reports referenced in their paper support this finding: for example, 'no evidence that chlorine intoxication produced residual pulmonary disease' in the 33 most severely affected victims of a major accident; a large survey of industrial exposures did not find 'any evidence of permanent damage to the respiratory tract' another study including war casualties found that 'permanent pulmonary injury was rare'.

18.15.2 Development of model

A further set of probit equations for lethality for use in the Vulnerability model was derived by Perry and Articola (1980). For chlorine the authors quote without reference a set of 'best estimates' which seem close to the data set given by Eisenberg, Lynch and Breeding (Table 6–4) but use a slightly different value of n (2.64 instead of 2.75). For ammonia, they refer again to the data set given in Eisenberg, Lynch and Breeding (Table 6–4). They use in this case an appreciably different value of n (1.36 instead of 2.75).

***Table 18.17** Relation between the lethal concentration of chlorine for the general population and a vulnerable population (Eisenberg, Lynch and Breeding, 1975)*

Level of effect	*Deaths* (%)	
	General population	*High risk population*
Severe harassment with some risk	0	25
Lethal	3	50
Lethal	50	100

For hydrogen cyanide the authors use estimates made by McNamara (1976) based on animal data. They also adapt these data for two other gases, acrylonitrile and hydrogen sulfide, having found no suitable data for these substances. In the latter case they quote C.L. Evans (1967) on the similarities between the effects of the two gases. For acrylonitrile they use the same lethal dose values and probit equation as for hydrogen cyanide, whilst for hydrogen sulfide they double the lethal dose values compared with hydrogen cyanide and thus obtain a different probit equation.

For hydrogen fluoride they utilize data from an earlier study for the Vulnerability model by Rausch, Tsao and Rowley (1977) based on data from Braker and Mossman (1970), Darmer, Haun and MacEwen (1972), Higgins *et al.* (1972), MacEwen and Vernot (1974) and Wohlslagel, DiPasquale and Vernot (1976). They adopt the same value of n namely $n = 1$; in other words, Haber's law.

For hydrogen chloride, Perry and Articola utilize data from another previous study for the Vulnerability model by Rausch, Eisenberg and Lynch (1977). The value of n is 1.0. They use same lethal dose values and value of n for sulfur dioxide (in mg/m^3), the difference in the probit equations being due to the conversion to parts per million.

For phosgene, the authors again utilize data from Rausch, Eisenberg and Lynch. The value of n is 1.0.

Two probit equations for non-lethal injury are also given: by Eisenberg, Lynch and Breeding for chlorine and one derived by the authors themselves for hydrogen fluoride.

The values of the parameters in the probit equations obtained by Perry and Articola are given in Section 18.20.

The support for the probit equations in the Vulnerability model is in some cases rather slight and the level of physical activity to which they are applicable is not well defined.

18.16 Gas Toxicity: Major Industrial Gases

The toxicity of a number of major industrial gases is now considered in more detail. In general, toxic hazard from these gases arises from their manufacture, storage and use in the manufacture of other chemicals. In some cases, hazard arises from another cause. For example, a common cause of gassing by hydrogen sulfide is its presence as an impurity in crude oil and in confined spaces. The overview of the physiological effects of the main industrials gases given in *Noxious Gases* (Henderson and Haggard, 1943) provides a useful introduction to this aspect.

For irritant gases, an important parameter is the solubility in water, which largely determines the part of the respiratory system attacked. Haggard (1924) gives the following relative figures for the solubility of such gases in water at 40°C: ammonia, 444 (extrapolated); hydrogen chloride, 385; sulfur dioxide, 18.7; bromine, 9.4; and chlorine, 1.4. No value is given for phosgene, which decomposes in water.

Incidents involving toxic gases are described in Section 18.27.

18.16.1 Chlorine

There are two industrial toxic gases which in liquefied form are handled on a large scale and are readily dispersed and which therefore present a major toxic hazard. Chlorine is one, and ammonia the other.

Chlorine is a highly toxic gas. The long- and short-term OESs are 0.5 and 1 ppm, respectively. The values represent a small reduction from the TLV (TWA) of 1 ppm that held for many years. Physiologically, chlorine is an irritant gas. The effects of a single exposure include irritation of the mucous membranes, attack of the respiratory tract and pulmonary oedema. A fuller account is given in Section 18.18.

Early work on chlorine includes that Eulenberg (1865), Lehmann (1887, 1899a,b) and Hess (1911). Chlorine was the first gas used in major gas attacks and is treated in virtually all the war gas texts referred to in Section 18.14, and in particular in Underbill (1920), Winternitz, Lambert *et al.* (1920), Gilchrist (1924), F. Haber (1924), Vedder (1925), Flury and Zernik (1931), Prentiss (1937), and by Black, Glenny and McNee (1915), Bradford and Elliott (1915–16), L. Hill (1915, 1920), Schafer (1915), Kramer (1917), Haldane, Meakins and Priestley (1918a,b, 1918–19), Schultz (1918a,b), Schultz and Hunt (1918), Achard (1919), Barbour (1919), Barbour and Williams (1919), Baskervffle (1919), Burrell (1919), Herringham (1919, 1920), Hjort and Taylor (1919), Meakins and Priestley (1919), Vinet (1919), Gunn (1920), Flury (1921a, 1928), Chlopin (1927–), Flury and Zernik (1932), Abbott (1933), Gilchrist and Matz (1933) and Freitag (1940). More recent work includes that by Ceiling and McLean (1941), Cralley (1942), Silver and McGrath (1942), Silver, McGrath and Ferguson (1942), Fowell (1949), A.T. Jones (1952), Elmes and Bell (1963), Gay (1963), Flake (1964), D.P. Bell and Elmes (1965), Kowitz *et al.* (1967), C.G. Kramer (1967), Rupp and Henschler (1967), Schlagbauer and Henschler (1967), Krause, Chester and Gillespe (1968), Beach, Jones and Scarrow (1969), Chester, Gillespie and Krause (1969), Sartorelli (1969), Faure *et al.* (1970), Sessa *et al.* (1970), Kaufman and Burkons (1971), Leube and Kreiter (1971), Barrow and Smith (1975), Colardyn *et al.* (1976), Barrow *et al.* (1977), Chester *et al.* (1977), Bitron and Aharonson (1978), Barrow and Dodd (1979), Barrow *et al.* (1979), Withers and Lees (1985a,b), Withers (1986a) and Zwart and Woutersen (1988). Work on chlorine is also included in treatments dealing with a number of gases, including those by Zeehuisen (1922), Haggard (1924), Setterstrom and co-workers (McCallan and Setterstrom, 1940; Thornton and Setterstrom, 1940; Weedon, Hartzell and Setterstrom, 1940), Carpenter, Smyth and Pozzani (1949), Beck (1959), and Buckley *et al.* (1984).

The toxicity of chlorine has been reviewed in *Chlorine and Hydrogen Chloride* by the (WHO, 1982 EHC21) and in the *Chlorine Toxicity Monograph* (MHAP, 1987); an account from the latter work has been given by Withers (1985). The Monograph estimates that in the absence of any subsequent medical treatment the LC$_{50}$ for 30 min for healthy adults is of the order 400 ppm.

Probit equations for chlorine have been given by Eisenberg, Lynch and Breeding (1975), Perry and Articola (1980), ten Berge and van Heemst (1983), Withers and Lees (1985b), and ten Berge, Zwart and Appelman (1986), in the Rijnmond Report (Rijnmond Public Authority, 1982), and by the Center for Chemical Process Safety (CCPS) and the CPD. Dangerous dose values are given by the HSE, as described below.

Chlorine is one of the gases considered in the hazard assessment study of Back, Thomas and MacEwen (1972). The evidence is that serious long-term effects of non-lethal single exposure to chlorine are rare. This aspect is discussed in Section 18.15.

A fuller treatment of chlorine toxicity is given in Section 18.18.

18.16.2 Ammonia

The other principal industrial toxic gas is ammonia. Like chlorine, it is a severe toxic hazard because it is handled on a large scale, it is a liquefied gas and is therefore readily dispersed, and it is highly toxic. Ammonia has long- and short-term OESs of 25 and 35 ppm, respectively.

Physiologically, ammonia is an irritant gas. The effects of a single exposure include irritation of the mucous membranes, attack of the respiratory tract and pulmonary oedema. Ammonia is very much more soluble in water than chlorine, and therefore tends to attack particularly the upper respiratory tract, stripping the lining, and inducing laryngeal oedema.

Early work on ammonia includes that by Lehmann (1886, 1893), Matt (1889), Hess (1911) and Ronzani (1908, 1909). Ammonia does not appear to have been a candidate war gas, but it is discussed by Flury (1921a, 1928), Flury and Zernik (1931) and Henderson and Haggard (1943). More recent work includes that by Boyd, MacLachlan and Perry (1944), Silver and McGrath (1948), Silver-man, Whittenberger and Muller (1949), Alpotov and Michailov (1963), H.A. Mitchell (1963), Alpotov (1964), Helmers, Top and Knapp (1971), Mayan and Merilan (1972), Hilado, Casey and Furst (1977), Verberk (1977), Richard, Jounay and Boudene (1978), Dodd and Gross (1980), Appelman, ten Berge and Reuzel (1982), Kapeghian *et al.* (1982), ten Berge and van Heemst (1983), Withers (1986b) and Pedersen and Selig (1989). Work on ammonia is also included in treatments dealing with a number of gases, including those by Haggard (1924), Setterstrom and co-workers (McCallan and Setterstrom, 1940; Thornton and Setterstrom, 1940; Weedon, Hartzell and Setterstrom, 1940), Carpenter, Smyth and Pozzani (1949), Coon *et al.* (1970), Stupfel *et al.* (1971), Vernot *et al.* (1977) and Buckley *et al.* (1984).

The toxicity of ammonia in the specific context of process plants has been considered by D.P. Wallace (1979).

The toxicity of ammonia has been reviewed in *Ammonia* (WHO, 1986 EHC54) and in *Ammonia Toxicity Monograph* (MHAP, 1988).

Probit equations for ammonia have been given by Eisenberg, Lynch and Breeding (1975), Perry and Articola (1980), ten Berge, Zwart and Appelmann (1986), the CCPS and the CPD. Dangerous dose values are given by the HSE, as described below.

Ammonia is one of the gases considered in the hazard assessment study done by Back, Thomas and MacEwen (1972).

There is little evidence of serious long-term effects of non-lethal single exposure, except where the exposure has been so serious that death has been prevented only by medical attention, when respiratory deficiencies may occur.

18.16.3 Acrylonitrile

Acrylonitrile is an irritant gas and is also assigned the 'risk phrase' R45. It has a long-term MEL of 2 ppm, but no quoted short-term limit.

Physiologically, acrylonitrile vapour causes various irritant effects including pulmonary oedema. Various other effects such as vomiting, convulsions and incoordination have been reported in animals.

Most work on the toxicity of acrylonitrile has been carried out since 1940. Studies include those of Dudley and Neal (1942), Dudley, Sweeney and Miller (1942), R.H. Wilson (1944), R.H. Wilson, Hough and McCormick (1948), Carpenter, Smyth and Pozzani (1949), McOmie (1949), Smyth and Carpenter (1949), Brieger, Rieders and Hoders (1952), Knobloch *et al.* (1971), Rogaczewska (1975), McNamara (1976), Appel, Peter and Bolt (1981) and ten Berge, Zwart and Appelman (1986).

Probit equations for acrylonitrile have been given by Perry and Articola (1980), ten Berge, Zwart and Appelman (1986), the CCPS and the CPD. Dangerous dose values are given by the HSE, as described below.

18.16.4 Bromine

Bromine is a highly toxic gas. It has long- and short-term OESs of 0.1 and 0.3 ppm, respectively. The toxic properties of bromine are somewhat similar to those of chlorine, but there are also significant differences.

Physiologically, bromine is an irritant gas. The effects of a single exposure include irritation of the mucous membranes, attack of the respiratory tract and pulmonary oedema. Bromine is less soluble than ammonia, but more soluble than chlorine. It tends to attack the upper respiratory tract as well as the lungs, stripping the lining and, inducing suffocation. It also tends to cause more severe sublethal injury than chlorine.

Most work on bromine has been conducted in conjunction with work on chlorine, which has led experimenters to compare the toxicity of the two gases. Early work on bromine was carried out by Lehmann (1887, 1893) and Hess (1911). Experiments conducted during the First World War are described by L. Hill (1915, 1920), Symes (1915a,b) and Chlopin (1927–). More recent work includes that by Rupp and Henschler (1967), Schlagbauer and Henschler (1967) and Bitron and Aharonson (1978). Work on bromine is also included in treatments dealing with a number of gases, including that of Haggard (1924).

From this work Withers and Lees (1986b) concluded that bromine is some 1.5 times as toxic as chlorine. Adopting essentially the same methodology as in their work on chlorine, described below, they give for the standard level of activity for the regular population the following probit equation for the lethality of bromine:

$$Y = -9.04 + 0.92 \ln L^* \qquad [18.16.1]$$

with

$$L^* = \sum C^2 T \qquad [18.16.2]$$

where C is the concentration (ppm), L^* is the toxic load (ppm^{2}min) and T is the exposure time (min). This probit equation is discussed by P.C. Davies and Purdy (1987) and Withers and Lees (1987a).

Further probit equations for bromine have been given by ten Berge, Zwart and Appelman (1986), the CCPS and the CPD, as described below.

18.16.5 Carbon dioxide

Carbon dioxide is an asphyxiant, but also a toxic gas. It has long- and short-term OESs of 5,000 and 15,000 ppm, respectively. At a concentration of 10% it can cause unconsciousness within 1 min. It is odourless.

Hazard from the use of carbon dioxide in manufacturing arises where it is used in processes or where it is generated by combustion.

18.16.6 Carbon monoxide

Carbon monoxide is a chemical asphyxiant. It combines with haemoglobin in the blood, thus displacing the oxygen. It has long- and short-term OESs of 50 and 300 ppm, respectively. It is odourless.

Hazard from carbon monoxide arises where it occurs as a process gas or where it is generated, as in combustion processes. Carbon monoxide is responsible for a significant proportion of deaths from gas poisoning.

18.16.7 Hydrocarbons

Hydrocarbons vary in toxicity. Some are asphyxiants, for example, propane; others are assigned an OES, for example, butane, which has long- and short-term OESs of 600 and 750 ppm, respectively.

18.16.8 Hydrogen chloride

Hydrogen chloride has a short-term OES of 5 ppm with no quoted long-term value. Physiologically, hydrogen chloride is an irritant gas. The effects of a single exposure include irritation of the mucous membranes, attack of the respiratory tract and pulmonary oedema.

Early work on hydrogen chloride includes that by Lehmann (1886) and Hess (1911). Hydrogen chloride does not appear to have been a serious candidate war gas. More recent work includes that by Machle *et al.* (1942), Greenfield *et al.* (1969), Darmer, Kinkead and Dipasquale (1972, 1974), Nagao *et al.* (1972), Hilado and Furst (1976), Barrow *et al.* (1977), Hilado and Gumming (1978), Barrow, Lucia and Alarie (1979), Hartzell *et al.* (1985) and Hartzell (1989). Work on hydrogen chloride is also included in treatments dealing with a number of gases, including those of Haggard (1924), Higgins *et al.* (1972), MacEwen and Vernot (1972), Vernot *et al.* (1977) and Buckley *et al.* (1984).

The toxicity of hydrogen chloride has been reviewed in *Chlorine and Hydrogen Chloride* (WHO, 1982 EHC21).

Probit equations for hydrogen chloride have been given by Perry and Articola (1980), ten Berge, Zwart and Appelman (1986), the CCPS and the CPD, as described below.

Hydrogen chloride is one of the gases considered in the hazard assessment study of Back, Thomas and MacEwen (1972).

18.16.9 Hydrogen cyanide

Hydrogen cyanide has a short-term MEL of 10 ppm with no quoted long-term value. Physiologically, hydrogen cyanide is chemical asphyxiant. It causes cyanide poisoning, which is a form of asphyxia caused by the arrest of internal respiration. Its action can be very rapid.

Early work on hydrogen cyanide includes that by Geppert (1889), Matt (1889), Ahlmann (1905), Hess (1911), Fiihner (1919), Drescher (1920), Koelsch (1920), Reed (1920), Hasselmann (1925a,b), Dschang (1928), R. Schwab (1929), Hug (1932), Wirth and Lammerhirt (1934) and Wirth (1935, 1937). Hydrogen cyanide was considered for use, but found little application, as a war gas, and its toxicity is dealt with in some of the texts on war gases, including those of F. Haber (1924), Vedder (1925), Ireland (1926), Flury and Zernik (1931), Foulkes (1934), Muntsch (1935), Hanslian (1937), Prentiss (1937), Wachtel (1941), Henderson and Haggard (1943) and by Flury (1921, 1928) and Chlopin (1927–). More recent work includes that of MacNamara (1976), Hilado and Furst (1976), Hilado and dimming (1978), Hartzell, Priest and Switzer (1985) and Hartzell (1989). Work on hydrogen cyanide is also included in treatments dealing with a number of gases, including those of Schutze (1927), Walton and Witherspoon (1928) and Setterstrom and co-workers (McCallan and Setterstrom, 1940; Thornton and Setterstrom, 1940; Weedon, Hartzell and Setterstrom, 1940), Higgins *et al.* (1972) and Vernot *et al.* (1977).

Probit equations for hydrogen cyanide have been given by Perry and Articola (1980), ten Berge, Zwart and Appelman (1986), the CCPS and the CPD, as described below.

Hydrogen cyanide is one of the gases considered in the hazard assessment study done by Back, Thomas and MacEwen (1972).

18.16.10 Hydrogen fluoride

Hydrogen fluoride has a short-term OES (as F) of 3 ppm, with no quoted long-term value. Physiologically, hydrogen fluoride is an irritant and also has systemic effects. The irritant effects of a single exposure include irritation of the mucous membranes, attack of the respiratory tract and pulmonary oedema. There is also evidence of systemic effects on organs including the liver, kidney, heart, spleen and thymus.

Hydrogen fluoride is subject to oligomerization, the extent depending on the pressure and temperature. At typical atmospheric conditions the apparent molecular weight is in the range 68–78.

Accounts of the properties of hydrogen fluoride are given by Muehlberger (1928), Simons (1931), Rushmere (1954), Maclean *et al.* (1962), Schotte (1987) and Clough, Grist and Wheatley (1987).

Early work on hydrogen fluoride includes that by Matt (1889), Ronzani (1908, 1909), Kehoe *et al.* (1932), Machle *et al.* (1934), Machle and Kitzmiller (1935) and Machle and Scott (1935) and Stokinger (1949). Hydrogen fluoride does not appear to have been a serious candidate as a war gas, but it is discussed by Flury and Zernik (1931) and Henderson and Haggard (1943). More recent work on the gas includes that by Rosenholtz *et al.* (1963), MacEwen and Vernot (1970), Darmer, Haun and MacEwen (1972), Hilado and Furst (1976), Hilado and Cumming (1978), Valentine (1988) and Mudan (1989a). Work on hydrogen fluoride is also included in treatments dealing with a number of gases, including those of Higgins *et al.* (1972), Wohlslagel, DiPasquale and Vernot (1976) and Vernot *et al.* (1977).

Probit equations for fatal injury by hydrogen fluoride have been given by Perry and Articola (1980), ten Berge, Zwart and Appelman (1986), Mudan (1989a), the CCPS and the CPD. Dangerous dose values are given by the HSE, as described below.

Mudan (1989a) derives his probit equation as follows. He utilizes primarily the more recent work of Rosenholtz *et al.*, MacEwen and Vernot, Darmer, Haun and McEwen, Higgins *et al.*, Wohlslagel, DiPasquale and Vernot, and the preliminary results of Valentine; MacEwen and Vernot give raw data, some of which is used by Darmer, Haun and MacEwen. From the results of these various workers he first establishes, using four data sets, that Haber's law applies, namely, $ct = \text{Constant}$. He then obtains LCt_{50} values of 26,880 ppm min for mice, 46,900 ppm min for small rats, 84,000 ppm min for large rats, 64,900 ppm min for guinea pigs and 106,440 ppm min for monkeys. Applying the toxicologist's rule-of-thumb that consistent results from three animal species may be applied to humans, he obtains for the latter the estimated LCt_{50} of 59,200 ppm min. Next he obtains separate probit equations for each of the species and from these a median best estimate of the slope of 4.853, thus yielding the desired probit equation:

$$Y = -48.33 + 4.853 \ln L^* \qquad [18.16.3]$$

Where

$$L^* = Ct \qquad [18.16.4]$$

where C is the concentration (ppm) and t is the time (min). Mudan also determines the 90% confidence limits on the slope as 2.854 and 8.348. Using the lower value of the slope he obtains the further '90% slope probit' equation:

$$Y = -26.36 + 2.854 \ln L^* \qquad [18.16.5]$$

The mortality given by these two probit equations is shown together with the experimental values in Figure 18.6.

Hydrogen fluoride is one of the gases considered in the hazard assessment study done by Back, Thomas and MacEwen (1972).

18.16.11 Hydrogen sulfide

Hydrogen sulfide has long- and short-term OESs of 10 and 15 ppm, respectively. Physiologically, hydrogen sulfide is an irritant and a chemical asphyxiant. The irritant effects of a single exposure include irritation of the mucous membranes, attack of the respiratory tract and pulmonary oedema. It also has an asphyxiant effect, caused by inhibition of cytochrome oxidase and resulting in arrest of respiration at the brain.

The gas can be detected at low concentration, but the sense of smell is lost after 2–15 min exposure, thus making it impossible to detect dangerous concentrations. Moreover, the odour of hydrogen sulfide can be masked by the presence of other chemicals: tests have shown that concentrations below 1 ppm could be detected by odour in air, but in the presence of light hydrocarbons such as propane or butane even 5–10 ppm could not be smelt.

Early work on hydrogen sulfide includes that by Biefel and Pollock (1880), Lehmann (1892, 1893, 1899a), Hess (1911), Haggard and Henderson (1922), Haggard (1925),

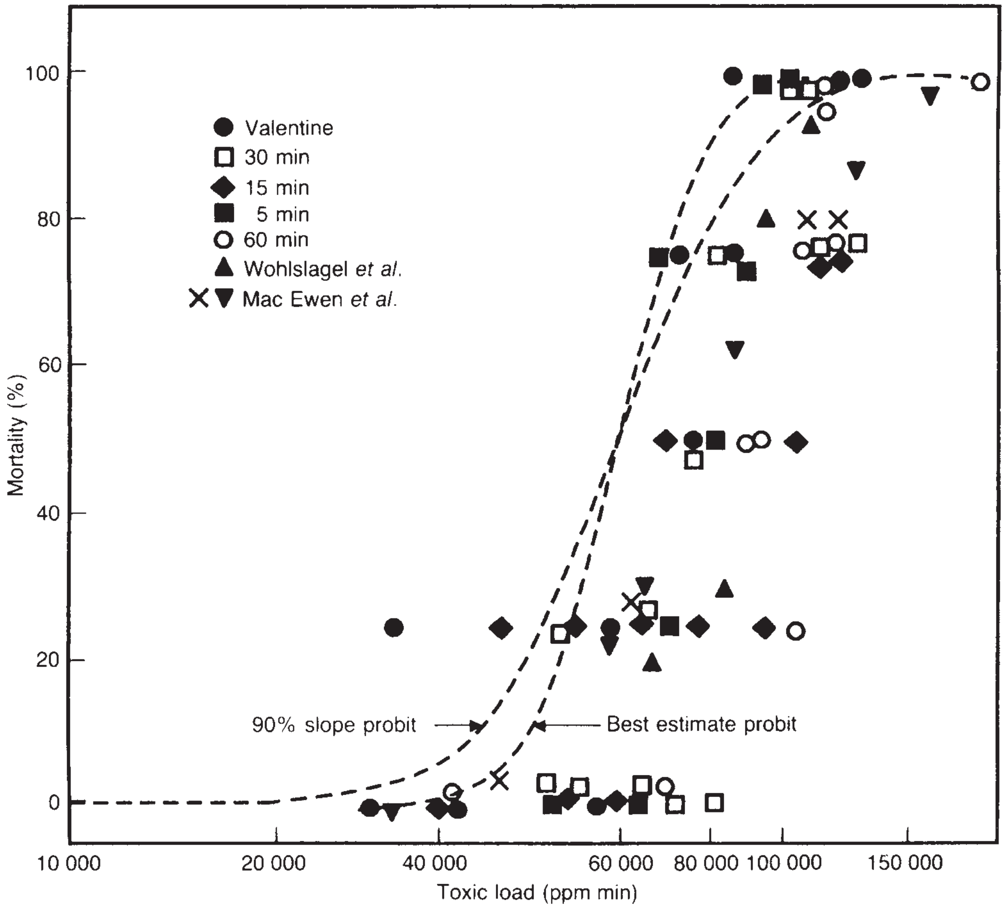

Figure 18.6 *Mortality–toxic load response from best estimate probit for hydrogen fluoride (Mudan, 1989a) (Courtesy of the American Institute of Chemical Engineers)*

C.W. Mitchell and Yant (1925), Gerbis (1927), Flury (1928), Aves (1929) and Yant (1930). Hydrogen sulfide was considered for use, but found little application as a war gas, and its toxicity is dealt with in some of the texts on war gases, including those of Vedder (1925), Flury and Zernik (1931), Foulkes (1934), Muntsch (1935), Hanslian (1937), Henderson and Haggard (1943) and by Flury (1928). More recent work on the gas includes that by Rubin and Arieff (1945), Adelson and Sunshine (1966), Lund and Wieland (1966), Kosmider, Rogala and Pacholek (1967), Hays (1972), Archibald (1977), Beck, Cormier and Donini (1979), NRC (1979), Tansy *et al.* (1981), Ammann (1986), Lopez *et al.* (1987), Prior *et al.* (1988) and Lopez *et al.* (1989). Work on hydrogen sulfide is also included in treatments dealing a number of gases, including those of Schutze (1927), Walton and Witherspoon (1928) and Setterstrom and co-workers (McCallan and Setterstrom, 1940; Thornton and Setterstrom, 1940; Weedon, Hartzell and Setterstrom, 1940) and Vernot *et al.* (1977).

The toxicity of hydrogen sulfide has been reviewed in *Hydrogen sulphide* (WHO, 1983 EHC19).

Probit equations for hydrogen sulfide have been given by Perry and Articola (1980), ten Berge, Zwart and Appelman (1986), the CCPS and the CPD. Dangerous dose values are given by the HSE, as described below.

Hydrogen fluoride is one of the gases considered in the hazard assessment study done by Back, Thomas and MacEwen (1972).

18.16.12 Methyl isocyanate

Methyl isocyanate (MIC) has, like all isocyanates, long- and short-term MELs (as NCO) of 0.02 and 0.07 mg/m^5, respectively. Physiologically, MIC is an irritant and its effects include pulmonary oedema.

MIC came to prominence as the gas responsible for the toxic gas disaster at Bhopal, described in Appendix 5.

Prior to Bhopal, there seems to have been relatively little work published on the toxicity of MIC, with the exception of a study by Kimmerle and Eben (1964). Subsequent work has been done by ten Berge (1985). Probit equations for MIC have been given by ten Berge (1985), the CCPS and the CPD, as described below.

18.16.13 Oxides of nitrogen

Oxides of nitrogen are toxic gases. They have little irritant effect, but inhalation can cause death some hours later. Nitrogen monoxide has long- and short-term OESs of 25 and 35 ppm, respectively. Nitrogen dioxide has long- and short-term OESs of 3 and 5 ppm, respectively.

Hazard from oxides of nitrogen arises from their use in the manufacture of sulfuric and nitric acids and from their generation in welding.

18.16.14 Phosgene

Phosgene has long- and short-term OESs of 0.02 and 0.06 ppm, respectively. Until recently the gas had a long-term OES of 0.1 ppm, with no quoted short-term value (see EH 40/92). The current values therefore represent a significant reduction.

Physiologically, phosgene is an irritant. The effects of a single exposure include pulmonary oedema. Phosgene is less soluble than chlorine, attacks the respiratory tract less, but passes deep into the lung. Its effects may not be felt immediately, but may develop some hours later.

Early work on phosgene includes that of Lehmann (1893), Matt (1889) and Hess (1911). Phosgene followed chlorine as a prime war gas, generally as a phosgene–chlorine mixture. Its toxicity is dealt with in most of the main texts on war gases including Underbill (1920), Fries and West (1921), Gilchrist (1924), F. Haber (1924), Vedder (1925), Ireland (1926), Flury and Zernik (1931), Foulkes (1934), Muntsch (1935), Hanslian (1937), Prentiss (1937), Wachtel (1941), Henderson and Haggard (1943), Courtice and Foss (1916), Dunn (1918), Eyster and Meek (1920), Herringham (1920), L. Hill (1920), Winternitz *et al.* (1920), Flury (1921a, 1928), Laqueur and Magnus (1921), Chlopin (1927–), Flury and Zernik (1932) and Richters (1936a,b). More recent work includes that by Cameron, Courtice and Foss (1941), Boyland, McDonald and Rumens (1946), Weston and Karel (1946, 1947), Box and CuUumbine (1947), Karel and Weston (1947), Gerard (1948), Suess and Lerner (1956), Henschler and Laux (1960), Ardran (1964), de Rooij, van Eick and van de Meent (1981), Diller and Zante (1982), Diller (1985), Mulder *et al.* (1986) and Zwart (1987). Work on phosgene is also included in treatments dealing with a number of gases, including those by Zeehuisen (1922) and Zielhuis (1970).

The toxicity of phosgene as a war gas has been the subject of extensive study. It was evidently his work on phosgene which led Haber to formulate his law that $ct = \text{Constant}$. He expressed the toxicity of gases in terms of a mortality product, or lethal index. Haber (1924) himself gave for cats a value of 450 mg/m^3 of this index, whilst Wachtel gives a value of 900 mg/m^3. From analysis of comments by Flury and Zernik (1932), Withers and Lees (1985a) conclude that the value of 900 mg/m^3 is equivalent to the LCt_{50}. This corresponds to $LCt_{50} = 220$ ppm min. They also quote Wachtel to the effect that cats are particularly sensitive to toxic gases and that as a rough approximation the corresponding value for man is twice as great, in other words $LCt_{50} = 440$ ppm min.

Experience of phosgene in war shows that personnel who have been gassed by it have often not felt immediate effects and have continued working, only to fall dead some hours later. The toxicity of phosgene has been reviewed in *Phosgene Toxicity Monograph* (MHAP, 1993).

Probit equations for phosgene have been given by Perry and Articola (1980), the CCPS and CPD, as described below.

Phosgene is one of the gases considered in the hazard assessment study done by Back, Thomas and MacEwen (1972).

18.16.15 Sulfur dioxide

Sulfur dioxide has long- and short-term OESs of 2 and 5 ppm, respectively. Physiologically, sulfur dioxide has various irritant effects.

Early work on sulfur dioxide includes that of Ogata (1884), Lehmann (1893) and Ronzani (1908, 1909). Sulfur dioxide does not appear to have been a serious candidate as a war gas. More recent work on sulfur dioxide includes that of Leong, McFarland and Sellers (1961) and Bitron and Aharonson (1978). Work on sulfur dioxide is also included in treatments dealing with a number of gases, including those of Zeehuisen (1922), Setterstrom and co-workers (McCallan and Setterstrom, 1940; Thornton and Setterstrom, 1940; Weedon, Hartzell and Setterstrom, 1940), Zielhuis (1970) and Buckley *et al.* (1984).

Sulfur dioxide is a principal lethal component of smog such as that which was once prevalent in London. A thick fog which covered the Meuse Valley in Belgium in 1930 resulted in several hundred cases of severe respiratory disturbance, followed shortly after by 63 deaths which were attributed to it (Weedon, Hartzell and Setterstrom, 1939; Logan, 1953). The lethality of the four day London smog of December, 1952, has been studied by Anon. (1953) and Logan (1953). The latter attributes to the fog some 4000 deaths. The Los Angeles smog is described by A. Mills (1957).

Probit equations for sulfur dioxide have been given by Perry and Articola (1980), the CCPS and the CPD, as described below. An account is also given below of the HSE dangerous dose values for sulfuric acid mist.

Sulfur dioxide is one of the gases considered in the hazard assessment study of Back, Thomas and MacEwen (1972).

18.16.16 Toluene diisocyanate

Toluene diisocyanate (TDI), like all isocyanates, has long- and short-term MELs (as NCO) of 0.02 and 0.07 mg/m^3, respectively.

Physiologically, TDI has a systemic effect, attacking the nervous system. It is a sensitizer, carrying the notation 'Sen'. The effects of exposure may be immediate and/or delayed. Exposure to TDI can cause firefighters to become euphoric and disregard danger. Delayed effects include nervous disorders.

Hazard arises from its manufacture and use, and from its generation from polyurethane foam or in hot cutting operations.

18.17 Gas Toxicity: MHAP Studies

The toxicity of three gases – chlorine, ammonia and phosgene – is the subject of a set of monographs by the MHAP, convened under the auspices of the Institution of Chemical Engineers (IChemE).

18.17.1 Chlorine

The Chlorine Toxicity Monograph (MHAP, 1987) is in two parts: the First Report of the Working Party and an account by Davies and Hymes of the HSE of the approach by that body to the development of criteria for hazard assessment.

The working party reviews the data on chlorine toxicity. Many of the data quoted for humans are derivative and appear poorly founded. It is therefore necessary to resort to the use of animal data. The authors present data for the LC_{50} for different exposures and for a number of species. These animal data indicate a mean lethal concentration for a 30 min exposure of $LC_{50} = 400$ ppm and a concentration–time relation of the form $ct^{1/2} = \text{Constant}$, or, alternatively $c^2t = \text{Constant}$.

In respect of the concentration lethal to man, the authors find that: the effects of acute inhalation of chlorine are similar in animals and humans, the prime lethal effect being pulmonary oedema; the factors bearing on differences between species may be divided into those which govern delivery of the chemical to the target organ and those which govern the effect on this and other organs; and that the effect of chlorine is to cause damage to the respiratory system itself, so that metabolic factors do not come into play.

The dose per unit body weight is some ten times greater for animals such as mice and rats than for humans at comparable levels of physical activity, but whereas humans are likely to respond to exposure to chlorine with a high level of activity, experimental animals are very passive. There is also the fact that rodents are obligatory nose breathers, which results in a degree of filtering and reduces somewhat the concentration reaching the respiratory tract, though the authors do not attach great importance to this feature. They conclude that there is little basis for supposing that the sensitivity of humans to chlorine is significantly different from that of small animals.

The working party suggest, therefore, that the relations for the lethal toxicity of chlorine quoted above for animals can be applied to humans also, namely for a 30 min exposure:

$$LC_{50} = 400 \text{ ppm}$$

$$C^2t = \text{Constant}$$

where C is the concentration (ppm) and t is the time (min). They consider, however, that the data do not justify the derivation of a probit equation for the lethality of chlorine to humans.

The monograph also gives an account of medical measures for handling cases of gassing by chlorine and summaries of some 11 papers on its toxicity.

The contribution by Davies and Hymes states the, then developing, HSE view that for the purpose of land use planning a toxic load criterion corresponding to a much less severe level of injury than 50% lethality is appropriate and quotes the Major Hazards Assessment Unit (MHAU) as using for this purpose the criterion

$$C^{2.75}t = 3.2 \times 10^6 \qquad [18.17.1]$$

where C is the concentration (ppm) and t is the time (min). This echoes the views expressed earlier by the same authors (P. Davies and Hymes, 1985) and foreshadows the development of the HSE specified level of toxicity (SLOT) values described in Section 18.21.

18.17.2 Ammonia

The *Ammonia Toxicity Monograph* (MHAP, 1988) follows a broadly similar format. The data on ammonia toxicity are reviewed and animal data are presented for the LC_{50} for different exposures and for a number of species. These animal data indicate a lethal concentration for a 30 min exposure of $LC_{50} = 11{,}500$ ppm and a concentration–time relation of the form $ct^{1/2} = \text{Constant}$. The authors consider that for ammonia the animal data available are of higher quality than those for chlorine.

With regard to the applicability of these data to man, the authors advance the following argument. Like chlorine, ammonia has an irritant action, but due to its solubility the relative effect on the tracheal as opposed to that on the bronchial region is much more marked. They identify two opposing factors. On the one hand, there is the much higher dose per unit body weight in animals than in humans, but on the other, due to the less effective filtering in humans, a greater proportion of the gas will reach the trachea. The authors conclude that taking these factors into account, it is reasonable apply the animal data to humans.

They therefore propose that the relations for the lethal toxicity of ammonia quoted above for animals can be applied to humans also, namely:

$$LC_{50} = 11{,}500 \text{ ppm for a 30 min exposure}$$

$$C^2t = 6.3 \times 10^4 \qquad [18.17.2]$$

They derive from this the probit equation for the lethality of ammonia

$$Y = -35.9 + 1.85 \ln C^2t \qquad [18.17.3]$$

where C is the concentration (ppm) and t is the time (min). They advise caution, however, in the application of this relation outside the limits of 20–80% lethality.

The monograph also gives an account of medical measures for handling of cases of gassing by ammonia, brief descriptions of case histories involving the gas and summaries of some 24 papers on its toxicity.

18.17.3 Phosgene

The *Phosgene Toxicity Monograph* (MHAP, 1993) again rejects many of the data quoted for humans as being second-hand and unreliable. The same applies to many of the animal data, but a small number of data sets are considered to be of high quality. These animal data indicate a lethal concentration–time relation of the form ct = Constant, or Haber's law, and a lethal load of

$$\mathrm{LCt}_{50} = 570 \text{ ppm min}$$

The authors also refer to work on the gassing of human subjects by phosgene given in evidence by Bickenbach (1947). The experiments were barbarous, but the data exist and cannot be neglected. The median lethal concentration for a 25 min exposure was 22.8 ppm, yielding

$$\mathrm{LCt}_{50} = 570 \text{ ppm min}$$

In respect of the application of the animal data to humans, the authors argue that the main acute effect of phosgene for both animals and humans is on the lung, that large differences in response between species would not be expected and that this is borne out by the similarity of the results obtained for the various species, including man. They conclude that the animal data may be applied to humans.

Utilizing the most appropriate sets of animal data and applying these to man, they obtain for the lethal toxicity of phosgene for humans

$$\mathrm{LCt}_{50} = 552 \text{ ppm min}$$

and the probit equation

$$Y = -27.2 + 5.1 \ln Ct \qquad [18.17.4]$$

where C is the concentration (ppm) and t is the time (min).

The monograph also gives an account of medical measures for handling of cases of gassing by phosgene and brief descriptions of case histories involving the gas.

18.18 Gas Toxicity: Chlorine

A further account is now given of the toxicity of chlorine, based on the work of Withers and Lees (1985a,b). This work is described in some detail, both because the hazard of chlorine is important in its own right and because the work illustrates the problems of and possible approaches to the toxicity of irritant gases.

There are in the literature a number of estimates of chlorine toxicity that vary widely. Generally, individual estimates are not well supported by critical review and the choice of a particular value has often tended to be arbitrary.

An estimate of chlorine toxicity that has had considerable currency in hazard assessment is that of Eisenberg, Lynch and Breeding (1975), who gave in the Vulnerability model a probit equation for chlorine. The LC_{50} for a 30 min exposure given by this probit equation is about 35 ppm for healthy adults. More recent estimates tend towards a considerably higher figure.

