An account of the application of a number of NDT and condition monitoring techniques to ammonia plants has been given by Madhavan and Sathe (1987).

There are a large and growing number of condition monitoring methods. Some of these are as follows:

(1) vibration monitoring;
(2) corrosion monitoring;
(3) acoustic emission monitoring;
(4) ultrasonics;
(5) infrared thermography;
(6) strain measurement;
(7) debris analysis;
(8) magnetic signature monitoring;
(9) temperature measurement;
(10) position measurement;
(11) speed measurement;
(12) torque measurement.

There is, therefore, no shortage of methods for condition monitoring. The problem is rather to select the appropriate technique, inspection interval and action level.

The inspection interval depends on the rate at which the fault monitored can develop. There are some faults that can occur within a matter of minutes, while others take weeks or months to develop. Continuous monitoring is necessary to detect faults that develop rapidly.

Whereas NDT methods are well established and are formally recognized in pressure vessel construction codes such as BS 5500, the role of condition monitoring techniques in inspection codes is generally less well defined.

The use of the process computer for monitoring performance and condition is discussed in Chapter 30.

19.11.1 Vibration monitoring

A widely used method of condition monitoring is the monitoring of vibrations. This is applied mainly to rotating process machinery, but also to static plant equipment. For rotating machinery in particular, it is often possible to relate the vibrations obtained to specific faults in the machine. Since large rotating machines are often critical to the operation of process plants, vibration monitoring has proved an especially valuable aid. It is described in more detail in Section 19.12.

19.11.2 Corrosion monitoring

Another widely practised form of monitoring is corrosion monitoring, which is applied principally to static plant. Corrosion monitoring may be used to track corrosion progressing at a relatively uniform rate and also to identify bursts of intense corrosion activity and to relate these to particular process conditions. The monitoring of corrosion is described further in Section 19.13.

19.11.3 Acoustic emission monitoring

Another monitoring technique which is finding growing application is AE monitoring, which is applied to static plant and also to leaks. This method is based on the detection of the AEs that occur as defects undergo changes, notably those accompanying crack growth. It thus differs from most other techniques for monitoring static plant in that it is not the steady state of the defects that are measured but the dynamic changes. A fuller account of AE monitoring is given in Section 19.14.

19.11.4 Ultrasonics

Ultrasonics is widely used not only for the initial examination of plant equipment, as described in Section 19.5, but also for on-going monitoring. In particular, it is extensively used to determine metal thickness and to identify and characterize cracks in metal structures.

19.11.5 Infrared thermography

An infrared camera can be used to detect differences in the surface temperature of, and hence heat radiation from, plant. The different temperatures may be displayed as different colours or shades of black and white on a cathode ray tube or on a photograph. The technique is known as infrared thermography or thermal image monitoring. Accounts are given by Norda (1976, 1977), L.M. Rogers (1976), Weismantel and Ramirez (1978), Imgram and McCandless (1982), E.G. Jones and Duckett (1985), Tuss (1985) and Baker-Counsell (1986c). Plate 18 shows the thermal image of a distillation column. Some applications of thermography are:

(1) refractory and lagging deterioration –
    (a) refractory wear,
    (b) lagging loss,
(2) furnace tube deterioration –
    (a) hot spots,
    (b) coking,
(3) process flow abnormalities –
    (a) heat exchangers,
    (b) steam traps,
    (c) relief valves,
(4) electrical equipment faults –
    (a) cable terminations,
    (b) cable splicing faults,
(5) machinery faults –
    (a) gearboxes,
    (b) couplings,
(c) corrosion.

Thermography has long been used by electrical engineers to detect faults in electrical power systems, but there are now numerous applications in the process industries. Wear of refractories, loss of lagging or moisture penetration of lagging shown up as hot or cold spots. In furnaces, corrosion or other thinning of tubes and coking up of tubes are revealed by temperature changes. The deterioration of flow patterns in a heat exchanger gives a changed temperature pattern. Leaks in steam traps and relief valves which discharge into closed pipelines are shown by a change in the temperature of these lines. Defects in electrical equipment such as bad terminations or cable splicing faults often show up as hot spots. Deterioration of machinery such as couplings or gearboxes tends to generate heat. It is even possible to detect some forms of corrosion.

Figure 19.4 shows a pair of normal and thermographic photographs of refractory lined vessels. The arrows in Figure 19.4(b) indicate areas of one of the vessels where the refractory is wearing thin.

A number of routine applications of thermography in one company are described by Weismantel and Ramirez (1978). These include the detection of leaking steam traps, faults in gearboxes and couplings, and electrical cable splicing defects. Another use described by these authors is to detect leaks beneath the insulation on liquefied natural gas (LNG) tanks.

Imgram and McCandless (1982) describe the use of thermography to detect leaking pressure relief valves. They also describe applications to the deterioration of a catalytic cracker refractory lining wear, a crude heater insulation loss and furnace tube coking. Plates 17 (a) and 17(b) show an application similar to the one described by these authors; of the pair of pressure relief valves shown, the one on the right-hand side is leaking.

The application of thermography to the identification of blockages in the relief header of a synthetic rubber plant is described by E.G. Jones and Duckett (1985). The technique used was to pass steam along the line and to observe the thermal transient, blockage points appearing initially as cold spots.

The applications mentioned by Baker-Counsell (1986c) include the use of thermography to detect hydrogen corrosion. The blisters formed cause a decrease in heat transfer and hence, when steam is used, a cold spot.

The main application of thermography is as a method for the normal inspection of the plant, but it may also be used for other purposes such as the acceptance testing of new equipment.

The distances between the thermal camera and the object may be as much as 100 m or more. Coverage of the temperature range −30°C to 2000°C and accuracies within 1°C are claimed. Thermographic equipment is relatively expensive.

19.11.6 Strain measurement

There are a number of methods of measuring strain in plant equipment. They include

(1) displacement measurement;
(2) strain gauges;

Figure 19.4 *Normal and thermographic photographs of a refractory lined vessel (A GA Ltd): (a) normal photograph; (b) thermographic photograph, with arrows indicating thin spots*

(3) lacquers and coatings;
(4) X-ray diffraction;
(5) interferometry –
  (a) Moire grid,
  (b) speckle,
  (c) holographic.

Strain may be measured by mechanical displacement or by electrical strain gauges. The latter are widely used as a means of measuring strain in a laboratory, but are rather less suitable for site work. A strain gauge measures strain in one direction only and has relatively low sensitivity. The application of the strain gauge method to the monitoring of steam pipework has been described by Ghia *et al.* (1983).

Photoelastic coatings and brittle lacquers may be used to give an indication of the existence of strain.

Interferometric techniques are available which show a two-dimensional strain pattern and are more sensitive. In the Moiré grid method a linear grid is applied to the object and distortions of the grid are measured.

If the diffusely reflecting surface of an object is illuminated by a laser beam, a speckle pattern is produced. This pattern undergoes regular changes if the surface is displaced by strain. Oxidation of the surface may affect the pattern, but special coatings are available to deal with this problem.

The procedure in the holographic method involves taking a silicone replica of the strained surface and analysing it in a laboratory using a fairly powerful laser (> 1 W). Figure 19.5 shows a crack around a fatigue specimen obtained by the Optecord holographic method.

19.11.7 Debris analysis

The debris produced by process machinery in distress may be used to obtain information about the wear which is occurring by using the techniques of debris analysis. Accounts are given by A.E. Davies (1972), Collacott (1975), Wilkie (1987a) and Rudston (1989). The fundamentals of wear are treated by M.C. Shaw (1971).

Debris analysis techniques have been developed primarily in the aerospace and defence fields. Their application is widespread in the transport industry, where debris analysis is utilized for aircraft, marine, rail and road equipment, but its exploitation in the process industries has been somewhat slower.

Debris analysis is closely related to lubrication technology and is also referred to as lubricant monitoring. A monitoring package generally includes analysis of the lubricant itself as well as of the debris which it contains.

The lubricant tests in such a package are fairly standard. They include measurements of: the density of the oil; the viscosity of the oil; the breakdown products of the oil; the contaminants in the oil, such as water and insolubles; the total base number and the characterization of the metal particles.

The fate of metal particles in the system depends on their size. In essence, large particles (0.1 to <0.5 mm) settle out in the lubricant return tank; medium sized particles (10–50 μm) circulate but may be trapped by a filter; and small

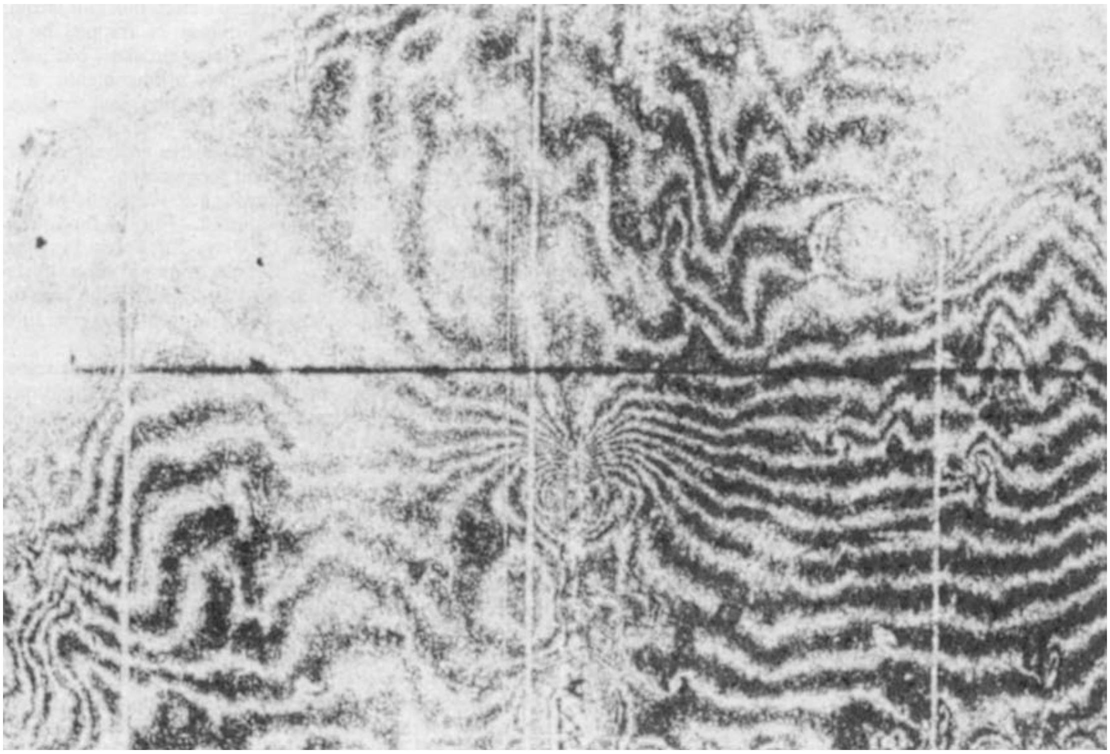

Figure 19.5 Holographic investigation of a fatigue crack: (a) specimen; (b) holographic photograph (Reproduced with permission of Scottish Technical Development Ltd and the University of Strathclyde)

particles (1–5 μm) also circulate, but pass through any filter. The filtering arrangements are generally designed to minimize abrasion and erosion from metal particles.

There are two main methods for the analysis of the metal particles: spectrometry and ferrography.

Spectrometric oil analysis involves the analysis of the chemical elements in the oil itself. The method was originally developed by the US Navy Air Force and has been known in the United Kingdom as the spectrometric oil analysis programme (SOAP). The method is claimed to be able to detect wear debris at the level of one part in 10^{12} (Collacott, 1975).

Figure 19.6 (A.E. Davies, 1972), shows the wear rates of an Olympus engine in the *Concorde* prototype aircraft as measured by spectrometric oil analysis. Stripping of the engine revealed heavy fret wear on the port gearbox-driven bevel splined location on the lay shaft.

For ferrography, metal particles may be obtained by magnetic chip detection or filter collection. Magnetic chip detection is used in lubricating or hydraulic oil systems to collect debris from ferromagnetic materials. The detector is periodically examined and the debris analysed. The use of magnetic chip detectors is quite widespread in the process industries. Filters in oil systems are also used to collect debris particles for analysis.

In the aircraft industry the analysis of debris is a well developed technique. Filter elements are removed under conditions of almost clinical cleanliness and the debris is examined by microscope and analysed chemically. Samples of filter washings are preserved under transparent covers on record cards.

Some typical normal and alert wear/corrosion ranges given by Rudston (1989) are as follows:

	Spectroscopic metals		*Ferrographic readings*	
	Ferrous	*Non-ferrous*	*Large debris*	*Small debris*
Rotating Machinery	≥ 8 (0–5)	≥ 8 (0–5)	≥ 15 (0–5)	≥ 2 (0–5)
Reciprocating Machinery	≥ 150 (0–100)	≥ 20 (0–15)	≥ 120 (0–100)	≥ 40 (0–30)

The values shown without brackets are alert values and those shown in brackets are normal values. These provide a general guide, but monitoring of a given machine is usually based on deviations from the previous pattern shown by that machine.

Particular wear processes tend to give characteristic particle shapes and much can be learned by examining the particles under a microscope. Some typical debris characteristics are shown in Table 19.11.

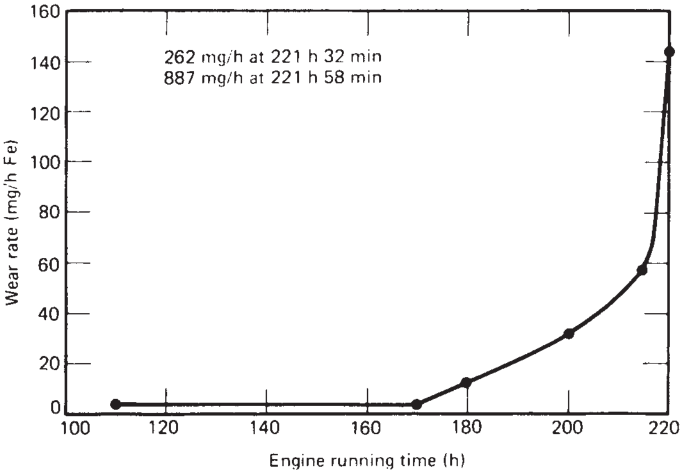

Figure 19.6 *Trend record of a spectrometric oil analysis on an Olympus 59332 engine in the Concorde prototype aircraft (A.E. Davies, 1972) (Courtesy of the Institution of Marine Engineers)*

Table 19.11 *Some typical characteristics of metal particle debris in lubricating oil*

A

Conditions	*Particle appearance*
Running in	Feathery or flaky
Roller bearing distress	Heavy rectangular shape with regular crossing marks (team lines)
Ball bearing distress	Shiny, roughly circular, petalled chips

B

Damage process	*Particle type*	*Surface appearance*
Mild wear (delamination)	Small flat reflective flakes	As machined but with more plateau area
Adhesion/scuffing	Larger ragged flakes often with temper colours	Rough and torn
Abrasion/cutting	Bright slivers and curls	Scratched and scored
Fatigue	Sharp metallic chunks and small spheres	Cracked and spalled
Erosion	Bright chunks or spheres	Pits or grooves with rough surface
Fretting	Fine red-brown iron oxide	Localized staining or indentation
Corrosive wear	Powdery non-reflective deposit	Fitted and discoloured

Sources: Collacott (1975); Rudston (1989).

19.11.8 Other general methods

Other methods that are used to monitor condition include the measurement of conventional variables such as temperature, position, speed and torque, and magnetic field measurements.

Temperature is used in particular to monitor plain bearings. It is not so good an indication for ball bearings, however.

Blades of rotating machinery such as turbines or fans may be magnetized or, if made of non-magnetic material, may be seeded with a magnetic implant. The 'magnetic signature' caused by the rotation of the magnetized part may then be monitored by a magnetic sensor.

There are numerous other physical phenomena that may be made the basis of a method of condition monitoring. Barnhart (1963) has listed some 387 physical laws and effects.

19.11.9 Specific ad hoc methods

In addition to the general methods described, there are a number of *ad hoc* methods for monitoring specific items of equipment. A good illustration of such methods is the rotary joint application described in Section 19.9.

Two further examples will suffice, one on pumps and one on valves. The first is the work of D. Harrison and Watkins (1983) on instability in pump mechanical seals, prompted by severe difficulties on main oil line pumps offshore. The problem involves vaporization between the seal faces of the pumped fluid that normally lubricates the seals. The authors describe the measurement of the seal leak chamber pressure as an indicator of the onset of instability.

D. Harrison and Heath (1983) have described work on the use of changes in valve torque as a measure of incipient failure to achieve the fully open or closed position.

19.11.10 Adaptive noise cancellation

In many monitoring applications there is an appreciable degree of background noise. One technique which has been developed specifically to deal with this problem is that of adaptive noise cancellation (ANC), described by Widrow *et al.* (1975).

An account of the application of ANC to the monitoring of rolling element bearings has been given by Tan and Dawson (1983).

19.12 Vibration Monitoring

Vibration monitoring is described in *Mechanical Fault Diagnosis* (Collacott, 1977b) and *Mechanical Vibration and Shock Measurements* (Broch, 1980) and by Fieldhouse (1970), Tustin (1971), F.G. Jones (1971), C. Jackson (1975–), Erskine (1976a,b), Goldman (1984) and Goggin (1987).

19.12.1 Machine vibration

Much information on the condition of machinery can be obtained by monitoring vibrations. Monitoring needs to be combined with a theoretical analysis of the vibration modes so that particular faults can be distinguished.

Accounts of vibration include *Vibration and Sound* (Morse, 1936), *Mechanical Vibrations* (den Hartog, 1956), *Engineering Vibrations* (Jacobsen and Ayre, 1958), *Shock and Vibration Engineering* (C.T. Morrow, 1963), *Structure-Borne Sound* (Cremer and Heckl, 1973), *Vibration Problems in Engineering* (Timoshenko, Young and Weaver, 1974), *Elements of Vibration Analysis* (Meirovitch, 1975), *Shock and Vibration Handbook* (C.M. Harris and Crede, 1976) and *Mechanics of Vibration* (Bishop and Johnson, 1979).

Broch gives an account of vibration and shock that covers its characterization, the response of mechanical systems to it, its effect on mechanical systems, its measurement, its analysis, and its use for machinery health monitoring.

As an illustration, consider the pinion gear assembly described by Fieldhouse (1970) and shown in Figure 19.7. The analysis given by this author of some of the frequencies of vibration generated by this mechanism is summarized in Table 19.12.

Numerous other analyses of the modes of machine vibration are available.

19.12.2 Vibration quantities

Vibration quantities that are measured are (1) displacement, (2) velocity and (3) acceleration. Each quantity is measured using a different type of transducer.

Displacement measurement is utilized for detecting the change in clearances. It is particularly useful on reciprocating machines. It discounts and is not suitable for high frequencies (>1000 Hz).

Velocity measurement is a commonly used method for both machines and structures. It gives equal weighting to both low and high frequencies, since it is the product of the displacement and frequency of each harmonic component.

Acceleration measurement is useful for detecting impact effects. It discounts and is not suitable for low frequencies.

The choice of vibration quantity and measurement device is discussed by Broch (1980). There has been a trend towards higher frequencies, and measurements may be made at 10 Hz or higher. Broch's account emphasizes the use of accelerometers, with velocity or displacement obtained by integration.

The units of measurement commonly used are

Displacement	μm	mil
Velocity	mm/s	in./s
Acceleration	m/s^2	ft/s^2

There are also several different signal quantities that may be measured. These are (1) peak, (2) peak-to-peak, (3) average and (4) root mean square (rms). All these quantities are used in the various instruments currently available for the measurement of the vibration quantities (displacement, velocity and acceleration).

The peak and peak-to-peak values give, respectively, the peak vibration loading and the swing in loading; the average and rms values give, respectively, the average vibration loading and the power in the loading. The peak and peak-to-peak values are dependent on the waveform, but the average and rms values are not.

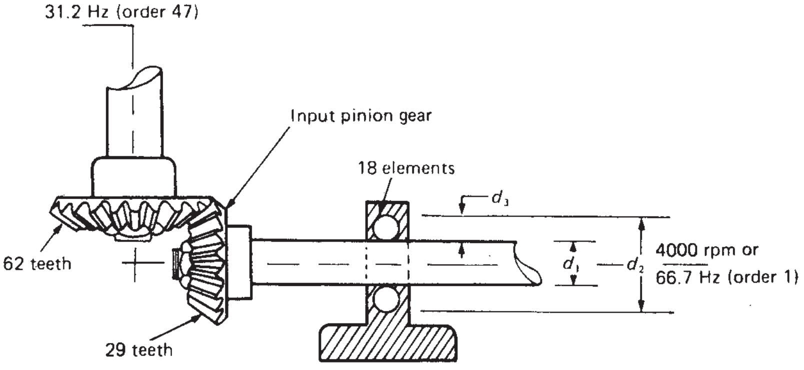

Figure 19.7 *Pinion gear assembly (Fieldhouse, 1970) (Courtesy of Sound and Vibration)*

***Table 19.12** Some frequencies arising from a pinion gear assembly (after Fieldhouse, 1970) (Courtesy of Sound and Vibration)*

Assembly parameters:	
No. of teeth on input gear, N_1	29
No. of teeth on output pinion, N_2	62
Diameter of inner race, d_1	3 in.
Diameter of outer race, d_2	4 in.
Diameter of balls, d_3	0.5 in.
Number of balls, N	18
Speed of rotation of input shaft, n_1	4000 rev/min
Constant D_1 ($=d_1/(d_1+d_2)$)	0.428
Constant D_2 ($=d_2/(d_1+d_2)$)	0.572

Assembly frequencies:	Hz	Order
Frequency of rotation of input shaft, f_{n1}	66.7	1
Fundamental gear mesh frequency, f_{gm}($=f_{n1}N_1$)	1934.3	29
Frequency of rotation of output shaft, f_{n2} ($=f_{gm}\ /\ N_2$)	31.2	0.47
First upper sideband of gear mesh frequency, f_u ($=\mathrm{f}_{gm}+f_{n1}$)	2001	30
First lower sideband of gear mesh frequency, f_1($=f_{gm}-f_{\mathrm{n1}}$)	1867.6	28
Differential frequency of rotation of inner and outer races, f_r ($=f_{n1}$)	66.7	1
Frequency of ball spin, f_s ($=f_rD_1(d_2/d_3)$)	228	3.4
Frequency of ball train passage, f_t ($=f_rD_1$)	28.5	0.43
Frequency of flaw on inner race, f_{f1}($=f_rND_2$)	687	10.2
Frequency of flaw on outer race, f_{f2}($=f_rND_1$)	514	7.7
Frequency of flaw on ball, f_{f3}($=2f_s$)	456	6.8

The peak vibration velocity is the quantity generally considered to be the most useful signal by some authors (e.g. Erskine, 1976a). If a peak value is required, it is important to ensure that a true peak reading meter is used, as described below.

Alternatively, the full power spectrum of the signal may be produced. Spectral analysis instruments are available to generate the power spectrum.

An illustrative example showing the value of signal filtering is given by Goldman (1984). He considers the monitoring of a gearbox which has a mesh frequency of 1 Hz and an outer race ball pass frequency of 236 Hz. Typical signals might be:

	Velocity (in./s)		
Week	*Overall*	*Mesh* (1 Hz)	*Bearing* (236 Hz)
1	0.1	0.1	0.01
2	0.1	0.1	0.02
3	0.1	0.1	0.03
4	0.1	0.1	0.04
5	0.11	0.0	0.05

Measurement of the strength of the overall signal would show relatively little change, but separate measurement of the mesh and bearing signals would show the bearing beginning to fail at about week 3 and being close to failure by week 5.

19.12.3 Vibration measurement

The instrumentation used for vibration monitoring consists of a transducer, a signal conditioning amplifier and a readout meter. The transducer may measure displacement, velocity or acceleration directly. Alternatively, acceleration may be integrated to give velocity, and velocity to give displacement. An account of vibration measurement is given be Broch (1980).

The function of the amplifier is to give a larger power signal and to transform it into the signal quantity required. Many instruments scaled for peak, peak-to-peak or rms values in fact read the average value. The different types of circuitry are described by Erskine (1976a).

There are a number of practical aspects that need to be observed if satisfactory results are to be obtained in vibration monitoring work. On each occasion, the measurement should be taken at the same point and in the same direction. Therefore, if a portable monitor is used it is useful to indicate the point with a small circle of white paint with a small hole drilled in the centre. The tendency for a portable transducer to bounce can be overcome by the use of a 'mole' wrench as a clip. The same instrument should always be used to take a given reading, since instruments which ostensibly read the same parameter may in fact have different internal circuitry. The transducer should be calibrated at intervals of 18 months or less and the instruments at intervals of 3 months.

As far as possible vibration measurements should be made under the same machine conditions. Some variable speed machines have a rotor critical speed within the operating range, although the machine should not be operated at this speed. If it is being so operated, the additional vibration detected is an indication of maloperation rather than malfunction.

19.12.4 Vibration criteria

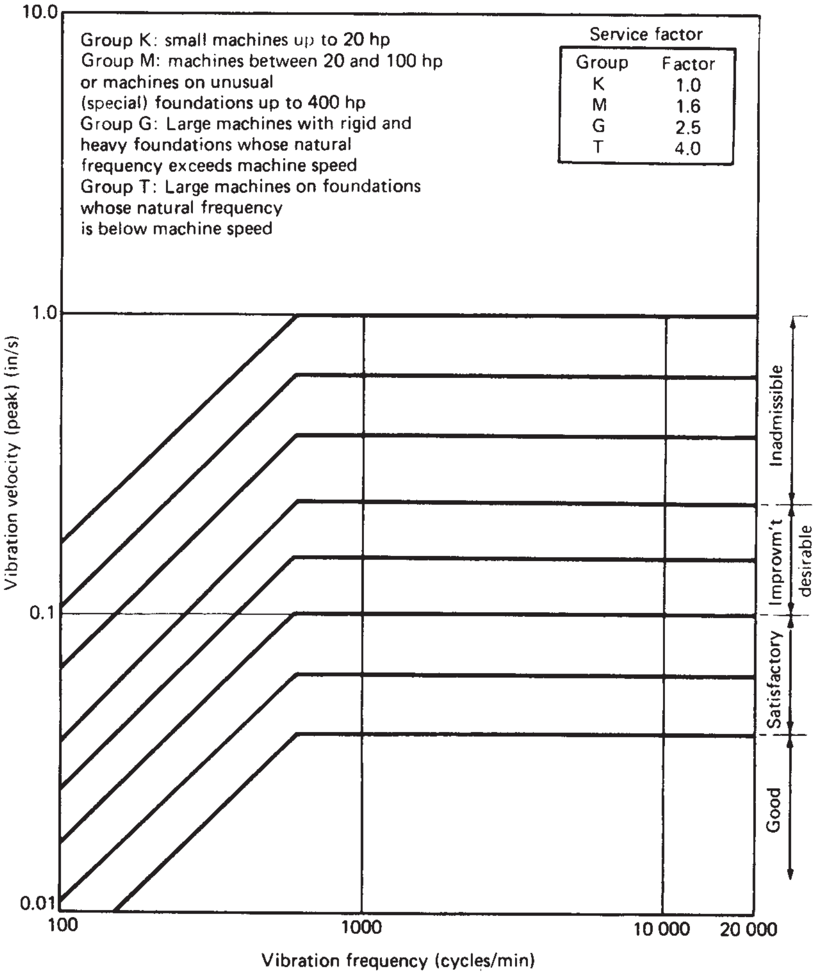
For rotating process machinery such as turbines, compressors, pumps and fans there are some general guidelines available to determine the level of vibration at which action is required, that is the vibration criteria. Early vibration criteria were those proposed by Yates (1949) and Rathbone (1963). A widely used set of vibration criteria is that of the IRD, the details of which are quoted by Collacott (1977b).

One of the most widely used guidelines for general process machinery is that given in VDI 2056: 1964 *Standards for Evaluation of Mechanical Vibration of Machines*.

Criteria for the balancing of machines are given in ISO 1940: 1986–*Mechanical Vibration–Balance Quality Requirements for Rigid Rotors,* ISO 2371: 1974 *Field Balancing Equipment: Description and Evaluation,* ISO 2953: 1985 *Balancing Machines: Description and Evaluation* and ISO 3945: 1985 *Mechanical Vibration of Large Rotating Machines with Speed Range from 10 to 20 r/s: Measurement and Evaluation of Vibration Severity in situ*.

Vibration criteria, both for independent bearings and for bearing housings in barrel casings, which have been developed from the VDI method and used in ICI, have been described by Erskine (1976a) and are given in Figure 19.8 The quantity used is the peak vibration velocity, which has the advantage that it is independent of the machine speed and vibration frequency. Experience also indicates that Figure 19.8 can be used for gearboxes if they are treated as Group T.

These vibration criteria provide general guidance. In practice, it is usual to take an initial baseline set of measurements on the particular machine and thereafter to monitor the trend on that machine.



To use chart:
(a) decide machine group
(b) divide readings by service factor
(c) determine from chart the region in which corrected readings fall
(d) for barrel casings divide by 1.5

Figure 19.8 *Vibration criteria for process machinery (Erskine, 1976a) (Courtesy of the Institution of Chemical Engineers)*

Another useful source of information for comparison may be the vibration levels on similar machines in a group.

Use may be made of certain rules of thumb. Goldman refers to the rule that a doubling of the signal strength is an indication of trouble, whilst a trebling is cause for concern.

19.12.5 Shock pulse monitoring

A particular type of vibration monitoring which is based on selective filtering is shock pulse monitoring. The shock pulse meter (SPM) exploits two facts. One is that at the natural frequency of a mounted accelerometer a large electrical output can be obtained from a small excitation. The other is that an instantaneous impact gives a signal that contains all frequencies at equal amplitude, in other words white noise. Thus, the signal given by an impact will contain the frequency required to excite the accelerometer. In a SPM, the signal at this frequency is amplified by the accelerometer, filtered and then measured.

The main application of the SPM is the monitoring of faults in ball bearings. If, for example, a single spall develops in the outer race, an impulse occurs each time a ball passes over the spall. As deterioration occurs, the level of white noise, and the signal from the meter, should increase.

In practice, there are certain problems which can arise. There may be sources of white noise which are unrelated to the defect and, as the defect grows, the signal generated may no longer be white noise. The situation can occur where the meter signal actually reduces as the deterioration progresses.

An enhancement of the SPM technique is the use of a stress wave analyser (SWAN), which exploits the fact that the amplitude of the impulse is proportional to the relative velocity between the two bearing surfaces and to the depth of the imperfection, and gives a signal proportional to the area of the bearing fault.

19.12.6 Plant applications

Vibration monitoring can be applied both to rotating machines and to static plant. The quality of information that can be obtained goes far beyond the detection of the fact that something is wrong, and it is often possible to pinpoint the fault quite precisely.

Some typical information given by vibration frequencies, particularly those that are multiples of the speed of rotation, is shown in Table 19.13.

Figure 19.9 illustrates time histories and power spectra of vibration signals for some typical rotating machine conditions.

Vibration methods can also be applied to static plant such as distillation and gas absorption columns and heat exchangers. Figure 19.10 shows the power spectrum of a heat exchanger under normal and abnormal conditions.

In many cases, the level of vibration at a particular frequency or frequency range is low, unless there is an abnormal condition. In such cases, arrangements can be made to filter out all other frequencies so that the level of signal retained is an unambiguous indication of the abnormality. Thus for the heat exchanger shown in Figure 19.10 a suitable filter is one which retains only frequencies in the range 250–750 Hz. The resultant signal can then be used to indicate heat exchanger rattling.

19.12.7 Monitoring policy

There is now considerable vibration monitoring activity in process plants. Some machine conditions are monitored by permanent instruments, others are checked by portable meters. On critical items such as turbines, compressors and large pumps there is a high proportion of continuous monitoring with alarms and trips. These machines are also the subject of further spot checks and of sophisticated spectral analysis by specialist staff. For other less critical machines, spot checks by less skilled personnel using portable meters are often sufficient.

Table 19.13 *Frequencies detected for some common process machinery faults*

Fault	*Frequency*[a]
Oil whirl	$\frac{1}{2} \times N$
Unbalanced, eccentric journals	$1 \times N$
Misaligned shaft	$1 \times N$
Aerodynamic forces (fan)	$1 \times N$
Reciprocating forces	$1, 2 \ldots \times N$[b]
Bent, cracked shaft	$1, 2 \times \mathrm{N}$[c]
Misalignment of couplings or bearings	$1, 2, 3 \times \mathrm{N}$[d]
Mechanical looseness	$1, 2, 3, 4 \times \mathrm{N}$[e]
Defective gear	$n_g \times N$
Blade defect	$\mathrm{n_t} \times N$
Failing coupling	$\mathrm{n_c} \times N$
Defective belt drive	$1, 2, 3, 4 \times n_b$
Defective bearings	Very high, several times N
Defective mountings (soft foot)	$1, 2 \times N$[f]
Structural resonance	$1 \times N$[g]

Sources: Lees (1980b); Goldman (1984); Goggin (1987).

[a] N, the rotational speed of the machine (rpm); n_b, the rotational speed of the complete belt; n_g, the number of gear teeth; n_t, the number of blades.

[b] 1, 2 × N and higher orders.

[c] Goldman gives $2 \times N$; Goggin usually gives $1 \times N$, or $2 \times N$ if bent at coupling.

[d] Goldman gives $2 \times N$; Goggin usually gives $1 \times N$, sometimes $2,3 \times N$.

[e] Goldman gives $1, 2, 3, 4 \times N$; Goggin gives $1, 2, 3 \times N$.

[f] Usually $1 \times N$, sometimes $2 \times N$.

[g] $1 \times N$, but often odd non-synchronous frequency.

An account of monitoring policy is given by Goldman (1984). Continuous monitoring is likely to be appropriate if (1) the machine is critical to production, (2) it is costly to replace and/or (3) its failure would be hazardous. Periodic monitoring may be carried out on machines where (1) the machine is moderately important for production, (2) its replacement is costly, (3) it is a major machine but is spared or (4) it has a poor operating history.

The vibration criteria at which action is required depend on the application. For meter checks by unskilled people it is essential to have very simple criteria, while specialist personnel may base their decisions on much more complex analysis.

19.13 Corrosion Monitoring

There are available a number of methods for the monitoring of corrosion, both on-line and otherwise. Accounts of corrosion monitoring are given in *Industrial Corrosion Monitoring* (Hines, J.G. (chrmn) (1978) and by Harrell (1978), Rothwell (1979), Strutt, Robinson and Turner (1981), Asher *et al.* (1983), Dawson, Eden and Hladky (1983), Robinson and Strutt (1983) and M. Turner and King (1986).

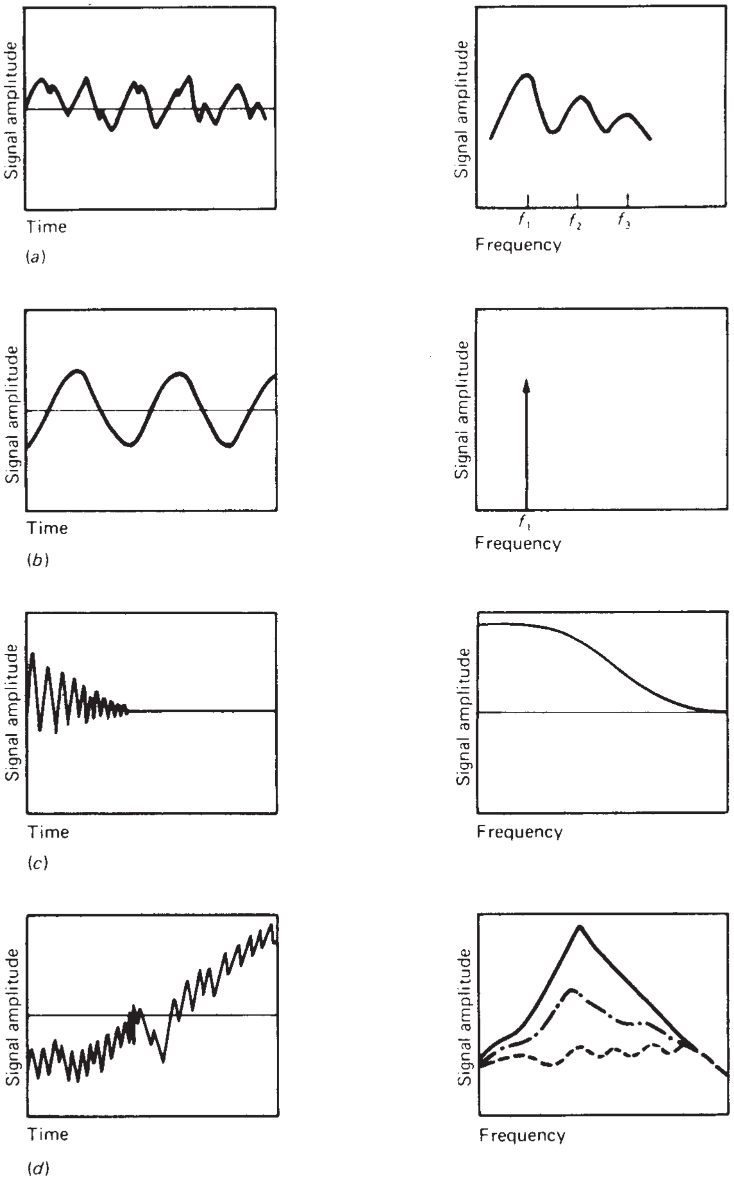


Figure 19.9 *Trend records and power spectra of some typical machine conditions (Collacott, 1975): (a) normal operation; (b) imbalance; (c) shock; (d) impending major failure*

Corrosion monitoring may be undertaken for a variety of reasons. It may be used to (1) inspect for corrosion and, in particular, give early warning of severe corrosion, and to (2) diagnose a problem, (3) monitor a solution to a problem, (4) correlate the corrosion regime with the plant operating conditions, (5) monitor the operation of the plant and (6) control the operation of the plant.

Corrosion is a complex phenomenon. This is so even under the controlled conditions of the laboratory and even more so on an operating plant. Corrosion has a number of causes and it is not advisable to place total reliance on a single method.

Some corrosion monitoring techniques identify the corrosion regime in the plant, whilst others indicate or measure the corrosion actually occurring. Taking the latter first, some principal methods are visual inspection, coupon testing and sentinel holes.

Visual examination requires access and is used particularly at shut-downs. There are a variety of aids to visual examination, including closed circuit TV and optical

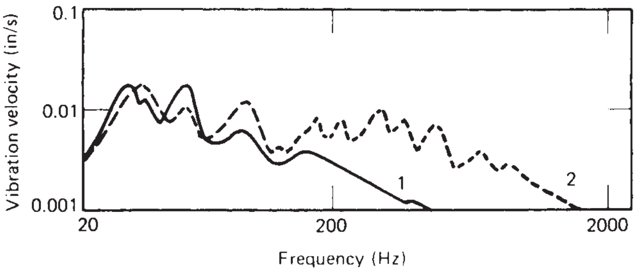

Figure 19.10 *Power spectrum of a heat exchanger (Erskine, 1976a): curve 1, exchanger quiescent; curve 2, exchanger rating (Courtesy of the Institution of Chemical Engineers)*

techniques. Coupon testing involves locating a sample element in the equipment and measuring the degree of corrosion of the element. A sentinel hole is a hole drilled through from the outside to a point close to the internal surface, so that it will leak if significant internal corrosion occurs.

Some authors include among the techniques of corrosion monitoring NDT methods such as radiography, ultrasonics, eddy current testing, AE testing and thermography.

Electrochemical methods of corrosion monitoring are described by Strutt, Robinson and Turner (1981). These methods are used for investigating the corrosion regime and include (1) chemical analysis, (2) the corrosion potential method, (3) linear polarization resistance (LPR), (4) electrochemical impedance, (5) potentiodynamic scans (PDSs) and (6) electrochemical noise.

The LPR, electrochemical impedance and PDS techniques all involve the investigation of current and voltage using a set of probes. The main difference between them is the form of input signal to the probe and the analysis performed on the output.

Electrochemical methods are best suited to providing early warning of corrosion behaviour and to correlating the corrosion regime with the operating conditions.

The control of electrochemical corrosion measurements and the display of data in various forms is a natural application for a microprocessor. The authors illustrate a number of plots that may be displayed, including trend charts, scatter diagrams, control charts, polarization diagrams and Nyquist diagrams. A polarization diagram is a plot of potential vs current and a Nyquist diagram a plot of resistance vs reactance over a range of frequencies.

An overview of corrosion monitoring methods is given by Rothwell (1979), who tabulates for each technique the type of information which it yields, the type of corrosion for which it is suitable, the environment in which it may be used, the time taken for the measurement to be made, the response to changes in corrosion, the application of the technique to an operating plant, and the ease of interpretation.

A method widely used to measure the actual rate of corrosion is coupon testing. The corrosion of the coupon may be measured gravimetrically by periodically removing and weighing it. It is important to locate the coupon so that it is representative of the corrosion to be monitored. It should generally be flush and in continuity with the vessel or pipe unless it is specifically desired to measure local corrosion/erosion effects. The choice of element size is a compromise between measurement sensitivity and replacement frequency.

The coupon testing method may be adapted to form the basis of an instrument for the measurement of the corrosion rate. The electrical resistance of the sample element increases as its cross-sectional area decreases and thus provides a measure of the cross-section remaining. Since the electrical resistance is sensitive to temperature, corrosion meters need to be temperature-compensated by using a reference element that is not exposed to corrosion. The corrosion rate is obtained by differentiating the reading of a corrosion meter.

The current in an electrical resistance corrosion meter is appreciable. For use in a hazardous area the intrinsic safety of the system may need to be checked.

Another technique for the measurement of the corrosion rate is radioactivation, as described by Baker-Counsell (1985g). This involves making mildly radioactive the surface which is subject to corrosion and measuring the change in radioactivity. In the thin layer activation version of this method, only a thin layer at the surface is activated. This has the advantages that the sensitivity of the measurement is high and the radioactivity so low as to obviate the need for taking any special precautions against it.

Typical corrosion rates are of the order of 10 mil/year (1 mil = 0.001 in.), but rates can vary widely and, in particular, under certain process conditions may accelerate dramatically.

Examples of the use of corrosion monitoring are given by Rothwell (1979). Case histories are described by Harrell (1978). A detailed account of the monitoring of a standard corrosion experiment, the corrosion behaviour of 316 stainless steel in 0.1 M NaCl, is given by Strutt, Robinson and Turner (1981).

Another method of monitoring corrosion and erosion is to measure the wall thickness by using ultrasonics. The use of ultrasonics in this application, and in particular as a method of obtaining results reproducible enough to track the progress of any thinning, is described by Browne and Constantinis (1983).

19.14 Acoustic Emission Monitoring

Many physical phenomena are associated with the emission of noise. Examples are the creaking of the branch of a tree and the 'cry' of tin. AEs may be picked up by a microphone and used to monitor both pressure vessels and process machinery.

AE monitoring is dealt with in *Mechanical Vibration and Shock Measurements* (Broch, 1980), the two IChemE guides described below, and by McFarland (1970), Witt (1971a), Fowler and Scarpellini (1980), Cole (1983, 1988, 1990, 1992), LM. Rogers and Alexander (1983), Treleaven (1983), Fowler (1986, 1987, 1988, 1992), Pollock (1986), Clough (1987), Heiple and Carpenter (1987), Frieshel and Jones (1988), Prasek (1988), Zhang (1988) and Hewerdine (1991).

The earlier guide published by the IChemE, *Guidance Notes on the Use of Acoustic Emission Testing in Process Plants*, was prepared by a working party of the International Study Group on Hydrocarbon Oxidation (ISGHO) (1985), and the current guide, *Plant Integrity Assessment by Acoustic Emission Monitoring* (Hewerdine, 1993) (the IChemE AE Monitoring Guide), was prepared by the International Process Safety Group (IPSG), the successor to the ISGHO.

19.14.1 AE sources

When a defect undergoes change, such as a crack experiencing growth, there is a release of energy, part of which is converted to elastic waves. This acoustic energy may be detected, and this forms the basis of AE monitoring. Some principal AE sources are crack growth, corrosion product fracture and local yielding.

19.14.2 AE signals

An AE occurs when a defect in a metal plate is put under stress. An elastic stress wave travels through the plate. The measurement of this wave is the basis of the AE technique. The emissions of interest occur in 'bursts', each burst being known as an event. Figure 19.11 illustrates a typical AE event. The start of the event occurs with the initial signal at arrival time t_o. There then occur a number of excursions, or counts, outside the set threshold. The event is characterized by the arrival time, the duration, the number of counts and the amplitude of the largest count, or maximum amplitude.

An AE is not emitted on all occasions when a defect is put under stress. It was held in early work that an emission occurs only when the stress is taken to a value higher than that previously applied. This is the Kaiser effect and it assumes that the energy release is irreversible. Later work showed that this was not the whole story, and that if a sufficient recovery period is allowed the emissions can again be obtained at lower stresses. This disappearance of the Kaiser effect is known as the Felicity effect. The significance of this is that if the fading of the Kaiser effect did not occur, it would be possible to use AE monitoring only for applications where a vessel was subject to successively higher pressures, which would be a severe limitation.

Different materials exhibit different AE characteristics and in order to apply the technique it is necessary to establish these. AE monitoring has been applied *inter alia* to carbon steel, stainless steel and fibre reinforced plastic (FRP) equipment.

19.14.3 AE measurement

A typical set-up for the AE monitoring of a vessel is a set of three or more probes. By using a set of three probes to give 'triangulation' and utilizing the travel times of the emission waves measured by the probes, it is possible, in principle to locate the source of the emission.

There are in fact a number of practical problems in doing this: the level of background noise; interference between one event and another; the assumption that the stress wave travels at a constant, known velocity and the calibration of the AE equipment.

The assumption of a constant stress wave velocity applies to flat steel plate. There are differences in velocity for waves in flat steel plate and in the curved walls of vessels. Also, the different frequency components travel at different velocities.

An approach based on zone location rather than source location, described by Fowler (1987), attempts to overcome some of these difficulties.

19.14.4 AE signal analysis

Early approaches to AE monitoring concentrated primarily on the location of defects. More recent work has extended this to the characterization of the parameters of the signal and of the defects. To this end extensive use is made of computer processing of the signals obtained.

19.14.5 AE monitoring characteristics

AE monitoring is therefore a technique for detecting the occurrence, and measuring of the magnitude of, dynamic changes occurring in defects rather than of the static defects. This is a fundamental difference between AE monitoring and conventional NDT methods. It has a number of implications.

One is that AE signals occur only whilst changes are taking place. Thus AE monitoring is typically conducted on a periodic basis, when plant loading is being altered, rather than continuously.

Another consequence is that a site which gives a signal detectable by AE monitoring may not give one detectable by NDT methods, and vice versa. AE monitoring can detect cracks that are growing, even though they may still be small, whereas NDT detects only larger cracks. On the other hand, the AE technique may not detect even such larger cracks unless they are experiencing growth at the time when the measurements are made.

Since AE methods give information on defect changes they complement well the techniques of fracture mechanics described in Chapter 12.

AE has the advantage that it is a global monitoring technique that allows the whole of a structure or vessel to be monitored. This distinguishes it from many NDT methods, such as ultrasonics or eddy current testing, which inspect a limited area. Furthermore, AE monitoring requires only limited access to the equipment and allows remote detection and location of flaws.

Limitations of AE monitoring are that: the structure has to be loaded; the source activity is highly dependent on the material; there may be interference from noise; the interpretation of the results can be difficult; the location of the flaw may not be very accurate; and identification of the type of defect may not be readily made.

19.14.6 AE monitoring standards and codes

There are a number of standards and codes applicable to AE monitoring. ASTM standards include: ASTM E 569−91E1, giving general guidance; ASTM E 1067–89, on FRP tanks and vessels and ASTM E 1211–87, on leak detection.

Treatments proposed by the ASME include those on the use of AE in lieu of radiography (1982), FRP vessels (1983) and on metallic pressure vessels (1989).

The Society of the Plastics Industry (SPI) (1987) has also issued a recommended practice for FRP tanks and vessels.