Withers and Lees review information on the lethal toxicity of chlorine and present a model for its toxicity to humans. The model gives values of 500 and 250 ppm for the LC_{50} for 30 min for base and standard cases for healthy adults.

18.18.1 Experimental work on and estimates of toxicity

Data on chlorine toxicity are given by Flury and Zernik (1931). Many of the values quoted are attributed to Lehmann, who published a series of papers over the period 1887–99 (e.g. Lehmann, 1887, 1883, 1899a,b) and to Hess (1911).

Chlorine was the first main toxic gas used in the First World War and work on chlorine toxicity was carried out by the principal combatants, particularly the Germans. The German work is described by F. Haber (1924), Flury and Zernik (1931), Muntsch (1935) and Wachtel (1941).

Haber's work, apparently that on phosgene in particular, seemed to indicate for lethality the relation

$$ct = \text{Constant} \qquad [18.18.1]$$

which became known as Haber's law and gave rise to the concept of a lethal dosage, also known as the mortality product or lethal index.

Values of the lethal index are quoted by military authors such as Hanslian (1937), Vedder (1925) and Prentiss (1937). There are considerable variations in the values given. Withers and Lees suggest that values refer variously to the LC_{10}, the LC_{50} and the LC_{50}, and quote comments by Flury and Zernick (1932) in support of this.

An important series of experiments on dogs was carried out towards the end of the war by Underhill (1920). For chlorine he used some 112 animals in seven groups ranging in size from 9 to 23. The exposure period was 30 min. The results of this work are shown in Table 18.18 and are plotted in Figure 18.7. The figure shows the best line through the points and the 95% confidence limits obtained from the method of Litchfield and Wilcoxson (1949). The LC_{50} for a 30 min is 650 ppm.

Since 1918 there have been a number of studies on chlorine toxicity, using mainly rodents. Some of the principal sets of experiments are briefly described here.

More detailed accounts are given by Withers (1986) and Withers and Lees (1985a).

Weedon, Hartzell and Setterstrom (1940) carried out experiments in which mice and rats, in groups of 4 and 8, respectively, were exposed to concentrations of chlorine of 16, 63, 250 and 1000 ppm for periods of 1, 4, 15, 60, 240 and 960 min until they died, or for a maximum period of 960 min. The three latter concentrations corresponded to the LC_{50} for mice at exposure periods of >960, 440 and 28 min, respectively, and to that for rats at exposure periods of >960, 440 and 53 min, respectively.

Lipton and Rotariu (1941), in a report by Ceiling and McLean, describe experiments in which mice in groups of 20 were exposed to concentrations of chlorine ranging from 310 to 2357 ppm for a period of 10 min with an observation period of 10 days. The LC_{50} obtained was 628 ppm.

Silver and McGrath (1942) carried out experiments on 49 groups of mice, 45 groups of 20 and 4 groups of 40, in two series. In the first series certain sources of error were revealed which were corrected in the second series. In the two series of experiments mice were exposed to concentrations of chlorine in the range 252–1139 ppm for 10 min with a 10-day observation period. In the first series the LC_{50} was 524 ppm and in the second series 597 ppm. Most of the deaths occurred within the first 24 h.

Silver, McGrath and Ferguson (1942) carried out further experiments on 15 groups of 20 mice. Again they used a 10 min exposure time and a 10-day observation period. In this third series the concentrations of chlorine used were in the range 379–890 ppm and the LC_{50} was 676 ppm. Out of 154 deaths, one was due to mild oedema and congestion, and two to pneumonia; the rest were due to severe oedema. Most of the deaths occurred within the first 24 h.

Table 18.18 *Concentration of chlorine lethal to dogs in Underhill's work (Withers and Lees, 1985a; after Underhill, 1920). Exposure time 30 min (Courtesy of Elsevier Publishing Company)*

		Concentration[a]						
	(mg/l) (ppm)	*0.16–0.80* *50–250*	*1.27–1.58* *400–500*	*1.58–1.90* *500–600*	*1.90–2.22* *600–700*	*2.22–2.53* *700–800*	*2.53–2.85* *800–900*	*2.85–6.34* *900–2000*
Deaths within 3 days		0	1	2	9	9	20	13
Delayed deaths		1	4	2	5	2	1	0
Total deaths		1	5	4	14	11	21	13

Overall mortality (%)		11	29	40	67	61	91	93

[a] The conversion of concentrations from mg/l to ppm by Underhill in this table corresponds to a temperature of 0°C. Henceforth, these concentration values in ppm have been recalculated to a temperature base of 25°C.

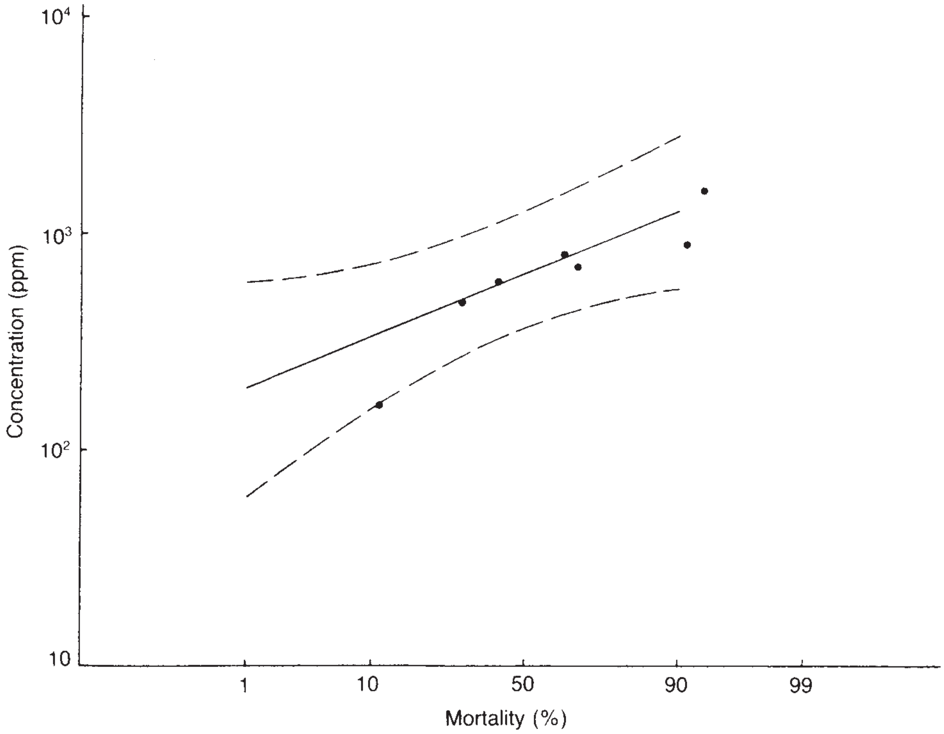

Figure 18.7 *Concentration of chlorine lethal to dogs in Underhill's work (withers and Lees, 1985a; after Underhill, 1920). Exposure time 30 min. Dotted lines are 95% confidence limits (Courtesy of Elsevier Science Publishers)*

Schlagbauer and Henschler (1967) carried out experiments in which mice in groups of 10 were exposed for 30 min to concentrations of chlorine of 55, 62, 69, 110, 125, 132, 145, 160 and 179 ppm. The deaths occurring in the intervals 0–2 and 2–4 days after exposure were recorded. There were no deaths later than 4 days after exposure. The LC_{50} obtained was 127 ppm.

These authors also report work at lower chlorine concentrations and longer exposure periods. They carried out experiments in which 10 mice were exposed for 3 h to concentrations of chlorine of 10 and 22 ppm with an observation period of 4 days. The mortality of the mice at these two concentrations was 8/10 and 10/10, respectively.

Experiments were carried out by Bitron and Aharonson (1978) in which mice in groups of 16 were exposed to concentrations of chlorine of 170 and 290 ppm for periods of 15–160 and 5–30 min, respectively. The times of death after exposure were recorded over an interval of 30 days. The LC_{50} values obtained were 170 and 290 ppm for exposures of 55 and 11 min, respectively.

The LC_{50} values obtained by these and certain other authors are shown in Table 18.19. The concentration lethal to various animal species, based on the research just described and on other work, is shown in Figure 18.8.

In addition to the LC_{50}, it is desirable also to be able to estimate the LC_{10} and LC_{90} or the ratio LC_{90}/LC_{10}, which is the slope of the concentration–mortality line. There are three data sets, those of Underhill, of Silver, McGrath and Ferguson and of Schlagbauer and Henschler, from which estimates of this ratio may be obtained.

Underhill's work yields values of the LC_{10} and LC_{90} of 334 and 1,266 ppm, respectively, and hence a value of the ratio LC_{90}/LC_{10} of 3.8.

There are two sets of experiments, those of Weedon, Hartzell and Setterstrom and of Bitron and Aharonson, in which the exposure time was varied and which may therefore be used to estimate the trade-off between concentration and time. These two data sets are shown in Table 18.20.

Then using Equation 18.11.3 for the lethal toxic load, the data in Table 18.20 suggest that the best estimate of the index n is 0.5 so that

$$L = CT^{0.5} \qquad [18.18.2]$$

The range of concentrations and time covered by the data on which this equation is based are 170–1,000 ppm and 11–440 min.

Equation 18.18.2 may be used to convert different sets of experiments to a common exposure time. Such sets may also be normalized with respect to the LC_{50} found in each case to give a set of data that may be used to determine the slope of the concentration–mortality line. Three such sets of data are shown in Table 18.21.

Information on acute and delayed deaths is also relevant. In the work of Lipton and Rotariu and of Silver, McGrath and Ferguson most of the deaths occurred within the first 24 h. Likewise, in Schlagbauer and Henschler's work almost all the deaths occurred in the interval 0–2 days after exposure. The only deaths in the interval 2–4 days were at a concentration of 132 ppm, for which two of the six deaths were in this interval. In Bitron and Aharonson's work, by contrast, most of the deaths were delayed deaths, the mortality being only 10% or less during the day after exposure and most of the deaths occurring in the interval 5–7 days after exposure.

Further information on acute deaths is given by the work of Underhill on dogs. He defines acute death as a death occurring within the first 3 days after exposure. Figure 18.9(a) and (b) shows the proportion of acute deaths in his work as

a function of the concentration and as a function of the mortality, respectively.

18.18.2 Physiology and pathology of poisoning

The physiology and pathology of chlorine gas poisoning have been studied by a number of workers, including many of those already mentioned.

Many of those who have done experimental work on animals have discussed this aspect. Lehmann gives a wide-ranging discussion of the topic. Accounts by German workers active around the time of the First World War include those by Flury and Zernik (1931) and Wachtel (1941) and among American workers those of Underbill (1920) and Winternitz *et al.* (1920). The overall picture that emerges is that while chlorine attacks the whole of the respiratory system, the cause of death is lung oedema.

There is also a large amount of information that is directly applicable to man. There are a number of accounts of the treatment of chlorine gas casualties by British doctors. The Chemical Warfare Committee of the Medical Research Council did extensive work, including that of Gunn (1920) on the action of chlorine on the respiratory system. The official military account is given in *Diseases of the War* (Macpherson *et al.*, 1923).

The extensive American work from that time is described by Underbill and Winternitz *et al.*, while the official military account is given by Ireland (1926). Additional information is given by Haggard (1924) and by Henderson and Haggard (1943). Further accounts are given by other military authors such as Vedder (1925) and Prentiss (1937).

Investigations of the long-term effect of gas warfare exposure are described by Meakins and Priestley (1919),

Vedder (1925), Gilchrist and Matz (1933) and Penington (1954).

Chlorine is a strong oxidizing agent. A number of different explanations have been given of the way in which it causes damage. An early suggestion was that its effect is through the formation of hydrochloric acid. Another early suggestion was that it gives rise to nascent oxygen. More recent suggestions are the action of hypochlorous acid and of chlorine itself.

Chlorine is an irritant gas and the most serious effect of acute chlorine poisoning is damage to the respiratory system. Another important irritant gas that was also used as a war gas is phosgene and many discussions of gas poisoning treat the two gases together, although there are differences. The symptoms of chlorine poisoning are: at a concentration of about 15 ppm, irritation of the nose, throat and eyes with cough and tears; at about 30 ppm, restriction of breathing and chest pain; and from about 50 ppm, development of pulmonary oedema. Other symptoms are described in some of the accounts given below.

The description by Haggard (1924) of the action of irritant gases on the respiratory tract has already been quoted.

In the present context it is severe acute poisoning that is of primary interest. Herringham (1920) states:

> The whole course of events, and the various degrees of severity, are all due to but one cause, the want of oxygen in the blood due to the wall of oedema interposed between the air and the blood vessels.

An extensive discussion of chlorine poisoning is given in *Diseases of the War* and the following extracts give an overview of the principal aspects. The threat to life is due almost entirely to pulmonary oedema and other effects are relatively unimportant, but later infection can also be dangerous:

> The respiratory organs, eyes and skin, bore the brunt of the attack. Yet even if one recognizes this, one must be prepared for serious effects that are secondary to these primary lesions. Severe though temporary shortage of oxygen, resulting from acute pulmonary oedema or interference with the oxygen-carrying power of the blood, may exercise lasting effects on the heart, the central nervous system, or other organs of the body, while secondary bacterial infection may delay recovery or even be the prelude to a fatal termination.

> The points where the gases classed as acute lung irritants exercise their most pronounced effect are the alveoli of the lungs and the smaller bronchial tubes, and the great danger to be feared, which is common to them all, is the onset of acute pulmonary oedema. It is in the main this oedema which, in the acute stage of poisoning, threatens the life of the subject, for if abundant it causes death by

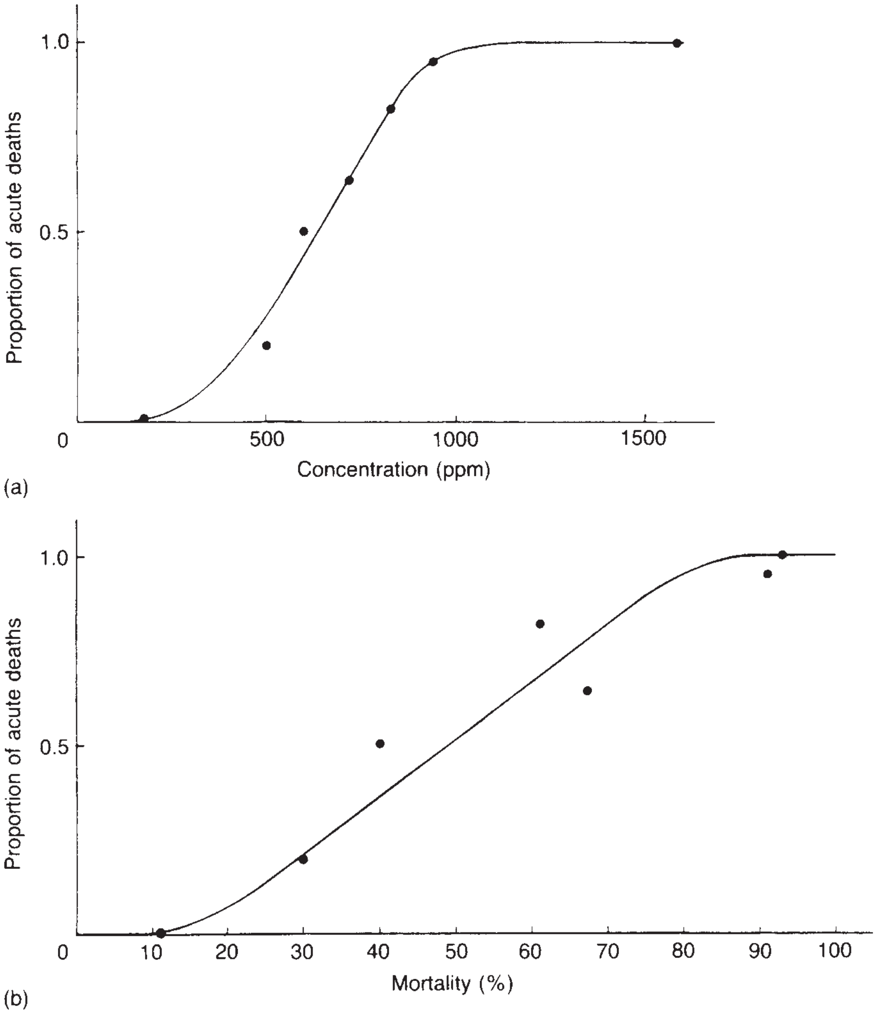

Figure 18.9 *Proportion of acute deaths by chlorine poisoning in Underhill's work (Withers and Lees, 1985a). Exposure time 30 min, (a) Proportion of acute deaths as a function of concentration; (b) proportion of acute deaths as a function of mortality (Courtesy of Elsevier Science Publishers)*

asphyxiation, the patient being in fact drowned by his own eduction.

The rate of onset and the degree of oedema are dependent on the particular gas and on its concentration, and, though in some cases to a less degree, on the duration of exposure.

Any pathological changes found in organs of the body other than the lungs are really attributable to changes resulting secondarily from the gross damage in the respiratory apparatus, and from the consequent asphyxia, and that the direct effects of the gas are limited to the lungs and bronchial tubes.

The effect of oedema is to cause a reduction in the supply of oxygen to the blood:

> These gross changes in the lungs are responsible for serious interference with the gaseous exchange between blood and air, and the indications for asphyxia were obvious in all severe cases of poisoning by the acute lung irritant gases. The cases fell into two categories: the one was characterized by intense florid and deep cyanosis, with vascular congestion and engorgement of the veins, the other exhibited no venous engorgement but pallor akin to that seen in collapse, with grey or lilac-coloured lips and tongue. Both classes had the common feature that the colour of the blood indicated a grave deficiency of oxygen.

The symptoms tended to follow a common pattern:

> All the men gave a similar description of what they felt as the greenish-yellow fumes enveloped them. Immediate choking, coughing, gasping for breath and inability to speak proved the irritation and spasm of the respiratory tract. In many the eyes smarted and ran with water. Retching was at once experienced by some, but many did not vomit until an hour or two later. There was severe pain behind the sternum, which soon radiated outward on each side into the chest and added greater suffering to the distressed breathing. The throat burned and the dry mouth produced an intense sensation of thirst.
>
> Very soon the developing pulmonary oedema led to the phenomenon of oxygen shortage, with headache, a sense of weakness in the legs, and such1 lassitude that the men dropped prone upon the ground, the spasmodic violence of their respiratory efforts being then largely quietened.
>
> Milder cases in areas where the concentration of chlorine in the air was relatively low, suffered chiefly from lassitude and a great sense of fatigue.

The complete arrest of breathing due to spasm was not observed and is not regarded as an important factor:

> The question has often been discussed as to whether a man might be killed by immediate asphyxiation on the field through such a spasmodic closure of his larynx and bronchi that respiration was completely arrested. Sudden shock and collapse from extreme sensory irritation has been noted in animals immediately upon exposure to chloropicrin; and it might be that this factor would also play its part in determining early death upon the field. But no proof was ever obtained that a man has thus been choked to death on the field. If it ever did happen, it was of little practical importance. No medical officer in the trenches ever had the chance of attempting to treat such a case.

Pulmonary oedema and its effects are therefore the important factors:

> A rapid development of pulmonary oedema, interfering with gaseous respiration and also with the circulation itself, was probably always the actual cause of death.
> It is thought that the entire action of pulmonary irritants is exercised solely upon the surface layers of the body with which the gases come into contact, the early circulatory failure being caused only the influence of pulmonary oedema upon gaseous respiration and blood-flow and by 'shock'.

A similar picture emerges from the accounts of their work given by Underbill and by Winternitz *et al.* Acute death is associated with oedema and blood changes. Underhill attributes the effects of oedema not so much to the blockage of oxygen transfer in the lung as to a decrease in the fluid content of the blood and a consequent increase in the solids content and viscosity and a reduction in the oxygen-carrying capacity.

Physical exertion following gassing can be dangerous, even for men apparently unaffected:

> When the tension of a gas attack had passed way, it sometimes happened that, among those who had been exposed to the irritant vapour but who had not reported sick, a man would stop working, complain that he felt done in, and die in a few minutes. Others might survive for an hour or two after a similarly sudden collapse. Their deaths were at first thought to have been caused by heart failure due to a direct intoxication by the gas. Autopsies, though not made in the dramatic cases of abrupt death, always proved the existence of advanced pulmonary oedema, the condition being really identical with that of 'grey' collapse as seen after the ordinary acute onset.

The effect of exertion after exposure appears, however, to have been observed mainly with phosgene rather than with chlorine.

There has been some expression of doubt about the prevalence of pulmonary oedema among those who have treated people gassed by chlorine in industrial accidents. Thus A.T. Jones (1952) states that in the period 1932–48 he and his colleagues dealt with 820 such cases, of which 9 were severe, but even in these cases neither pulmonary oedema nor pneumonia ensued, although he indicates awareness of pneumonia in other cases. Industrial gassing is also discussed by Haggard, who states

> Even an exposure insufficient to induce the acute symptoms of lung irritation may lead to the development of pneumonia and under industrial conditions the infections thus produced constitute a greater cause of death than primary oedema.

Although the descriptions quoted on the effect of irritant gases are undoubtedly strongly influenced by experience with phosgene, the account of Black, Glenny and NcNee (1915), who treated 685 cases of poisoning from chlorine between 2 and 7 May, 1915, before phosgene had been used, shows clearly that the acute deaths involved pulmonary oedema. This was confirmed by 210 post-mortems carried out by these doctors.

If acute death does not occur, there is still the danger of delayed death. The cause of delayed death is described variously as bronchitis, bronchial pneumonia or pneumonia. Black, Glenny and McNee state that the acute stage passes off in about 36 h, that there is then a quiet stage of some 12 h and that the bronchial infection is then liable to develop. Underbill found that the dogs which survived gassing were liable to die of pneumonia, and set 3 days after gassing as the dividing line between acute and delayed deaths.

The mortality from chlorine gassing may be reduced by appropriate medical treatment. It is not clear how much can be done to increase the chances of survival of acute cases, but for the delayed cases the prospects appear much better. There are descriptions of the treatment given and of its effects in many of the accounts already quoted.

The long-term effects of chlorine gassing are also important. Broadly speaking, both the statistical and clinical evidence suggest that these effects are not great. Weill *et al.* (1969) studied 12 people who were severely gassed in an accidental chlorine accident near La Barre in 1961. All had pulmonary oedema when examined just after the accident, but when examined 3 and 7 years after the event showed little long-term damage.

A summary of the findings of these authors given by Eisenberg, Lynch and Breeding (1975) has been quoted in Section 18.15. The evidence from this work is that persons who survive acute exposure to chlorine gas tend not to suffer significant permanent lung damage.

18.18.3 Concentrations intolerable to humans

Some values given in the literature for chlorine concentrations tolerable and intolerable to humans are shown in Table 18.22.

At concentrations of about 4 ppm irritation is said to be experienced and normal work to be impossible. Dangerous concentrations are variously given as 14–21 and 40–60 ppm for 0.5–1 h, but the degree of danger is ill defined. A concentration of about 50 ppm is said to cause loss of fighting efficiency and one of 100 ppm to incapacitate and to be intolerable. The data were apparently obtained by observation of the effects of chlorine on man. The basis of the data is different, therefore, from those for the lethality to man derived from animal experiments. They include, presumably, the effects of any enhancement of activity which may have occurred.

18.18.4 Concentrations lethal to humans

Some values given in the literature of chlorine concentrations lethal to humans are shown in Table 18.23.

18.18.5 Limit values for humans

The TLV for chlorine recommended by the ACGIH has for many years been 1 ppm. In the United Kingdom the OES is now an 8-h TWA of 0.5 ppm.

Zielhuis (1970) has made proposals for EELs for chlorine. His values are 7, 5, 4 and 3 ppm for exposures of 5, 15, 30 and 60 min, respectively. The proposals of the NAS-NRC (1973a) for public emergency limits (PELs) are 3, 2, and 2 ppm for exposures of 10, 30 and 60 min, respectively.

18.18.6 Probit equations given in literature

Probit equations both for lethality and non-lethal injury due to chlorine were given by Eisenberg, Lynch and Breeding (1975) in the Vulnerability model. The probit equation for the lethality of chlorine is

$$Y = -17.1 + 1.69 \ln \left(\sum C^{2.75} T\right) \qquad [18.18.3]$$

And that for non-lethal injury due to chlorine is

$$Y = -2.40 + 2.90 \ln \mathrm{C} \qquad [18.18.4]$$

where C is the concentration (ppm) and T is the time (min).

Equation 18.18.3 gives an LC_{50} for 30 min of some 35 ppm. It is apparently derived from a graph consisting of an arbitrary concentration scale vs a percentage mortality scale on which various sets of experimental results for animals are plotted as straight lines. The LL_{50} points on these lines are: for dogs, 70; for rats, 3.5 and 1.4; for mice, 20,

***Table 18.22** Concentrations of chlorine tolerable and intolerable to man (Withers and Lees, 1985b) (Courtesy of Elsevier Publishing Company)*

Author(s)	*Effect*	*Concentration* (ppm)	*Exposure time*	*Source*

Wachtel (1941)	Concentration which causes severe irritation	3		
	Concentration which causes loss of fighting capacity	47		
Patty (1962)	Concentration which causes irritation	3–6		
	Intolerable concentration	100	1 min	

[a] Quoted without reference by Flury and Zernik (1931).

15, 3.5 and 0.7; composite for all animals, 1; and for man, 0.25. It is not clear what the justification is for this low value for man, but the choice appears to be a conservative one.

In a further development of the Vulnerability model, Perry and Articola (1980) give revisions of the Eisenberg equations. Their equation for the lethality of chlorine is

$$Y = -36.45 + 3.13 \ln (\Sigma C^{2.64} T) \qquad [18.18.5]$$

and that for chlorine injury is again Equation 18.18.4.

The industrial comment on the *Rijnmond Report* (Rijnmond Public Authority, 1982) proposes the equation

$$Y = -11.4 + 0.82 \ln (\Sigma C^{2.75} T) \qquad [18.18.6]$$

This equation is also recommended by N.C. Harris and Moses (1983). ten Berge and van Heemst (1983) propose the equation (in the units used here)

$$Y = -5.04 + 0.5 \ln (\Sigma C^{2.75} T) \qquad [18.17.7]$$

Harris and Moses effectively argue that there is no justification for taking a low value of the ratio of the lethal load for man to that of animals, or for assuming a very narrow spread of response, and set the parameters in Equation 18.18.6 accordingly. ten Berge and van Heemst apparently derive their parameters from the work of Bitron and Aharonson (1978), together with information on the concentrations causing irritation in man.

The probit equations given in the literature for the lethal toxicity of chlorine are summarized in Table 18.24. Further probit equations produced subsequent to this study are described below.

18.18.7 Toxicity values used in hazard assessments

Some values of the lethal concentration or dosage of chlorine used in a number of hazard assessments are given in Table 18.25. Most correspond to an LC_{50} for 30 min of about 35 ppm. The much higher value of 430 ppm used by Meslin (1981) is an exception.

18.18.8 Model for humans

On the basis of the information just described, Withers and Lees (1985b) have derived for chlorine a model for the lethal

Table 18.23 *Lethal concentrations of chlorine quoted in standard toxicology texts (Withers and Lees, 1985b) (Courtesy of Elsevier Publishing Company)*

Author(s)	*Effect*	*Concentration* (ppm)	*Exposure time*	*Source*

[b] Lowest lethal concentration recorded.

[c] A death was recorded in the concentration range 50–250 ppm (his values) at a 30 min exposure in Underhill's work (1920).

toxicity to humans. The model is based on estimates for humans of the LC_{50}, the slope of the concentration–mortality line, or ratio LC_{90}/LC_{10}, and the lethal load function together with factors for inhalation rate and for medical treatment, and involves a separate treatment of the vulnerable population. Before considering the model proper, it is convenient to consider these latter aspects.

18.18.9 Physical activity

It is to be expected that man will not simply remain passive in the face of a toxic threat but will react by some form of physical activity such as seeking to escape or to obtain shelter.

There are two main effects of such activity. The first is that larger volumes of contaminated air are inhaled. Data on inhalation rates were given in Table 18.16. It is clear from these data that the inhalation rate is greatly increased by activity and that the factor can be as high as 15. The injury suffered as a result of more rapid inhalation is likely to be increased, and allowance needs to be made for this.

The other effect of enhanced activity is that larger amounts of oxygen are required by the body. Data on this aspect also were given in Table 18.16. This increased oxygen demand may occur during exposure and/or after exposure.

The level of physical activity is taken into account by defining a base level of activity, which corresponds to rest, and a standard level of activity that corresponds to a normal mixture of sitting, standing and moving about and for which the inhalation rate is twice that of the base level.

18.18.10 Inhalation rate

The effect of inhalation rate on the injury caused by a given concentration of chlorine in air is not obvious, but it is important because it is quite conceivable that high inhalation rates will increase the injury several-fold. The assumption made in the model is that over a given inhalation period injury is a function of the mass of chlorine absorbed.

The rate of absorption of chlorine in the lung is a mass transfer process and this process may be modelled. An account of the respiratory system, including quantitative data, was given in Section 18.13. The amount of chlorine absorbed is the product of the alveolar ventilation rate and the difference in the inhaled and exhaled chlorine concentrations. It is also equal to the product of the pulmonary diffusion capacity and the difference between the actual and equilibrium partial pressures of chlorine at the alveolar membrane wall. Finally, it is also equal to the sum of the amount of chlorine transported out of the lung capillaries by the blood and of that reacted in the alveolar tissue.

The situation with respect to the solubility of chlorine is complicated by the hydrolysis of chlorine to hypochlorous acid. The solubility of chlorine and its hydrolysis have been extensively studied and data are available on the solubility of unhydrolysed chlorine and on the equilibrium and rate constants for the hydrolysis. There do not appear to be any data on the solubility of chlorine in blood plasma, but the solubility of other gases such as oxygen, carbon dioxide and nitrogen is some 10% less in plasma than in water.

If it is assumed that the chlorine is simply absorbed into the blood, there will be a gradual accumulation of chlorine in the blood that will exert a corresponding equilibrium partial pressure at the alveolar membrane so that the concentration of chlorine in the blood will rise exponentially to an equilibrium value and absorption will tail off. However, this model does not appear to be consistent with

Table 18.24 *Some probit equations for chlorine given in the literature (Withers and Lees, 1985b) (Courtesy of Elsevier Publishing Company)*

the information available on the damage done to the body by chlorine. The evidence indicates that the damage is essentially confined to the lung.

A more appropriate assumption appears to be that the lung is a sink for the chlorine, which reacts with the alveolar tissue. This means that the venous blood entering the lung capillaries will contain very little chlorine. The maximum concentration of chlorine in the blood leaving the lung may then be obtained by solving the mass balance. Simple calculations based on the physiological parameters and the solubility of unhydrolysed chlorine indicate that for a man at rest the concentration of exhaled chlorine will be less than half the inhaled concentration. The actual value will be less than this maximum, since the concentration in the blood will be reduced both by hydrolysis and by reaction with the tissues. Thus even at rest almost all the chlorine inhaled will be absorbed. This will also be true for moderate increases in physical activity, since the increase in inhalation rate is accompanied by an increase in the circulation of blood through the lungs.

Further support for this interpretation is afforded by experiments by Lehmann (1893), who measured the inlet and outlet concentrations of chlorine in chlorine-contaminated air breathed by men. The inlet concentration was 2 ppm, the outlet concentration was undetectable, the absorption thus being total. This evidence is not conclusive, since the chlorine concentration was low, but it points in the right direction.

As a first approximation, therefore, the inhalation rate is taken into account by defining a factor ψ_1 that is applied directly to the concentration in order to correct for inhalation rate.

18.18.11 Medical treatment

Appropriate medical treatment may effect a reduction in the mortality from exposure to chlorine. It is likely to be much more effective in preventing delayed deaths than acute deaths.

As described above, the proportion of acute deaths is a function of mortality. From analysis of war gas casualties the proportion P_a of acute to total deaths, or the acute death factor, is

$$P_a = 0.8 + 0.2P \qquad [18.18.8]$$

where P is the total mortality.

The effect of medical treatment is taken into account by defining a factor ψ_2 that is applied to the proportion of delayed deaths, or rather, in this context, potential delayed deaths, to yield the proportion of recoveries.

18.18.12 Vulnerable populations

So far consideration has been limited to the effect of toxic gas on healthy adults. A significant proportion of the population, however, is more vulnerable. It is necessary to distinguish, therefore, between the less vulnerable, or regular, population and the more vulnerable, or simply vulnerable, populations, which together make up the general, or average, population.

The principal categories of people vulnerable to chlorine gas are children, old people and people with respiratory or heart disorders. The less vulnerable members of the population are healthy youngsters and adults. The estimate given by Hewitt for the proportion of vulnerable people was given in Table 9.26. A rough value is some 25% of the population.

One approach that has been used in hazard assessment is that of Eisenberg, Lynch and Breeding, who used for chlorine and ammonia the relations between the general population and the vulnerable population given in Table 18.17. There are several points that should be noted in connection with this table. The general population is not well defined, particularly as to whether or not it includes the vulnerable population. Also it has been shown by Withers and Lees that the relations given imply a lower spread of lethal concentrations for the vulnerable than for the regular population.

The vulnerability of part of the population may be handled either by treating the whole population as a single homogeneous population with vulnerable members or by treating the regular and vulnerable sections as two populations. In the first approach there is a single distribution, whereas in the second there are two separate distributions with distinct modal values. It is not self-evident which approach is most likely to fit such data as may exist, but it is clear that for hazard assessment it is more convenient to handle the vulnerable population separately and to have a separate distribution applicable to that population. This is therefore the approach adopted. It may be noted, however, that if two distinct distributions are used, they do not in general yield a distribution of the same type for the average population. Specifically, if the distributions for the regular and vulnerable populations are both log-normal, that for the average population cannot be expected to be log-normal.

18.18.13 Lethal load

The different forms of the lethal load function have been described in Section 18.11. The lethal load functions used in the model are

$$L = CT^m \qquad [18.18.9]$$

and

$$L^* = \Sigma C^n T \qquad [18.18.10]$$

Equation 18.18.9 is the natural form for the correlation of the basic data, but Equation 18.18.10 is the more convenient for hazard assessment.

The animal experiments indicate for m a value of 0.5 and this is used in the model for humans. The corresponding value of n is 2.

18.18.14 Lethal concentration: regular population

In the model the estimate of the LC_{50} is based primarily on the judgement that the most weight should be given to the work on dogs by Underbill, and this is then interpreted in the light of the other animal experiments.

The animal experiments described above give average LC_{50} values for 30 min exposures of 256, 414 and 650 ppm for mice, rats and dogs, respectively. The LC_{50} used in the model for man is 500 ppm for 30 min for the regular population at the base level of activity.

The high weight given to Underbill's work on dogs is based on a number of factors. One is the similarity of the respiratory systems of dog and man. Another is the quality of the experimental work.

In Underbill's work, the dogs tended to lie passively with their paws folded so that movement was minimal. This behaviour has been taken as corresponding to the base level of activity.

This estimate of the LC_{50} for man is intended to be a best estimate rather than a conservative one.

The slope of the concentration–mortality line, or ratio LC_{90}/LC_{10}, which is used in the model is 4. This also is based primarily on the value of 3.8 obtained from Underbill's work on dogs. The two other values obtained from the animal work are 4.4 (Silver and McGrath, 1942; Silver, McGrath and Ferguson, (1942) and 1.9 (Schlagbauer and Henschler, 1967) on mice.

The lethal load at the base level of activity then follows directly. For 50% mortality at a 30 min exposure

$$\begin{aligned} LL_{50} &= CT^{0.5} = 5000 \times (30)^{0.5} \\ &= 2,739 \text{ ppm min}^{1/2} \end{aligned} \qquad [18.18.11]$$

Similarly, the lethal loads for 10% and 90% mortality are 1,369 and 5,477 ppm $\text{min}^{0.5}$, respectively.

18.18.15 Lethal concentration: vulnerable population

The lethal concentrations for the vulnerable population are based on an estimate that the LC_{10} for a 30 min exposure for the vulnerable population at the base level of activity is 100 ppm. This estimate is derived partly from information derived from the animal experiments and partly from the concentrations reported as intolerable to man. In the experimental work on animals there was no fatality at a concentration below 50 ppm for a 30 min exposure. The nearest approach was a single fatality at 62 ppm in Schlagbauer and Henschler's work. A concentration of 100 ppm is shown in Table 18.22 as being some four times that which causes coughing and equal to that which is intolerable or incapacitating.

It is also assumed in the model that the slope of the concentration mortality line, or ratio LC_{90}/LC_{10}, is same as for the regular population. This gives for the vulnerable population values of 200 and 400 ppm for the LC_{50} and LC_{90} for 30 min.

18.18.16 Inhalation rate factor

The inhalation rate factor ψ_1 used in the model is the ratio of the inhalation rate at the actual level of activity to that at the base level, which corresponds to rest in bed and for which the inhalation rate is 6 l/min. This factor is applied directly to the inhaled concentration.

The normal, or standard, level of activity involves some movement and for this the inhalation rate is about 12 l/min. Thus for the standard level of activity $\psi_1 = 2$.

It is intended in the model that for the regular population the default level of activity be taken as the standard level, unless there is a reason to take some other level. For the vulnerable population the level of activity for old people and young children may approximate to the base level and the standard level, respectively.

18.18.17 Medical treatment factor

In the model the proportion of delayed deaths is estimated from Equation 18.18.8 and the effectiveness of medical treatment in converting delayed deaths into recoveries is accounted for using the medical treatment factor ψ_2. This is taken as 0.9 and 0.7 for the regular and vulnerable populations, respectively, which means that for these populations some 90% and 70% of the potential delayed deaths convert to recoveries. These are necessarily approximate estimates, but their overall effect on the mortality is not great, since most deaths are sudden rather than delayed.

It is not appropriate to claim credit for the mitigating effect of medical treatment unless there exist the organization, the expertise and the facilities commensurate with the accident envisaged.

18.18.18 Probit equations

From the foregoing the following probit equations may be derived:

Regular population
Base level of activity:

$$Y = -9.57 + \ln(\Sigma C^2 T) \quad [18.18.12]$$

Standard level of activity:

$$Y = -8.29 + 0.92 \ln(\Sigma C^2 T) \quad [18.18.13]$$

Vulnerable population
Base level of activity:

$$Y = -7.88 + 0.92 \ln(\Sigma C^2 T) \quad [18.18.14]$$

Standard level of activity:

$$Y = -6.61 + 0.92 \ln(\Sigma C^2 T) \quad [18.18.15]$$

The lethal concentrations for exposure times of 10 and 30 min for the regular and vulnerable populations given in the model, as expressed in these probit equations, are shown in Tables 18.26 and 18.27, respectively.

18.18.19 Overall methodology

The overall methodology used in the model for the estimation of the mortality from an accidental chlorine release given the concentration–exposure time profile may be summarized as follows.

A straightforward estimate of the mortality for the regular and vulnerable populations with the standard level of activity may be obtained using Equations 18.18.13 and 18.18.15, respectively.

If it is desired to derive an estimate that takes account of other conditions and makes at least some allowance for the other factors discussed, the approach is as follows:

(1) Estimate the inhalation rate factor and apply it to the concentration;
(2) estimate the toxic load using the corrected concentration;
(3) calculate the uncorrected mortality, estimate the acute deaths factor and apply it to this mortality;
(4) estimate the medical treatment factor and apply it to the proportion of potential delayed deaths;
(5) calculate the corrected mortality.

18.18.20 Gas warfare cross-checks

Since chlorine was the first major war gas, attempts have been made to cross-check estimates for the lethal toxicity of chlorine against the effects of gas attacks. One such attempt is that by Nussey, Mercer and Fitzpatrick (1986). Another is that by Withers and Lees (1987b, 1992) to check the model just described. Critiques of this work by R.F. Griffiths and Fryer (1988) and V.C. Marshall (1989b)

Table 18.26 *Concentrations of chlorine proposed as lethal to humans for an exposure time of 10 min (Withers and Lees, 1985b) (Courtesy of Elsevier Publishing Company)*

E Average population: standard level of physical activity		
80	10	438
210	50	1150
465	90	2547

have held that the uncertainties surrounding these attacks are simply too great to make a cross-check.

18.19 Gas Toxicity: Green Book Relations

Another, more recent, treatment of the toxicity of industrial gases is that given in *Methods for the Determination of Possible Damage* by the CPD in the Netherlands (1992b) (the Green Book) based on research by TNO. An account is given by de Weger, Pietersen and Reuzel (1991).

This work was preceded by the study of probit equations for individual species by ten Berge of Dutch State Mines (DSM) and Zwart and van Heemst of TNO (ten Berge, Zwart and Appelman 1986), to which reference has already been made.

In this methodology a distinction is made between locally acting substances and systemically acting substances.

18.19.1 Locally acting substances

For a locally acting substance the specific dose D'' is defined as

$$D'' = D/A \qquad [18.19.1]$$

where A is the surface area of the lungs (m^2), D is the inhaled dose (mg) and D'' is the inhaled dose per unit area of lung (mg/m^2). The dose D is taken as

$$D = (V_a/1000)Ct \qquad [18.19.2]$$

where C is the concentration of gas in the atmosphere (mg/m^3), t is the exposure time (min) and V_a is the minute volume (l/min). From empirical physiological relations

$$V_a \propto W^{0.70} \qquad [18.19.3]$$

$$A \propto W^{0.92} \qquad [18.19.4]$$

where W is the body mass (kg).

Then from Equations 18.19.2–18.19.4

$$D'' \propto W^{-0.22} \qquad [18.19.5]$$

The body masses of man, the rat and the mouse are 70, 0.3 and 0.03 kg, respectively. It follows then from relation 18.19.5 that the load on a rat and on a mouse are, respectively, some 3.3 times and 5.5 times that on a man.

This treatment has not allowed for absorption of gas in the air passages. Such absorption hardly occurs in humans, but most test animals are nose breathers and absorption occurs to a much greater degree.

There is considerable uncertainty as to whether the same dose per unit area of lung has the same effect on humans and animals. A safety factor, f, of 5 is applied to allow this.

18.19.2 Systemically acting substances

For a systemically acting substance the specific dose D' is defined as

$$D' = D/W \qquad [18.19.6]$$

where D' is the inhaled dose per unit body mass (mg/kg). In this case the mass absorbed is proportional to the oxygen consumption rather than the minute volume. Oxygen consumption is in turn, a function of body weight, being proportional to $W^{0.7}$ as in relation 18.19.3. Hence from relations 18.19.2, 18.19.3 and 18.19.6

$$D' \propto W^{-0.3} \qquad [18.19.7]$$

Then using the same body masses as before, relation 18.19.7 implies that the load on a rat and on a mouse are, respectively, some 5.1 times and 10.2 times that on a man.

There is uncertainty as to whether the same dose per unit body mass has the same effect on humans and animals. In this case a safety factor, f, of 10 is applied.

18.19.3 Extrapolation factor

The foregoing treatment incorporates certain safety factors, of 5 for locally acting substances and 10 for systemically acting ones. The dose values apply to inhalation rates for persons at rest. A further safety factor of 2 is then applied which allows for increased inhalation rates in the population during a toxic gas emergency.

An extrapolation factor f_d is now determined for extrapolation of results from each species to humans. Thus, for example, for a rat:

Load animal f_d = *Load man*	*Safety factor*	*Extrapolation factor*			
Local effect	3.3	5 × 2	0.33	0.25	0.25
Systemic effect	5.1	10 × 2	0.26	0.26	

The LC$_{50}$ value for humans is obtained by multiplying the LC$_{50}$ value for the test animal by the extrapolation factor. Values of the extrapolation factor f_d are as follows: rat, 0.25; mouse, 0.5; guinea pig, 0.2; and hamster, 0.3.

18.19.4 Probit equations

Probit equations for use in hazard assessment are then derived as follows. The basic approach is to assume a value for k_2 in Equation 18.11.6 and, if necessary, a default value of n, and to determine the constant k_1 from animal LC$_{50}$ data.

The constant k_2 is assigned a value of 1.0 in all cases. This corresponds to a high value of the ratio LC$_{95}$/LC$_{05}$, and for concentrations below the LC$_{50}$ is the conservative assumption. For the index n the default value used is 2.

Then starting from an animal LC$_{50}$ value for some time t, the first step is to obtain the LC$_{50}$ for 30 min. This is then converted to a 30-min LC$_{50}$ for humans by application of the extrapolation factor f_d.

Where there are data for more than one animal species, a further step is taken. This is to obtain the average animal 30-min LC$_{50}$ and to multiply it by a factor of 2 before applying the extrapolation factor f_d to obtain the 30-min LC$_{50}$ for humans. This has the effect of reducing the overall safety factor that is applied.

The probit equations obtained are considered further in Section 18.20.

18.20 Gas Toxicity: Probit Equations

As described above, probit equations are available for a number of the toxic gases of industrial interest. They include in particular the collections given for the Vulnerability model by Perry and Articola (1980), in the *QRA Guidelines* by the CCPS (1989/4) and in the *Green Book* by the CPD (1992b). The limitations of probit equations have been discussed in Chapter 9 and need not be rehearsed here.

In addition to the inherent limitations of probit equations, it is also necessary to consider in each particular case both the situation to which it is intended to apply and the degree of conservatism incorporated. The basic data are generally obtained from experiments on animals that tend to remain passive, but the use of the correlation is presumably for humans in an emergency situation. In some cases the probit equation is explicitly conservative, whilst in others it is not, reflecting a difference of philosophy as to the point at which any safety factor should be applied.

Table 18.28 gives the parameters for probit equations for industrial toxic gases.

18.21 Gas Toxicity: HSE Dangerous Dose

As described in Chapter 9, the HSE use for the purpose of land use planning the concept of a 'dangerous dose'.

For toxic substances the interpretation of the dangerous dose concept and the methodology by which a value is derived is described in *Assessment of the Toxicity of Major Hazard Substances* (R.M. Turner and Fairhurst, 1989a).

The authors discuss the paucity of data on the effect of toxic gases on man and the problems of probit equations. They propose for land use planning the use not of probit equations but of a toxic load value that they call the SLOT. This is expressed in the form of an equation for the dangerous toxic load (DTL) and of a set of values for the SLOT computed from this relation.

The SLOT is defined as a value associated with a situation in which: (1) almost all persons suffer severe distress; (2) a substantial fraction require medical attention; (3) some persons are seriously injured, requiring prolonged treatment; or (4) any highly susceptible person might be killed. Typically the SLOT used corresponds to a mortality of 1–5%. The SLOT selected depends, however, on the substance, and in some cases it may be appropriate to use several SLOTs.

Essentially the SLOT is a criterion for individual risk. For societal risk the authors refer to the use of the method described by Poblete, Lees and Simpson (1984) and extended by Lees, Poblete and Simpson (1986), which is described in Chapter 9.

The methodology described by Turner and Fairhurst for the derivation of a SLOT is broadly as follows. Since there is a lack of toxicity data for humans, it is necessary to resort to the use of data from experiments on animals. The most

Table 18.28 *Parameters in probit equations for lethality for some principal industrial toxic gases*

[a] Both sets of parameters are for toxic gas fatality probit equations of the form

$$Y = k_1 + k_2(c^n t)$$

where t is the time (min). In the CCPS equation (and in those of Perry and Articola (1980)) the units of concentration c are ppm, whilst in the CPD equation the units are mg/m^3.

[b] CCPS *QRA Guidelines* (1989/5). Except as described in (d) and (e) below, these are the values given by Perry and Articola (1980), who discuss the derivations.

[c] CPD *Green book* (1992b); de Weger, Pietersen and Reuzel (1991). In all cases $k_2 = 1$.

[d] Perry and Articola give:
Ammonia: $k_1 = -28.33$; $k_2 = 2.27$; $n = 1.36$;
Chlorine: $k_1 = -36.45$; $k_2 = 3.13$; $n = 2.64$;
Hydrogen fluoride: $k_1 = -25.87$; $k_2 = 3.354$; $n = 1.00$.

[e] Perry and Articola do not give values for these substances.

reliable data generally relate to the LC_{50} values and the associated exposure times, and it is this that is taken as the starting point. Data are gathered for a number of species and usually the data adopted are those for the most sensitive species. Next, estimates are made of the LC_{50} or LC_{01} values. In some cases the data available permit an extrapolation based on probits. If this is not possible, an alternative approach is to use an empirical value of the ratio LC_{50}/LC_{05}, or LC_{50}/LC_{01}, as the case may be.

At this stage, therefore, the method yields a single value of the SLOT LC_{50} or LC_{01} with an associated exposure time. It is then necessary to determine the trade-off between the concentration c and the time t, or, in other words, the value of the index in the toxic load $c^n t$. Essentially this requires data on concentration vs time for a given level of effect, such as the LC_{50}. The authors warn against the use for this purpose of values from different sets of experiments on different species, since the results may then owe more to differences between species than to differences in exposure time.

The SLOTs obtained are then correlated as a DTL equation. These SLOTs and the DTL are applicable to an animal species. Collateral evidence may then be sought to confirm that it is reasonable to apply the relation to humans.

One feature of this approach is that the use of an LC_{50} or LC_{01} rather than an LC_{50} value means that there is more likely to be some data on humans that can be used as collateral evidence. Another feature is that, insofar as the animal data used are generally for the most sensitive species, the approach may be regarded as conservative.

The application of this methodology is now illustrated for a number of industrial toxic gases. Table 18.29 shows for these gases some physico-chemical properties and the SLOT and DTL values. Each of the studies described gives a table detailing results of single exposure inhalation studies in animals and a table of LC_{50} values for different species.

The accounts given below are necessarily brief summaries; the arguments adduced in support of the values chosen are much fuller in the original references and these should be consulted.

18.21.1 Acrylonitrile

The SLOT values for acrylonitrile are derived in *Toxicology of Substances in Relation to Major Hazards: Acrylonitrile* (R.M. Turner and Fairhurst, 1989b). The gas has an irritant effect.

The experimental data for animals are sparse and most are for long exposures; none were found for exposure periods of less than 30 min. The more sensitive species were dogs, in work by Brieger, Rieders and Hoders (1952), and mice, in work by Knobloch *et al.* (1971). From the data for these species the authors derive the single SLOT value of 40 ppm for 4 h. They do not give a precise interpretation of this SLOT, but it would appear to correspond to a value of the order of LC_{05} to LC_{01}. They make use of several studies which bear on the relation between concentration and time and settle on a value of $n = 1$. The resultant SLOTs and DTL equation are then as given in Table 18.29.

18.21.2 Ammonia

The SLOT values for ammonia are derived in *Toxicology of Substances in Relation to Major Hazards: Ammonia* (Payne, Delic and Turner, 1990). Ammonia is an irritant gas which, being highly soluble, tends to attack the upper respiratory tract, causing laryngeal oedema, as well as pulmonary oedema. The authors suggest that reported cases of laryngeal spasm probably involved laryngeal oedema. The essential toxic effect is therefore irritation.

For ammonia there is a considerable amount of experimental data on animals. The most sensitive species is the mouse, but the authors also make some use of data for rats. For mice, the work of Silver and McGrath (1948) yields an LC_{50} of 10,150 ppm for a 10 min exposure and that of Kapeghian *et al.* (1982) an LC_{50} of 4230 ppm for a 60 min exposure. From work on rats by Appelman, ten Berge and Reuzel (1982) a value of the index $n = 2$ may be obtained. It happens that this value of $n = 2$ is also consistent with the two LC_{50} values just mentioned. Data from these same studies were used to estimate values of the LC_{05} and LC_{01}. The resultant values for the LC_{01} are 6,129 and 3,296 ppm, respectively. Adopting the former and utilizing the value of

Table 18.29 *HSE DTL and SLOT values for some principal industrial gases*

	Acrylonitrile	*Ammonia*	*Chlorine*	*Hydrogen fluoride*	*Hydrogen sulfide*	*Sulfuric acid mist*
MW	53.06	17.03	70.9	20.0	34.1	98.1
Boiling point (K)	350.3	−33.42°C	328.4	292.5	211.2	563−603
Freezing point (K)	189.5	−77.74°C	172	190	187.5	283[c]
Conversion factor ($ppm-mg/m^3$)[a]	2.2	0.7	2.9	0.83	4.4	
DTL	9600 ppm min	3.76×10^8 ppm^2 min	108,000 ppm^2 min	2,400,000 ppm^2 min	2×10^{12} ppm^4 min	2.16×10^5 (mg/m^3) min
SLOT values (ppm)[b]						
5 min	1920	8670	147	693	800[d]	208 mg/m^3
10 min	960	6130	100	490	669	147 mg/m^3
30 min	320	3540	60	283	508	85 mg/m^3
60 min	160	2500	42	200	427	60 mg/m^3
120 min	80	1770	30	141	359	42 mg/m^3
240 min	40				302	
480 min						21 mg/m^3

[a] Conversion factor for vapour at 25°C and pressure 1.0133×10^5 Pa, except for hydrogen fluoride for which the conversion is based on 0°C.
[b] Units for all gases except for sulfuric acid mist, for which the units are mg/m^3.
[c] Value for 100% acid.
[d] Ceiling value for exposure period 0−5 min.

n quoted yields the SLOTs and DTL equation given in Table 18.29.

18.21.3 Chlorine

The SLOT values for chlorine are derived in *Toxicology of Substances in Relation to Major Hazards: Chlorine* (R.M. Turner and Fairhurst, 1990a). The gas has an irritant effect.

For chlorine there is a considerable amount of experimental data on animals. The mouse appears the most sensitive species. For mice, the work of Schlagbauer and Henschler (1967) gives an LC_{50} of 127 ppm for a 30 min exposure. Data from this study were used to estimate values of the LC_{05} and LC_{01} for this exposure time, the values obtained being 70 and 56 ppm, respectively. The index n is obtained from a critical review of the large variety of values quoted in the literature, the authors settling on $n = 2$. The resultant SLOTs and DTL equation are then as given in Table 18.29.

The generally conservative nature of the approach taken is illustrated in this case. The LC_{50} value derived from the work of Schlagbauer and Henschler on which the SLOTs are based towards the lower end of the range of LC_{50} values for animals given in the literature.

18.21.4 Hydrogen fluoride

The SLOT values for hydrogen fluoride are derived in *Toxicology of Substances in Relation to Major Hazards: Hydrogen Fluoride* (R.M. Turner and Fairhurst, 1990b).

Hydrogen fluoride is an irritant gas, but it also has some systemic effects. Whilst there is little information on the long-term effects of a single non-lethal exposure, the general toxicological properties of the gas point to the possibility of permanent injury.

For hydrogen fluoride there is a limited amount of experimental data on animals, the most sensitive species being the mouse. The work of Wohlslagel, DiPasquale and Vernot (1976) gives for mice an LC_{50} of 342 ppm for a 60 min exposure. Using data from this same study, Turner and Fairhurst obtain for the LC_{05} and LC_{01} at this same exposure time values of 230 and 205 ppm, respectively. From work on rats by Rosenholtz *et al.* (1963) they derive a value of the index $n = 2$. This then yields the SLOTs and DTL equation given in Table 18.29.

18.21.5 Hydrogen sulfide

The SLOT values for hydrogen sulfide are derived in *Toxicology of Substances in Relation to Major Hazards: Hydrogen Sulphide* (R.M. Turner and Fairhurst, 1990c).

In addition to being an irritant gas hydrogen sulfide also causes inhibition of intracellular respiration. The second of these effects grows in relative importance as the concentration increases.

For hydrogen sulfide the limited amount of experimental data on animals available show reasonable consistency. Turner and Fairhurst distinguish several concentration regions: 750–100 ppm; 450–750 ppm and 200–350 ppm. High concentrations, in the range 750–1000 ppm, cause rapid unconsciousness and death within a few minutes. The authors therefore take 800 ppm as a ceiling value, independent of exposure time. From examination of data on a number of species, including work by Prior *et al.* (1988) and Tansy *et al.* (1981), the authors obtain the following LC_{50} estimates: 300 ppm for 4 h; 400 ppm for 60 min; and 500 ppm for 30 min. This set of values corresponds to a value of the index of $n = 4$. In the study by Prior *et al.* for an exposure time of 4 hours the LC_{50} was 501 ppm and the LC_{10} was 422 ppm, giving an LC_{50}/LC_{10} ratio of 1.19, which was then used to obtain the SLOTs. The resultant SLOTs and DTL equation are then as given in Table 18.29.

18.21.6 Sulfuric acid mist

The SLOT values for sulfuric acid mist are derived in *Toxicology of Substances in Relation to Major Hazards: Sulphuric Acid Mist* (R.M. Turner and Fairhurst, 1992).

Sulfuric acid mist is an irritant that has two main effects. One is constriction of the airways (bronchioconstriction and possibly laryngeal spasm). The other is damage to the respiratory tract accompanied by oedema and haemorrhage. These toxic effects depend on the size of the droplets.

Sulfuric acid mist is formed from releases of sulfur trioxide or oleum, a mixture of sulfuric acid and sulfur trioxide. On release these react with water in the atmosphere and form a dense cloud of mist. The mist is likely to contain submicron droplets that remain airborne until they absorb additional water and rain out or are deposited onto surfaces. In an accident, the size of the droplets inhaled can be expected to exceed that on release and the authors assume a droplet size of 1 μm. As it happens, this is the size for which most of the data are available.

For sulfuric acid mist the bulk of data on animal experiments relates to guinea pigs. This is also the most sensitive species. From the work of Amdur, Schulz and Drinker (1952) the authors obtain an estimate of the LC_{50} of 60 mg/m^3 for a 60 min exposure. For the index n Turner and Fairhurst use the values of the LC_{50} at an 8 h exposure of 18, 30 and 50 mg/m^3 reported by Amdur, Schulz and Drinker and by Wolff *et al.* (1979), and obtain the value $n = 2$. These data form the basis of the SLOTs. There is no explicit recourse to LC_{05} or LC_{01} values, but the LC_{50} is that for the experiments in which the animals were most sensitive; in other work by Treon *et al.* (1950) and Amdur (1958) no deaths were recorded at concentrations up to 42 and 121 mg/m^3 for an exposure time of 60 min. The resultant SLOTs and DTL equation are then as given in Table 18.29.

18.22 Gas Toxicity: Combustion Gases

A somewhat separate problem concerns the toxicity of combustion products. Much of the research interest in such gases centres on the combustion of furnishings, but work in this area is also relevant to toxic clouds from combustion of materials on plant and in storage, particularly warehouses.

Work on the toxicity of combustion products has been described in a number of publications. This includes work described in *Smoke and Products of Combustion* (Hilado, 1973) and by Hilado and co-workers (Hilado and Furst, 1976; Hilado, Casey and Furst, 1977; Hilado, Cumming and Casey, 1978; Hilado and Cumming, 1978; Hilado and Huttlinger, 1980, 1981b,c), Hartzell and co-workers (Kaplan and Hartzell, 1984; Hartzell, Packham *et al.,* 1985; Hartzell, Priest and Switzer, 1985; Hartzell, Stacy *et al.,* 1985; Hartzell, 1987, 1989; Hartzell, Grand and Switzer, 1987), Underwood (1978), Alexeeff *et al.* (1986), Tsuchiya and Nayaka (1986) and the CPD (1992b).

The toxicity of combustion products in the context of hazard assessment has been considered by D.A. Carter (1989), G.T. Atkinson, Jagger and Kirk (1992) and

G.T. Atkinson and Jagger (1994). The toxicity of the breakdown products of the fire extinguishant bromochlorodifluoromethane (BCF) has been studied by Doe *et al.* (1986).

18.23 Ultratoxic Substances

The Seveso disaster in 1976 showed that there is a serious hazard from small quantities of ultratoxic substances. At Seveso some 2.5 kg of 2,3,7,8-tetrachlorodibenzoparadioxin (TCDD) were released to the atmosphere. Abnormal reaction conditions occurred in a chemical reactor, the pressure rose and the relief valve operated. The TCDD was not a normal reaction product but the product of a side reaction that occurred at an appreciable rate only under abnormal conditions. The toxicity of TCDD is such that it is more akin to a chemical warfare agent than an industrial chemical and it has been called the most poisonous substance in existence. The surrounding area was contaminated and had to be evacuated. People in the area at the time of the incident suffered rashes. But, more seriously, there were expected to be long-term carcinogenic, teratogenic and/or mutagenic effects. Further details of the Seveso incident are given in Appendix 3.

A further disaster involving a very highly toxic, if not ultratoxic, chemical occurred at Bhopal in 1984, where a reaction occurred in a storage tank containing methyl isocyanate (MIC), the relief valve lifted and released a cloud of the gas onto housing, killing a large number of people, the official death toll being now 4,000, but other estimates being rather higher. This was much the worst accident experienced at a chemical plant. Further details of the Bhopal incident are given in Appendix 5.

18.24 Plant Design for Toxic Substances

Plants handling toxic substances need to be designed to minimize both large accidental releases and fugitive emissions. An overview of the design of plant for the handling of toxic substances is given by S.D. Green (1980). He deals with: the collection and assessment of toxicological information; process reviews covering random leaks and intermittent releases; design strategies of substitution, prevention and containment; ventilation; separation distances; and protection measures.

18.24.1 Design against large releases

As far as concerns large toxic releases, this is not solely a matter of the mechanical design of the plant, important though that is. Inherently safer design also has an important part to play, in minimizing the effects of any failure through the choice of the substances used in the in process and the operating conditions.

The mechanical design of plants, and particularly pressure systems, to high standards of integrity is treated in Chapter 12, and is not considered further here.

18.24.2 Design against fugitive emissions

There are a number of accounts, both by plant designers and occupational hygienists, of the design and operation of plant handling toxic substances to counter fugitive emissions and the resultant chronic toxic hazard. These include *Fugitive Emissions of Vapours from Process Equipment* (Jones *et al.,* 1984, BOHS TG3), (the BOHS *Fugitive Emissions Guide*), *Health Hazard Control in the Chemical Process Industry* (Lipton and Lynch, 1987) and *Handbook of Health Hazard Control in the Chemical Process Industry* (Lipton and Lynch, 1994) and by Payne (1978), S.D. Green (1980), Kusnetz and Phillips (1983), Kusnetz and Lynch (1984), Whitehead (1987) and Crowl and Louvar (1990).

Other potential sources of guidance are design practices for chemical plant under vacuum and for nuclear plant.

Emissions of toxic substances to the atmosphere are not confined to continuous leaks from the plant. They also occur as a result of operations carried out on the plant, particularly those involving purging or breaking into equipment for operations or maintenance purposes. The design of plants to minimize exposure to toxic substances is essentially a two-pronged one, based on the reduction of fugitive emissions and the provision of ventilation.

The problem of fugitive emissions on process plants is discussed in Chapter 15. There has been a growing concern over the emission of hydrocarbons and of volatile organic compounds (VOCs). Two points made there bear reiteration. One is that there is considerable variability between plants in the levels of emission, and the other that it is possible for plants to achieve very low levels of emissions, though as always this is easier in the design of a new plant.

Most of the data on fugitive emissions relate to hydrocarbons and VOCs. They provide a useful initial indication, but in view of the wide differences in the results obtained and the rather different nature of the problem in the case of toxic materials, care should be exercised in applying them to toxic emissions.

The BOHS *Fugitive Emissions Guide* provides guidance on the main leak sources: flanges and seals, with applications of the latter on valves, agitators, pumps and compressors.

The topics treated by Lipton and Lynch (1987) are (1) occupational health hazards, (2) sources of exposure, (3) exposure evaluation, (4) fugitive emissions, (5) hazard control, (6) rotating equipment, (7) valves and flanges, (8) sampling, and (9) drains, sewers and wastewater emissions.

18.24.3 Ventilation

Design to minimize fugitive emissions is complemented by provision of good ventilation. Ventilation is discussed in Chapter 10 in relation to plant layout, and again in Chapter 25 in relation to occupational hygiene, and is therefore not treated at this point.

18.24.4 Material transfer

On plants handling toxic materials, transfer systems such as pumps are one of the main sources of emissions, which can occur either as random leaks or in the course of activities such as maintenance. An account of this problem and measures to deal with it has been given by Grossel (1990a).

This author considers centrifugal pumps, positive displacement pumps, sealless pumps, jet pumps, pressurized gas and vacuum systems. He describes centrifugal pumps for toxic-liquids which are fitted with double mechanical seals, in double inside or tandem arrangement, and with a seal failure alarm. A buffer liquid may be used, which may have to be cooled to remove heat or heated to reduce its viscosity. A minimum flow bypass is often desirable and may need to be provided with a cooler. For a heat sensitive toxic liquid it may be necessary to provide the pump with a high temperature trip.

For low flows, positive displacement pumps are frequently used. Diaphragm metering pumps or air-operated diaphragm pumps have no seals and are able to operate at low flow without excessive temperature rise. For highly toxic liquids, Grossel advises double diaphragm pumps. The space between diaphragms can be monitored. For rather higher flows use may be made of rotating positive displacement pumps such as the gear, vane, lobe or screw types, fitted with double mechanical seals or using magnetic drives. Positive displacement pumps require pressure relief to an external source. Grossel emphasizes the need for such external relief even where the pump is equipped with an internal relief valve.

Sealless pumps such as canned pumps and magnetic drive pumps are another option, but these also are not without problems. One weak point may be the shell, which may be relatively thin so as not to impede the magnetic field. Another may be the bearings which are lubricated by the pumped fluid. Failure of a bearing can cause the rotor to rub against the can and rupture it. Manufacturers offer various arrangements to overcome these problems, such as secondary containment with monitoring of the intervening space or monitoring of the bearings. Operating problems include flashing of low-boiling liquids, dry running and blockage by solids.

Grossel also gives details of systems for transfer by pressurized gas or by vacuum, and discuss other aspects such as plant layout, equipment installation, remotely operated isolation valves and ventilation hoods.

18.25 Toxic Gas Detection

A release of toxic gas may be detected by the visual appearance of the cloud, by its odour or by instrumentation. Detection by these means is discussed in the *Vapor Release Mitigation Guidelines* (CCPS, 1988/3).

18.25.1 Colour

Some gases have a characteristic colour. Chlorine gives a gas cloud of greenish-yellow colour, bromine one of reddish-orange colour, and so on. Even if there is no such colour, the gas may well form a visible fog. Some gases tend to form a fog by taking up moisture from the air to form an aerosol. Such gases include ammonia, hydrogen chloride, hydrogen fluoride and sulfur trioxide. Liquefied gases such as Liquefied natural gas (LNG), liquefied petroleum gas (LPG), liquid ethylene and liquid ammonia cause water in the atmosphere to condense and create a fog.

18.25.2 Odour

Many gases give a characteristic odour. The concentrations at which such an odour is detectable vary by orders of magnitude.

Accounts of odour are given in *Human Responses to Environmental Odors* (Turk, Johnston and Moulton, 1974), *Industrial Odor Technology and Assessment* (Cheremisinoff and Young, 1975), *The Identification and Measurement of Refinery Odours* (CONCAWE, 1975 8/75), *Compilation of Odor and Taste Threshold Values Data* (Fazzalari, 1978), *The Perception of Odors* (Eugen, 1982) and *Odor Thresholds for Chemicals with Established Occupational Standards* (AIHA, 1989/17), and by Leonardos, Kendall and Barnard (1969), Amoore and Hautala (1983), Polak (1983), Lynskey (1984 LPB 60) and J.C. Stevens, Cain and Weinstein (1987). Odours are also discussed in Appendix 11.

Some odour thresholds (OTs) are very low indeed. The threshold for hydrogen sulfide is given in the CONCAWE document as 0.001–0.014 ppm and in the CCPS Guidelines as 0.0002 ppm. The latter give data on the relation between the OT and the immediately dangerous to life and health (IDLH) limit. These include the following:

Gas	*OT* (ppm)	*IDLH* (ppm)	*IDLH/OT*
Carbon monoxide	(none)	1500	N/A
Phosgene	0.47	2	4.3
Ammonia	21	500	25
Chlorine	0.31	25	80
Hydrogen sulfide	0.0002	300	1,500,000

In some cases a person can become desensitized to an odour. The classic case is hydrogen sulfide. This is discussed in Section 18.16.

18.25.3 Instrumentation

In some cases it is appropriate to install toxic gas detectors. Accounts of toxic gas detectors and detection are given in *Detection and Measurement of Hazardous Gases* (Cullis and Firth, 1981) and by Dailey (1976), Johanson (1976), Warncke (1977), Lichtenberg and McKerlie (1979), Harbert (1983, 1984), Krigman (1984), Zanetti (1986b) and Atallah and Guzman (1987).

Whereas much flammable gas detection is based on combustible gas detectors, toxic gas detection tends to utilize a wider variety of detectors, corresponding to the variety of toxic gases. Some principles of operation in the sensors used include (1) hot wire combustion, (2) catalytic combustion or reaction, (3) some other chemical reaction, (4) electrical effects, and (5) absorption and scattering effects. Use is also be made of closed circuit TV monitors. Details of sensors and their response times are given in the CCPS Guidelines.

The purpose of a toxic gas detection system should be clearly defined. One purpose may be to give a rapid warning of a major release. Another may be to detect fugitive emissions of a toxic gas for occupational hygiene purposes. It is the former that is considered at this point.

In locating the detectors there is a choice between monitoring specific potential leak sources and giving good area coverage. For the monitoring of a leak source Johanson (1976) suggests an angular separation between detectors of 10° and a separation between detectors of no more than 30 ft (10 m). He recommends detector heights of 1.5 ft (0.5 m) and of 6–8 ft (2–2.5 m) for buoyant gases.

The CCPS Guidelines emphasize that a toxic gas detection system with an insufficient number of detectors or inadequate maintenance may be worse than no system at all, particularly if it leads to less human surveillance or to confusion arising because a field report of a leak is not confirmed by the detection system.

Guidance is available on gas detection systems for specific toxic gases. For chlorine information is given in the *Chlorine Manual* (Chlorine Institute, 1986 Pmphlt 1). The monitoring of ammonia is discussed by Lichtenberg and McKerlie (1979).

18.26 Toxic Release Response

Essentially the control of the toxic release hazard means, on the one hand, the prevention of serious loss of containment and, on the other, the elimination of hazardous concentrations in the environment. There are also the intermediate problems of dealing with small quantities of toxic materials arising mainly from leaks and spillages and from maintenance operations.

Aspects of the process and plant design and of the storage and transport of toxic chemicals are described in Chapters 11, 12, 22 and 23, respectively. Another aspect is planning for toxic emergencies, which is described in Chapter 24. The assessment of the hazard of large toxic releases is dealt with in Sections 18.28–31.

Elimination of hazardous concentrations in the working environment requires assessment of leaks and other sources of toxic substances. Engineering measures can then be taken to improve the leak-tightness of plant.

It is also necessary to have ventilation and monitoring of the atmosphere and medical checks on personnel. These latter aspects comprise industrial hygiene and are discussed in Chapter 25.

In addition, there should be procedures for the handling of abnormal leaks and spillages.

18.26.1 Leaks and spillages

If the plant is in the open, small leakages from the plant may be dispersed by the wind. If the plant is in a building, mechanical ventilation is necessary. The toxic hazard should be a principal consideration in deciding whether to put a plant in a building or in the open.

Provision should be made for handling larger emissions. It may be necessary to have emergency isolation valves and relief, blowdown and gas absorption facilities in order to reduce the amount likely to escape.

Methods of dealing with liquid spillages vary with the chemical concerned. Thus, for example, the treatments recommended in the respective codes are different for chlorine and for phosgene. In both cases the principle applies of restricting by containment the area available for evaporation. But, whereas the evaporation of chlorine can be reduced by applying mechanically produced water-based protein foam, this should not be utilized for phosgene, for which the use of kerosene impregnated with dry sawdust is suggested.

In dealing with spillages, actions should be avoided which actually increase the rate of evaporation. For example, water should not be sprayed on a chlorine spillage. In contrast, a spillage of ethylene oxide, which is miscible with water, may be diluted and rendered more safe by the addition of large quantities of water. Restricted amounts of water, however, may only serve to increase the vaporization.

The handling of toxic liquids spilled into bunds, and the use of foams, is considered in more detail in Chapter 15.

18.26.2 Emergency action

The effect of a large toxic release can be greatly mitigated if the people exposed take the right action. In plant handling toxic materials workers have protective buildings and equipment and are trained in emergency procedures. It is commonly considered that, provided these precautions are taken, workers in the factory itself are at no more risk than members of the public.

In order to prepare instructions to be issued to the public in the event of a large release, it is necessary to decide whether it is safer for a person to flee from the gas cloud or to stay indoors taking measures to prevent ingress of the chemical. Methods are available for the calculation of the rate at which a toxic gas diffuses into buildings. An account of these methods was given in Chapter 15.

The usual practice in assessing a toxic release hazard is to consider a range of scenarios. For some scenarios the best course of action may be to evacuate, while for others it may be to stay indoors. It should be borne in mind, however, that any instruction to be issued to the public should be simple and clear. In most cases the preferred advice to the public is to stay indoors and shut doors and windows.

Emergency procedures for toxic releases are treated in more detail in Chapters 20 and 24.

18.27 Toxic Release Case Histories

By far the worst accident in the history of the process industries occurred on 3 December 1984 at Bhopal, where water entered a storage tank of methyl isocyanate, causing overheating and release of methyl isocyanate vapour which spread over a shanty town close to the works and killed some 4000 people. This incident is described in Appendix 5.

There have been a number of major accidents involving chlorine. A list of major chlorine accidents worldwide has been given by Simmons, Erdmann and Naft (1974) and is reproduced in Table 18.30. Another list of chlorine accidents has been given by V.C. Marshall (1977b) and is shown in Table 18.31.

In 1939, failure of a chlorine storage tank at Zarnesti, Romania, resulted in the death of about 60 people. This is the largest death toll from any industrial chlorine accident.

As the tables show, tank failures were also the cause of two other major chlorine accidents: at St. Auban, France, in 1926, for which the death toll is given variously as 19 and 40; and at Rauma, Finland, in 1947, where 19 died.

An explosion in a rail tank car at Mjodalen on 26 January 1940 resulted in a chlorine release of 7–8 te and caused the gassing of 85 people, of whom three died (Römcke and Evensen, 1940; Hoveid, 1966).

A large release of chlorine occurred at Baton Rouge, Louisiana, on 10 December 1976 (Case History A79), which the *Second Report* of the ACMH (Harvey, 1979b) described at the time as believed to be the largest civil chlorine release recorded. An explosion occurred which is thought to have dislodged a chlorine tank and caused it to fall on a protruding object and to puncture. Approximately 90 te of chlorine escaped, but there were no deaths.

Another smaller but more lethal chlorine release occurred from a derailed rail tank car at Youngstown, Florida, on 26 February 1978 (Case History A94). Seven people were killed.

Another large release of chlorine occurred on 1 August 1981 when a train derailment near Montana, Mexico (Case History A100), resulted in the rupture of two 55 te chlorine tankers. The gas spread through a narrow valley and caused the deaths of 17 people.

A derailment of a chlorine train at La Barre, Louisiana, on 31 January 1961 (Case History A29) gave rise to a release of chlorine. There was a house occupied by a family only 50 yd from the crashed chlorine rail tank car. A child taken out of doors died, but an infant who remained in the house survived. The incident is of interest, therefore, in relation to the protection provided by buildings.

There have also been a number of non-fatal chlorine releases. The chlorine accidents at Cornwall, Ontario, in 1962, at Philadelphia, Pennsylvania, in 1963, and at Los Angeles, California, in 1966, resulted in the gassing, but not the deaths, of quite large numbers of people.

Table 18.30 *Significant chlorine accidents (after Simmons, Erdmann and Naft, 1974) (Courtesy of the American Institute of Chemical Engineers)*

Date	*Location*	*Chlorine release* (ton)	*Fatalities*	*Comments*
Storage tanks				
1926 Dec. 13	St. Auban, France	25	19	Tank burst

Cylinders				
1920	Niagara Falls, NY		3	150 lb cylinder burst
1925	De Noya, OK		1	Suckback of gasoline
1947 Jan. 13	Natrium, VA		2	150 lb cylinder exploded
1954 Jun. 25	Montreal, Quebec		1	Cylinder fell into hold of steamship

Three chlorine releases from pipelines at Dominguez, California, in 1966 and 1967, are recorded by Solomon, Rubin and Okrent (1976). In each instance the amount of chlorine released was 500 lb. In one case the pipe was accidentally cut by a welder, in the other two it was accidentally dug up.

The release of 100 lb of chlorine from a cylinder into the subway system of Brooklyn, New York, in 1944, which is described by Chasis *et al.* (1947), resulted in the gassing, but not the deaths, of 208 people. It illustrates the effect of an escape in a confined space.

Another chemical that presents a serious toxic release hazard is ammonia. A list of ammonia accidents has been given by V.C. Marshall (1977b), as shown in Table 18.31.

A road tanker crash that released ammonia at Lieven, France, in 1968 resulted in five deaths (Medard, 1970), and an ammonia release from a crashed rail tank car at Crete, Nebraska, in 1969 killed eight people.

There was a release of 160 ton of ammonia from a storage tank at Blair, Nebraska, in 1970 (Case History A47), but there were no casualties.

The ammonia accident at Potchefstroom, South Africa, on 13 July 1973 (Case History A65), in which 18 people were killed when an ammonia storage tank failed and released an estimated 39 ton, appears to be the worst accident involving ammonia for which details are available.

In 1976, a road tanker crashed on the Southwest Freeway, Houston, Texas (Case History A84), and released 19 te of ammonia which killed six people.

Phosgene					
1928 May 20	Hamburg, Germany	Storage tank	10?	10	1.0?

[a] This value differs from that given by Simmons, Erdmann and Naft (1974).

[b] The date quoted in the original reference has been corrected (F.P.L.).

[c] This value is about 10% less than that given by Simmons, Erdmann and Naft (1974).

[d] This incident is referred to elsewhere in this book as McPherson, Kansas.

An ammonia release at Cartegena, Columbia, in 1977, is reported to have caused a death toll which is now set at 21 (MHAP, 1988). This is the largest number of deaths from an industrial ammonia accident.

On 20 March 1989 a refrigerated atmospheric ammonia storage tank containing some 7,000 te of liquid ammonia failed at Jonova, Lithuania (Case History 128). The ammonia ignited and an ammonium nitrate storage caught fire. It is estimated that some 1400 te of ammonia evaporated and that a further 700 te of ammonia and nitrous fumes participated in the toxic fire plume. The plume is described as spreading some 35 km and affecting an area of some 400 km^2. Seven people were killed.