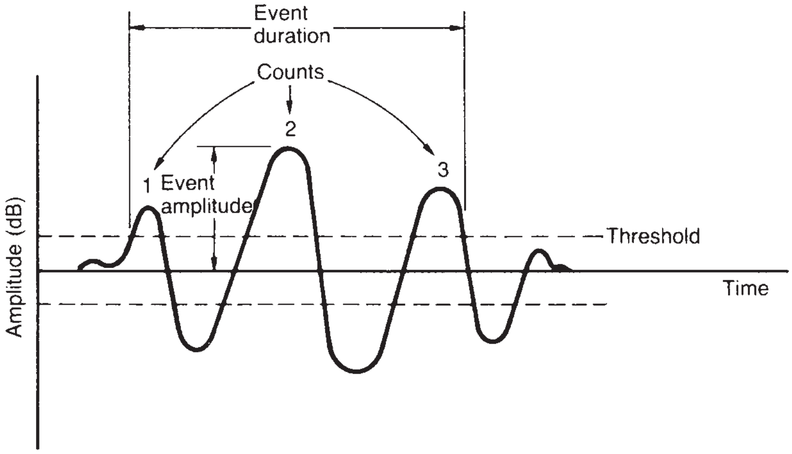

Figure 19.11 *A typical signal from an acoustic emission test*

Rail tank car monitoring is covered by a procedure of the Association of American Railroads (AAR) (1991).

With regard to the status of AE monitoring as a recognized method in pressure vessel codes, the technique has not achieved this status. The testing of new vessels is adequately covered by existing NDT techniques. Where AE has found a niche is: in the testing of new FRP vessels, where conventional NDT methods are less effective; as a complement to hydrostatic testing and in the operational monitoring of critical vessels. Since AE is a global inspection method, it appears a strong contender to satisfy any code requirements that may be developed for the inspection of pipework.

19.14.7 AE monitoring procedures

The effective application of AE monitoring requires adherence to a properly formulated procedure. A widely used procedure is MONPAC, developed in and licensed by Monsanto (1990). The procedure specifies the material and equipment covered, the maximum background noise, and the maximum sensor spacing.

The results obtained in the procedure are allocated to one of five grades, from A indicating minor source/no action, to E indicating intense source/immediate action. An account of the use of MONPAC is given by Cole (1990).

19.14.8 AE monitoring applications: FRP vessels

AE monitoring was applied early to the testing of new metal pressure vessels, but at first with limited success. It was found, however, that AE monitoring was of particular value in the testing and monitoring of FRP pressure vessels.

The use of AE for the testing and monitoring of FRP vessels has been described by Fowler and Scarpellini (1980) and Fowler (1987, 1988), who give an account of its development in one company. Initially the failure rate of FRP vessels, both new and in service, was unacceptable, some of the failures being total ruptures. Many of the conventional NDT techniques are not, however, applicable to FRP. It was therefore attractive to use AE, provided it could be made to work. In fact some problems which occur with the use of the technique on metal vessels, such as background noise, are less severe with FRP. The method proved successful to the extent that there is no record of any significant FRP defect escaping AE testing, and that it became possible to prevent catastrophic failures of FRP vessels. The technique has been adopted within the FRP industry in the United States.

Some relevant standards and codes are given Section 19.14.6.

19.14.9 AE monitoring applications: metal equipment

Despite initial difficulties, AE monitoring of metal equipment has been developed and now constitutes the main area of use. The applications of AE to metal equipment are principally for the monitoring of pressure vessels during hydrostatic pressure testing and of operating pressure vessels, particularly during the transients that occur during start-up and shut-down.

AE monitoring is also used in the testing of certain equipment such as large field-erected storage tanks and vessels in certain special materials such as titanium.

Since it is defect changes that AE monitoring detects, continuous monitoring is less common, but is practised in some instances. In some cases, vessels are fitted with permanent equipment for AE monitoring.

The use of AE monitoring during the hydrostatic testing of pressure vessels has been described by McFarland (1970). Adam (1982) has given an account of its use on ammonia storage spheres. Its application to large, refrigerated storage tanks for liquid ammonia, which are difficult to inspect internally, is described by Prasek (1988). Parry (1980) has given an account of its use to investigate potential problems on ammonia converters, including stress corrosion cracking and fretting of shrunk-on bands.

Some applications of AE monitoring to process equipment have been described by Cole (1983). These include a jacketed reactor, a reactor train, a multi-wall high pressure vessel and storage tanks, as well as FRP vessels. For the jacketed reactor, the technique was able to detect defects in the inaccessible space between the shell and the jacket (the 20 min period following admission of steam to the jacket giving strong AEs) and associate with thermal stress and corrosion. The reactor train exemplifies early detection of stress corrosion cracking. The multi-layer reactor is an illustration of an equipment that is difficult to inspect by conventional means. The application to storage tanks exploits the technique's ability to give good volumetric coverage.

The application of AE monitoring to propagating fatigue cracks in node joints and crane pedestals on offshore structures is described by L.M. Rogers (1983). Of particular value is the ability of the technique to give global coverage of all welded joints, including those that are otherwise inaccessible.

An application of continuous AE monitoring is that on the blast furnace stove domes at Redcar, described by Cole (1983). Other applications are described in the IChemE *AE Monitoring Guide*.

19.14.10. AE *monitoring applications: leaks*

High pressure and high velocity leaks give characteristic noise, as does pump cavitation, and the detection of these is another application of AE monitoring. The use of this method to detect tube failures in heat exchangers and boilers has been described by Ghia et al. (1983).

19.14.11 IChemE AE Monitoring Guide

The IChemE *AE Monitoring Guide* deals with the technique under the following headings: (1) scope, (2) role in structural integrity assessment, (3) applicability to process vessels and pipework, (4) practical requirements, (5) specific examples and (6) practical experience, as given by a user survey. It includes appendices on (1) AE basics, (2) AE test and report specifications, (3) standards and codes, (4) survey returns, (5, 6) questionnaires and (7) bibliography.

The *Guide* emphasizes the importance of defining the purpose for which AE monitoring is to be conducted and gives a flow diagram for the development of the monitoring strategy. The work should be undertaken only if both the plant and the technique are suitable, the level of background noise is not excessive and the exercise is economic.

Under practical requirements the *Guide* deals with the definition of the responsibilities of the operator and the AE contractor, the establishment of the feasibility of AE testing, the experience and qualifications of the contractor, the essential information on the containment, and the test specification, covered in Appendix 1.

The practical applications described cover a liquefied petroleum gas (LPG) storage sphere, an ammonia storage sphere, an ethylene storage bullet, a refrigerated ammonia storage tank and storage tank floor; a nitric acid column, a stainless steel column and an insulated carbon steel and stainless steel columns; a Hastelloy B reactor; a boiler drum; a deaerator; glass reinforced plastic storage tanks for sulfuric acid and hypochlorite; pipework; a crane and bearings.

Detailed results are given from the user survey, the sections of which cover the number of tests done by the participant companies, the types of test done, the types of structure tested, the materials of construction of these structures, the perceptions of success and the future intentions. It contains in Appendix 4 single-sheet summaries of individual applications.

The survey indicates that the majority of applications are to metal structures and use commercial packages, principally MONPAC. The main use is for in-service testing of pressure storage vessels and other vessels and storage tanks. More experienced users also conduct pre-service tests.

The *Guide* gives recommendations on the use of AE monitoring.

19.15 Plant Monitoring: Specific Equipment

As the foregoing account indicates, monitoring techniques can be applied to a wide range of plant equipment.

For defects in rotating equipment, prime techniques are performance monitoring and vibration monitoring. Another important method is debris analysis.

For static equipment such as tanks, vessels, columns and pipework, widespread use is made of ultrasonics. Such NDT methods are increasingly being complemented by AE monitoring. Corrosion monitoring is another technique that is widely applied, to static plant particularly.

19.16 Pipeline Inspection and Monitoring

19.16.1 Pipeline inspection

Pipelines present a rather different inspection problem from that posed by regular process plant in that they are outside the factory fence, are very long, are usually buried, and are normally required to operate without shutdown.

Traditional methods of inspection include liaison with local farms through whose land the pipeline passes, walking the pipeline and aerial survey of the pipeline. In some cases, bar holes may be sunk near the pipeline to take gas detectors. Use may be made of a search gas or radioactive tracer.

Inspections may also be made of the CP of the pipeline such as checking on coupons of the material and on the pH of the electrolyte in contact with the protected surface.

19.16.2 Inspection vehicles

The alternative to these conventional, and rather limited, methods is the use of an inspection vehicle, or 'intelligent pig'. This device is now routinely used by British Gas for the inspection of its pipeline grid. An account has been given by Braithwaite (1985). The company operates some 17,000 km of high pressure natural gas transmission pipeline in Britain. A typical line interval for inspection is about 80 km.

The inspection specification for the pig required that it should detect, locate and size defects and distinguish defects from other features with a low incidence of spurious indications. Three types of defect were of interest. One is geometric damage, which includes ovality, dents and wrinkles. Another is metal loss due to corrosion or impact. The third is crack-like defects such as plate rolling laminations, stress corrosion cracks and fatigue cracks. The avoidance of spurious indications is of some importance, because frequent spurious indications leading to the excavation of the pipeline would rapidly cause a loss of credibility.

The engineering specification required that it be capable of passing through the line without sudden changes of speed and without jamming in the line.

The pig is designed to operate in pipelines containing gaseous or liquid hydrocarbons. The pig contains three principal systems: the NDT equipment, the electronics and the power pack. There are three NDT systems: one surveys the geometry of the pipe, another detects metal loss, and the third inspects for cracks.

The quantity of data generated by the inspection equipment is very large. An area of 1 cm^2 is significant in defect terms and a typical line section of 80 km has an area of some $3 \times 10^9 cm^2$. It is not practical to store all the data generated and a computer is included to perform on-board data handling.

Braithwaite also describes the selection of the maximum inspection intervals, the field operations and the reporting and rectification procedures.

19.16.3 Pipeline leak monitoring

There are a number of methods available for monitoring the detection of leaks in pipelines. An account is given by Ellul (1989).

One approach is the use of acoustic monitoring. When a leak occurs, the sudden pressure drop creates a rarefaction wave that propagates away from the leak point at the speed of sound. This wave can be detected by acoustic monitoring.

Acoustic monitoring gives information on the existence and location of a leak, but little on its size. In ideal conditions it can detect very small leaks, but it is less effective against a background of noise from compressors and valves.

An alternative approach is to monitor the behaviour of the pipeline using some form of model. One technique is to determine a line volume balance model over some fixed period. This involves calculating the difference between the inflow and outflow, or net inflow. Different balance intervals are appropriate for different purposes. For a typical pipeline, a short-term balance over 1–2 h is suitable for relatively rapid detection of the leak, whilst a long-term balance over 3–6 h gives greater accuracy. Detection of a leak as small as 0.5% of throughput may be achieved.

Use may also be made of a more sophisticated model incorporating values of the pressure, temperature, flow and density at various points in the pipeline. The operation of the line is monitored by comparing the measured and the model values. The occurrence of a leak should cause excursions of some of these parameters outside their control limits. Criteria can be devised to flag the existence of a leak.

19.17 Notation

Section 19.7

c	corrosion allowance
f_a	nominal design strength at test temperature
f_t	nominal time-independent design strength (see text)
p	design pressure
p_t	test pressure
t	nominal thickness of section under consideration

Section 19.8

L	leak rate (Pa m^3/s)
P	pressure (Pa)
t	time (s)
V	volume of vessel (m^3)

For alternative units see text

Section 19.10

Equations 19.10.1 and 19.10.2

L	fraction of gas leaking
p_i	suction pressure
p_o	discharge pressure
T_i	inlet temperature (before addition of bypass gas)
T_o	discharge temperature
T_s	suction temperature
ΔT_H	correction for Joule-Thomson effect
μ	constant, approximately equal to ratio of gas specific heats

Equation 19.10.3

A	jet nozzle exhaust area
G_a	compressor air pumping capacity
N	compressor speed
P_d	compressor discharge pressure
T_d	compressor discharge temperature
T_i	turbine inlet temperature
W_f	fuel flow
Δ	normalized increment of variable
η	compressor efficiency

Plant Operation

Contents

Accidents on process plants arise as often from deficiencies of operations as from those of design. It is difficult, therefore, to overstress the importance of plant operations in safety and loss prevention.

Accounts of plant operation include *Process Plant Design and Operation* (D. Scott and Crawley, 1992) and those by E. Edwards and Lees (1973) and London (1982). Some reference to plant operation is also made in many of the Chemical Industries Association (CIA) codes and guidelines and the Health and Safety Executive (HSE) guidelines mentioned in Chapter 11. Selected references on plant operation are given in Table 20.1.

Many aspects of operation are dealt with in other chapters. In particular, these include: plant management (Chapter 6); hazard identification (Chapter 8); pressure systems (Chapter 12); process control (Chapter 13); human factors (Chapter 14); fire protection (Chapter 16); plant inspection (Chapter 19); plant maintenance and modification (Chapter 21); emergency planning (Chapter 24); personal safety (Chapter 25); and information feedback (Chapter 27).

The present chapter deals with some important aspects of operation which are not treated elsewhere. These are:

(1) operating discipline;
(2) operating procedures;
(3) emergency procedures;
(4) handover and permit systems;
(5) operator training;
(6) plant patrols;
(7) modifications to the process;
(8) operation and maintenance;
(9) start-up and shut-down;
(10) start-up of refinery units;
(11) shut-down of refinery units;
(12) operation of fired heaters;
(13) operation of driers;
(14) operation of storage;
(15) operational activities and hazards;
(16) sampling;
(17) trip systems;
(18) identification measures:
(19) exposure of personnel;
(20) security.

Before considering these detailed aspects, however, it is emphasized again that the safe operation of hazardous plants requires in particular competent and experienced managers and formal, well considered and fully understood systems of work. The aspects of operation mentioned are now discussed.

20.1 Operating Discipline

The safe operation of a process plant requires adherence to a strict operating discipline. This discipline needs to be formulated, along with the safety precautions, during design and then enforced in operation. An account of operating discipline is given by Trask (1990).

The impetus for the development of operating disciplines in the author's company came in the 1960s from the perceived need to ensure that the technology was uniformly applied in all the company's plants, both in the United Kingdom and overseas, and in the 1970s from the need to ensure that human technical skills were maintained in the face of increasing automation.

The steps involved in developing the operating discipline are: (1) to identify the important operating parameters, specify operating limits on these parameters, and arrange for them to be measured, controlled and monitored, using both trend records and alarms; (2) to ensure mass and energy balances and (3) to develop and document operating procedures, safety precautions and remedial actions.

20.1.1 Operating envelope

The design of the plant specifies the conditions at which it is to operate. In some cases, such as operation at different throughputs, it may specify several sets of conditions. There is, however, a degree of latitude in operation, and some divergence from the nominal design conditions is acceptable. In fact, since the design embodies inaccuracies of various kinds, it is inevitable.

It is necessary, therefore, to define the envelope of conditions within which variations are allowed but across which excursions are not permitted. In the first instance, this envelope is defined by the designer in terms of constraints related to the pressure envelope, such as vessel design pressure and temperature limits, and also to the process conditions such as flow limits related to static electricity or temperature limits related to freezing or hydrate formation. The envelope may subsequently be modified to some degree on the initiative of the plant management, but in consultation with the design function. At any given time, however, the operational envelope should be clearly defined and strictly enforced.

20.2 Operating Procedures and Instructions

Fundamental to the safe operation of plant is the development of suitable operating procedures. The procedures are normally formulated during the plant design and are modified as necessary during the plant commissioning and operation.

20.2.1 Regulatory requirements

In the UK the provision of operating procedures is a regulatory requirement. The Health and Safety at Work etc. Act (HSWA) 1974 requires that there be safe systems of work. A requirement for written operating procedures, or operating instructions, is given in numerous codes issued by the HSE and the industry.

In the USA the Occupational Safety and Health Administration (OSHA) draft standard 29 CFR: Part 1910 on process safety management (OSHA, 1990b) states:

(1) The employer shall develop and implement written operating procedures that provide clear instructions for safely conducting activities involved in each process consistent with the process safety information and shall address at least the following:
  (i) Steps for each operating phase:
    (A) initial start-up;
    (B) normal operation;
    (C) temporary operations as the need arises;
    (D) emergency operations, including emergency shut-downs, and who may initiate these procedures;
    (E) normal shut-down and
    (F) start-up following a turnaround, or after an emergency shut-down.

- (ii) Operating limits:
  - (A) consequences of deviation;
  - (B) steps required to correct and/or avoid deviation; and
  - (C) safety systems and their functions.
- (iii) Safety and health considerations:
  - (A) properties of, and hazards presented by, the chemicals used in the process;
  - (B) precautions necessary to prevent exposure, including administrative controls, engineering controls, and personal protective equipment;
  - (C) control measures to be taken if physical contact or airborne exposure occurs;
  - (D) safety procedures for opening process equipment (such as pipe line breaking);
  - (E) quality control of raw materials and control of hazardous chemical inventory levels; and
  - (F) any special or unique hazards.

(2) A copy of the operating procedures shall be readily accessible to employees who work in or maintain a process.

(3) The operating procedures shall be reviewed as often as necessary to assure that they reflect current operating practice, including changes that result from changes in process chemicals, technology and equipment; and changes to facilities.

20.2.2 Operating procedures

Accounts of the generation of operating procedures and instructions have been given by R. King (1990) and I.S. Sutton (1992).

In designing a plant, the designer necessarily has in mind the way in which it is to be operated. It is desirable that this design intent be explicitly documented, otherwise it has to be inferred from the equipment provided. In the case of batch and other sequential processes the designer normally defines the operations required to execute the sequence.

Practice in the formulation of operating procedures varies. The lead is normally taken by the plant manager. In the case of a new plant the commissioning manager is often the prospective plant manager, and will therefore undertake the task.

Operating procedures may be developed using a team of experienced people who examine successively the procedures necessary for testing and pre-start-up activities, normal start-up, normal shut-down, emergency shut-down, etc.

The information required in order to formulate procedures includes: the order in which operations should be carried out; the valve states and valve changes associated with each operation; the time required to perform the operation; and the operations which have to be completed before another operation can be initiated.

For a new plant an initial set of operating procedures is devised, but these are likely to be modified as the result of experience during the commissioning. Likewise, procedures for an existing plant will undergo changes based on operating experience, as well as changes due to process or plant modifications.

The extent to which process operators are involved in the formulation of operating procedures varies. Some operating procedures are modelled on the practice of the 'best' operator. Operators also devise short cuts. These should be examined, and accepted or rejected, as appropriate, with reasons given.

A formal method of analysing the operator's task is available in task analysis, which is described in Chapter 14.

It is the task of management in formulating operating procedures to clear up muddled thinking, to identify incorrect assumptions, to resolve differences and to eliminate inconsistencies. The ultimate responsibility for the operating procedures rests with the plant manager.

20.2.3 SRDA Operating Procedures Guide

A systematic approach to the development of operating procedures is given in *Developing Best Operating Procedures* (Bardsley and Jenkins, 1991 SRD SRDA-R1) (the SRDA *Operating Procedures Guide*).

The SRDA *Guide* distinguishes between two basic types of documentation to support operator performance: (1) manuals and (2) job aids. Essentially a manual is a resource, which is a store of information to which managers, engineers and trainers may refer. The information contained in it, however, is usually not in a form best adapted for direct use by the operator. What he requires for immediate use is a job aid.

Operator support documentation may take the form of (1) procedures, (2) checklists or (3) decision aids. The simplest form of procedure is a set of actions which are performed in sequence with a minimal feedback requirement. More complex procedures involve actions which are dependent on a lapse of time and/or the state of the process, or which involve sets of actions other than a straightforward sequence. The typical checklist is an *aide memoire* used to check the state of items on the plant, notably valves, prior to undertaking some operation such as start-up. Decision aids, in the form of decision trees, or flowcharts or algorithms, guide the operator through the decision pathways. There are also other types of decision aids, used particularly for fault diagnosis, such as functional diagrams. In addition to these specific forms, documents often contain explanations.

The *Guide* poses six basic questions to be asked concerning the operator's use of a support document. The writer needs to ask how the operator decides when to use the document, how he locates the document itself and how he locates the required help within it. Furthermore, the writer must ask whether the document provides the information sought in a form such that appropriate action is selected, whether it indicates the circumstances in which an alternative course of action is required and whether it states how the action is to be controlled. Finally, the writer should check that the document has been successful by means such as monitoring of feedback.

In addressing the question of operator support documentation, the first step is to establish that there really is need for it. One general justification is compliance with regulatory requirements or company policy. Another justification is the nature of the task.

On this the *Guide* both gives some general pointers and also outlines some specific techniques. With regard to the former, some task characteristics that may indicate the need for job aids are that: it is critical; it is difficult, for example fault diagnosis; it is performed infrequently, for example an emergency procedure; and/or it is long and involves memory load. If a job aid is to be provided, there must be time for it to be located and used.

It needs to be borne in mind that a job aid may not prove as effective as expected. Some reasons for this are that it remains unused, that it is seen as taking the skill from the task and that it may restrict the choices available to a skilled person.

The specific techniques referred to are those of task analysis and human reliability analysis.

The *Guide* describes the process of designing and implementing an operating support document in terms of the following stages: (1) the definition of the purpose and scope and the selection of a format (manual or job aid), (2) the establishment of collaboration with sources of information, (3) the establishment of information content, (4) the prototyping, (5) the preparation of a draft, (6) a review of the draft both for technical content and usability, (7) implementation and (8) maintenance.

An account is given of hierarchical task analysis and of human reliability analysis, both of which have been described in Chapter 14. In respect of the latter, the two techniques considered are SHERPA and CADA.

The writing of an operating support document which can be understood requires careful attention both to the written text and to the alternatives to such text. Aspects of the written text treated in the *Guide* are: the use of a comprehensive vocabulary, supported if necessary by a glossary, and of conventional terms as opposed to jargon; the use of the active rather than the passive tense; care with the use of negatives; retention of the definite and indefinite articles; the use of short sentences; the presentation of instructions as a sequence; and an indication of any applicable preconditions. The *Guide* gives detailed guidance on character style, punctuation and layout.

The *Guide* also describes the use of tables and figures. Tables provide a good format for stating the courses of action to be taken in different situations. The types of tables given are the condition-action table and the decision table, both akin to a truth table, and the look-up table. The types of figures described are decision aids in the form of flowcharts, and various kinds of equipment diagrams, including photographs. Equipment diagrams include: drawings, or sketc-hes, of single equipments or ensembles, which are useful for identifying and locating components; line diagrams showing the main items of equipment and the connections between them; and functional flow diagrams giving the functional as opposed to the physical structure of the system.

Guidance is also given on document organization and layout. A hierarchical organization is recommended and aids to moving around the document are described. The need for consistency is emphasized.

Finally, the *Guide* discusses the tools available for the production of the document such as word processors, desk top publishing packages, object oriented drawing packages and so on.

20.2.4 Operating instructions

Accounts of the writing of operating instructions from the practitioner's viewpoint are given by Kletz (1991e) and I.S. Sutton (1992).

Operating instructions are commonly collected in an operating manual. The writing of the operating manual tends not to receive the attention and resources which it merits. It is often something of a Cinderella task.

As a result, the manual is frequently an unattractive document. Typically it contains a mixture of different types of information. Often the individual sections contain indigestible text; the pages are badly typed and poorly photocopied; and the organization of the manual does little to assist the operator in finding his way around it.

Operating instructions should be written so that they are clear to the user rather than so as to absolve the writer of responsibility. The attempt to do the latter is a prime cause of unclear instructions.

A set of instructions which illustrates the above principles has been given by Kletz, as shown in Figure 20.1. Further examples are given by Sutton.

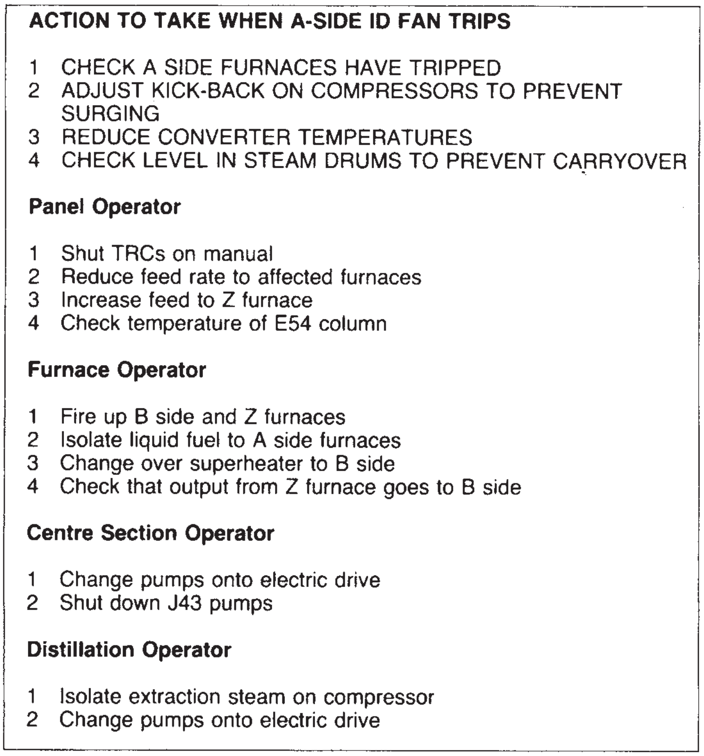
This latter author describes a method of writing the operating instructions, and of creating the operating manual. Basic requirements for the operating instructions are that they should be complete, up-to-date, properly indexed and easy to use.

The operating manual is organized in the format of a tree that is developed from the top down. It starts with broad categories of procedure such as start-up, normal operation, normal shut-down, etc., and is developed until it reaches, at the bottom level, the sets of specific operating procedures, or modules. It may be noted that this layout conforms closely to the tree structure used in task analysis.

A distinction is made between information, rules, procedures and checklists. Information is provided for reference, but selectively. Rules are stated, although these are likely to be of more interest to managers and supervisors than to operators. Checklists are given as appropriate.

Instructions are given for each procedure. The procedure may be based on a generic procedure, such as that for pump start-up, but with specific modifications for the operation in question. The level of the instructions should be such as to allow an experienced operator to run the plant with minimal reference to the supervisor. Each instruction should have an imperative verb in the active tense. Warnings, cautions and notes are inserted in the text of the procedure, as appropriate; a warning should precede the procedure.

As described by Sutton, a module may be referenced in any part of the manual and by any writer, but only by its title; reference should not be made to the content of the



ACTION TO TAKE WHEN A-SIDE ID FAN TRIPS

1 CHECK A SIDE FURNACES HAVE TRIPPED
2 ADJUST KICK-BACK ON COMPRESSORS TO PREVENT SURGING
3 REDUCE CONVERTER TEMPERATURES
4 CHECK LEVEL IN STEAM DRUMS TO PREVENT CARRYOVER

Panel Operator

1 Shut TRCs on manual
2 Reduce feed rate to affected furnaces
3 Increase feed to Z furnace
4 Check temperature of E54 column

Furnace Operator

1 Fire up B side and Z furnaces
2 Isolate liquid fuel to A side furnaces
3 Change over superheater to B side
4 Check that output from Z furnace goes to B side

Centre Section Operator

1 Change pumps onto electric drive
2 Shut down J43 pumps

Distillation Operator

1 Isolate extraction steam on compressor
2 Change pumps onto electric drive

Figure 20.1 *Format of operating instructions: extract from a plant instruction showing the action to be taken by an operating team of one supervisor and four operator when the induced draught (ID) fan providing air to a row of furnaces (known as A side) stops (Kletz, 1991e) (Courtesy of the Instituition of Chemical Engineers)* module. This discipline, which has much in common with that followed for computer program subroutines, facilitates the updating of the manual by allowing a single module to be replaced at any time.

The manual is more readable by basing it on graphics rather than text so that the text supports the graphics rather than vice versa. Modules are written in a two-page format, which is what the user actually sees at a given time.

The manual should define clearly the authorization for particular actions.

Commonly the manual contains a section on troubleshooting. This activity is quite different from that of following a procedure for normal operation. Such a procedure is a closed activity and the instructions for it are intended to be followed without deviation. Troubleshooting, by contrast, is open-ended and creative. The procedures for it are not definitive and do no more than offer guidance.

The creation of the operating manual involves, first, the definition of the manual structure, then the collection of the information and, finally, the writing of the modules. Sutton estimates that his method may involve an effort which is an order of magnitude greater than the conventional approach. A further account of the creation and contents of the operating manual is given by R. King (1990), with a detailed discussion of suitable contents.

Commonly the operating manual is a hard copy document. It should be available on the plant. Some personnel may be given a personal copy. Authority to make modifications to the manual should be clearly defined. The manual should be kept up to date, including personal copies where issued.

The advent of computer aids such as word processing and graphics packages opens up an alternative approach in which the master version of the operating manual is kept in the computer with various options for hard copy.

In addition to the treatment given by these three authors the following comments may be made. Regard should be had to the intended users of the operating instructions. These include (1) novice operators, (2) operators whose experience has been on other plants but who are being trained for the plant in question and (3) operators experienced on that plant. The organization of the operating manual into successively more detailed levels goes some way towards meeting their different needs. An experienced operator may require operating instructions mainly for safety critical operations or operations performed only rarely.

The simplest operating instruction is a linear sequence of actions. There is a limit to the degree to which an operating instruction may be extended to include decision trees, branches and loops. Generally these are avoided if possible, except for diagnosis. On the other hand, it is common to include general advice about and/or specific instructions for recovery from potential problem situations.

Practice with regard to use of graphics appears to vary. As stated, Sutton's approach is that the text is there to support the graphics. At the other end of the spectrum operating instructions are written which make minimal use of graphics.

Operators are typically provided with operating instruction sheets/checklists which may well be reproductions of sheets in the operating manual and which they can take out onto the plant. It may also be appropriate to provide other aids such as a list of alarms and trips.

The writing of the operating instructions is a significant task. Some principal sources of information are the quantities flowsheet, the engineering line diagram, the design manual and vendors' manuals. The contractors may provide very little and vendor information may become available only late in the day. The situation is eased if an operating manual is available from a previous plant.

The first task faced by the person charged with producing operating instructions tends actually to be the provision of instructions for commissioning. This can be as large a task as the creation of the instructions for normal operation. Commissioning activities for which instructions may need to be provided include plant water testing, control loop testing, load cell testing and checks on vessel fill times, completeness of vessel emptying, and heating and cooling rates. The instructions should also cover checks to ensure that before an equipment is brought into use each of its instruments is operational.

Many operations involve the reading of instruments. The instructions need to specify the readings at which action must be taken. A considerable part of the effort required to write the instructions may have to be devoted to specifying these readings and the writer may have to search through a number of documents. In addition, water testing requires some readings to be specified also for water as the fluid.

In devising operating instructions regard should be had to the practicality of the individual actions and sequence of actions required. It is not desirable, for example, to create a sequence of actions in which one has to be performed at the top of a tower, the next back down at ground level and the next up at the tower top again. Another area where thought is necessary is the response to alarms and the settings on alarms. For example, the implications of and the response times available for a particular fractional fill may be different from one vessel to another.

If the plant is a computer-controlled batch plant the number of operator interventions may be quite small and may involve relatively little decision-making. In this case the proper operating instructions are likely to be a mix of computer sequences with occasional manual operations such as additions and instructions on recovery from problems.

The operators will require training in the operation of the plant based on the operating instructions. It is necessary, therefore, to provide a training manual. This may draw on the operations manual. Typically it contains an operating instruction section together with other material such as a training plan, workbook exercises, an assessment plan and performance criteria. The need for a training manual may be regarded as a principal justification for the creation of the operating manual. Training in operating procedures is discussed in Chapter 14 and is mentioned in many other chapters.

20.3 Emergency Procedures

A set of operating procedures of particular importance are the emergency procedures. It is generally recognized that it is not possible to provide detailed procedures for all possible emergency scenarios. In the *Guide to Safe Practice in the Use and Handling of Hydrogen Fluoride* (CIA, 1978) the following two-pronged approach is recommended:

> Firstly, careful consideration should be given to what major emergencies can be reasonably foreseen, and the detailed procedure for tackling these (few) serious situations should be dealt with specifically both by training sessions and special instructions.

> Secondly, since it is impossible to cover all eventualities by instructions which will be effectively remembered or found for reference during an emergency, it is advisable to give a series of general instructions, amply backed by training, which will provide guidance for the correct action in those emergency or potential emergency situations which have not been dealt with by specific cases. Such aspects as equipment isolation, the recognition of hazardous conditions, and communications are fundamental matters which can be treated in this way.

Emergency procedures are commonly treated in codes under the following headings: (1) leak detection and characterization; (2) raising the alarm and associated actions; (3) isolation of leaks; (4) handling of leaks and spillages; (5) action against fire; (6) emergency equipment and (7) special features of particular chemicals.

These topics are considered at this point, except that raising the alarm and associated actions are treated in Chapter 24 and the treatment of action against fire is limited – the main account being given in Chapter 16.

20.3.1 Emergency equipment

Emergency equipment commonly listed in codes includes (1) protective clothing, (2) breathing apparatus, (3) emergency tool kits and (4) fire fighting equipment.

20.3.2 Leaks and spillages

Leaks and spillages are a relatively common occurrence on process plants and it is necessary to have procedures for dealing with them. Discussions of leaks and spillages have already been given in Chapters 10, 15, 16 and 18 in relation to plant layout, dispersion, fire and toxic release. It is appropriate here, however, to review some of the more general aspects of the problem from the operational point of view.

Plant management should formulate procedures for dealing with leaks and spillages. The range of actions required varies with the nature and size of the leak. In all cases personnel handling the leaks should wear any necessary protective clothing and breathing apparatus.

A small leak may often be stopped relatively easily. If the leak is more serious, other measures are required. The ICI LFG Code (ICI/RoSPA 1970 IS/74) lists these for liquefied flammable gases. If it is practical to do so, the leak should be isolated. This is not always possible with manually operated valves that may be enveloped in the gas cloud. Remotely operated isolation valves may be used if installed. Instructions should take account of possible difficulties in effecting isolation. Other measures to reduce leakage include depressurizing and blowdown.

Personnel involved in controlling the situation should avoid entering the vapour cloud. The leak should be approached only from upwind. Other personnel should not be allowed in the area. There should be some method of warning and evacuating them, and also of sealing off the area.

Measures should be taken as appropriate to disperse or contain the leakage. This aspect is discussed in Chapters 15 and 16.

The area to which a flammable vapour cloud is likely to spread should be cleared of sources of ignition, which include not only activities such as hot work but also traffic. It may be necessary to close roads and railways that the vapour could reach.

The emergency services should be alerted as appropriate.

After the incident is over, any record required by the reporting system should be made.

20.3.3 Leaks and spillages: detection and characterization

For large releases, detection of a leak and characterization of the resultant cloud are important. These are discussed in the CCPS *Guidelines for Vapor Release Mitigation* (1988/3).

For detection the first line of defence is gas detectors. The *Guidelines* discuss the detectors available and their positioning. Accounts of detectors for flammable and toxic gases are given in Chapters 16 and 18, respectively.

In most plants there are personnel who may detect the presence of the gas. Detection by humans is discussed in *The Perception of Odors* (Eugen, 1982) and data on odour thresholds are available in texts such as *Compilation of Odor and Taste Threshold Value Data* (Fazzalari, 1978). Selected data are given in the *Guidelines*. Appendix 11 contains a further discussion of odours.

If a leak occurs, which gives rise to a large vapour cloud, it assists in handling the emergency if personnel are able to estimate the size and movement of the cloud. Their ability to do so depends on its visibility. A small number of substances yield, at a sufficiently high concentration, a vapour cloud which is visible by virtue of its colour. Principal examples are chlorine and bromine, which give a greenish-yellow and a reddish-orange cloud, respectively.

A more common form of visible cloud is that caused by fog formation. Liquefied flammable gases and other liquefied gases such as ammonia, hydrogen chloride and hydrogen fluoride may give rise to fog, depending on the conditions of release and the atmospheric humidity. The *Guidelines* devote an appendix to fog correlations and give the following relation for the concentration at the interface between the regions where fog is and is not generated

$$C = k\ln(1/\psi) \qquad [20.3.1]$$

with

$$k = \frac{1.75 \times 10^6}{H_s^{2/3}} \qquad [20.3.2]$$

where C is the interface concentration (ppm), H_s is the heat of solution (cal/gmol), ψ is the fractional humidity (% relative humidity/100) and k is a constant.

20.3.4 Leaks and spillages: water and foam

One method of dealing with a liquid spillage is the application of foam. Regular foam is mainly water and its use will often actually increase the rate of vaporization of the spilled liquid, thus making the situation worse. On the other hand, there are legitimate uses of foam. The use of foam on liquid spillages is discussed in Chapter 15. Some limited comments are given below.

If the chemical is completely miscible with water, water may be applied to dilute it. However, the number of industrial chemicals which pose a significant hazard and which are water miscible are limited.

20.3.5 Leaks and spillages: particular chemicals

The response to a leak or spillage emergency depends also upon the specific characteristics of the chemical released.

For hydrocarbons the main hazard is that of fire or explosion, and also that of injury by freezing due to contact with cold liquefied gas. The best way of dealing with an unignited leak of hydrocarbon is to shut it off by isolation. A spillage of liquid hydrocarbon should be contained to the extent possible. This is principally a matter of plant layout and the operational measures which can be taken are fairly limited.

The CIA codes and guidelines give some guidance on handling leaks and spillages of other substances. Mention is made here of just one or two of these to illustrate the principles involved.

An acrylonitrile spillage should be contained with sand or earth and covered with a 150 mm layer of mechanical foam and an emulsifying agent or absorbent material. Aqueous solutions may be treated with calcium or sodium hypochlorite in appropriate proportions. Where these treatments are not readily available, surface spillages may be diluted with large quantities of water.

A spillage of ethylene oxide may be handled by diluting it with a quantity of water sufficient to render it non-flammable. This may be done using water sprays or, where available, water monitors. It may be noted, however, that in discussing the disposal of the contents of a storage tank the guidelines state that it is not usually practical to dilute liquid ethylene oxide to the point of non-flammability and that liquid which has not been rendered non-flammable needs to be treated as a flammable liquid.

For a vinyl chloride spillage the preferred method of control is the use of high expansion mechanical foam. For this not to aggravate the situation, the pool needs to be not still spreading but contained and at least 2 in. deep.

20.3.6 Action against fire

A large proportion of plant fires are due to hydrocarbons. If the fire consists of an ignited leak burning as a jet flame on the plant, the usual practice is to let it burn. It is generally not desirable to seek to extinguish the flame on such a leak, since this risks creating a vapour cloud, which might then explode. The other main form of hydrocarbon fire is a pool fire. The fighting of hydrocarbon fires is discussed in Chapter 16.

There is a limited amount of guidance in the CIA codes and guidelines on action against fire of other substances. The guidance given for pool fires of vinyl chloride (CIA, 1978 PA15) illustrates some of the principles. For a large pool fire, foam can be effective in limiting vaporization and thus in controlling the fire. There is an option to seek to extinguish the fire by using a larger quantity of foam but, unless there are pressing reasons for doing otherwise, it is preferable to let the fire burn out under controlled conditions.

Vinyl chloride also illustrates the problem of toxic combustion products, the products in this case being hydrogen chloride and carbon monoxide. Use may be made of water sprays to disperse and absorb some of the hydrogen chloride. But in any event, persons downwind should be evacuated.

20.3.7 Case history

A case history has been described which illustrates the value of good emergency procedures (Anon., 1991 LPB 98 p. 25). In the course of a stress relieving operation on a 50 mm pipe on a chlorine storage module, a 0.5 m section was burned away by an iron-chlorine fire. The leak was picked up by the gas detectors, the gas alarms operated and the operator went to investigate. He called on the lead operator to sound the chlorine alarm, donned a breathing apparatus set and went and closed the appropriate valves. The site emergency teams arrived and within 3 minutes set up water curtains, but these were not needed as the leak had already been isolated and the cloud was dispersing.

20.4 Handover and Permit Systems

20.4.1 Handover systems

Most large process plants operate round the clock on a shift system. It is essential that information on the state of the plant be communicated by the outgoing shift to the incoming shift. A formal handover system is necessary to ensure this.

The lack of such a system was held to have been a cause of the Piper Alpha disaster. As described in Appendix 19, the operating crew attempted to start-up a pump which was actually under maintenance and thus initiated the leak. The lead maintenance hand told the Inquiry that there were no written procedures for handover and no specification of the information to be communicated at handover. Thus maintenance work was not always covered in the operator's log. He stated: 'There were always times when it was a surprise when you found out some things that were going on'. As it happens, the Piper Inquiry also heard evidence that shortly before the disaster a fatal incident had occurred in which there had been inadequate communication of information from the day shift to the night shift.

There should be a formal and detailed procedure for shift handover. It should cover both operating and maintenance personnel. On the operating side these will normally include the lead operator, the control room operator and other operators who are normally out on the plant, and the lead maintenance hand. There should be a formal logbook that is signed by the incoming person responsible for the particular function. Such a system requires that sufficient time be allowed for the handover to take place and for the outgoing shift to brief fully their counterparts on the incoming one.

An aspect of handover which is of particular importance is the status of permits-to-work. Much of the information which needs to be communicated at handover is likely to relate to such permits.

20.4.2 Permit systems

Another important form of communication is the permit-to-work system just mentioned. Permits are raised mainly in connection with maintenance work and discussion is deferred to Chapter 21. Here it is sufficient to note that the actions of handing over a section of plant to maintenance, and receiving it back, are important not only for maintenance but also for the operating function.

20.5 Operator Training

The process operator runs the plant and deals with the faults which arise in it. He has many training needs which must be met if he is to do the job properly. An account of the principles underlying the training of process operators has been given in Chapter 14. This chapter also discusses some of the specific topics in the area of process operation on which the operator requires training. Safety training of operators is considered in Chapter 28. Other references to operator training are given throughout the text.

As regards the content of operator training, consideration needs to be given not just to the operating procedures and safety training, but also to other topics where the operator has some responsibility. These include, for example, plant maintenance and modification and plant security.

The training of process operators should not be a once-and-for-all exercise, but should involve updating as appropriate. There may also be special additional training such as that associated with the commissioning of a new plant.

20.6 Plant Patrols

One of the principal functions of operators on process plants is the detection of faults. The detection of faults by the process operator in the control room has already been discussed. Other faults, particularly leaks, are detected by operators during routine patrols.

In one study of the detection of nearly 400 abnormal occurrences, analysis showed that some 40% were detected by routine patrols and another 5% by people who were in the plant area.

An investigation of pipework failures by Bellamy, Geyer and Astley (1989) found the following pattern of detection:

	No. of incidents	*Proportion of incidents* (%)
Alarm	12	26
Automatic detection	4	8.5
Human	27	57
Delayed	4	8.5
Total	47	100.0

Routine patrolling is therefore important and specific arrangements need to be taken to ensure that it is carried out. In particular, steps may be taken to ensure that certain vulnerable features are regularly passed by an operator. Thus in design certain instruments may be located at points which cause the operator to pass by such features, whilst in operation, instructions may be issued for the taking of regular readings from such instruments.

20.7 Modifications to the Process

A process rarely operates for long without undergoing some modification. There are almost always changes in raw materials, in the operating conditions, such as flows, pressures and temperatures, concentrations, or in other aspects. The Flixborough disaster has drawn attention to the potential hazards of modifications to the plant. But modifications made to the process are also potentially hazardous.

As it happens, Flixborough provides an illustration of a process modification also. The reactors were provided with agitators, but at the time when the explosion occurred the agitator in No. 4 Reactor was not in use. The absence of agitation is a crucial point in the hypothesis advanced by R. King (1975c, 1977, 1990) that there was a sudden evolution of water vapour in that reactor.

There is clearly little point in paying meticulous attention to ensuring close control of plant modifications so that the pressure system retains its capability to handle the design conditions for the operating variables, if there is no check on changes made to these parameters. A system is required, therefore, for the management of change in the process as well as in the plant. A system for the control of both process and plant modifications is described in Chapter 21.

20.8 Operation and Maintenance

Maintenance and modification work may present hazards both to the plant and to the workers involved. It is important, therefore, for the plant manager to give full consideration to the implications of such work being carried out on his plant and for him to take appropriate precautions. As a minimum these precautions should be the operation of a suitable permit-to-work, as described in Chapter 21, but in addition some operations require extra measures.

The types of precaution which may be required are illustrated by those described by Hahn (1975) for hot tapping. This is a potentially hazardous operation involving drilling a hole into and fitting a branch on a pipe while it is still on line; the technique is described more fully in Chapter 21. The aspects requiring consideration include (1) pipeline fluid conditions, (2) elimination of leaks, (3) local hazards, (4) emergency isolation, (5) warning system, (6) access and escape routes, (7) fire and rescue services, (8) welders' protective clothing, (9) welding supervision and (10) operations supervision.

The plant manager should check the pipeline fluid conditions, such as flow, pressure and temperature, under normal operation, should agree with the welding manager the conditions to be held during the hot tapping operation and should take steps to ensure that these are maintained. The drains in the area of the welding operation should be sealed off and a review made of sources of flammable or obnoxious materials such as leaking joints or lutes. Any local hazards, including those not connected with the welding operation, should be considered and the personnel involved should be fully briefed about these hazards. Arrangements should be made to isolate the pipeline and affected areas in the event of an emergency. A warning system should be set up to inform plant personnel and emergency services if an emergency occurs. Access should be checked so that emergency services can reach the tapping point and the plant, and the areas sealed off to other traffic if necessary. A check should also be made on escape routes, which at night may need additional illumination. A rescue man from the works fire service should stand by during the operation with a radio link to the fire station to summon the fire rescue services in an emergency. He should be prepared for fire fighting and should have the necessary equipment. A plant fireman should also stand by. A check should be made that the welders have the appropriate protective clothing. The work should be supervised by personnel from both the welding and the plant functions. If possible, the plant manager should be present.

The arrangements described indicate that some maintenance or modification work requires the rather close involvement of the operations side.

20.9 Start-up and Shut-down

As take off and landing are more hazardous operations for an aircraft, so on a process plant the hazard is greater during start-up and shut-down. General principles of plant start-up and shut-down are discussed by D. Scott and Crawley (1992). The procedures for the start-up, operation and shut-down of particular types of plant are considered in the following sections.

Most accounts of the operation of process plants distinguish the following modes:

(1) normal start-up;
(2) normal operation;
(3) normal shut-down;
(4) emergency shut-down.

Shut-down is not always total. Sometimes there is a partial shut-down to a condition of 'hot standby'. This avoids the need to go through the full sequence of shut-down and start-up operations, and allows operation to be resumed more quickly.

There are, however, further relevant distinctions. Leaving aside the initial start-up when the plant is commissioned, there are variations in start-up depending on the condition of the plant prior to start-up. Some distinctions are:

(1) normal shut-down condition;
(2) hot standby condition;
(3) emergency shut-down condition;
(4) major scheduled shut-down, or turnaround, condition;
(5) prolonged shut-down, or mothballing condition.

The condition of the plant following emergency shut-down depends on the cause of the shut-down, and hence this category actually includes a whole set of different pre-start-up conditions.

The start-up considered here is not the initial commissioning, which is dealt with in Chapter 19, but the resumption of operation after a shut-down.

The actual procedures for start-up and shut-down depend on the process, and vary somewhat. Start-up of a plant with a low temperature section, for example, has special features.

20.9.1 Normal start-up

Start-up requires that the plant be taken through a predetermined sequence of stages. It is important that this sequence be planned so that it is safe and avoids damage to the plant and so that it is flexible enough to handle difficulties which may arise. The conceptual and detailed design of the start-up sequence is discussed in Chapter 11. The personnel involved in the start-up should understand the reasons for the sequence chosen and should adhere to it.

The extent to which detailed procedures can be formulated for start-up depends on the condition prior to start-up. For start-up following a major scheduled shut-down it may not be practical to provide fully comprehensive instructions and it may be necessary to rely instead on the use of checklists for equipment and activities. On the other hand, for start-up from hot standby or a short shut-down it may be possible to provide relatively complete procedures.