There have also been a number of non-fatal releases of ammonia. A release of about 600 ton of ammonia occurred from a pipeline in Floral, Arkansas, in 1971 (Chementator, 1971 Jul. 26, 55). There was a fish kill, but no injuries. There was an escape of some 230 ton of ammonia on a pipeline at McPherson, Kansas (Case History A64), in 1973.

Further incidents involving ammonia release are related by Slot (1938), Caplin (1941) and Trotter (1983). Other accounts are referenced by Payne, Delic and Turner (1990).

In general, the recorded releases of ammonia usually involve larger quantities than those of chlorine, but are not more lethal. As Table 18.31 shows, there are a number of recorded ammonia releases in excess of 100 te.

The toxicity of ammonia is appreciably less than that of chlorine and, although it behaves on release as a heavy gas, it has a molecular weight (MW 17), less than that of air, which eventually aids dispersion.

Some other major toxic release accidents include those tabulated below:

Date	*Location*	*Chemical*	*Deaths/injuries*
1928	Hamburg, Germany	Phosgene	10 d
1930	Lüttich, Belgium	Hydrogen fluoride, sulfur dioxide	63 d
1950	Poza Rica, Mexico	Hydrogen sulfide	22 d, 320 i
1978	Chicago, IL	Hydrogen sulfide	8 d, 29 i

The phosgene release in Hamburg in 1928 (Case History A6) was due to a pressure vessel failure. It caused the gassing of some 300 people and resulted in 10 deaths.

A gassing incident involving hydrogen sulfide at Poza Rica, Mexico, in 1950, is described by McCabe and Clayton (1952). There are numerous accounts of lesser hydrogen sulfide gassing incidents, including those by Haldane (1896), Poda (1966) and Burnett *et al.* (1977). Other accounts are referenced by R.M. Turner and Fairhurst (1990).

There have also been several fire incidents, described by the MHAP (1993), in which significant quantities of phosgene are said to have been generated. More generally, large fires are a source of toxic products. A fire in a fertilizer warehouse at Nantes in 1987 led to the evacuation of some 40,000 people (Pietersen, 1988b). The decision to evacuate was made on the basis of one measurement, taken inside a car, and may well have been unnecessary.

A even larger evacuation was that at Mississauga, Toronto, in 1979 (Case History 97), when a holed chlorine rail tank car led to an extended emergency in which some 215,000 people were evacuated. This incident is also described in Chapter 24.

Another major evacuation occurred at Glendora, Mississippi, in 1969 (Case History A43), where a ruptured rail tank car of VCM caused some 30,000 people to be evacuated.

In some cases the material release is flammable as well as toxic. The ignition of the ammonia release at Jonova has already been described. Another case where a toxic release was ignited occurred at Nuremburg in 1980, when vinyl chloride issuing from a large hole in a derailed rail tank car found a source of ignition within seconds (Ernst, 1983).

Another type of toxic incident is the release of an ultratoxic substance, such as TCDD. Case histories involving TCDD are given in Appendix 3 on Seveso in 1976.

18.28 Toxic Release Risk

18.28.1 Historical experience

Only a small proportion of the major accidents listed in the loss prevention literature are toxic releases. Many toxic releases disperse rapidly, causing relatively few casualties.

In general, for all three major hazards – fire, explosion and toxic release – the large number of fatalities given by some theoretical estimates, assuming the most unfavourable and improbable circumstances and using models which may prove to be based on pessimistic assumptions, has been in contrast with the small number of fatalities shown by the historical record. Until 1984, this discrepancy was particularly striking for toxic releases. However, in that year the disaster at Bhopal demonstrated that, very rarely, an event occurs which gives some credence to the more pessimistic estimates.

Of the incidents described in Section 18.27, the worst accidents for particular major industrial toxic gases have been:

		No. of deaths
Bhopal	Methyl isocyanate	*c.*4000
Lüttich	Hydrogen fluoride, sulfur dioxide	63
Zarnesti	Chlorine	60
Poza Rica	Hydrogen sulfide	22
Cartegena	Ammonia	21
Hamburg	Phosgene	10

Prior to Bhopal, the most serious toxic incidents involved mainly chlorine and or/ammonia.

Analysis of chlorine incidents has indicated that, with one exception, fatalities occur within about 400 m of the release, and generally within 250 m (MHAP, 1987).

In the United Kingdom there have been very few fatal accidents in chlorine factories and, as far as is known, none to the public, if such accidents as those arising from misuse of chemicals such as sodium hypochlorite are excluded.

The relation between the size of toxic release and the number of people killed has been investigated by V.C. Marshall (1977b), who has developed a mortality index (deaths/te) for toxic releases similar to that for explosions described in Chapter 17.

The list of toxic accidents given by V.C. Marshall (1977b), which is similar to but not identical with that given by Simmons, Erdmann and Naft (1974) and which also includes ammonia and phosgene accidents, has been given in Table 18.31. The table shows the number of fatalities and the mortality index.

In addition to the overall mortality index for chlorine, which is given in Table 18.31 as 0.52, the mortality index for chlorine storage tanks is also of interest. The value obtained for this from the incidents listed in Table 18.31 is 0.96.

Some values of the mortality index from the table are plotted in Figure 18.10. This figure may be compared with Figure 17.133, which gives a mortality index for explosions;

the broken line in Figure 18.10 is that given for explosions in Figure 17.133.

Of these industrial releases those from cylinders tend to have a high mortality index. The amount of gas released is generally small, but the release probably often occurs in a building. A few deaths from such a release are sufficient to give a high value of the index.

It should be emphasized, however, that whereas in the case of explosions there is a well-established relationship between the quantity of material and the explosion overpressure from which lethal effects can be estimated, there is at present no such relation for toxic releases.

18.28.2 Hazard assessment

The alternative approach to the determination of the risk from a large toxic release is the use of hazard assessment involving assumed scenarios of release and with appropriate estimates of emission, dispersion and toxic effects. The hazard assessment may be generic or may address a particular situation, whether at a fixed site or in transport.

The largest number of hazard assessment studies has been done for chlorine. A large chlorine release has generally been regarded as one of the most serious hazards. The following account deals principally with chlorine, but some mention is made of other toxic substances, notably the other main toxic gas, ammonia.

Some early generic studies were those by Howerton (n.d., 1969) and Simmons, Erdmann and Naft (1974) on chlorine; Eisenberg, Lynch and Breeding (1975) on the vulnerability model on chlorine and ammonia; and Solomon, Rubin and Okrent (1976) on a variety of chemicals.

These studies had a number of features that would now be regarded as inappropriate. They generally made very pessimistic assumptions, as the authors emphasize. Two points may be noted in particular. Some of the release rates assumed are extraordinarily high, and in most cases no credit is given for mitigation. In addition, the studies used passive gas dispersion models.

Studies were also made for specific situations. These include a study of chlorine releases from a factory by Dicken (1974, 1975) and Sellers (1976) and a study of the modes of transport for chlorine by Westbrook (1974).

The next stage in hazard assessment of toxic releases is exemplified by the two Canvey Reports (HSE, 1978b, 1981a) and the Rijnmond Report (Rijnmond Public Authority, 1982). The Canvey Reports gave hazard assessments for ammonia and hydrogen fluoride, and the Rijnmond Report for acrylonitrile, ammonia, chlorine, and hydrogen sulfide, from a hydrodesulfurizer. These reports are described in Appendices 7 and 8, respectively. These studies are characterized by a more detailed treatment of the emission scenarios and flows, the use of heavy gas dispersion models and, to some extent, an allowance for

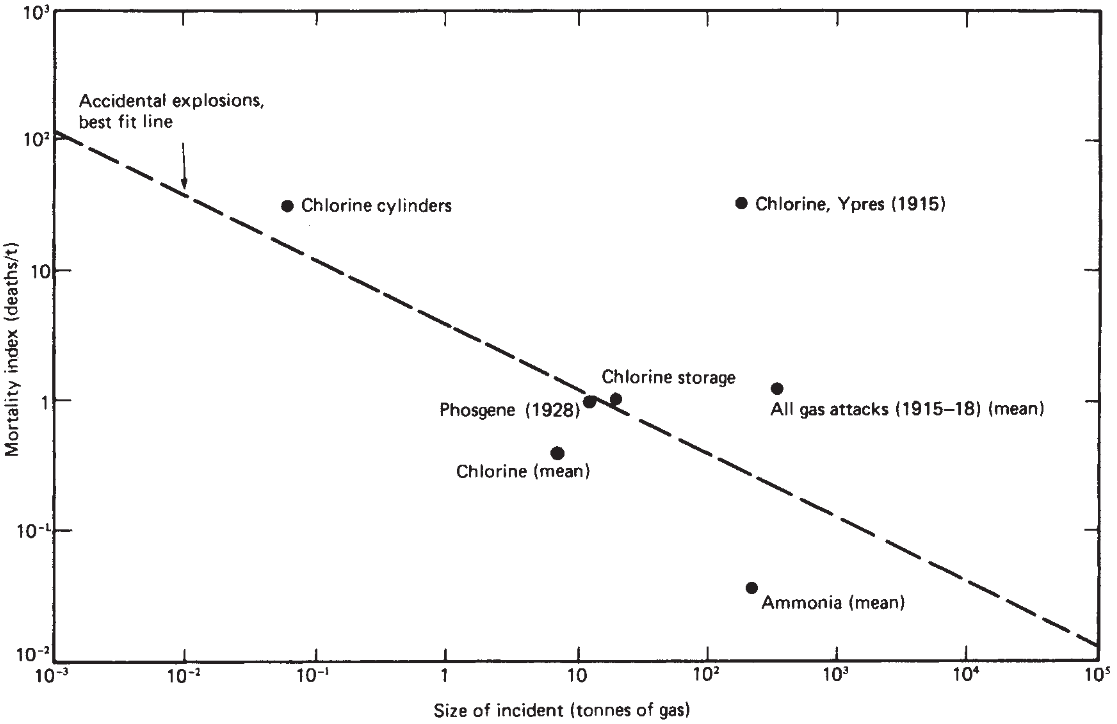

Figure 18.10 *Mortality index for Releases (after V.C. Marshall, 1977b) (Courtesy of the Institution of Chemical Engineers)*

mitigating factors. Subsequent work on the hazard assessment of toxic releases has generally retained the basic approach, but has significantly refined the methodology.

A further stage is the hazard assessment of toxic gases is the work described in the ACDS Transport Hazards Report (1991), which covers chlorine and ammonia and which is described in Chapter 23 and Appendix 17.

Accounts are given in Sections 18.29 and 18.30 of some of the hazard assessments just mentioned and in Section 18.31 of developments in the methodology. These should be taken in conjunction with the accounts in the Canvey Reports, the Rijnmond Report and the ACDS Transport Hazards Report.

18.29 Chlorine Hazard Assessment

18.29.1 Fixed installations

A major study of the assessment and control of the hazard of chlorine release from a large chlorine factory in the United Kingdom has been described by Dicken (1974, 1975), Sellers (1976) and Hewitt (1976). The chlorine factory concerned is shown in outline in Figure 18.11. It includes cellrooms, compression plant, liquefaction plant, gas absorption plant and distribution to user plants. The study falls into three parts: the development of risk criteria, the assessment of the hazards and the recommendations for improvements.

Four categories of hazard were defined. Category 0 involves no nuisance to the public, whereas Categories I-III do involve such a risk. Category I is the least serious and constitutes a nuisance to the public, but no more. Category II is a more severe release that could cause distress to people and damage to vegetation, and could give rise to claims for compensation. Category III is a major emission which, in addition, could result in injury or loss of life. The maximum frequencies suggested for events in Categories I and II were once in 1 and 10 years, respectively. A Category III release was considered acceptable once in 100 years, which was estimated to be roughly equivalent to a risk to the public of 10^{-7}/year per person.

Information on the toxicity of chlorine was studied and the relations between toxicity and exposure shown in Figure 18.12 were produced. The hazard categories were then defined more closely in terms of the toxic effects and the relations shown in Figure 18.13 were derived.

In assessing the effects of toxic substances, consideration needs to be given to members of the public who may be more susceptible than the average adult worker. Some relevant data quoted by Hewitt (1976) in this study were given in Table 9.22.

The historical data on chlorine releases throughout the works were also collected. These are shown in Table 18.32. Using these data as a guide, the works was divided into some 23 units and each unit was allocated a proportion of the target level of risk for the whole works. This allocation is shown in Table 18.33. Three two-man teams were then set up to study the 23 units, using in particular the hazard and operability study method.

With the situations leading to release thus identified, quantitative assessments were made of the frequency, size and effect of such releases. Estimates of frequency were based on reliability calculations and data, those on size on emission calculations, and those on effects on dispersion calculations, and toxicity data. These methods have been described in Chapters 7–9 and 15.

Extensive gas dispersion calculations were carried out using a specially developed computer program. The

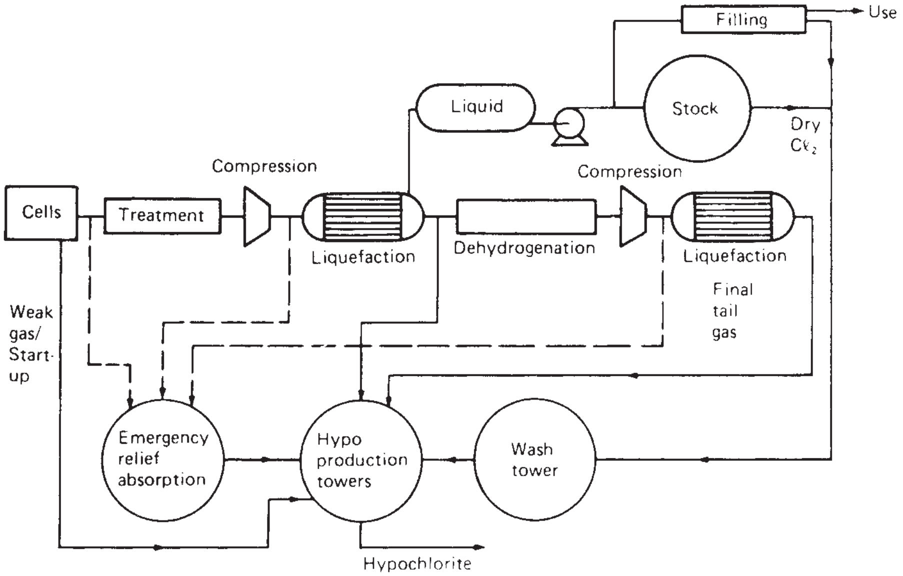

Figure 18.11 *Chlorine production, liquefaction and distribution system (Dicken, 1974) (Courtesy of the Electrochemical Society)*

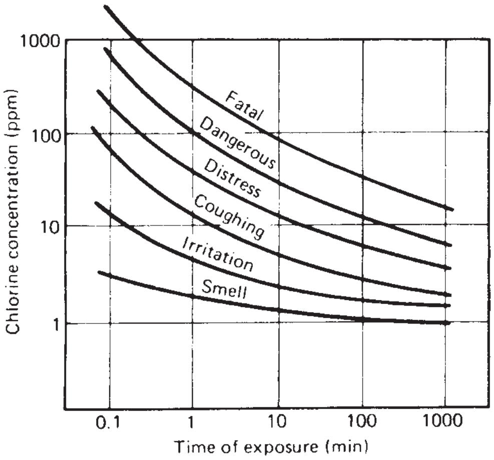

Figure 18.12 *Effects of exposure to different concentrations of chlorine vapour (Dicken, 1974) (Courtesy of the Electrochemical Society)*

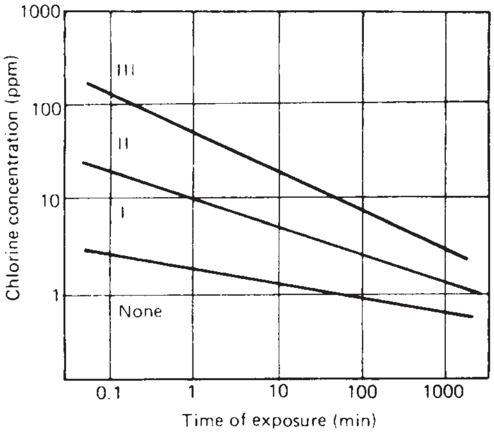

Figure 18.13 *Categories of chlorine release (Dicken, 1974) (Courtesy of the Electrochemical Society)*

dispersion equation quoted is that formulated by Pasquill (1961) and used by Bryant (1964 UKAEA AHSB(RP) R42):

$$C = \frac{168QF}{\theta hdu} \qquad [18.29.1]$$

with

$$F = \exp(-2.303H^2/h^2) \qquad [18.29.2]$$

where C is the ground level concentration on the axis of the plume (m^3/m^3), d is the downwind distance (m), F is the stack correction factor, h is the vertical spread of the plume at distance d (m), H is the effective height of the stack (m), Q is the gas release rate (m^3/s), u is the wind speed (m/s); and θ is the lateral spread of the plume (°). The lateral spread θ and the vertical spread h are both functions of the atmospheric stability. Equation 18.29.1 is discussed in more detail in Chapter 15.

It is also stated that both instantaneous and continuous releases were studied. For a given emission point the investigation covered 18 wind directions, 6 wind speeds and 6 stability categories, making 648 permutations. Other factors taken into account were plume rise from the stack (where applicable), downwash from neighbouring buildings and multipoint sources such as ventilation ducts on the cellroom roof.

For a given emission situation and one permutation of weather conditions the maximum concentration at or outside the works boundary was computed and converted to a hazard of Category 0, I, II or III. From all the permutations the probabilities of hazards in the different categories were determined. Some examples of the results obtained are given in Table 18.34.

The validity of the assessment procedure was checked by comparison with historical data. Normally the ratio of the predicted to the observed frequency of release was in the range 1–2.

The study made recommendations for improvements both of hardware and of software, although not all proved practical. Some £1 m capital was spent, of which about a third was on the emergency absorption plant.

Hardware changes included the installation of additional equipment, such as stand-by power supplies or duplicate pumps, and of extra instrumentation. The availability of the equipment has sometimes been poor. Changes in software covered areas such as operating instructions and inspection and test methods. It is claimed that the work has resulted in a 40% reduction in the number of chlorine

releases recorded in the areas covered and in an increase in plant availability.

Similar investigations have been carried out for other gases such as bromine, hydrogen chloride, hydrogen fluoride and phosgene. Another study in this area is the assessment of the hazard from acrylonitrile storage tanks described by Siccama (1973).

18.29.2 Transport

Howerton (n.d., 1969), in a generic study of the hazards of chlorine handling and transport, gives estimates of the areas affected by different chlorine releases based on calculations of (1) liquid and vapour discharges from containers, (2) flash-off and evaporation from liquid chlorine, and (3) dispersion from instantaneous and continuous point sources at ground level.

He considers both instantaneous and continuous releases and uses the Pasquill–Gifford equations. The equation used for a continuous point source is Equation 15.16.41 that gives the concentration profiles. The values of the dispersion coefficients used are those given by Singer and Smith (1966).

The scenarios considered are an instantaneous release of 25,000 lb and continuous releases of 1, 5 and 10 lb/s of chlorine in a 5 mile/h wind in both moderately stable and moderately unstable conditions. The dangerous chlorine concentration is taken as 35 ppm. Graphs are given showing the lines of constant chlorine concentration, or chlorine isopleths, for these eight cases. For the instantaneous release the cloud is hemispherical in shape and travels with the speed of the wind. The cloud first expands in size and then contracts. But, whereas under stable conditions the cloud is continuing to expand even at a distance of 10 miles, under unstable conditions it starts to contract again after some 1.5 miles, as shown in Figures 18.14(a) and 18.14(b), respectively. In both cases the envelope of the area swept by the cloud is cigar shaped, but for stable conditions Figure 18.14(a) shows only the expanding part of the envelope, while for unstable conditions Figure 18.14(b) shows the envelope terminating within about 2.5 miles. The time of passage of the cloud in stable conditions is quite short, about 5–15 min. For the continuous release of 10 lb/s the isopleth under stable conditions is approximately cigar shaped and reaches about 3 miles as shown in Figure 18.14(c), while under unstable conditions it is ovoidal and reaches only about 1/8 mile as shown in Figure 18.14(d).

The conditions under which the highest gas concentration can occur at large distances are those of an instantaneous release under stable weather conditions at low (but not zero) wind speeds. In this sense, this is the worst scenario. In such a case, however, the cloud travels slowly and the warning time is long.

Simmons, Erdmann and Naft (1974) in another generic study of the hazards of chlorine transport have estimated the area affected by a chlorine release. They consider an instantaneous release and use the Pasquill–Gifford equations. The equation used is Equation 15.16.66a, which gives the dosage profiles. The values of the dispersion coefficient σ_y used are those given by D.B. Turner (1970). They are fitted to the following equation:

$$\sigma_y = kx^n \qquad [18.29.3]$$

with

	Pasquill category
$k = 0.20$	C
$k = 0.13$	D
$k = 0.078$	E, F
$n = 0.91$	

Table 18.33 Allocation of proportion of works chlorine releases between works units (Sellers, 1976) (Courtesy of the Institution of Chemical Engineers)

	Percentage of works acceptable level
Major cellrooms	20
Emergency absorption plant	10
Compression and liquefaction plant	10
Small cellrooms	10
Liquid storage and pipelines	7
Container filling	4
Drum, cylinder and hypochlorite users	1
User plants (6 at 5% each)	30

Table 18.34 Predicted chlorine releases and their consequences (Sellers, 1976) (Courtesy of the American Institute of Chemical Engineers)

Incident	*Frequency* (events/year)	*Release rate* (m^3/h)	*Release duration* (min)	*Severity of event*					
				Percentage in class (%)			*Frequency of class* (events/year)		
				I	*II*	*III*	*I*	*II*	*III*
Cell offtake shut	0.7	70	5	30	2	0	0.21	0.014	0
Cell explosion	1.5	2	5	11	0	0	0.17	0	0
Control fails but relief operates	0.95	60	3	29	0	0	0.28	0	0
Control fails and relief fails	0.011	840	2	16	39	13	0.002	0.004	0.001
Total							0.7	0.02	0.001

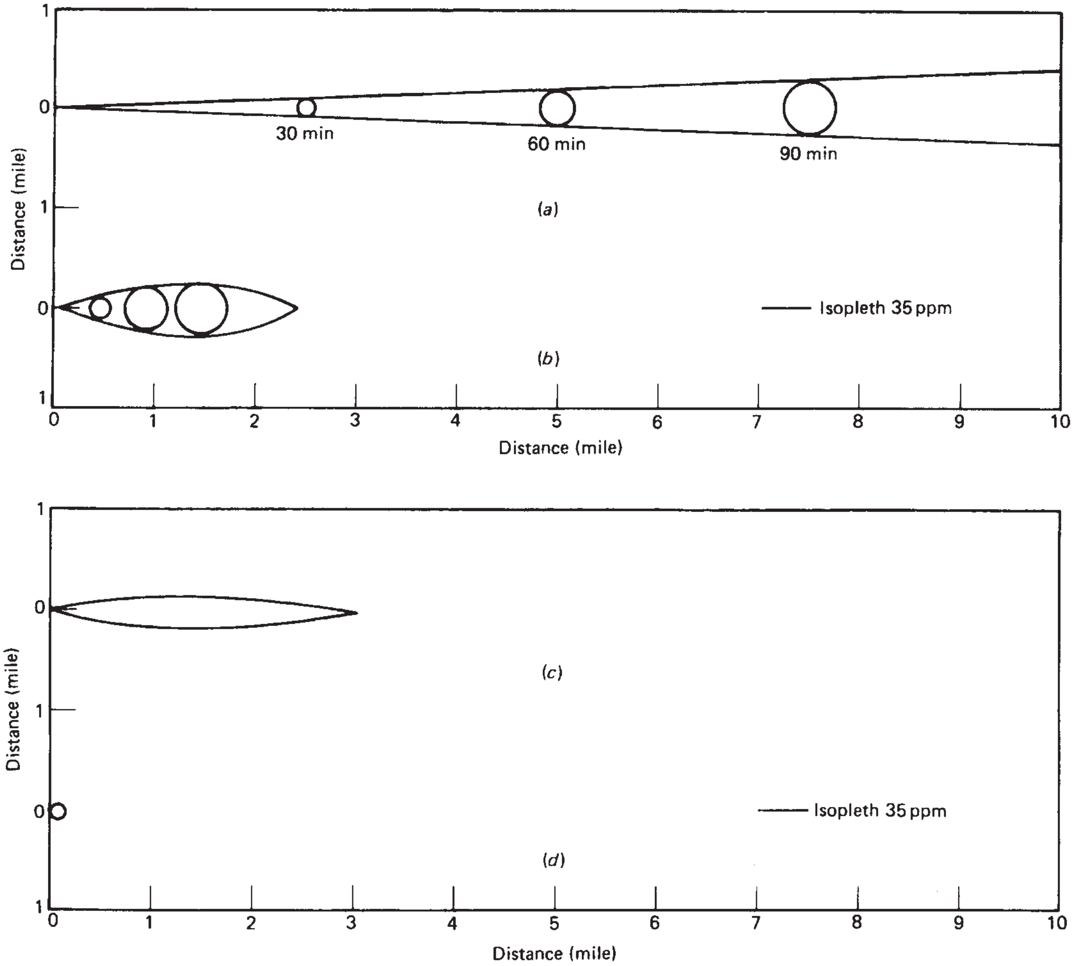

Figure 18.14 Concentration profiles for chlorine release from a point source at ground level (after Howerton, 1969): (a) instantaneous release of 25,000 lb in stable conditions; (b) instantaneous release of 25,000 lb in unstable conditions; (c) continuous release of 10 lb/s in stable conditions; (d) continuous release of 10 lb/s in unstable conditions (Courtesy of American Institute of Chemical Engineers)

where x is the distance in the downwind direction (m), σ_y is the dispersion coefficient in the crosswind direction (m), k is a constant, and n an index. It is assumed that the dispersion coefficient σ_z is

$$\sigma_z = 0.2\sigma_y \qquad [18.29.4]$$

where σ_z is the dispersion coefficient in the vertical direction (m).

The relation between dosage and fatalities is taken to be as follows. For chlorine vapour in air

$$1 \text{ ppm} = 2.9 \text{ mg/m}^3 = 2.9 \times 10^{-6} \text{ kg/m}^3$$

The lethal dosage LCt_{50} is taken as

$$LCt_{50} = 1000 \text{ ppm min} = 0.17 \text{ kg s/m}^3$$

The scenario considered is the initial flash vaporization of 15.7 ton of chlorine from a spillage of 90 ton of chlorine, this being the capacity of a standard chlorine rail tank car. The area of lethal dosage LCt_{50} is a function of wind speed and stability conditions and may be represented by the equation

$$A = k'u^{-n'} \qquad [18.29.5]$$

where A is the area of lethal dosage (km^2), u is the wind speed (m/s), k' is a constant, and n' is an index. For the case considered:

	Pasquill category
$k' = 1.72$	A–C
$k' = 2.83$	D
$k' = 4.92$	E, F
$n = 1.06$	

The areas of lethal dosage for this case are shown in Figure 18.15.

The conditions under which the area of lethal dosage from an instantaneous spillage is greatest are again those of release under stable weather conditions at low wind speeds. In this sense, this is again the worst case.

The authors compare their method of calculating the area of lethal dose with that of Howerton. For the 25,000 lb instantaneous release considered by Howerton the area of 4 km^2 calculated by him is greater by a factor of almost 4 than that obtained by their method. This is attributed to the use of different values of the dispersion coefficient.

The estimate of the area of lethal dosage is then used by Simmons, Erdmann and Naft in conjunction with data on the frequency of particular meteorological conditions and on population densities to calculate the potential fatalities for transport accidents, as described below. These are presented as histogram data for a range of accidents of increasing severity. The most severe accident calculated involved 5000–20,000 deaths with a frequency of 2.6×10^{-4}/year.

Eisenberg, Lynch and Breeding (1975) in the vulnerability model work already described have studied among other things the area affected by, and the lethality of, chlorine and ammonia releases.

They consider any instantaneous release from a marine spillage and use the Pasquill–Gifford equations. The equation used for an instantaneous release is Equation 15.16.40.

For chlorine the scenarios considered are instantaneous releases of 0.9, 15 and 1090 te of chlorine. The latter corresponds to the load of a large barge. The relation between dosage and fatalities is that given in the probit Equation 18.15.2. The populations at risk are defined in terms of the cell model already described.

Some results obtained are given in Table 18.35. These results indicate that the conditions under which the calculated lethality of the release is highest depend on the size of the release. For the small release of 0.9 te the lethality is higher under neutral conditions. With unstable conditions the gas is more rapidly diluted below its lethal concentration. For the large release of 1090 te the lethality is higher under unstable conditions. With unstable conditions the gas is more rapidly dispersed, but remains above its lethal concentration. The authors draw attention to the need to use short time steps in the calculation of $\sum C_i^n T_i$ in Equation 18.15.2 if accurate results are to be obtained.

For ammonia the scenarios considered are instantaneous releases of 8.2, 251 and 16,340 te. The relation between dosage and fatalities is that given by the probit Equation 18.15.3.

Some results obtained are as follows:

Ammonia spillage (t)	*Time of travel* (min)	*Distance travelled* (km)	*Fatalities*
8.2	Any	Any	0
251	10	2.4	921
	30	7.2	8,033
16340	10	2.4	2,177
	30	7.2	18,151

The wind speed was 4 m/s. Toxic injuries were not assessed.

Major assessments of the hazard of chlorine transport have been described by Simmons, Erdmann and Naft (1974) and Westbrook (1974). Simmons, Erdmann and Naft have reviewed the methods used for the transport of chlorine in the United States, the historical experience of accidents involving chlorine and the hazards arising from its transport. They found that chlorine ranked sixth among chemicals in terms of the quantity produced. Some 4.4×10^6 ton of liquid chlorine were transported in 1972 and this amount was expected to rise to about 10×10^6 ton by 1990. Transport of chlorine is important, because accidents to carriers are relatively frequent, population densities along the main transport routes are relatively high, and the substance is very toxic.

The sizes of chlorine containers are basically as follows. Storage is typically in large pressure vessels or refrigerated atmospheric tanks containing 1000 or 2000 ton each.

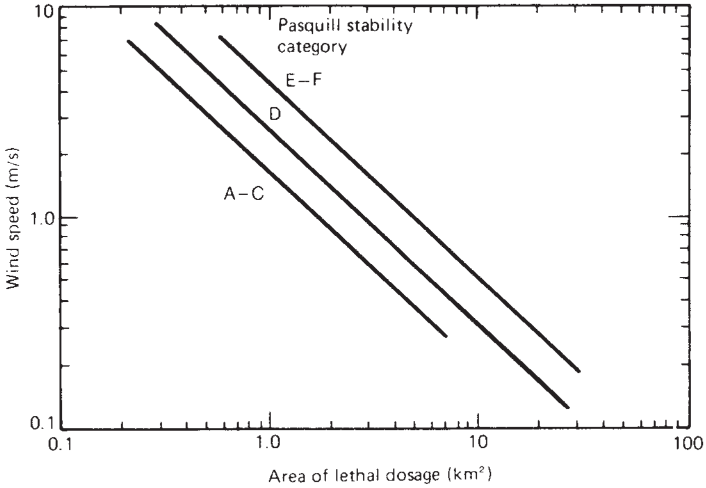

Figure 18.15 *Areas of lethal dose for initial flash vaporization from a 90 ton chlorine spill (Simmons, Erdmann and Naft, 1974) Courtesy of the American Institute of Chemical Engineers)*

Table 18.35 *Effects of marine spillages of chlorine (after Eisenberg, Lynch and Breeding, 1975)*

Chlorine spillage (t)	*Stability condition*	*Wind speed* (m/s)	*Time of travel* (min)	*Distance travelled* (min)	*Distance travelled* (km)	*Fatalities*	*Injuries*
0.9	Neutral		4	10	2.4	277	645
	Unstable	5	8	2.4	0	0	
	Neutral		4	30	7.2	277	5748
	Unstable	5	24	7.2	0	2	
15	Neutral	4	4	10	2.4	921	0
	Unstable	4	10	2.4	921	0	
	Unstable	5	8	2.4	0	921	
	Neutral		4	30	7.2	9,995	865
	Unstable	4	30	7.2	1,020	6,334	
	Unstable	5	24	7.2	340	7,425	
1090	Neutral	4	4	10	2.4	921	0
	Unstable	5	8	2.4	1,823	5,734	
	Neutral		4	30	7.2	13,628	937
	Unstable	5	24	7.2	18,152	4,946	

Barges usually carry four pressure vessels each containing 275 ton, making 1,100 ton total capacity. Rail tank cars are pressure vessels ranging in size from 16 to 90 ton, but only the latter size is now made. Road tankers are also pressure vessels and normally have a capacity of 16 ton. Cylinder sizes are usually 1 ton, 150 lb or smaller.

All containers for chlorine transport are pressure vessels made in steel and equipped with safety devices such as pressure relief valves and excess flow valves, and are regularly inspected and pressure tested. Details of chlorine containers are given in the publications of the Chlorine Institute.

Chlorine is also transported by pipelines. Such pipelines range from 1 to 6 in. in diameter. The longest run quoted is 10,000 ft of a 4 in line.

The authors' tabulation of chlorine accidents has already been given in Table 18.30. Storage of chlorine had not resulted in a single accident in the United States in the 40 years up to 1974. There have been several accidents in small storages in Europe, but it is possible that these have been due to the presence of water and the resultant corrosion; this is avoided in good modern practice.

Barge accidents are few, possibly because the barge structure forms a means of protection for the chlorine tanks, in contrast to the situation on petroleum barges, where the barge shell is also the containing wall.

Rail tank car accidents have been more frequent. One major cause of these, the cracking of the tank at the anchor, which is the attachment of the tank body to the frame, has been largely eliminated by replacing forged anchors with welded ones, but accidents still occur, mainly by derailments and collisions. Department of Transportation (DOT) statistics indicate that there are approximately five rail tank car accidents per year that result in the release of chlorine, but only a small proportion of these involves a multiton release.

Road tanker transport is less significant and gives rise to fewer accidents.

Accidents with containers of 1 ton or less are important. As Figure 18.10 shows, some of the worst accidents have resulted from releases from cylinders and other small containers. This is probably because the releases took place in buildings and other confined spaces. It is considered by the authors that the dominant hazard is transport of chlorine by rail tank car. Some chlorine transport accidents are described in Case Histories A94, B66 and B67.

It was estimated by the Chlorine Institute that the proportions of chlorine distributed by the different modes of transport in the years 1965 and 1966 were: rail, 70% pipeline, 20%; and barge, 7%. Thus, assuming the same division, some 3.1×10^6 ton of chlorine were transported by rail in 1972 and this figure was expected to grow to about 7.2×10^6 ton by 1990. It is clear from these data that rail transport is the dominant mode of distribution.

The problem principally considered by Simmons, Erdmann and Naft, therefore, is incidents involving rail tank cars carrying 90 ton of chlorine. Their treatment consists of the determination of (1) the frequency of accidents involving chlorine spillage and (2) the number of fatalities resulting from spillage.

Statistics kept by the Railroad Administration of the DOT and by the Chlorine Institute showed that there are some 7,000 chlorine rail tank cars in service, that each tank car makes an average six trips a year and that the average length of journey is 250 miles. Since 1930 there have been seven accidents in which most or all of the contents of a tank car have been lost, although three of these were due to the failure of a forged tank anchor, a cause presumably now eliminated. On the other hand, the amount of traffic is increasing. On balance, therefore, the best estimate of accident frequency from these data is once in 10 years.

Other data are available on accidents to the same type of rail tank car as is used for chlorine in the transport of liquid ammonia and LPG. In a study covering 1966–70 the Association of American Railroads (AAR) found that for this type of rail tank car and for all cargoes, including chlorine, the accident rate was 2.3×10^{-5} per trip. Applied to the approximately 40,000 trips (7,000 tank cars × 6 trips/year) made by chlorine tank cars these data would give an accident rate of once per year. The order of magnitude difference between this and the previous figure remains an unresolved discrepancy, but the authors suggest that it may be due to the way in which chlorine shipments are handled. They tentatively adopt the lower figure of 0.1 accidents per year.

The determination of the area of lethal dosage for spillage from a 90 ton tank car with flash vaporization of 17.5% of the tank contents, or 15.7 ton, was described above. This calculation is then combined by Simmons, Erdmann and

Naft with the above estimate of frequency and with data on the frequency of meteorological conditions to obtain estimates of potential casualties.

The population density assumption made is that a large spill is equally likely anywhere along the rail shipping route. This assumption is not conservative, since data for all rail accidents indicate a somewhat higher frequency in urban areas, the higher speeds in rural areas presumably being more than balanced by the higher density of traffic and switching activities in towns.

Estimates of potential fatalities were made for some 13 different weather conditions and 9 population densities, making 117 permutations in all. Accidents were then divided into 7 size ranges and a histogram was constructed. There were some 75 accidents involving 50 or more potential fatalities and the average number of fatalities was 13 per year. The histogram data are approximately as shown in Table 18.36.

From these histogram data the authors derive for the number N of fatalities the density function $f(N)$

$$f(N) = 0.15N^{-1.61} \qquad [18.29.6]$$

Simmons, Erdmann and Naft quote unpublished work by G.D. Bell (n.d.) on toxic releases that likewise gives an exponent of −1.6 for Equation 18.29.4, although in this latter case there were insufficient data to determine a realistic value of the constant factor.

The fatalities calculated in this work are described as 'potential', because no allowance is made for the effectiveness of any post-accident action to limit the effects. In fact, public warning and evacuation would probably greatly reduce the number of deaths.

It should be noted in particular that the conditions that give the highest number of fatalities are those in which the wind speed is low and the time available for evasive action is relatively long. In such cases, therefore, it is more probable that evacuation will be effective and that the ratio of actual to potential deaths will be relatively low.

For the 40-year period covered by the data given in Table 18.30, 204 people were gassed and one killed (excluding the small release in the Philadelphia incident) in railroad chlorine accidents. This compares with a value from the histogram data and equation 18.29.4 of 570 persons expected to be killed. The comparison indicates, on the one hand, support for Equation 18.29.6, in that the figures for people affected agree quite well, and on the other the effectiveness of evacuation, in that people fled and were gassed, but were not killed.

Table 18.36 *Accident scale–frequency relationship for chlorine rail transport accidents (after Simmons, Erdmann and Naft, 1974)*

Accident size (Potential deaths)	*Frequency* (events/year)
50–100	1.4×10^{-2}
100–250	1.0×10^{-2}
250–500	4.0×10^{-3}
500–1000	1.5×10^{-3}
1,000–2,500	1.2×10^{-3}
2,500–5,000	7.2×10^{-4}
5,000–20,000	2.6×10^{-4}

It is emphasized by the authors, however, that estimates of this kind involve many unknown factors, particularly in respect of accident frequency, and that the associated uncertainty is estimated to be a factor of 10.

The method described uses a mixture of historical data for accident frequency and estimation of the scale and frequency of the results of the accident.

As the authors point out, in some cases the historical data may be too sparse or non-existent, and then the accident frequency must also be estimated.

Simmons, Erdmann and Naft compare the risk to the whole US population from chlorine railroad accidents of 13 potential fatalities per year with other risks to which the public are exposed. These include estimated risks in the range of 10–100 fatalities per year from the failure of dams and in the same range for aircraft crashes (persons on the ground only).

Westbrook (1974) has made a comparative study of the relative hazards of the transport of chlorine by rail, road and pipeline by the principal UK producer, ICI.

Much of the work was concerned with the determination of accident data. Here difficulties were experienced because data tend to be reported in forms that are not readily convertible, for example ton-miles, vehicle-miles, train-miles. The approach adopted, therefore was to consider the transport of the entire amount shipped (200,000 ton/ year) by each mode in turn.

The investigations involved the determination of (1) the frequency of significant accidents, (2) the probability that a significant accident results in a spillage and (3) the number of fatalities resulting from a spillage.

The frequency of accidents was determined from accident records. The accidents referred to are 'significant' accidents. For rail, such an accident is the one that is judged to be potentially most dangerous, and includes all derailments and most collisions. Such accidents represent 32% of all reported train accidents. For road, a significant accident is one that results in injury or death and is what the police call a 'reportable' accident.

The relevant accident data for rail for 1971 were:

Capacity of rail tank car = 28 ton
Number of rail tank cars in chlorine train = 4
Number of rail journeys = 200,000/(4 × 28) = 1786
Distance travelled per train journey = 160 mile
Total distance travelled as train journeys = 1786 × 160 = 286,000 train-mile/year
Accident frequency for goods trains = 3.79×10^{-6} accidents/train-mile
Accident frequency for chlorine trains = $286{,}000 \times 3.79 \times 10^{-6} = 1.08$ accidents/year

The data for road were:

Capacity of road tanker = 19 ton
Number of vehicle journeys = 200,000/19 = 10,526
Distance travelled per journey = 160 mile
Total distance travelled = $10{,}526 \times 160 = 1.684 \times 10^6$ vehicle-mile/year
Accident frequency for goods vehicles = 2.03×10^{-6} accidents/vehicle-mile
Accident frequency for chlorine vehicles = $1.684 \times 10^6 \times 2.03\times10^{-6} = 3.42$ accidents/year

The above data refer to all journeys, but on average half the journeys made are with empty tanks. Thus the numbers of significant accidents by the two modes of transport become:

Accident frequency for rail transport (loaded)
= 0.54 accidents/year
Accident frequency for road transport (loaded)
= 1.71 accidents/year

The probability that a significant accident results in a spillage was estimated from consideration of mechanical strength of the tank and of the force of impact. It was thought initially that at normal road tanker speeds of about 30 mile/h there might not be sufficient energy to puncture the pressure vessel. It was shown, however, by tests and calculations, that puncture can occur under expected accident conditions and that all road tanker accidents should be assumed to be potential spillage accidents.

The probability of puncture is a function of kinetic energy. It was found, however, that the average speeds of chlorine rail tank cars and road tankers are almost equal. Thus it was possible to consider damage levels in terms of mass only.

A rail tank car in a train is subject to wagon-to-wagon collisions. A relation was derived for the damage to a wagon in a train involved in a front-end collision with an immovable object. It is assumed that the damage is proportional to the mass of the wagon involved and that it is shared equally between the wagons. Then for the first wagon behind the engine the damage D is proportional to its own mass W for the first collision, which is with the engine, to $\frac{1}{2}W$ for the second collision, which is between the first and second wagons, to $\frac{1}{3}W$ for the third collision, which is between the first three wagons, and so on. Thus:

$$D_1 = W\left(1 + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \cdots\right) \qquad [18.29.7a]$$

where D_i is the damage to wagon i (mass units) and W is the mass of a single wagon (mass units). For the second wagon

$$D_2 = W\left(\frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \cdots\right) \qquad [18.29.7b]$$

And for the nth wagon in a train of N wagons

$$D_n = \left(\frac{1}{n} + \frac{1}{n+1} + \frac{1}{n+2} + \frac{1}{n+3} = \cdots + \frac{1}{N}\right) \qquad [18.29.7c]$$

A group of m adjacent chlorine rail tank cars can occupy $N-m+1$ positions in the train. Then, assuming $W = 1$, the average damage per train D_{tn} is

$$D_{\mathrm{tn}} = \frac{1}{N-m+1} \sum_{n=1}^{N-m+1} (D_n + D_{n+1} + D_{n+2} + D_{n+3}) \qquad [18.29.8]$$

and the average damage per rail tank car D_{rc} is

$$D_{\mathrm{rc}} = \frac{D_{\mathrm{tn}}}{m} \qquad [18.29.9]$$

The probability that the rail tank car will be punctured is proportional to the average damage.

If the train has 25 wagons ($N = 25$) and if there are four chlorine rail tank cars ($m = 4$)

$D_1 = 3.82$ mass units
$D_2 = 2.82$ mass units
$D_3 = 2.32$ mass units
$D_{25} = 0.04$ mass units

and

$D_{\mathrm{tn}} = 3.645$ mass units
$D_{\mathrm{rc}} = 0.911$ mass units

A chlorine road tanker and a rail tank car have a mass of 30 and 40 ton, respectively. Thus on the assumption that the probability of puncture is proportional to the mass, the ratio r of the probability of puncture for a rail tank car to that for a road tanker is as follows:

$$\text{First position behind engine } r = \frac{3.82}{30} \times 40 = 5.1$$

$$\begin{aligned} \text{Average position in train } r &= \frac{0.911}{30} \times 40 \\ &= 1.22 \text{ for one tank car} \\ &= 4 \times 1.22 \\ &= 4.86 \text{ for train} \end{aligned}$$

The analysis is relevant to the positioning of chlorine rail tank cars in the train in that it indicates that for a front-end collision the least desirable position is immediately behind the engine.

Collisions other than front-end collisions are also considered by Westbrook. A head-on collision of two trains is considered no worse since, although more energy is involved, it is distributed among more wagons. On the same argument, a back-end collision of two trains is less serious, since the energy involved is no greater than a front-end collision, but it is distributed among more wagons.

An absolute estimate of the probability of a spillage given a significant accident was made from the North American data for rail furnished by the Chlorine Institute and shown in Table 18.37. Over the period 1960–72 there were 67 accidents to chlorine trains, of which six resulted in spillage of chlorine. The probability of chlorine spillage in a significant rail accident in North America was therefore taken as 6/67 = 0.09.

This use of North American data was necessary, because equivalent data for the United Kingdom were lacking. American conditions differ, however, in a number of respects:

	UK	*North America*
Rail tank car mass	40 ton	87 ton
Average No. of goods Wagons	25	100
Average No. of chlorine Rail tank cars	4	2
Average speed	15 mile/h	23 mile/h

The American pressure vessel is 0.753 in thick compared with the British 0.526 and requires 26% more energy to pierce it.

Table 18.37 Accidents in bulk carriage of chlorine in the USA and Canada (Westbrook, 1974) (Courtesy of Elsevier Publishing Company)

	Significant leakage – no accident	*Accident*	*Accident, leakage*	*Accident, fire*	*Accident, leakage, fire*	*Accident, leakage, death*
1961		3				1
1962	1	1			1	
1963		1			1	
1964		4	1			
1965		8				
1966		1	1	1		
1967		7		1		
1968		7				
1969		6				
1970		8		1		
1971	1	8		1		
1972		4	1			
Total	2	58	3	4	2	1

Since under American conditions there are two rail tank cars in a 100-wagon train

$$D_{\mathrm{tn}} = 1.967 \text{ mass units}$$

But the mass units in this case are greater than those for the British case by the following factor, which takes into account the different kinetic energy:

$$\frac{87}{40} \times \left(\frac{23}{15}\right)^2 \times \frac{1}{1.26} = 4.05$$

Then the probability of chlorine spillage in a significant rail accident in the United Kingdom is estimated as

$$\begin{aligned}&\text{Probability of chlorine spillage for rail transport}\\&\quad = 0.09 \times \frac{3.645}{1.967} \times \frac{1}{4.05} = 0.041 \text{ occasions/accident}\\&\text{Frequency of chlorine spillage for rail transport}\\&\quad = 0.041 \times 0.54 = 0.022 \text{ spillages/year}\end{aligned}$$

and the probability of chlorine spillage in a significant road accident in the United Kingdom is

$$\begin{aligned}&\text{Probability of chlorine spillage for road transport}\\&\quad = 0.041/4.86 = 0.0084 \text{ occasions/accident}\\&\text{Frequency of chlorine spillage for road transport}\\&\quad = 0.0084 \times 1.71 = 0.0144 \text{ spillages/year}\end{aligned}$$

The number of fatalities resulting from a spillage depends on the following factors listed by Westbrook: (1) warning time; (2) emission from the tank; (3) dispersion over the downwind area; (4) population density in the area affected; (5) chance of escape.

The time elapsing before warning is given was estimated as 24 min for rail and for road. A random sample of 17 accident reports from the files of British Rail headquarters at Marylebone indicated that it took, on average, 12 min for the first public aid vehicle (police, fire or ambulance) to arrive at the scene of a rail crash. It was considered that this delay was no longer than might be expected for a road accident. The figure of 12 min was then doubled to allow for the communication of an effective warning to the public.

For emission it was assumed that the initial temperature in the tank was 38°C, that the puncture holes in the vapour space were 19 in. and those in the liquid space were 7 in., and that the latter hole was at a level that allowed only one-third of the tank contents to remain in the tank. Under these conditions it was estimated that some two-thirds of the chlorine liquid would flash off or form spray and vaporize within the first 4 min and that the remaining liquid would boil off over a period of about 2 h.

The situation for dispersion is intermediate between an instantaneous and a continuous release. At a given point downwind there is a distance/velocity lag before the cloud arrives, then the concentration rises rapidly to a maximum as the instantaneous release cloud passes and then falls to a steady value as the continuous release plume becomes established. Dispersion calculations were done using the Pasquill method assuming a 5 mile/h wind speed and a dangerous chlorine concentration of 20 ppm. On the assumption that 24 min would elapse before effective warning would be given, the chlorine cloud would have drifted 2 miles. Then the areas in which a dangerous chlorine concentration would exist were estimated to be:

$$\begin{aligned}&\text{Area of dangerous chlorine concentration for rail spillage}\\&\quad = 0.076 \text{ mile}^2\\&\text{Area of dangerous chlorine concentration for road spillage}\\&\quad = 0.052 \text{ mile}^2\end{aligned}$$

Estimates of population density were made on the rail and road routes to one of the principal customers for chlorine. Estimates of the number of people within, on average 100 ft, of an accident were made by travelling the road route by car and the rail route by brake van. The numbers obtained were three and five persons on the rail and road routes, respectively. But, since road accidents tend to give rise to congestion, the figure for the road case was increased to 20. Other coarser scale surveys of the routes were made using maps, but in this case there was little difference in population density, and the average value of 700 persons/mile^2 applicable to Great Britain was taken.

Then, applying this population density to the areas at risk from spillage and including those people within 100 ft:

Number of people at risk from rail spillage

$$= 0.076 \times 700 + 3 = 56$$

Number of people at risk from road spillage

$$= 0.052 \times 700 + 20 = 56$$

The chances of escape were estimated as follows. The Chlorine Institute data given in Table 18.37 indicate that there were eight substantial chlorine spillages in North America in the period 1960–72. If on each occasion two-third of the tank contents had been released, then calculations show that the area affected within a 24-minute period would have been 0.133 mile^2. With an average population density of 60 persons/mile^2 the number of people at risk from the eight incidents would have been

$$8 \times 0.133 \times 60 = 64$$

But in fact in these incidents 156 people received medical treatment and one person died. These figures suggest that the population density at the scene of the accidents may have been higher than average and that the assumed warning period of 24 min may be too low. Press reports of the incidents suggest that a high proportion of those at risk received medical attention.

Applying a ratio of 1 death in 156 to the number of people at risk from either a rail or a road spillage gives:

Frequency of fatalities from rail or road spillage

$$= 1 \times \frac{56}{156} = 0.359 \text{ deaths/spillage}$$

Then:

Frequency of fatality from rail transport

$$= 0.022 \times 0.359 = 0.0079 \text{ deaths/year}$$

Frequency of fatality from road transport

$$= 0.0144 \times 0.359 = 0.0052 \text{ deaths/year}$$

Westbrook also discusses the sensitivity of the calculations to changes in the assumptions. He considers three such changes:

A Rail and road tankers both suffer one significant accident per year more than the national average.

B Damage estimate in rail crashes is pessimistic and is reduced by factor of 2.

C Estimate of number of people at risk in road accidents is optimistic and is increased by 50.

The frequency of fatalities then becomes

Case	*Frequency of fatalities*	
	(rail deaths/year)	(road deaths/year)
A	0.023	0.0082
B	0.0039	0.0052
C	0.0079	0.0098

These calculations suggest that neither rail nor road has a marked advantage over the other from the point of view of safety in the transport of chlorine.

The study also considered the distribution of chlorine by pipeline and by vehicles with refrigerated atmospheric tanks. For the pipeline the case considered was a line of 4 in. diameter and 20 mile long carrying 25 ton/h of chlorine at 15°C for 2,000 h/year. From a study of pipeline records in the United Kingdom and the United States, it was concluded that a pipeline of this length might sustain damage once in 10 years and that on one occasion in 10 there would be a massive release of chlorine. The fracture was assumed to occur between excess flow valves 2 miles apart, 1.5 miles from one valve and 0.5 mile from the other, allowing emission of chlorine from both ends. It was further assumed that the excess flow valves would take 30 s to close. The calculations involved the difficult problem of emission under two-phase flow conditions. The results obtained were

Initial flow rate of chlorine = 60.3 ton/h per 4 in. orifice = 120.6 ton/h total
Total quantity of chlorine emitted in 24 min = 28.4 ton
Size of cloud of dangerous concentration = 0.101 mile^2
Number of people at risk = 74
Frequency of fatalities from pipeline break = 0.48 deaths/break

$$= \frac{0.48}{10 \times 10}$$

$$= 0.0048 \text{ deaths/year}$$

The pipeline conveys 50,000 ton/y of chlorine over 20 miles. Comparison with rail or road transport requires that they be put on the same basis. If this is done, the frequency of fatalities is 0.0005 and 0.00032 deaths/year for rail and road transport, respectively. Therefore rail and road transport appear to be an order of magnitude safer than a pipeline.

It may be noted, however, that the assumption made by Westbrook on the frequency of damage to a chlorine pipeline is perhaps pessimistic. Information on pipeline failure rates is given in Chapter 23.

The transport of chlorine using refrigerated vehicles has not been studied so thoroughly at the time of writing. Preliminary work suggests that low temperature transport would be safer, perhaps by a factor of about 4, but it would not affect the choice between rail and road.

This work of Westbrook illustrates an approach to the assessment of the hazards of transport of toxic substances. Many assumptions and uncertainties are involved and the results are both approximate and tentative. It should be emphasized that the study is concerned with a comparative assessment of the different modes of transport, particularly rail and road. Such comparative assessment is difficult and demands accurate estimates if the results are to be meaningful in discriminating between transport modes.

18.30 Other Chemicals Hazard Assessment

Solomon, Rubin and Okrent (1976), from a study on the hazards of the storage of chemicals, give estimates of the areas affected by and the lethality of releases of chlorine, acrylonitrile, hydrogen cyanide and parathion. Parathion has the formula $(C_2H_5O)_2PSOC_6H_4NO_2$ and is much heavier than air.

They consider both instantaneous and continuous releases and use the Pasquill–Gifford equations. The equations used are, for instantaneous and continuous releases, Equations 15.16.40and 15.16.41, respectively, and for dosage, Equation 15.16.66a. The values of the dispersion coefficents used are those given by Equations 18.29.3 and 18.29.4.

The relations assumed between dosage and fatalities or injuries for the chemicals studied are given in Table 18.38. The lethal dosages used are as follows:

Chlorine	40-60 ppm for 30--60 min
Acrylonitrile	200-400 ppm for 30 min
Hydrogen cyanide	100 ppm for 1 min
Parathion	30 mg (dermal)

The authors refer to these as LD_{50} lethal doses, but in terms of the terminology used here the first three are strictly LCt_{50} lethal dosages.

The base scenario considered for all the chemicals is a release rate of 100 kg/s with 20% flash-off for 30 min exposure in an area of a population density of 1000 persons/km^2 under stability conditions Pasquill category A and at a wind speed of less than 2.5 m/s. For parathion it is assumed that there is no deposition from the air to the ground.

Cases without and with evacuation are considered. With evacuation the evacuation half-time was 30 min. Some results obtained are shown in Table 18.39. Of the 12,000 deaths calculated for chlorine, about 3000 occur as a result of the initial flash-off and the remainder as the result of the subsequent steady flow.

Table 18.38 *Assumed relationship between dosage and fatality for toxic releases (after Solomon, Rubin and Okrent, 1976)*

Lethal dosage (%)	*Assumed mortality* (%)	*Assumed decrease in life expectancy* (years)
<1	0	0
1–10	5	0.08
10–25	10	0.25
25–50	20	1
50–100	40	1
100–200	65	10
>200	95	20

Table 18.39 *Effects of releases of some toxic chemicals without and with evacuation (after Solomon, Rubin and Okrent, 1976)*

Chemical release	*Evacuation*	*Fatalities*
Chlorine	No	12,000
	Yes	9,800
Acrylonitrile	No	5,500
Acrylonitrile	No	5,500
	Yes	4,600
Hydrogen cyanide	No	49,000
	Yes	39,000
Parathion	No	9,600
	Yes	6,600

Assuming a tank rupture rate of 1×10^{-6}/tank-year and the probability of the assumed meteorological conditions as 5×10^{-2}, the frequency of the maximal chlorine accident considered is estimated by the authors as 5×10^{8}/year for such a storage tank in such an area.

18.31 Hazard Assessment Methodology

Developments in the methodology for the hazard assessment of toxic releases have occurred in a number of areas, including the following: (1) source term, (2) heavy gas dispersion, (3) concentration fluctuations, (4) mitigation by barriers and sprays, (5) mitigation by shelter and evacuation, (6) toxicity relations, (7) degree of injury, (8) specific gases, (9) population exposure, (10) plant layout, (11) warehouse fires and (12) computer aids.

18.31.1 Source term

One area in which the hazard assessment of toxic releases has become much more realistic is in the handling of the source term. Much early work was based on the outright failure of a pressure vessel and, often, the ejection of its entire contents.

It is recognized that the total failure of a pressure vessel is very rare. Better estimates are available of lesser failures such of those of pipework. Allowance is made for emergency action such as the closure of emergency isolation valves.

As described in Chapter 15, methods have been developed to guide the choice between continuous and quasi-instantaneous release models, and thus reduce the proportion of cases where the more pessimistic quasi-instantaneous case is assumed.

Progress has been made in the modelling of the release of pressurized or refrigerated fluids. Models are available for the behaviour of the inventory on rupture of a pressure vessel and for two-phase flow from leaks on pipework. The models for evaporation from the pool formed following emission of a liquid are also much improved.

18.31.2 Gas dispersion

In most cases, the vapours of the principal toxic liquids exhibit heavy gas behaviour and great strides have been made in heavy gas dispersion modelling. The methods now available, which include models for manual use such as the Workbook models, computer codes such as HEGADAS and the three-dimensional models as well as physical modelling using wind tunnels, provide a set of tools capable of handling not only dispersion over flat, unobstructed terrain, but also the effects of slopes, buildings, barriers and water sprays. The concentration estimates yielded by these heavy gas models tend to be quite different from those of passive gas dispersion models.

18.31.3 Concentration fluctuations

It has long been appreciated that there are considerable fluctuations in the concentrations at a fixed point in a gas cloud. Methods are now available which allow estimates to be made of these concentration fluctuations. It is also appreciated that these fluctuations must have some influence on the effective toxic load, as pointed out by R.F. Griffiths and Harper (1985). Methods of treating this aspect are given by D.J. Wilson and Sims (1985), D.J. Wilson (1991a) and J.K.W. Davies (1987, 1989a).

18.31.4 Mitigation: terrain, barriers and sprays

As just stated, the heavy gas dispersion models available can now treat situations where mitigatory features exist. Since the typical release occurs in a works, the gas dispersion will be strongly affected by the presence of buildings, which tend to enhance the dispersion. An illustration of a hazard assessment of a toxic release in the presence of buildings is given by Deaves (1987b).

Further mitigation can be obtained by the use of barriers and sprays, and models are available to allow these to be taken into account in the assessment (e.g. Meroney, 1991).

18.31.5 Mitigation: shelter and evacuation

Another major form of mitigation occurs where the exposed population remains indoors and thus benefits from shelter. Methods have been developed to estimate the indoor concentration–time profile, and hence toxic load, given the profile of the outdoor concentration. The development of models for the effect of shelter is illustrated by the work of P.C. Davies and Purdy (1986) and D.J. Wilson (1987, 1990, 1991b).

18.31.6 Toxicity relations

The form of injury relation generally used in the hazard assessment of toxic releases has been the probit equation. An account has been given above of the development of probit equations for this purpose.

The use of probit equations involves a number of problems. In large part these reflect the basic difficulty of determining the human response to a toxic load. One problem is that a probit equation is available only for a relatively small proportion of toxic gases. Even where a probit equation exists, it may be subject to considerable uncertainty. The accuracy of the relation can be expected to be highest close to the LC_{50}, but relatively low when extended to an LC_{05} or LC_{01} level. Yet in many cases the number of persons exposed to these lower loads is much higher than that for those exposed to the higher load; where there is a cordon sanitaire around the site, as there usually is to some degree, the difference is increased.

There has been some exploration of alternatives to probit equations. The use of the IDLH value as an alternative to the probit equation in hazard assessment has been explored by MacFarlane and Ewing (1990).

Particularly where the purpose of the hazard assessment is to identify the contour for a particular level of toxic effect, as in land use planning, use may be made not of a probit equation but of some fixed toxic load, such as the HSE SLOT value.

18.31.7 Degree of injury

Whereas the effect commonly estimated in hazard assessments of toxic releases has tended in the past to be the number of fatalities, there is some trend to estimate lesser degrees of injury. Thus the HSE SLOT value is a toxic load that is estimated not to be fatal to the vast majority of persons exposed. However, this type of criterion tends to be used not to determine the total number of persons exposed to the toxic load but the location of the contour around the site where the load will occur.

18.31.8 Specific gases

There have also been significant advances in the characterization of the toxicity of a number of common industrial gases, as described in Sections 18.15–18.21. In particular, reference may be made to the CPD Green Book probit equations, the HSE SLOT values and the toxicity estimates and probit equations of the MHAP.

18.31.9 Population exposure

Another area that has become more sophisticated is the characterization of the exposed population. As described in Chapter 9, there now exist what are, in effect, population exposure models, such as those given by Petts, Withers and Lees (1987) and in the *Green Book* (CPD, 1992b).

18.31.10 Plant layout

Increasingly, the effect of flammable and toxic releases is taken into account in plant layout, although the extent to which this is practical is greater for flammable and explosive materials than for toxic ones. An account of the work of Mecklenburgh (1985) on the use of hazard assessment in plant layout is given in Chapter 10.

18.31.11 Warehouse fires

Another type of toxic hazard is that arising from warehouse fires. Most work on the quantitative treatment of this hazard is relatively recent. It includes the work of D.A. Carter (1989), G.T. Atkinson, Jagger and Kirk (1992) and G.T. Atkinson and Jagger (1994).

18.31.12 Computer aids

The computation either of the consequences of a toxic release or of the risk to the population around an industrial site or along a transport route is a natural application for computer codes, and a considerable number of codes are available. Accounts of certain codes such as WHAZAN, SAFETI and RISKAT are given in Chapters 9 and 29.

18.32 Notation

C	concentration
k_1, k_2	constants
LC_i	concentration lethal at i% level
LCt_i	concentration–time product lethal at i% level
LD_i	dose lethal at i% level
LL_i	toxic load lethal at i% level
T	exposure time interval
Y	probit

Section 18.3

c	concentration
d	dose
D	dose rate
D_o	dose
k_e	elimination constant
L	toxic load
m	index
t	time
$t_{1/2}$	half-life
V	apparent volume of distribution of chemical in body
X	mass of chemical in body

Section 18.6

C_i	time-weighted average concentration of *i*th component
L	overall occupational exposure limit
L_i	occupational exposure limit of *i*th component

Section 18.11

c	concentration
C	concentration (ppm)
D	dosage
k	constant
L	toxic load
L^*	toxic load (alternative formulation)
m, n	indices
t	time
T	time interval (min)

Section 18.13

C_{O2}	concentration of oxygen in liquid phase (mol O_2/ml fluid)
D_L	pulmonary diffusion capacity (ml/min (mmHg))
D_{LCO}	pulmonary diffusion capacity for carbon monoxide (ml/min (mmHg))
D_{LCO2}	pulmonary diffusion capacity for carbon dioxide (ml/min (mmHg))
D_{LO2}	pulmonary diffusion capacity for oxygen (ml/min (mmHg))
ERV	expiratory reserve volume (ml)
f	respiration rate (breaths/min)
F_{AO2}	concentration of oxygen in alveolar space (ml O_2/ml air)
F_{EN2}	concentration of nitrogen in exhaled air (ml N_2/ml air)
F_{EO2}	concentration of oxygen in exhaled air (ml O_2/ml air)
F_{IN2}	concentration of nitrogen in inhaled air (ml N_2/ml air)
F_{IO2}	concentration of oxygen in inhaled air (ml O_2/ml air)
FRV	functional reserve volume (ml)
H_{O2}	Henry's law constant for oxygen (ml O_2/ml fluid (mmHg O_2))
IC	inspiratory capacity (ml)
IRV	inspiratory reserve volume (ml)
P_{AO2}	partial pressure of oxygen in alveolar space (mmHg)
$P_{AO2'}$	equilibrium partial pressure of oxygen in alveolar space and above pulmonary capillaries (mmHg)
$P_{O2'}$	equilibrium partial pressure of oxygen (mmHg)
$P_{O2a'}$	equilibrium partial pressure of oxygen above arterial blood (mmHg)
$P_{O2v'}$	equilibrium partial pressure of oxygen above venous blood (mmHg)
RV	residual volume (ml)
TLC	total lung capacity (ml)
TV	tidal volume (ml)
V_A	alveolar space (ml)
$\dot{V}_A$	alveolar minute volume, alveolar ventilation (ml/min)
V_D	anatomical dead space (ml)
V_E	volume exhaled (ml)
$\dot{V}_E$	exhaled minute volume (ml/min)
$\dot{V}_I$	inhaled minute volume (ml/min)
$\dot{V}_{o2}$	rate of absorption of oxygen, oxygen consumption minute volume (ml/min)
V_T	tidal volume (ml)
$\dot{V}_T$	minute volume (ml/min)
V_C	vital capacity (ml)

Plant Commissioning and Inspection

Contents

19.1 Plant Commissioning

The commissioning, or initial start-up, is a period when the plant is particularly at risk. It is also a time when equipment may be maltreated or damaged so that its subsequent operation is affected. Moreover, delays in bringing the plant up to full output can have a marked effect on the economics of the plant. For all these reasons it is essential to organize the commissioning of the plant efficiently and to allocate sufficient resources to it.

An account of plant commissioning is given in *Process Plant Commissioning* (Horsley and Parkinson, 1990), *Process Plant Design and Operation* (D. Scott and Crawley, 1992) and by Troyan (1960), Finlayson and Cans (1967), Kingsley, Kneale and Schwartz (1968–69), Gans and Benge (1974), Unwin, Robins and Page (1974), Fulks (1982), Gans, Kiorpes and Fitzgerald (1983), Fraylink (1984), Ruziska *et al.* (1985) and Smet (1986).

In the following sections an account is given of plant commissioning and of some of its problems and hazards. It should be said at the outset, however, that in many cases these have been very successfully overcome by good organization and engineering so that, for example, large ethylene plants have been brought up to full output within about 3 days (Chementator, 1977 6 June, 67; 24 October, 73). Selected references on plant commissioning are given in Table 19.1.

Extensive use is made during plant commissioning of checklists. It is common for a writer on the topic to include one or two such checklists. A rather comprehensive set is given by Horsley and Parkinson, both in the text and the appendices, as indicated in Table 19.2.

19.1.1 Contract

The responsibility for the construction and commissioning of the plant is normally shared between the user company and its contractors, but the division of responsibility may vary considerably. The different types of contract are discussed by Horsley and Parkinson. The project may be predominantly in-house, utilizing a small number of subcontractors, or it may be undertaken as a 'turnkey' by a contractor. The contract may be fully reimbursable or fixed cost.

It is essential that the conditions of contract use unambiguous terminology and give clear guidance on the responsibilities of the parties for the various stages of the commissioning and for the associated documentation. Model conditions of contract for different types of contract are available and those of the Institution of Chemical Engineers (IChemE) are widely used for process plants, as described in Chapter 11.

The procedure developed by one UK process plant contractor to define responsibilities is illustrated in Table 19.3 (from Horsley and Parkinson). These authors give further demarcation schedules governing phases A–G of the project.

Table 19.3 *Demarcation between contractor and client of work and responsibility in construction and commissioning (Horsley and Parkinson, 1990) (Courtesy of the Institution of Chemical Engineers)*

Construction and pre-commissioning:

PHASE A	Prepare plant/equipment for pre-commissioning/mechanical testing
PHASE B	Prepare services: clean and pressure test systems
PHASE C	Check and prepare major mechanical equipment, instrumentation and protection systems
PHASE D	Final preparations for start-up

Commissioning:

PHASE E	Charge with feedstock, etc. Start-up plant and operate
PHASE F	Performance test and plant acceptance
PHASE G	Remainder of maintenance period

PHASE	A	B	C	D	E	F	G
1 Control of works by:		Contractor construction			Client		
2 Basic responsibilities and phases for various categories of staff at site							Return for corrective work
Construction		Site manager and team of construction specialists			Defects correction under contractor's direction		
Contractor Comm		Witnessing inspection & testing			Advising start-up & operation of plant	Witnessing performance test	
			Training client's operators				
Client		Witnessing inspection & testing			Plant maintenance and normal adjustments by client		
			Operators receiving training		Preparing for start-up: staring up and operating plant		
Equipment vendors		Testing and commissioning presence on site				On-call to site to end of maintenance period	
3 On completion of construction			CERTIFICATE OF MECHANICAL COMPLETION/TAKING OVER CERTIFICATE		CERTIFICATE OF ACCEPTANCE OF PLANT PERFORMANCE		FINAL CERTIFICATE

In the account that follows, it is convenient to assume that, unless otherwise stated, the project is a turnkey one undertaken by a major contractor.

19.1.2 Commissioning phases

The overall process of plant commissioning passes through a number of phases. It starts with the completion of erection. This term covers the end of installation of the equipment and is used sometimes, but not here, to cover also pre-commissioning. There then follows the phase of pre-commissioning. During this period there occurs mechanical completion and pre-commissioning; installation and checking of the control system and process commissioning.

By the end of process commissioning the various sections of the plant have been operated with process fluids. There then follows the performance testing in which the plant is operated and, if it meets its specification, accepted.

The activities during these phases may be illustrated by considering those in phases A–E of the contract scheme just mentioned. In broad terms, these are:

A Safety precautions; preparation of utilities; gland packing; preparation for line flushing.
B Commissioning utilities; machine rotation; pressure and leak testing; vessel cleaning; line flushing; relief value testing and re-installation.
C Chemical cleaning; machine alignment; lubrication systems; machine short running tests; instrumentation checks.
D Final preparations for performance testing.
E Charging of feedstock.
F Performance testing.

In the scheme described, the three areas of responsibility are supervision, trades and labour and inspection. Essentially, the responsibility for the first lies with the contractor, and in phase C the vendor also; responsibility for the second is with the contractor up to phase D, when the client has a roughly equal input and responsibility for the third passes increasingly from the contractor to the client over phases A to E. It is the client who carries out the performance testing of phase F.

19.1.3 Organization

It is important to organize the commissioning thoroughly and to provide the appropriate personnel. There is no simple model for the organization and personnel for commissioning. These depend on the nature of the process, the size of the plant, the involvement of other parties, such as licensors and contractors and so on. What is essential is that the management allocate sufficient resources to do the job efficiently. The commissioning of a large plant is a major enterprise and failure to recognize this is likely to increase costs and hazards.

The main conditions for success in commissioning, as listed by Kingsley (1990), are: an ably led, well balanced, well trained and committed commissioning team; a well structured relationship at senior level with site construction management and future operational management; thorough planning and implementation of preparations; adequate involvement in design stages and safety studies; meticulous attention to hazards and safety; ready availability of assistance from supporting disciplines and an expeditious approval system for plant modifications.

Some aspects of the organization of plant commissioning are

(1) regulatory and code requirements;
(2) contractual arrangements;
(3) quality assurance;
(4) safety;
(5) personnel and other resources;
(6) budgetary control;
(7) planning and scheduling;
(8) modification arrangements;
(9) communications;
(10) documentation.

The design, construction and operation of the plant are subject both to regulatory requirements and to the requirements of the codes and standards adopted. The latter should be clearly specified and there should be full information available about both sets of requirements.

The regulatory constraints on the discharge of gaseous effluents to the atmosphere and of liquid effluents to drains are generally of particular importance in commissioning.

The design, construction and operation of process plant are governed by quality assurance (QA). The extent of the QA system and its requirements varies between companies, but the trend is towards a formal system. The QA requirements need to be clearly laid down and arrangements put in place to ensure compliance. The QA system will generally cover the quality of the equipment and services supplied by the contractors and subcontractors and the installation and testing of the equipment. Where a full QA system is in operation, it will generally cover many of the aspects of plant commissioning discussed below.

Similarly, the plant design, construction and operation have to conform to the safety system and requirements. These too need to be clearly laid down and arrangements made to ensure compliance.

The definition of the relative responsibilities of contractors and the user needs to be particularly clear in both areas of QA and safety.

Plant commissioning requires the deployment of a considerable resources of various kinds and its organization is in large part concerned with ensuring that they are available in sufficient quantity and at the right time. Foremost among these resources is a wide range of personnel, who are considered below.

The various activities which have to be performed as part of the commissioning should be reviewed and arrangements made to furnish the necessary resources, of personnel, equipment or services. Mechanical precommissioning, process commissioning and performance testing are phases that may well require special resources.

A budget needs to be prepared for the cost of these resources. Full allowance should be made both for extra costs incurred by the main categories of personnel involved, such as overtime, travel and accommodation, and for costs of back-up services. It may be necessary to separate the costs of pre-commissioning from those of commissioning. In some cases, the two sets of costs are on a different basis, with the former being fixed price and the latter reimbursable.

Plant commissioning involves the planning and scheduling of a large number of activities. This aspect is treated in Section 19.1.5.

Arrangements need to be made to handle the plant modifications that are almost invariably required during commissioning. These should ensure that proposals to modify the plant are subject to review and that, where appropriate, the proposal is referred back to the design authority. Steps should be taken to ensure that this process is rapid and does not cause undue delay in the commissioning. This aspect is treated in Section 19.1.10.

Communications between the parties involved are always important in process plants and never more so than during plant commissioning. The information needs and the communication arrangements should be reviewed. Relevant aspects include documentation, written communications and meetings.

It should be arranged that the necessary documentation is available throughout the various stages of the project and that at termination of the commissioning the project is adequately documented.

It has been not uncommon that the commissioning period involves a series of crises, but this is not the most efficient way of doing it. As it has been put by Horsley (1974):

> It is also evident that the fun and personal satisfaction of being in the thick of things, having a tremendous degree of responsibility, working long hours and so on, are not efficient ways to start-up a plant. In fact, an efficient start-up without the emergence of numerous challenging technical problems would probably be slightly dull and disappointing to technologists and experts.

19.1.4 Personnel

Responsibility for the commissioning should rest with a single individual. It is normal to appoint a commissioning manager who has this responsibility. For the case considered, that of a turnkey project, the commissioning manager is appointed by the contractor.

The typical composition of a contractor's commissioning team for a large ammonia plant is given by Horsley and Parkinson as a commissioning manager and deputy, four shift leaders, four assistants, a chemist and mechanical, electrical and instrument specialists.

Where the project is done in-house, a common practice is to appoint a plant manager for the new plant some time in advance to let him familiarize himself with it, and to make him the commissioning manager. The job of the project manager is normally a separate one. Experience indicates that it is usually not good practice to attempt to combine the roles of project manager and commissioning manager. The commissioning team for an in-house project should be a strong one, with good technical capability and relevant experience. The team may consist of the personnel assigned to the plant supplemented by others who are brought in for the limited period of the commissioning only. It is necessary that the commissioning manager should be able to command the resources necessary to carry through the commissioning. Unforeseen problems can often result in considerable demands on resources. It may be desirable, particularly on large projects, to create an additional troubleshooting team. The organization of an extra fieldwork team for this purpose has been described by Horsley (1974). Some of the many variations in commissioning team composition are described by Troyan (1960), Finlayson and Cans (1967) and Garcia (1967).

There are many variations in the ways of organizing the management team for commissioning. One is to design and impose the organization. An alternative, described by Horsley (1974), is to let this evolve by negotiation of roles among the managers with division of 'ownership' of particular features among them.

During commissioning there is likely to be conflict between individuals. This may be due, to some extent, to clashes of personality, but it is generally due mainly to differences of role and hence viewpoint which are inherent in the situation.

There is also a need for specialists, particularly with regard to proprietary items such as rotating machinery. Many problems which would otherwise prove difficult and time-consuming can be resolved if an expert is present at the right time.

The workload of individuals should be checked to ensure that it is not extreme. If someone is excessively overloaded and tired, he tends to become both less effective and more prone to error.

19.1.5 Planning and scheduling

Plant commissioning requires the coordination of a large number of activities carried out by many different people. Some aspects for which planning is particularly important include:

(1) commissioning activities –
    (a) pre-start-up activities,
    (b) initial start-up;
(2) budgets;
(3) documentation;
(4) recruitment;
(5) training.

The design and construction of a large process plant is normally scheduled using such methods as the project evaluation and review technique (PERT) and critical path scheduling (CPS). Usually these methods are implemented on a computer.

The scheduling of commissioning may be done as a separate exercise. An account of such scheduling has been given by Cans and Benge (1974), who quote typical figures of effort required of 1000 man-hours for a major project, or alternatively, 3 man-hours per major piece of equipment.

The method of scheduling is broadly as follows. All activities are broken down into their constituent parts. The man-hours and machine-hours needed to perform each activity are determined. The length of time required to perform the activity is calculated on the basis of the availability of men and machines. The duration of the activity is then assessed, taking account of such factors as running-in time. The conditions at which work can begin on the activity are then determined.

Again methods such as PERT and CPS may be used, but it is more common with commissioning than it is with design to do the scheduling by hand, using aids such as bar charts and arrow diagrams.

Modifications are then made such as speeding up an activity or paralleling activities. When this has been done, it is possible to calculate the slack, which is the difference between the earliest and latest time at which an activity can start, to work out programmes for a day or a week, to determine the resources of men and machines required and to assess the expenditures involved.

In many large plants, critical path features are the reactors or the instrumentation.

It is easy to incur extra expenditure during commissioning and it is necessary to exercise close control on costs by controlling budgets for the various cost centres.

The communication of information is crucial in commissioning and it is essential to ensure that adequate documentation is available at the time when it is needed. Planning should include, therefore, a review of the documentation required.