Start-up is an operation which needs to be properly planned so that all the resources are available when required. This applies particularly to personnel, for example instrument fitters, and to utilities, for example inert gas.

Start-up should be preceded by a series of pre-start-up checks. These should be governed by a formal system. The plant is first checked to ensure that it is mechanically complete, that there are no missing items such as valves, pipes or instruments, that the status of vent, drain and sample points is correct and that slip plates have not been erroneously left in pipework. A check is then made to ensure that the instruments are working. The availability of the utilities is confirmed. The hand valves are then checked to ensure that the status of each is correct.

In many cases the plant is linked through flows of products and by-products to other plants and the start-up needs to be co-ordinated with the operation of these interlinked plants. Similar considerations apply to the utilities.

Many plants generate services such as fuel gas, steam or electricity which they reuse and recover heat through complex heat exchange arrangements. Features of this sort add considerably to the complications of start-up.

The start-up period is one when serious damage can be inflicted on plant equipment. Thus mention has already been made of the danger of using up a large proportion of the creep life during commissioning. Similar damage can be inflicted in regular start-ups.

Start-up is a time when there is a much higher than average risk of getting unwanted materials such as air or water into the plant. It is necessary to pay particular attention to these hazards.

Instruments are of particular importance during start-up, but unfortunately are likely to be less accurate or reliable than during normal operation. This should be borne in mind if an instrument failure could give rise to a hazardous condition.

It is an essential requirement, therefore, that there be a formal but practical system to control start-ups, that there be proper documentation and that the personnel be fully trained in the procedures.

20.9.2 Normal operation

The normal operation of the plant is discussed in Chapter 13 and is not considered in detail in this section, but there are several points that may be restated.

The plant management should ensure that the objectives of, and constraints on, the operation of the plant are clearly defined and well understood by the process operators.

There should be a full understanding of the relative roles of the operator and the trip system in the face of a developing abnormal condition. In essence, it is the function of the operator to try to prevent this condition developing to the point where a parameter goes outside its permitted envelope and that of the trip system to shut-down if such an excursion is imminent.

It is desirable that there be holding states, or fall-back positions, short of full shut-down, to which the operator can move the plant while a problem is sorted out.

In any event, management must make it clear beyond doubt that any conflict between production and safety is to be resolved in favour of the latter.

20.9.3 Normal shut-down

Normal shut-down starts from the condition of normal operation and its preceding condition is therefore relatively well defined. This makes it practical to formulate shut-down procedures more fully than for some of the start-up situations mentioned.

Many of the features of start-up mentioned earlier, such as the effect on other plants and on utilities, apply *mutatis mutandis* to shut-down.

20.9.4 Emergency shut-down

Emergency shut-down may be effected by an automatic protective system or by the operator. In the first case the operator's function is to forestall the activation of the automatic system by averting the threatened parameter excursion, whilst in the second he has the additional function of performing the shut-down if it becomes necessary.

In some systems an intermediate case occurs, where the automatic system shuts down part of the plant but it is left to the operator to shut-down other parts. This is the case, for example, on some oil production platforms, where the main oil line may be shut-down automatically but the gas lines to and from the platform, which are linked to other platforms, are shut-down manually, thus allowing a degree of coordination with other platforms which would be affected.

The emergency shut-down procedure is generally designed so that the conditions which should trigger it are unambiguously identified and the actions to be taken are clearly defined. A typical shut-down condition is the imminent excursion of a parameter. Typical shut-down actions are shutoff of heat input and depressurization of vessels.

For emergency shut-down by the operator, emergency shut-down procedures should be provided, in the form of a general emergency shut-down procedure. There may be some variability in this procedure depending on the event forcing the shut-down, but an excessive number of variations should be avoided.

These emergency shut-down procedures are to be distinguished from the procedures required to deal with escapes from the plant, which are generally referred to as emergency procedures.

Emergency shut-down is discussed further in Chapters 13 and 14.

20.9.5 Prolonged shut-down

If shut-down is prolonged, precautions should be taken to prevent deterioration of the plant. Typical examples are inspection of equipment to check for external corrosion and 'turning over' of pumps to avoid 'brinelling'. Prolonged shut-down, and start-up from this condition, is discussed further in Chapter 10.

20.9.6 Restart after discovery of a defect

If it is necessary to shut the plant down on account of a fault, the cause and implications of the fault should be established and any necessary measures taken before the plant is started-up again. This situation should be covered by a procedure which details the steps to be taken after such a fault is discovered and before the plant is restarted.

At Flixborough it was found that No. 5 Reactor had developed a crack 6 ft long, but the plant was put back on stream without a thorough examination of the other reactors, an omission which is criticized in the Flixborough Report.

20.10 Start-up of Refinery Units

Accounts of the start-up and shut-down of refinery units are given in *Safe Ups and Downs* (American Oil Company, Amoco/4) and by Hayes and Melaven (1964). Some principal hazards are:

(1) mixing of air and hydrocarbons;
(2) contacting of hot oil and water;
(3) water shots and water freezing;
(4) over- and underpressuring of equipment;
(5) thermal and mechanical shock to equipment;
(6) corrosive and poisonous fluids;
(7) pyrophoric iron sulfide.

The last item is a hazard mainly during shut-down, but the other hazards occur during both start-up and shut-down. Fired heaters present particular hazards and are dealt with in Section 20.12. Start-up should include the following phases:

(1) preparatory activity;
(2) removal of air;
(3) leak testing;
(4) disposal of purge material;
(5) removal of water;
(6) bringing on stream.

The plant should be inspected to check that it is ready for start-up. The auxiliary systems such as the utilities, instruments and gland oil systems should be activated. Shut-down blinds should be removed and running blinds installed.

There are various hazards associated with the activation of the steam system, including water hammer, over-pressuring, and thermal and mechanical shock. Steam should be introduced into the unit gently, with vents and drains open. When the unit is up to temperature, the vents and drains should be closed and the steam traps commissioned. Measures should be taken to avoid collections of condensate which may give rise to water hammer or may freeze.

The activation of the water system presents the hazards of introducing water where it is not wanted and of its freezing. Water connections used only for washing down during shut-down should be blinded off.

There should be a formal procedure with proper documentation for the installation and removal of blinds, so as to ensure that all blinds installed for shut-down purposes are removed and all blinds required for running are installed.

Air should be removed by purging with a suitable material. This is commonly done using water or steam. Use is also made of inert gases such as nitrogen, carbon dioxide or gas from an inert gas generator.

Steam is an effective material for purging. Besides removing air, it vaporizes water, melts ice and reveals blockages in vents and drains. The purging should be done with high-point vents and low-point drains open, but with instrument connections closed except on pressure gauges. The steam should generally be introduced at the bottom of the unit, not only because it is lighter than air and tends to rise but also because this gives a refluxing and cleaning action which is not otherwise obtained.

Purging may also be carried out by filling with water. High-point vents should be opened and the unit filled until the water flows out of the top. Water purging may be done by filling several equipments simultaneously. This method is suitable, however, only if the water will do no damage to process features, for example catalysts, and if the equipment is capable of supporting the weight of water.

Another method of purging is the use of inert gas. The purging should be done with vents and drains open. The pressure should be kept positive, but low so as not to waste gas.

If an inert gas generator is used, the quality of the gas should be monitored. It is necessary for the oxygen content of the gas to be kept well below the target value for the atmosphere in the unit in order to avoid using excessive quantities of the gas.

Closed systems, such as flare and blowdown systems into which relief valves discharge, should also be purged with inert gas. This may require special purge connections.

With steam or inert gas, purging should be continued until analysis shows that the oxygen content is below the desired level. This is typically 0.5% v/v or less.

The vent and drain points at which analytical tests are to be made should be specified and records kept of the tests.

Vacuum equipment may be freed of air by evacuating and refilling with inert gas, this cycle being repeated two or three times.

The equipment should then be raised to a suitable pressure to allow testing for leaks. The testing is carried out by closing the vents and drains after purging and admitting more steam, water or inert gas until the required pressure is reached. All joints and connections should then be inspected for leakage. Leak testing is considered in more detail in Chapter 19.

The positive pressure should be maintained in the equipment after the test. With steam or water a few high-point vents may be opened and a small flow maintained. Condensate should be drawn off periodically from low-point drains. With inert gas, vents and drains should be kept closed.

Vacuum equipment should be given a leak test under pressure, as just described, followed by a vacuum test.

It is then necessary, except for vacuum equipment, to remove the purge materials. This is normally done using fuel gas, which is an essentially hydrocarbon material, is readily available and can be returned to the fuel gas system.

If steam is the purge material, there should be a gradual and simultaneous opening of the fuel gas valve and closing of the steam valve. Drains should be cleared of condensate and both vents and drains closed when the fuel gas flows out.

It is important to allow sufficient fuel gas in the unit to maintain a positive pressure and avoid either allowing air in if the vents are open or underpressuring the unit if the vents are closed.

If the purge material is water, the vents should be closed, the fuel gas admitted at the high point, the drains opened, and the water gradually displaced. Drains should be closed when the fuel gas comes out.

If inert gas purging is used, the fuel gas should be allowed to flow in and mix with the inert gas.

In all cases the fuel gas flow should be maintained until the required pressure is reached. If this is the normal fuel gas line pressure, the unit may be left connected to the line, while if it is some lower pressure, the unit should be shut off or left connected but under pressure control.

With vacuum equipment the purge gas is removed by evacuation.

Residual water should now be removed before hot oil is introduced. This is done by circulating oil which is initially cold (10–40°C) and is then heated to warm (40–80°C) or hot (80–175°C or above). Generally, the oil used is that normally charged to the unit, but suitable low pour point gas oil can be utilized.

While the cold oil is circulating, water should be drained from the system. Since a water–oil emulsion may form, the circulation should be interrupted every 30–40 minutes to let the emulsion break and the water settle so that it can be drained off.

When water is no longer draining, the oil temperature should be raised to warm. This may release some more water by melting ice and breaking emulsions. This water also should be drained away.

If the unit normally operates below the boiling point of water, it is not usually necessary to raise the oil temperature further, but if it operates at higher temperatures, then the oil temperature should be raised to hot.

Usually at this stage the oil flow is changed from circulatory to once-through, the oil being pumped to specified receivers.

Units which operate at higher temperatures often have their own fired heaters and these can be started up and used to heat the oil.

The instrumentation should be brought into service as far as is possible during these operations.

Additional flushing of sections of the unit such as reflux lines and drums and blowdown lines should also be carried out using warm oil. There should be frequent draining of water to prevent violent contact with hot oil. The exact procedures depend on the type of unit.

Finally, the unit should be brought on stream by making the specified staged adjustments to the main parameters, such as flow, pressure and temperature, until the normal operating conditions are reached. This is generally straightforward, but certain hazards may occur. The equipment may be subjected to overpressure or thermal or mechanical shock. Common causes are too rapid changes in operating parameters or a lack of appreciation of the temperature relations between different parts of the system. Water and air may again find their way into the plant from various sources.

20.11 Shut-down of Refinery Units

The same sources also describe the shut-down of refinery units. Shut-down should include the following phases:

(1) cooling and depressurizing;
(2) pumping out;
(3) removal of residual hydrocarbons;
(4) removal of corrosive or toxic materials;
(5) removal of water;
(6) blinding activities;
(7) removal of pyrophoric iron sulfide.

The heat input to the unit should be stopped and fired heaters shut-down. The feed flow should be reduced and then cut off. Excess pressure should be relieved by releasing the hydrocarbon gases to the gas collecting system.

If cooling might cause underpressure, inert gas should be introduced to maintain the pressure close to atmospheric.

Vacuum units should be cooled, the vacuum-producing equipment shut off and the vacuum broken by introducing inert gas.

When the unit is cooled and depressurized, the materials should be pumped out to specified receivers.

Care should be taken that during pumping out centrifugal pumps are not allowed to lose suction completely, since even a short period of running dry can do serious damage. Reciprocating pumps are less susceptible.

The oil pumped out should be cooled so that it is below its flashpoint and is sufficiently cold not to cause trouble if it contacts water in the lines.

The pressure in the unit should be maintained during pumping out by admitting inert gas so that under-pressure and air inleak are avoided.

Residual hydrocarbons should then be removed by purging with steam, water, or water followed by steam. Details of shut-down purging methods are given by Hayes and Melaven (1964).

After purging, air should be allowed into the unit. The inflow of air should be sufficient to prevent under-pressure.

Residual corrosive or toxic materials that may be present should likewise be removed. Essentially similar purge materials and methods may be used. A further discussion of equipment purging and cleaning for maintenance is given in Chapter 21.

Water left in the unit from normal operations or from purging should be removed to prevent damage during the downtime and start-up. Freezing of water in the equipment can do serious damage and should be avoided. The water should be completely drained from the unit and blocked drains identified and cleared.

The installation of shut-down blinds and the removal of running blinds should then be carried out under the control of a proper procedure with appropriate documentation, as already described. The methods of isolation and line breaking are described in Chapter 21.

If there is a possibility that pyrophoric iron sulfide might be present, men should stand by ready to spray the sulfide when the equipment is opened up. The fluid used may be water or a suitable light oil. The latter wets more thoroughly and evaporates less rapidly, and may be preferable unless it constitutes a further fire hazard. Complete mechanical removal of the sulfide should then be carried out.

20.12 Operation of Fired Heaters

The operation of a rather different item of plant is illustrated by that of fired heaters. Some of the hazards of fired heaters and some features of their design relevant to safety are discussed in Chapter 12. Here consideration is given to the safe start-up and operation of such units.

Safe operation of fired heaters is dealt with in *Safe Furnace Firing* (American Oil Company, Amoco/3), *Handbook of Industrial Loss Prevention* (FMEC, 1967) and the CCPS *Engineering Design Guidelines* (1993/13) and in the codes and other publications cited in Chapter 12.

20.12.1 Burner start-up

The essential features of the safe start-up of burners have been described above, but some of these may be re-emphasized in relation to operation.

Every effort should be made to prevent the leakage of fuel into the firing space. Shut-off valves should be checked for leak tightness. Double block and bleed valves should be operated as intended, with the bleed valve open when the block valves are closed.

It should be appreciated that it may not take long for fuel sufficient to create a flammable atmosphere to pass into the firing space. With oil firing the quantity flowing in the few seconds between the flame extinction and shut-off valve may be enough, while with gas firing a flammable mixture may form by leakage through a shut-off valve during the few minutes which it takes to remove a slip plate. Partly for this reason slip plates are not considered a good means of isolation for gaseous fuel. Leakage flows of gas through shut-off valves are often in the range 1–10 l/min.

The air flow should be established and the firing space purged by opening the dampers and starting the fans.

The atmosphere in the firing space should be tested before ignition is attempted. Delay between this test and the ignition should be avoided. If time does elapse, a repeat test should be made.

If a separate device such as a pilot burner is used to effect ignition, this should be lit before the fuel to the burner is turned on. A check should be made that the pilot light is established. The check should be on the flame itself rather than on some quantity from which the presence of the flame might be inferred.

If the main flame goes out, the proper start-up procedure, including purging and testing of the firing space, should be carried out. Short cuts such as simply attempting to relight the burner should not be taken.

The presence of a flame should be monitored by a flame failure device. The device should 'see' the flame to be monitored and not other flames such as the pilot light.

If there are multiple burners, it should be borne in mind that fuel may leak through from burners which are shut off so that a flammable mixture is formed and is then ignited by an operating burner. In some circumstances, it may be appropriate to avoid this by firing with all the burners.

The flame is normally extinguished by shutting off the fuel and injecting snuffing steam.

The possibility of interactions between furnaces linked by common headers should be borne in mind.

20.12.2 Tube failures

Overheating of furnace tubes can result in rapid or delayed failure. Rapid failure can occur if the flow of feed through the tubes is too low or is lost altogether, or if there is direct flame impingement on the tubes. Failure can also result from less intense overheating over long periods. It is very easy to cause a drastic reduction in the creep life of tubes by maloperation.

Typically a furnace tube has a creep life of 10 years at 500°C. Then its creep life will be reduced approximately as follows by operation at higher temperatures:

Temperature (°C)	*Creep life*
506	6 years
550	3 months
635	20 hours

The reduction in creep life is *pro rata*. Thus, for example, the creep life for a tube with the characteristics just given will be used up by operation for 5 years at 500°C and $1\frac{1}{2}$ h months at 550°C.

The measurement of the furnace tube temperature is difficult, but temperature measuring devices are available for this duty. It is now normal practice to measure the tube temperature. The measurements may be used to generate alarms to warn the process operator and/or to initiate trips which shut the furnace down. A trip system may be effective against gross overheating, but is less appropriate to prevent overheating which is not so severe, but which can nevertheless cause a serious reduction in creep life.

It is essential, therefore, for the process operator to understand the penalties of overheating and, in particular, those arising from the relatively small increases of tube temperature that he may otherwise regard as insignificant.

20.13 Operation of Driers

An item of equipment which has much in common with a fired heater but is rather more complex is a drier. An account of the start-up, operation and shut-down of a drier is given in *Prevention of Fires and Explosions in Driers* (the IChemE *Drier Guide*) (Abbott, 1990).

There are a number of different types of drier. Abbott gives first a general account of the operation of a drier, which, broadly, is applicable to any type, and then considers the variations applicable to particular types of drier. The account given here is based on this general account and assumes that inerting is used.

20.13.1 Pre-start-up checks

Before the drier is started up, checks should be made on the mechanical condition of the plant, its internal state, its instrumentation and the control settings. There should be no leaks of fuel or lubricating oil and the air filter should be clean. Explosion vents should be intact and clear to operate. The plant should be free of spillages and deposits and of maintenance equipment. The instrument should be operational, as should explosion suppression devices. The damper settings should be correct. It should also be checked whether there has been any modification to the plant or the material to be dried.

20.13.2 Normal start-up

Essentially, the operation of a drier involves steering a course between overheating or underdrying the product. The product temperature must not be allowed to rise to a point where a runaway reaction can occur and deposits in the drier must not reach their self-ignition temperature. On the other hand, the product must not be underdried which, besides giving off-specification material, can cause blockage in the discharge system and caking in conveying and storage.

It is also necessary to ensure that the exhaust gas temperature remains above its dewpoint in the dust recovery equipment. The exhaust gas temperature is controlled by manipulating (1) the heat input, (2) the feed flow and/or (3) the evaporative load. The heat input is the variable principally used, but the response may be slow due to large time lags.

The plant should be started up by starting the product discharge valves and conveyors and the fans. On an indirectly heated drier the heating medium should then be admitted. Assuming, as stated, that the system is operated under inert gas, it should be purged until the outlet oxygen concentration has fallen to the operating value. Assuming also that the heater is fired by gas or oil, it should be started up using a safe fired heater start-up procedure. Once the exhaust gas temperature has reached its operating value, the feed of wet material should be started.

The drier is then gradually brought up to full load, within the constraints mentioned. This is generally the stage of the process that is most difficult to control.

20.13.3 Normal operation

In normal operation the same control objectives apply, that is to avoid overheating or underdrying the product, and the same means of control are available. The operation of the heater should be closely monitored. The product should be checked for specks of burned, charred or discoloured material, signs of a smouldering or burning deposit in the drier.

20.13.4 Normal shut-down

The same control objectives apply for normal shut-down. Again the process passes through a critical stage as conditions pass through a transient.

The shut-down is initiated by shutting off the feed. Then the heater is shut off. Purging with inert gas is continued until all the product material has left the drier. The inert gas is then purged from the drier with air. The fan, discharge valves and conveyors can then be switched off.

The inside of the drier should be inspected under a permit-to-work system. Potential hazards include a low oxygen content and smouldering material.

20.13.5 Emergency shut-down

The appropriate procedure for emergency shut-down depends on the condition causing the emergency. This may be a material blockage, an equipment failure, or a fire or explosion.

For either of the first two events, the objective should be to prevent overheating of the product. Methods available are to shut off the heat input, to get the material out of the drier and to maintain the evaporative load. One way of effecting the latter is the use of a water spray.

The emergency procedures for dealing with a fire or explosion are given in the *Drier Guide*.

20.14 Operation of Storage

A large number of incidents occur associated with the bursting or collapse of atmospheric storage tanks due to maloperation.

An atmospheric storage tank is typically designed to withstand an internal pressure of 8 in. WG (20 mbar) or a vacuum of $2\frac{1}{2}$ h in. WG (6 mbar). These are very low pressures, which it is easy to exceed unless there is careful operation.

If the pressure inside the tank is not kept within these limits, the failure of the roof or of the side walls may occur. Two principal modes of failure are overstressing of the roof due to excessive internal pressure and instability of the side walls due to excessive vacuum.

Generally a roof fails under internal pressure either at the seams between the roof and the side walls or along the diametral seams in the roof itself. The failure typically has a cod's mouth appearance. Large tanks are particularly vulnerable.

For internal pressure the shear stress σ_s in the seam between the roof and the wall is proportional to the pressure p and the diameter d and inversely proportional to the thickness of the tank wall t:

$$\sigma_s \propto pd/t \qquad [20.14.1]$$

The bending stress σ_b in the roof itself is proportional to the internal pressure and the square of the diameter and inversely proportional to the square of the thickness:

$$\sigma_b \propto p(d/t)^2 \qquad [20.14.2]$$

The side walls are designed to withstand the maximum head of liquid which can occur in the tank. The internal pressure is thus relatively less important in this case. But, again, the hoop stress in the side wall σ_h due to the internal pressure is proportional to the pressure and the diameter and inversely proportional to the thickness:

$$\sigma_h \propto pd/t \qquad [20.14.3]$$

The vulnerability of large storage tanks to overpressure may be illustrated by considering the relative stresses in the roof and side walls of (1) a baked bean tin and (2) a 1000 m^3 fixed roof storage tank. It is assumed that the baked bean tin has a diameter of 7.5 cm and a thickness of 0.25 mm, and that the storage tank has a diameter of 12 m and a thickness of 5 mm. Then the ratios of the stresses in the tin and in the storage tank are as follows:

	Stress in storage tank / *Stress in baked bean tin*
Side wall, σ_h	8
Roof, σ_b	64

Similarly, for vacuum the stresses are much greater in large tanks.

The effect of vacuum on the side walls of a storage tank is to induce instability. The analysis of tank instability is complex, but some understanding may be obtained by considering the effects of slight distortions in the shape of the tank. These effects may be summarized by saying that for internal pressure small changes in shape do not tend to cause the side walls to fail, but for vacuum such changes do tend to cause failure.

This situation may be explained by the following simplified argument (Aird, 1977b). Consider a small element of the wall of the storage tank, as illustrated in Figure 20.2(a), where r is the radius of the tank, t is the thickness of the wall, δ is the width of the element and the angles α and ϕ and the vectors of forces F_1 and F_2 are as shown. Then with an internal pressure p and an external pressure of zero

$$F_1 = \int_{-\alpha}^{\alpha} p\delta r \cos\theta \, d\theta \qquad [20.14.4a]$$

$$= 2p\delta r \sin\alpha \qquad [20.14.4b]$$

$$= 2p\delta r\alpha \qquad \alpha \ll 1 \qquad [20.14.4c]$$

$$F_2 = \sigma_h t\delta \qquad [20.14.5]$$

where σ_h is the hoop stress.

The vector of forces ΣF in the vertical direction in Figure 20.2 (a) is thus

$$\Sigma F = F_1 - 2F_2 \sin\phi \qquad [20.14.6a]$$

At equilibrium this vector of forces must be zero

$$\Sigma F = 0 \qquad [20.14.6b]$$

For the case where there is no distortion of the element

$$\phi = \alpha \qquad [20.14.7]$$

Hence from Equations 20.14.4–20.14.7

$$\sigma_h = \frac{pr}{t} \qquad [20.14.8]$$

and

$$F_2 = pr\delta \qquad [20.14.9]$$

Now consider the cases where distortion occurs. For a small inwards distortion

$$\phi < \alpha \qquad [20.14.10]$$

and hence

$$\Sigma F = 2p\delta r(\sin\alpha - \sin\phi) > 0 \qquad [20.14.11]$$

Thus the net resultant force due to distortion tends to move the element outwards and so to return it to its original shape. For outwards distortion

$$\phi > \alpha \qquad [20.14.12]$$

and hence

$$\Sigma F < 0 \qquad [20.14.13]$$

Thus the resultant force due to distortion tends to move the element inwards and so again to return it to its original shape. These effects are shown in Figure 20.2(b).

Conversely, with an internal vacuum the vector of forces in the vertical direction is

$$\Sigma F = -F_1 + 2F_2 \sin\phi \qquad [20.14.14]$$

For inwards distortion relation 20.14.10 applies and hence

$$\Sigma F < 0 \qquad [20.14.15]$$

Thus the resultant force due to distortion tends to move the element inwards and so reinforce the distortion. For outwards distortion relation [20.14.12] applies, and hence

$$\Sigma F > 0 \qquad [20.14.16]$$

Thus the resultant force due to distortion again tends to move the element outwards and so reinforce the distortion. These effects are shown in Figure 20.2(c).

A fuller treatment is given by den Hartog (1952, p. 274).

Atmospheric pressure is maintained in a storage tank by a vent to the atmosphere. The tank may be subjected to pressure or vacuum which it cannot withstand, not only if this vent is blocked, but also if it does not have the capacity to handle the flows required to equalize the pressure.

Some ways in which overpressure can occur include (1) pumping in liquid too fast, (2) an increase in the temperature of the liquid contents, (3) pumping hot liquid into water and (4) blowing in air, steam or gas.

An increase in the temperature of the liquid in the tank can occur due to pumping in hot liquid or to a high ambient temperature. For many substances a temperature rise of 6°C is enough to give an increase in vapour pressure of 8 in. WG. Pumping hot oil into water raises the water temperature and causes it to exert a higher vapour pressure, or even to boil off as steam.

Similarly, ways in which vacuum can occur include (1) pumping out liquid or emptying liquid under gravity too fast, (2) a decrease in the temperature of the liquid contents and (3) condensation of the steam or vapour contents or a depletion of the gas content.

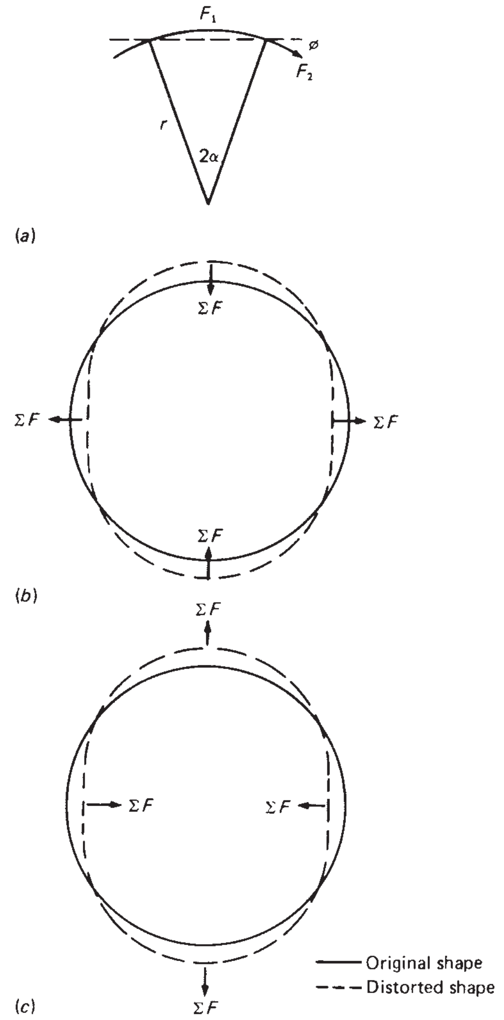


Figure 20.2 *Forces acting on the side wall of an atmospheric storage tank: (a) element of side wall; (b) positive internal pressure – resultant forces tend to correct distortion; (c) negative internal pressure – resultant forces tend to reinforce distortion*

Condensation of steam or vapour in the tank can occur as a result of a sudden shower of rain.

Vents on tanks are liable to blockage by debris or by polymerization or crystallization of the liquid. The vent normally has a flame arrester, which is particularly liable to blockage. Vents are sometimes blanked off to allow maintenance work to be done.

It is emphasized, however, that it is not necessary for a vent to be blocked for a tank to burst or collapse. All that is required is for the vent capacity to be insufficient to handle the flow required to equalize the pressure.

The systems to which an atmospheric storage tank is likely to be connected mostly are at, or can generate, pressures sufficient to overpressure the tank. This applies to equipment such as transfer pumps and to services such as steam, air or nitrogen.

Some situations which can lead to the bursting or collapse of a storage tank are shown in Figures 20.3 and 20.4. Bursting or collapse may result from a combination of the vent conditions shown in Figure 20.3 and the operations or situations shown in Figure 20.4.

As an illustration of storage tank collapse, consider the following case. Welding had to be done near the roof of a storage tank containing a volatile flammable liquid soluble in water. The tank had an open vent with a flame arrester on it. The maintenance supervisor connected a flexible tube to the flame arrester and immersed the other end of the tube in a drum filled with water. When liquid was run out of the tank a vacuum developed and the tank, designed to withstand $2\frac{1}{2}$ in.WG, collapsed inwards. Moreover, if instead liquid had been run into the tank, overpressure would have developed corresponding to the depth of immersion of the tube and the tank, designed for 8 in. WG internal pressure, would have burst.

Other examples of storage tank collapse are described in Case Histories B44–B48.

20.15 Operational Activities and Hazards

20.15.1 Water hammer

The term 'water hammer' is applied to two somewhat different phenomena, both of which generate forces sufficient to rupture the pipeline.

One kind of water hammer, or hammer blow, results from the sudden closure of a valve in a long pipeline filled with water. The force on the valve is then proportional to the rate of dissipation of the momentum of the fluid. Such water hammer is familiar in domestic water systems, where its effects are usually not serious. On an industrial scale, however, hammer blow can be very destructive. The phenomenon is considered in more detail in Chapter 12.

The other kind of water hammer occurs when a slug of condensate is flung against the pipework by steam. Typical features of a situation giving rise to this effect are as follows. The steam main is not used for some time, but the steam pressure is maintained. Condensate collects at low points. The steam traps and drains that should drain the condensate out are not working. The steam flow is suddenly increased and water hammer occurs. Again the effect can be highly destructive.

Steam mains should be designed to allow condensate to be drained from low points by steam traps and drains. These traps and drains need to be maintained so that they work effectively. It is a help if they are so installed that they can be drilled through under pressure if they get blocked.

It is also essential to exercise care when it is necessary to make large alterations to steam flows, particularly in situations such as start-up. Suitable precautions are checks on condensate accumulation and on the operation of steam traps, and slow operation of the steam valves. It should be appreciated that alteration of the opening of a valve in a steam ring main can have a great effect on the flows in that main.

Both kinds of water hammer, but particularly the first, can occur with fluids other than water.

20.15.2 Slopover

If hot oil is brought into contact with water, there is liable to be a rapid evolution of water vapour and the formation of a

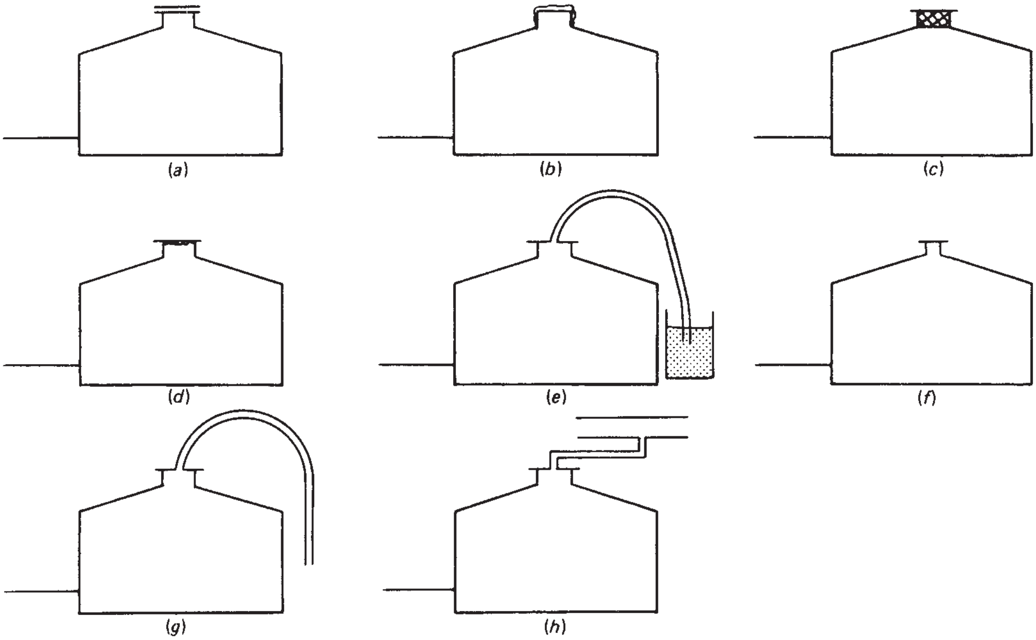

Figure 20.3 *Some vent conditions which can lead to the bursting or collapse of an atmospheric storage tank: (a) vent blanked off; (b) plastic bag over vent; (c) vent choked; (d) flame trap choked; (e) vent connected to water seal; (f) vent too small; (g) flexible tubing connected to vent; (h) vent modified*

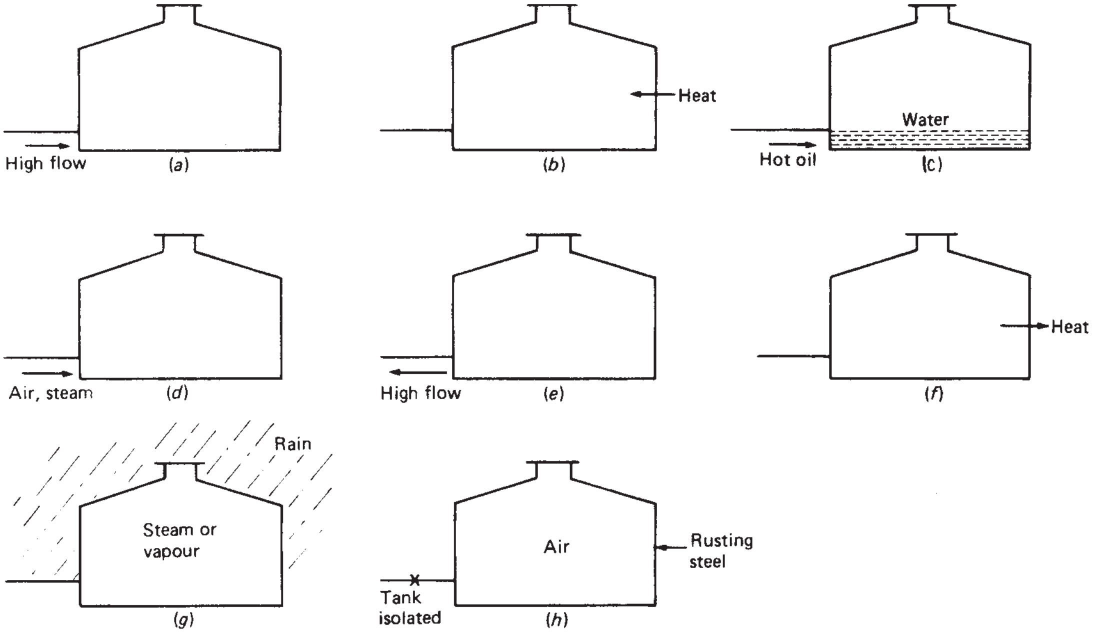

Figure 20.4 *Operations and situations which can lead to the bursting or collapse of an atmospheric storage tank: (a) overpressure – pumping in liquid too fast; (b) overpressure – increase in the temperature of liquid contents; (c) overpressure – pumping hot oil into water; (d) overpressure – blowing in air, steam or gas; (e) vacuum – pumping out liquid too fast; (f) vacuum – decrease in the temperature of liquid contents; (g) vacuum – condensation of steam or vapour; (h) vacuum – depletion of oxygen*

large volume of foam. This condition typically occurs when oil with a water layer is heated up or when hot oil is run into a vessel containing water, or oil and water. The effect is similar to that occurring when wet chips are put into boiling fat in a chip pan. It is variously known as 'slopover', 'boilover', 'foamover' and 'puking'.

The effect created when water is vaporized is illustrated by the eruption of the volcano Krakatoa in 1883. A cubic mile of water was vaporized and a cubic mile of rock was thrown into the air. Rock fragments travelled to a height of 14 miles and the sound was heard 3000 miles away.

Incidents involving slopover are quite frequent and can be serious. Slopover is one of the hazards described in *Hazard of Water* (American Oil Company, Amoco/1).

Although it is water which is most commonly involved, a similar phenomenon can occur with a volatile oil. A serious accident which was probably caused by this effect occurred at the Shell refinery at Pernis in 1968 (Fontein, 1968). Hydrocarbons in a slops tank boiled over. A vapour cloud formed, found a source of ignition and exploded violently, causing extensive blast damage and a large fire. Owing to cold weather, it had been necessary during the two previous weeks to heat the oil in the tank. It is believed that the steam coils had become covered in a water-in-oil emulsion which reduced the heat transfer to the supernatant oil, so that the two oil layers were at substantially different temperatures, and that vapour formation at the interface between the oil layers initiated mixing, causing further vapour evolution so that the tank overflowed, the hydrostatic pressure at the bottom of the tank was reduced and violent boil-up occurred. The incident is described in Case History A41.

20.15.3 Water draining

In the storage of liquefied petroleum gas (LPG) small amounts of water usually accumulate in the vessel. This water is commonly removed by the periodic action of an operator who drains it off manually. If for any reason the operator loses control, a hazardous situation is liable to arise in which the fluid issuing from the drain point is no longer water but LPG.

This hazard was realized in the Feyzin disaster in 1966, described in Case History A38, where an operator found himself unable to shut off the valves at the bottom of a propane storage sphere and a large vapour cloud formed, ignited and caused a series of BLEVEs.

As described in Chapter 22, the preferred arrangement is the use of a drain line with two valves. The method of operation of these valves is described in *The Storage of LPG at Fixed Installations* (HSE, 1987 HS(G) 34) as follows:

> Particular care should be taken when draining storage vessels in service in order to minimize the escape of LPG. Of the two drain valves, that nearer the vessel, should be fully opened first and draining then controlled by gradually opening the second valve. If, on opening the second valve, no flow occurs, both valves should be closed immediately to allow subsequent investigation. On completion of the draining operation, the valve furthest from the storage vessel should be closed first, then the other valve.

20.15.4 Gas cylinders

There are a number of hazards that can arise from the use of gas cylinders. One of the most frequent types of incident is misidentification of the gas in the cylinder. Thus, for example, oxygen may be used in an application where an inert atmosphere is required. Gas cylinders are marked with an identifying colour code. Common causes of incidents are that the coloured paint has been rubbed off or that people handling the cylinders are not familiar with the code. Cylinders on which the code is not clear should be taken out of service and personnel should be trained to recognize the identification scheme.

Overfilling of cylinders sometimes occurs. This may be due to a defective filling machine or to the use of a machine too small for the cylinder, so that only part of the cylinder rests on the machine.

Cylinders are sometimes heated to give a steady gas supply. There is then the hazard that the isolation valve is turned off and the cylinder explodes. It may be possible, however, to design a cylinder heating system that will not allow the cylinder to overheat sufficiently to cause an explosion, even if the isolation valve is closed accidentally. A suitable system is heating with warm air, the air itself being heated by steam or electricity. Heating of a cylinder by steam or a heat transfer medium is best avoided, because these methods are more liable to cause not only overheating but also corrosion of the cylinder.

The correct method of drawing gas from a cylinder is to set the pressure regulator screw to zero and then to open the isolation valve. Failure to observe this procedure on an oxygen cylinder, for example, can lead to rupture of the regulator diaphragm and an explosion/fire.

With oxygen there is the hazard of igniting materials, such as the plastic caps used to cover the nozzle. Such caps should be entirely removed before the valves are opened.

Another hazard with gas cylinders is that the isolation valve may be damaged in such a way as to allow a rapid flow of gas from the cylinder. In such circumstances the cylinder can become a projectile propelled by the escaping gas.

20.16 Sampling

Sampling is a common cause of accidents to personnel in the chemical industry. It needs to be addressed by the provision of suitable equipment and of formal systems of operation. Accounts of sampling have been given by Ducommun (1964a,b) and Lovelace (1979) and in the ICI LFG Code.

Sampling is carried out to monitor product quality, the material balance or equipment operation, or for the purposes of troubleshooting.

A sampling technique should aim to minimize the risk of leakage from the sample point, to safeguard the person taking the sample, to provide a safe means of carriage of the sample to the laboratory and to protect the laboratory personnel handling the sample.

Two principal problems are corrosive liquids and flammable gas and liquids. Before considering these, consideration is given to some general points on liquid sampling.

20.16.1 Liquid sampling

An approach to the safe sampling of liquid streams has been described by Lovelace (1979). He utilizes a proforma for the specification of liquid sampling which covers: the hazards; the sampling conditions, including the frequency of sampling and the size of sample required; any special considerations; the equipment, both installed and portable; and the details of the installed equipment.

The sample point should be treated as a piece of equipment in its own right and designed accordingly. There is no single system that is suitable for all applications.

Sampling systems may be classified as direct or indirect line systems. An ordinary sample valve is a direct line system. Another device is the piston-type sampling valve, in which the sample offtake is set at a 45° angle and is normally kept closed by a piston that moves along the axis of the main sample line. This gives a positive rodding out action and is used in applications where blockage may occur.

In an indirect line system the sample is trapped in a fixed volume and then withdrawn. A simple device which effects this is a sampling plug valve which is installed in line in a pipe. This is a type of ball valve with a sample offtake line and a vent line located in the body of the valve perpendicular to the main pipe, so that when the valve is rotated, the sample trapped in the plug can flow down the sample line. In another type of device the sample is withdrawn using a piston.

A sample chamber is attached directly to the line to be sampled and the liquid is admitted to it by a valve system. One system which minimizes leaks is a double block and bleed valve arrangement.

For syringe sampling use may be made of a septum.

Where sampling can give rise to hazardous fumes, good ventilation is essential. Another method of protection against fumes and leaks is the use of a sampling enclosure, essentially a simple box with the sample pipe entering through the top and the sample bottle connection through the bottom. Details of the design of such an enclosure are given by Lovelace.

20.16.2 Corrosive liquids

The following procedure may be used for the sampling of corrosive liquids. The person taking the sample should wear the appropriate protective clothing such as goggles and gloves. The sample bottle should not be held in the hand but on a stand. It is desirable that the sample point be provided with remote operation or with a protective covering around the sample point. The sampler should stand as far as possible from the sample point. If there is no remote operation, he should turn the sample valve using an outstretched arm. The sample bottle should be carried in a bottle carrier.

20.16.3 Flammable fluids

Flammable gases and liquids are usually sampled using a metal bomb. Typical sampling methods are described in the ICI *LFG Code*. For a liquefied flammable gas (LFG) the bomb is a stainless steel cylinder as shown in Figure 20.5(a). A liquid sample is taken as follows. The ullage end of the bomb is connected to the sample point, the bomb is held vertically with the ullage end at the bottom, and both the top and the bottom valves are fully opened. The needle valve is then opened slowly and the bomb is filled. When it is full, liquid emerges from the top valve and all the valves are closed. The bomb is then disconnected from the sample point and inverted so that the ullage end is at the top. The top valve is opened so that liquid issues out until the level in the bomb falls below the bottom of the ullage pipe. When vapour starts to come out instead of liquid, the valve is closed. The ullage for LFG is 20%.

Methods of sampling LFG as gas include (1) evacuation of the bomb before sampling, and (2) purging of the bomb with the gas sampled, the purge being passed to the vent system. Suitable bombs for these two methods are shown in Figures 20.5(b) and 20.5(c), respectively. The ICI *LFG Code* should be consulted for full details of these sampling procedures. Failure to vent a bomb after sampling LFG may result in an explosion if the liquid warms up by heat transfer from the atmosphere. A sample bomb explosion from this cause has been described by Ducommun (1964a).

Ducommun (1964b) also describes a system for avoiding such incidents. The bomb itself is effectively treated as a small pressure vessel, is of special design and is regularly inspected. There is a requirement that the bomb be vented immediately after sampling to give the specified ullage and that this be checked by weighing or other means. The sampling procedure is simple and standardized, personnel are well trained in it and notice of sampling operations is given to the process personnel. The sampling operations are monitored and documented by the laboratory.

20.16.4 Particular chemicals

Certain chemicals require special sampling methods. Techniques for particular chemicals are given, for example, in some of the *Codes of Practice for Chemicals with Major*

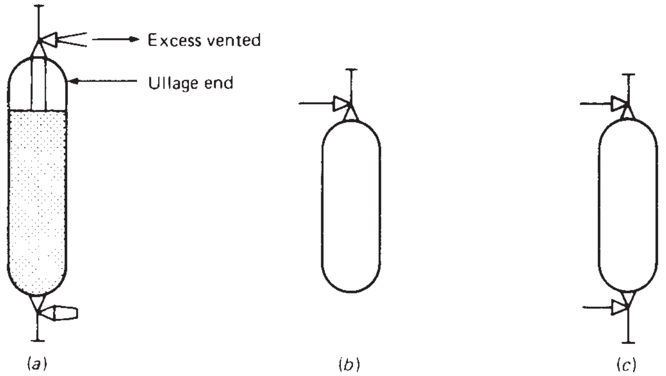

Figure 20.5 *Some sample 'bombs' for liquefied flammable gases (LFGs) (Imperial Chemical Industries Ltd, ICV RoSPA 1970 IS/74; reproduced by permission): (a) sample bomb for liquids; (b) sample bomb for gases (inlet only); (c) sample bomb for gases (inlet and outlet)*

Hazards by the CIA, such as those for ethylene dichloride and phosgene.

20.17 Trip Systems

Trip systems are provided to protect the plant against certain hazardous situations by shutting it down if particular parameters go outside the specified limits.

There are differences, however, in the extent to which it is essential to provide trip protection with no disarming allowed and in the level to which trip systems can be economically engineered to ensure this. Some trip systems are very sophisticated and provide protection not only during normal operation but also during other conditions such as start-up. In other cases, however, it is necessary to disarm the trip system temporarily to allow the plant to be started up.

Disarming of trips is a permissible practice provided that it is done in accordance with the design intent and with proper procedures. Otherwise, it is an extremely dangerous practice. Probably the most common error is to disarm a trip temporarily, usually during start-up, and to forget to restore it.

The *Flixborough Report* (R.J. Parker, 1975, para. 40) revealed that an automatic system, which initiated safety actions such as shut-off of the air supply and initiation of a nitrogen purge if the level of liquid nitrogen supply fell too low, could be readily overridden by setting to zero the timer for fixing the duration of the purge. Although such action does not appear to have contributed to the explosion, such disarming is a hazardous practice.

If the disarming of trips is to be practised, there should be a procedure that ensures that the trip is correctly restored. Methods used to ensure that disarming is done safely include both key interlocks and permit systems.

If spurious trips occur due to trip initiator unreliability, the operator has an incentive to disarm the trip in order to continue operating, and incidents occur in which operators disarm trips for this reason. Again hardware or software methods may be used to prevent disarming. But it is highly desirable in such cases to improve trip system reliability.

Disarming is not the only way in which a trip can be rendered ineffective. A similar result is often achieved by an alteration of the trip setting. It is equally essential, therefore, to ensure that there is no interference with trip settings.

A trip system should be designed so that it does not reset itself when the trip condition disappears, for example valves closed by the trip action should not reopen. It is important, however, that the operations side appreciate the hazards that can arise if the trip system does reset itself. A typical hazard in this case might be the entry of atmospheric air into a vessel filled with hydrocarbon vapours so that an explosive mixture is formed.

20.18 Identification Measures

It is essential, if errors are to be avoided, that plant vessels and equipment be given appropriate marking so that they are readily identified and any hazards associated with them are understood. Equipment identification is of particular importance for maintenance work and is considered in Chapter 21. Here consideration is confined two aspects that particularly concern process operators. These are the identification of hand valves and the labelling of in-plant containers.