The recruitment of personnel needs to be carefully planned. There is usually some uncertainty about the precise start time of various activities and this makes recruitment something of a problem. The problem is aggravated if there are difficulties at the recruitment end. In view of the uncertainties, recruitment in advance of requirement may be necessary, but it should be borne in mind that an excessive period waiting to start work can be demoralizing.

The training of both the management and the workforce needs to be planned. Important aspects are the scheduling and documentation of training.

19.1.6 Management preparation and training

The effectiveness of the commissioning depends to a considerable extent on the thoroughness of preparation by management. The commissioning manager normally prepares himself by studying the process and the plant, by visiting or working on similar plants, by involvement in the project through work on design committees, by preparing plant documentation and operator training schemes, and so on.

There are some particular aspects on which he is well advised to brief himself thoroughly. One is process information and know-how which has been purchased from outside. If problems arise in a bought-in process, it tends to be more difficult to put them right. Somewhat similar considerations apply to proprietary equipment, such as package units and complex machinery. It is also desirable for him to have a good grasp of the general economics and contractual features of the project. These range from raw material supply contracts to acceptance conditions for equipment.

It should not be assumed that it is only the process operators who need preparation and training for commissioning. These are required by management also. Some of the training requirements of the plant manager, and in particular the safety aspects, are discussed in Chapter 6.

19.1.7 Operations preparation and training

The operation of process plant requires the creation of a large number of systems and procedures. Many of these have to be formulated by the plant manager prior to and during commissioning.

The operating instructions are particularly important. These should be drafted early on, so that they can be used for operator training, but they are likely to need some modification in the light of operating experience.

It is also necessary to create a system of process records. The process log kept by the operator is one element in this, but there are numerous other records required for management purposes.

A process plant often receives its raw materials from or sends its products and/or by-products to other plants. The commissioning of such a plant tends to involve some degree of disruption of these plants. There is need, therefore, to coordinate the initial start-up so as to minimize such disruption. It may also be necessary to make arrangements to deal with unusable materials produced during the start-up, such as off-specification product.

Another feature that requires consideration is laboratory analysis and quality control. Safe operation requires a capability to analyse the material in the plant and ensure that it is within acceptable limits. This means working out methods of sampling and analysis, devising suitable tests and setting acceptance levels for raw materials, intermediates and products. It is also necessary to specify the associated paperwork.

The main training of the process operators is usually carried out jointly, during commissioning, by the training department and the plant management. The principal objectives of the training are to familiarize the operators with the chemicals handled, with the nature of the equipment and its location on the plant and with the procedures for operating the plant. A more detailed account of some of the principles and content of the training is given in Chapters 14 and 28 and a list of some of the documentation required for training is given in Chapter 6. Specific training in safety and loss prevention should be worked in with the other training material.

It may be appropriate to use lectures for the communication of certain basic information, but in general participative methods are likely to be more effective, and the commissioning situation lends itself well to the use of such methods. Workshops may be used to familiarize personnel with the hazards and with precautions and procedures. In some cases, use is made of a simulator to provide training in normal operating and emergency procedures.

Further training is obtained on the plant itself, where the trainees become familiar with the layout and learn to operate equipment and instrumentation. Testing with safe fluids provides particularly valuable experience. Often a strong team spirit develops during this period of training.

The operators should become familiar at an early stage with the hazards of the materials, the plant and the process and the alarm, fire and emergency systems. There should be drills for evacuation and fire fighting.

The commissioning environment is one where participation by the whole workforce is natural. It offers the opportunity, if management is so minded, to build the participative culture required for total quality management.

Generally, the training activities reveal certain inadequacies in the procedures and these should be rectified. The appropriate changes should be made in the documentation.

Usually much of the instruction is done by managers and supervisors who can benefit greatly from this, since instructing others is an effective way of learning. It is necessary to allow a sufficient number of management personnel to ensure that training is effective. It is a not uncommon experience that the level of training achieved at the end of the commissioning period is not bettered during the subsequent life of the plant.

Further accounts of process operator training during commissioning are given by Finlayson and Gans (1967), de Regules (1967), Kingsley, Kneale and Schwartz (1968–69) and R. Parsons (1971a).

19.1.8 Maintenance preparation and training

Prior to and during commissioning the maintenance engineer should set up the appropriate maintenance systems and documentation. Each major item of equipment should be given an identification code, which should be marked on the equipment itself.

The maintenance manuals for the equipment should be obtained from the manufacturer and reviewed. Sometimes the manuals will be considered inadequate in some respect. If so, the manufacturer should be contacted concerning modification. More often, however, problems arise because the manuals have not been consulted.

The maintenance of the equipment, both preventive and breakdown maintenance, should be planned. Schedules for regular preventive maintenance should be drawn up. A system of maintenance records should be instituted, containing details of the equipment in the plant and of the maintenance and modification work done. Details of the records required for pressure vessels, for example, are given in Section 19.3, but the records should not be limited to such equipment. The quality of the data available for analysis for reliability, availability and maintenance of the plant depends critically on these records. It is far easier to create an effective system initially than to try to improve a defective one. It is particularly important to obtain good information on the symptoms and causes of faults, and on the action taken.

A system of spares holdings should be created. Important features of such a system are that it show clearly what spares are available, what spares are being consumed and what the delivery situations are. Only if this information is available, is it possible to make rational decisions on the spares holdings.

A system for the control of slip plates should be devised so as to ensure that at each stage, such as normal operation or shut-down, all the slip plates required, but no others, are in position. The system should include provisions to prevent confusion with contractors' slip plates.

Maintenance personnel should check the plant during construction for accessibility and ease of maintenance. It may be necessary to make some alterations to the layout, to the equipment or to the lifting arrangements. The maintenance function is also involved in many of the pre-start-up activities such as checking and testing, and suitable preparations need to be made for this.

Maintenance personnel typically serve a number of plants and generally receive only limited instruction in respect of a particular plant, but they do need to be trained in the hazards of the materials, in the alarms and emergency procedures and in the maintenance of equipment specific to the plant. This may include some training at the vendor's works.

19.1.9 Pre-commissioning documentation

It is difficult to overemphasize the importance of having a comprehensive and up-to-date set of documentation. The documentation as a critical feature of the management system was described in detail in Chapter 6.

It is appropriate here, therefore, only to re-emphasize certain aspects that are of particular importance in commissioning. The documentation available at the pre-commissioning stage should include:

(1) operating manual;
(2) operating instructions;
(3) safety instructions;
(4) permit system documents;
(5) pressure vessel register;
(6) pressure piping systems register;
(7) protective device register;
(8) maintenance systems and documents;
(9) checklists.

The plant should be covered by a comprehensive system of permits-to-work as described in Chapter 21. These are needed during the commissioning as much as during operation and should be developed in good time.

The registers for pressure vessels, pressure piping systems and protective devices should be established before commissioning. Details of individual items can then be entered as they are installed and examined. The registers are described more fully in Sections 19.3 and 19.4.

There are several systems of documentation required for maintenance, as already described.

A major part of commissioning is the checking of systems, both of hardware and of software. This is greatly assisted if suitable checklists have been prepared.

19.1.10 Modification control

There should be a system for the control of modifications during commissioning, as described in Chapter 21, so as to ensure that a safe design is not rendered unsafe by a modification. The system should ensure that proposed changes are identified and routed to the design authority and that there is a prompt response.

There should be a single channel through which modifications are communicated to the contractor, so that there is less risk of confusion. On a large project, this may require the appointment of a commissioning modifications engineer.

Any modification arising from the commissioning should be referred for examination by a hazard and operability (hazop) study in a manner akin to that pertaining during design and using similar criteria to decide whether such a study is necessary.

A modification proposed may be to an existing plant rather than to the plant or plant section being commissioned, in which case there will be additional matters to allow for. A major consideration is whether the modification is to be done during a plant shut-down or with the plant in operation. In either case, it is necessary to take account of the hazards, to see that the plant is in a stable operating condition and to ensure that contractors are aware of the hazards.

19.1.11 Mechanical completion and pre-commissioning

A particular aspect of pre-commissioning is mechanical completion. The term is applied to individual items of equipment and is used to cover the activities between installation and process commissioning.

Mechanical completion ensures that the installed equipment is ready for commissioning and involves checking that it is installed correctly, that the component parts operate as specified and that any ancillary equipment is installed and working. Some typical checks and tests carried out on process equipment and machinery are listed in Table 19.4.

The plant should be given a thorough visual inspection. A check should be made on all plant equipment and pipework to ensure that it is installed in accordance with the engineering drawings. Any discrepancies should be marked on drawings to show the 'as built' condition. These discrepancies should be reviewed and corrected if necessary. In one instance, for example, a safety shower was found to contain not water but caustic soda. The inspection should check for items such as loose bolts or missing valve wheels and for construction aids or debris left in the plant.

The plant layout should be checked with respect to features such as: means of access and escape routes; floors, stairs and handrails; lighting; fire equipment and safety equipment.

Mechanical equipment should conform to the specified codes and standards, should be installed in accordance

Table 19.4 *Some checks and tests carried out on process equipment and machinery during plant commissioning*

Pre-installation inspection, checking and testing of:
  pressure vessels
  process machinery
Plant checking against piping and instrument diagram
Checks on materials of construction
Pressure vessel and system tests:
  inspection
  pressure tests
  leak tests
  protective devices tests
Process machinery tests:
  inspection
  dry runs
  load runs
  performance runs
Subsystem and system tests:
  dynamic safe fluid test (water test)
  dynamic process fluid test
Also tests on:
  utilities
  instrumentation
  unit operations
  simulated faults

with the relevant drawings and should meet the performance tests specified.

Each item of equipment received should be checked for compliance with specification. In some cases, this may mean witnessing aspects such as examination or testing at the manufacturer's works.

Errors in the materials of construction actually installed are quite common. A check should be made, therefore, on the materials. In critical applications it may be appropriate to carry out a 100% check using a device such as a Metascope.

The installation of internal fittings, such as trays, weirs, downcomers and thermocouple pockets in distillation columns, should be checked. It is important that these internal fittings have the right dimensions, are correctly located and are firmly secured.

For rotating equipment, checks are required on foundations, lubrication systems, other ancillary systems, alignment and vibration-related features.

Piping systems should be checked for: conformity with pipework isometric and other drawings; the presence of fittings such as isolation valves, drain and sample points, etc; the orientation of fittings such as non-return valves, where applicable; satisfactory making of joints; adequate pipework supports and for satisfactory installation of expansion joints and bellows. A test sheet for piping systems given by Horsley and Parkison is shown in Table 19.5. Much use is made of checklists in assuring mechanical completion. Many of the checklists given in Table 19.2 apply to this phase.

For virtually all the features mentioned there are associated documents and/or drawings. The process of checking involves the marking up of drawings and the completion of test certificates and various forms of contractual certificate.

There are also a number of pre-commissioning activities to be carried out on the mechanical systems. These activities need to be coordinated both with the site construction manager and with the plant operations and maintenance management.

Typically the pre-commissioning activities include: first, commissioning of the utilities so that services are available; checks on the individual equipments and systems for mechanical completeness and listing of missing items; pressure tests on pressure vessels and defined pressure piping systems; cleaning of vessels and flushing out of pipework; loading in of catalysts and packings and leak testing.

The inspection and testing of pressure vessels is described in Section 19.3.

At the same time, rotating machinery is run off-load and instrumentation is set up, calibrated and given functional tests.

A list of some of the checks and tests carried out on process machinery such as pumps, compressors and centrifuges, is given in Table 19.6.

It is common practice to fit start-up filters on rotating equipment to protect it from debris which could cause damage. Sensitive instrumentation that could be damaged is also temporarily removed.

Subsystems are frequently tested using a safe medium, usually air or water, prior to testing with the process fluid. Compressors may be run on air on open circuit, and pumps may be run on water.

19.1.12 Control systems

The installation of the instrument and control system cannot be completed until most of the mechanical equipment is installed. Its installation tends to overlap with the commissioning of the rest of the plant.

Guidance on the installation and testing of instrument and control systems is given in BS 6739: 1986 *Code of Practice for Instrumentation in Process Control Systems: Installation Design and Practice*.

Most control systems are now based on some form of computer control, and this is assumed in the account given here. The computer is first tested at the supplier's works. These tests cover the computer hardware, the input/output equipment and any non-standard software. The functions to be performed through the configurable software are entered, such as signal conditioning, trend records, overview displays, alarms, control algorithms, etc., and are then tested. Likewise, applications software for functions such as sequential control or fault diagnosis is entered and tested.

Table 19.6 shows some of the checks carried out on instruments. A check should be made that the instrument is installed in accordance with the drawings and with the manufacturer's instructions. It should also be checked that shipping restrictions have been removed. Usually parts and springs are wired down, critical parts are covered with protective coating and leads may be plugged; all these restrictions need to be taken out.

Installation of the instrumentation is followed by checking. The responsibility for this normally lies with the contractor, but involvement of the user's instrument personnel assists familiarization.

Circuits should be checked for continuity from the panel to the instrument, and back. The movement of a control valve should be checked by 'stroking' it and that of a controller by observing its response to the output of the measuring element. The response of the alarms and interlocks to the measuring elements should be checked, as should the alarm settings and the actions of devices actuated by the interlocks. Similar checks should be made on trip systems.

Instrumentation received will have been calibrated by the manufacturer but some degree of recalibration on site may be required, whether as a result of damage ELD, engineering line diagram; GA, general arrangement; NDT, non-destructive testing; NR, non-return; RV, relief valve sustained or as a matter of policy, and this necessitates appropriate test equipment.

These checks are then followed by functional testing. Some functions are commonly executed by the main, computer-based system and some by separate systems.

Early installation of the computer system allows progress to be made with the testing of the instrumentation connected to it and of the functions allocated to it, in particular of non-standard systems software, configurable software and applications software.

Some common functions that are often separate from the computer system are (1) management information, (2) specialized instruments, (3) packaged units, (4) control loops, (5) trips, (6) sequence control, (7) emergency shut-down and (8) stand-by supplies.

Checklists for the functional testing of a control loop and of a sequence are given by Horsley and Parkinson (1990). The headings of the checklist for a control loop are (1) input channel, (2) faceplate/bar display, (3) trend display, (4) archiving, (5) alarm handling, (6) control functions, (7) output channel and (8) documentation. Those for a sequence are (1) declarations, (2) structure, (3) timing, (4) contention handling, (5) operator access, (6) recovery options, (7) recipe

Table 19.5 Typical pressure piping test sheet (Horsley and Parkinson, 1990) (Courtesy of the Institution of Chemical Engineers)

Design and Test Data		
Availability of the following data relevant to the piping systems	Engineering line diagram	
	Piping test schedule	
	Piping arrangement drawing	
	Pipe, line schedule	
	Piping and valve specifications	
	Piping isometrics	
	Piping test procedure	
	Piping fabrication and erection codes	
	Pipe support details and schedule	
Test certificates for	Off-site fabricated piping	
	Heat treatment or other	
	Process/Utility valves, control valves, etc.	
	NDT (X-or γ-ray, etc.)	
	In-line process equipment	
Piping and valve material analysis certificates		
Welders qualification certificates		
Pre-test Visual Inspection		
Routing and size correct to ELD arrangement drawing/ piping isometric		
Installation of piping and piping components complete	Joints bolts nuts and gaskets expansion loops and bellows	
	Fixed anchors, sliding supports, guides spring or fixed hangers	
	Jacket/jumpers,tracing conductive bolts/ earthing straps	
Installation/orientation with respect to flow	Process and utility valves, NR valves process control valves orifice plates and flowmeters	
Location of in line components for access, operation maintanence and safety of operatives		
Location and installation of	Vents, drains, drip legs, drip rings, utility station connections, steam traps, filters, strainers line blinds, spectable plates, bypasses, instrument tapping points for pressure, temperature and flow, plugs, rodding out points	
Installation of field mounted instruments that is Thermowells, pressure guages, etc.		
Check and ensure system devoid of insulation and paint		
Pre-test Preparation		
Prepare a written test plan and mark ELD/GA with location of all spools, spades, blanks, vent valves, strainers, etc., agree with site manager and initiate		
Obtain spades, blanks, strainers, vent valves, bolts, nuts, gaskets and fabricate pipe spools		
Remove RVs for bench, testing and orifice plates for checking, make good joints or blank off		
Remove or spade off any control valve or instrument liable to damage under test pressure, replace with spool or make good joint and open any bypass valves		
Spade off or isolate process equipment with lower allowable pressure than test pressure		
Spade off all overflows, close drains, fit vent valves, ensure test medium available		
Calibrate test gauge and check range adequate for test pressure and detect pressure loss		
Define testing fluid		
Pressure Test Procedure		
Site manager's clearance obtained, other contractors informed and safety notices positioned		
Ensure all test personnel are competent and briefed regarding extent, duration and limits of test		
Open up system, flush or blow through to remove mill scale/rubbish, fit temporary strainers and close		
Hook up test pump to line and test medium, open vents and commence filling system		
Conduct test per test procedure, attend to remedial works and bring to test pressure and hold		
Invite client's representative to witness test		
Prepare test certificate and record	System title, line numbers, plant reference	
	Numbers, date, time and duration of test	
	Pressure, test certificate number and obtain client's signature	
Post-test Procedure		
Open up, drain down, remove and account for all spades, blanks, spools, plugs, vent valves, strainers and test equipment, flush or blow through and dry out		
With new gaskets, re-install at bench tested RVs, orifice plates, control valves, thermowells, flowmeters pressure gauges and remove safety notices, etc.		
Check installation complete and purge or chemically clean if part of take-over procedure		
Complete construction works, for example paint, insulate, colour code. etc.		

***Table 19.6** Some elements of the checking and testing of process machinery and instruments (after Gans and Benge, 1974) (Courtesy of the Institution of Chemical Engineers)*

Process machinery:
Field disassembly and reassembly
Lubrication system: cleaning and check on circulation (flow, temperature)
Cooling water system: cleaning and check on circulation (flow, temperature)
Pre-commissioning of instruments
Check on free and unhindered rotation
Check on anchor bolts
Disconnection of piping to check that it does not stress equipment
Installation of temporary filter
Setting of system for 'no load' running
Running of motor uncoupled
Coupling of motor
Check on alignment
Check on vent system
Check on seal system
Dry run: check on vibrations and overheating of bearings
Load run
Performance run

Instruments:
Instrument checking against drawings and manufacturer's requirements
Removal of shipping restrictions
Calibration
Continuity check
Movement check
Alarms check
Interlocks check
Analysers check

handling, (8) firmware interface, (9) sequence display and (10) batch logging.

The pre-commissioning of the control system should be governed by formal procedures. Test forms should be specified for each system to be tested. Guidance and model forms are given in BS 6739: 1986.

Proposals for modification to functional specifications or to the computer software should be referred for review by a hazop study in a manner similar to that pertaining in design. There should be a formal system to ensure that changes made to the computer software are recorded and that development of the software proceeds by way of discrete, identifiable and documented versions.

It is necessary to ensure by formal means that the segregation of signals is not compromised by modification. Segregation of signals may be according to signal type, plant area and process function, and has implications for features such as intrinsic safety, electrical isolation and emergency shut-down.

Formal control should be exercised over access to the computer system. Parties requiring access are control engineers commissioning the control system and process engineers commissioning the plant. Levels of access should be defined and controlled by means such as passwords or key switches.

The checks on the instrumentation should be extended where practical to cover operation with process fluids and conditions that are realistic but nevertheless safe.

Documentation for the instrument and control system should include: the system manuals; piping and instrument diagram; loop diagrams; wiring/circuit diagrams; termination rack layouts; tag number lists; database tables; sequence flow diagrams; etc.

19.1.13 Process commissioning

Process commissioning is begun only when the pre-commissioning is complete and the defects identified have been corrected to the extent judged necessary. This commissioning may be undertaken on equipments or sections of plant as they become available, but only under close control so as to prevent hazardous interaction between the two activities of plant construction and process operation. One method of control is to require for the equipment a formal handover certificate verifying mechanical completion, with minor deficiencies listed. Before the process commissioning starts, it is usual to carry out a final check. Checklists applicable at this stage are one of those most commonly given.

The order in which the process commissioning is done may vary. The typical sequence cited by Horsley and Parkinson (1990) is (1) utilities, (2) laboratory, (3) raw material storage, (4) ancillary equipment, (5) reaction system, (6) work-up system and (7) product storage. Where there is no reaction system, the overall process system may be substituted for stages (5) and (6).

The quality control laboratory needs to be in a position to take samples from the plant and conduct analyses as specified. If there is any deficiency in its ability to do this, which is sufficiently serious, commissioning should not be started. The laboratory needs also to be prepared to handle the augmented number of analyses likely to be required during the commissioning period.

Ancillary equipment can often be commissioned separately from the equipment that it serves. Where this is possible, it is prudent to do this, so that when commissioning of the main equipment is begun, the ancillary equipment is ready for use.

A supply of raw materials is necessary for the process commissioning. These may come from a bulk storage or from other containments such as drums or transportable containers. Bulk raw materials storage will normally be commissioned some time in advance. It is also necessary to commission the intermediates and products storage, which is generally bulk storage. A checklist for the commissioning of a storage tank is referenced in Table 19.2.

The reaction section may be continuous or batch. Since this section is generally a critical one, its commissioning should be prepared with particular care. The commissioning team should be at full strength and fresh.

For a continuous reactor, the commissioning will aim to start-up and achieve a steady state as smoothly as possible. Critical features in achieving this are the utilities, the feeds, the machinery and the control system. A checklist for the commissioning of a continuous reactor is referenced in Table 19.2.

It may well happen that the conditions obtained are not those desired or that some fault occurs and the product produced is off specification. Horsley and Parkinson advise that, provided it is safe to do so, it may be better to continue running until it is established that the desired product quality can be made before shutting down, thus avoiding repetition of start-up and shut-down.

For a batch reactor the problems are rather different. Here the requirement is to ensure that correct charges are made, that the desired sequence is followed, and that at each stage the process is controlled as specified. Critical features in this case are the charging, the control system for the sequences and the process conditions.

For both types of reactor a full record of the trials should be kept to allow the design to be checked and any deficiencies experienced corrected.

19.1.14 Handover: contractor project

The conditions for acceptance of the plant from the constructor by the operator are normally specified in the contract. A handover certificate is usually issued which contains a list of reservations of items on which further work is required. The handover needs to be carried out formally and with particular regard to safety. The plant should be in a safe condition when it is handed over.

With a large plant it may be desirable to have selective handover of plant systems as they are completed. This applies particularly to such systems as steam-raising plant, steam pipework and cooling water systems.

If parts of the plant are to be operated while other plants are still under construction, it is essential to take steps to ensure that these two activities do not interact in such a way as to create a hazard. The problem is similar to that arising in a major plant extension, and this is discussed in Chapter 21.

A typical reservations checklist is given by L. Pearson (1977b) and is shown in Table 19.7. The checklist referenced in Table 19.2 is similar.

19.1.15 Start-up and performance testing

With the end of the process commissioning, the next stage is to charge the feedstocks and start-up and operate the whole plant and subject it to performance testing in order to determine whether it meets its specification. This initial start-up of the plant should be thoroughly prepared. It should be recognized that the start-up may be prolonged and arrangements made to relieve personnel so that they do not have to work excessively long hours. It is valuable to keep fairly comprehensive records of the start-up, and personnel should be briefed on the recording requirements.

All the formal systems for control of hazards and errors should be operational. These include in particular the permit-to-work systems as well as the systems for the control of slip plates and of vents and drains.

Before start-up, a careful check should be made by ‘walking the plant’. The inspection should include a check on the state of all valves, which may be assisted by use of marked drawings and a register. Likewise, a check is required to ensure that all slip plates that need to be removed have been removed; again this can be done, using drawings and a register.

It may be necessary during start-up to use filling and bypass lines that need to be closed again when the plant is operating. A register of such lines is needed to ensure that this action is taken.

The disarming of certain trips may also be necessary during start-up, particularly those for low flow, pressure and temperature. There should be a formal system to cover this which ensures that such disarming occurs only as authorized and that the instruments are restored again when the need for disarming has passed.

Checklists given by L. Pearson (1977b) of measures to be taken before process fluids are admitted are given in Table 19.7. The checklists referenced in Table 19.2 are similar. Start-up procedures are described further in Chapter 20.

The purpose of performance testing is to confirm that the plant can be operated at design conditions and that with a specified raw materials quality and at these conditions it will perform to specification in respect of throughput, yield and product quality. There may also be specifications for features such as utility usage, effluent quantities and compositions and reliability. A schedule of performance tests will have been drawn up and the levels of performance that the plant must meet specified.

The feedstocks are charged to the plant and it is started up and operated to determine whether it meets these performance criteria. The outcome of the performance testing may be: (1) that the plant performs satisfactorily; (2) that the plant does not perform satisfactorily and there is minimal prospect that it ever will or (3) that the performance of the plant, whilst falling short of specification, can be remedied. In case (3) the contractor may either put the matter right at his own expense or agree compensation with the client, whilst in case (2) the contractor has a financial liability.

19.1.16 Handover: in-house project

For a turnkey contract, the system of formal handover sets a term to the commissioning period. For an in-house project, the possibility exists that the commissioning period will become unduly extended.

The commissioning period should not be terminated until the plant is giving reasonably satisfactory operation. The rate of improvement inevitably slows down when the additional support of the special commissioning team is withdrawn. On the other hand, the development of a plant is a continuing process and the commissioning cannot be allowed to drag on indefinitely.

Some criteria for termination are given by Kingsley, Kneale and Schwartz (1968–69) as follows: (1) competence of operating staff; (2) reasonable level of plant reliability; (3) attainment of acceptable quality standards; (4) satisfactory use of resources (staff, materials, utilities, throughput) and (5) acceptable level of maintenance.

19.1.17 Safety audit

The plant should be given a comprehensive safety audit during the commissioning period. The audit should cover both hardware and software aspects. Details of such a safety audit have been given in Chapter 8.

19.1.18 Commissioning problems

Many of the problems associated with commissioning have been mentioned explicitly or are implicit in the comments made, but it is appropriate at this point to give a further review of some of the problem areas in commissioning. These include:

(1) lack of process information;
(2) design changes;
(3) unsuitable equipment;
(4) lack of expert advice;
(5) lack of spares and supplies;
(6) construction and maintenance errors;
(7) safe fluid testing;
(8) water traces;
(9) operating errors.

Table 19.7 *Checklists of measures to be taken before process fluids are admitted on a chemical plant (L. Pearson, 1977b) (Courtesy of Hydrocarbon Processing)*

(a) Pipelines and pipework checklist

(1) Screwed plugs in pipes, only permissible on air, water, nitrogen under 100 psi, $1\frac{1}{2}$ in. NB and below
(2) Faulty welding
(3) Correct joints
(4) Odd sized bolts
(5) Black bolts in cold joints
(6) Faulty pipeline supports
(7) Pipe not resting on supports
(8) Are expansion slippers safe (e.g. will they push off structure when line is hot?)
(9) Check spring hanger settings
(10) Faulty spring hangers
(11) Low point drains fitted where necessary, and high points vents
(12) Lagging – missing, damaged, loose, etc.
(13) Vent and drain blanks fitted where necessary
(14) 'Weep holes' in relief valve exhaust lines, only on non-H/C or atmospheric, RVs
(15) Have all slip plates been removed and spectacle plates turned?
(16) Spring hangers – have restraining pins been removed?
(17) Make sure pipework is up to the piping and instrument diagram specification
(18) Necking-off hazard – is there any equipment or small bore pipe projection that can be accidentally broken off?
(19) Are small branches, that is drains, sufficiently clear of pipe supports?
(20) Do drain lines run to underground drains? They should not flow over paved areas
(21) Flanges lagged up

(b) 'Chemicals and hydrocarbons in' checklist (jobs to be done before chemicals or hydrocarbons can be safely brought into the plant)

(1) Complete all necessary reservations
(2) Nitrogen purge systems prepared and leak tested
(3) Blowdown system 'live'
(4) Oil/water separator in commission
(5) New perimeter fence erected, with 'dematched area' notices
(6) Dematching hut in position and gateman available
(7) Brief all construction people on consequence of plant becoming a 'dematched area'
(8) Fire alarm I/C and all position tested
(9) Compressed air sets in position
(10) Fire extinguishers in position
(11) Eye wash bottles in position
(12) Personnel showers in position and checked
(13) Fire hoses in position
(14) Fire main I/C and check that hoses fit hydrants
(15) Drench water sprays tested
(16) Fire steam hoses in position and check they connect securely
(17) Fire permits in use
(18) Flush drains to prove them free from obstructions
(19) Plant areas clean (fire hazards removed – rags, paper, wood, etc.)
(20) Check plant lighting
(21) Remove contractors' buildings, tarpaulins, etc.
(22) Remove non-flameproof equipment
(23) Nominate shift fire teams and arrange practice alarm
(24) List all possible welding jobs – get most done beforehand
(25) Check that welding sets pass works electrical inspection
(26) Check gas detectors
(27) Hazard and safety notices to be in position
(28) Obtain 'means of escape' certiciate
(29) Check that segregation plates can be easily removed
(30) Inform fire station
(31) Invite safety department to inspect and pass comment
(32) Carry out through search for matches
(33) Make sure that neighbouring plants know how this affects them
(34) Inform services (affect their drains)
(35) Inform Factory Inspector and Alkali Inspector
(36) Inform local authorities
(37) Inform records sections

H/C, hydrocarbon; I/C, in commission; NB, nominal bore; RV, relief valve.

The difficulties inherent in a situation where basic information about the process is inadequate have already been mentioned. This is due sometimes, but by no means always, to the purchase of know-how from outside.

Although some modifications of the original design are almost inevitable, they tend to be disruptive and expensive, and should be kept to a minimum.

Unsuitable equipment can be a source of much trouble. It is sometimes suggested that equipment that comes as a package unit or is purchased from the main contractor can be troublesome. It may well be, however, that in many cases the problem lies with the user. Certainly, it is essential that he gives a full specification for such equipment as for other items.

The need for expert advice has already been mentioned. The behaviour of equipment during the running-in period may be different from that in normal operation. In one case, for example, commissioning was delayed because the lubricating oil from the bearing of a ball mill was found to contain a high concentration of metal particles: the vendor then confirmed that this was normal during running-in.

Shortages of spares and other materials can result in delays. The need for an adequate spares system has already been emphasized, but provision of other items is equally important.

Mistakes in construction are commonplace. In addition to the use of incorrect materials of construction for the main equipments and pipework, errors often occur in minor items such as bolts or gaskets. For example, mild steel bolts may be fitted where stainless steel bolts have been specified, which in a low temperature application is a serious hazard. Likewise, a hazard can be introduced by the use of a wrong gasket.

Safe fluid testing can sometimes introduce its own problems. The use of water instead of a hydrocarbon means that the weight of the fluid is greater. There may be a risk of overpressuring the base of tall columns or of overstressing vessel supports.

Likewise, it is not unknown for damage to be done to compressor systems by an air inlet line choked by polyethylene bags.

Certain plants, notably cryogenic plants, are sensitive to even small quantities of water. Ice and hydrates can cause numerous problems, particularly on instrumentation. It may be necessary to remove water by blowing through the drains and by a warm air purge of the plant.

Inexperience on the part of the process operators can result in maloperation that does considerable damage to the plant. For example, a pump may be allowed to run dry or to pump against a closed valve.

Operation of equipment at higher temperatures than intended so that the creep rate is greatly increased can be particularly serious. It is quite possible to use up a large proportion of the creep life, say 30%, during the commissioning. It is important, therefore, that this be avoided as far as possible and that the records be kept such as to allow an estimate of creep effects during commissioning to be made.

Some specific problems arising during commissioning have been reviewed by Kingsley, Kneale and Schwartz (1968–69) and are summarized in Table 19.8. Design errors do occur, but are most frequent in detailed rather than fundamental aspects. Emulsions and foams may occur on the full-scale plant, even though these have not shown up in the pilot plant. Gas phase balancing errors can lead to difficulties with levels and flows. Lack of a net positive suction head causes pumps to cavitate. Heat transfer phenomena that can be troublesome include polymerization and scaling up. The former occurs more frequently than is admitted. Separation operations, especially those involving particulate systems, give rise to many difficulties.

Automatic control problems include measurement of unusual variables, the oversizing of control valves and the control of non-linear variables and of loops with large time lags and/or dead time.

Table 19.8 ***Table 19.8*** *Some typical problems arising during plant commissioning (after Kingsley, Kneale and Schwartz, 1968–69) (Courtesy of the Institution of Mechanical Engineers)*

- Design errors:
  - emulsions and foams
  - venting arrangements
  - liquid head arrangements
- Heat transfer phenomena:
  - polymerization
  - scaling up
- Separation operations:
  - liquid–liquid separation, for example centrifuges
  - liquid–solid separation, for example filtration
  - gas–liquid separation, for example demisting
  - gas–solid separation, for example gas filtration
- Automatic control:
  - long time lags, dead time
  - valve sizing
  - control of non-linear variables, for example pH
  - unusual measurements
  - unsuitable equipment
- Leaks:
  - sudden leaks
  - leaks in vacuum equipment
- Vibration phenomena
- Mounting errors
- Mechanical handling equipment
- Materials of construction

19.1.19 Commissioning hazards

The process and plant designs should already have been subjected to the various checks described in Chapter 8. In particular, the hazop study conducted should have covered operations that are carried out only in commissioning. There are certain specific hazards associated with commissioning.

The pressure testing of equipment, which is described in Section 19.7, is a hazardous operation. The hazard is minimized by the use of hydraulic rather than pneumatic testing, but the energy released if the vessel fails is appreciable even with a hydraulic test, and it is important to ensure that the correct test procedure is followed and that personnel not involved in the test are cleared from the area.

Many of the test and other operations carried out during commissioning require the use of temporary connections. These are often hoses. Hose connections have been responsible for many accidents and particular care should be exercised with them.

Plant are tested for leaks, but, even so, leaks tend to develop due to features such as loose joints, open valves, gasket and seal failures, vibration, thermal expansion and contraction and corrosion. It is important, therefore, to keep a lookout for such leaks. Leaks from high pressure plant can cause direct injury to personnel, leaks of flammable materials can cause a fire or explosion and leaks of flammable liquids can contaminate lagging, creating a further fire hazard.

Nitrogen purging is a frequent operation in commissioning. The use of nitrogen for large-scale purging operations involves the hazard of asphyxiation of personnel.

Commissioning requires the use of utilities in large quantities. It is important to ensure that other plants are not run short of essential utilities and so put at risk. There is the further hazard of contamination of the utilities by fluids from the plant being commissioned.

19.1.20 Post-commissioning documentation

During the commissioning a large amount of information is generated which needs to be properly documented. Modifications are made to the plant; a wide variety of tests and examinations are performed on individual items of equipment and on the plant as a whole; the computer software is modified and parameters entered; modifications are made to the systems and procedures and the associated documentation; reviews are made of safety and environmental features and there are matters to be carried forward.

Some principal features of the post-commissioning documentation are:

(1) modifications records;
(2) equipment examination records –
    (a) pressure vessels,
    (b) pressure piping,
    (c) protective devices;
(d) equipment test records –
    (a) pressure and leak tests,
    (b) pressure relief valve tests,
    (c) rotating machinery tests,
    (d) instrument tests,
    (e) computer system tests;
(f) computer records;
(g) spare inventories;
(h) safety reviews records –
    (a) hazop follow-up,
    (b) safety audit,
(c) environmental review records;
(d) reservation list.

There should be records of any modifications made to the plant and also to the process. This aspect has already been discussed.

The registers for the pressure vessels, pressure piping systems and protective devices should have been prepared prior to commissioning, but much information on the equipment and on its initial examination and testing will be entered at the commissioning stage.

Records should be kept of the tests done on the whole range of equipment, including pressure vessels and the pressure piping system, pressure relief valves, rotating machinery, instruments and the computer system. Any modifications made to the computer software or to the parameters entered should be recorded.

It is common practice to hold an inventory of commissioning spares. With the end of commissioning this should be replaced by the regular spares inventory, which should be documented.

There should be records of any safety and environmental reviews conducted. The safety reviews should include any matters requiring follow-up consequent on the main hazop study or any further hazop studies performed as a result of commissioning modification and the post-commissioning safety audit.

There will also have been modifications made to the various types of documentation such as operating instructions, test procedures, etc., and these changes should now be incorporated and tidy documents produced.

19.2 Plant Inspection

Plant inspection is an essential aspect of the fabrication, construction, commissioning and operation of pressure systems. Accounts of plant inspection are given in *Pressure Vessel Systems* (Kohan, 1987) and *Inspection of Industrial Plant* (Pilborough, 1989) and by Erskine (1980).

Relevant codes are the *Pressure Vessel Examination* Code (IP, 1993 MCSP Pt 12) and the *Pressure Piping Systems Examination* Code (IP, 1993 MCSP Pt 13). These are codes with international application but are aligned with the Pressure Systems and Transportable Gas Containers Regulations 1989.

Another code is the *Registration and Periodic Inspection of Pressure Vessels Code* (ICI/RoSPSA 1975 IS/107) (the ICI *Pressure Vessel Inspection Code*). This is now out of print but remains a good illustration of the fundamental principles of such codes.

In the United States, the *Guide for Inspection of Refinery Equipment* by the API (1962–) has long been a principal inspection code but is now out of print. The *Guide* has some 20 chapters that are listed in Appendix 27. It is being replaced by other publications. One of these is API RP 510: 1989 *Pressure Vessel Inspection Code: Inspection, Rating, Repair and Alteration*.

The following description is concerned mainly with the inspection of pressure vessels, pipework and protective devices, but it illustrates general principles for inspection which are relevant also to many other types of equipment.

Selected references on plant inspection, testing and monitoring are given in Table 19.9.

19.2.1 Regulatory requirements

The statutory requirements for inspection of pressure vessels and the legislative background to these were described in Chapter 3. The basic position in the United Kingdom is that until 1989 there were statutory requirements covering the construction and maintenance, including inspection of steam boilers and receivers, air receivers, gasholders and gas cylinders and containers for transport, but not for other pressure vessels. Thus, many pressure vessels containing hazardous substances were not subject to specific statutory controls. Moreover, the pressure system components which were the subject of statutory requirements were strictly limited. Principally they were the protective devices associated with steam boilers and receivers and air receivers. Thus many pressure system components containing hazardous substances, including pipework and other components listed in Section 19.3, were not subject to specific statutory requirements. However, although many pressure systems were not covered by specific statutory controls, the general duty to provide safe equipment, which is strengthened by the Health and Safety at Work etc. Act 1974, might be considered to require that the integrity of pressure systems handling hazardous substances should not be less than that of systems handling steam and air.

The Pressure Systems and Transportable Gas Containers Regulations 1989 (the Pressure Systems Regulations), described in outline in Chapter 3, have introduced comprehensive controls on pressure systems as well as pressure vessels. Guidance on these regulations is given in HS(R) 30 *A Guide to the Pressure Systems and Transportable Gas Containers Regulations* 1989 (HSE, 1990). The regulations are supplemented by COP 37 *Safety of Pressure Systems* (HSE, 1990). The scope and general requirements of the Pressure Systems Regulations are described in Chapter 12 and the those for inspection are described here.

It is normal industrial practice to exercise close control of all parts of a pressure system, including both pressure vessels and other components, and to do this throughout the life of the system, starting with design and continuing through fabrication, installation, commissioning, operation, inspection, maintenance and modification, by means of external and in-house standards and codes. The inspection system is the main means of exercising this control after the design stage.