20.18.1 Valve identification

One of the principal ways in which the plant is affected by operator actions is through the opening and closing of isolation valves, or hand valves. It is not uncommon for the operator to have difficulty in identifying the right valve, as described in Chapter 14. Yet an error in the identification of a valve can have serious results.

The identification of hand valves is discussed by R. King (1990). A hand valve should be identified on the piping and instrument diagram (P&ID), in the operating manual and on the plant. The P&ID should allow space for the hand valve identification numbers to be inserted; it is often difficult to insert such numbers due to lack of space. The operating instructions should identify hand valves by number.

On the plant a problem arises in maintaining permanent identification of a hand valve. A tag may be put on the valve, but a valve tends to lose its tag or, if it does retain it, it may be removed and put back at some other point. A method that overcomes these difficulties is the marking of the valve number on the pipework, or insulation, with an arrow pointing to the valve in question.

20.18.2 In-plant container labelling

The operation of a process plant can involve the transfer within the plant of a number of chemicals and it is necessary to ensure that these are correctly identified at all times. A programme for the in-plant labelling of containers for such substances has been described by Kmetz (1990).

These containers are those entering the plant, those generated within and retained with the plant, and those leaving the plant. Each container is required to have three pieces of information: the name of the substance, the hazard warning and the party responsible for it.

Employees are responsible for checking that an incoming chemical is labelled. The party initiating shipment is responsible for seeing that an outgoing chemical is labelled and has a material safety data sheet. For in-plant labelling some latitude is allowed. A container used by one person within one shift does not have to be labelled.

20.19 Exposure of Personnel

Of the two main ways of reducing the size of a potential disaster, mention has already been made of one, that is the limitation of inventory in the process design. The other is the limitation of exposure of personnel in plant operation.

The *First Report* of the Advisory Committee on Major Hazards (ACMH) (Harvey, 1976) suggests that limitation of exposure should be an explicit objective. The Second Report (Harvey, 1979b) gives guidelines for the limitation of exposure.

The hazard to which personnel are exposed may be a large fire, an explosion or a toxic release. Various scenarios for such hazards should be reviewed so that zones in which exposure is controlled can be delimited on a rational basis.

Exposure is most simply limited by not having people there in the first place. For those whose presence is essential much may be done to provide protection, particularly through the siting and design of buildings. This latter aspect is discussed in Chapters 10 and 24. Only the reduction in the numbers present by management control is considered here.

Typically, a large process plant has a number of shift process operators who man the control room and work about the plant opening and closing valves, changing pumps, replacing filters, taking samples and performing various other tasks. Some operators spend most of their time in the control room, others are mainly out on the plant. There are also several shift mechanical and instrument maintenance fitters. All these personnel patrol the plant and observe any abnormalities such as leaks or spillages and they are available to deal with plant upsets. Laboratory personnel also go out on to the plant to take samples for analysis.

In general, the numbers of shift operating and maintenance personnel on modern process plants are already at the minimum level consistent with safe and efficient operation. In most cases further reduction would make it difficult to deal with emergency situations.

During the day there is a rather larger number of maintenance personnel on the plant. The plant manager and the plant engineer are also on the plant during the daytime. In addition, there are often other technologists concerned with carrying out investigations of all kinds.

If a plant extension is being carried out, there will also be a fairly large number of construction personnel on the plant or very near it.

The numbers of men on a large process plant might be expected to be approximately as follows:

Shift operating personnel	5–25
Shift maintenance personnel	0–5
Day maintenance personnel	10–100
Managers, technologists	2–10
Construction workers	10–50

In the event of an emergency, the shift personnel have specific instructions on the action which they should take and on the alarm or other instruction at which they should evacuate. The order to leave the plant is given to the day maintenance personnel and to construction workers on the appropriate alarm signal or on instruction from their respective supervisors.

For the purposes of limitation of exposure, personnel may be divided into the following categories of exposure in the hazard area:

Category 1 Continuous exposure (e.g. process operator).
Category 2 Intermittent exposure:
  (a) short periods (e.g. technologist);
  (b) infrequent long periods (e.g. fitter).
Category 3 Infrequent exposure (e.g. accounts clerk).

The works site may be divided up into areas of (1) major hazard, (2) intermediate hazard and (3) low hazard.

The limitation of exposure of personnel is effected by controlling (1) permanent location and (2) movement.

The number of people permanently located in a major hazard area should be kept to a minimum consistent with safe and efficient operation. In particular, personnel in Category 2 should be there only if their presence is essential, as opposed to merely convenient. Examples of such personnel include technologists, training officers, maintenance planners, laboratory analysts and clerical assistants.

Personnel usually located in the intermediate hazard area include maintenance and other services. Again the number should be kept as low as is reasonably practicable.

Personnel should be given protection by suitably designed buildings, as described in Chapter 10. In the major hazard area the main protective building is the control room. The type of protection afforded by this will depend on the nature of the hazard (fire, explosion or toxic release). Buildings in the intermediate hazard area should also offer some protection. The ACMH suggests that personnel exposed to this intermediate level of hazard should have a work base such that they would not expect to be seriously hurt. Buildings such as the site office should be in the low hazard area, but should still be designed to minimize injury.

The other main control is on movement. There should be formal procedures, including a permit system for entry into the major hazard area. This permit system should be enforced and audited. The procedure should ensure that the number of people in the major hazard area is considered and that their identity is known at any given time.

It is particularly important for the system to afford good control of situations such as major plant construction and modification, in which there may be quite large numbers of people in the major hazard area. It should be borne in mind that the presence of a large construction team, who are relatively unfamiliar with the plant, is in itself a further cause of hazard.

20.20 Security

Another important aspect of plant operation is security. This is treated in *Vandalism* (C. Ward, 1973), *Introduction to Security* (G. Green and Farber, 1974) and *Industrial Security* (D.L. Berger, 1979). The *Compendium of Fire Safety Data* (FPA, 1992) contains a section on security precautions (the SEC series). Accounts are also given by Hamilton (1967), Oliver and Wilson (1972), K.G. Wright (1972), Spranza (1981, 1982, 1991, 1992) and Pitt (1987).

Security systems management is described by Spranza as being essentially a blend of traditional security concepts and modern management methods.

The management system should include an explicit requirement for a review of the security system. This review should cover both hardware and software aspects and should involve a critical examination in which problems are identified, alternative solutions are generated, and a suitable approach is selected and implemented.

In assessing the security problem the categories of person who need to be considered include employees, visitors and intruders; the types of behaviour to be considered include innocent actions, theft and malicious acts.

Central to security is control of access. The security system should ensure that unauthorized persons do not have access to the site, whether or not they have hostile intent. The minimum requirement is a formal pass system that covers employees and visitors. There then needs to be physical arrangements to ensure that access to the site is controlled at all points. This aspect of security is clearly related to plant layout and is considered in Chapter 10. The Flixborough Report found that, although in general proper attention was paid to security, there were two unguarded gates through which it was possible for anyone at anytime to gain access to the site.

In addition, it may be necessary to exercise control of access to particular areas within the site.

It is also desirable for the operational system to be capable of detecting the presence of any unauthorized persons who do get onto the plant. The patrolling of the plant by the process operators is relevant here. So also are formal arrangements for the limitation of exposure of personnel by the control of access to major hazard plant.

With regard to intruders, there are available various devices which may be used to give warning. Good lighting is one obvious feature. Other measures include detectors buried in the earth between two fences, heat sensitive detectors and closed circuit TV cameras. The use of some devices may, however, encounter difficulties on process plant, such as those due to heat radiation from the plant itself.

Another basic principle of security is to create conditions that assist in the rapid detection of any unauthorized deviation. A simple illustration is the maintenance of tidy storage of laboratory chemicals, so that a missing item is readily detected. But the principle is of much wider application.

Some facilities have their own characteristic problems with regard to security. Those of storage are described by Pitt (1987). One common defect is access by unauthorized vehicles. Other defects occur in drum and cylinder storage, where drums are often placed too close to the boundary fence and cylinders are left all over the place. The particular problems of security in laboratories, also discussed by Pitt, are considered in Appendix 9.

The most difficult security problem is a deliberate attack by well trained and organized saboteurs. Defence against such an attack is a matter for the military which is outside the scope of this book. There are several things, however, which can be done to make such an operation more difficult. The potentially more vulnerable units can be sited away from the periphery and can, to some extent, be designed to limit the damage caused by explosives, and an effective security system can reduce the amount of material which a saboteur can bring in and the time which he can spend on his task.

The security problem is not confined to outsiders, however; the threat not infrequently comes from the company's own employees. Theft by employees can in some cases pose a threat to the plant, particularly where there are high priced materials which it may be attractive to steal. The sort of incident which occurs and which may have safety implications is the theft of sections of copper cabling carrying the power supply to electric motors while the plant is shut down.

More serious interference by employees may involve sabotage or arson. Arson is one of the causes of fire on process plants considered in Chapter 2. The *Compendium of Fire Safety Data* (FPA, 1992) contains an 'arson dossier' (the AR series). Arson is one of the topics dealt with in the *NFPA Handbook* (Cote and Linville, 1986).

The effective operation of a security system requires that all involved are fully trained so that they understand what the functions of the system are, how it works, what their own role is and how they should discharge it.

20.21 Notation

Section 20.3

C	interface concentration (ppm)
H_s	heat of solution (cal/gmol)
k	constant
ϕ	fractional humidity (% relative humidity/100)

Section 20.14

d	diameter of tank
F_1, F_2	forces defined in Figure 20.2(a)
ΣF	vector of forces defined in Figures 20.2(b) and 20.2(c) for positive and negative internal pressures, respectively
p	pressure
r	radius of tank
t	thickness of tank wall
α	angle defined in Figure 20.2(a)
δ	width of element in Figure 20.2(a)
σ_b	bending stress in tank roof
σ_h	hoop stress in tank wall
σ_s	shear stress between tank roof and wall
ϕ	angle defined in Figure 20.2(a)

Equipment Maintenance and Modification

Contents

21.1 Management of Maintenance

The need for maintenance of equipment implies some abnormality and often some change or increase in hazard. The conduct of the maintenance work may also introduce its own hazards to the equipment. In addition, the maintenance activities may be a hazard for the personnel involved in them. Careful control of maintenance work must be exercised in order to eliminate hazards to the equipment and to the personnel.

The consequences of failure to exercise this control can be serious. The Piper Alpha disaster was caused by failures in isolation procedures, the permit system and the handover system associated with maintenance work.

Some work constitutes change rather than maintenance. In previous chapters emphasis has been placed on the need to maintain the integrity of the equipment. This integrity may be degraded by equipment modifications unless they are closely controlled. The Flixborough disaster was judged to have been caused by a change which reduced equipment integrity.

Thus, both equipment maintenance and equipment modification require systems of control with a fairly high degree of formality. Equipment maintenance needs to be administered through some kind of permit system, while equipment modification requires a system to manage changes.

Maintenance activities are regulated by numerous codes, standards and guidelines. Some of which are: Occupational Safety & Health Administration (OSHA), Environmental Protection Agency (EPA), Department of Transportation (DOT), Department of Energy (DOE), Nuclear Regulatory Commission (NRC), National Institute for Occupational Safety & Health (NIOSH), National Fire Protection Association (NFPA), American Society of Mechanical Engineers (ASME), American Institute of Chemical Engineers (AIChE), National Association of Corrosion Engineers (NACE), Institute of Electrical & Electronics Engineers (IEEE), International Electrotechnical Commission (IEC), American Society of Testing & Materials (ASTM), American National Standards Institute (ANSI), National Board Inspection Code (NBIC) and American Petroleum Institute (API).

The safe maintenance of process equipment is dealt with in *Safety in Inspection and Maintenance of Chemical Plant* (BCISC, 1959/3), *Safety and Management* (ABCM, 1964/3), *Permit Systems* (CAPITB, 1977 Inf. Pap. 16A), *Refining Safety Code* (IP, 1981 MCSP Pt 3), *Deadly Maintenance* (HSE, 1985b), *Liquefied Petroleum Gas*: vol. 1, *Large Bulk Pressure Storage and Refrigerated LPG* (IP, 1987 MCSP Pt 9) (the IP *LPG Code*), *Guidance on Permit Systems in the Petroleum Industry* (OIAC, 1991) (the OIAC *Permit Systems Guide*) and *Maintenance of Process Plant* (the IChemE *Maintenance Guide*) (Townsend, 1992). Selected references on equipment maintenance are given in Table 21.1.

21.1.1 Safe systems of work

The US Occupational Safety and Health Act of 1970 requires employers to provide a workplace free from recognized hazards that are causing or likely to cause death or serious physical harm to employees. Employees are also required to comply with Occupational Safety and Health Standards (29CFR1910) promulgated under the Act of 1970.

The requirement of the UK Health and Safety at Work Act (HSWA) 1974, for safe systems of work is particularly

Construction, demolition hazards
HSE (1981/2)

relevant to the maintenance of process equipment, where there are many jobs which involve degree of potential hazard, but which can be done safely provided proper control is exercised. It is also characteristic of maintenance that it often involves quite a large number of people and that systems to ensure good communications are important.

Basic elements of the overall safe system of work are: equipment documentation – written procedures for non-trivial tasks; permit and handover systems; systems for control of a large workforce and for dealing with contractors and supervision and training.

21.1.2 Equipment documentation

Critical information on all equipment must be documented so the design basis, operating parameters and materials of construction are known. The primary document is a piping and instrument diagram for mechanical equipment and electrical one-line diagrams for electrical equipment. Various other sources like equipment specification sheets, equipment drawings, instrument loop diagrams, pump curves, relief system design, safety system documentation and material certifications will provide detailed information. The documentation must be kept accurate and up to date.

21.1.3 Maintenance procedures

Any regular maintenance task which is non-trivial should be governed by a formal written procedure. This procedure should address the specific task and should complement the general permit and handover systems described below. In particular, there should be formal procedures for the installation and removal of slip blinds and blind flanges. The principles underlying the writing of operating procedures are applicable in large part to maintenance procedures also.

21.1.4 Permit system

Maintenance work should be governed by a formal permit system. The purposes of such a system are: to see that proper consideration is given to the job, its hazards and the precautions required; to ensure that these are understood by all persons involved; and to facilitate effective communication between the parties concerned.

The permit system is intimately bound up with the hazards of maintenance and with the various preparations and precautions required to make a plant safe for maintenance work. These are therefore described first and the permit thereafter in Section 21.8.

21.1.5 Handover system

The permit system should be complemented by formal shift handover procedures. These procedures are described in Chapter 20 with particular reference to handover between operators, but essentially similar considerations apply to the maintenance function.

21.1.6 Control of workforce

The workforce involved in maintenance and related work may be quite large and varied. The core maintenance workforce of company employees may be supplemented by contractors working on routine maintenance and on equipment testing and recertification. In addition to the workforce thus engaged, there may well be extended periods when other plant modification or expansion work is going on involving a considerable number of people. All this work needs to be controlled through the permit system. The need to exercise control may in some cases set a limit on the volume of work which can be undertaken.

21.1.7 Contractors

A portion of the workforce engaged in maintenance work may be contractors. The trend in recent years has been towards increasing use of contractors, not only on construction work but also on more routine jobs such as equipment testing and recertification. The reasons for the use of contract maintenance are discussed by C.J. Carter (1980) and the identification and control of contractor hazards are described by Whitaker (1993).

There should be a system of quality assurance for work to be bid out. It is normal to require the contractor to provide evidence of the quality and safety of his work, supervision and training, and of his own quality assurance and safety procedures. The OSHA process safety management standard requires employers to obtain and evaluate information regarding contractor's safety performance and programmes. The standard defines employer and contractor responsibilities. A sample contractor pre-qualification form was jointly created by the Chemical Manufacturers Association (CMA) and the API.

In some cases a contractor's personnel may work on a site for years on end and become as familiar with the systems as company personnel, but in others they may be there for quite a short time. In any event, it is necessary that before new personnel from a contractor start work they are properly trained in these systems. Contractor safety orientations should be held for all contract employees highlighting the plant safety requirements and hazards.

The need for this was highlighted by the Piper Alpha disaster, where a two-man team of contractors was carrying out testing and recertification work on pressure relief valves on the platform, but the senior of the two was on his first tour as supervisor and had not received adequate instruction in the permit system.

21.1.8 Supervision and training

It will be evident that supervision and training are essential in ensuring that maintenance work is done safely. The permit and handover systems provide a structure for the supervision of maintenance work, but by no means exhaust the contribution of supervision.

With regard to training, maintenance personnel should be trained not only in their own craft, but also in the hazards of the chemicals and the equipment, the jobs which they do such as isolation and vessel entry, in the permit and handover systems, and in making the distinction between a routine maintenance task and a modification. The training of maintenance personnel is considered further in Chapter 27.

21.2 Hazards of Maintenance

As already stated, maintenance work on process equipment involves a number of hazards. An account of maintenance hazards and accidents is given in *Deadly Maintenance* the (HSE, 1985b), *Dangerous Maintenance* (HSE, 1987a) and HS(G) *49 Human Factors in Industrial Safety* (HSE, 1989) and by Deacon (1988).

The first of these is a study by the Accident Prevention Advisory Unit (APAU) of the Health and Safety Executive (HSE) of maintenance accidents in British industry during the period 1980–82. In this period, there were over 100 deaths per year caused by maintenance work, and over the 3-year period there were a total of 106 deaths (33%) associated with the maintenance of equipment and machinery. The fatalities were assigned to the following categories: breakdown and scheduled maintenance work, 66%; cleaning, 25%; and examination, lubrication, painting, 9%. A feature of these statistics is the prominence of accidents in cleaning.

Although maintenance craftsmen comprised the largest single category of deaths (37%), fatalities to operators were almost as numerous (33%). Other groups included labourers (7%), service engineers (6%), and managers, supervisors and proprietors (13%). The relatively large number of deaths among operators is accounted for only in part by cleaning operations.

The accidents were classified by equipment type, accident type and major cause. There were 66 accidents assigned to identified categories of machinery and 32 to identified categories of equipment, the balance of 8 being assigned to machinery and equipment in general. Of the machinery accidents, 23 were caused by conveyors and elevators, but few of the others identify process machinery. The breakdown of plant accidents is: storage tanks, 7; furnaces and associated equipment, 6; boilers, heating and ventilation equipment, 5; chemical, gas, oil, process equipment, 5; dust or fume extraction equipment, 5; and degreasing equipment 4.

The classification by accident type is: machinery, 50, of which 17 involved entanglement and the rest some form of crushing; falls, 21; burns, 10; gassing, 9; electrocution, 6; asphyxiation, 5; and struck by falling materials or equipment, 5.

By major cause, the classification is: absence or failure of system of work, 35; absent or defective equipment, guards or working platforms, 23; failure of management organization or supervision, 11; inadequate or lack of training, instruction or information, 8; human error, 10; unauthorized activity, 5; defective design of equipment or machinery, 5; and unknown or unforeseeable incident, 9.

The authors present three case studies of generic types of accident, associated with (1) conveyors and elevators, (2) overhead travelling cranes and (3) confined spaces.

The APAU publication also contains some 99 case histories of accidents in maintenance work. Other specialized collections include *Safety in Maintenance* (API, 1981 Safety Digest 4) and that given by Kletz (1982f), whose other work is also replete with maintenance case histories. Complete maintenance work also features strongly in many general collections of case histories.

Confined spaces present a number of hazards, and these are described in Section 21.7. Other hazards are mentioned throughout this chapter.

21.3 Preparation for Maintenance

There are a number of preparatory measures which may need to be taken before maintenance work is started. The principal means of control of such work is the permit system. The preparatory measures to be taken should be specified on the permit.

Many of these measures are aimed at allowing work inside equipment to be done safely. If work is to be done internally on an item of equipment, it should be prepared by the following operations: (1) depressurization, (2) cooling down, (3) isolation, (4) removal of contents (gas, liquid, solids) and (5) cleaning.

21.3.1 Identification of equipment

Many incidents occur on process equipment due to errors in the identification of the equipment on which work is required. Plants can often seem a confusing maze of vessels and piping, much of it lagged, and it is often difficult to identify equipment unaided simply by tracing the course of piping or by the use of other clues. This point has already been made in Chapter 14 in relation to the work of the process operator. It is necessary, therefore, to adopt a more positive policy for the identification of equipment.

One method which may be used is to attach a permanent identification to a particular equipment. This is an effective system provided precautions are taken against certain types of error which can occur.

There are certain standards and codes of practice for the identification of equipment. In particular, mention may be made of BS 1710: 1984 *Specification for Identification of Pipelines and Services*.

Identification should be consistent and should agree with reasonable expectations. It is asking for trouble to number equipment unsequentially, when it forms a natural sequence, such as pumps in parallel or reactors in series. Another situation to be avoided is ambiguity as to which of two adjacent pieces of equipment an identifier refers to.

Much maintenance work involves breaking into pipe joints. Permanent identifiers are not as suitable in this case. An identification tag can be used.

The identification of pipe joints is particularly important, because incidents are frequent in which the wrong joint is broken. Many such occurrences could be avoided by a positive system in which the identification tag is put on the joint to be broken.

For the type of work described, a permit is required. The identification of the equipment, whether permanent or temporary, should be given on the permit form. A walk down by the operator issuing the permit and the maintenance technicians to physically locate the equipment is beneficial.

The system described is not foolproof, of course. The person putting the identification tag on the equipment can make a mistake. But, in general, it does appear to be an effective system in practice.

The use of the identification tag system is preferable to merely pointing out to the maintenance fitter the equipment to be repaired. Incidents have occurred which suggest that this is not always adequate.

21.3.2 Depressurization

If the equipment contains liquid heated above its boiling point under pressure, it may be necessary to let it cool down prior to depressurization in order to avoid excessive flashoff. Depressurization should be performed in accordance with the design intent. For flammable or toxic gases this should preferably be to another part of the process. Alternatively, it may be to flare, to a scrubber system, or in some cases to the atmosphere. For inert gases venting is often to a vent stack or vent pipe.

21.3.3 Cooling

If the equipment has not already been cooled down sufficiently prior to depressurization, it should now be cooled down. Cooling involves the hazard of vacuum collapse. This may be guarded against by inert gas injection to maintain the internal pressure at atmospheric pressure.

21.3.4 Isolation

When the equipment has cooled down, the equipment to be worked on should be isolated. This includes isolation of vessels and piping from process and utilities, isolation of machinery from its power sources (electric, hydraulic, pneumatic) and isolation of electrical equipment. Isolation is crucial both to the safety of the equipment and to that of the personnel. It is considered in detail in Section 21.4.

21.3.5 Emptying of liquids

Once the equipment has been isolated, the next step is to remove its contents. If it contains liquid, this is usually pumped away to another part of the equipment or to storage, or, if non-hazardous, to drain. The liquid may leave behind hazardous residues, which are considered in Section 21.3.7.

21.3.6 Gas freeing

If the contents of the equipment are gas or vapour, there are a number of methods of gas freeing which may be used to replace them with air. These methods include (1) forced ventilation, (2) flushing with water and forced ventilation, (3) purging, (4) steaming and (5) chemical cleaning.

Equipment often contain flammable or toxic residues. If these are sufficiently volatile, they may constitute a continuous source of contamination.

The choice of method of gas freeing depends on the type of equipment, on its initial contents, including residues, and on the work to be done. Where steaming is used for cleaning, gas freeing occurs at the same time.

Purging is discussed in Section 21.5. Other methods of gas freeing are described in relation to tank cleaning in Section 21.12. An account of the gas freeing of crude oil storage tanks is given by Moros, Howells and Ryall (1993).

21.3.7 Removal of solids

Solid process materials include raw materials and final products, and catalysts and adsorbents. Raw materials are often removed by continuing to run the process until they are exhausted. Products, catalysts and adsorbents are generally transferred to suitable containers.

There are a number of hazards associated with solid process materials which need to be guarded against. Solid materials may be flammable, toxic or pyrophoric. Flammable dusts may give rise to a dust explosion. Adsorbents may give off flammable or toxic material, and in some cases ignite spontaneously in the presence of air.

The other type of solid is residues in the form of deposits and sludge. These also may be flammable or toxic. It is generally necessary to remove these by cleaning, although for certain activities there may be alternative sale methods of working, as described below.

A particular pyrophoric material often encountered in refinery processes is iron sulfide. If dry, this will burst into flames on contact with air, but if wet it is harmless. It may be dealt with by injecting inert gas and soaking the iron sulfide with water.

Oil soaked insulation, removed while it is still hot, can behave like a pyrophoric material and burst into flames on contact with air.

21.3.8 Cleaning

There are a number of methods available for cleaning. The choice of method of cleaning depends on the type of equipment, on its initial contents, including residues, and on the work to be done. The methods are described in Section 21.6.

21.4 Isolation

As already described, much maintenance work is subject to potential hazards from noxious materials, energy sources, rotating equipment and electrical power. Where work is to be done, the necessary isolations should be made to ensure that it can be done safely. Accounts of isolation are given in the IP *Refining Safety Code*, the IP *LPG Code*, the OIAC *Permit Systems Code*, the IChemE *Maintenance Guide* and by Kletz (1982f).

Isolation is governed by OSHA standards 1910.147 *The Control of Hazardous Energy* (Lockout/tagout) and 1910.146 *Permit Required Confined Spaces*. Isolation may be required prior to installation, inspection, repair, cleaning or dismantling. Where a job involves isolation of equipment, there should always be a permit for the job. Permit systems are described in Section 21.8.

21.4.1 Isolation of vessels and pipes

The methods available for isolating a vessel or pipe are, in ascending order of effectiveness, the use of (1) a closed and locked valve, or valves, (2) a double block and bleed valve system, (3) a blind and (4) physical disconnection.

The least effective of these methods of isolation is the use of a closed and locked isolation valve. There have been numerous incidents in which either the valve has corroded or jammed and has passed fluid or it has been opened in error. Even two isolation valves in series do not always prevent the passage of fluid.

More positive isolation is obtained by the use of a double block and bleed valve system as shown in Figure 21.1(c) The two block valves are closed, the bleed valve is open and all three are locked. If the fluid passes through the first block valve, it is vented by the bleed valve so that no pressure should build up which would allow the material to pass through the second block valve. A build-up of pressure can occur if the bleed line is too small or too long, or if it discharges into a vent system in which there may be a back pressure.

As shown in Figure 21.1(a), isolation may be accomplished by the insertion into the line of a slip blind. In the system shown, the valve is first closed and locked and the slip blind is then inserted. If a spacer blind or figure 8 blind is installed, it may be used instead of a slip blind.

The most positive method of all, shown in Figure 21.1(b), is complete physical disconnection of the line, with a blind flange, or blank, put on the 'live' line.

Where isolation is by means of a closed valve, this should be an isolation valve rather than a control valve, unless the latter can be tightly shut, disconnected from any power source, locked in the closed position and the isolation tested as being effective.

Isolation valves should be locked and tagged. The preferred arrangement is a valve which can be locked with a captive key system or which has lugs for padlocking. The alternative is the use of a chain and padlock. A tag should be securely attached to the valve, stating whether it is locked in the open or closed position and prohibiting unauthorized movement of it, and showing the equipment identification number, the isolation lock number and the isolation permit number.

On systems containing hazardous fluids such as hydrocarbons under pressure, the arrangements for closing off the end of a line with a blind flange should ensure that the joint is leak tight. The fixed flange and the blind flange should be inspected for deterioration, a ring-joint blank should be fitted with a new ring and the bolts should be properly tightened.

The blind used should be strong enough to withstand the highest pressure which may occur in the main if the shut-off valves are opened accidentally. The blind must be thick enough to withstand hydrotest pressure if the system isolated has to be hydrotested. Each blind should have an identification tag.

Where there is to be work on a pressurized hydrocarbon system or entry into a vessel, physical disconnection is the recommended method of isolation. If this method is not reasonably practicable, the next best method is the insertion of a blind.

The closed and locked isolation valve method should be used only for the isolation of low hazard fluids. Another principal use is to effect preliminary isolation while a blind is inserted.

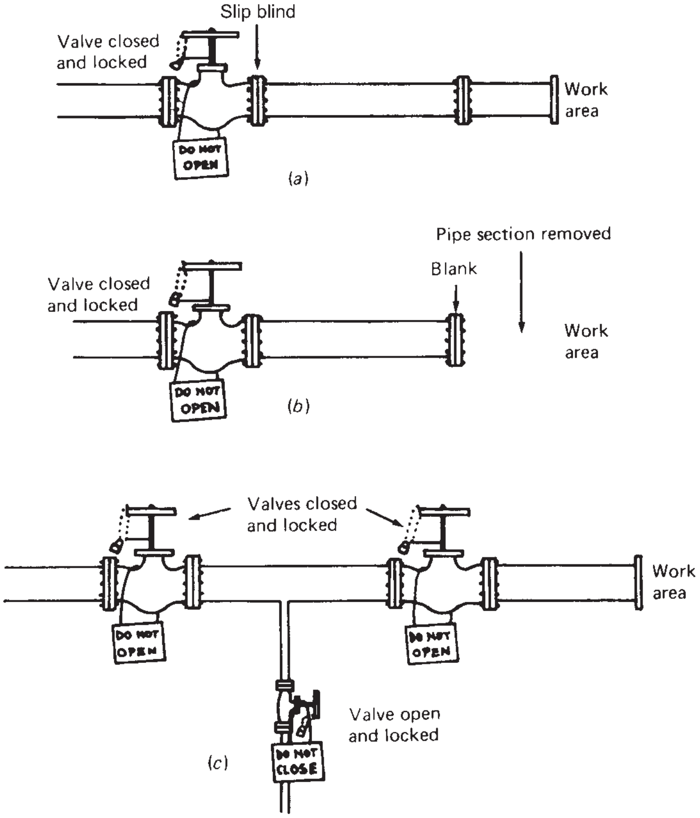

Figure 21.1 *Some methods of isolation of piping – 1: (a) locked valve with slip blind; (b) locked valve with blind flange and with section removed; (c) locked double block and bleed valves*

The double block and bleed system is more effective than a closed isolation valve and is used for more hazardous fluids. It does not, however, provide adequate isolation for long periods. This method also finds a principal use in effecting preliminary isolation while a slip plate is inserted.

Figure 21.2 shows the methods of isolation given in the IChemE *Maintenance Guide*. In addition, there are certain preferred arrangements for isolation in specific cases. For entry into a vessel or confined space, isolation should be by physical disconnection.

For the isolation of relief valves and vent lines, physical disconnection is again the preferred method. Where this is not possible, the relief valve or vent line should be blinded off first and deblinded last.

The need should be considered for isolation of drains and sewers through which hazardous materials may spread to other sections of the plant.

The equipment should be designed to facilitate isolation, particularly at points where isolations are likely to be frequent. A pressure gauge and drain point can be provided downstream of an isolation valve which is used to provide preliminary isolation for the insertion of a blind. A double block and bleed valve system can be installed to provide more positive isolation for the same purpose. Spectacle blinds can be provided. All critical valves should be identified with a permanent marking.

There should be a system for the identification and control of blinds and blind flanges for different duties. The system should ensure that blinds are correctly identified and that they do not become mixed up. It should also ensure that blinds are neither left in when they should be taken out nor left out when they should be inserted. For equipments where a number of blinds need to be inserted for isolation, it is helpful to have a blind list and a diagram showing the insertion points. Permanent blinds should also be labelled and shown on P&IDs.

21.4.2 Isolation of machinery

Where work is to be done on powered machinery, the source of power should first be isolated. Sources of power include electrical, hydraulic and pneumatic power, and engines.

A hydraulic or pneumatic supply should be isolated as follows. First, preliminary isolation should be completed by closing a valve. Then the supply and return pipes should be disconnected, or otherwise made safe. The isolation of electrical supplies is described below.

Isolation of an engine-driven system should be done by shutting off the engine fuel supply and then isolating and disconnecting all starting systems.

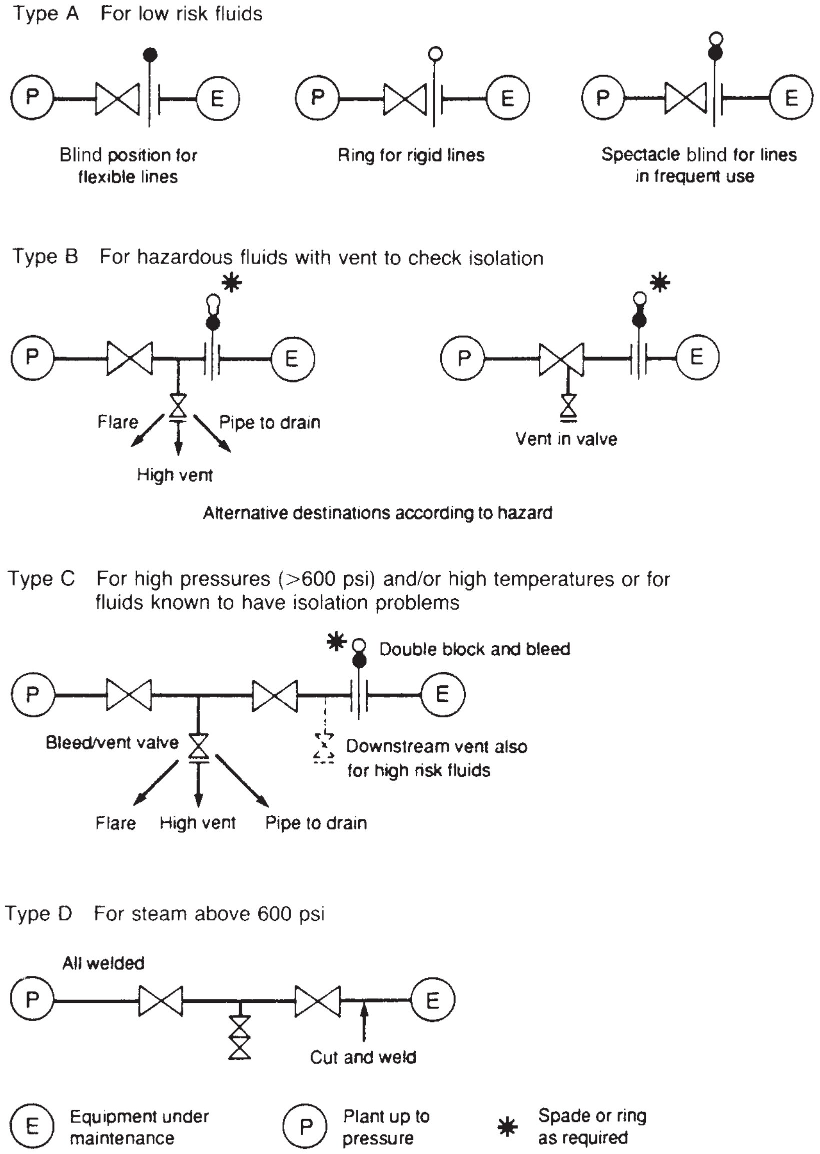

Figure 21.2 *Some methods of isolation of piping – 2 (Townsend, 1992) (Courtesy of the Institution of Chemical Engineers)*

It may sometimes be possible for the machinery to move even though it is disconnected from its power source, and in such cases it should be secured to prevent such movement.

A lockout/tagout system should be used based on principles similar to that for the isolation of equipment.

21.4.3 Isolation of electrical equipment

Electrical isolation may be required either to immobilize machinery or to protect personnel working on electrical equipment.

Situations involving electrical isolation include work on powered equipment, including rotating machinery and machinery with moving parts, and entry into vessels which contain stirrers or agitators.

Where isolation of fluids is required, electrical isolation should be a complement to, but not a substitute for, mechanical isolation.

OSHA standards 1910.147 and Subpart S, govern maintenance work on electrical systems. The isolation of electrical equipment is governed by the UK *Electricity at Work Regulations* 1989 and advice is given in the associated *Memorandum of Guidance* (HSE, 1989 HS(R) 25). Electrical isolation should be performed only by an electrically competent person.

Two methods of isolating electrical equipment are to withdraw the fuses and to lock-out the breaker. There is evidently some difference of view on the merits of the two methods. Some references describe systems based primarily on breaker lock-out. The IChemE *Maintenance Guide* describes fuse withdrawal as suitable where breaker lock-out is not available, as with instruments, heaters, lighting circuits. Anon. (1983 LPB 49, p. 7) argues that a fuse is always liable to be replaced. On the other hand, Kletz (1982f) states that experience has shown that breaker lock-out is not always effective. He recommends fuse withdrawal where the work to be done is on electrical circuitry. A system of electrical isolation based on breaker lock-out is described by Anon. (1983 LPB 49, p. 7).

A lock-out device is a mechanism or arrangement which allows the use of key operated padlocks to hold a switch lever or handle in the 'off' position. The lock-out procedure is to switch off or de-energize electric power, lock-out, tagout and confirm lock-out by checking that the equipment will not restart. The lock-out should be applied to the breaker or disconnect switch itself and not to some remote stop/start button, selector switch or interlock. Where there is more than one power source, all should be locked out and tagged.

The lock-out system is as follows. For operations, each padlock should be issued through the operations foreman and should be capable of being opened only by the one key issued with it. There should be a lock-out log for recording the identification of the locked-out equipment, the date and time of application of the padlock and the operator applying it, and the date and time of its removal and the operator removing it. The maintenance craftsman applies his own lock to the breaker before starting work and removes it when they are finished. Where the equipment is to be worked on by several crafts, each craftsman applies this procedure. If a shift change occurs, the outgoing craftsman removes his lock and the relieving one applies his own lock. When the job is complete, the last lock to be removed is that of the operator.

With regard to the isolation of electrical systems, to protect personnel working on or near them, guidance is given in the relevant OSHA standards, API recommended practices and British Standards.

All items of electrical equipment should have permanent labels, and their separate parts should be identifiable. For a prime mover, the IChemE *Guide* gives these as the drive unit, the breaker/disconnect and the stop/start button. A system of warning tags should also be used.

21.5 Purging

Purging involves replacing one gas or vapour with another. It is performed for a variety of purposes and using a number of different purging media. Guidance on purging is given in *Purging Principles and Practice* (AGA, 1975) (the AGA *Purging Guide*). Further accounts of purging are given in the IP *Refining Safety Code*, CS 15 (HSE, 1985), the IP *LPG Code*, the IChemE *Maintenance Guide*, and by Kletz (1982f).

Purging may be used to take a unit out of service by replacing flammable or toxic process gas with an inert medium and then with air. It may be used to bring a unit back into service by replacing air with an inert medium and then with the process gas.

The AGA *Purging Guide* gives purging end-points for a number of different cases. The end-point data cover two purge gases: nitrogen and carbon dioxide. Values are quoted for the concentration which will just render a mixture non-flammable and for that which allows a 20% 'safety factor'. Selected purge end-points taken from the guide, are shown in Table 21.2. Section A gives inert gas end-points for purging into service (i.e. purging air out of a system subsequently to be filled with flammable gas), together with an alternative set of oxygen end-points which may be more convenient to use. Section B of the table gives inert gas end-points for purging out of service (i.e. purging flammable gas out of a system subsequently to be filled with air), together with an alternative, and often more convenient, set of combustible gas end-points. The values given without brackets are the concentrations required to just render the mixture non-flammable, while those in brackets give the 20% safety factor.

Further details of the purging of equipment prior to entry or hot work, including sources of purge gas, purge end-points and precautions, are given in Section 21.12. The purging of refinery units is described in Chapter 20.

21.6 Cleaning

There is a wide variety of methods of cleaning equipment. They include (1) water washing, (2) chemical cleaning, (3) steaming, (4) water jetting, (5) solvent jetting, (6) shot blasting and (7) manual cleaning.

The choice of cleaning method depends on the type of equipment and on the nature of the material to be cleaned out. Most of these methods are described in CS 15 and/or the IChemE *Maintenance Guide*.

Some methods of cleaning are now described. Further details of cleaning of tanks prior to entry or hot work are given in Section 21.12.

21.6.1 Water washing

In some instances, adequate cleaning may be obtained by flushing with water. In most cases, however, something more is required.

Washing with cold water, or even purging with air, have sometimes been used in an attempt to remove oil, but these are generally not effective methods for this purpose and reliance on them has been the cause of many accidents.

Another process, also referred to as water washing, comprises immersion of the article in a boiling aqueous caustic or detergent solution. This may be used for small equipment which can be completely immersed. It is necessary to select the cleaning agent so as to avoid chemical attack, to exclude air and to boil for at least 30 min.

Another form of water washing is the use of a high pressure jet of hot detergent solution directed onto the interior surfaces. This latter method is used in combination with steaming to clean drums.

21.6.2 Chemical cleaning

Equipment may be cleaned by chemical cleaning using special chemicals. Surfactants can be used as a general cleaning agent. Some forms entrain hydrocarbon. Chemicals such as acids can be circulated through equipment to clean the system. All chemical cleaning solutions and by-products must be disposed of properly.

21.6.3 Steaming

Steam cleaning is used particularly for fixed and mobile equipment. The basic procedures is as follows. Steam is

***Table 21.2** Selected end-points for purging (after American Gas Association, 1975)*

A Inert gas and oxygen end-points for purging into service

Gas	*Concentration of gas to render mixture non-flammable* (% v/v)[a]	
	Nitrogen	*Oxygen*
Hydrogen	71 (77)	5.0 (4.0)
Methane	36 (49)	12.1 (9.7)
Propane	42 (54)	11.4 (9.1)
Butane	40 (52)	12.1 (9.7)
Ethylene	49 (59)	10.0 (8.0)
Propylene	42 (54)	11.5 (9.2)

B Inert gas and combustible gas end-points for purging out of service

Gas	*Concentration of gas to render mixture non-flammable* (% v/v)[a]	
	Nitrogen	*Combustible gas*
Hydrogen	95 (96)	5 (4)
Methane	86 (89)	14 (11)
Propane	94 (95)	6 (5)
Butane	95 (96)	5 (4)
Ethylene	94 (95)	6 (5)
Propylene	96 (97)	4 (3)

[a] Values without brackets are the concentrations to just render the mixture non-flammable, those in brackets are the concentrations which give a 20% safety factor.

added to the equipment, taking care that no excess pressure develops which could damage it. Condensate should be drained from the lowest possible point, taking with it the residues. The temperature reached by the equipment walls should be sufficient to ensure removal of the residues. A steam pressure of 30 psig (2 barg) is generally sufficient, and this temperature is held for a minimum of 30 min. The progress of the cleaning may be monitored by the oil content of the condensate.

There are a number of precautions to minimize the risk from static electricity. There should be no insulated conductors inside the equipment. The steam hose and equipment should be bonded together and well grounded; it is desirable that the steam nozzle have its own separate ground. The nozzle should be blown clear of water droplets prior to use. The steam used should be dry as it leaves the nozzle; wet steam should not be used, as it can generate static electricity even in small equipment, but high superheat should also be avoided, as it may damage equipment and even cause ignition. The velocity of the steam should initially be low, though it may be increased as the air in the equipment is displaced. Personnel should wear conducting footwear.

Consideration should be given to other effects of steaming. One is the thermal expansion of the equipment which may put stress on associated piping. Another is the vacuum that occurs when the equipment cools again. Equipment openings should be sufficient to prevent the development of a damaging vacuum.

Truck tankers and rail tank cars may be cleaned by steaming in a similar manner. Steaming may also be used for large tanks, but in this case the supplies of steam required can be very large. There is also the hazard of static electricity, and in some companies it is policy for this reason not to permit steam cleaning of large storage tanks which have contained volatile flammable liquids.

21.6.4 Water jetting

Another method of cleaning is high pressure water jetting. A high pressure water jet can cut through most metals and polymers and can clean a surface of paint or deposits. Accounts of water jetting are given by Donaldson (1986) and Jacob (1990). The relevant code is *Code of Practice for the Use of High Pressure Water Jetting Equipment* (High Pressure Water Jetting Contractors, 1982).

The technique is widely used for a variety of purposes, varying from the cleaning of buildings, roads and drains to the removal of spalled concrete. It is now being increasingly used in the process industries. One application is the removal of deposits from equipment such as heat exchangers and tanks. Another is the cutting of metal, which is used for the cutting up structural steel, equipment and piping during demolition.

In water jetting, the jet is held quite close to the surface, about 3–4 in. (75–100 mm). A water jet can remove material from a surface if the energy transferred per unit area exceeds a threshold value which is characteristic of the material. Since the energy is a function of the jet velocity and this in turn is a function of the pressure, this threshold energy can be specified in terms of the nozzle pressure for typical practical flows. The pressures used in water jetting have risen from about 3000 psi (200 bar) through 15,000 psi (1000 bar) and are now up to 30,000 psi (2000 bar).

A 30,000 psi (2000 bar) jet may operate with a flow as low as 2.5 gpm (10l/min). At this flow, the reaction force is of the order of 33 lbf (15 kgf), which is manageable for an operator. A maximum recommended value is 1055 lbf (25 kgf). The cutting rate is controlled by adjusting the flow rather than the nozzle pressure and any increase in flow results in an increase in reaction force. One hazard of water jetting is the loss of control of the jet. Numerous incidents have occurred where water jet operators have injured themselves with the high pressure water.

Another potential hazard is the aerosol produced, which can be harmful, depending on the material involved. The use of protective clothing is necessary.

In addition to manual cleaning operations, water jetting is used in fixed systems for cleaning tanks and vessels. A typical arrangement is a set of four jets set at right angles to each other on the same plane and mounted on a head which itself rotates to give coverage in all directions. In such equipment cleaning applications, the travel distance for the jets is much greater, and their removing power correspondingly less.

Static electricity hazard can be a hazard in water jetting.

21.6.5 Solvent jetting

Another method used for cleaning is high pressure solvent jetting, with recirculation of the solvent. The method is promoted for difficult residues. The solvents used are flammable and create a flammable atmosphere inside the equipment. It is necessary to take precautions against static electricity and to undertake gas freeing afterwards.

21.6.6 Shot blasting

A quite different method of cleaning is the use of shot blasting, or grit blasting. In this method a stream of fine abrasive particles is directed at the surface to be cleaned in a jet of air. The method is widely used for cleaning surfaces, particularly for painting. Walnut shell blasting has been used to clean rotating machinery internals.

21.6.7 Manual cleaning

In some cases it is necessary to resort to manual cleaning. This method may have to be used, for example, where a equipment contains residues which are difficult to shift in any other way but physically removing them. A typical case is the removal of flammable residues or solids in a large equipment in preparation for hot work. Manual cleaning is generally a last resort; it is laborious and unpleasant, and requires full precautions against flammable, toxic and asphyxiation hazards. Proper protective equipment must be worn.

21.6.8 Cleaning in place

A method of cleaning which is now a standard one in the pharmaceutical, as well as the food industry, is cleaning in place (CIP), using detergents. Accounts are given by Hyde (1985) and Kirkland (1986).

CIP systems offer a number of advantages. They minimize downtime by more rapid cleaning and generate less effluent, and can be less costly. They minimize manual operations and hence, both safety and health problems. In particular, hazards of vessel entry and slippery surfaces are reduced.

CIP systems come both as systems dedicated to particular units and as mobile systems which can be used on a number of units. They may operate under manual control or under automatic control, with a program sequence.

The equipment to be cleaned may be closed or open. For open equipment, Kirkland describes the use of a spray ball, custom-designed by computer, for the particular vessel.

A typical CIP sequence is: (1) a water pre-rinse, to remove gross material; (2) detergent circulation, to remove debris and scale; (3) an intermediate water rinse, to remove detergent; (4) sterile circulation, to destroy residual organisms; and (5) a final water rinse, to remove CIP solutions.

There are various techniques for water recovery and for minimizing the quantity of solutions used.

21.6.9 Line clearing

It is often necessary to remove debris, as distinct from shifting a complete blockage, from a line by flushing with water or blowing it with air.

A treatment of the effectiveness of this operation has been given by Junique (1988). This is based on the following simple model of flushing or blowing:

$$F \propto \rho u^2 \qquad [21.6.1]$$

where F is the drag force on the particle, u is the fluid velocity relative to the particle and ρ is the density of the fluid. He defines a cleaning disturbance factor such that

$$C = \frac{\rho_1 u_1^2}{\rho_2 u_2^2} \qquad [21.6.2]$$

where C is the cleaning disturbance factor and subscripts 1 and 2 denote cleaning and operating conditions, respectively. The condition for effective flushing or blowing is $C > 1$.

The author gives an example of the application of the method.

21.6.10 Waste minimization

Cleaning operations generate an appreciable fraction of the liquid effluents from process equipments and measures to reduce effluents from this source can contribute significantly to waste minimization. This aspect is considered in Appendix 11.

21.7 Confined Spaces

Accidents associated with entry into and work in confined spaces and vessels have occurred with depressing regularity. This activity is recognized as presenting particular potential hazards and is governed by a statutory requirement for a permit. Permits as such are considered in Section 21.8. The account given here is confined to the hazards of confined spaces and to precautions which should be taken. Accounts of these hazards and precautions are given in the IChemE *Maintenance Guide*, in a series of articles in the *Loss Prevention Bulletin* (Anon., 1975 LPB 3, p. 8; Anon., 1980 LPB 31, p. 11; Anon., 1983 LPB 53, p. 15; Anon., 1984 LPB 56, p. 24; Anon., 1985 LPB 63, p. 31), in the work of Kletz (notably Kletz, 1982f, 1985b), and by Arney (1977a,b), Bond (1984 LPB 59), Keller (1987) and Trowbridge (1987).

Requirements for confined spaces are governed by OSHA 1910.146 *Permit Required Confined Space*, NIOSH *Recommended Standard for Working in Confined Spaces*, API 2217A *Guidelines for Confined Space Work in the Petroleum Industry* and ANSI Z117.1 *Safety Requirements for Confined Spaces*. Current guidance for the United Kingdom is given in Construction Sheet 15 *Confined Spaces* (HSE, 1991).

21.7.1 Confined spaces

In some cases it is fairly obvious what constitutes a 'confined space', in others it is less so. OSHA 1910.146 defines confined space as:

(1) large enough and so configured that an employee can bodily enter and perform assigned work;
(2) limited or restricted means for entry and exit;
(3) is not designed for continuous employee occupancy.

1910.146 further defines a 'permit-required confined space (permit space)' as a confined space that has one or more of the following characteristics:

(1) contains or has a potential to contain a hazardous atmosphere;
(2) contains a material that has the potential for engulfing an entrant;
(3) has an internal configuration such that an entrant could be trapped or asphyxiated by inwardly converging

walls or by a floor which slopes downwards and tapers to a smaller cross-section;
(4) contains any other recognized serious safety or health hazard.

Permit spaces must be labelled with appropriate signage. The HSE (1991 Construction Sheet 15) defines a confined space in the following terms:

> A closed equipment with restricted access may be the obvious example of a confined space, but it also includes open manholes, trenches, pipes, flues, ducts, ceiling voids, enclosed rooms such as basements, and other places where there is inadequate natural ventilation.

Open top tanks, furnaces and ovens, even those with a large aperture open to the atmosphere, are confined spaces.

21.7.2 Flammable substances

It is frequently necessary for personnel to enter a equipment or vessel which has contained flammable materials. Before this is done, it is obviously necessary to empty the equipment and to purge and clean it so that flammable materials are no longer present. Despite this, incidents occur in which a flammable atmosphere builds up and is ignited. Other incidents occur in which the flammable residues are ignited when hot work is done.

If a flammable mixture is ignited inside an equipment or vessel, the resultant explosion is likely to destroy it, since even pressure vessels are not generally designed to withstand an explosion. Unburned and burned gases and burning liquid may be expelled and missiles generated from the disintegration of the equipment.

There are several situations which can lead to the existence of a flammable atmosphere in the equipment. One is simply that flammable vapour which was originally present has not been completely removed. Another is that flammable residues remain in the equipment and evaporate. In some cases, the residues are trapped in structural members. In other cases, there may be solid residues which vaporize when heat is applied such as from welding. Another way in which flammable gases may build up again is through isolations which are not leak-tight. In particular, the use of a single closed isolation valve is an unreliable means of isolation and there have been many instances where flammable fluid has entered a equipment through a passing isolation valve. A fourth way is the generation of a flammable gas by chemical reactions, for example the action of water on steel can generate hydrogen.

Liquid residues should be drained, while solid residues should be removed by cleaning. Fluid leakage into equipment should be prevented by positive isolation, as described in Section 21.4.

Prior to entry into equipment, a gas test should be done to confirm that the space is free of flammable gas. In some incidents there has been a failure to free the equipment completely of flammable gas and to test for this. More commonly, however, incidents occur because flammable gas builds up in the equipment atmosphere after it has been checked and found to be free of flammables.

Even if gas tests show the equipment atmosphere to be essentially free of flammables, however, there may still be flammable residues or deposits which can be ignited by hot work. It is necessary, therefore, to check separately for these and to clean them away before hot work is undertaken.

21.7.3 Toxic substances

There is a parallel hazard with toxic substances. The precautions taken to ensure that the equipment atmosphere is free of toxic gas are essentially similar to those taken from flammable substances. The equipment should be emptied, purged, cleaned and tested for the relevant toxic gases. But a toxic atmosphere may still arise from residues remaining in the equipment or from leaks through inadequate isolation.

21.7.4 Hazardous atmospheres

Hazardous atmospheres may expose employees to the risk of death, incapacitation, impairment, injury, or acute illness from one or more of the following causes:

(1) flammable gas, vapour or mist in excess of 10% of its lower flammable limit (LFL);
(2) airborne combustible dust at a concentration that meets or exceeds its LFL;
(3) atmospheric concentration below 19.5% or above 23.5%;
(4) atmospheric concentration of any substance for which a dose or a permissible exposure limit is published and which could result in employee exposure in excess of its dose or permissible exposure limit;
(5) any other atmospheric condition that is immediately dangerous to life or health.

21.7.5 Oxygen-deficient atmospheres

The removal of flammable gas from a equipment is often accomplished by purging with nitrogen. This inert gas is then replaced with air by purging or ventilation so as to give a breathable atmosphere. Incidents occur in which workers are asphyxiated because the atmosphere is deficient in oxygen.

An oxygen-deficient atmosphere may arise in several ways. The original purging or ventilation may be inadequate. Alternatively, the purge may have been conducted inadvertently using nitrogen instead of air. One way in which such inadvertent use of nitrogen in place of air may occur is where the air line has been connected to a nitrogen supply line. Another is the use of a cylinder which is supposed to contain air, but contains some other mixture.

An atmosphere can also be rendered oxygen deficient if there is some process occurring which consumes the oxygen present, such as the rotting of vegetation or the rusting of metal. Oxygen may be adsorbed on steel surfaces, especially where these are damp.

Where the hazard of an oxygen-deficient atmosphere exists, a test of the oxygen content should be done.

Requirements for the oxygen content of breathable air vary. The oxygen content of air at sea level is 21%, but at high altitudes it can fall to 19.5%. The concentration usually quoted to sustain life is 16%. OSHA 1910.146 quotes a minimum of 19.5% oxygen by volume. CS 15 quotes a minimum oxygen concentration of 19%.

21.7.6 Oxygen-enriched atmospheres

In some cases, an oxygen-enriched atmosphere may occur in a confined space. Such an atmosphere is hazardous because it can enhance strongly the flammability of clothing. Oxygen-enriched atmospheres contain more than 23.5% oxygen by volume.

One way in which the atmosphere may become oxygen rich is by leakage of oxygen from an oxygen cylinder used in cutting or welding operations.

Another way is where the atmosphere is originally a mixture of nitrogen and oxygen which is nitrogen rich compared with air and where oxygen has been added in an attempt to raise the concentration to that present in air. This is poor practice because it involves this hazard.

21.7.7 Noxious fumes

There are a number of other ways in which noxious fumes may enter a confined space. One is from processes being carried out in that space. A common source is the fumes arising from welding. Another source is an adjoining space which has not been isolated. Other sources of noxious fumes are sludge and residues and combustion products.

Trenches, tunnels and manholes can fill with carbon dioxide. Other fumes may occur where the ground is contaminated. Where these spaces are connected even temporarily to sewers, the atmosphere may become contaminated with flammable and/or toxic gases or rendered oxygen deficient.

21.7.8 Atmosphere gas tests

Prior to entry into equipment, internal atmospheres shall be tested for oxygen content, flammable gases and vapours and for potential toxic air contaminants. The gas tests which are commonly done are for hydrocarbons, carbon monoxide and hydrogen sulfide and oxygen, together with tests for any toxic substance which has been contained in the equipment.

21.7.9 Air supplies

Measures to ensure that nitrogen is not supplied when it is intended to supply air to render an atmosphere breathable are described by Anon. (1975 LPB 3, p. 8). Incidents have occurred where an air line has been connected to a nitrogen supply, a nitrogen cylinder has been used instead of an air cylinder, and where an air cylinder has contained an oxygen deficient mixture.

There are certain precautions which may be taken to ensure that an air line is not connected in error to a nitrogen supply line. One is to put an identification sign at each nitrogen take-off point. A more positive measure is to ensure that the connections for nitrogen and air lines are different and that their designs are such as to prevent an air line from being connected to a nitrogen line.

Measures should also be taken to ensure that where air is to be supplied from a cylinder, the gas obtained actually is air. A positive means of preventing inadvertent use of a nitrogen cylinder instead of an air cylinder is the provision of different connections on the two types of cylinder, though this is outside the authority of the user company. Otherwise, procedures should be established to avoid identification errors.

Cylinders of breathable air should be analysed at a frequency that is sufficient to ensure the contents meet the specifications.

It is preferable not to use reconstituted air, made by blending nitrogen, oxygen and other gases, for breathing purposes, but if this is done each cylinder should be analysed.

21.7.10 Entry into confined spaces

It will be apparent that entry into a confined space or vessel needs to be governed by procedures which ensure that the hazards are identified and precautions taken. This is accomplished by the permit system, which is now considered. Entry procedures are a prime example of the application of a permit system.

21.8 Permit Systems

Maintenance work on process equipments should be controlled by a formal permit system. Accounts of such systems are given in *Permit Systems* (CAPFTB, 1977 Inf. Pap. 16A), *Guidance on Permit Systems in the Petroleum Industry* (OIAC, 1991) (the OIAC *Permit Systems Guide*) and the IChemE *Maintenance Guide*, and by Kletz (1982f), V.C. Marshall (1986b), S. Scott (1992) and Butler and Bonsall (1993).

21.8.1 Regulatory requirements

US companies use a work permit system to control maintenance activities in process units and entry into equipment. The United Kingdom uses a similar system of permits-to-work (PTWs).

In the United States of America, OSHA 1910.146 Permit Required Confined Spaces defines the requirements for entering in confined spaces. OSHA Process Safety Management Standard 1910.119k addresses hot work permit requirements. The OSHA Occupational Safety and Health Act of 1970 requires safe work places.

In the United Kingdom, there has long been a statutory requirement for a permit system for entry into vessels or confined spaces under the Chemical Works Regulations 1922, Regulation 7. There is no exactly comparable statutory requirement for other activities such as line breaking or welding. The Factories Act 1961, Section 30, which applies more widely, also contains a requirement for certification of entry into vessels and confined spaces. Other sections of the Act which may be relevant in this context are Sections 18, 31 and 34, which deal, respectively, with dangerous substances, hot work and entry to boilers. The requirements of the Health and Safety at Work etc. Act 1974 to provide safe systems of work are also highly relevant.

21.8.2 Objectives of permit system

In essence, the objectives of the permit system are to exercise control over the maintenance activities by assigning responsibilities, ensuring communication between interested functions, and requiring that proper consideration be given to the job, its hazards and the precautions required. More explicitly, the objectives are to ensure that:

(1) there is a system of continuous control of the work to be done;
(2) the persons responsible for overall control of the work and for its execution are identified;
(3) the person responsible for the operation of the equipment is aware of the work;
(4) the other functions with an interest in the work are identified and communications with them are established and maintained;
(5) the work is properly defined;
(6) the work is properly authorized by the person responsible;
(7) the person responsible for the operation of the equipment is aware of what is going on;
(8) the personnel involved in doing the work understand its exact nature and extent, the hazards involved,

any limitations on the extent, and the time allotted for the work;

(9) the isolations and de-isolations required are properly performed;
(10) the precautions to be taken are specified and understood;
(11) the equipment is available and the arrangements are in place to support these precautions;
(12) there is cross-referencing of permits where there is interaction between jobs;
(13) the permits are suitably displayed;
(14) there is a formal handover procedure from operations to maintenance;
(15) there is a formal handback procedure from maintenance to operations;
(16) there is a procedure covering situations where the work extends beyond a single shift;
(17) there is a procedure covering situations where the work has to be suspended;
(18) there is a record showing that the nature of the work and the precautions necessary were checked by the appropriate person(s).

21.8.3 Issuing and performing authorities

It is a principal objective of the permit system to define the responsibilities of all concerned. In the normal system there is an issuing authority and a performing authority. The issuing authority is the operations supervisor. The performing authority is usually the maintenance craftsman who is to do the work, but may sometimes be the maintenance supervisor.

It is the responsibility of the issuing authority to ensure that the equipment is safe for the work to proceed. The performing authority is responsible for ensuring that the further working precautions are taken. In certain cases, such as maintenance work on switchgear, the operations supervisor is not competent to give clearance, and so the maintenance supervisor has a greater degree of responsibility than usual.

It is the responsibility of these same two authorities to terminate the permit. The normal system is that on completion of the work, the performing authority signs that the work is complete and the issuing authority, after inspecting the work site, signs that the permit is complete.

There may be a requirement that in certain defined cases, where work at a particular unit may affect an adjacent unit, the operations supervisor on the latter should countersign the permit.

21.8.4 Types of permit

There is a variety of types of permit, some of which have special names, for example clearance certificates, fire permits, etc. Permits may be classified by reference to the operation to be performed, the equipment to be worked on, the classification of the areas where the work is to be done, the special hazards which may be encountered, the equipment to be used or the time of day specified for the work. A list of typical permits, which illustrates all these categories, is as follows:

Operations
Equipment removal
Excavation
Hot work
Leak sealing
Line breaking
Vessel entry
Waste disposal

Equipment worked on
Electrical equipment
Interplant pipelines
Sprinkler system

Area classification
Flammable area

Special hazards
Corrosive substances
Fire
Toxic substances
Ionizing radiations

Equipment used
Mobile crane

Time of day
After-hours work

A common basic set of permits covers entry, cold work, hot work and electrical work. Some companies use a single permit system to cover all work activities. The IP *Refining Safety Code* gives model permit forms for the following: general work, electrical work, hot work and work involving ionizing radiations; line disconnecting and vessel opening; entry; and excavation.

21.8.5 Permits for isolation

Isolation before a job and de-isolation after it should be treated as separate activities in their own right. Thus, for a job which requires isolation there may be permits for (1) isolation, (2) the main job and (3) de-isolation.

Some equipment is isolated and de-isolated solely by operations. Operations work is typically not permitted, so the only permit required would be for the maintenance work. Some systems cover the entire job from isolation to de-isolation using a single permit.

21.8.6 Contents of permit

The contents of a permit need to be carefully defined. Accounts of permit contents are given in the OIAC *Permit Systems Guide*, the IChemE *Maintenance Guide* and by S. Scott (1992). Such accounts usually distinguish between features which are essential and those which are desirable. The essential features of a permit are:

(1) company name and address;
(2) permit title;
(3) permit number;
(4) period of validity;
(5) location of work (unit, equipment);
(6) description of work;
(7) isolation;
(8) hazard identification;
(9) precautions required;
(10) protective equipment required;
(11) authorization;
(12) expansion;
(13) handback;
(14) cancellation.

The period of validity, in terms of the date, start time and end time, should be entered, as an elementary requirement for control. The location of the work should be specified in terms of the unit, area or building and vessel or equipment. Proper titles should be used, not informal names. The equipment may be identified by an identification tag/name and this should be cross-referenced on the permit. The description of the work should state the work to be done, the reason for it and the method to be used and any limitations on the extent of the work. There should be confirmation that the isolation required has been accomplished. The potential hazards should be identified. In some cases these may be partially covered by a checklist of actions to be taken such as depressurization, cleaning, etc., in which case it is the residual hazards which are entered. The precautions already taken and those still to be taken should be stated. The protective clothing and equipment to be used should be specified. The issuing authority should sign that the work is authorized to start and the performing authority should sign that the permit is accepted. On completion, the performing authority should sign to indicate that the work is complete and the issuing authority should sign to show that the permit is completed.

Particular types of permit require additional features. For example, a hot work permit should contain an entry for the hazardous area classification of the location of the work and gas test results.

The IChemE *Maintenance Guide* gives a number of additional desirable features. It is desirable to include a caution to the effect that the permit is a legal document; a caution to the issuing authority that, although work may be delegated, responsibility remains with them; an indication of the levels of hazard, so that high hazard situations are highlighted and those involved are prompted to consider whether there are other parties who should be consulted; an indication of work progress, so that cases are identified where the work is tending to expand beyond that originally envisaged and those involved are prompted to reappraise it.

21.8.7 Design of permit forms

Sample permit forms are given in a number of publications, including the IP *Refining Safety Code*, the IP *LPG Code* and the IChemE *Maintenance Guide*.

A typical permit, referred to by the company concerned as a clearance certificate, is shown in Figure 21.3. This permit dates from 1977, but still provides a clear illustration of many of the basic principles.

Figure 21.4 shows the typical entry permit given in the IChemE *Maintenance Guide*.

21.8.8 Entry permits

Entry into vessels and other confined spaces has resulted in numerous accidents. As a result this operation has had a unique status.

OSHA 1910.146 defines entry permit requirements. The entry permit identifies:

(1) permit space to be entered;
(2) purpose of entry;
(3) date and authorized duration of the entry permit;
(4) authorized entrants by name;
(5) personnel, by name, serving as attendants;
(6) individual, by name, currently serving as entry supervisor;
(7) hazards of permit space to be entered;
(8) measures used to isolate the permit space and to eliminate or control permit space hazards before entry;
(9) acceptable entry conditions;
(10) results of initial and periodic gas tests;
(11) rescue and emergency services that can be summoned and the means for summoning those services;
(12) communication procedures used by authorized entrants and attendants to maintain contact during the entry;
(13) equipment such as personal protective equipment, testing equipment, communications equipment, alarm systems and rescue equipment to be provided;
(14) any other information necessary to ensure employee safety;
(15) any additional permits such as hot work that have been issued to authorize work in permit spaces.

Vessel and confined space entry have a specific legal requirement for a permit system. This requirement is given in the Chemical Works Regulations 1922, Regulation 7, now superseded, and in the Factories Act, Section 30. It is appropriate, therefore, to describe this permit in some detail as an illustration. In order to avoid repetition it is also convenient to describe here the associated hazards and procedures.

Entry permits are dealt with in *Safety and Management* (ABCM, 1964/3), *Permit Systems* (CAPFTB, 1977 Inf. Pap. 16A) and by Kletz (1982f). Early HSE guidance was given in TON 47 *Entry into Confined Spaces: Hazards and Precautions* (HSE, 1975) and GS 5 *Entry into Confined Spaces* (HSE, 1977) and current guidance in Construction Sheet 15 *Confined Spaces* (HSE, 1991). The hazards of work in a vessel or confined space are described in Section 21.7.

A significant proportion of accidents in vessels or confined spaces are fatal and some involve multiple deaths. OSHA 1910.146 and The Factories Act 1961, Section 30, describes precautions which have to be taken where work has to be done inside equipment in which the atmosphere is liable to be such as to involve the risk of people being overcome by dangerous fumes or lack of oxygen.

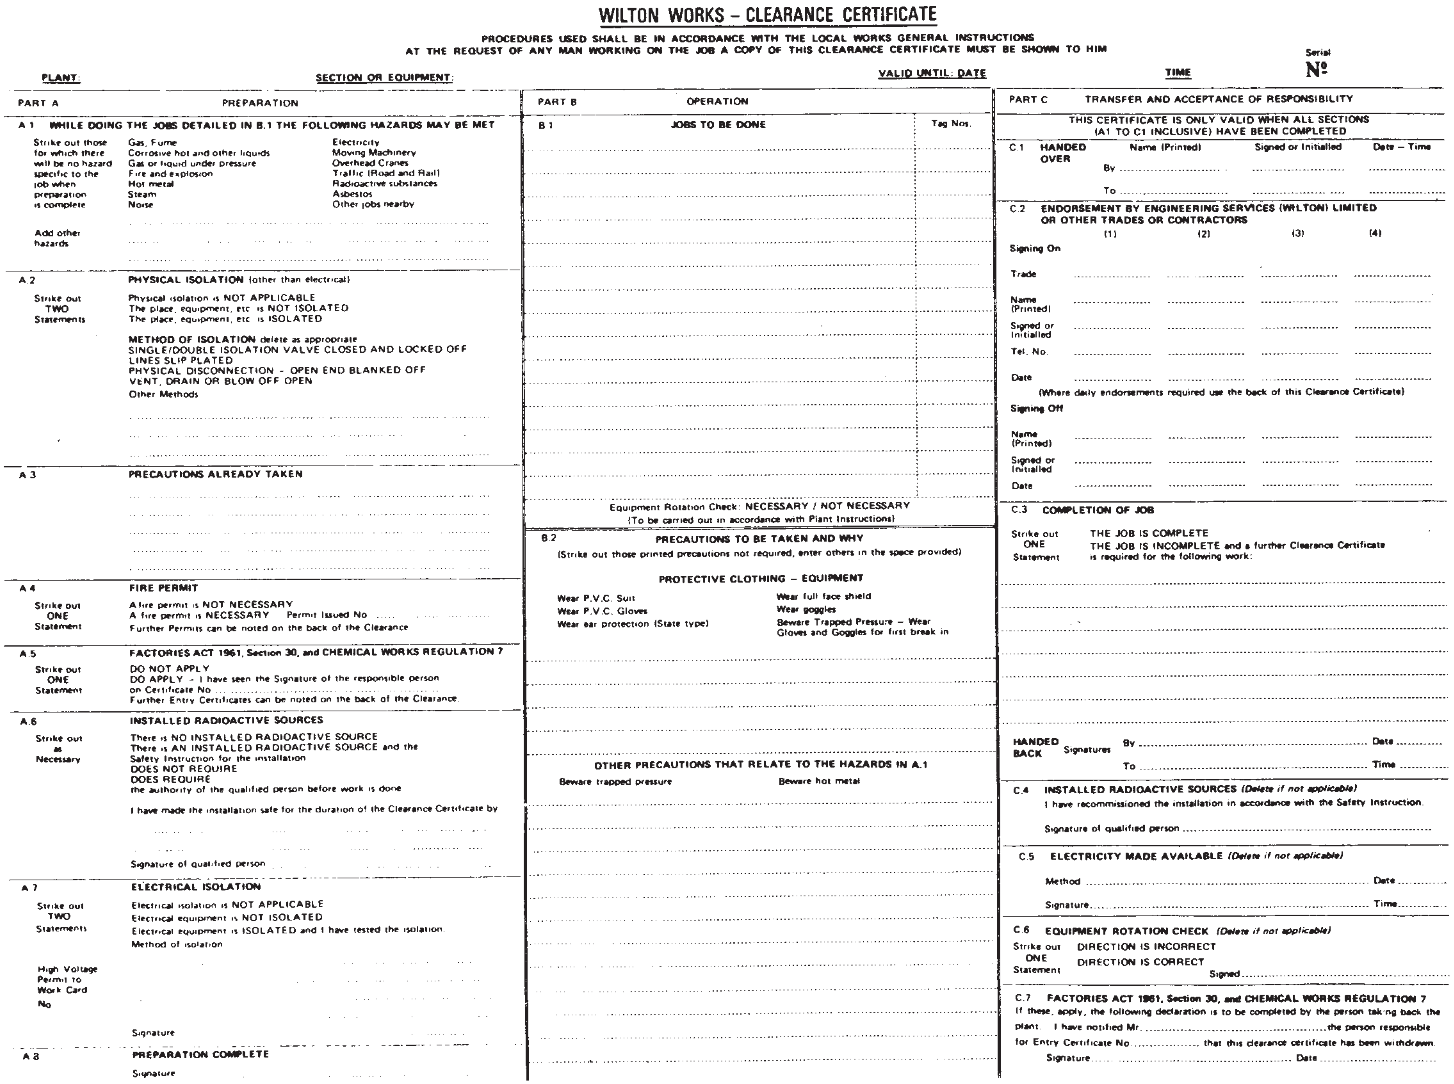
The requirements of the Act are summarized in TON 47 for atmospheres in which dangerous fumes are liable to be present:

> No-one may enter or remain for any purpose in a confined space which has at any time contained or is likely to contain fumes liable to cause a person to be overcome unless

(1) He is wearing a suitable breathing apparatus.
(2) He has been authorized to enter by a responsible person.
(3) Where practicable, he is wearing a belt with a rope securely attached.
(4) A person keeping watch outside and capable of pulling him out is holding the free end of the rope.

Alternatively, a person may enter or work in a confined space without breathing apparatus provided that

(1) Effective steps have been taken to avoid ingress of dangerous fumes.
(2) Sludge or other deposits liable to give off dangerous fumes have been removed.
(3) The space contains no other material liable to give off such fumes.



WILTON WORKS – CLEARANCE CERTIFICATE

PROCEDURES USED SHALL BE IN ACCORDANCE WITH THE LOCAL WORKS GENERAL INSTRUCTIONS
AT THE REQUEST OF ANY MAN WORKING ON THE JOB A COPY OF THIS CLEARANCE CERTIFICATE MUST BE SHOWN TO HIM

PLANT: **SECTION OR EQUIPMENT:** **VALID UNTIL: DATE** **TIME** Serial **Nº**

PART A PREPARATION

A 1 WHILE DOING THE JOBS DETAILED IN B.1 THE FOLLOWING HAZARDS MAY BE MET

Strike out those for which there will be no hazard specific to the job when preparation is complete

Gas, Fume	Electricity
Corrosive hot and other liquids	Moving Machinery
Gas or liquid under pressure	Overhead Cranes
Fire and explosion	Traffic (Road and Rail)
Hot metal	Radioactive substances
Steam	Asbestos
Noise	Other jobs nearby

Add other hazards

A.2 PHYSICAL ISOLATION (other than electrical)

Strike out TWO Statements
- Physical isolation is NOT APPLICABLE
- The place, equipment, etc is NOT ISOLATED
- The place, equipment, etc is ISOLATED

METHOD OF ISOLATION delete as appropriate
SINGLE/DOUBLE ISOLATION VALVE CLOSED AND LOCKED OFF
LINES SLIP PLATED
PHYSICAL DISCONNECTION – OPEN END BLANKED OFF
VENT, DRAIN OR BLOW OFF OPEN
Other Methods

A 3 PRECAUTIONS ALREADY TAKEN

A 4 FIRE PERMIT

Strike out ONE Statement
- A fire permit is NOT NECESSARY
- A fire permit is NECESSARY Permit Issued No ....
- Further Permits can be noted on the back of the Clearance

A.5 FACTORIES ACT 1961, Section 30, and CHEMICAL WORKS REGULATION 7

Strike out ONE Statement
- DO NOT APPLY
- DO APPLY – I have seen the Signature of the responsible person on Certificate No ....
- Further Entry Certificates can be noted on the back of the Clearance.

A.6 INSTALLED RADIOACTIVE SOURCES

Strike out as Necessary
- There is NO INSTALLED RADIOACTIVE SOURCE
- There is AN INSTALLED RADIOACTIVE SOURCE and the Safety Instruction for the installation
- DOES NOT REQUIRE
- DOES REQUIRE
- the authority of the qualified person before work is done

I have made the installation safe for the duration of the Clearance Certificate by

Signature of qualified person ....

A 7 ELECTRICAL ISOLATION

Strike out TWO Statements
- Electrical isolation is NOT APPLICABLE
- Electrical equipment is NOT ISOLATED
- Electrical equipment is ISOLATED and I have tested the isolation.

Method of isolation

High Voltage Permit to Work Card No

Signature ....

A 8 PREPARATION COMPLETE

Signature ....

PART B OPERATION

B 1 JOBS TO BE DONE	Tag Nos.

Equipment Rotation Check: NECESSARY / NOT NECESSARY
(To be carried out in accordance with Plant Instructions)

B.2 PRECAUTIONS TO BE TAKEN AND WHY

(Strike out those printed precautions not required, enter others in the space provided)

PROTECTIVE CLOTHING – EQUIPMENT

Wear P.V.C. Suit	Wear full face shield
Wear P.V.C. Gloves	Wear goggles
Wear ear protection (State type)	Beware Trapped Pressure – Wear Gloves and Goggles for first break in

OTHER PRECAUTIONS THAT RELATE TO THE HAZARDS IN A.1

Beware trapped pressure	Beware hot metal

PART C TRANSFER AND ACCEPTANCE OF RESPONSIBILITY

THIS CERTIFICATE IS ONLY VALID WHEN ALL SECTIONS (A1 TO C1 INCLUSIVE) HAVE BEEN COMPLETED

C.1 HANDED OVER	Name (Printed)	Signed or Initialled	Date – Time
By	....	....	....
To	....	....	....

C.2 ENDORSEMENT BY ENGINEERING SERVICES (WILTON) LIMITED OR OTHER TRADES OR CONTRACTORS

Electrical supply returned to equipment			Electrical section

Figure 21.4 *Entry permit (Townsend, 1992) (Courtesy of the Institution of Chemical Engineers)*

(4) The space has been adequately ventilated and tested for fumes.
(5) There is a supply of air adequate for respiration.
(6) The space has been certified by a responsible person as being safe for entry for a specified period without breathing apparatus.

The person who enters the confined space must be warned when the safe period specified in (6) above will expire. In all cases a sufficient supply of approved breathing apparatus, belts and ropes, and suitable reviving apparatus and oxygen must be kept readily available, properly maintained and regularly examined.

The requirements for oxygen-deficient atmospheres are summarized in TON 47 as follows:

> No-one may enter or remain in a confined space in which the atmosphere is liable to be deficient in oxygen unless either he is wearing a suitable breathing apparatus, or the space has been and remains adequately ventilated and a responsible person has tested and certified it as safe for entry without breathing apparatus.

The same section of the Act also requires confined spaces to be provided with manholes and specifies minimum dimensions. Circular manholes, for example, should not be less than 18 in. in diameter or, on tank wagons and mobile plant, 16 in. in diameter. Manholes larger than these minimum sizes should be provided wherever possible. In particular, practical tests have shown the minimum size on mobile equipment to be barely negotiable by men of average build.

The control of work in vessels and confined spaces is described in TON 47, which lists the following features:

(1) assessment;
(2) withdrawal from service;
(3) isolation;
(4) cleaning and purging;
(5) testing;
(6) certification;
(7) precautions during work
    (a) entry without breathing apparatus,
    (b) entry where breathing apparatus is necessary,
    (c) rescue;
(8) cancellation of permit;
(9) return to service.

The issuance of the permit should be done by the responsible person in accordance with the procedures described in Section 21.8.3. The issuing authority should have a sufficient familiarity with both the chemistry and the engineering aspects of the situation and should check personally the actions required.

The need for entry should be considered carefully and entry should not be made unless it is essential. The hazards of vessel entry should be reviewed, paying particular attention to any hazard arising from nearby plant and to any special circumstances or precautions.

Withdrawal from service should be a formal procedure. Operating personnel should be informed and warning notices displayed.

The isolation of the vessel should be completed in accordance with the procedures described in Section 21.4. The recommended method of isolation for vessel entry is physical disconnection. A closed and locked valve is not an adequate method.

If there is machinery inside the vessel, such as an agitator or mixer, it should be isolated by electrical isolation or by physical disconnection. In addition, if necessary, it should be secured to prevent its moving. There may also be pumps which should be isolated electrically. The vessel should then be emptied.

Cleaning of the vessel may be accomplished in several ways. Steaming out is a common method. This may be preceded by washing with water, solvent or neutralizing agent. The steaming itself should be continued long enough to clean the vessel thoroughly. The steaming time is often determined by experience, but it is essential to continue steaming until the vessel is clean rather than simply for a predetermined time. It is important to ensure that equipment attached to the main vessel is also cleaned thoroughly. The period of steaming and the completion of steaming should be checked by the responsible person. If several hours elapse after steaming, it is advisable to steam the vessel again immediately before entry. It should be ensured that the steaming is done safely and without either overpressuring the vessel with steam or causing it to collapse under the vacuum created by steam condensation.

Other cleaning methods include thorough washing with cold or hot water or with solvents or neutralizing agents and boiling with water. Some cleaning agents such as solvents can create a secondary hazard and may need to be removed by steaming. Boiling water cleaning requires precautions against overpressure and vacuum collapse of the vessel.

It is sometimes necessary to resort to hand cleaning to remove sludge and residues. In such cases, it is essential to work with the full precautions of breathing apparatus, a safety line, and rescue equipment and personnel.

On the completion of cleaning all liquid should be run out and the manholes opened for ventilation. If steam cleaning has been used, opening of the manholes while the vessel is hot assists air circulation by natural convection. It may be necessary, however, to use forced ventilation from a blower or compressed air line.

If the vessel is hot, it should be allowed to cool before any entry is made.

If the vessel has contained a flammable gas or vapour, it may be purged with an inert gas such as nitrogen or carbon dioxide. This then creates, however, an asphyxiation hazard. It is thus necessary to purge the inert gas with air.

Testing of the atmosphere in the vessel must be carried out before it is certified as safe to enter or before the safety precautions for entry are specified. The tests should check the presence of toxic and/or flammable fumes and, if necessary, the adequacy of the oxygen content. The tests should be conducted by a competent person. If the work is at all prolonged, the tests should be repeated. Continuous gas testing may be required throughout the work and must be noted on the permit.

The general testing of working atmospheres is dealt with in Chapter 25 and is therefore not considered here. As far as testing in vessels is concerned, entry into the vessel should be avoided if possible. Instead, samples should be drawn from inside the vessel through sample tubes. It is essential, however, to test throughout the vapour space; factors which may cause this not to be homogeneous include release of fumes from sludge or residues and layering of inert gases.

If entry into a vessel for testing is unavoidable, this should be done with breathing apparatus, a safety line, and rescue equipment and personnel.

With regard to the permissible concentration of toxic materials, it has been common practice for many years to use the threshold limit value (TLV).

When the above stages have been completed, the responsible person can decide on the precautions to be taken on entry and, in particular, whether (1) entry is safe for a specified period without breathing apparatus or (2) entry requires breathing apparatus, a safety line and other precautions.

The permit can then be issued detailing the safety measures already taken (e.g. isolation, cleaning and purging, testing), those to be taken (e.g. ventilation, repeat testing, breathing apparatus, a safety line, and rescue equipment and personnel) and the period of validity.

Precautions during the work depend on whether the method of entry involves the use of breathing apparatus or not. If breathing apparatus is not used, good ventilation is essential. This means at least several changes of air per minute. If there are sufficient top and bottom openings, natural ventilation may suffice, but more usually forced ventilation is necessary using compressed air or blowers. The air line or blower piping should extend to the bottom of the vessel to assure the removal of heavy fumes and give good air circulation. If there is a static electricity hazard, it may be necessary to bond the air line or piping to the metal of the vessel. Gaseous oxygen should not be introduced into the vessel to increase the oxygen content of the atmosphere, since it creates the hazard of an oxygen-enriched atmosphere.

If breathing apparatus has to be used, it should be either the self-contained breathing apparatus type or the air line type. Canister respirators should not be used, because they do not provide adequate protection against high concentrations of toxic flumes and are useless in atmospheres deficient in oxygen.

The person entering the vessel should also wear a safety harness and lifeline wherever practical. The free end of the line should be held by a person outside. The harness should be worn so that the worker can be pulled head first up through the opening.

It is the duty of the person outside, or safety watch, to keep hold of the safety line and observe the person working inside the vessel. They should have a means of summoning assistance rapidly. If possible, there should also be other workers nearby.

If the person in the vessel is overcome, the safety watch should raise him head first through the opening. An unconscious man is a heavy weight and the safety watch should have both adequate strength and training for his task.

There should be rescue equipment, such as additional breathing apparatus and safety lines and reviving equipment and medical oxygen.

The restrictions on entry apply also to entry for rescue. In addition, if entry has been permitted without breathing apparatus and the person inside has been overcome, entry for rescue should be made only wearing breathing apparatus and a safety line and with other personnel available to give assistance. Multiple fatalities have occurred where men have gone in to rescue their fellows without proper protection.

When the work is finished, the equipment used should be removed, the work site should be inspected and the permit completed in accordance with the procedures given in Section 21.8.3.

Personnel should be warned that the vessel is no longer safe for entry. Accidents occur due to persons entering vessels which are no longer safe in order to recover tools, etc.

The de-isolation of the vessel should be done in accordance with the procedures described earlier and the vessel returned to service.

21.8.9 Types of permit system

The normal permit system is a single permit issued by the issuing authority to the performing authority. As stated earlier, the norm is that the issuing authority is the operations supervisor and the performing authority the person who is to do the work, but in some cases the performing authority is the maintenance supervisor.

There are, however, variations on this system. In some companies, certain permits are issued by the safety officer.

In a particular permit system, a given job may require more than one document. There may well be other certificates which are necessary before the main permit can be issued. One example is an isolation permit, in a system where separate permits are used for isolation, and de-isolation. Another is a test certificate for analysis of the working atmosphere.

Some types of permit relate to higher levels of hazard than others, so that there can be a hierarchy of permits.

21.8.10 Design of permit systems

The effectiveness of a permit system depends in large part on the way in which the system is designed and operated.

Aspects of the design of a permit system include (1) standardization, (2) the personnel involved, (3) scope, (4) cross-referencing, (5) display, (6) multiple jobs, (7) change of intent, (8) suspension, (9) handback, (10) training and (11) monitoring, auditing and review.

It is desirable that the permit system used within a company be as uniform as is practicable. This applies not just to the design of permit forms but to the whole system. A standard system eases the problem of training and reduces the probability of confusion and hence error.

There are constraints, however, on complete standardization. A permit system is a means of communication between the interested parties and must, therefore, reflect the organizational structure. It is also a formalization of the operating and maintenance procedures. While uniformity is desirable, a mismatch between the permit system and either this structure or the procedures is too high a price to pay, in that it is likely to undermine acceptance of the permit system and hence compliance with it.

The personnel involved in the issue of a permit should be identified. In some systems, the number may be quite large, perhaps as high as 15–20.

There may be a requirement that in certain defined cases, where work at a particular unit may affect an adjacent unit, the operations supervisor on that unit should countersign the permit.

The permit should ensure that the scope of the work to be done is fully defined.

The design of the permit form should allow for the necessary cross-referencing. There should be cross-references to: other jobs, by description of job as well as permit number; isolations and the associated permit numbers; and equipment identification tags. In particular, the cross-referencing should cover the case where isolation is common to more than one job.

A copy of the permit should be clearly displayed in the control room.

Another copy should be displayed at the work site, except when the job is done at a number of locations, in which case it should be kept by the person in immediate charge of the work. If this person is not also the performing authority, the latter should also have a copy.

For given equipment, there should be only one permit, but it may cover work by more than one trade.

Sometimes there is a change of intent while the job is being done. An example is a change from work on pump seal flush lines which does not involve breaking into the process line, to a pump overhaul which does. If such a change of intention occurs, a separate permit may be issued.

It may well happen that it is necessary to suspend the work. This can occur because: work is carried out only for one shift each day; spares are on order; the activity is incompatible with another which has higher priority, as with suspension of hot work while a flammable gas sample is taken; or there is an emergency.

One option is that the permit is cancelled so that resumption of the work requires a new permit. This may well be the best policy if the work is being suspended for an undefined and possibly extended period and the equipment can be rendered safe. Alternatively, the permit itself may be suspended. If this option is taken, the permit should be clearly displayed in a suitable place and clearly marked as suspended; the condition in which the equipment has been left and the consequences for other activities should be stated; and prior to reactivation the issuing authority should verify that it is safe for the work to proceed. The OIAC *Permit System Guide* gives further guidance on the procedures for the suspension of a permit.

A suspended permit was at the centre of the events which led to the Piper Alpha disaster and the view was then urged that the suspension of a permit should not be an option. The Inquiry recognized the dangers but did not recommend prohibition.

The procedures for handback of the permit, described earlier, should be clear.

The permit system should ensure that both operations and maintenance personnel, company employees as well as contractors are trained in the system which applies at the actual plant where they work. It is not enough to have instruction in the general principles of a permit system; personnel must be clear about the details of the operation, and the reasons for, the particular permit system governing their own work.

There should be built into the permit system arrangements to ensure that the operation of the system is monitored regularly and is subject to a more searching audit at specified intervals, and that a review of the appropriateness of the system is undertaken at specified, longer intervals.

21.8.11 Operation of permit systems

If the permit has been well designed, the operation of the system is largely a matter of compliance. If this is not the case, the operations function is obliged to develop solutions to problems as they arise.

As just stated, personnel should be fully trained so that they have an understanding of the reasons for, as well as the application of the system.

It is the responsibility of management to ensure that the conditions exist for the permit system to be operated properly. An excessive workload on the plant, with numerous modifications or extensions being made simultaneously, can overload the system. The issuing authority must have the time necessary to discharge his responsibilities for each permit.

In particular, he has a responsibility to ensure that it is safe for maintenance to begin and to visit the work site on completion to ensure that it is safe to restart operation.

Where the workload is heavy, the policy is sometimes adopted of assigning an additional supervisor to deal with some of the permits. However, a permit system is in large part a communication system, and this practice introduces into the system an additional interface.

The communications in the permit system should be verbal as well as written. The issuing authority should discuss, and should be given the opporutnity to discuss, the work. It is bad practice to leave a permit to be picked up by the performing authority without discussion.

The issuing authority has the responsibility of enforcing compliance with the permit system. He needs to be watchful for violations such as extensions of work beyong the original scope.

21.8.12 Deficiencies of permit systems

An account of deficiencies in permit systems found in industry is given by S. Scott (1992). As already stated, some 30% of accidents in the chemical industry involve maintenance and of these some 20% relate to permit systems.

The author gives statistics of the deficiencies found. Broadly, some 30–40% of the systems investigated were considered to be deficient in respect to system design, form design, appropriate application, appropriate authorization, staff training, work identification, hazard identification, isolation procedures, protective equipment, time limitations, shift change procedure and handback procedure, while as many as 60% were deficient in system monitoring.

21.8.13 Audit of permit systems

It is not enough to create a permit system to control maintenance work. There should also be a routine audit of the system to ensure that it is operating properly. These may consist of a specific instruction to the plant manager to check each week a portion of the permits issued.

21.8.14 Checklist for permit systems

The OIAC *Permit Systems Guide* gives a checklist for permit systems. This is shown in Table 21.3.

21.9 Maintenance Equipment

21.9.1 Tools

Tools such as hammers and wrenches have been considered a possible source of ignition, and so-called non-sparking tools have been developed. Materials used in such tools are, typically: aluminium, bronze or monel, for tools that have to withstand impact or torque such as hammers, wrenches and crowbars; copper–beryllium alloy, for tools requiring a cutting edge or gripping teeth such as knives, chisels, saws, drills, pliers and shears; and plastics, leather, fibre and wood, for shovel and scraper tools.

These tools have a number of disadvantages. Generally, they are more expensive and they are softer and tend to burr. Moreover, particles can more easily become

Table 21.3 *A checklist for permit-to-work systems (Oil Industry Advisory Committee, 1991) (Courtesy of HM Stationery Office. Copyright. All rights reserved)*

The purpose of this checklist is to help everyone concerned with the preparation of permit-to-work systems to decide whether a particular example covers all the points which are considered essential. If the answer to any of the questions below is ‘no’, the system may need to be reconsidered and changed.

The system

1. Does the permit system in force satisfy all the legal requirements applying to that site or installation?
2. Is the permit system recognized throughout the site or installation as being essential for certain types of work?
3. Are the types of work, types of job or areas where permits must be used clearly defined and known to all concerned?
4. Does the permit system extend to contractors and their employees?
5. Is it clearly laid down who may issue permits?
6. Is it clearly laid down how permits should be obtained for specific jobs?
7. Is the permit system flexible enough to allow it to be applied to other potentially hazardous work, apart from that which may have been specifically identified when the system was established?
8. Is the issue of a permit by a person to themselves prevented?
9. Does the system provide both for the recipient to retain the permit and for a record of live permits and suspended permits to be maintained at the point of issue?
10. Does the system require a copy of the permit to be displayed at the workplace?
11. Does the system require the display of live and suspended permits so that process operating staff can readily see and check plant status?
12. Is there a set of properly documented isolation procedures for working on potentially dangerous items of plant and does it provide for long term isolation?

Training and competence

13. Is the permit system clearly covered during site or installation safety induction training?
14. Are personnel who have special responsibilities under the permit system, e.g. issuing and isolating authorities, properly authorized and trained to undertake the duties required of them?
15. Do these people have sufficient time to carry out these duties properly?
16. Does the system require formal assessment of competence of personnel before they are given responsibilities under the permit procedure?
17. Is a record of training and assessment maintained?
18. Do training and competence requirements include contractors?
19. Are individuals provided with written confirmation of successful completion of relevant training and are these documents checked before appointments are made within the permit-to-work system?

The permit

20. Is there a clear requirement for work being done under a permit to be stopped if any new hazards have arisen or old hazards recurred?
21. Does the permit contain clear rules about how the job should be controlled or abandoned in the event of an emergency?
22. Do permits specify clearly the job to be done?
23. Do permits specify clearly to whom they are issued?
24. Does the system require the potential hazards at the work site to be clearly identified and recorded on the permit?
25. Does the permit clearly specify the precautions to be taken by the issuing and performing authorities?
26. Do permits specify clearly the plant or geographical area to which work must he limited?
27. Does the recipient have to sign the permit to show that they both read the permit and understood the conditions laid down in it?
28. Do permits specify clearly a time limit for expiry or renewal?
29. Does the permit include a handover mechanism for work which extends beyond a shift or other work period including work which has been suspended?
30. Is a handback signature required when the job is complete?
31. Is there a procedure to bring to the attention of the site manager tasks which require inhibiting safety devices, e.g. fire detectors, to ensure that contingency plans and precautions are in place?

Co-ordination

32. Are copies of permits issued for the same equipment/area kept and displayed together?
33. Is there a means of co-ordinating all work activities to ensure potential interactions are identified?
34. Is there provision on the permit form to cross-reference other relevant certificates and permits?
35. Is there a procedure to ensure that the agreement of others who could be affected by the proposed work is obtained before starting the work or preparations for it?
36. Where there are isolations common to more than one permit, is there a procedure to prevent the isolation being removed before all the permits have been signed off?

Monitoring

37. Is there a system of spot checks to ensure that permits are being followed?
38. Is there a procedure for reporting any incidents that have arisen during work carried out under a permit and for reviewing procedures as necessary?
39. Are audits carried out on the permit-to-work system at least once a year, preferably by people not normally employed at that site or offshore installation?

embedded in them, thus reducing their non-sparking qualities.

The American Petroleum Institute (API) has issued a number of reports over a period of years on the appropriateness of using non-sparking tools in petroleum operations. The general conclusion is that an incendive spark of steel would be unlikely to be produced manually and that power operation would be needed. Its current position is stated in API Publ. 2214: 1989:

> The Institute's position is that the use of special non-ferrous hand tools, sometimes referred to as nonsparking tools, is not warranted as a fire-prevention measure applicable to petroleum operations.

Certain gases handled in the chemical industry are particularly susceptible to spark ignition, notably hydrogen, acetylene, ethylene and carbon disulfide. One policy described on non-sparking tools in this industry is that instead of utilizing all types of non-sparking tool in flammable areas a more limited use is made, restricting their application to the use of non-sparking hammers (though not wrenches) for the hardening up of joints on lines containing the above four gases.

The extent to which tools may act as ignition sources is discussed in more detail in Chapter 16.

21.9.2 Lifting equipment

Lifting equipment has been the cause of numerous accidents. There have long been statutory requirements, therefore, for the registration and regular inspection of equipment such as chains, slings and ropes. Extreme care should be taken with handling and storage of lifting equipment to prevent damage. It should never be modified and repair work should be performed by manufacturer or qualified personnel.