Nevertheless, in the United Kingdom there have in the past been some differences between pressure vessels that

were covered by specific regulations and those that are not. In general, with the former the letter of the law applied, whilst with the latter the degree of flexibility based on engineering judgement was rather greater.

One aspect that is of particular importance is the inspection interval. Basic statutory inspection intervals were 14 months for steam boilers and 26 months for large steam boilers, steam receivers and air receivers. In principle, dispensations for longer intervals might be granted by the Health and Safety Executive (HSE), but these were difficult to obtain and it remained the case that the statutory inspection intervals for these items are an inhibiting factor in industry.

As described in Chapter 12, the Pressure Systems Regulations extend the scope of pressure systems to cover essentially all systems that depart significantly from atmospheric pressure. They create a requirement for a formal system of records and examinations. Regulation 5 requires that certain information be provided about the pressure system, Regulation 8 that there be a written scheme of examination, Regulation 9 that examinations be conducted in accordance with this written scheme and Regulation 13 that records be kept.

Regulation 5 requires that sufficient information be provided about the pressure system in respect of design, construction, examination, operation and maintenance, and about any repairs or modifications made to it.

Regulation 8 requires that there be a written scheme for the periodic examination by a competent person of

(a) all protective devices;
(b) every pressure vessel and every pipeline in which (in either case) a defect may give rise to danger; and
(c) those parts of the pipework in which a defect may give rise to danger.

It states that such a scheme shall not be drawn up unless it is suitable and

(a) specifies the nature and frequency of examination;
(b) specifies any measures necessary to prepare the pressure system for safe examination other than those it would be reasonable to expect the user (in the case of an installed system) or owner (in the case of a mobile system) to take without specialist advice; and
(c) where appropriate, provides for an examination to be carried out before the pressure system is used for the first time.

Before the regulations were made, there was much discussion as to how ‘pipework’ should be covered. The term has been widely defined but the *Guidance* states that the effect of Regulation 8 and of COP 37 is to exclude most ‘pipework’ from the written scheme.

In contrast to the legislation which they replace, the regulations do not give specifed intervals for any equipment; the intervals formerly specified for steam boilers and for steam and air receivers are not carried forward. In practice, however, these intervals are often retained in examination schemes.

Regulation 9 requires that the examination be performed by a competent person and that a written report be produced of the examination. The report should: state which parts have been examined, the condition of the parts and the results of the examination; specify any repairs or modification required and the date by which they should be done; give the date beyond which the equipment should not be operated without further examination and state whether the scheme of examination is suitable or whether it needs modification, and if so why.

Regulation 13 requires that records be kept which include: the basic information specified in Regulation 5; the report of the last examination; the previous reports where they contain information on whether the system is safe to operate or whether any repairs or modifications to the system can be carried out safely and information on any postponement of an inspection beyond the previously specified date.

The statutory controls are not the only external influence which industry has to consider. Adherence to a system similar to the statutory one is generally a condition of obtaining insurance. Much inspection of process plant is in fact carried out by insurers.

19.2.2 Inspection bodies

There are a number of parties who may conduct inspection of a pressure vessel during its manufacture. They include (1) government, (2) the manufacturer, (3) the user, (4) an insurer and (5) a consultant. The same set of parties, except for the manufacturer, may undertake inspection during operation.

Government inspection may be undertaken for two rather different purposes. One is to assure the quality of the government's own purchases, and the other is for regulatory purposes.

In the United Kingdom, the requirements of government, particularly in defence, have greatly influenced the evolution of inspection systems. Mention should be made in particular of the Aeronautical Inspection Directorate (AID), renamed in 1969 the Aeronautical Quality Assurance Directorate (AQD), which has developed an inspection system which is the basis of many contracts by government and by other organizations. Some basic principles of the system are that: there must be verification that every requirement of every specification and drawing has been met; there is a complete chain of responsibility for inspection at every stage and there are full inspection records. The manufacturer's inspection system has to be approved. His subcontractors also have to be approved or else special arrangements made. The full requirements of the system are expensive, however, so that a user who does not require this degree of control may adopt a modified system.

It will be apparent that this system was a forerunner of the QA systems, based on BS 5750 and ISO 9000, which are now becoming widespread throughout industry.

A different type of government involvement is inspection by government inspectors in relation to statutory requirements under such legislation as the Factories Act 1961 or the Nuclear Installations Act 1959.

The manufacturer usually has his own inspection system to assure quality. In some cases, the user may be involved in specifying the type of inspection system which the manufacturer should operate. Often the user sends his inspectors to carry out inspections of the equipment during its manufacture. This is routine procedure with large oil and chemical companies.

Pressure vessels are often built to the survey of insurers, particularly in the oil and chemical industries. The oldest and best known insurance organization is Lloyds of London and the certification 100 A1 at Lloyds is an accepted cachet of high quality.

Inspection is also carried out by consultant engineers, some of whom specialize in this work.

19.2.3 Approval organizations

In the United Kingdom, the *Report of the Committee of Enquiry on Pressure Vessels* (Ministry of Technology, 1969a) led to the setting up of the Pressure Vessel Quality Assurance Board (PVQAB) in 1981. The PVQAB operates a system of approval for inspection organizations.

In the United States, an approval system is operated by the National Board of Boiler and Pressure Vessel Inspectors (the National Board).

19.2.4 Inspection organization

Within the company, it is essential to have a management system which ensures effective control of all aspects of the plant, and in particular of the pressure system, throughout all the stages of its life. Such a management system was described in Chapter 6.

The inspection organization plays a key role in this system. It is responsible for the initial inspection of new equipment during its fabrication and construction, and for the periodic inspection of operating equipment throughout its working life.

The framework within which the inspection organization operates is determined by the design and operating authorities. The design authority should determine the parameters within which the plant is to operate, should specify the design codes and should carry out the actual design. It should also specify the standards for fabrication, construction and testing and should prescribe the documentation required on these aspects. The operating authority should provide a code for the regular inspection of the plant. In addition, it should create a system to control both plant and process modifications.

The inspection organization may be a part of the design authority or it may be an external body such as an engineering inspection agency or an insurance company, but whatever arrangement is adopted the inspection organization should be independent of the operating authority.

In many cases, the inspection work is divided between the company's own inspection organization and an external inspection agency. In particular, outside inspectors are commonly used to carry out the statutory inspections of steam boilers and receivers and air receivers.

The inspection organization is concerned normally with pressure vessels, pipework and protective devices. The inspection of many other types of equipment such as rotating machinery or instrumentation is carried out by the appropriate specialists, who are usually not part of the inspection organization.

19.2.5 Competent persons

Inspection is a specialist matter and should be done only by a qualified inspector. For statutory equipment such as steam boilers, the competence of the inspector has been a specific requirement of the Factories Act 1961, section 33(9).

The question of the competent person for the inspection of boilers and pressure vessels was considered in the *Report of the Advisory Committee on the Examination of Steam Boilers in Industry* (Honeyman, 1960) (the *Honeyman Report*). The report states in connection with the requirement for a competent person:

> What appears to be contemplated is that the person should have such practical and theoretical knowledge and actual experience of the type of machinery or plant which he has to examine as will enable him to detect defects or weaknesses which it is the purpose of the examination to discover and to assess their importance in relation to the strength and functions of the particular machinery or plant.

The Pressure Systems Regulations 1989 require that certain functions such as approval of the scheme of examination for pressure vessels be done by a competent person. This is discussed further in Section 19.3.

19.2.6 Inspection in manufacture and operation

Inspection activities cover the stages of (1) manufacture, (2) commissioning and (3) operation. It is hardly necessary to emphasize that the existence of an inspection system and the presence of an inspector has an important influence on the quality of the work done. Frequently the function of inspection is combined with that of progressing the work, since this has been found to be an effective way of reducing lead times.

An important aspect of inspection is planning. Specifications and drawings should be made available to the inspector as early as possible so that he can plan the stages of inspection. The inspector should try to make sure that the manufacturer's personnel are fully informed of the inspections required at the different stages of fabrication. The inspection of features such as the base metal properties and the dimensions of components should be timed to fit in with the overall fabrication schedule.

The results of inspections should be recorded as detailed inspection/test reports, but in addition it is normal to issue release notes or inspection statements, which are less detailed, or, in the case of non-acceptance, a rejection note.

The inspection of welds and other features is discussed below.

Inspection of pressure vessels during commissioning covers essentially similar features together with pressure and leak tests and other commissioning tests as described in Sections 19.7 and 19.8.

Inspection of pressure vessels during operations is carried out regularly according to a system such as that defined in Section 19.3. This relies basically on visual examination supplemented by other methods of non-destructive examination and non-destructive testing (NDT) and by condition monitoring methods. In some cases, pressure testing is necessary.

The basic principles of inspection apply also to the inspection of other equipment such as rotating machinery. In this case, however, the inspection is particularly concerned with checking the condition of the main components of the machine, the performance of the machine under the various test conditions specified and the alignment and balancing of the installed machine, as well as the condition and performance of ancillary equipment such as lubrication systems.

A certain amount of information is available in the human factors literature on errors in inspection. The main finding is that the probability of detecting a defect decreases as the probability of the defect decreases.

19.2.7 Inspection of welds

One of the most important aspects of the inspection of pressure vessels is checking the quality of welds. The methods of welding were described in Chapter 12. Minimum inspection requirements for the fabrication of welds are laid down in BS 5500: 1991 and other standards. Welds are also one of the main aspects inspected in regular inspections during operation.

An inspection system exercises control of weld quality by (1) approval of welders, (2) specification of welding materials, (3) specification of welding methods, and (4) examination/testing of welds.

There are standard qualifications and tests for various classes of welder, including BS 1295: 1987, BS 4872: 1976– and the American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code, Section IX*. In general, a welding method is specified, giving details of electrodes, welding rods, flux, shielding, metal preparation, actual welding, heat treatment and testing.

Visual examination of a weld should ensure (Pilborough, 1971):

(1) freedom from undercut, cracks, craters, blowholes and marked irregularities;
(2) correct profile;
(3) good appearance – a smooth even finish and freedom from pockets will avoid the possibility of stress concentrations leading to cracking;
(4) smooth joints where new electrodes have been started;
(5) good penetration at the root of the weld, as judged from the bead on the underside (in the case of a butt weld) prior to the application of the sealing run.

Illustrations of typical weld defects are given in BS 499: 1980 – *Welding Terms and Symbols*.

In some cases pressure vessels are fabricated on site, because they are too large to be transported. The conditions of site fabrication often make it advisable to carry out more comprehensive checks on materials and welds than the minimum code requirements.

19.2.8 Inspection of other features

Other features that are examined in pressure vessel inspection include:

(1) equipment dimensions;
(2) base metal;
(3) surface condition;
(4) wear situations;
(5) high stress situations;
(6) dissimilar metals;
(7) stray electric currents;
(8) gaskets, seals and joints;
(9) lagging;
(10) protective finishes;
(11) venting and draining;
(12) access.

The inspection should check that the dimensions of the equipment are within the permitted tolerances, that the base metal used is that specified, and that it has met the requirements. The condition of the metal surface should be inspected for defects that may give rise to crack growth. A check should be made on assemblies which may be subject to wear and on stress raisers such as sharp angles, changes of section and attachments such as nozzles or lugs. The presence of dissimilar metals and stray electric currents that may give rise to corrosion should be considered. The suitability of joints, gaskets and seals should be checked, as should that of the lagging and protective finishes. The adequacies of the vents and drains on the vessel should be confirmed and the means of access reviewed.

Other aspects of inspection, such as tests during commissioning and pressure and leak testing, are considered in Sections 19.1, 19.7 and 19.8, respectively.

19.2.9 Inspection register and records

It is essential to keep a register of the equipment to be inspected and records of the results of the inspections. The precise contents of the register depend on the item concerned, but in general should include:

(1) identification number, order number and drawing number;
(2) specification, design parameters, process fluids;
(3) inspection/test reports during manufacture;
(4) inspection category, interval, method;
(5) special features relevant to deterioration, failures;
(6) materials/parts list;
(7) design life/remnant life prediction;
(8) date of entry into service.

Such a register is equally appropriate to pressure vessels, protective devices, rotating machinery or instrumentation.

The specific information requirements given in the Institute of Petroleum (IP) *Pressure Vessel Examination Code* for the registration of pressure vessels are described in Section 19.3.

For a pressure vessel there should be full information on the inspections/tests done during its manufacture, including reports on tests on the material of construction, radiographs or other records of tests on welds, and reports on pressure and leak tests.

Reports of the regular inspections/tests on the equipment should be prepared and filed in the register. These reports should generally cover the results of the main inspection/test and of any additional monitoring and tests, any deterioration or failure detected and repairs carried out, and any modifications or changes of duty.

19.3 Pressure Vessel Inspection

The inspection of pressure vessels and their protective devices is crucial to the maintenance of the integrity of the pressure system and is a principal activity of the inspection authority.

Pressure vessels come within the Pressure Systems Regulations 1989 and are covered in the guidance HS(R) 30 and in COP 37. A relevant code is the *Pressure Vessel Examination Code* by the IP (1993 MCSP Pt 12). The account of pressure vessel inspection given here is based primarily on this code.

19.3.1 Competent person

The IP *Pressure Vessel Examination Code* defines the competent person as the person or body authorized by the user to draw up or approve the scheme of examination and to perform the examination. In the United Kingdom, the competent person may be company personnel or an external body specializing in the inspection of pressure vessels. The attributes of the competent person are given in COP 37.

19.3.2 Design authority

The design of the pressure vessel is the responsibility of the design authority. The IP *Pressure Vessel Examination Code* states that the design authority may be a vessel design group responsible to the user, an authorized design contractor, an independent design consultant, the engineering authority or the competent person. In some countries, the design authority is a state agency.

19.3.3 Engineering authority

The engineering authority is responsible for the maintenance of the pressure vessel and is authorized to do this by the user.

19.3.4 Definition

In considering an inspection scheme, it is necessary first to define the equipment which is to be brought within the scope of the pressure vessel inspection system. The IP *Pressure Vessel Examination Code* defines a pressure vessel as follows:

> A closed vessel consisting of one or more independent chambers, any or each of which may be subject to an internal pressure greater than 0.5 barg, or as defined by National Legislation.

The code explicitly excludes vessels subject to pressure solely by static head and storage tanks designed and constructed to codes and standards such as BS 2654 and BS 2594.

This definition of a pressure vessel supersedes that given in the previous *Pressure Vessel Inspection Safety Code* by the IP (1976 MCSPPt 12) which was:

> (i) A closed vessel of not less than 0.1 m^3 capacity consisting of one or more independent chambers any or each of which may be subject to an internal pressure greater than 70 mbar gauge or less than 930 mbar absolute or
>
> (ii) A closed vessel wherein $P \times V > 1$ where P is the internal pressure in bars and V is the enclosed volume in cubic metres.

Also of interest is the definition given in the ICI *Pressure Vessel Inspection Code* for vessels falling within the scope of that code:

> A pressure vessel is a closed vessel of any capacity consisting of one or more independent chambers, any or each of which is or may be subjected to internal pressure greater or less than atmospheric.

This definition includes:

> (a) Vessels not normally subject to internal pressure but in which internal pressure would occur in the event of a failure of any part, maloperation, isolation or other circumstances, for example, the failure of an internal steam coil in a vessel not adequately vented to prevent a pressure rise.
>
> (b) Vessels in which vacuum can develop, for example, steam receivers, steam condensers and other vessels containing condensable gases and vapours.

For other equipment the code states:

> Consideration should also be given to the registration and routine inspection of other items which although not normally classified as pressure vessels may give rise to hazardous situations, e.g. fired equipment, large diameter piping, expansion bellows, and pressurized equipment subjected to erosive or corrosive conditions. Where cross-country pipelines are employed special arrangements will be necessary for their routine examination.

The *IP Pressure Vessel Examination Code* defines a protective device as:

> A device designed to protect the pressure system against system failure and certain devices designed to give warning that system failure might occur, safety valves, bursting discs or combination of both.

The definition of a protective device given in the ICI *Pressure Vessel Inspection Code* is:

> Any automatic device which protects equipment from over-pressure, over-temperature, over-filling, corrosion, explosion or other hazardous conditions; including atmospheric vents, lutes, flame traps, deadweight flaps, some non-return valves, relief valves, fusible plugs, bursting discs and instrumental trip systems, many of which incorporate an advance alarm indication.

The ICI *Code* also lists equipment which, subject to approval, may be excluded from the requirements of the code itself, although it may still require some degree of inspection. Some important items in this list are vessels subject to static head only or to applied pressure not exceeding $+0.07$ bar ($+1$ $\mathrm{lb_f/in.^2}$) and not subject to corrosive risks; parts of prime movers and machines driven by them; protective devices whose failure does not result in a hazard.

19.3.5 Registration

A pressure vessel identified as such should be registered before it is brought into service. The system given by the IP *Pressure Vessel Examination Code* is broadly as follows.

The vessel should be given an identification number and there should be created for it a records file and, where applicable, a scheme of examination.

The required contents of a records file as described in the IP *Code* are essentially similar to those given in the ICI *Pressure Vessel Inspection Code*, which are as follows:

> For equipment the file shall include its identification number, the order number, the drawing reference, specifications, materials lists, inspection reports during manufacture, test certificates relating to the material and tests on the completed equipment. It shall also contain details of the design conditions, the process fluids, of the expected operating conditions, and the date of entry into service. In addition, the file shall include a note of any special kinds of deterioration – for example, stress corrosion – to which the equipment may be subject.

The IP *Code* requires that the information include the safe operating limits of the vessel and, where available, the limit criteria for its retirement with notes on their derivation.

The record file should give the equipment classification and inspection categories. It should specify the initial and subsequent inspection intervals, the type of inspection to be done and, where appropriate, the inspection acceptance standards.

To this initial information should be added other relevant information generated during the life of the equipment. This includes: reports of periodic inspections and tests; reports of failures, failure examinations and repairs; records of corrosion and other condition monitoring and details of modifications or changes of duty. Where a document cannot be kept in the record file itself, there should be a cross-reference to it.

The registration of protective devices is along broadly similar lines. The IP *Code* requires that its record file contain information on its function and operation, including drawings, a specification of the duty, supplier's details on the style and type of device, materials of construction and any special features, together with reports of examinations and tests.

19.3.6 Classification

A pressure vessel is generally classified according to whether or not it is subject to legal requirements for inspection. The IP *Pressure Vessel Examination Code* assigns a vessel to Classification A or B. Class A includes all vessels and their protective devices that are subject to periodic examination in accordance with national or regional legal requirements. The extent of the classification is therefore a function of the country or state where the vessel is to be used. Class B includes all vessels and their protective devices not assigned to Class A. It covers all vessels which are not subject to legal requirements.

Where the legal requirements permit, Class A pressure vessels and protective devices should be further allocated to a grade, namely to Grade 0, 1, 2 or 3, as described in Section 19.3.7.

The code states that the regulatory requirements in the United Kingdom are primarily aimed at ensuring the periodic examination of equipment which contains significant quantities of stored energy from compressible fluids and that many items of equipment which contain flammable or toxic liquids are effectively exempt, but that such examination is nevertheless beneficial, and it suggests that the inspection philosophy described for Class A equipment be applied to Class B equipment also.

19.3.7 Grading

As stated above, the IP *Pressure Vessel Examination Code* requires that, where legal requirements permit, the pressure vessel and its protective device be allocated to a grade. The grade indicates the maximum interval that may elapse between major examinations.

The principles of grading are that: the vessel receives a pre-commissioning examination before entering service; it is initially allocated to Grade 0 and is given a first thorough examination after a relatively short period of service; it is then either retained in Grade 0 or allocated to Grade 1 or 2; subsequently, after a second thorough examination, it is allocated to Grade 1, 2 or 3 and, as it approaches the end of its design life or predicted remaining life, it is reallocated to a lower grade if necessary.

Equipment is allocated to Grade 0 when it first enters service and also where the foreseeable deterioration is at a fairly rapid rate, but still consistent with this grade, or where there is insufficient knowledge of operational effects to predict its behaviour in service.

Equipment is allocated to Grades 1 or 2 where deterioration is at a rate that is predictable and consistent with the grade, the knowledge of its actual behaviour justifies allocation to the grade or where there are reliable means of assessing the operational effects and/or the associated deterioration.

Equipment is allocated to Grade 3 where deterioration is at a rate that is low and consistent with the grade, or the knowledge of actual service conditions justifies allocation to the grade.

Transfer between grades, either upwards or downwards, is made on the basis of the examinations.

A variation to this procedure may be used where a group of vessels are substantially the same with regard to design and construction and to conditions of service so that they may reasonably be expected to deteriorate in a similar way and, where the appropriate grade is Grade 1 or above, grading may be based on sample examinations of vessels in the group. The IP *Code* gives the rules governing this procedure.

Another permitted variation applies where a substantially new vessel is the same with regard to design and construction as an existing vessel and is to be used under the same, known conditions of service. In this case, the vessel may be allocated the same grade as the existing vessel.

A grading review of a vessel is required in any one of the following circumstances: (1) there is a significant change in its conditions of service; (2) an abnormal incident has occurred which could affect its deterioration; (3) on-line inspection indicates a significant change in its condition or (4) it is approaching its design life, or it is proposed to extend its service life beyond the design value.

The grading of protective devices is subject to two general principles. The interval between examinations for the device should not exceed that for the vessel protected and it should not exceed that given in Section 19.3.8. Factors which govern the inspection interval are discussed in Chapter 13.

19.3.8 Examination intervals

The maximum examination intervals given in the IP *Pressure Vessel Examination Code* are shown in Table 19.10, Section A. The longest of these maximum intervals is therefore 144 months, or 12 years. On the basis of the classification of equipment it is possible to specify inspection categories that define the interval between inspections.

19.3.9 Examination principles

The IP *Pressure Vessel Examination Code* states that the purpose of examination is:

> To ensure that equipment remains in a satisfactory condition for continued operation consistent with the prime requirements of safety, compliance with statutory regulations and economic operation until the next examination.

The code distinguishes between the pre-commissioning examination, the first examination (after the vessel has been put into service) and subsequent examinations. The purpose of the pre-commissioning examination is to ensure that the examination and tests specified for the manufacture of the equipment have been done, that the documentation is in place with a record of any significant defects, that there is a basis for the assessment of deterioration in future examinations and that a check is made to ensure that no damage has occurred since the examination during manufacture. The first in-service examination is done to ensure that any defect in design or materials is detected and that suitable components are selected, examined and measured, so as to form the basis for the assessment of corrosion or wastage in future examinations.

The ICI *Pressure Vessel Inspection Code* defines the objectives of inspection as follows:

> The objective of vessel inspection is to detect any deterioration such as corrosion, cracking or distortion indicating possible weaknesses that may affect the continued safe operation of the vessel. Primarily inspection should be visual, but it shall be supplemented by other techniques and measurement when necessary to determine the extent of any losses of thickness, pitting, cracking, etc. Resorting to a pressure test as the sole method of periodic inspection is an inferior alternative to examination and should be used only when examination is not practicable or the findings of the visual examination are inconclusive.

The inspection should also include an examination of protective devices.

19.3.10 Examination practices: pressure vessels

The maximum interval between examinations is set by the grade to which the vessel is allocated. The IP *Pressure Vessel Examination Code* gives a number of additional factors that are to be taken into account in deciding on the actual interval. These include: any regulatory requirements; the works policy; the severity of the duty; the performance of other vessels on similar duty; the ability to carry out meaningful on-stream inspection and the remaining design life and the predicted remaining life. Other factors in particular applications are catalyst life and regeneration intervals, and performance of internal linings. It is also necessary to consider the consequences of failure.

The IP *Code* also refers by way of caution to three aspects that may require special attention: (1) lined vessels; (2) internal fittings and (3) external lagging, cladding and fireproofing. Lining failure may cause a vessel to deteriorate rapidly and this should be taken into account in setting the examination interval. Internal fittings hinder inspection and are often difficult to remove, but may also promote deterioration; they should be removed as necessary to permit adequate examination. Parts of the outer shell and

Table 19.10 *Maximum examination intervals for pressure vessels, protective devices and piping systems (Institute of Petroleum, 1993 MCSP Pts 12 and 13) (Reproduced by permission)*

	Grade 0	*Grade 1*	*Grade 2*	*Grade 3*
Piping systems	36	48	84	144

features such as anchor bolts, skirt attachments and saddle support surfaces may need to be checked at each examination. Sections of lagging or fireproofing may need to be removed for examination where conditions favourable to external corrosion exist.

There are various preparatory measures that need to be taken before an inspection is carried out. The inspector should brief himself on the history of the vessel and, where applicable, on that of other similar vessels.

The vessel is normally taken out of service, isolated, emptied and cleaned. The surfaces of the vessel are then exposed and prepared for examination. This may involve such measures as cleaning of internal surfaces, the removal of some internal fittings and the removal of lagging from the outside of the vessel. These activities should be covered by appropriate procedures and permit-to-work systems, as described in Chapter 21. The examination is then carried out.

The matters to be recorded following the examination are given in the IP *Code*. They should cover: the scope of the examination; the items examined and the examination techniques used; a qualitative description of the findings backed up by a quantitative measure; a specification of any repairs or modifications required; relevant repair and non-destructive examination procedures; a note of any changes to the safe operating limits or any remaining life predictions; a review of the scheme of examination and the grading previously selected and a date for the next examination. The *Code* gives an appendix containing examples of examination reports.

The IP *Code* recognizes the value of on-stream methods of examination, but states that in general they complement rather than replace visual examination.

19.3.11 Examination practices: protective devices

The IP *Pressure Vessel Examination Code* divides protective systems into pressure-actuated devices and other devices. In the former category it discusses regular safety valves, pilot-operated safety valves and bursting discs.

For a safety valve, the code requires that the valve be removed, immediately tested on a suitable test rig to determine the pressure at which the valve would have lifted in service and the results recorded. The valve should then be dismantled, cleaned, repaired, restored, lapped and reset to the correct cold differential test pressure. For pilot-operated safety valves, where it is not normally practical to remove the main valve, the testing is confined to the pilot valve.

In the second category the IP *Code* deals with: fusible plugs; thermal sensors, alarms and trips; sensors and alarms on other variables and non-return valves.

The *Code* also discusses the need to maintain adequate overpressure protection of the vessel at all times and the isolation practices necessary to achieve this.

19.3.12 Modification and repair

The *IP Pressure Vessel Examination Code* requires that any modification necessary on a pressure vessel should be approved by the design authority and the competent person, and that the design and execution of any modification or repair be under the control of the latter. The effect on any protective devices on the piping system of any modifications or repairs on that system should be considered.

Records should be kept of any modifications or repairs carried out, and should include the original approval procedure documents together with details of materials and techniques, drawings and test certificates.

Where a vessel has been subject in its construction to stress relief or heat treatment, welding should not be undertaken without the approval of the competent person.

19.3.13 Vessel testing

The *IP Pressure Vessel Examination* Code discusses five forms of testing: (1) strength testing, (2) leak testing, (3) NDT, (4) destructive testing and (5) materials analysis. Any of these may be used at the various stages of the vessel's life, but the last two are used mainly at the construction stage or in connection with modification or repair.

Pressure and leak testing are considered in Sections 19.7 and 19.8, respectively.

19.3.14 Defects and failures

An account of defects and failures in pressure vessels is given by Pilborough (1989). Some of the features that may be revealed by an inspection are:

(1) internal corrosion;
(2) surface defects;
(3) weld defects;
(4) wear defects;
(5) deposits and debris;
(6) high stress situations;
(7) inadequate drainage;
(8) external corrosion.

Some of the types of internal corrosion that occur in process plant were described in Chapter 12. Corrosion may reduce not only the thickness of the metal but also its strength. Methods of detection include visual examination, thickness measurement, including measurements by ultrasound and corrosion monitoring. Changes to a base metal such as graphitization or hydrogen embrittlement may be detected by metallurgical examination.

Surface defects such as cracks or pitting arising from such causes as corrosion, erosion or crack growth may be detected by visual examination or by methods such as magnetic particle or dye penetrant techniques. The avoidance of surface defects is particularly important where there is a risk of fatigue failure, since a rough surface can greatly reduce the fatigue strength of steel.

These methods of crack detection may also be used to find weld defects. The latter include weld deterioration, which may arise due to the roughness of the weld, or weld decay, which is intergranular corrosion and occurs in austenitic stainless steels.

Cracks may be particularly serious as they can grow and lead to failure. It is often possible to remove a crack from a weld by chipping it out and depositing fresh weld metal. Small cracks may sometimes be stopped by drilling small holes at the extremity, which reduces the stress concentrations.

Wear on moving parts is normally found by visual examination and may result in failure if not rectified.

The build-up of deposits of materials and/or debris can create a hazard if equipment such as pipes and valves, or devices such as vents, pressure relief valves or instruments become blocked. Such deposits are revealed by visual examination.

There are certain undesirable features which, insofar as is practicable, are eliminated in the original design of equipment, but which may be reintroduced by plant modifications. High stress situations may have been created at vessel connections or at lugs. There may be elements that are under stress due to the limitation of thermal expansion or contraction. Similarly, modifications may have been made which impede complete drainage. Visual examination may detect these facts.

External corrosion of the plant is detected by visual examination. It can be severe and can lead to serious loss of metal thickness.

19.4 Pressure Piping Systems Inspection

Most releases occur not from pressure vessels but from the associated piping systems. Inspection of piping systems is therefore important. Pressure piping systems come within the Pressure Systems Regulations 1989 and are covered in the guidance HS(R) 30 and in COP 37. A relevant code is *Pressure Piping Systems Examination Code* (IP, 1993 MCSP Pt 13). The account of pressure piping systems inspection given here is based primarily on this code. The provisions of this code largely mirror those of the *Pressure Vessel Examination Code* (IP, 1993 MCSP Pt 12), and to the extent that this is so they are not repeated here.

The definitions of the competent person, the design authority and the engineering authority for piping systems are essentially the same as those for pressure vessels, with the former term being substituted for the latter one.

19.4.1 Selection

The process of selecting pipework for registration in the inspection system is the equivalent to the definition of pressure vessels. The IP *Pressure Piping Systems Examination Code* states that pipework need not be physically identified on site by an identification number provided the major plant items are so marked that pressure piping attached to them can be identified.

The criteria for selecting piping for registration are that there is a legal requirement or that the piping is known or suspected to deteriorate and its failure would give rise to an unacceptable situation.

19.4.2 Registration

For new piping the IP *Pressure Piping Systems Examination Code* recommends that the records file contain the identification number, the drawing references, the isometric drawing, specifications, materials lists, the material specification, the constructional acceptance and test certificates, the design data/safe operating limits, the scheme of examination and the retirement limit criteria.

For existing piping the *Code* states that where some of the above information is not available, the recommended records are the identification number, the drawing references, an up-to-date drawing/sketch defining the extent of the system, the piping specification to which repairs or modifications should conform, the design data/safe operating limits, the scheme of examination and a recent assessment report.

For piping systems there is no process corresponding to that of the classification of pressure vessels, but it is necessary to make arrangements to ensure that unregistered piping systems are nevertheless examined so that they remain fit for continued service.

19.4.3 Grading

The IP *Pressure Piping Systems Examination Code* states that, where legal requirements permit, a registered piping system should be allocated to a grade.

The principles of grading are that: the piping system receives a pre-commissioning examination before entering service; it is allocated to Grade 0 unless knowledge of service conditions is such that it can be allocated to Grade 1 or 2; subsequently, following the first and second thorough inspections and on the basis of knowledge of service conditions and of the condition of the piping system, it is allocated to Grade 1, 2 or 3 and as it approaches the end of its design life or predicted remaining life it is reallocated, where necessary, to a lower grade.

The detailed rules for grade allocation and grading review of piping systems given in the *Code* are essentially similar to those for pressure vessels. For protective devices, the code refers to the IP *Pressure Vessel Examination Code*.

19.4.4 Examination intervals

The maximum examination intervals prescribed by the IP *Pressure Piping Systems Examination Code* are given in Table 19.10, Section B. The longest of these intervals is thus 144 months, or 12 years.

19.4.5 Examination principles

The purpose of the examination of piping systems given by the IP *Pressure Piping Systems Examination Code* is essentially the same as for pressure vessels.

The *Code* distinguishes between the pre-commissioning examination, the first examination (after the piping system has been put into service) and subsequent examinations. For the former it also draws a distinction between new and existing installations. For new installations the purpose of the pre-commissioning examination is to ensure that the examination and tests specified have been done and that the documentation is in place, whilst for an existing installation it is to establish any history of deterioration and to ensure that the condition of the pipework is surveyed. The first in-service examination is done to ensure that any defect in design, fabrication or materials is detected and that suitable components are selected, examined and measured, and the results recorded, so as to form the basis for the assessment of corrosion or wastage in future examinations.

19.4.6 Examination practices

The maximum interval between examinations is set by the grade to which the piping system is allocated. The IP *Pressure Piping Systems Examination Code* gives in Appendix A a number of additional factors which are to be taken into account in deciding on the actual interval. They include: any regulatory requirements; the age and general condition; the severity of the duty, in terms of corrosion, erosion and vibration; the proximity to systems containing corrosive fluids; any abnormal flows; any vulnerable components such as bellows and expansion joints and small bore connections; the pipework supports; any special features and the ability to carry out meaningful on-stream inspection. It is also necessary to consider the consequences of failure.

Any necessary preparatory measures should be taken before an examination is carried out. These may include the provision of a means of access and lighting and preparation of surfaces.

The matters to be recorded following the examination are given in the IP *Code*. They should cover: the scope of the examination; the items examined and the examination techniques used; a qualitative description of the findings, backed up by a quantitative measure; a specification of any repairs, renewals or modifications required; the relevant repair and NDE procedures; any changes to the safe operating limits or any remaining life predictions; a review of the scheme of examination and of the grading previously selected and a date for the next examination.

The IP *Code* also refers by way of caution to several aspects that may require special attention: (1) lined pipes; (2) external lagging and fireproofing; (3) valves and fittings; (4) buried piping and (5) bellows. The considerations relevant to lined pipe and external lagging and fireproofing are broadly similar to those pertaining to pressure vessels. Valves and fittings need special consideration on account of possible casting defects, regions of high turbulence, local stress concentrations due to thermal expansion and other stresses and vibration. Buried pipelines are usually protected from external corrosion by cathodic protection (CP), but there are vulnerable areas near ground level where protection can break down and corrosion occurs. The CP systems themselves should be subject to periodic examination and a record kept of the CP potentials. Consideration should be given to the inspection of the inside of the pipeline by an 'intelligent pig'. Bellows should be examined immediately after commissioning to check: that the relative movement is being absorbed as intended and examined periodically to look for cracks or leaks; for any distortion or yielding of anchors or seizing or binding of guides; for any unanticipated movement of the parent piping and for any permanent distortion of the bellows.

If the pipework has been subjected to any abnormal operating conditions or other abnormal conditions such as fire, appropriate checks should be made. Possible causes of deterioration may be: damage to bellows; cracking of ferritic alloy or austenitic stainless steels; hardening of air-hardening ferritic alloy steel or zinc embrittlement of stainless steel.

The examination practices for protective devices are essentially as given in the IP *Pressure Vessel Examination Code*.

19.4.7 On-stream examination methods

The IP *Pressure Piping Systems Examination Code* states that some piping systems may be satisfactorily examined by means of on-stream methods and gives in Appendix B guidance on methods that may be applied.

The methods described are: (A) walking the main; (B) selective and (C) extensive non-destructive testing (NDT) for thickness gauging; (D) selective and (E) extensive removal of insulation and external examination; (F) monitoring by indirect measurement; (G) use of thermal indicators and thermal imaging; (H) profile radiography and (I) flash radiography. The methods of indirect measurement cited include corrosion probes and coupons and pH recording. The thermal indicators mentioned are temperature sensitive paints or crayons. Profile radiography involves firing a beam tangential to the wall of the pipe and produces a profile image of the internal and external profile of the pipe. Flash radiography is similar but gives information on the external surface.

Features to be checked in walking the main include: damage to the pipe; damage to insulation; the condition of joints, valves and fittings; lack of adequate support; lack of ground clearance; vibration or excessive movement; leaks from or onto the pipe and abuse of the pipe.

The *Code* also gives in the same appendix the following off-stream methods: (J) hammer testing; (K) pressure testing; (L) internal examination; (M) interval viewing and (N) special techniques.

19.4.8 Modification and repair

The IP *Pressure Piping Systems Examination Code* requires that any modification made to a registered pressure system should be approved by the design authority and any repair be subject to the approval of the competent person.

The effect on any protective devices on the piping system of any modifications or repairs on that system should be considered. Following modification or repairs a grading review should be carried out.

Records should be kept of any modifications or repairs carried out, and should include the original approval procedure documents together with details of materials and techniques, drawings and test certificates.

Where there may have been in the original construction of piping system a requirement for heat treatment, a check should be made and, if it was required, reference should be made to the engineering authority or competent person who should then define any requirements.

19.4.9 Piping system testing

The account of testing given in the IP *Pressure Piping Systems Examination Code* follows essentially that given in the IP *Pressure Vessels Examination Code*, and deals mainly with strength testing by hydraulic or pneumatic pressure tests and with leak testing.

19.5 Non-destructive Testing

Non-destructive testing techniques are used to detect defects in equipment such as pressure vessels and pipework during both its construction and its operational life.

Equipment is tested by NDT testing methods during fabrication. Pressure vessel codes such as BS 5500: 1991 lay down detailed NDT requirements. These are minimum requirements. For some pressure equipment, it may be necessary to carry out more extensive testing. This is particularly the case where equipment has been fabricated on site.

It may be necessary to carry out further NDT of some equipment during construction and commissioning.

The condition of the equipment during the operation of the plant is checked by NDT, particularly, but not exclusively, during plant shut-down.

Once the plant is operational, it becomes difficult to obtain access for visual examination of some parts of the equipment, for example the internal surface of a refrigerated storage tank, so that NDT techniques that can be used externally become very attractive.

Accounts of NDT are given in *Non-Destructive Testing* (Hinsley, 1959), *Techniques of Non-Destructive Testing* (Hogarth and Blitz, 1960), *Principles and Practice of Non-Destructive Testing* (Lamble, 1962), *Non-Destructive Testing* (Birchon, 1975), *Pressure Vessel Systems* (Kohan, 1987), *Non-Destructive Testing of Large Diameter Pipe for Oil and Gas Transmission Lines* (Weisweiler and Sergeev, 1987) and *Inspection of Industrial Plant* (Pilborough, 1989).

Some NDT and monitoring methods are:

(1) visual inspection –
    (a) boroscopes;
(2) radiography –
    (a) X-rays,
    (b) γ-rays;

(3) ultrasound;
(4) magnetic methods –
    (a) magnetic particles,
    (b) magnetic prints,
    (c) eddy currents;
(5) dye penetrant methods;
(6) stress wave emission monitoring;
(7) holography;
(8) electrical measurements –
    (a) resistivity,
    (b) capacitance.

These methods are now described in more detail.

19.5.1 Visual examination

Visual examination is the original and most widely used method of inspection and is non-destructive. Accounts are given in *Visual Examination* (Keymed Industrial, 1983) and by Elonka (1975), Kohan (1987) and Pilborough (1989).