The rated capacity of lifting equipment must never be exceeded. Charts are available from the manufacturer, published standards and numerous professional organizations. Before each use, lifting equipment should be examined and verified that it is capable of handling its intended function.

Lifting equipment is governed by OSHA 1910.184 Slings and 1926.251 Construction Rigging Equipment. UK requirements are given in the Factories Act 1961, Sections 22–27, and in the associated legislation, including the Chains, Ropes and Lifting Tackle (Register) Order 1938, the Construction (Lifting Operations) Regulations 1961 and the Lifting Machines (Particulars of Examination) Order 1963. Some of these regulations are superseded by the consolidating Provision and Use of Work Equipment Regulations 1992.

In process plant work incidents sometimes occur in which a lifting lug gives way. This may be due to causes such as incorrect design or previous overstressing. Ultrasonic testing or X-ray of lifting lugs may be necessary if there is concern over its integrity.

21.9.3 Lift plans/permits

Critical or major lifts should have a detailed lift plan prepared. This includes detailed drawings of the lift and swing, calculations on lifting equipment and crane(s), certification of lifting equipment, review of matting and ground conditions (surface and underground) as well as potential hazards.

The use of lift permits is required by some companies. This requirement documents the lift to be made and enables a review by the appropriate personnel.

21.9.4 Mobile cranes

Mobile cranes present several different types of hazard. One is that of collision with process equipment, particularly pipe racks, when the crane is on the move. A minimum measure to prevent this is clear identification of pipe racks including labelling with clearance height. A spotter should be used to walk mobile equipment when it is being moved. A positive protection is the installation of a crossbeam in front of the pipe rack.

Another type of hazard is the overloading or overturning of the crane onto process equipment. Each crane must have a capacity chart for lifting over the rear and over the side either posted on the crane or available in the cab. For a given crane, there is a maximum safe load and maximum safe radius. There is normally a safe load indicator, but nothing to indicate the safe radius. If either is exceeded, the potential for an incident exists. If the radius is exceeded, the crane may topple. Numerous crane failures are in the literature. It is equally important that personnel performing the rigging and lifting are trained in determining capacity of lifting equipment and cranes. They also must know proper set-up and limitations of lifting. It is important for crane drivers to be well trained in the operation and limitations of their cranes and in the special hazards of process equipment.

Another hazard with crane operation is overhead electrical lines. A minimum 10 ft separation distance is required. Additional guidance is provided in OSHA 1910.333. A rather less obvious hazard in cranes hired from outside contractors is the use of cab heaters which are not suitable for hazardous areas. A heater is needed, but it should be of an appropriate type.

Regulatory reference is OSHA 1910.180 Crawler Locomotive and Truck Cranes, 1926 (Construction) Subpart N, O and 1926.952.

21.9.5 Lift trucks

Lift trucks, including forklifts, present another set of hazards. One is the hazard due to any moving vehicle, especially in a relatively congested plant area. A specific aspect of this is impact on equipment. Incidents are numerous in which lift trucks are driven into and damage buildings and equipment; pipe racks are particularly at risk. Impact is more likely if the truck is travelling with arms extended. A lift truck may also run over and crush pipe or cabling.

Overturning is another hazard, the causes of which include misleading, sudden braking or sharp turning and traversing of rough or sloping terrain.

Personnel operating lift trucks should be well trained in the operation and limitations of their cranes and in the special hazards of process equipment.

A lift truck is a vehicle with projecting and moving parts. It, therefore, has some of the characteristics of a machine. The power source, batteries or engine, on a lift truck may act as a source of ignition.

Guidance on lift trucks is given in OSHA 1910.178 Powered Industrial Trucks, HS(G) 6 Safety in Working with Lift Trucks (HSE, 1992). HS(G) 6 states that lift trucks are responsible for about one-third of the 20,000 reportable injuries each year which involve transport. In the period 1986–1991, 112 people were killed in accidents involving lift trucks.

Prevention of lift truck accidents requires attention to (1) equipment layout, (2) working practices and (3) training.

Specific preventive measures fall mainly under the following headings: (1) traffic, (2) imbalance, (3) impact and crushing and (4) moving parts.

Measures which address the traffic aspects include the layout of the lift truck workplace, use of driving practices which specifically address lift truck dangers, limitation of driving to trained personnel, avoidance of obscuration of the driver's view by the load and removal of people from the vicinity of the truck, using both segregation and warning devices. Prevention of imbalance requires the application of loading rules and avoidance of unsuitable terrain. Measures to prevent impact include use of layout and barriers and travelling with lift arms lowered. The danger from working parts may also be minimized by suitable layout and working practices.

21.9.6 Manlifts

Manlifts are used to hoist personnel. They provide quick access for work at elevated heights. Personnel operating the manlift must exercise care so as not become entangled in the work area. They should never exit the manlift platform.

It is important for manlift operators to be well trained in the operation and limitations of their manlifts and in the special hazards of their use.

OSHA 1910.68 governs manlifts.

21.9.7 Scaffolding

Scaffolding is used as a temporary platform for work. It should be constructed by qualified personnel. Before initial use, scaffolding should be inspected by a competent person and certified as safe for use. A tagging system is commonly used to indicate that the scaffold is safe for use or that it is being built and should not be used.

Scaffolding is governed by OSHA 1910.28 Safety Requirements for Scaffolding.

21.9.8 Robots

A less conventional form of equipment is a robot. The use of robots in relation to process equipment is most developed in the nuclear industry and in offshore activities, but a gradual growth of their use in special applications on conventional process plants can be envisaged.

Accounts of robots are given by Collins (1982), T.J. Williams (1983), Siddle (1986b) and R.M. Taylor and Lewis (1987). HSE guidance on robots is given in HS(G)43 Industrial Robot Safety (1988) (the HSE Robot Safety Guide).

The term 'robot' has been used to describe a variety of devices. The definition given by the Robot Institute of America (RIA) is a 'reprogrammable', multifunctional manipulator designed to move materials, parts, tools or specialized devices through variable preprogrammed motion for the performance of a variety of tasks'. The Japanese Industrial Robot Association defines four levels of complexity in robots. The first level is a manual manipulator which performs preset sequences; a typical application is as a means of remote manipulation in hazardous environments. The other three levels are playback robots, numerically controlled robots and intelligent robots. A robot is distinguished from a manual manipulator by its program, and from the single-task devices used in much factory line production by its flexibility.

Features of a robot are the program, the control system, the power, the sensors, the axes of movement and the lifting capacity. A common form of control system is one in which the robot is taken through a sequence under manual guidance, the sequence is repeated automatically to check it out and it is then committed to memory.

Industrial applications include robots which perform the operations of pick-and-place, spraying and painting, resistance welding, continuous path welding, and assembly.

The more advanced applications of robots depend heavily on the availability of suitable sensors, both contact and non-contact types.

The use of robots to reduce exposure of personnel at a nuclear plant is described by R.M. Taylor and Lewis (1987). They use the term 'robot' to include non-programmable remotely operated manipulators and a large proportion of the robots used are evidently of this type. Three applications are described. One is a bagout facility robot and another is a sampling aisle robotic system. In both cases the point-to-point movement is programmed while the operator selects and monitors the sequence of moves. The third application is a large robotic system used to dismantle obsolete equipment. This consists of a five-axis manipulator integrated with a three-axis gantry serving a 70×20×20 ft work area. The operator can operate the manipulator by remote control as well as carry out sequences under automatic control.

Robots may be used to relieve humans of tasks which involve a degree of hazard, and this is likely to be a principal use in the process industries. They do, however, bring their own hazards in that a robot is both powered and capable of movement.

HS(G) 43 deals primarily with the fixed 'teach and play back' type of robot. For the purposes of the treatment given, the guide takes the term to mean ' a manipulating device which is automatically controlled, is reprogrammable and is capable of serving a number of different purposes'. It deals with robot safety under the following headings: (1) safeguarding robot systems, (2) safety in design and manufacture, (3) safety during installation and commissioning, (4) safety during use, (5) safety during programming and (6) safety during maintenance. It also deals with training for robot safety and gives a number of appendices which cover *inter alia* hazard identification and risk assessment, safeguarding methods and case studies.

The hazards posed by a fixed robot are those of a machine, essentially striking and trapping and entanglement. The characteristic problem with a robot is the realization of these hazards due to aberrant behaviour. Two potential causes of such behaviour are power transients and program errors.

The approach to the safeguarding of robot systems described in HS(G) 43 is based on: hazard identification, including failure modes and effects analysis; formulation of strategies of hazard elimination and mitigation; definition of levels of integrity for the safety controls and interlocks; and risk assessment for the system as a whole.

The conventional methods of machine guarding, described in BS 5304 and also BS 2771 and BS 6491 and PM 41, are in large part applicable to robots also. Their application is considered in Appedix 2 of the *Guide*.

These may be complemented by critical examination of the need for close approach to the robot and the development of a suitable strategy for situations where close approach is unavoidable, the principal elements of which are that the robot should be operated at low speed and that its control should rest in the hands of the person who is to approach it.

There are a number of features which can be incorporated in the design of a robot to minimize hazards. Trapping points should be avoided. Variable speed controls and a facility for single stepping should be provided and the control pendant ergonomically designed. The robot should have brakes and/or hydraulic stop valves to arrest movement. The arcs of movement of the robot's arms should be restricted, and suitable stops, fixed or adjustable, provided. Another precaution is limitation on the forces which can be exerted by the arms. A gripper should be designed so that it can cope with the static and dynamic forces created by the load, including emergency stop, and so that it does not release the load on power failure. The design should provide a parking position and should cater for the return of the robot to normal operation after different types of interruption, with movement always being by a specified trajectory. The *Guide* also details numerous aspects of the design of the control pendant. The robot should be supplied with high quality documentation. Design aspects of the overall robot system include a layout to facilitate viewing and the use of interlocks.

The robot system should be subject to suitable methods of hazard identification and risk assessment, as described in Appendix 1 of the *Guide*. The hazard identification should include a review of the states of the robot, its functions and its interaction with the plant.

With respect to installation and commissioning aspects of robot safety, HS(G) 43 deals mainly with the development of safe working procedures. The safe use of a robot largely centres around control of access. A fixed robot generally operates in a 'cell', the access to which is controlled using appropriate methods of safe-guarding Appendix 2 of the Guide describes the various options. The approach taken follows that of BS 5304, which details the methods and gives an approach to selection based on the level of risk. Basic protection is provided by perimeter fencing and interlocks. Electrosensitive safety systems are available uitlizing various forms of proximity sensor such as photoelectric (PE) devices, capacitance devices and pressure sensitive mats. Other safety devices include: trips and emergency stops; brakes; positive stops; and enabling controls, or devices working on the dead man's handle principle. A form of the latter suited to robots is the two-hand control, requiring the use of both hands, which it thus protects.

Safety is also consideration in the programming of the robot. For this HS(G) 43 refers to the guidance given in the HSE *PES Guide*.

Safe maintenance of a robot requires well thought-out maintenance procedures and precautions to prevent sudden, unpredictable movements.

Robot case studies given in HS(G) 43 include a robot serving in a machine installation, robot arc welding and robot water jetting.

21.10 Flanged Joints

21.10.1 Making joints

The normal pipe joint on a process plant is the flanged joint, as described in Chapter 12. The two main varieties are the gasketed joint and the ring-type joint. For high pressures, the ring-type joint is used.

Accounts of the making up of flanged joints, and in particular of bolt tightening, are given by Graves (1966), Briscoe (1976), K. Gibson (1986) and Garner (1993).

The joint to be made up may be between two sections of pipe, between a section of pipe and equipment such as a vessel, valve or pump or between a section of pipe and a blind flange, closing off the end of the pipe.

If the joint is a gasketed one, the surfaces of the flanges should be free of deterioration, clean, and the gasket used should be of the correct type. Metallic spiral wound gaskets are the most common type used. When a flanged joint is opened, the gasket should be not be reused. A new gasket should always be installed.

In the case of a ring-type joint, the surfaces of the flanges should again be free of deterioration, clean, and the ring used should be of the correct type. New rings should always be used whenever the joint is opened.

The bolts or studs used should be those specified in all relevant respects. They should be of the correct diameter, length and material of construction. The nuts likewise should be of the right material. Short bolting is not acceptable.

The pipe or other equipment to which the flanges to be joined are attached should be properly supported and aligned so as to facilitate the making of the joint.

In making up a flange, it is bad practice to tighten all the bolts on one side, then the bolts on the other side. The proper procedure is sequence tightening, which involves gradual tightening of the bolts following a criss-cross pattern.

There are a number of methods of tightening the bolts. Taking the case of a ring-type joint, one is to screw the nuts on until they are finger tight. This method is suitable for attaching a blind flange for the purpose of keeping out dirt, but not as a method of making up a leak-tight flange. A flange may be made up hand tight by tightening with a wrench, a hammer wrench and hammer or with an impact.

The bolt tightness obtained by such methods are variable and there is a trend to the use of more sophisticated methods, as described by K. Gibson (1986). Three basic methods are available, two involving cold tightening and one hot tightening. The first cold tightening method is the regular one of rotating the nut against the thread helix angle. The other is to stretch the bolt longitudinally, index the nut and release the stretching load. The hot tightening method is to heat the bolt, causing it to undergo thermal expansion, index the nut and let the bolt cool down.

There are a variety of tightening tools available. They include: traditional wrenches and torque wrenches, where the applied torque varies with the length of the lever arm; impact wrenches, either hydraulic or pneumatic; pneumatic torque multipliers; and hydraulic torque wrenches. There are various bolt stretching devices, notably direct-acting bolt tensioners. Likewise, there are a variety of techniques for measuring bolt stress. One of the simplest is the micrometer, which measures strain, from which stress may then be calculated.

In order to stretch a bolt accurately by a torque method, it is necessary to exercise accurate control of the torque and to know the coefficient of friction of the thread and nut-set interfaces. Alternatively, the tension may be determined by measurement as just described.

As indicated, a bolt or stud has a design pre-tension or pre-stress. This pre-stress should be such that the bolt is not stretched beyond the elastic limit. In this condition, the bolt acts like a spring. It then exerts on the flange the rated damping force. If the pre-stress is too low, the bolt may work loose. If it is too high, the bolt may yield or fracture.

The pre-stress is obtained by the application of torque. However, as indicated, a large proportion of the torque is lost in friction of the thread, under the bolt head and/or the seating surface of the nut. Garner (1993) estimates this proportion as 60–90%. The bolt manufacturer provides data on the relation between torque and pre-stress, but these are necessarily based on average values for the friction.

Lubrication may be used to reduce the friction and to give more uniform tensioning. The lubricant should be matched to the application, selection being a specialist matter.

A particular problem in bolt tightening is that of leaks on heat exchangers, which is discussed by Briscoe (1976). He quotes the results of experiments using both hand wrenches and hammer wrenches, showing the unreliability of standard torque-tension relations. On one of his graphs the lowest stress is 43,000 psi and the highest 120,000 psi. He indicates that in heat exchanger work for studs larger than 1 in. diameter the only method found to be reliable is hydraulic stud tensioning.

There are a number of problems with studs on heat exchanger flanges. One is differential expansion of the flange itself and of the stud, equivalent in the example quoted to a differential force of 21,000 psi. Another is the difference in the temperatures of studs at different positions on the flange, with the air beneath the flange cold but that above it hot; in one case quoted, the temperatures of the studs at the 6 and 12 o'clock positions were 220°F and 440°F, respectively, which is equivalent to a differential force of more than 45,000 psi. Another feature is the effect of insulation on stud temperature.

Live loading of flanged joints has become a common practice to maintain the required bolt tension to keep the gasket seal pressure substantially above the required minimum. Live loading prevents flange leakage due to high temperatures and varying pressure and temperature. On 26 May 1983 at Bloomfleld, New Mexico, a compressor head gasket ruptured, resulting in a gas leak and an explosion in the compressor house (Case History A105). The investigation report (NTSB, 1983 PAR-83–04) found that the bolts on the compressor head flange had been improperly tightened and that there were wide variations in the bolt tightness. One of the potential leak scenarios considered at this inquiry was a leak due to failure of bolts on the reciprocating compressors (Bett, 1989). Inspections in the first half of 1988 revealed that on one cylinder on the A machine, 7 stud bolts out of 16 had failed. The condition was described by the expert witness as potentially serious. An inspection of a cylinder on the B machine 4 months later found 5 failed bolts.

The leak-tightness of a blind flange on the end of a pipe was a key issue at the Piper Alpha Inquiry (Cullen, 1990). Evidence given included: an account of the making up of a joint, and in particular the different methods of bolt tightening (Ritchie, 1989; Whalley, 1989); experimental measurements of bolt stretch vs torque, which illustrated the variability of the bolt extensions (Davie, 1989); and measurement of the torques obtained by hand tightening and by hammering up (Standen, 1989).

Defects in flanged joints include: the use of incorrect or defective bolts, studs or nuts; the use of incorrect or defective gaskets or rings; undertightening of the bolts so that the joint is not leak-tight; overtightening of the bolts so that they are overstretched; and subjecting the bolts to additional stresses.

It is not unusual for a flanged joint to leak. A common response is to tighten the bolts. This may be effective if the bolts were loose in the first place. However, further tightening of bolts which were correctly tensioned originally is bad practice. The National Transportation Safety Board (NTSB) report states:

> Bolted assemblies should not be tightened under pressure. *Never* 'tighten down' a leaking gasket in an assembly that is properly torqued. The assembly should be taken apart and inspected for causes of the leak and a new gasket installed on reassembly.

Another incorrect response to a leaking flange is the use of larger, strong bolts. As explained by Graves (1966), this is liable to make the flange bow and to exacerbate the leak.

21.10.2 Breaking joints

Breaking into a line can involve a number of hazards and it is necessary to exercise considerable care. OSHA Process Safety Management 1910.119(o) requires safe work practices for opening process equipment or piping. Safe methods for the breaking of pipelines are described in *Safety in Inspection and Maintenance of Chemical Plant* (BCISC, 1959/3).

For the breaking of a line there should be clear instructions on the work and on the area in which it is to be done. Information should be given on the material in the line and its hazards, and on the precautions to be taken. The joint to be broken should be indicated by an identification tag. The work is normally covered by a permit.

Some preliminary measures and precautions include:

(1) isolation of the working area and posting of warning notices;
(2) provision of safe access;
(3) support of the pipe on either side of the joint;
(4) isolation of the pipe section;
(5) release of pressure from the pipe section;
(6) draining of the pipe section and disposal of the fluid drained;
(7) precautions against fire;
(8) protection of personnel.

The joint to be broken should be isolated. Pumps and other devices which could put the joint under pressure should be switched off and locked out. Measures should be taken to release the pressure in the line.

It should be assumed, however, that the pipe may be full and under pressure, and precautions should be taken accordingly. In particular, it may be necessary to use protective hoods or equivalent equipment.

There is a correct way to break a joint. The principle is to loosen adjacent nuts and bolts first so that they can be retightened quickly if necessary. The loosening should be done slowly and continuously. The preferred sequence is shown in Figure 21.5. Bolt 1, which is the furthest away, is slackened first, then bolts 2 and 3. Bolt 4, which is the nearest, should not be slackened until the wedge has been used to open the joint and drain the line completely.

Some joints are difficult to break and thus constitute a potential hazard. A persistently troublesome joint should be reported by the maintenance personnel. An alert supervisor will recognize such a joint as a problem.

The piping designer also has a contribution to make by building into the design enough 'spring' to facilitate the breaking of joints which must be broken frequently. Alternatively, a swing blind may be installed.

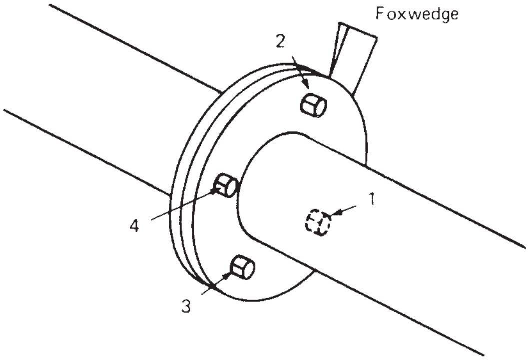

Figure 21.5 *Sequence of operations in breaking a flanged joint*

It can occur that a bolt, or stud, breaks while it is being undone. The correct procedure for dealing with a broken bolt, in a single isolation situation, is to replace it with a new one before proceeding.

The danger of not following this procedure is illustrated by the following incident (Anon., 1977 LPB 14, p. 2), which occurred during the breaking of a flange on a liquefied petroleum gas (LPG) main at 200 psig. As the joint was being broken, a first stud snapped, the opposite one was tried and also snapped. A third one was attempted but broke also, whereupon the fourth stud sheared. The single isolation, which had been tested and was thought to be good, did not prevent a release of liquid.

After breaking, a line is sometimes found to be plugged. The blockage may be removed by means such as digging it out. It is not good practice to clear blockages by using air or gas pressure. The danger here is that the plug of material will be ejected as a projectile.

After breaking, the ends of lines should be blinded off.

21.10.3 Breaking joints on valves

A particular hazard occurs on certain types of valve, where a joint containing the process fluid is liable to be broken in error. An account of this hazard is given by Kletz (1982f, 1984l).

Some situations where this hazard has been realized are shown in Figure 21.6. In the incident on the valve shown in Figure 21.6(a), the fitter was required to remove the valve actuator, secured on a stud which also held in place the valve bonnet; the latter was removed by mistake. Figure 21.6(b) illustrates the valve involved in another incident. In this case, it was intended that the air motor should be removed, but the joint on the valve itself was undone. In the third incident, on the valve shown in Figure 21.6(c), the fitter removed a piece which he thought was an adaptor but which was in fact a integral part of the valve itself.

21.11 Hot Work

Hot work such as welding and cutting is a common activity on process equipment, but involves potential hazards both to equipment and personnel, and needs to be closely controlled. OSHA 1910.119(k) requires a hot work permit and 1910 Subpart Q provides general requirements for welding, cutting and brazing operations. Additional guidance is provided by API RP 2009: *Safe Welding, Cutting and other Hot Work Practices in the Petroleum and Petrochemical Industries*, API Publ. 2201: *Procedures for Welding or Hot Tapping on Equipment in Service*, API RP 1107: 1991 *Pipeline Maintenance Welding Practices* and NFPA 51B: 1999 *Cutting and Welding Processes*. Also relevant is HS(G) 5 *Hot Work* (HSE, 1979) (the HSE *Hot Work Guide*).

The HSE *Hot Work Guide* deals with hot work operations under the following headings: (1) general principles, (2) environment, (3) equipment, (4) methods, (5) operations in buildings, (6) limitation of operations, (7) prohibited operations, (8) welding technology, (9) control of operations and (10) procedure. It includes appendices on the regulatory requirements, various types of seal plug, welding on water-sealed and waterless gas holders and flammable gas detectors.

The *Guide* deals particularly with welding operations on equipments containing flammable fluids, which is also the aspect of hot work of principal concern here. The welding should be confined to manual electric arc methods.

The welding methods described in the *Guide* require for their safe performance strict adherence to the procedures laid down. The account given here draws on the *Guide*, but is no more than an outline. The *Guide* itself should be consulted for the conduct of such welding operations.

Welding as such is treated in Chapter 12 and the personal safety aspects of welding are discussed in Chapter 25.

21.11.1 Regulatory requirements

Welding operations are covered by Section 31(4) of the Factories Act 1961, which states:

> No plant, tank or vessel which contains or has contained any explosive or inflammable substance shall be subjected
>
> (a) to any welding, brazing or soldering operation;
>
> (b) to any cutting operation which involves the application of heat;
>
> (c) to any operation involving the application of heat for the purpose of taking apart or removing the plant, tank or vessel or any part of it; until all practicable steps have been taken to remove the substance and any fumes arising from it, or to render them non-explosive or non-inflammable; and if any plant, tank or vessel has been subjected to any such operation, no explosive or inflammable substance shall be allowed to enter the plant, tank or vessel until the metal has cooled sufficiently to prevent any risk of igniting the substance.

Section 31(5) provides that, where he is satisfied that compliance is unnecessary or impracticable, the Chief Inspector may grant exemption from any of the above requirements by the issue of a certificate, which may contain conditions.

21.11.2 Control of welding operations

The welding operations should be controlled by a permit system. The general arrangements of a permit system are described in Section 21.8, but certain points of particular relevance to welding merit mention.

The issuing authority should have both the knowledge required to appreciate the hazards of the work and the precautions to be taken and the authority necessary to draw on and coordinate specialist expertise. The permit should

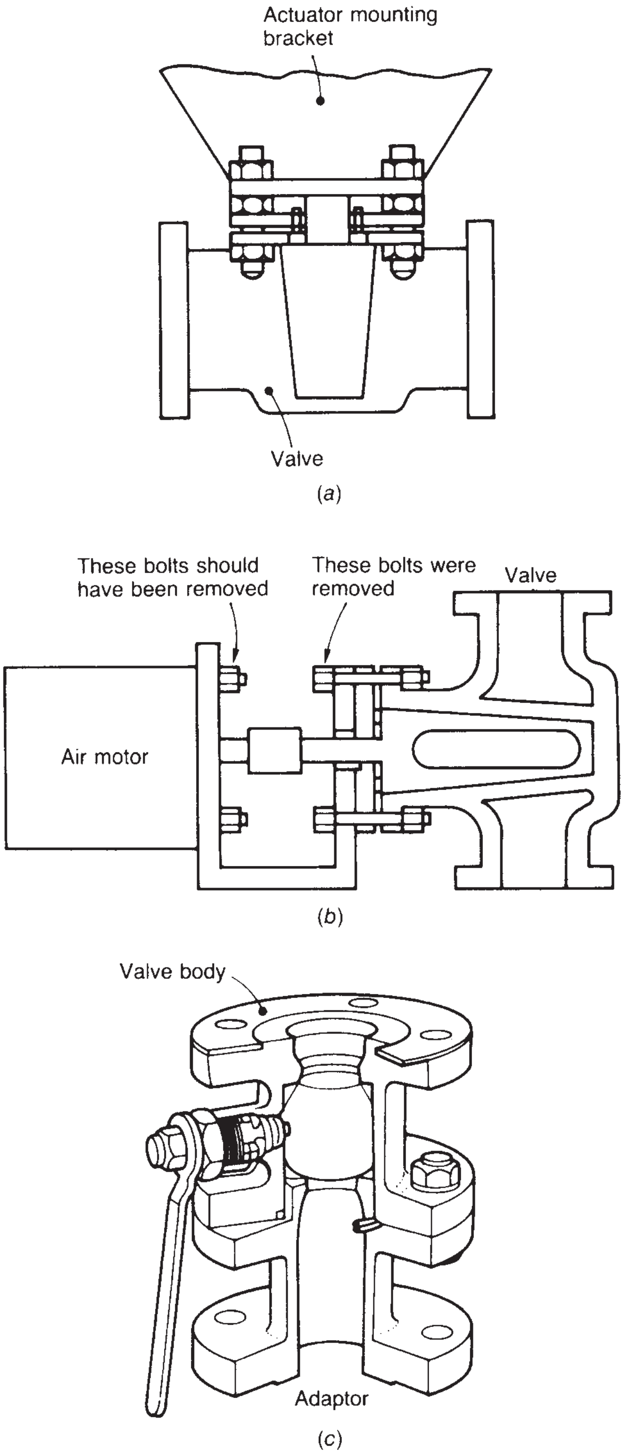

__Figure 21.6__ Some valve types involved in joint breaking incidents (Kletz, 1984l): (a) valve and actuator, held by same bolts; (b) valve and actuator, held by separate bolts; (c) valve with adaptor – an integral part of valve (Courtesy of the Institution of Chemical Engineers)

specify clearly, and in detail, the date and time authorized for hot work, the equipment on which the work is to be done, the precise nature of the operation, the weld point, and fire prevention and protection requirements. The issuing authority should inspect the work site to ensure that all necessary precautions are in place. A full explanation of the work, the hazards and the precautions to be taken is particularly necessary where the work is to be done by contractors.

21.11.3 Precautions for welding operations

A principal hazard of welding is that it introduces a source of ignition. If the work is to be done at a location where this fact is significant, and particularly within a classified hazardous area where sources of ignition are normally excluded, this should be entered on the permit and special precautions taken.

The welding site should be free of flammables, whether gases, liquids or solids. The atmosphere to a radius of 45 ft (15 m) and to a height of 6 ft (2 m) above ground level or above the point at which welding is to be done, whichever is the greater, should be free of flammable gas. The surfaces of the surrounding equipment should be free of flammable deposits. There should be no flammable liquids on the ground within a radius of 45 ft (15 m). Drains over the same area should be covered. It may also be necessary to provide shielding to contain weld spatter.

The equipment to be worked on should normally be isolated, emptied and cleaned, tested for flammables and inspected before welding is undertaken. There are certain procedures which are exceptions, as described below, but they in no way weaken this general rule.

There should be good access to the welding site for the welders and equipment and also for emergency services. For elevated locations, suitable staging and scaffolding should be provided, again with good access. There should be adequate lighting. For welding on underground pipelines, an excavation should be made of sufficient size, with adequate shoring, ladder access and secondary means of escape.

For welding in any confined space, including an excavation, there should be ventilation sufficient to ensure dispersion of fumes.

Suitable protective clothing should be provided for all persons involved in the welding operation. There should be present as a 'fire watch' at least one person, who should be provided with fire extinguishers, the dry powder type being generally used. First aid equipment such as breathing apparatus and resuscitation equipment should be to hand.

Personal safety in welding operations is considered in Chapter 25.

21.11.4 Welding on equipment containing flammable fluids

The conditions under which welding may be carried out on equipment containing flammable fluids are defined in API 2201 and HSE *Hot Work Guide*.

For welding on the external surface of equipment containing a flammable liquid, the metal at the location of the weld should be wetted by liquid. For welding on the external surface of a tank, the weld should be below the liquid level and for welding on a pipeline, the pipeline should be full of liquid. In the latter case it is also necessary to ensure that abnormal pressures cannot arise due to the generation of vapour or expansion of the liquid. The usual method of avoiding this is to maintain a liquid flow that is high enough to prevent overheating but not so high as to cause overcooling; a liquid velocity of at least 3 ft/s (1 m/s) is usually required. Measures should be taken to ensure that penetration of the metal does not occur. These include ensuring that the thickness of the metal in the area of the weld is sufficient and that the welding is performed properly.

Where welding is to be done on the internal surface of equipment, which has contained a flammable liquid, precautions should be taken to ensure that the surfaces are free of deposits and that no liquid is trapped in hollow members or behind metal linings or wear plates. Trapped liquid should be released by drilling suitable holes and the space purged with steam, air or inert gas, as appropriate.

Welding on the equipment containing a flammable gas involves a higher potential hazard in that the gas has a much lower capacity for the removal of heat than does liquid. There is, thus, a greater risk of overheating which may result in penetration by the welding operation or rupture due to the internal pressure. The operating pressure and temperature should be adjusted to allow for this.

21.11.5 Methods of temporary isolation

Some of the welding operations described below require the temporary isolation of a section of pipe. Where possible, isolation should be accomplished by conventional means, but in some cases it is necessary to use seal plugs or bag seals.

Four types of seal are used. These are (1) atmospheric seal plugs, (2) high pressure stopple or seal plugs, (3) frozen product seal plugs and (4) bag seals.

An atmospheric seal plug is inserted into the open end of a pipe which has been isolated by other means, drained and cold cut, but which has not been cleaned along its entire length and into which flammable liquid or gas may leak. It consists of a rubber sealing ring compressed between two discs so as to provide a peripheral seal against the inside of the pipe. It provides isolation between the welding point and the empty line.

A high pressure stopple is inserted into an operating pipeline, using a stopple insertion unit. There are a number of designs of such seal plugs. The insertion of two high pressure stopples allows a section of pipe to be isolated.

A frozen product seal plug is created by freezing the liquid in a section of the line, using a freezing mixture, commonly of solid carbon dioxide and isopropanol. Where the liquid cannot be frozen in this way, it may be possible to use the alternative method of replacing it with water which can then be frozen.

A bag seal is inserted into an operating gas pipeline through a bag tube. The bag consists of an inflatable rubber bladder with an outer fabric cover. Bag seals are used only for pipelines containing gases at low pressure.

Full details of each of these seal methods, of their applicability and limitations, and of the precautions to be taken in their use are given by numerous companies supplying these services and in the HSE *Hot Work Guide*.

21.11.6 Welding on operating pipes/pipelines

API 2201, 1107 and the HSE *Hot Work Guide* describes the method to be followed in welding operations on pipelines carrying flammable fluids. They deal primarily with welding on a pipeline for the purpose of replacing a length of pipe. It treats both the case where the pipeline has to remain in operation and that where it can be taken out of service.

For the former case, the method described is to isolate the section of pipeline on either side of the pipe section to be replaced. If the isolations cannot be achieved by conventional means, use may be made of a suitable seal plug. This will often be a high pressure seal plug. The method of inserting such a seal plug is broadly as follows. A stub connection is welded to the pipeline, a special valve is mounted on the connection and the drill is mounted on the valve. A check is made to ensure that the fittings and welds can withstand the pipeline pressure. The valve is then opened, the drilling is done, the drill is withdrawn again, the valve is closed and the drill is removed. The stopple insertion unit is mounted and the stopple inserted. If the flow is to be maintained, this may be done by putting in first a temporary bypass, again by welding on stub connections and tapping in a similar manner, and joining the bypass pipe on by a flanged or welded joint. Further stubs are welded on to the pipe section to take vent and drain connections and these are tapped. The arrangement is illustrated in Figure 21.7. The pipe section is drained and vented and a check is made that the stopples are making satisfactory seals. The pipe section is then removed, which should be done by cold cutting; this does not include the use of an abrasive wheel. The pipe ends are cleaned and the new section of pipe is then fitted, either with flanged or welded joints. If there is to be a delay before the pipe section is fitted, the open ends should be sealed with atmospheric seal plugs or bag seals and the space behind these seals vented by flexible hose to a safe area.

A permanent branch connection may be installed to an operating pipeline in a manner essentially similar to that just described for installing a temporary bypass, and a valve or flowmeter may be installed in a manner similar to that described for installing a new section of pipe.

Another case is where the pipeline can be taken out of service and the section of pipeline isolated and drained, but it is not practical to clean and purge it over its whole length. In this case, the isolations should be checked and the line drilled to ensure it is depressurized to atmospheric pressure. The pipe section is then removed by cold cutting. As before, the pipe ends are cleaned and the new section of pipe is then installed, with fitting of seals and venting of the space behind them if installation of the new pipe section is to be delayed.

Yet another case is where it is necessary to make a repair on an operating pipeline to counter internal or external corrosion. It is sometimes possible to use a mechanical clamp, but often the only recourse is to weld over the affected area a patch or leak box.

21.11.7 Limitations and prohibitions on welding operations

There are a number of limitations on the welding operations on equipment containing flammable fluids. Welding should not generally be carried out on equipment where the metal thickness is less than 0.2 in. (5 mm); on the external surface of a tank at a point less than 3 ft (1 m) below the liquid surface, or on equipment at a temperature below 45°F (7°C), unless it can be shown to be safe to do so.

Welding on a pipeline should not be undertaken where the operating pressure and temperature exceed those which ensure that the thickness and strength of the metal are such as to preclude failure and that the strength remains unaffected on cooling.

Welding should not be done on the vent and blowdown systems of operating equipment, unless it can be shown to be safe to do so. Such systems should not be isolated while the equipment is operating unless alternative arrangements have been made.

There are also a number of prohibitions on welding operations on equipment containing flammable fluids. Welding should not be carried out where: either the equipment contains a flammable mixture or the welding itself may create one; the equipment contains a substance liable to undergo reaction or decomposition; or the equipment contains either compressed air or an oxygen-enriched mixture together with hydrocarbons deposited on internal surfaces or otherwise present.

Furthermore, welding should not be carried out on: equipment in ferritic steel containing gas in which the partial pressure of hydrogen exceeds 100 psi (7 bar), unless it can be shown by tests to be safe to do so; equipment in a material susceptible to stress corrosion cracking, unless appropriate stress relief treatment can be given; equipment

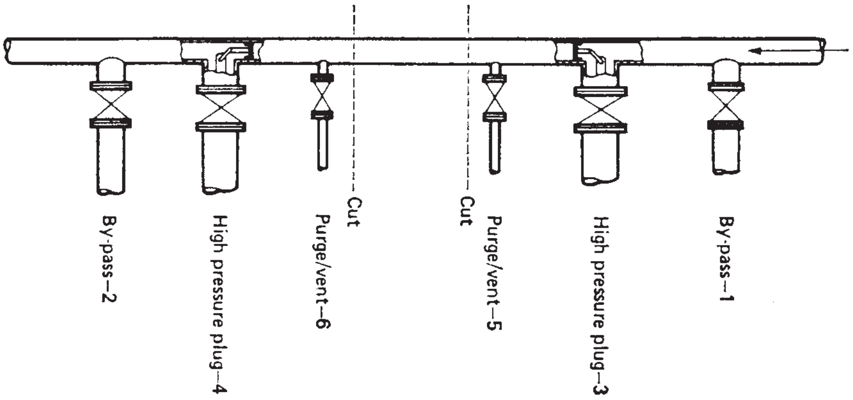

Figure 21.7 *Arrangement for welding on an operating pipeline (HSE, 1979 HS(G) 5) (Courtesy of HM Stationery Office. Copyright. All rights reserved)*

for which post-weld heat treatment is necessary; equipment designed to advanced, or high stress, codes; or any part of a flare system over which effective control cannot be exercised.

There is an extreme hazard of welding on equipment containing pure liquid or gaseous oxygen. For equipment containing high purity ethylene gas it had been demonstrated that welding may be safely done at pressures up to 400 psi (28 bar) and temperatures up to 300°F (150°C) and that work was continuing on this topic.

21.11.8 Procedures for welding operations

The HSE *Hot Work Guide* gives the procedures to be followed in welding operations on a pipeline in the form of a checklist, under the headings of: (1) initial planning of operations, (2) site preparations, (3) stand by services, (4) pipeline preparation, (5) fitting alignment, (6) welding procedure, (7) action immediately prior to welding, (8) action during welding, (9) integrity of the completed weld and (10) final completion.

The initial planning covers: inspections on regulatory requirements and company codes; notifications to external interested parties; reviews of the process conditions, of the condition the pipeline, of the fittings and consumables and of the site conditions; lists of the fittings, equipment, and services required, plans of the site; sketches of the work; a list and plan of emergency procedures; and preparation for the issue of the permit. The site preparations are essentially the precautions given in Section 21.11.3, but include also the provision of adequate supports for the pipeline, fittings and any other equipment, and removal of groundwater where necessary, likewise, the stand by services to be provided as appropriate are those mentioned in that section.

The pipeline preparations include checking the material of construction of the pipeline, removing insulation, cleaning the surface, checking the roundness, measuring the wall thickness, examining the external condition, investigating where necessary the internal condition, and grinding flush any external weld which might interfere with a flush fitting.

The fittings alignment requires that the fittings be correctly positioned and aligned, the pipeline and fittings adequately supported, and the weld preparation and the clearances checked. The welding procedures cover the competence and approval testing of welders, the routing of the welding cables though areas free of flammable gases and liquids, the condition of these cables, and the clamping of the return current cable close to the weld point.

The actions immediately prior to welding are to confirm the identity of the pipeline to be welded, the pipeline operating conditions, the welder and welding supervisor's understanding of the work to be done, the temperature of the pipe wall and fitting, the welding current and compliance with the permit. The actions during welding are to monitor the pipeline operating conditions and the absence of flammables in the environment.

The integrity of the completed weld should be such that it is able to withstand any operating conditions to which the pipeline may be subject, after heat treatment where necessary. The integrity of the weld should be checked by some suitable means. Reference is made to hydraulic pressure testing, pneumatic leak testing and non-destructive testing. Where the latter is used, the acceptance standards utilized should be stated. Where pressure testing is used, care should be taken to avoid over pressurizing the pipeline itself.

The final completion consists of the usual termination procedures: a check that the site is left free of hazards, notification to interested parties that the work is complete and signoff of the permit.

21.11.9 Hot tapping

The procedure of fitting a branch onto a pipeline which is still operational is known as hot tapping. This procedure has already been described in outline but is of sufficient importance to merit further discussion. As already stated, guidance is available in API RP 2201, RP 1107 and the HSE *Hot Work Guide*.

Several of the accounts on hot tapping published in the mid-1970s provide useful background information. They include those of Elder and Batten (1975), Hahn (1975), W.B. Howard (1975a), Howden (1975), Letchford (1975) and Warren (1975a). Howden (1975) describes a long-term programme of work on hot tapping in the American Gas Association (AGA) line Pipe Research programme at the Battelle Columbus Laboratories. Guidelines produced by the American Society of Mechanical Engineers (ASME) Gas Piping Standards Committee are outlined by Elder and Batten (1975). The development of a code of practice for hot tapping has been described by Letchford (1975) of British Gas.

It is expensive to shut-down units or equipment and there is a strong economic incentive to make the modification when the equipment is in service. Nevertheless, hot tapping should be avoided as far as possible and should only be done in essential cases.

The Factories Act 1961, Section 31(4), quoted above, forbids work on plant, tanks or vessels containing any explosive or flammable substance which entails the application of heat until all practicable steps have been taken to remove the substance and any fumes arising from it and to render it non-explosive or non-flammable.

If air or other oxidizing substance is excluded from equipment which contains a fluid that can burn or explode when mixed with air, then the fluid may be regarded as non-explosive and non-flammable. Such exclusion is the basis for the justification of hot tapping as an industrial practice (Hahn, 1975).

There are several hazards in hot tapping. One is that there will be a leak during the hot tapping operation itself. This is most likely to result from welding, but could also occur if the hot tap valve or tapping machine were to fail or if the tapping machine were to pierce the pipe on the far side. Another hazard is the explosive decomposition of the fluid in the pipe due to the heat applied during the welding. A third hazard is the failure of the modified equipment at some later date. There are also the usual hazards of welding on the equipment.

The normal hot tapping arrangement is shown in Figure 21.8. A branch is welded onto the pipe, a valve is put on the branch and a tapping machine is used to drill via the valve and branch into the pipe.

Hot tapping requires careful preparation, including consideration of the following factors:

(1) the process fluid and the process design operating conditions in the pipeline;
(2) the process operating conditions at the start of work;
(3) the material of construction, the dimensions and the condition of the pipeline;
(4) welding constraints, preparations and procedures;

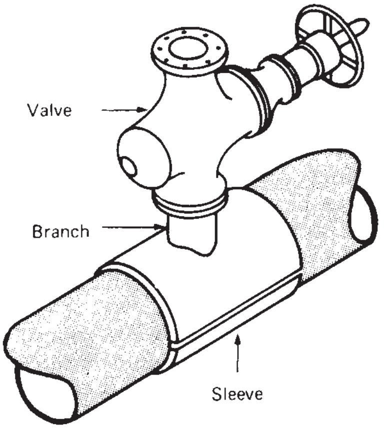

Figure 21.8 *Valves arrangement for hot tapping*

(5) the fittings and equipment required for the work;
(6) the services required for the work;
(7) the equipment operational procedures and precautions;
(8) the permit systems, notification to third parties and emergency arrangements.

If possible, the pipeline should be taken out of service to make the hot tap. Where this cannot be done, the operating pressure above atmospheric should be reduced as far as possible while the work is being done so that the hazard is also reduced.

The material of construction, the thickness and the condition of the pipe to be welded should be thoroughly checked. The material of construction is important for strength calculations and for the selection of welding electrodes. There is a minimum thickness below which the pipe should not be welded. Welding should not be carried out if the condition of the pipe has deteriorated so as to make operation unsafe, and the pipeline should be thoroughly checked by non-destructive testing (NDT).

Some guidelines on what is and what is not permitted in one company, ICI, have been given by Hahn (1975). Basically, these restrict hot tapping to the following conditions:

(1) pipelines to be made of specified grades of steel;
(2) pipe wall thickness to be not less than 0.22 in.;
(3) process fluid pressure to be not greater than 550 psig and not less than atmospheric; if hydrogen is present, the partial pressure to be not greater than 100 psig;
(4) process fluid temperature to be between 7°C and 370°C throughout the operation; preheating by steam or electrical methods, but not flame heating, to be used as necessary to achieve this;
(5) welding not to be done on lines containing
    (a) oxygen (except under 1%),
    (b) compressed air,
    (c) decomposables,
    (d) caustic soda,
    (e) process materials which could cause hardening by reaction with hot metals to a dangerous degree.

Hahn also discusses the extent to which these basic restrictions can be modified and states the conditions under which his company would do hot tapping on low alloy steels, on thinner pipes, at higher pressures and outside the given temperature range. On the other hand, he also gives certain limits which would not be overridden: welding would not be done on oxygen or chlorine pipes, because steel can burn in these materials, nor on compressed air lines, which often contain oil or carbon deposits that might ignite if heat were applied to the pipe. Areas of doubt which he discusses are pipelines containing ethylene and those containing hydrogen above 100 psig partial pressure.

The problem of ethylene decomposition during welding on ethylene pipelines is considered by W.B. Howard (1975a), who describes experiments to determine the process conditions under which hot tapping may be regarded as safe. Hahn states that his company has gone from a policy of permitting such work to a complete ban and thence to a partial relaxation of the ban. It is of interest that during the period of the complete ban, a method was developed for bonding fittings in place using epoxy resins.

With regard to hydrogen, Hahn suggests that the hazard which is a greater limitation than that associated with hydrogen partial pressure is that the red hot part of the heat-affected zone may reach the pipe internal surface with the result that the hydrogen diffuses rapidly through the weld pool, so that weld cracking occurs.

The welding work has several important aspects. The welding is done by the electric arc method. The welding procedure should be defined in respect of the electrode selection, the welding technique, the preheat and the post-weld treatment, if any.

Preheat may be provided by steam or electrical methods. Different views have been expressed on the advisability of flame heating. The ICI instructions described by Hahn state that it should on no account be used. On the other hand, Letchford describes its use in British Gas.

The surfaces to be welded should be uniform and free of pipe coating, rust, scale, oil and moisture. The pipe should be supported on both sides of the section to be welded.

The welding current should be checked. The ammeter on the welding set is not always reliable. It is usually required that the meter be checked using scrap material. The pipe should be completely grounded and the risk of arcing at the ground clamp eliminated.

The welders should be fully qualified, experienced and reliable, and should wear appropriate protective clothing.

If the weather conditions are bad, the welding should be stopped.

There can be a significant cooling effect from the gas flow. This may require the use of higher welding current to overcome this cooling effect. It can also result in cracking due to the quench effect when the source of heat is removed.

The hot tap valve requires special attention. Such a valve may be subjected to pressure and temperature shocks and its integrity should be assured. The valve should be new. It should be given NDT, pressure and leak tests.

The hot tapping equipment should also be carefully checked. This check should again include NDT and pressure testing and tests on the cutter teeth and pilot drive.

The equipment operational procedures and precautions which should be taken during hot tapping were described in Chapter 20 as an illustration of the role of plant management during plant work.

Hot tapping is a complex operation which is potentially hazardous, but which can be done safely if the correct practices are followed. It is emphasized, however, that hot tapping is a matter for specialists.

21.12 Tank Cleaning, Repair and Demolition

A set of operations of some importance in the maintenance of equipment is the cleaning, repair and demolition of tanks for storage of flammable liquids. Guidance is given in OSHA 1910.146: *Permit Required Confined Space*, API Std 2015: *Requirements for Safe Entry and Cleaning of Petroleum Storage Tanks*, API Std 653: *Tank Inspection, Repair, Alteration, and Reconstruction*, NFPA 326: *Safeguarding of Tanks and Containers for Entry, Cleaning and Repair*, CS 15 *The Cleaning and Gas Freeing of Tanks Containing Flammable Residues* (HSE, 1985).

21.12.1 Preparation for entry or hot work

Two principal purposes for which entry into a tank is required are inspection and repair or modification, which usually involves hot work.

It cannot be assumed that a tank which has been emptied and gas freed, or even one which has been cleaned with a water wash, is completely free of flammable or toxic gas. Before entry, ventilation of the tank should be established, the atmosphere should be gas tested to be free of flammable or toxic gas, and repeat gas tests should be made at intervals to confirm that the atmosphere is still gas free. On entry, a check should be made for potentially hazardous residues.