Visual inspection is effective in detecting surface defects ranging from cracks to corroded areas, and defective assemblies.

The range of visual examination can be extended by the use of aids such as periscopes or boroscopes. Boroscopes are available with lens or fibre optics. They are used to examine the condition of internal components such as the blades of turbines and compressors.

BS 5500 requires only visual examination for Category 3 pressure vessels.

19.5.2 Radiography

An important NDT method is X-ray radiography. Radiographic examination is covered by BS 2600: 1973– *General Recommendations for the Radiographic Examination of Fusion Welded Butt Joints in Steel* and in various other British Standards, some of which are given in Appendix 27. Accounts are given by Kohan (1987) and Pilborough (1989).

X-ray radiography is used during fabrication to detect internal defects, principally in welds but also in the parent material.

BS 5500 requires NDT by radiography and/or ultrasound for welded joints on Category 1 and 2 pressure vessels. Details are given below.

The X-rays used are produced by an X-ray machine which is relatively immobile and expensive. X-rays are recorded on a photographic plate. In X-ray radiography it is important that there be a high quality image. Standards generally call for a technique which is capable of recording deviations from the normal of not more than 2% of the maximum thickness of the item under test and specify the use of image quality indicators, or penetrameters. Image indicators are dealt with in BS 3971: 1980.

The interpretation of X-ray radiographs is a skilled matter and contains a considerable subjective element. The first step is to identify the type of defect and the second is to quantify it, if quantification is appropriate. The terminology and symbols for weld defects are given in BS 499: 1980 and BS 4727: Part 5, Group 01: 1985. Some of the principal defects that occur in welds are:

(1) planar defects –
    (a) cracks,
    (b) lack of fusion (side, root, interrun),
    (c) lack of root penetration;
(2) cavities –
    (a) porosity (isolated, localized, linear),
    (b) wormholes (isolated, aligned),
    (c) crater pipes,
    (d) surface cavities;
(3) slag inclusions;
(4) other solid inclusions –
    (a) tungsten,
    (b) copper.

Once a defect has been identified, it is necessary to decide whether it is sufficiently serious to require that the weld be rejected. This has again tended to be a subjective matter and has therefore caused considerable difficulty. In consequence, much work has been done to develop acceptance standards. BS 5500 contains a list of defects similar to that given above, together with corresponding acceptance levels.

X-ray radiography is used to detect internal defects in the parent metal, such as in pressure vessel walls, pipework or castings, as well as in welds.

γ-rays are also used for radiography. They are produced by a radioactive isotope source such as cobalt-60. Equipment using γ-rays is portable and relatively cheap. It is used particularly for the radiography of castings. The method is to arrange the castings in a circle with the γ-ray source in the centre and with photographic plates behind the castings. Isotope sources have a relatively large area emitting radiation (usually about 2–6 mm diameter) and therefore tend not to give such good definition as X-rays.

If a permanent record is not required, X-rays may be used with a fluorescent screen instead of a radiographic plate. X-ray fluoroscopy is widely used for the rapid inspection of components on conveyor belts in order to detect coarse defects and unwanted objects. Another technique for rapid inspection is nucleonic gauging of the thickness of materials by passing β-rays through the material.

19.5.3 Ultrasonics

Ultrasonics is another important NDT technique. This is dealt with in BS 3923: 1972– *Methods for Ultrasonic Examination of Welds*, and the terminology is given in BS 3683: Part 4: 1985. Accounts are given by Birchon (1975), Kohan (1987), Weisweiler and Sergeev (1987) and Pilborough (1989).

Ultrasonics is used during fabrication as an alternative to radiography, to detect internal defects in parent metal and in welds. It is also used to measure thickness. BS 5500 generally gives ultrasonics as an acceptable alternative to radiography for examining welded joints on Categories 1 and 2 pressure vessels.

Ultrasonic waves are generated by a transmitter and detected by a receiver and are usually displayed on an oscilloscope or recorder. Two basic techniques in ultrasonics are (1) transmission and (2) reflection.

In a transmission method the ultrasonic waves are generated by a transmitter on one side of the item under test and are detected by a receiver on the other. The method is shown in Figure 19.1 (a).

The reflection method generally uses pulsed waves that are generated by a transmitter and detected by a receiver on the same side of the item. One way in which the method may be applied is shown in Figure 19.1(b), which is known as the A scan. Another application is the B scan, which is shown in Figure 19.1(c). Both these methods give the depth of the

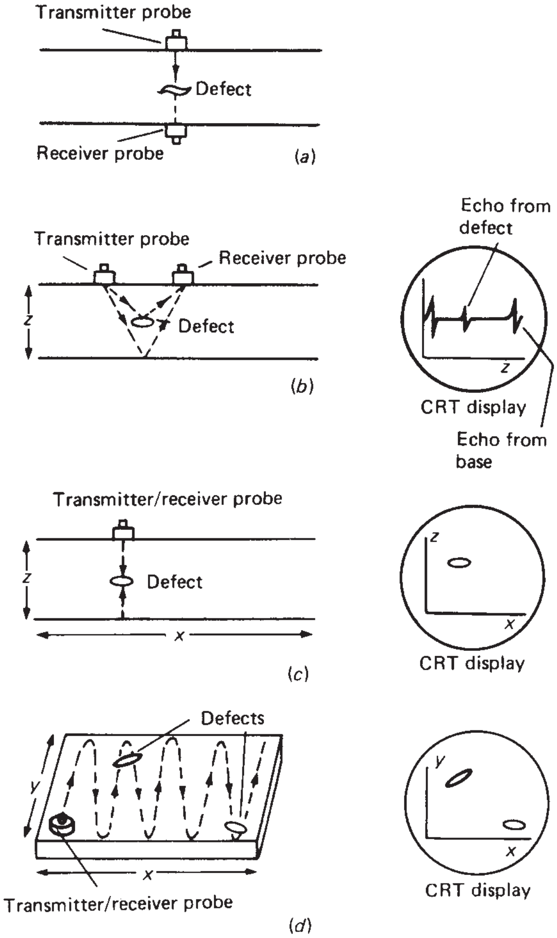

Figure 19.1 *Some ultrasonic testing methods: (a) transmission method; (b) reflection method – A scan; (c) reflection method – B scan; (d) reflection method – C scan*

defect. A third method is the C scan, shown in Figure 19.1 (d), which does not show the depth.

A number of other arrangements for the application of ultrasonics are described by Weisweiler and Sergeev (1987).

The beam of waves produced in ultrasonics is not a simple parallel bundle of uniform intensity over the cross-section, and some expertise is required in the interpretation of ultrasonic measurements.

With regard to the choice between radiographs and ultrasonic techniques for welded joints, BS 5500 states:

> Radiographic and ultrasonic methods both have advantages and disadvantages in so far as flaw detection, identification and sizing are concerned. Radiography is particularly suitable for the detection and identification of Volume' defects such as cavities and solid inclusions and incomplete penetration where a gap exists. Ultrasonic flaw detection is very suitable for the detection and sizing of planar defects such as cracks, lack of fusion and 'tight' incomplete penetration in ferritic steels. The two techniques are therefore to be regarded as complementary and the method chosen which is most suited to the particular application and material. An important consideration is joint geometry that may have an overriding influence on the choice of method. In exceptional cases it may be necessary to employ both methods on the same seam.

Ultrasonics is also used during operational inspections to detect weld defects and to measure thickness.

19.5.4 Magnetic particle methods

A method applicable mainly to surface defects is magnetic particle inspection. This is treated in BS 6072: 1981 *Method for Magnetic Particle Flaw Detection* and in several other British Standards, some of which are listed in Appendix 27. The terminology is given in BS 3683: Part 2: 1985. Accounts are given by Birchon (1975), Kohan (1987) and Pilborough (1989).

Magnetic particle methods are applicable to ferromagnetic materials and are used to detect surface and some subsurface defects. BS 5500 gives magnetic particle techniques as an acceptable method for the testing of welds for surface defects.

There are various methods of magnetic particle testing, but the basic principle is to magnetize the item and coat it with a dry powder of iron or iron oxide particles, or, more usually, a wet powder or 'ink' of particles suspended in kerosene. The particles concentrate at places where there is no continuous magnetic path such as cracks. Defects may then be detected visually. As a further aid to visual detection, a fluorescent substance may be added to the particles and an ultraviolet lamp used. Defects show up best when they are at right angles to the lines of magnetic flux, and it is usual to test the component in two different planes. It is often necessary to demagnetize the item, which is usually done by subjecting it to a magnetic field in the reverse direction to that of the initial one and then gradually reducing the field strength.

19.5.5 Eddy current methods

Magnetic particle methods are applicable only to ferromagnetic materials. An alternative that can be used for the detection of defects in conducting materials, ferrous and non-ferrous, is eddy current testing.

Eddy current testing is dealt with in BS 3889: 1966 *Methods for Non-destructive Testing of Pipes and Tubes* and terminology is given in BS 3683: Part 5: 1965. Accounts are given by Birchon (1975), G. Johnson and McFarlan (1978), Holloway, Bauer and Pittman (1981), Kohan (1987 and Pilborough (1989).

In eddy current testing the item is subjected to an alternating magnetic field that induces eddy currents in it. These induced currents are measured and defects are detected from variations in the current.

Eddy current testing is used principally for the detection of flaws in tubes, both in production lines and on plant. Figure 19.2 shows a defect in a brass tube which passed a 1000 lb/in.^{2} hydraulic test but was detected by eddy current testing.

In the process industries, eddy current testing is used particularly on heat exchanger tubes. An account of this application is given by G. Johnson and McFarlan (1978), who describe the testing of tubes by the insertion of a probe. Defects that can be detected include pitting corrosion and wall thinning.

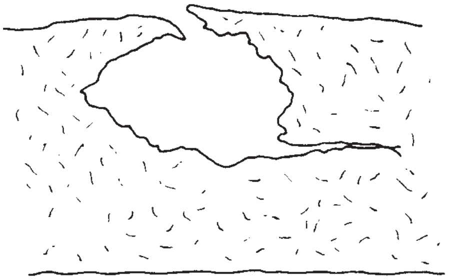

Figure 19.2 *Defect in the wall of a brass tube which had passed a hydraulic test but which was found by an eddy current test (Pilborough, 1989) (Courtesy of Gower Press)*

An account of eddy current testing of furnace and reformer tubes with emphasis on the metallurgical aspects, is given by Holloway, Bauer and Pittman (1981).

19.5.6 Dye penetrant methods

Another method for the detection of surface flaws is dye penetrant testing. This is covered in BS 6443: 1984 *Method for Penetrant Flaw Detection* and the terminology is given in BS 3683: Part 1: 1985. Accounts are given by Birchon (1975), Kohan (1987) and Pilborough (1989).

BS 5500 gives dye penetrant methods as an acceptable method of testing welds for surface defects, and requires this method, rather than magnetic particle testing, to be used for austenitic steels.

The original dye penetrant method was to immerse the item in a heated mixture of paraffin and oil, dry it and clean it, and then dust it with chalk. On cooling, the oil seeps out of any cracks in the article and stains the chalk. More modern methods use variations on this, such as special white developer and red dye.

19.5.7 Other methods

There are a growing number of other NDT methods, such as stress wave emission analysis, holography and electrical resistance methods. In some cases these techniques are used for inspection mainly during fabrication, but in others their application is to operational inspection. Some of the latter are considered in Section 19.11.

19.5.8 Non-destructive testing of welds

The distinction between different categories of pressure vessel is largely based on the extent of the NDT of welds. For vessels in Category 1, BS 5500 gives the following requirements for the examination of internal flaws:

> The full length of all Type A welds shall be examined by radiographic or ultrasonic methods. Unless otherwise agreed between the purchaser and the manufacturer (see table 1.5), the full length of all welded joints of Type B in or on pressure parts shall be examined by ultrasonic and/or radiographic methods where the thinnest part to be welded exceeds the limits given in table 5.6.4.1.1.

For the examination of surface flaws, the Standard states:

> The full length of all Type B and all other attachment welds shall be examined by magnetic particle or penetrant methods. Type A welds shall be examined by these methods when agreed between the manufacturer, the purchaser and the Inspection Authority (see table 1.5).

For vessels in Category 2 the requirements of the Standard for internal flaws are radiographic and/or ultrasonic examination of 10% of the welds at certain defined locations, the minimum length of weld to be examined at each location being 200 mm or the length of the weld, whichever is the lesser. There are also certain requirements for particular features. For surface flaws the Standard requires examination by magnetic particle and/or dye penetrant methods and states that examination is to be conducted on both of the following:

> (a) the full length of welds attaching nozzles, branches and compensating plates, to shell and end plates; (b) at least 10% of the length of all other attachment welds to pressure components.

For vessels in Category 3 the Standard does not require NDT for internal flaws unless details producing significant thickness tensile stress are used. Magnetic particle or dye penetrant methods may be used as an aid to visual examination, which is required.

19.5.9 Acceptance standards

It is difficult to overemphasize the importance of acceptance standards. Unless the increasing number of techniques that are capable of detecting defects is matched by the development of standards that define levels of defects below which no action is necessary, there is an obvious danger of unnecessarily frequent rejection.

Much work has been done on the problem by bodies such as the Welding Institute and the American Welding Society, and there is an increasing amount of guidance available.

As mentioned above, BS 5500 lists acceptance levels for certain defects. BS PD 6493: 1980 *Guidance on Some Methods for the Derivation of Acceptance Levels for Defects in Fusion Welded Joints* gives an approach based on fracture mechanics.

19.6 Materials Verification

The fact that, not infrequently, an incorrect material is used in the construction of the plant creates a requirement for inspection to identify such situations. Accounts of material verification are given by Ostrofsky (1980–) and R.J. Sherwood (1989).

The range of tests and instruments available to identify materials is described by Ostrofsky. They include (1) chemical and acid spot tests, (2) tests with tools such as a hammer and chisel or a file, (3) fracture tests, (4) eddy current tests, (5) thermoelectric characterization, (6) spark tests, (7) optical emission spectroscopy and (8) X-ray emission spectroscopy.

The author describes a number of spot tests. A more detailed account is given in *Spot Tests* (Feigel, 1958). Spot tests are also the subject of ASTM STP 550. Ostrofsky also gives details of spark tests, with an illustration of the characteristic sparks obtained with materials such as low carbon steel, high carbon steel and nickel, and of instruments for field testing which are based on some of these techniques. There are several which utilize optical emission spectroscopy. These include the Metascope referred to earlier.

A programme for verifying the materials installed in the piping of some ten plants is outlined by R.J. Sherwood (1989). Plant sections where the design required materials other than carbon steel were identified; marked-up drawings, pipework tables and inspection procedures were done; access was gained and surfaces prepared and tests were made using ultrasonics, magnetic particle detection and field analysis instruments.

19.7 Pressure Testing

It is normal to carry out a pressure test on a pressure vessel in order to check that it can be safely operated at the design pressure, but such testing is a potentially hazardous operation. Pressure testing is covered in BS 5500, in the *Pressure Vessel Examination Code* and the *Pressure Piping Systems Examination Code* by the IP (1993 MCSP Pts 12, 13), and also in the ICI *Pressure Vessel Inspection Code* (ICI/RoSPA, 1975 IS/107) and is discussed by Pilborough (1989). Safety precautions are given in these sources and in GS/4 Safety in *Pressure Testing* (HSE, 1992). Also relevant is *A Guide to the Pressure Testing of In-service Equipment* (EEMUA, 1990 Publ. 168).

BS 5500 requires that a pressure test be carried out on any vessel constructed in accordance with the Standard and that the first test should be carried out in controlled conditions with appropriate safety precautions. Adherence to BS 5500 is given in the guidance to the Pressure Systems Regulations 1989 by the HSE (1990 HS(R) 30) as a means of compliance.

The Standard requires that the pressure test procedure should be agreed at the design stage. The test should be performed in the presence of the Inspecting Authority.

19.7.1 Types of pressure test

The types of pressure test given in BS 5500 are:

(1) standard hydraulic acceptance test;
(2) pneumatic acceptance test;
(3) hydraulic proof test;
(4) combined hydraulic/pneumatic test.

A 'standard' test for acceptance is carried out on a pressure vessel where the required thickness of all pressure parts can be calculated. The object of the test is to confirm that the calculated design pressure is a safe work-ing pressure.

If it is not possible to calculate the strength of a vessel satisfactorily, a 'proof' test for acceptance may be conducted to establish a design pressure. In this case, the purpose of the test is to determine whether the expected design pressure is a safe working pressure.

In addition to these tests, which are carried out just before or after installation, there are periodic routine tests that are carried out during the operational life of the vessel.

BS 5500 gives certain basic requirements for any type of test. Factors to be considered in the choice of test method include the test fluid and the size and location of the vessel. The procedure should define any areas at risk and the controls to be applied to these.

19.7.2 Standard test pressure

The standard test pressure for a hydraulic, pneumatic or hydraulic/pneumatic test given in BS 5500 is for Category 1 and 2 vessels

$$p_t = 1.25\frac{pf_a t}{f_t(t-c)} \qquad [19.7.1]$$

where c is the corrosion allowance, f_a is the nominal design strength at the test temperature, f_t is the nominal time-independent design strength, or its nearest equivalent, at the design temperature (or the highest temperature at which time-independent strengths are given in the standard, if this is lower than the design temperature), p is the design pressure, p_t is the test pressure, and t is the nominal thickness of the section under consideration. For Category 3 vessels the standard test pressure is that given by Equation 19.7.1 or by

$$p_t = 1.5p \qquad [19.7.2]$$

whichever is the higher. Various qualifications to these test pressures are given in the standard. Other test pressures are given for proof tests.

19.7.3 Basic test method

Before any test is carried out, the vessel should be given as thorough a visual inspection as is practicable. It may also be desirable to carry out a leak test and, provided that the pressure is not raised to more than 10% of the design pressure, this may be done without the full set of precautions otherwise required for a pneumatic test.

The basic test method described in BS 5500 is to raise the pressure in the vessel gradually to 50% of the specified test pressure and thereafter to increase it in stages of approximately 10% until the test pressure is reached. The test pressure is to be maintained for 30 min, except for certain smaller vessels.

The vessel should be inspected during the test for defects, but this needs to be done with care. BS 5500 states:

> At no stage shall the vessel be approached for close inspection until the pressure has been positively reduced to a level lower than that previously attained. The pressure (s) at which the vessel will be approached for close inspection shall be specified in the test procedure. Such pressure (s) need not exceed design pressure but, if in excess of this figure, shall not exceed 95% of the pressure already obtained and held for at least 15 min.

During the test, the vessel should exhibit no sign of plastic yielding.

The test is normally carried out at about ambient temperature. The risk of brittle fracture should be assessed at the design stage. This may affect the choice of material and/or of the temperature at which the test is performed.

There are special test requirements for vessels with multiple compartments.

19.7.4 Hydraulic test

The method of pressure testing preferred in the Standard is the hydraulic rather than the pneumatic method. In the latter, the energy available is large and any failure during the test is likely to be highly explosive. This aspect is discussed in Chapter 17.

For a hydraulic test, the test fluid should normally be water, but other liquids may be utilized instead if necessary. If another liquid is used, any appropriate precautions should be observed.

Where hydraulic testing with water is not used, the reasons are generally that the vessel and the structure cannot withstand the weight of water, that the water may be difficult to remove completely or that it may freeze.

19.7.5 Pneumatic test

BS 5500 states that pneumatic testing should only be carried out

> Either on vessels of such design and construction that it is not practicable for them to be filled with liquid, or on vessels for use on processes that cannot tolerate trace liquids and where the removal of such liquids is impracticable.

Testing should only be carried out in consultation with the Inspecting Authority.

Before a pressure test is performed, BS 5500 requires that all welds that have not already been non-destructively tested should be tested by magnetic particle and/or dye penetrant methods.

All suitable precautions should be taken against the hazard of vessel failure. BS 5500 refers in particular to:

> (1) The adequacy of blast protection; (2) the extent of area cleared for test safety purposes; (3) the degree of confidence in stress analysis of vessel details; (4) the adequacy of any non-destructive testing carried out before the test; (5) the resistance of the vessel material to fast fracture; (6) the procedure to prevent local chilling during filling and emptying of the vessel and (7) the extent of remote monitoring provided during the test.

BS 5500 states that it is permissible to carry out pressure testing with air or gas up to 1.1 times the design pressure on any vessel that has satisfactorily withstood the standard hydraulic, pneumatic or combined hydraulic/pneumatic test.

19.7.6 Proof hydraulic test

In a proof hydraulic test the vessel normally is equipped with strain gauges or is covered with a strain-indicating coating. The pressure is increased gradually until either the standard test pressure for the expected design pressure is reached or significant yielding of some part occurs. From this test the design pressure and a corresponding standard test pressure can be determined. Further details are given in BS 5500.

19.7.7 Pressure testing: safety precautions

The safety precautions to be taken in the pressure testing of pressure vessels are described in GS 4.

The test should be conducted by a competent person. There should be safe systems of work covering *inter alia* the conduct of the test itself and the regular examination of the equipment used in testing, using, respectively, suitable permit-to-work systems and inspection systems. GS 4 details a number of features that should be included in these systems.

All personnel should be kept out of the test area by a system for the control of access. Personnel conducting the test should do so at a suitable distance and with facilities for remote viewing of the vessel.

Hazards which should be considered are the explosion of the vessel and ejection of blanks and plugs, of high velocity fluid jets and of dirt.

Increasingly, pressure vessels under test are monitored for acoustic emissions (AEs), this being a prime application of the technique. Further details of the method are given in Section 19.14.

19.7.8 Hydraulic testing: safety precautions

There are various precautions that should be taken before doing a hydraulic test using water. Checks should be made on the effects of static head, on the ability of the vessel and the structure to withstand the weight of water, and on the strength of any temporary pipes, connections or blanks.

The hazard of brittle fracture should be considered. In order to avoid the risk of freezing, the temperature of the water should be not less than 7°C.

If water is used with austenitic stainless steel, it is essential to control the chloride and alkali content. The ICI *Code* specifies the use of demineralized or clean condensate with a chloride content less than 1 ppm.

Measures should be taken to prevent overpressure of the vessel during the test. Accurate and reliable means of measuring the pressure should be provided in the form of a pressure gauge that is freshly calibrated and preferably duplicated. The possibility of overpressure due to water temperature rise and expansion should be considered and, if necessary, a liquid relief valve should be provided. The vessel should have suitable vents so that air can be completely removed. Pockets of air left in the vessel constitute a pneumatic explosion hazard. All filling lines and other equipment that are not intended to be subject to the test pressure should be disconnected before that pressure is applied. Any blanking off devices should be secured so that they will not be ejected during testing.

If a test liquid other than water is used, the hazards should be reviewed. With regard to the choice of liquid, the ICI *Code* states that the liquid should be well below its boiling point and, if flammable, should have a flashpoint above 45°C. The precautions described for water testing are applicable to testing with other liquids.

The test pressure to be applied should be such as not to overstress the vessel. It is normally specified in standards and codes. GS 4 states that in the absence of such guidance the test pressure should be limited to 90% of the proof, or yield, strength. It should be applied gradually in 10% increments.

The vessel under test should not be subject to any form of shock loading such as hammer testing.

19.7.9 Pneumatic testing: safety precautions

As stated, pneumatic testing should be employed only where hydraulic testing is impractical. In particular, pneumatic testing should be avoided if the vessel is constructed of a material that is liable to brittle fracture. Where the system consists of a number of items that can be tested separately, this is good practice insofar as it minimizes the volume under test, and thus the energy release potential.

If a pneumatic test is to be conducted, a review of the hazards should be undertaken. The vessel should be inspected in accordance with the *Code* requirements, as described above. Inspection requirements are also detailed in GS 4.

Consideration should be given to the possibility of condensation in the vessel, which can defeat the purpose of using pneumatic testing which has been chosen in order to exclude water.

Local chilling effects should be minimized in order to reduce the risk of brittle fracture. A gas let down from high pressure may undergo a significant temperature drop due to the Joule–Thomson effect. A pneumatic test should be carried out in such a way that the temperature of the gas entering the vessel does not fall below the test temperature. Similar considerations apply to gas flows out of the vessel.

If the source of pressure is higher than the test pressure, the vessel should be provided with protection against overpressure by the use of suitable reducing valves, pressure gauges and pressure relief valves.

Where pneumatic testing is conducted using a range of air pressures, positive measures may be taken to ensure that the correct test pressure is applied by arranging that there is for each pressure a different type or size of connection on the air supply, with a corresponding connection on the vessel.

Flexible connections used in pneumatic testing should be firmly secured. Safety restraints may be used to reduce the risk to persons nearby. Equipment used in pneumatic testing, such as pressure relief devices and flexible connections, should be subject to regular examination. Details are given in GS 4. The vessel under test should not be subject to any form of shock loading.

The personnel carrying out the test should be provided with a safe place from which the progress of the test can be observed and controlled. On completion of the test the vessel should be emptied in such a way as not to cause underpressure and collapse.

Underwater pneumatic testing may be employed as a form of a combined pressure test/leak test. The precautions required in such a test are detailed in GS 4.

19.7.10 Multi-compartment vessels

The testing of multi-compartment vessels involves additional hazards and gives rise to fatalities. These tend to occur when a person enters the vessel to inspect leaks from the compartment walls before the strength of the latter is fully tested. Walls may collapse at quite low pressure differentials. Entry should not be made into a multi-compartment vessel for the purpose of leak inspection until the integrity of the compartments has been established by appropriate pressure testing.

19.8 Leak Testing and Detection

19.8.1 Leak testing

Leak testing is carried out to check that a pressure vessel does not have significant leaks at the design operating conditions.

Leak testing is described in BS 3636: 1963 *Methods for Proving the Gas Tightness of Vacuum or Pressurized Plant*, the *Pressure Vessel Examination Code* and the *Pressure Piping Systems Examination Code* of the IP (1993 MCSP Pts 12, 13), the ICI Pressure Vessel Inspection Code and by Troyan (1960) and Pilborough (1989). Safety precautions in leak testing are given in these sources and in GS 4 (HSE, 1992).

19.8.2 Pressurization for leak testing

Most leak testing methods involve pressurizing the equipment, although the pressure used may be well below the design pressure. In general, pneumatic leak testing should not be performed until the integrity of the vessel has been established by pressure testing.

It is sometimes desirable, however, to leak test a vessel before a pressure test. As stated above, BS 5500 allows this to be done without observing the requirements for a pneumatic test, providing the pressure during the leak test does not exceed 10% of the design pressure. The guidance given in GS 4 is similar.

Once a pressure test has been carried out, leak testing may be done at pressures in excess of 10% of the design pressure. Nevertheless, the pressure used in leak testing should be kept as low as possible. There is usually little to be gained by the use of high pressures.

The vessel to be leak tested should first be inspected. GS 4 advises that visual examination may need to be supplemented by inspection using NDT methods.

If a pressure leak test is used and if the source of pressure is higher than the test pressure, the vessel should be provided with protection against overpressure by the use of suitable reducing valves, pressure gauges and pressure relief valves.

As described below, there are methods of leak testing available which do not involve pressurizing the vessel.

19.8.3 Leak location methods

Leak testing is performed for two distinct, but related, purposes: to locate the leak and to determine the leak rate. The main methods used for leak location are:

(1) pressure testing;
(2) search gas methods.

There are a number of leak location methods which involve pressurizing the vessel and then detecting leaks visually. The equipment may be pressurized hydraulically and liquid leaks observed. Detection of leaks may be assisted by the use of some kind of coating which shows them up more clearly. Alternatively, pressurization may be pneumatic and detection effected using a soap bubble or similar technique. If the vessel is sufficiently small to be immersed in a liquid, the evolution of air bubbles may be used to detect leaks in a manner similar to that used in repairing a bicycle inner tube puncture.

Another group of methods is based on the use of a search gas. The gas is introduced into the air pressurizing the vessel and is detected by a suitable device. Some commonly used combinations are:

Search gas	*Detector*
Halogen gas	Halide torch Halogen diode detector
Hydrogen	Thermal conductivity detector
Helium	
Nitrous oxide	Infrared absorption detector

A variation of this method is to use not a search gas but a radioactive tracer.

Some practical aspects of leak detection are discussed by Troyan (1960).

19.8.4 Leak rate

The leak rate may be defined in terms of the fall in pressure in the vessel

$$L = -V\frac{\mathrm{d}P}{\mathrm{d}t} \tag{19.8.1}$$

where L is the leak rate (Pa m^3/s), P is the pressure (Pa), V is the volume of vessel (m^3) and t is the time (s).

Until quite recently, the internationally agreed unit of leak rate has been the torr l/s ($=0.133$ Pa m^3/s). Thus in Equation 19.8.1 if, instead of the units given, $V = 1$ l and $\mathrm{d}P/\mathrm{d}t = 1$ torr/s, then $L = 1$ torr l/s. Since this unit is rather large, use has also been made in the United Kingdom of the lusec (1 lusec $= 0.001$ torr l/s). An account of leak rate units is given by Pilborough (1989).

Since the leak rate depends on the difference between the vessel pressure and atmospheric pressure, this should be specified when quoting leak rates. Where the leak rate is for a vacuum plant and the difference is not specified, the assumption is that the pressure difference is 1 atm.

Typical leak rates are given by Pilborough (1971) as follows:

	Leak rate (lusec)
Water can	10
Chemical plant	1
Vacuum plant	0.01

19.8.5 Leak rate methods

The main methods for leak rate determination are:

(1) pressure decay method;
(2) flow method;
(3) search gas flow method.

The pressure decay method is to pressurize the system, isolate it and measure the rate of pressure decrease.

The flow method involves measuring the inlet flow required to maintain the pressure constant.

In the search gas flow method, air is passed over the surface of the equipment and through some form of hood or containment and the flow of air and concentration of search gas in the air are measured.

19.8.6 Leaks in vacuum plant

Leaks are particularly important in vacuum plant. Their detection and measurement is a specialist activity. Accounts are given in texts on vacuum technology and by Pilborough (1989).

19.8.7 On-line leak detection

Methods are also required for the detection of leaks in operating plant. In some cases it is possible to utilize the techniques just described such as the soap bubble, pressure decay and search gas methods.

For high pressure leaks, use may be made of AE monitoring, as described in Section 19.14. For leaks in pipelines another form of acoustic monitoring may be used, as described in Section 19.16.

19.9 Plant Monitoring

The plant equipment, including the pressure vessels and pipework and the process machinery, may be monitored during commissioning and over its operational life.

The monitoring of the state of the equipment may be based on (1) performance or (2) condition. The difference is self-explanatory. Performance monitoring is able to detect faults which have an effect on performance, but there are many others which have little effect until failure actually occurs. The latter may often be detected, however, by monitoring the condition.

The monitoring of instrument performance and condition has been discussed in Chapters 13 and 14 and such monitoring of other equipment is discussed below.

19.9.1 Monitoring strategy

Plant monitoring can yield great benefits, but it can consume appreciable resources. It is essential, therefore, to define clearly the purposes for which such monitoring is to be carried out and to adopt a coherent monitoring strategy.

This is particularly relevant with some types of monitoring, of which AE monitoring is one, and the point is discussed further below in relation to this type of surveillance.

19.9.2 Monitoring interval

The interval between condition monitoring checks depends on the nature of the signal. If the development of a failure is shown by a slow and reproducible increase in signal level over a long time interval, periodic monitoring may be sufficient, but if the failure gives little advance warning and the signal level is liable to rise from a low to a high level suddenly, then continuous monitoring is necessary.

The problem is one of information sampling and is in many ways similar to that considered in Chapter 14, in relation to the sampling of information by the process operator. Continuous monitoring is generally more expensive and the choice of monitoring interval is usually a compromise between these factors.

Where the quantity monitored is not the state of the plant but changes in that state, as in AE monitoring, different considerations apply. In this case, periodic monitoring, undertaken during changes in the plant state, is the norm.

19.9.3 Action level

The problem of acceptance standards in inspection and NDT is paralleled by that of the action level for condition monitoring. The decision has two dimensions, since it is necessary to decide not only whether to take action but also whether action must be immediate or whether it can be deferred.

A condition monitoring device produces a signal which varies with time. The signal characteristic of normal operation tends to be specific to the individual equipment monitored. It is a deviation from the equipment's own normal signal rather than from some ideal signal which indicates its abnormal condition.

In many cases, there is a fairly reproducible and unambiguous increase in signal level when a failure is imminent. In others, however, the signal is liable to fluctuate, rising to quite high levels and then subsiding, and/or to increase suddenly to failure. There is a considerable problem in these latter situations in deciding whether to take action.

The methods of reliability engineering have been applied to the treatment of the results from condition monitoring. Bellingham and Lees (1976b) describe a method of using the monitor signal to make a running estimate of the probability of survival, that is the reliability of the equipment. The method assumes that *a priori* information is available on (1) the failure density function of the equipment and (2) the probability density function of the signal, and uses the signal to condition this information to give the reliability estimate.

An illustrative example of the type of information obtained is shown in Figure 19.3. In the case considered, the failure distribution of the equipment is assumed to be exponential. Curve 1 gives the reliability calculated from the failure distribution without using the signal information. Curves 2 and 3 show the reliability estimated from the *a priori* information and the signal for the cases where the signal level is low and high, respectively. The former case indicates a healthy condition and the reliability in the immediate future is high, while the latter case indicates an unhealthy condition and the reliability falls off rapidly.

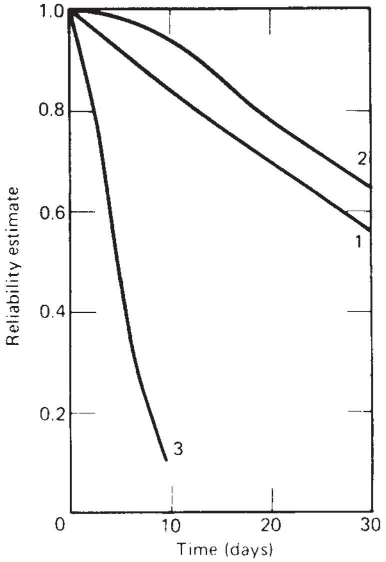

Figure 19.3 *Use of monitor signal to condition the estimate of equipment reliability (Bellingham and Lees, 1976b): curve 1, no monitor signal; curve 2, monitor signal healthy; curve 3, monitor signal unhealthy (Horsley and Parkinson, 1990; reproduced by permission of the Institution of Chemical Engineers)*

Applications of the extreme value distribution to the interpretation of results from ultrasonic survey have been described by Wylde and Shaw (1983). One application given is the estimation of the remaining life of a tank wall from measurements of the wall thickness at various points on a corroded band of the wall. Another example quoted is the estimation of the number of deep pits per unit length of pipe from measured values of pit depth.

19.9.4 On-condition maintenance

The various techniques of non-destructive examination and condition monitoring may be used to determine when maintenance should be done on an equipment, as an alternative to either breakdown or scheduled maintenance. This policy is known as on-condition maintenance. An account of on-condition maintenance as a maintenance policy is given in Chapter 7.

19.9.5 On-condition maintenance: illustrative example

Some of the condition monitoring techniques described below involve specialist equipment and sophisticated inter-pretation. But, as the following example shows, on-condition maintenance may also be based on some very simple measurement.

A maintenance policy for a paper machine has been described by A. Kelly (1981). One component which was prominent in the maintenance was a rotary joint, the main failure being that of one of the seals, which had a life varying between 6 and 30 months. It was realized that the wear on this seal could be determined by measuring the movement of the housing relative to the rotating part of the joint. Thus, the condition of the seal could be monitored using a simple measurement of position.

19.10 Performance Monitoring

One basic approach to the surveillance of the health of equipment is to monitor its performance. Typically, performance monitoring is based on the use of a model of the equipment performance with ranges of values of the parameter in the healthy state. These parameters are monitored to detect excursions into unhealthy states. The technique tends to involve the measurement of a number of parameters and to require fairly high measurement accuracy.

Some performances which may be monitored include: (1) the equipment pressure drop; (2) heat exchanger efficiency; (3) the pump characteristic and efficiency and (4) the compressor, turbine characteristic and efficiency.

Performance monitoring is carried out on large machines such as turbines and compressors in the aerospace, marine, power and process industries. It is usually done not only to detect failures but also to obtain improved performance. Since performance monitoring generally requires multiple measurement, computation and display facilities, it is a natural task for a process computer.

The performance monitoring of reciprocating compressors by computer has been described by Gallier (1968). The monitoring covered changes in compressor leakage and volumetric efficiency, in compressor and driver power efficiency and in loading capability.

Thus leakage was determined by measuring temperatures and using the equations

$$L = \frac{T_s - T_o}{(T_o + \Delta T_H) - T_i} \qquad [19.10.1]$$

$$\frac{T_o}{T_s} = \left(\frac{p_o}{p_i}\right)^{(1-\mu)/\mu} \qquad [19.10.2]$$

where L is the fraction of gas leaking, p_i is the suction pressure, p_o is the discharge pressure, ΔT_H is the correction for Joule–Thomson effect, T_i the inlet temperature (before the addition of bypass gas), T_o is the discharge temperature, T_s is the suction temperature, and μ is a constant, approximately equal to the ratio of the gas specific heats.

Collacott (1976b) has described the monitoring of a more complex set of 'gas path' relations in a single spool compressor. A simplified form of the model described is

$$\begin{bmatrix} \Delta P_d \\ \Delta T_d \\ \Delta W_f \\ \Delta A \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{bmatrix} \begin{bmatrix} \Delta T_i \\ \Delta G_a \\ \Delta \eta \\ \Delta N \end{bmatrix} \qquad [19.10.3]$$

where A is the jet nozzle exhaust area, G_a the compressor air pumping capacity, N the compressor speed, P_d is the compressor discharge pressure, T_d is the compressor discharge temperature, T_i is the turbine inlet temperature, W_f is the fuel flow, η is the compressor efficiency, and Δ is the normalized increment of the variable (change in value/absolute value).

The performance of the machine is monitored by observing changes in the Δ values of the variables. The method may be summarized as follows. First the coefficients a_{11}–a_{44} in Equation 19.10.3 are evaluated in healthy operation. Then to make a check of machine performance the dependent variables P_d, T_d and W_f are measured at constant speed and the normalized increments ΔP_d, ΔT_d and ΔW_f are calculated. Since the speed is constant, $\Delta N = 0$ and equation 19.10.3 can be evaluated by considering first the top left-hand, third-order matrix. Thus the normalized increments of the independent variables ΔT_i, ΔG_a and $\Delta \eta$ are determined. The normalized increment ΔA is then calculated.

If all the normalized increments are close to zero, there is no performance change. If there is a deterioration, however, ΔG_a, $\Delta \eta$ and ΔT_i; normally rise. An increase in ΔA indicates erosion of the nozzle.

Collacott describes the performance monitoring of a power station steam turbine in which there was a sudden reduction in the load, first stage pressure, intercept valve pressure and feedwater flow of about 4% in each case. It was decided that there was a restriction at the front end of the turbine. In fact, the stem of one of the four control valves had broken so that the sequence of valve opening was interrupted.

19.11 Condition Monitoring

The alternative to performance monitoring is condition monitoring, for which a variety of techniques are available.

Accounts of condition monitoring have been given in *Mechanical Fault Diagnosis* (Collacott, 1977b) and *On-line Monitoring of Process Plant* (D.W. Butcher, 1983) and by Kobrin (1970), Trotter (1973) and D. Neale (1974).