Ventilation and monitoring of the atmosphere in the tank should continue and personnel should not remain inside if the concentration of flammables rises to over 25% of the lower flammability limit. The source of the vapours must be located and controlled.

If it is not possible to establish a safe atmosphere in the tank, entry may be made using breathing apparatus.

Before hot work is undertaken, a thorough inspection should be made for hazardous residues and any such residues first removed by cleaning. Gas testing should also be performed.

It may be possible, particularly for smaller tanks, to avoid the need for hot work by cold repair techniques such as the use, where suitable, of materials based on epoxy resins, fibre glass or elastomers. Care should be taken not to incorporate into the tank structure elements which increase the hazard from static electricity.

21.12.2 Gas freeing of tanks

Methods of gas freeing are described in Section 21.6. They are forced ventilation, water washing and steam cleaning. Particularly with large tanks, the gas freeing or cleaning operation may involve the venting of quantities of flammable or toxic vapour, which is often denser than air, and therefore liable to collect at low points and poorly ventilated areas. Such operations should not be performed unless suitable precautions have been taken to disperse the gas and exclude ignition sources.

In some cases the operations will evolve quantities of flammable vapour sufficient to require measures to control its dispersion. Flammable purge gas mixture is sometimes burned off at an elevated vent stack, fitted with a pilot flame and a flame arrester to prevent flashback. Where large equipment, and therefore large volumes of flammable vapour, are involved, the dispersion of the vapour should be monitored, by measurement if necessary, and venting suspended if the vapour fails to disperse. Other precautions required include the covering off of drains and sewers to prevent ingress of vapours and restriction of access to the area. It may also be necessary to take measures to prevent ingress of vapour into buildings.

21.12.3 Emptying of liquid from equipment

Liquid should be emptied into a suitable receiver. Large equipment is typically pumped out, while small vessels may be drained.

A particular technique used to flush out light hydrocarbons from a tank bottom is to introduce water and raise the hydrocarbons to the level of the suction line so that they can be pumped out. Care is needed to avoid generating static electricity either by high fluid velocities or by splashing, bearing in mind the enhancing effect of the water content on the generation of static electricity in liquid hydrocarbons.

Where a vessel has an external jacket for the circulation of a flammable heat transfer liquid, it is suggested that this may be drained out and replaced with water, maintaining a vent open to the atmosphere to prevent any pressure build-up during hot work.

Suitable measures should be taken to ensure that ancillary equipment does not constitute a hazard. Ionizing radiation sources should be locked out and removed by a competent person. Stirrers and heaters should be isolated. Cathodic protection should have its power supply isolated 12 hours in advance so that depolarization occurs. Where it is necessary to maintain heating from steam coils or an electric immersion heater in order to assist pumping out of the liquid, the heat input should be isolated before the liquid falls to within 1.5 ft (0.5 m) of the heating surfaces or temperature sensors.

21.12.4 Ignition at equipment

Precautions should be taken to ensure that ignition of flammables does not occur. The main precautions are the elimination of a flammable mixture and the avoidance of hot work where there may be flammable residues; but where there are flammables which might be ignited, control of ignition sources should be exercised. Ignition sources and situations which are particularly relevant to equipment are: direct flames from hot work; hot surfaces occurring due to hot work; self-heating of oil-soaked insulation; and pyrophoric iron sulfide. Hot surfaces may cause ignition either by hot surface ignition or by raising the temperature of the bulk gas to its autoignition temperature. There is a volume effect for autoignition, the autoignition temperature decreasing with an increase in volume, and since the volume differences are large between the volumes in which determinations have been made and those of large equipment, it is prudent to assume that any significant rise in the wall temperature may ignite a flammable mixture in a large tank.

21.12.5 Gas freeing and cleaning of small equipment

For small equipment, drums and other small containers, use should be made of positive gas freeing methods and reliance should not be placed on natural ventilation. One positive method of gas freeing is forced ventilation. Gas freeing also occurs as a result of cleaning by water washing or steam cleaning.

Methods of cleaning small equipment are water washing, steam cleaning and solvent jetting. An account of the use of these methods for the cleaning of small equipment is given in Section 21.6.

21.12.6 Gas freeing and cleaning of mobile tanks

Mobile tanks are those on truck tankers and rail tank cars. Positive methods should be used for gas freeing. One such method is thorough water washing and forced ventilation by the use of an air eductor or air mover. Another is to do gas freeing as part of steam cleaning. The usual method of cleaning, and thus of gas freeing, is the use of steam cleaning. The procedure is similar to that for small equipment.

Before hot work is undertaken on a multi-compartment tank vehicle, the design of the tank should be reviewed and a check made that there is no flammable material trapped in the bulkheads or other cavity.

21.12.7 Gas freeing and cleaning of large equipment

The usual method of gas freeing large equipment is by forced ventilation using air eductors or air movers. The eductor or blower is lowered to the equipment bottom and the equipment is freed of gas through the roof manholes. The opening of manholes in the side of the equipment may release dense vapour creating a potential hazard, as described above. Precautions should be taken against ignition.

Ventilation should be continued until the concentration of vapour falls to less than 5% of the lower flammability limit. At this point, the risk of an outflow of flammable mixture is minimal and all the manholes may be opened. The flammable concentration should be allowed to fall to zero and to stay there for at least 30 min.

Methods of cleaning large equipment are steam cleaning, water jetting, solvent jetting and manual cleaning. An account of the use of these methods for the cleaning of large equipment is given in Section 21.6.

In many cases, the bottoms of large tanks are covered with sludge, residues and corrosion products, and are perforated to some degree. There may be hazardous residues in defective seams or in voids. It is necessary to check on, and deal with, such residues before hot work is undertaken.

Relevant advice is given in API Publ. 2207: 1999 *Preparing Tank Bottoms for Hot Work*. If there is flammable liquid under the tank bottom, one technique of dealing with it is to drill and flood the bottom with water to displace the liquid.

21.12.8 Hot work on outside of equipment

If it is required to carry out hot work on the outside of a equipment, which for some reason cannot be gas freed and cleaned, an alternative procedure is to inert the equipment. This method is not suitable if the product concerned is one which decomposes, such as ethylene oxide. Another procedure is to fill the equipment with the flammable liquid and then perform the hot work, as described in Section 21.11.

21.12.9 Inerting of equipment

Inerting may be accomplished by filling with water or with an inert gas such as nitrogen, carbon dioxide or combustion gas. A simple method of inerting for small equipment is filling with water. Any necessary check should be made on the load created by the water on the equipment and its supports.

The inert gas method requires that the gas be mixed effectively. Mixing is promoted by the introduction of the inert gas at a number of points and with high velocity. Failure to achieve good mixing creates various problems. It is difficult to monitor the uniformity of mixing and it may be necessary to maintain the gas flow throughout the period of the hot work.

Nitrogen is less reactive than carbon dioxide and may be used where products might be adversely affected by the latter. It is available as compressed gas in cylinders or as the bulk liquid. Where the latter is used, the vaporizers should be large enough to ensure an adequate supply and should be able to warm the gas to at least 14°F (−10°C) to guard against low temperature embrittlement. Using nitrogen inerting, which gives a mixture of hydrocarbons, nitrogen and oxygen, the limiting concentration of oxygen for combustion is about 12% and it is usual to purge down to below 5% to allow an adequate safety margin.

Carbon dioxide is more reactive than nitrogen. It too is available as compressed gas in cylinders or as the bulk liquid. Carbon dioxide has a tendency to form solid particles. In the case of cylinders, this creates a risk from static electricity. The use of the cylinder gas is not advised for this reason. Discharge from the bulk liquid should be designed to prevent the formation of 'snow'. It should be checked that the equipment can withstand the low temperature caused by liquid or solid carbon dioxide. Precautions should be taken to protect personnel from 'cold burns'. Using carbon dioxide inerting, the limiting concentration of oxygen for combustion is about 14%, and for safety it is usual to purge to below 5%.

A third type of inert gas is combustion gas obtained from the controlled combustion of hydrocarbons in gas generators, followed by purification. The resultant mixture typically contains 12–15% carbon dioxide, 12% oxygen and the remainder nitrogen.

Another inerting technique involves the use of foam. The foam may be an air foam or a nitrogen foam. High expansion foam blown with air has been used to inert equipment which have held high flashpoint liquids, but there is some doubt whether air foam will prevent flame propagation if vapour is evolved in any quantity and it should not be used for liquids with a low flashpoint <90°F (<32°C). Instead use may be made of nitrogen foam. The principal advantage of using nitrogen in foam form is economy in the use of the gas. Since the gas in the equipment is displaced by the foam rather than removed by completing a number of purge gas changes.

21.12.10 Demolition of equipment

Methods for the demolition of equipment are given in API Std 653: *Tank Inspection, Repair, Alteration and Reconstruction* and GS 29/3 *Health and Safety in Demolition Work. Part 3: Techniques* (HSE, 1984).

A demolition survey should be made and the demolition procedures defined. The equipment should be emptied and gas freed. Ignition sources should be controlled. The roof should be removed by cold cutting. If a power tool is used, precautions should be taken to avoid its acting as an ignition source. Before any hot work is done, the equipment should be cleaned from the outside, by use of steam hoses, washing with water or water sprays. Washing with a high flashpoint oil is another method, but the oil should not be sprayed. The wash fluid should be collected and pumped away.

If steam is used, the usual precautions should be taken, the steam pipe being grounded and bonded to the equipment. The equipment should be allowed to cool and the atmosphere tested before entry is made.

In some cases, the technique is used of covering the bottom sludge with about 6 in. (0.15 m) of water.

Further details of equipment demolition are given GS 29/3, which also describes specific methods for the demolition of various types of equipment, including small and large fixed roof tanks, floating roof tanks and leaded petroleum tanks. It also deals with tank walls and tank floors.

21.13 On-Line Repairs

There has been a steady growth in the development of techniques for on-line, or on-steam repair and in their application. An account of on-line repair methods in general is given by G.W. Harrison (1980).

The growth of such techniques has been driven by a number of factors, including general economic pressures and the need to accommodate the lengthening of times between scheduled shut-downs, or turnarounds; to keep major pipelines operating; to economize on energy and reduce steam leaks; and to reduce hydrocarbon emissions.

One family of on-line repair methods is that concerned with carrying out hot work on operating pipelines, including hot tapping. This has already been described in Section 21.11.

Among the applications of on-line repair described by Harrison are the use of: drill-and-tap methods to repair packing on leaking valves and also on pumps and agitators; leak sealing methods to eliminate flanged joint leaks, piping and fitting leaks, vessel leaks and compressor and turbine case joint leaks; hot tapping and line stopping on pipelines; various leak sealing methods for heat exchangers; and the crimping of deteriorated reformer tubes.

An account of on-line repair of insulation is given by Bloom and Pebworth (1979).

21.13.1 General leak sealing

One of the most common types of on-line repair is the sealing of a leak. A variety of simple methods are used to seal leaks such as steam leaks, including clamps and various forms of enclosure or box. These may often be applied without the need to weld on an operating line.

21.13.2 Compound leak sealing

A specialized leak repair technique is that of on-line compound leak sealing. One of the main points where a leak is liable to occur is at a flanged joint. If the leak is severe, there may be no choice but to shut-down and repair it, unless it can be repaired on line with the equipment still operating. Accounts of compound leak sealing are given by Stroud (1981), Maushagen (1984 LPB 55), Bond (1986 LPB 69) and J.K. Rogers (1988).

Compound leak sealing of a flanged joint involves putting a containment around the joint and injecting a sealant under pressure. J.K. Rogers (1988) describes the Furmanite system of leak sealing. This is applicable over the pressure range vacuum to 5000 psi (350 bar) and the temperature range cryogenic to 1000°F (600°C). A family of sealing compounds is used, depending on the application. The applications quoted are not only to flanged joints on pipes but to various other types of equipment, including riveted joints, welded joints, screwed couplings, valves and heat exchangers.

An investigation of the hazards associated with this technique is described by Maushagen (1984 LPB 55). In essence, the process of leak sealing tends to lead to an increase in the stress on the flange and on the bolts. There is thus, a potential hazard of rupture at the flange, which is particularly likely to be realized if the flange assembly has a burst pressure below the nominal value due to incorrect design, incorrect materials or deterioration. The author defines a factor relating the stress on the bolts after sealing to that on the bolts as installed, and quotes values of up to 2 for this factor. Each application needs, therefore, to be assessed before sealing is undertaken.

He also describes a number of case histories of flange rupture during leak sealing. In one case in Czechoslovakia in 1981, a 12 in. (300 mm) diameter pipe at 4350 psi (300 bar) pressure containing synthesis gas for an ammonia plant developed a leak at a ring joint. A leak sealing operation was undertaken by non-specialists. During the injection of the sealant there was a massive failure of the flange, resulting in a fire and explosion which killed four people.

Further leak sealing incidents are described by Bond (1986 LPB 69). Nevertheless, he argues that leak sealing is not a particularly risky operation. In the United Kingdom, some 25,000 leaks are sealed each year by some 100 technicians.

Bond outlines the precautions required to minimize the risks of leak sealing. Where possible, it is preferable to use conventional means of repair, such as repair or renewal of components, rejointing of flanges and repacking of glands.

If leak sealing is to be undertaken, it should be assessed by a competent engineer and a formal work plan agreed, covered by a permit. The assessment should cover: the hazard of a major release; the residual thickness of the pipe, including the method of, and apparatus for, its measurement, the bolts, including materials, deterioration, initial and final stresses; the external loads on the pipe and flange; the record of past injections; the maximum injection pressure to be used; the design codes and procedures for the boxes and clamps; the possibility of internal blockage of the pipe by the sealing compound; the access to the site; the personal protection required; and the expected life of the temporary repair. The temporary repair should be dismantled and a conventional repair performed at the earliest opportunity.

The work should be done by a competent contractor. The author highlights in particular, competence in the design of boxes and clamps. Once the method to be used has been decided, no deviation should be permitted.

21.13.3 Pipeline repair

On-line repair methods have been used for many years for pipeline repair. The methods of hot tapping were developed in this application.

An account of the technique of half-soling is described by P.M. Scott and Kiefner (1984). This consists of welding to the pipeline a curved plate which is concentric with, and extends around, one-half the circumference of the pipe. The half-sole may be cold formed from steel plate or obtained by splitting a segment of pipe longitudinally, the former being the more usual. It is attached to the pipeline by a fillet weld. The technique is used both for leaking and non-leaking defects.

Numerous pipe wrap materials are also available. These are pliable woven material that can be wrapped around the pipe sealing a leak or preventing one from happening on thin lines until the pipe can be replaced.

21.14 Maintenance of Particular Equipment

The deterioration and failure of equipment, which is dealt with by maintenance, has causes in design and installation as well as operation, and has first to be detected by inspection. The intimate links between maintenance and these other activities may be illustrated by considering the maintenance of some particular types of equipment. OSHA PSM standard 1910.119 (j) Mechanical Integrity requires programs to maintain the integrity of various types of process equipment. These include: pressure vessels, and storage tanks, piping systems including components, relief and vent systems and devices, emergency shut-down systems, controls and pumps. Accounts of maintenance of particular equipment are given in the Standard Plant Operators Manual (Elonka, 1975), Pressure Vessel Systems (Kohan, 1987) Plant Engineers Reference Book (Snow, 1991) and Marks Handbook.

21.14.1 Pressure vessels

The assurance of the integrity of pressure vessels depends largely on inspection and pressure relief. Pressure vessel maintenance and inspection guidance is provide API RP 510: Pressure Vessel Inspection Code, RP 572: Inspection of Pressure Vessels, RP 579: Fitness-for-Service, RP 580: Risk Based Inspection, RP 573: Inspection of Fired Boilers and Heaters, RP 570: Inspection, Repair, Alteration, and Rerating of In-Service Piping Systems.

The maintenance function should maintain a general oversight of pressure vessels, focusing on external corrosion, support defects, stress inducing features, disabled relief protection and disabled instrumentation.

The ancillary features of a pressure vessel should be maintained in good condition. The condition and tension of the bolts on flanged joints should be correctly maintained. The relief system of the vessel should be maintained, as described below.

Where it is necessary to carry our repairs on a pressure vessel, this should be done in accordance with the appropriate codes and systems. In the United States of America, the code is the ASME *Boiler and Pressure Vessel Code*. The National Board of Boiler and Pressure Vessel Inspectors (NB) certifies organizations for the repair of pressure vessels and issues the National Board Inspection Code, which gives guidance on pressure vessel repair. In the United Kingdom, the relevant code is BS 5500.

Some of the problems which may occur in field repairs of pressure vessels by welding are discussed by Kohan (1987). They include: incomplete removal of the defect being repaired; increased stress and distortion; slag inclusions; undercut, overlap and incomplete joint penetration; weld porosity; weld cracks; and unfavourable access and environmental conditions.

Repairs described by Kohan include: pitting repair; repair of wasted or general corroded areas; flush-welded inserts; repair to cracks, including weld cracks and lap cracks; repairs to heat exchangers; repairs to stainless steel; and repairs to dissimilar metals.

21.14.2 Pressure relief devices

Pressure relief systems provide essential protection for pressure systems and much effort goes into their design. This is negated if the relief system is not properly maintained. Guidance on inspection of pressure relief systems is provided in API RP 576: Inspection of Pressure Relief Devices. Accounts of the maintenance of relief systems are given by Anon. (1977 LPB 14, p. 2; 1977 LPB 17, p. 15), Woolfolk and Sanders (1984, 1987), J.K. Rogers (1988) and Duckworth and McGregor (1989). The account by Duckworth and McGregor covers the maintenance of relief devices along with their installation and inspection.

The maintenance of relief devices such as pressure relief valves and bursting discs requires suitable training. Maintenance personnel need to understand the reasons for the use of such devices, the types of device, the methods of installation and the methods of testing. They should appreciate that these are delicate items of equipment and should be treated on a par with, say, instrumentation.

When installing a relief device, attention should be paid to the orientation, the alignment, the gaskets and the bolt torquing. A bursting disc assembly may be rendered useless if it is incorrectly assembled, installed upside down or interfered with by an unsuitable gasket.

Before removing a relief device for testing, a check should be made on its general condition to see whether it has suffered damage or interference, whether it has suffered excessive corrosion or whether there is any process fluid or deposit which could affect its operation. In the shop, inspections should be made as to whether the set pressure is correct and whether there is any wear, damage, corrosion or restriction which could affect its operation. Where relapping of a relief valve seat is required, this should be done on a proprietary lapping machine or a good quality lapping plate.

A large site will generally have a large number and wide variety of types, duties and settings of pressure relief valves. There is considerable potential for incorrect installation. One measure to prevent this is to mark the valve location with a permanent code number and to put the same number on the valve itself.

An account of a program for the maintenance of safety relief valves (SRVs) on a 688-acre site with 20 separate units has been given by Woolfolk and Sanders (1987). The program described covers relief at 2200 locations with valves ranging in size from 1/4 in. to 12 in. and made by 25 different companies. The SRVs are tested, disassembled, cleaned, examined, repaired, lubricated, reassembled, retested and sealed.

The original test equipment utilized a low air volume. The testing of SRVs on this was not satisfactory and it was replaced by a system of larger volume, which proved more suitable. The authors comment that it is sometimes claimed that where an SRV has a bursting disc installed below it, it can be tested *in situ*, but that since the volume between the disc and the valve is small, this is equivalent to the use of a low air volume test system.

In SRV testing, the valve seat usually receives attention to ensure that the valve is leak-tight. Woolfolk and Sanders also place emphasis on the guide area. This should be cleaned, polished and lubricated.

Woolfolk and Sanders give details of the test intervals which they generally use, which are as follows. A 12-month interval is used for boilers (local legal requirement), process vessels with heat sources, vessels containing corrosive chemicals, and positive displacement pumps or compressors; a 24-month interval is used for process steam headers and storage; vessels with no heat sources; and a 36-month interval is used for instrument air manifolds within dehumidified control rooms and lubricating relief valves on enclosed systems.

Methods have been developed for the *in situ* testing of pressure relief valves, as described by J.K. Rogers (1988). The principle is to overcome the closing force of the valve spring by the application of an external hydraulic force. Then from knowledge of the valve seat area and line pressure at the valve, the set pressure of the valve may be determined. The test can also determine whether the valve has been fully stroked.

A critique of *in situ* testing is given by Woolfolk and Sanders, who express the view that it has limitations where there are aggressive fluids and that it could fail to detect corrosion, partly bent or galled stems, partially plugged nozzles and certain misadjustments.

Some case histories of relief valve maintenance are described by Anon. (1977 LPB 14, p. 2).

21.14.3 Storage tanks

The maintenance of atmospheric storage tanks presents a quite different set of problems. Guidance on inspection of storage tanks is provided in API RP 575: *Inspection of Atmospheric and Low-Pressure Storage Tanks*, RP 653: *Tank Inspection, Repair, Alteration, and Reconstruction*. Accounts are given by Huston (1983) and Shtayieh (1983a,b).

Maintenance of storage tanks often involves entry into the tank. In this case, a large part of the maintenance activity is the purging and cleaning required before entry can be gained. This aspect is described in Section 21.12 and is not, therefore, repeated here.

The ancillary features should be maintained in good condition. In particular, the tank vent system should be maintained by a system similar to that applied to relief valves on pressure vessels.

Most descriptions of storage tank maintenance are concerned with leaks. The case described by Huston involved a storage tank with a leaking floor, a not uncommon occurrence. The identification of leaks, which may be no more than 3/16 in. (5 mm) diameter, is usually difficult due to the poor lighting in the tank and to the state of the tank floor. The author describes a method of improving the detection of the leaks by forcing water under the tank and filling the underside of the floor with water, so that water comes up through the leaks.

An account of leak detection and repair in a refrigerated propane tank is given by Shtayieh (1983b). The tank was of double wall construction with insulation between the inner and outer walls. Monitoring of the gas space between the two walls showed the presence of hydrocarbons at a concentration of 15–20%, indicating the existence of leaks. A thermographic survey was carried out on the outside wall which showed two cold spots at a temperature 35°F (1.5°C) lower than the rest of the wall. The tank was entered and eventually leaks were found. The main leak was on a manhole, where there was a faulty gasket and a badly machined blind flange gasket face and cover. There were two lesser leaks at the two 2 in. diameter nozzles of the level indicator, due again to damaged flanges. No leaks were found at the points suggested by the thermography. This example demonstrates the trouble caused by deficiencies in common installation activities, in this case the making up of flanges.

21.14.4 Ammonia storage spheres

The occurrence of stress corrosion cracking in ammonia storage spheres has created a considerable problem in the maintenance of such storages. Accounts are given by R.S. Brown (1982) and Guth and Clark (1985). They illustrate both the procedures for isolation, emptying, purging and entry, and for bringing back on stream for such storages and the procedures for inspection and repair. This work is discussed further in Chapter 22.

21.14.5 Heat exchangers

Heat exchangers are pressure vessels, but in addition their maintenance is affected by certain characteristic features of their own. Accounts are given by Yokell (1983) and Fijas (1989).

Where a heat exchanger is delivered to a construction site and is left in the open for sometime before it is installed, it may well suffer deterioration even before it begins operation. In order to avoid this, it should be stored carefully before installation and its surfaces cleaned periodically. The necessary measures are described by Fijas.

Heat exchanger tubes are liable to leak or even rupture and these faults may be induced by maintenance activities. One such activity is tube bundle withdrawal. There should be procedures for bundle withdrawal. The bundle should be supported on the tube sheets, baffles or blocks contoured to the bundle, but not on the tubes themselves.

It is usually necessary to clean the tubes to remove scale. If cleaning is deferred too long, maldistribution may occur in some tubes and the resultant differential thermal expansion of these tubes can cause damage and leaks.

Methods of cleaning heat exchangers are described by Fijas. Soft deposits may often be removed from the shell or tube sides of a heat exchanger by washing with hot oil and soft salt deposits by washing with hot fresh water. More stubborn deposits may be removed by chemical cleaning. He recommends against cleaning tubes by blowing steam through them, since it is liable to cause overheating and thermal expansion and thus induce tube leaks. Nor should tubes be hammered with a metallic tool. If they must be scraped, the tool should not be sharp enough to cut them.

Heat exchanger tubes are subject to vibration, which is liable to cause leaks. One cause of tube vibration is operation at too high a fluid velocity. Another is vibrations transmitted from a pump or compressor. A pulsation damper may be used to reduce vibrations from such a source.

When starting up and shutting down a steam heated exchanger, condensate should be drained out as a precaution against water hammer. If shut-down is at all prolonged, it may be necessary to drain the fluids from the exchanger to prevent freezing or corrosion.

21.14.6 Equipment supports

Equipment supports provide another illustration of the interaction between design, inspection and repair. An account of the maintenance of such supports is given by B.N. Pritchard (1983). The types of support which he considers are concrete supports and steel supports fireproofed by encasing them in concrete. Causes of deterioration include corrosion, overstressing, frost damage and also fire or explosion.

Concrete protects buried steel against corrosion partly by constituting a physical barrier to oxygen and moisture and partly by passivation of the steel by water made alkaline by the concrete. This latter effect decreases as the alkalinity falls off.

If the steel under the concrete does corrode, corrosion products are formed which have eight times the volume of the steel which they replace. This creates stresses which result in cracking and spalling of the concrete.

The author reviews the effects on the corrosion of steel encased in concrete of chlorides, sulfates and acids. In rare cases it may be promoted by a cement aggregate reaction.

Corrosion of steel encased in concrete may be reduced by: the use of dense concrete; good steel – concrete bonding; shaping the concrete so as to exclude rainwater, or the use of rainwater flashings; and the application of a suitable coating to the outside of the concrete. The author states that for fireproofing cast *in situ* concrete appears superior to gunnite, though the reason is unclear.

Paint applied to the steel provides a degree of protection not only for bare steel but also for steel encased in concrete or provided with lightweight fire-proofing.

Corrosion occurring inside the concrete casing may be detected by visual examination, and also by tapping. In general, hairline cracks are tolerable but stained cracks may indicate a more serious situation. For certain cases, the use of more sophisticated inspection may be justified. Early detection is highly desirable. Suitable timings for inspection are at 1 year after commissioning or after a material change of duty or environment, and at 4 year intervals thereafter. Formal records should be kept of the supports and their inspection.

Factors which govern the repair of supports are the features which have caused the deterioration, the further deterioration expected, the effects of the damage on the structure, the importance of the structure, the operating history of the equipment and the cost of repairs. The repairs should incorporate measures to remove the causes of the deterioration. Repair techniques include the sealing of cracks, cutting back to sound concrete and cutting back to the steel. Temporary supports may be necessary while repairs are being completed.

21.14.7 Foundations and dikes

Foundations and dikes also may require repair. Accounts of the repair of foundations are given by Renfro (1978, 1979). Containments are discussed by Hazen (1991).

21.15 Equipment Removal

The removal of equipment from the unit to the shop can create a hazard if flammable or toxic material are trapped inside it. It is necessary to have some procedure to deal with this problem.

21.15.1 Unused equipment

Equipment which is installed but is no longer required should normally be removed. This applies to all kinds of equipment whether it be vessels, pumps, pipes, instruments, etc. Unused and often disconnected equipment is a fertile source of accidents.

21.15.2 Equipment sent off site

Where equipment is sent away from the plant, whether for repair or because it is no longer required, the state of the equipment should be reviewed, any hazard identified and appropriate measures taken. In particular, there is the potential hazard that equipment may still contain residues of flammable or toxic material. Equipment should be tagged indicting its prior usage and potential hazards.

21.16 Deteriorated Equipment

The equipment on the plant starts to deteriorate from the first day of operation, and sometimes earlier if it has been neglected prior to installation. As the plant ages, it becomes necessary to take a view on the continued operation of some equipment.

21.16.1 Remaining life assessment

Some equipment is designed to have a limited life. The prime example here is equipment with a limited creep life. Creep is described in Chapter 12 and the shortening of creep life by abuse during operation is discussed in Chapter 20. Where there is reason to think that the latter has occurred, it may be necessary to attempt an assessment of the remaining life.

Another major form of deterioration is corrosion and, insofar as a particular corrosion allowance is made, in this case also the design implies a limit to the life of the equipment. The possibility of periods of corrosion at rates much higher than average means that here too there is a need for life assessment.

The assessment of the remaining useful life of equipment, or the remaining life assessment (RLA), is an established activity. API RP 579 provides guidance on evaluating the present integrity of the equipment and the projected remaining life. RLA is described by Baker-Counsell (1987b) and Grosshandler (1987a). If the equipment is nearing the end of its life, RLA provides the necessary wanting, while if it still has an appreciable fraction of its life left, the RLA provides assurance that it can continue in operation.

Much work in RLA is concerned with creep effects. Some techniques used are metallography, strain measurement, accelerated creep testing and stress analysis. The results of RLA may be expressed as a cumulative probability of failure, which allows the company to make its own judgement on how much longer to continue to operate the equipment.

A specific example of the application of RLA to corrosion of a pressure vessel and its nozzle is described by Grosshandler (1987a). Further accounts of obsolescence include those of Munro (1963) and Baas and Warner (1992), who describe the assessment of the remaining useful life of an ethylene plant.

21.16.2 Used equipment

The situation can arise where it is necessary to consider either the purchase or the sale of used equipment. Some of the considerations which arise have been described by J.P. Epstein (1967, 1978) and C. Butcher (1992d).

For purchase, three approaches may be taken: purchase 'as is', on approval, and rebuilt and guaranteed. Most equipment is bought 'as is'.

When purchasing equipment, inspections should be made on: the dimensions of equipment; the pressure integrity of pressure vessels; the wear sustained by moving parts of machinery; any ancillary equipment; and conformance to any regulatory requirements. Useful information can often be obtained by inspecting the equipment while it is still on site and in use. Equipment allowed to stand idle even for a short time can deteriorate or take on a bad appearance.

Specialist companies exist which deal with used equipment and it may be beneficial to use their expertise.

21.16.3 Fire damaged equipment

In the aftermath of a large fire, there may be equipment which has been in the fire. The question then arises as to the continued safe use of the equipment. In all such cases an inspection should be made. Pressure system integrity is of particular importance and should be investigated by experts.

A case history of the assessment of fire damage of a vessel is described by Dooner (1986). The vessel was to be used in a low temperature application down to −196°C. It had been in a fire which lasted some 2 hours and subject to an estimated temperature in the range 400–600°C. A metallurgical investigation showed that no significant deterioration had occurred and the vessel was put into service.

21.17 Some Maintenance Problems

21.17.1 Materials identification

Misidentification of materials is a significant problem. Mention has already been made in Chapter 19 of errors during the construction and commissioning stages, particularly in the materials used in piping. Materials errors also occur in maintenance work. Situations in which they are particularly likely are those where materials look alike, for example low alloy steel and mild steel, or stainless steel and aluminium painted steel. It is necessary, therefore, to exercise careful control of materials. Methods of reducing errors include marking, segregation and spot inspections.

Positive Material Identification efforts have been used on piping systems. It is not uncommon to find that 20% of the components are not the proper material.

21.17.2 Component identification

Another problem is mistakes in identifying components or equipments. Confusion can arise, for example, over pressure relief valve components, with the result that a relief valve may be put back with too high a setting. This type of error can readily occur with similar components made by the same manufacturer. Similarly, it is easy for blinds to become mixed up so that a slip blind suitable only for a low pressure duty is used on a high pressure application.

A particular type of component identification error is installing a component that alters equipment performance. Thus, the capacity of a control valve may be increased by putting in the wrong trim, or the delivery pressure of a pump may be increased by installing the wrong impeller.

21.17.3 External corrosion

External corrosion beneath insulation is a considerable problem on process equipment. It has already been described in Chapter 12. It is important that the maintenance system should check on external corrosion.

Such corrosion occurs particularly on steel equipment in the temperature range 32–257°F (0–125°C). Below 0°C, the surface is protected by ice, while over 125°C water evaporates. Use of types of mineral wool insulation that are acidic can exacerbate the problem.

There are various forms of corrosion which can occur due to agents other than water. Chloride attack occurs from chlorides which are leached out of some insulation materials. It can also arise from thermal decomposition of polyvinyl chloride (PVC) labels on very hot pipe surfaces. Nitrate attack arises from the use of nitrite treated water on equipment surfaces.

Supports for storage tanks and vessels are a common site of external corrosion.

21.17.4 Pumps and other equipments

Pumps are the source of a large proportion of leaks and fires. A common fault is seal failure with resultant leakage. The leakage often ignites and causes a pump fire. Another frequent fault is a bearing failure, which can induce a seal failure. After a pump fire it is not always easy to tell whether the seal or bearing has failed first.

Reduction of pump failures is partly a matter of design and selection, but maintenance aspects are also important. Many faults can be prevented by a careful overall check when a pump is taken out for other maintenance work.

In addition, it is not uncommon for faults to be introduced in the course of maintenance work. A simple example is misalignment of the impeller shaft when the pump is reassembled. Faults of this kind point to the need for proper systems of work for maintenance and for adequate training. Similar problems arise with other types of equipment.

21.17.5 Small bore connections

Small bore connections are another source of leaks and fires. Such connections are often abused. Heavy pressure gauges or valves may be fitted to them without adequate support. They are frequently over tightened, sometimes with a pipe wrench. People may stand on them to reach isolation valves.

21.17.6 Dead legs

Dead legs in piping systems are where no flow occurs. This can lead to internal corrosion from stagnation or freezing during inclement weather causing leakage. Dead legs should be removed.

21.18 Major Shut-Downs

Two particular kinds of shut-down merit specific mention. These are major scheduled shut-downs and mothballed shut-downs.

21.18.1 Scheduled shut-downs

Most units require a periodic major scheduled shut-down, or turnaround, in order to carry out maintenance and other jobs which cannot be done while the unit is operating. Accounts of turnarounds are given by Vargas (1979), Tropp (1986) and Feuless and Madhaven (1988).

The turnaround arrangements described are broadly as follows. The responsibility for the turnaround is assigned to a turnaround manager. The turnaround passes through four stages: (1) formulation, (2) planning, (3) implementation or execution and (4) start-up.

In the formulation stage, the turnaround manager solicits job requests from the interested parties. Each job is defined, given a priority rating and assigned to a person who is responsible for it. Three levels of priority may be used: (1) the job can be done only during turnaround and has high priority; (2) the job can only be done during turnaround, but is not critical; and (3) the job can, if necessary, be done outside turnaround. The responsibilities for the total set of jobs are spread widely, but for each job there is only one person responsible. A deadline is set a few weeks before the turnaround start date, and thereafter only priority jobs are accepted. A master job list is drawn up and a critical path network developed for each job. The parts and special tools required for each job are identified and the process is begun of obtaining them and transferring them to the tool room or warehouse storage.

Tropp (1986) states that the two faults to which turnarounds are most subject are unsuitable assignment of responsibilities and inadequate exchange of information. The normal roles which people play are often not appropriate to a turnaround. Failure to recognize this is a main cause of communication failures.

He describes a system of categorization of jobs by logical, chronological and priority groups. With regard to the first two, the logical group covers categories such as time, information, safety, manpower, materials, tools, etc., and the chronological group covers those of preparation, implementation and review. He gives detailed responsibility charts for the preparation and implementation stages. Entries in the chart are R, I, C and N for responsible, implement, consult and notify, respectively.

In the planning stage, the overall critical path network is developed together with a bar chart showing the start and end time of each job and the personnel required. A manpower requirements list is drawn up. Computer aids are available to assist in such planning. The plan needs to be flexible and able to accommodate unexpected jobs. Work continues to ensure that the parts and tools required are moved to storage and a parts review is carried out to ensure that nothing is missing.

Throughout the formulation and planning stages, there should be meetings to ensure that all interested personnel understand their role and make an appropriate contribution to the plan.

The job times should be the subject of detailed review by planners/estimators. Planning norms or a library of time estimates may be used. In estimating job, times allowance should be made for the fact that the time spent on turnaround jobs tends to be rather longer than that spent on equivalent routine jobs, and the fact that time is required to obtain materials, to purge and clean, and to await supporting functions such as safety or inspection.

Some of the worksheets developed are illustrated by Vargas (1979) and Feuless and Madhaven (1988). The former also gives a detailed account of the critical path scheduling.

The management of the implementation stage needs to be sufficiently flexible to accommodate the facts that some jobs may reveal problems, that some may take longer than planned, or require parts other than those expected, or that some completely new jobs may need to be done. It is not uncommon for 25% of the jobs done in a turnaround to be identified during execution. A meeting of those concerned is normally held daily to report progress and to modify plans as necessary.

There needs to be a procedure for dealing with those cases where the parts or materials specified are not available and the use of some alternative is proposed. Management of change procedures must be followed. For example, piping in some special steel may be on too long a delivery and there may be an intention to use a substitute material, or the type of pressure transducer specified may be unavailable but another type may be used which is equivalent.

The purpose of the turnaround is to get the work completed and the unit started up again. The emphasis, therefore, should be on the start-up, rather than simply completion of the turnaround.

When the start-up is over, the personnel involved should be debriefed and a report written while matters are still fresh in the mind. In particular, note should be made of times actually taken and the resources used for various jobs and activities, of problems encountered, equipment required, techniques developed or lessons learned, and of jobs which will need to be done in the next turnaround.

As soon as the turnaround is over, preparation for the next one should begin. Many of the jobs for the next turnaround will be based on the work just completed.

21.18.2 Mothballed shut-downs

During an economic recession, the decision may be made to take a unit out of commission and to 'mothball' it, with the intent to recommission it when times are better. Accounts of mothballing, and de-mothballing, are given by Twigg (1985), R.G. Miller and King (1987) and Savage, Portnoy and Parkinson (1988).

Mothballing is applied to a variety of installations and equipment, including oil field production systems, refineries, chemical plants, drilling rigs, oil tankers and special equipment. It is much used for military equipment, including vehicles, ships and aircraft.

The mothballing of entire plants or units is not an exercise to be undertaken lightly and the alternatives of selling or scrapping it should be carefully considered. The circumstances which make decommissioning necessary are attended by a number of problems. Personnel may well be somewhat demoralized. There is uncertainty as to how long the plant will be out of action. There is likely to be pressure to do a cheap job. The staff concerned will generally lack experience of laying up a full installation. The compilation of a complete set of documentation for the equipment is an unattractive chore.

There are a number of factors that affect the way in which the mothballing is done. The length of the shut-down is relevant, since the measures required to preserve the equipment for a few months differ from those required preserving it for 10 years, but is often unknown. The location affects factors such as the climatic conditions and vandalism. A hot, humid site promotes corrosion. A run-down urban area is more prone to theft and damage by outsiders. Some fluids such as seawater and sour gas are more corrosive and some materials of construction such as stainless steel have particular vulnerabilities.

It may not be appropriate to mothball every item. Some items of equipment and much instrumentation are particularly prone to obsolescence. For other items, such as small bore piping and valves, it may be more economic to let them go and replace them when the unit is recommissioned.

There are a number of methods used to guard the equipment against corrosion and other deterioration while it is mothballed. Items of equipment may be removed from the unit and stored after suitable treatment in a warehouse. Measures may be taken to ensure that the fluids in the equipment are benign. Examples are replacing seawater by fresh water, purging with nitrogen and adding an inhibitor to condition vapours. The equipment can be isolated from its environment by the use of various forms of barrier such as: paint, greases and waxes, boxes or bags, or cocoons. Other anticorrosion measures may be taken, such as the use of cathodic protection. Some parts of the unit may be kept in continued operation and some items may be periodically stroked or rotated, as the case may be. Methods particularly favoured by the military are the use of greases and waxes, and of cocooning.

Corrosion is liable to be much higher during a prolonged shut-down than in normal operation. R.G. Miller and King (1987) contrast a storage tank corrosion loss of 3 mpy (thousandths of an inch per year) in normal operation with one of 100 mpy in the shut-down condition, with an associated change from general to pitting corrosion. Corrosion may be worst in summer as warm air is driven out of equipment during the day and cold air with high humidity is drawn back in at night.

Cooling water systems can be troublesome unless suitable precautions are taken. Failure to protect adequately can result in rust and scale blocking of the tubes of heat exchangers all over the plant for months, or even years, after restart.

One form of internal corrosion which often occurs is microbiological corrosion. Precautions against this involve the use of good quality water and of organic biocides. Chlorination of the water tends to be ineffective.

If equipment becomes severely corroded, the penalty can be high. A case is quoted by Miller and King where breaking the line at a spool piece with corroded bolts took a team of 5 men using heavy equipment 5 days.

Two widely used methods of reducing corrosion are the use of dry inert atmospheres in vessels and the coating of surfaces with oil. Corrosion is reduced by the exclusion of oxygen, and filling vessels with nitrogen is an effective anticorrosion measure. The gas should be dry, with a dew point at least 40°F (5°C) below that of the lowest expected ambient temperature.

Oils or oil-based products can be used to reduce corrosion. Refinery equipment is frequently protected by filling it with oil and then running the oil out again. The thin film of oil gives protection until it eventually drains down. Alternatively, surfaces may be coated in oil or grease. Small items may be dipped in oil. Vapour phase inhibitors may be used for areas which are not readily wetted by oils.

The type of protection provided against corrosion may be matched to the intended period of shut-down, if this is known. Twigg suggests that for short period shut-downs, it may often be sufficient to flush and drain, while for longer ones greasing or painting may be necessary. Similarly, Miller and King suggest that for some equipment washing down and coating with diesel oil may suffice for a shutdown of 18 months, while shot blasting and painting may be preferable for one lasting 5 years.

External corrosion is liable to occur under insulation and on equipment supports. Features which promote such corrosion are damage to the insulation and chlorides from the insulation. One policy sometimes adopted to combat external corrosion during mothballing is to remove the insulation completely. Alternatively, if the insulation is not removed, any damage to it should be made good and it should be sealed.

Cocooning involves the use of strippable plastic coatings and gives an enclosure not dissimilar to vacuum packing. It can be very effective provided that moisture is excluded but moisture can pass through due to the breathing of the membranes and corrosion can occur unless the dew point of the air inside is kept low. The coatings have a tendency to come off in high winds.

Valves left unused for long periods are liable to seize up due to the hardening of lubricants. One solution is to remove them to store. Another is to leave them in but maintain and operate them occasionally.

Some parts of the unit may best be preserved by operating them periodically. Savage, Portnoy and Parkinson (1988) describe the preservation of a cooling system by running a high chromate solution through the system once every 2 weeks throughout the mothball period.

Rotating equipment should be turned at intervals to avoid ‘brinelling’. Frequencies recommended are typically in the range 1–6 months, depending on the type of bearings.

Cannibalization of the plant or units should not be permitted. Where there is a protective envelope, breaking in can negate it and lead to severe corrosion. The loss of parts is liable to be disproportionately disruptive when the time comes to recommission the equipment. Moreover, when equipment is removed in this way, damage is frequently done to other items.

The mothballing of equipment does not remove the need to inspect and maintain, or even to operate parts of it. Inspection is still required, but the techniques involved are somewhat different. There is also a need for some degree of maintenance.

A full set of documentation on the plant, and on its operating and maintenance procedures, needs to be compiled. Such documentation is necessary for any equipment, but it is crucial for one which is to be recommissioned at some date in the future by personnel who are likely to be unfamiliar with it. The documentation should include full details of the mothballing itself, of any items removed from the unit and the state of the remaining equipment.

The methods of protection used in mothballing may also be applicable where equipment arrives on site but cannot be installed immediately. Heat exchangers, in particular, are prone to deteriorate rapidly if left unprotected prior to installation.

The problems which arise when demand turns up and de-mothballing can be considered are discussed by Savage, Portnoy and Parkinson. Again, there are often alternatives such as debottlenecking and revamping existing units or building new units, and in view of the problems likely to be encountered in recommissioning, these should be given full consideration. If recommissioning is decided on it may well be combined with modifications to the equipment to achieve better product quality, higher output or improved efficiency. A prerequisite for recommissioning is the retrieval of a full set of documentation on the equipment.

Some items or systems are likely to have suffered considerable deterioration. Some equipment, such as valves, may well need to be reconditioned and some, such as small bore piping, may need to be replaced. Other equipment may need replacement due to obsolescence, which is particularly rapid in some instances, such as the instrument systems, including computers.

It will be apparent from the account just given that in addition to all the usual measures necessary for a commissioning, a recommissioning after mothballing needs to be preceded by an extremely thorough inspection of the equipment and review of the documentation if hazards are to be minimized.

21.19 Maintenance Information Systems

21.19.1 Maintenance information system

Information on equipment failures, repairs, and incidents is needed both for maintenance and safety and loss prevention (SLP) purposes. It should be a specific objective of the maintenance system to generate such information.

The principal data required are those for failure, repair and availability. The data are more valuable if they are of good quality. Failure data should preferably give for each equipment the time to failure in each failure mode rather than overall failure rates. Availability data should give throughput density rather than a single downtime figure. There are also other data which are needed. These include data on leaks and fires and on human errors.

Data on failure and related aspects are essential to the loss prevention approach. The maintenance engineer, therefore, has a crucial role to play here. They should make it their business to have an information system which generates the data. Such data are equally useful, of course, to the maintenance engineer. They normally monitor failures and failure modes at least in a semi-quantitative way, but if higher quality data is available they can analyse it to obtain additional information. Thus an early failure (Weibull parameter, $\beta < 1$) may point to the need for better supervision or training of maintenance workers or for the work to be done under less dirty conditions, while wear out failure ($\beta > 1$) may indicate the possibility of preventive replacement.

21.19.2 Maintenance information feedback

The requirement for failure data is one aspect of the more general need for feedback of information from the maintenance to the design function. This is the theme of terotechnology, which is discussed in relation to maintenance by Husband (1976). Again the maintenance engineer can play a key role in ensuring effective feedback of information and so reducing unreliable and hazardous features, and he should make this a definite objective.

21.19.3 Maintenance policies and effectiveness

The maintenance policies which are followed in a process plant can have a marked influence on its reliability, and availability, and hence its safety and economics. There is, however, no universally applicable policy. The policy appropriate in a given case depends on the failure pattern and the overall situation. Traditional policies have been based on breakdown maintenance and/or scheduled maintenance, and also opportunity maintenance, which are supplemented increasingly by on-condition maintenance and reliability-centred maintenance.

The effectiveness of the maintenance should be monitored using measures suitable for the policy adopted. Maintenance policies and effectiveness have been discussed in more detail in Chapter 7.

21.19.4 Maintenance of protective devices

Maintenance of the protective devices on the equipment is particularly important and should be covered by a formal system with full documentation.

Some of the principal protective devices are:

(1) pressure relief valves;
(2) bursting discs;
(3) tank vents and filters;
(4) other pressure relief devices;
(5) non-return valves;
(6) mechanical trips and governors;
(7) instrument trips;
(8) other instrumentation;
(9) alarm systems;
(10) fire and gas detection systems;
(11) sprinkler systems;
(12) fire water systems.

This list includes not only the more obvious protective devices, such as pressure relief valves, but also some other critical items which are not always thought of as protective devices, such as tank vents.

The maintenance of instrument trip systems is very important. The design of such systems is based on the assumption of proof testing at fixed intervals and is invalidated if this is not done correctly.

It is also important that the other instrumentation be maintained to a high standard. If the general instrument system is allowed to degrade with numerous incorrect measurements, false alarms and control loops on manual, the probability of control errors is greatly increased.

Fire protection equipment should be well maintained so that it is available when required. There have been many instances where equipment has failed to operate, often with serious consequences. Maintenance of such equipment is dealt with in NFPA 25: *Inspection, Testing and Maintenance of Water-Based Fire Protection Systems*.

21.20 Spares Inventory

The control of the spares inventory, or stock control, is of particular importance on process equipments, where the cost of downtime is generally very high. Accounts are given by Alford (1965), Corder (1976), Husband (1976), A. Kelly and Harris (1978), Vargas (1980b) and D.J. Smith (1985a). Generally, the proportion of management effort devoted to spares inventory control is small relative to that given to control of the workforce.

21.20.1 Spares holdings

Policy on the spare parts to be held in stock has to be a compromise between holding a large number of parts in an attempt to provide for virtually every contingency and holding only a small number in order to keep holding costs down. Some studies of maintenance systems have highlighted spares, or lack of them, as the main problem faced by the maintenance function.

Standard methods of stock control are the maximum–minimum level and the economical order quantity methods. The former sets minimum and maximum stock levels together with a reorder level. The economical order quantity for an item is given by the relation

$$Q = (2RP/H)^{1/2} \qquad [21.20.1]$$

where H is the annual cost of holding the item, P is the cost of procuring it, Q is the optimal order quantity and R is the annual requirement. This formula takes no account of the criticality of the item, the lead time for its delivery or of the relationship between the item and other items.

The methods of reliability engineering may in certain cases be used to determine the spares holdings. Some reliability models which may be used for this purpose are described by D.J. Smith (1985a). For an equipment which has n identical parts and a spares holding of r parts and for which the failure rate of these parts is known, the Poisson distribution may be used to determine the probability that over a specified period a situation will arise where the spares have run out. This model assumes that the equipment is a series system with respect to the n parts; it does not take account of any redundancy in the equipment involving some of the n parts or of the time to replace a part. These and other features may, however, be taken into account by the use of Markov models.

It is concluded by Husband that the soundest approach to the use of models may often be to base the holding on Pareto analysis of the main relevant features such as usage, criticality, lead time and cost.

Guidance on spares holdings may be available from the equipment manufacturer in the form of a recommended list of parts to maintain the equipment for a specified period. Such a list will generally be based on the manufacturer's experience and judgement. It may also utilize information on the number of parts which have been supplied to users on request. This information is hard data, but is liable to be incomplete, because many parts are either ordered from other suppliers or fabricated by the user company itself. It may well be, therefore, that better information even on the frequency of demand for particular parts is generated by the maintenance function itself. Certainly, maintenance is in a better position to assess the criticality of items and the lead times.

The level of spares will be affected by the degree of standardization. Indeed, it is a principal aim of standardization to reduce spares holdings.

Another feature affecting spares holdings is the least replaceable assembly. This is the module or part at which during maintenance the process of fault diagnosis terminates and a replacement is made.

Some of the factors relevant to the setting of spares holdings which are unique to a single equipment are the tolerable unavailability of the equipment, the failure frequency of the parts, the lead time and the costs of the parts.

Where spares are common to a number of equipments, the situation may become either more complex or simpler. If the number of other equipments is small and the failure frequency of the parts is low, it may be necessary to consider the set of equipments as a whole and the interaction between them. But if the frequency of demand for the parts becomes high, the simpler treatments such as the Poisson model may well become applicable.

Many accounts of spare holdings treat the demand for spares as a random process. In fact, where preventive maintenance (PM) is practiced, the demand for spares for PM work is more predictable. PM will also identify cases where parts will be needed in the near future.

Management should assess the need to hold slow-moving but critical items, and unjustified pressure to reduce the holding of such an item should be resisted. It may be possible to quantify the probability of requiring such an item and of not having it in stock and the consequences and costs of such a situation. But in any event it may be regarded as an insurance spare.

The spares holdings will be strongly affected by the extent to which a 'just-in-time' policy is practiced. While, in principle, many of the factors just described still apply, the actual values of the optimum spares holdings may be appreciably different.

21.20.2 Stores organization

Features of the spares organization are the stores layout, the stores documentation, the coding system, policies on aspects such as used parts and cannibalization of parts and access to the store. An explicit policy should be formulated for the stores and their organization.

Equipment spares may be grouped either by equipment or by common items, the latter being common to a number of plant equipment, for example bearings and seals. The system may well be a hybrid. There are three main types of item held in a store: equipment spares, consumables and tools.

The stores documentation should be designed to implement the stores policy. An account of typical stores records is given by Corder (1976). Since the use of computer systems is virtually universal in maintenance, the documentation must be compatible.

The system for coding of items is liable to become extremely cumbersome unless it is well designed. Corder gives the example of a bearing made by three bearing manufacturers and installed in the machines of six machine manufacturers, which then may well have 18 different code numbers. He discusses the method of classification and coding designed to overcome this.

It is necessary to establish a policy with respect to used parts. Parts may be reconditioned and returned to the store, but the mixing of used and deteriorated parts with new or as-new parts is not good practice.

A policy is also required on cannibalization. This can be extremely disruptive, which is an argument for prohibiting it. On the other hand, situations are likely to arise where a rigid ban could not only be very costly but could bring the policy into disrepute. It may be judged preferable to have a policy to control it.

Access to the store should be controlled, but in some cases it is policy to provide an open store with free access for minor items, where the cost of wastage is less than that of the control paperwork.

Materials for a major project should be treated separately from those for normal maintenance. Failure to do this can cause considerable disruption to the maintenance spares inventory. In this context a turnaround may count as a major project requiring its own dedicated store, as already described.

21.21 Computer Systems

The use of some form of computer system is virtually universal for maintenance systems on process equipment. Accounts are given by Trotter (1979), Redding (1980), McChrystal (1982), Collington (1989) and Project Software and Development Inc. (PSDI, 1991) and M. Taylor (1991).

Some functions which a computer-based maintenance information system may perform include (1) work orders, (2) planning and scheduling, (3) failure analysis, (4) cost and (5) budget.

Many computer-based systems have started as accounting systems dealing with the costs of maintenance work. Such systems may or may not adapt readily to a wider variety of functions. The constraints which may be posed by an existing system are not considered further here. The maintenance system will link closely with the accounting system.

Another system with which the maintenance system should link, and with which it may well be integrated, is the system for equipment inspection and inspection records.

The design of a computer-based system should start by trying to ensure that the source of data fed to it is of high quality. This is both important and difficult. The people who have most of the information required are the maintenance craftsmen. The problem has traditionally been that these craftsmen are reluctant to spend time on paperwork.

With a manual system, it is difficult to give maintenance personnel much incentive to furnish high quality information. A computer-based system, however, does provide the means of offering such an incentive by creating a system where they have access to information which is useful to them.

The basic building element of a computer-based system, as of a manual one, is the work order. Work orders for regular jobs can be held and orders for new jobs entered. The work order for a particular job will generally contain a wide range of information such as resources (labour and equipment, spares, timing and costs). This provides the basic data for the other features of the system.

Closely linked with the work order is the detailed plan for performing the work. The system facilitates the generation of job plans which give a complete description of the work to be done. This makes it easier to ensure that nothing is missed and that even small issues are corrected before they escalate.

A computer-based system is a natural tool for the planning and scheduling of the work orders. This includes orders both for breakdown maintenance and for PM. Resources such as labour and equipment can be scheduled. Work can be held until material is on-site. Schedules can be developed to accommodate backlogs and priorities.

Failure analysis is another widely utilized function, but the meanings attached to this term vary. It may involve an analysis of the causes, frequency and cost of repairs. Or it may extend to more sophisticated analyses such as Weibull analysis to determine the failure regime.

As already mentioned, cost was one of the first functions. There are a variety of features which come under this heading. Basic features include the cost of labour and parts. For routine jobs, standard cost estimates may be used. More advanced cost features include the handling of depreciation and assisting decisions on repair vs replacement.

Budgetary control is a standard feature, which facilitates not only determination of the budget for some forthcoming period, but control of day-to-day expenditure.

It may be advantageous to order items in a hierarchy within the system so that an overview can be obtained not only of basic elements but also of aggregations which constitute complete equipments or plant functions.

There are a number of pitfalls in the implementation of a computer-based system. One is the input of the initial data. One strategy to ease this task is to identify critical features and enter them, and then to build up the rest as particular jobs arise.

Experience of computer-based systems indicates a number of beneficial effects. One is that effort is freed so that more attention can be devoted to planning and to preventive work. A simple example cited is a reduction in the ratio of breakdown to PM jobs from 0 : 1 to 2.5 : 1. The reduction in the proportion of breakdown jobs means that the maintenance function gets more on top of its work and enters a virtuous circle. As preventive work becomes relatively more prevalent, the timing of such work becomes less critical, since the equipment is a better state of maintenance.

Another important benefit is in increase in the credibility of the maintenance function, because the data is available to support reliable operation. Improved relations with the operations function is another gain, signalled when production take the initiative in asking for equipment to be included in the PM schedule. More generally, an effective computer-based maintenance system becomes an important resource for many other functions, notably those of design and SLP.

The use of a computer-based system to handle the problem of a half-yearly PM whose schedule has slipped is outlined by Collington (1989). He describes in effect the creation of a form of expert system to assist with the current and future decisions.

A description of a particular computer-based system for an LPG terminal has been given by the PSDI (1991).

21.22 Modifications to Equipment

Some work goes beyond mere maintenance and constitutes modification or change. Such modification involves a change in the equipment and/or process and can introduce a hazard. The outstanding example of this is the Flixborough disaster. The Flixborout Report (R.J. Parker, 1975, para. 209) states: ‘The disaster was caused by the introduction into a well designed and constructed plant of a modification, which destroyed its integrity’.

It is essential, for there to be a system of identifying and controlling changes. Changes may be made to the equipment or the process, or both. It is primarily equipment changes which are discussed here, but some consideration is given to the latter.

OSHA PSM 1910.119 (l) requires a written program to manage changes to process chemicals, technology, equipment, procedures and facilities. OSHA PSM 1910.119 (i) also requires a pre-start-up safety review. The control of plant expansions is dealt with in *Major Hazards. Memorandum of Guidance on Extensions to Existing Chemical Plant Introducing a Major Hazard* (BCISC, 1972/11). The hazards of equipment modification and systems for their control are discussed by, Henderson and Kletz (1976) and by Heron (1976). Selected references on equipment modification are given in Table 21.4.

21.22.1 Types of changes

Changes may be classified according to the stage at which they are made:

(1) design;
(2) commissioning;

(3) operating.

They may be distinguished by the degree of permanence:

(1) temporary;
(2) permanent.

These different situations tend to have their own characteristic hazards. Some of these are illustrated by *Case Histories* B52–B56.

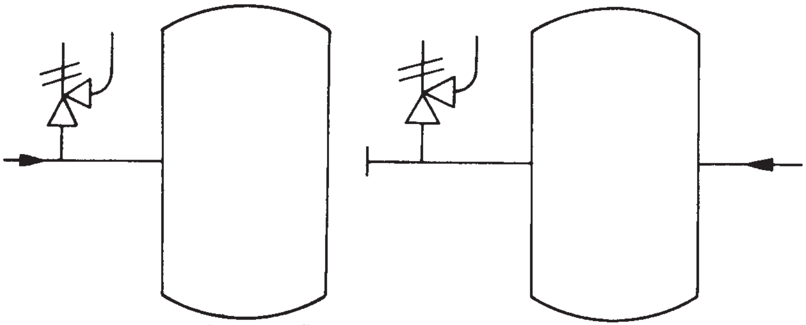
Changes made during the design process really fall outside the present discussion, which is mainly concerned with the stages of commissioning and operation. It is sufficient here to re-emphasize the points already made concerning the need to ensure that at the design stage there is an adequate system of identifying and documenting any changes made. The commissioning stage, and the immediately preceding pre-commissioning stage, is often a period when large numbers of changes are made, frequently under intense pressure. Commissioning changes tend to be aimed at making the equipment work. In the operations stage, the object is rather to keep the equipment going. But again changes may be done under considerable stress.

The scale of changes and the level at which expenditure is approved vary greatly. At one extreme there are minor changes with minimal approval but documentation required by the individual making the change. At the other end are changes requiring approval by senior management. For major changes, project approval is required to control costs and change approval is required to ensure safety. All changes must be managed properly.

21.22.2 Pressure relief and blowdown hazards

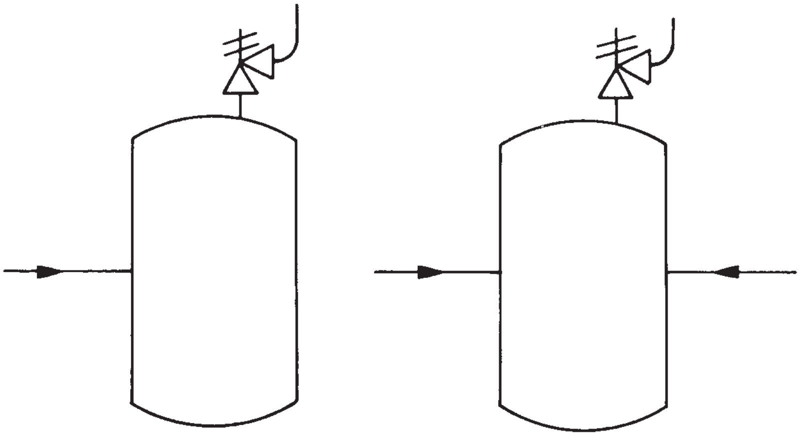
A major hazard which is liable to arise as a result of change and one which is particularly dangerous is the pressure relief and blowdown invalidation. Some illustrations of the way in which this can occur have been given by Henderson and Kletz (1994) and are shown in Figures 21.9–21.11. The situations are self-explanatory.

Another type of change is the de-rating of a equipment to a lower operating pressure. In this case, while the need to



The relief valve was fitted on the inlet branch so that the flow would keep the branch clear

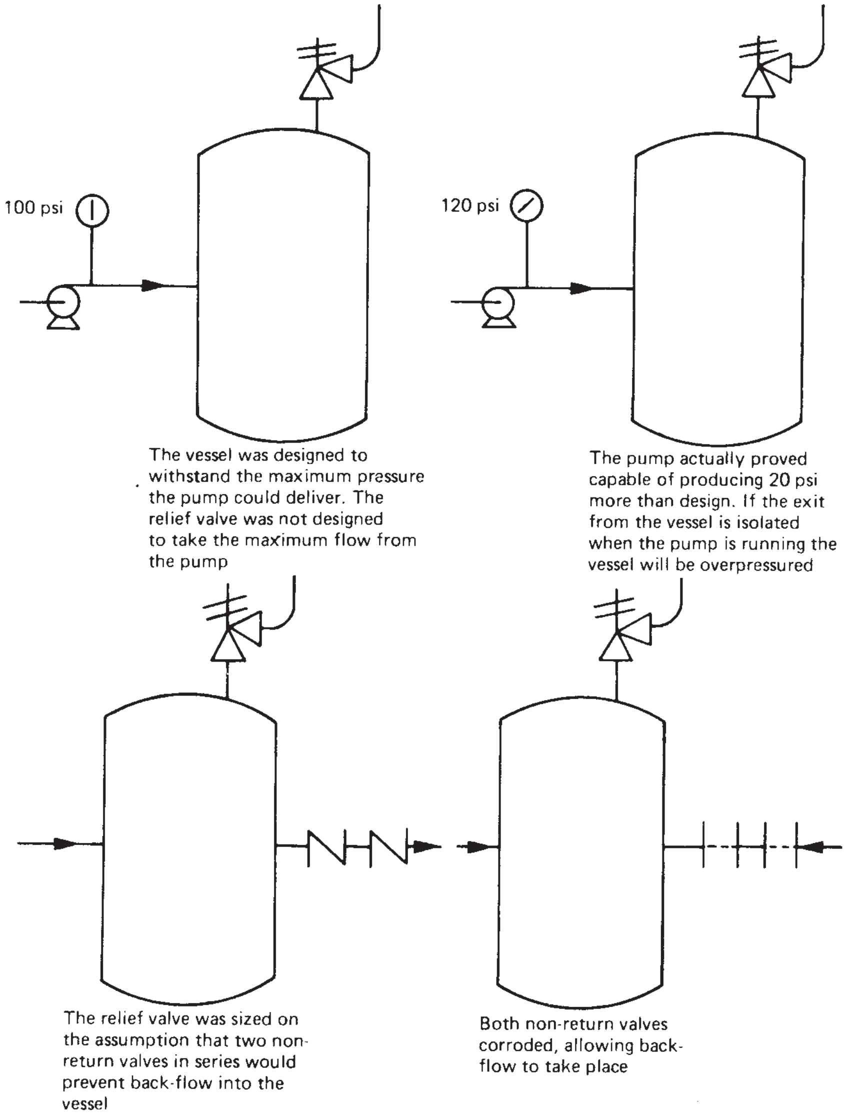
The inlet was moved to a new position leaving the relief valve on a 'dead leg'



The relief valve was sized to take the full inlet flow with all exit lines closed

An extra inlet line was added. If both lines are used together the relief valve will be too small

Figure 21.9 *Modifications invalidating pressure relief arrangements – 1 (Henderson and Kletz, 1976) (Courtesy of the Institution of Chemical Engineers)*



The vessel was designed to withstand the maximum pressure the pump could deliver. The relief valve was not designed to take the maximum flow from the pump

The pump actually proved capable of producing 20 psi more than design. If the exit from the vessel is isolated when the pump is running the vessel will be overpressured

The relief valve was sized on the assumption that two non-return valves in series would prevent back-flow into the vessel

Both non-return valves corroded, allowing back-flow to take place

Figure 21.10 *Modifications invalidating pressure relief arrangements – 2 (Henderson and Kletz, 1976) (Courtesy of the Institution of Chemical Engineers)*

alter the pressure relief valve setting is usually appreciated, it is sometimes forgotten that it is necessary also to check the relief valve capacity, which is reduced by the de-rating. Similarly, an increase in equipment throughput may require a change in pressure relief valve capacity.

The ease with which hazards associated with pressure relief arise mean that the review of pressure relief is particularly important.

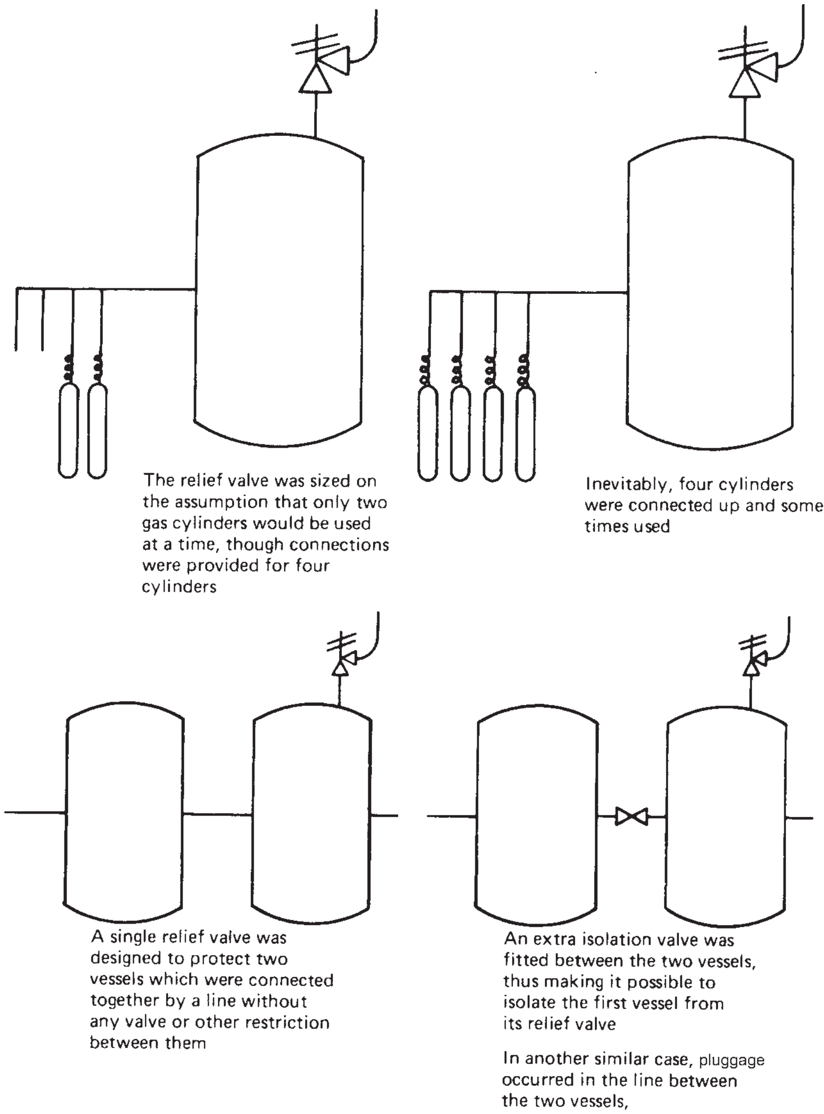
21.22.3 Other hazards of changes

Other hazards which can arise due to changes are exemplified by the case histories given in Appendix 1. Some of the general features from these are considered here.

Changes can invalidate not only pressure relief but also instrument systems. In particular, a situation may be created where an important measurement signal is degraded by the interposition of a restriction, filter, etc. This is illustrated by *Case History* B52.

A common change is the temporary replacement or bypassing of equipment such as a reactor or heat exchanger with a length of pipe. This appears to be a simple matter, but it is still necessary to design the pipe properly and to provide supports. The hazard is shown by the Flixborough disaster.

An alteration of a device which in some way limits flow or pressure can create a hazard. Examples include the removal of a regulator, orifice, etc. installed specifically to



The relief valve was sized on the assumption that only two gas cylinders would be used at a time, though connections were provided for four cylinders

Inevitably, four cylinders were connected up and sometimes used

A single relief valve was designed to protect two vessels which were connected together by a line without any valve or other restriction between them

An extra isolation valve was fitted between the two vessels, thus making it possible to isolate the first vessel from its relief valve

In another similar case, pluggage occurred in the line between the two vessels,

Figure 21.11 *Modifications in validating pressure relief arrangements – 3 (Henderson and Kletz, 1976) (Courtesy of the Institution of Chemical Engineers)*

restrict flow, and the increase in the size of a valve trim or installation of a pump impeller capable of a greater head.

Changes which appear quite minor can nevertheless introduce hazards. Other hazards are listed in the form for the control of modifications shown in Figure 21.12.

21.22.4 Changes to the process

The lesson commonly drawn from the Flixborough disaster is the importance of maintaining the integrity of the equipment and of avoiding degradation due to an equipment change. The equipment can also be put at risk, however, by the operation of the process outside the envelope of operating conditions for which the pressure system is designed. It is essential, therefore, to control such process changes as well.

Moreover, even if the envelope of operating conditions remains the same, a change in operating practice may affect features such as inspection and test intervals, which tend to be based on historical equipment experience.

21.23 Managing Change

The elements of a system for managing change are (1) procedures, (2) assessment, (3) inspection, (4) documentation and (5) training.

There should be a formal procedure which requires all modifications to be authorized by competent persons and a

Safety Assessor date

Checked by Plant Supervisor Checked by Engineer

Figure 21.12 Safety assessment form for plant modification work (Henderson and Kletz, 1976) (Courtesy of the Institution of Chemical Engineers) standard method of making the safety assessment; there should be a system of inspection of changes by a competent person to make sure the work has been done as intended and is complete; there should be a system of documentation to record the change; and there should be adequate training so that all personnel concerned understand the system of control.

OSHA PSM Standard requires a written procedure to manage changes. Several considerations must be addressed:

(1) technical basis;
(2) impact of change on safety and health;
(3) modifications to operating procedures;
(4) necessary time period for the change;
(5) authorization requirements.

Additional management of change (MOC) requirements are:

(1) employees involved in operating and maintaining the equipment shall be informed of, and trained in, the change prior to implementation of the change;
(2) process safety information shall be updated;
(3) operating procedures or practices shall be updated.

21.23.1 Identification of changes;

The identification of changes is a crucial problem. It is necessary, but not always easy, to identify items which in fact constitute changes. This requires that a change be defined. A simple definition of change is any addition, modification or replacement that is not a replacement-in-kind.

The following two-part definition is given by Henderson and Kletz:

(1) Any change in the equipment, temporary or permanent, which may affect the safety of the process or safety and integrity of the equipment. It does not include changes in engineering equipment which are not in contact with the process and cannot affect the safety of the process or the safety and integrity of the equipment.
(2) Any change in process materials, services, operating conditions or operating procedures, and including experimental programmes, which fall outside established practice.

The first part of this definition covers those equipment changes which are normally understood as equipment modifications. The second part brings in the process modifications also.

In the system described by these authors, it is the responsibility of the plant manager and plant engineer to identify modifications.

21.23.2 Authority for changes

Systems for managing change and the levels at which particular types of change can be authorized vary somewhat, but the basic principles are quite clear. There should be a well defined and understood system of authorization.

The system described by Henderson and Kletz (1976) is that any change to equipment or process must be authorized in writing by a competent manager and engineer. This applies to any change, however inexpensive and temporary, as well as permanent changes. The level of authorization is usually the lowest level of technical management. It is important that a proper review is held on every change. A varying group of individuals will be required based on the change being proposed. At a minimum, the operation, process and mechanical personnel should review and approve changes. If the change involves instruments or electrical modifications, an instrument and electrical engineer should also review and approve. The review team should be comprised of the personnel necessary to adequately review the change being proposed. It is essential that these personnel be capable of recognizing problems which lie outside their area of competence and be willing to consult other resources. Modifications proposed are not always necessary. Sometimes the proposal is a symptom of a problem which is better dealt with in some other way. The technique of critical examination, described in Chapter 11 in relation to design, is applicable to modifications also. Questions which may be asked concerning a modification are: Is it necessary? Is it economic? Is there a better alternative?

21.23.3 Design authority

Some changes require complete design by a specialty engineering group. There is a problem area here. Many plants are designed and built by outside contractors, who initially have the greatest expertise about the process and equipment, but also eventually lose touch with it. There is, therefore, typically a transfer of expertise to a design authority within the organization and often outside the company. Plant personnel must assure that design groups adhere to the safety requirements and change policy.

21.23.4 Procedure for changes

The procedure given by Henderson and Kletz requires that before authorizing a modification particular attention should be paid to ensuring that:

(1) The number and size of relief valves required are not changed (or any necessary changes are specified).
(2) The electrical area classification is not changed (or any necessary changes to the electrical equipment are specified).
(3) There are no effects on trips or alarms (or any necessary changes are specified).
(4) There are no other effects which might reduce the standard of safety.
(5) The appropriate engineering standards are followed.
(6) The right materials of construction and fabrication standards are used.
(7) Existing equipment is not subjected to conditions beyond the design basis without checking that it can withstand the new conditions.
(8) Any necessary changes in operating conditions are made.
(9) Adequate instruction and training are provided to operating and maintenance teams.

21.23.5 Safety assessment of modifications

The above procedures need to be supplemented by a system for the identification of hazards in the modification. The method described by Henderson and Kletz makes use of the safety assessment form shown in Figure 21.12. The form is best completed not by a single individual but by two or three people working together. The top half of the form provides check words which form the basis for a hazard and operability study and the bottom half gives a more conventional checklist. A similar assessment checklist and guidance is provided in CCPS, AIChE: *Guidelines for Hazard Evaluation Procedures*.

It is found helpful in making the safety assessment to assume that, until it is shown otherwise, any isolation valve or other restriction will isolate an equipment from its protective device, for example a vessel from its relief valve, and that any new line will introduce some unwanted contamination, overpressure of some equipment or more flow into some equipment than its outlet pipes can handle.

This procedure, therefore, makes use of a standard form to initiate a safety assessment which goes beyond the use of a checklist.

21.23.6 Inspection of modifications

It is the responsibility of the person authorizing a modification to carry out a pre-commissioning inspection of that modification and to satisfy himself that it is in accordance with the design intent, that the standards for design, construction and testing have been followed, that the provisions of the safety assessment have been met and that the work is complete.

21.23.7 Documentation of modifications

It is essential that equipment documentation be kept up to date and therefore that any modification be recorded. This requirement may be met by the use of a formal change procedure. If the modification requires alterations to operating or inspection practices, it is necessary that the appropriate changes be made in the documentation covering these aspects.

21.23.8 Training on modification systems

A system for the control of modifications can only work if all the personnel involved are aware of and have an understanding of the system through training. The process operator who may turn off an agitator, the maintenance fitter who may blind off a vent, and the instrument technician who may alter a trip setting, all need to be aware of the hazards which these types of modification may involve and of the system of control of modifications.

The plant supervisors and engineers who authorize modifications need to have the theoretical knowledge, general practical experience and experience of the particular process and equipment to recognize potential hazards, and also to appreciate situations where they should call in expert assistance.

21.23.9 Commissioning modifications

The commissioning stage tends to involve numerous modifications at a time when the plant staff are heavily loaded. It may be appropriate, therefore, to appoint special personnel to check these modifications. People who have been involved in hazard identification during the design stage may well be suitable for this task. It is also advisable to conduct a post-commissioning check of the pressure relief and blowdown arrangements about a year after start-up.

21.23.10 Variations in modification control

The system for control of modifications just outlined is essentially that described by Henderson and Kletz, and is intended primarily for larger continuous petrochemical plants. Other systems may be more appropriate for other types of equipment, although the basic principles remain applicable.

21.24 Some Modification Problems

21.24.1 Design codes and standards

Like equipment design, change should be done in accordance with applicable standards or codes. Design standards or codes are not applied retrospectively to existing equipment and its changes.

There is a problem, however, which arises from the nature of the advanced codes such as the ASME *Boiler and Pressure Vessel Code*, Section VIII, Division 2, BS 5500, and earlier BS 1515. The design criteria in such codes are quite complex, may require analysis of stress concentration sites, of fatigue and creep and assume finite equipment life. Design according to these codes is a specialist matter. Expert advice is necessary for any change to equipment designed to codes. Moreover, such advice may well be required in some cases for repairs on such equipment.

21.24.2 Repair and modification codes

The main guide for equipment repairs and modifications is API RP 510: *Inspection, Rating and Repair of Pressure Vessels in Petroleum Refinery Service*. API RP 510 gives an account of its origin as a complement to the ASME *Boiler and Pressure Vessel Code* before Section VIII of the latter was split into two divisions. The ASME *Code* is written for new construction. With respect to repair or modification, RP 510 states that where due to its new construction orientation the ASME *Code* cannot be followed, RP 510 has precedence.

21.24.3 Materials aspects

The materials for changes or repair should be 'suitable' and should have properties at least equal to that of the parent material originally used. If the codes apply, the materials should have guaranteed minimum properties and should be so certified. It is also necessary that both parent and replacement materials should be capable either of withstanding the fabrication processes without losing their required properties or of having these properties restored.

The availability of suitable materials may be a problem, either because a material is no longer made or because delivery times are long.

The parent material is sometimes degraded and may require treatment before welding can be done on it. Thus, for example, if there is surface sulfur contamination, it may be necessary to remove the contamination by grinding and then to preheat to allow welding. In some cases, the parent metal may have been rendered unweldable by high temperature exposure or hydrogen attack.

The application of quality control procedures can give rise to difficulties. There has been continuous progress in the measurement of defects in materials and in acceptance standards. The situation can easily arise, therefore, where the quality demanded for the replacement materials far exceeds that of the original equipment material.

The properties of both parent and replacement materials may be affected by activities such as cold working, preheating or welding. Material properties may be restored to some extent by suitable heat treatment, but the heat treatment operations which can be carried out are strictly limited.

21.25 Major Plant Expansions

Major plant expansions are in large part covered by the procedures for design, on one hand, and for change on the other. Nevertheless, such major expansion merits at least brief consideration in its own right. Reference has already been made to the British Chemical Industry Safety Council publication on plant extensions (BCISC, 1972/11). The control of major extensions is discussed by K. Wood (1971).

21.25.1 Design of changes

A major expansion involves changes on a greater scale than a normal equipment modification. This means that it is particularly necessary to check on the various facilities which may become inadequate or overloaded as a result of the expansion. Some features of the design which should be checked with this in mind are: (1) pressure relief valves; (2) vent, flare, blowdown and absorption systems; (3) drains and sewers and (4) safety trip systems.

The design, location and capacity of the pressure relief valves should be checked and sufficient spares provided. A review should also be made of the need for liquid thermal relief on long sections of off-site piping which could be blocked in.

The facilities for gas and vapour relief, for flaring, for liquid blowdown and for emergency absorption should be checked.

The check on sewers and drains should cover not only the capacity of the underground sewers, but also that of the surface drainage so as to ensure disposal of fire water.

A major expansion also involves more extensive changes of equipment configuration. It is particularly important, therefore, to check not only that there are suitable safety trip systems on the expansion itself, but that those on the existing equipment are also still appropriate.

21.25.2 Layout for expansions

The problems of piping work during the expansion should be given special attention. The number of live pipelines passing through the non-operating areas should be kept to a minimum. Despite the best safe-working procedures, incidents are frequent in which live lines are broken or cut open by construction personnel.

Utilities lines should be isolated from the non-operating area by block valves. Sewers should also be isolated from the non-operating area, since they present the hazard that flammable gas may flow through them from the operating into the non-operating area. Sewers should be isolated completely.

There should be adequate provision of blind points to permit pre-commissioning testing of equipment such as compressors on air or gas recycle, while maintaining isolation of the non-operating areas from flammable gas and utilities.

21.25.3 Safe-working procedures

A major expansion usually means that there are on site a large number of contractors' personnel. This situation is a particularly severe test of the safe working procedures and the normal procedures should be reviewed to check that they are adequate.

The original equipment usually continues in operation while construction work is in progress on the expansion. It then shuts down so that it can be tied in to the expansion facilities. It is necessary to control work in the non-operating area closely, so as not to interfere with the operating unit, and it is desirable that if it is necessary to carry out gas-freeing operations on shut-down, then hot work in the non-operating area should cease until this has been done.

The permit system is usually that in normal use. But the number of permits issued is likely to increase greatly and operations personnel may need to be assigned full time to analytical testing of atmospheres and issuing of permits.

In these circumstances, the identification of equipment becomes even more important. Permits should specify clearly the equipment to be worked on and there should be positive identification of equipment. A colour code agreed with the contractors may be used as an additional means of identification. Pipelines and equipment in the non-operating area which are live should be clearly marked with an agreed code, colour and tags.

It is necessary to ensure that the contractors' blinds are kept separate. The contractors blinds should be uniquely identified (physical features, colour, etc.) to distinguish them from normal facility blinds. Furthermore, there should be an instruction that neither party must remove the other's blinds. Incidents occur in which contractors' personnel remove blinds from live lines. As mentioned earlier, in some permit systems a separate permit is needed for the insertion or removal of blinds. This is particularly appropriate for work on major expansions.

There is need for an alarm system to cover the hazard of flammable gas release from an operating unit while hot work is being done in the non-operating area. Personnel in the non-operating area should be instructed to stop hot work when the alarm is raised. The normal alarm system should also be explained to them.

The hazard of illicit smoking should be reduced by the only effective means available, which is the provision of smoking areas.

The personnel involved in the expansion should be given training on the hazards and procedures.

Storage

Contents

By far the largest quantities of chemicals are found in storage facilities, which may be at chemical plants or in other storage terminals. The prevention of loss in storage is therefore extremely important.

It has long been appreciated that loss of containment from storage of toxic chemicals could have particularly serious consequences. The hazard of toxic release has been considered, therefore, in some detail in Chapter 18. The hazard was realized at Bhopal, which was the worst disaster which has ever occurred in the chemical industry. A toxic release with consequences on this scale, or anything approaching it, is extremely rare and stringent measures are taken to avoid it.

Losses through fires in storage, on the other hand, constitute a major part of the losses sustained by the industry. Mostly these result in financial loss rather than loss of life and tend to make relatively little public impact. But there are exceptions such as the disasters at Feyzin, Caracas and Mexico City.

Some idea of the potential for fire loss may be obtained by considering the value represented by a single storage tank. A 'jumbo' tank might contain 500,000 barrels of oil worth US$10 per barrel and might itself be worth US$4 per barrel capacity, making a total value of US$7 million (OIA, 1975 Loss Control Bull. 400–1). Jumbo tanks of from 300,000 to 1,000,000 barrels capacity are currently being used to store not only crude oil but also flammable intermediate and finished products.

Storage is one of the areas in which there is a good deal of legislation. This was described in Chapter 3.

Much storage is sited in or near urban areas. It is generally reckoned to be relatively safe and unlikely to cause large loss of life, but it is nevertheless a source of some public concern. There is, therefore, the problem of siting and of the relation between siting and preventive measures. This aspect is considered in Chapter 4. Storage is frequently one of the topics dealt with under the headings of plant siting and layout, and some aspects of storage have been considered in Chapter 10.

The location of storage in relation to the process is also important. Storage is most likely to be put at risk by a process. It is necessary, therefore, for the two to be segregated. This reduces the risk of a process incident hazarding the very large inventory in storage. It also makes it less likely that a minor incident in storage will put the process at risk.

There are numerous standards and codes of practice which are applicable to storage. The treatment of storage given here attempts to outline some of the principles described in the codes. There are differences, however, between codes and there are critics of the codes, and some of these points are mentioned also. The practices described should be regarded only as typical. In particular, the codes themselves should be used for design work.

Safety in storage is as much a matter of operation and maintenance as of design. Some aspects of operation and maintenance of storage were discussed in Chapters 20 and 21, respectively.

Good operation and maintenance depend on an effective management system. While it should be possible to assume that such a system exists in a large chemical works, there is potentially a problem in situations where products such as liquefied petroleum gas (LPG) or chlorine are stored and used in non-chemical and low technology industries. In this case, a particular responsibility rests on the supplier of the chemical to advise the user.

There is no UK code specifically for the storage of chemicals in general except insofar as these are covered by codes for petroleum products, flammable liquids, LPG and liquefied flammable gas (LFG), but there are codes for a number of individual chemicals.

The treatment given here deals in turn with the storage of flammable materials, the storage of toxic materials, loading and unloading facilities, drum and cylinder storage and warehouses. It also describes case histories and hazard assessments of storage.

Selected references on storage of hazardous materials are given in Table 22.1.

Roberts (1990); Chidambariah *et al.* (1991); Nejedly, Topinka and Skarka (1992)

22.1 General Considerations

22.1.1 Purpose of storage

The purpose of storage is to smooth fluctuations in the flows in and out. If the quantity in stock does not vary, there is no point in having storage. The exception is where the storage is held purely as an insurance.

Thus, there may be various ways of satisfying the design objective. The types of storage, which are economic in these alternative designs, may be different and may have different safety implications also. There may be considerable differences, for example, in the pressure and in the inventory. An account which illustrates the interaction between storage requirements and storage method is given by Hower (1961).

22.1.2 Storage conditions

The main sets of conditions for gas or liquid storage are

(1) liquid at atmospheric pressure and temperature (atmospheric storage);
(2) liquefied gas under pressure and at atmospheric temperature (pressure storage);

(3) liquefied gas under pressure and at low temperature (refrigerated pressure storage, semi-refrigerated storage);
(4) liquefied gas at atmospheric pressure and at low temperature (fully refrigerated storage);
(5) gas under pressure.

The fluids so stored are referred to for convenience as (1) volatile liquids, (2) flashing liquefied gases, (3) semi-refrigerated liquefied gases, (4) refrigerated liquefied gases and (5) gases under pressure, respectively.

The characteristics of these different types of storage have been discussed in Chapter 15. A leak of volatile liquid held at atmospheric temperature and pressure results only in a relatively slow evaporation of the liquid. Escape of a refrigerated liquefied gas at atmospheric pressure gives some initial flash-off and then an evaporation which is relatively slow but faster than the first case. Loss of containment of a liquefied gas under pressure and at atmospheric temperature, however, causes immediate flashing of a large proportion of the gas, followed by a slower evaporation of any residue, and is usually much the most serious case. The hazard from a gas under pressure is normally much less in terms of the amount of material held, but the physical energy released if a confined explosion occurs is large.

The economics of storage of liquefied gases are that it is usually attractive to use pressure storage for small quantities, pressure or semi-refrigerated storage for medium to large quantities and fully refrigerated storage for very large quantities.

It is generally considered, however, that there is a greater hazard in storing large quantities of liquefied gas under pressure than at low temperature, so that the trend is towards replacing pressure storage by refrigerated storage for large inventories.

22.1.3 Storage capacity

Methods of the estimation of the capacity of particular types of tank or vessel are given by Santi (1979) and Gallagher (1983).

22.1.4 Storage hazards

The hazards presented by storage depend on the material and on the type of storage. In broad terms, the principal hazardous events are as shown in Table 22.2, Section A. Some principal initiating events are given in Section B of the table.

On very rare occasions, a vessel or tank fails catastrophically. This may occur due to mechanical or metallurgical defects. The vessel or tank may be overpressured by overfilling. A tank may be overpressured by too rapid filling and underpressured by too rapid emptying. Other causes of tank failure are given in Chapter 20.

More commonly, release occurs from other equipment or from pipework or fittings. Equipment which may leak includes, in particular, pumps. Release from pipework may occur due to a crack or pinhole or by full bore rupture, or by a leak or failure at a flange, gasket or valve.

Release may occur due to an explosion in the tank or vessel. There are various ways in which this can happen. One is physical overpressure which causes the vessel or tank to burst. Another is the ignition of a flammable mixture. Another is evolution of gas due to the reaction of an impurity, material of construction, etc. A fourth is a runaway reaction within the vessel or tank.

Fire at a vessel or tank can cause it to fail. The fire may be a fire beneath it or a jet flame playing on it.

An operational activity which may cause either direct release or vessel or tank rupture is overfilling. Other operational events which may give rise to a release include draining and sampling operations. Maintenance activities may result in a release, generally by admission of fluid to a section which is not fully isolated.

Impact events which may cause loss of containment from a storage include impact from a carried item, a dropped load, a vehicle or an aircraft. A missile from an explosion is another form of impact, but is primarily an escalating rather than a true initiating event.

Natural events which may cause loss of containment include high winds, rainstorms, flooding, tsunamis and earthquakes, whilst lightning may start a fire.

Arson or sabotage are other causes of hazardous events. Sabotage may take the form of interference with the plant or direct initiation by impact, fire or explosion.

22.2 Petroleum Products Storage

It is convenient to start with a consideration of the storage used in the oil industry for crude oil and petroleum products.

There exist a number of standards and codes for the storage of petroleum products and flammable liquids generally. Standards and codes include API Std 620: 1990 *Design and Construction of Large, Welded, Low-pressure Storage Tanks* and Std 650: 1988 *Welded Steel Tanks for Oil Storage*, NFPA 30: 1990 *Flammable and Combustible Liquids Code* and the *Refining Safety Code* of the IP (1981 MSCP Pt 3). HSE guidance is given in HS(G) 50 *The Storage of Flammable Liquids in Fixed Tanks (up to 10,000* m^3 *Total Capacity)* (1990) and HS(G) 52 *The Storage of Flammable Liquids in Fixed Tanks* (Exceeding 10,000 m^3 Capacity) (1991).

Storage of petroleum is discussed here under the following headings:

(1) storage tanks and vessels;
(2) storage layout;
(3) venting and relief;
(4) fire prevention and protection.

These are now considered in turn.

22.3 Storage Tanks and Vessels

The main types of storage tanks and vessels for liquids and liquefied gases are (1) atmospheric storage tanks, (2) low pressure storage tanks, (3) pressure or refrigerated pressure storage vessels and (4) refrigerated storage tanks.

The API standards for storage tanks are API Std 620: 1990 *Design and Construction of Large, Welded, Low-pressure Storage Tanks* and Std 650: 1988 *Welded Steel Tanks for Oil Storage*. Relevant British Standards are BS 2594: 1975 *Specification for Carbon Steel Welded Horizontal Cylindrical Storage Tanks* and BS 2654: 1989 *Specification for Manufacture of Vertical Steel Welded Non-refrigerated Storage Tanks with Butt-welded Shells for the Petroleum Industry.*

Some of the main types of storage tanks and vessels are shown schematically in Figure 22.1 and are illustrated in Figures 22.2–22.5. Fuller descriptions and illustrations of storage tanks and vessels are available in various sources (e.g. J.R. Hughes, 1970; API, 1981 *Refinery Inspection Guide*, ch. 13; HSE, 1973 HSW Bklt 30). Tanks and vessels for the

Table 22.2 Some principal hazardous events and initiating events for storage

A Hazardous events

Materials	*State*	*Storage*	*Hazardous events*
Flammable	Liquid	Atmospheric	Liquid release, then Tank or bund fire Tank explosion, then Tank or bund fire
	Liquefied gas	Pressure	Flashing liquid release – flammable vapour cloud, liquid pool, then Pool fire Running liquid fire Jet fire Vapour cloud fire Vapour cloud explosion Fire engulfed vessel, then Jet fire BLEVE
	Liquefied gas	Refrigerated	Flashing liquid release – flammable vapour cloud, liquid pool, then Tank or bund pool fire Running liquid fire Vapour cloud fire Vapour cloud explosion Fire engulfed tank, then Tank or bund pool fire Running fire
Toxic	Liquid	Atmospheric	Liquid release, then Toxic gas cloud Tank explosion, then Toxic gas cloud
	Liquefied gas	Pressure	Flashing liquid release – flammable vapour cloud, liquid pool, then Toxic gas cloud Fire engulfed vessel, then BLEVE Toxic gas cloud
	Liquefied gas	Refrigerated	Flashing liquid release – flammable vapour cloud, liquid pool, then Toxic gas cloud Fire engulfed tank, then Toxic gas cloud

B Initiating events

Catastrophic failure of vessel or tank
Failure of or leak from other equipment, pipework or fittings
Explosion in vessel or tank
Fire engulfing vessel or tank
Jet flame playing on vessel or tank
Overfilling of vessel or tank
Release occasioned by operations
Release occasioned by maintenance
Impact event
Natural event
Arson, sabotage

storage of LPG, liquefied natural gas (LNG), ammonia and chlorine are considered further below.

22.3.1 Atmospheric storage

Some typical atmospheric storage tanks are shown in Figures 22.1(a–f). Figure 22.1(a) is a horizontal cylindrical tank. These tanks usually have riveted flat or welded dished ends. Figures 22.1 (b) and 22.1 (c) are vertical cylindrical fixed tanks with coned and domed roofs, respectively. Figures 22.1(d) and 22.1(e) are, respectively, another larger fixed roof tank and a large floating roof tank. Figure 22.1 (f) is a vapour dome tank with a flexible diaphragm in the dome.

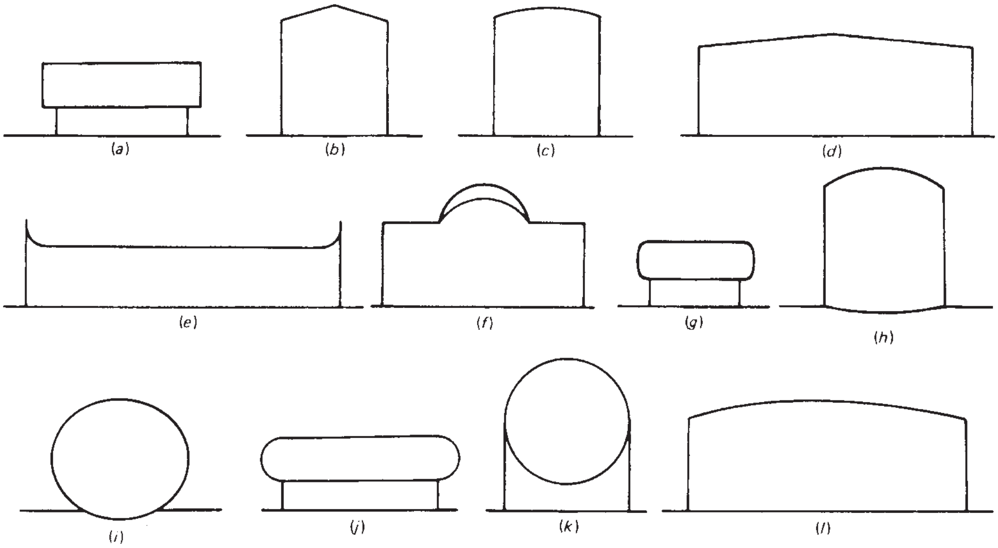

Figure 22.1 *Storage tanks and vessels: (a) horizontal cylindrical atmospheice tank; (b) vertical fixed roof atmospheric tank (coned roof); (c) vertical fixed roof atmospheric tank (domed roof); (d) vertical fixed roof atmospheric tank (large coned roof); (e) vertical floating roof atmospheric tank; (f) vapour dome atmospheric tank; (g) horizontal cylindrical low pressure tank; (h) vertical cylindrical hemispheroidal low pressure tank; (i) spheroidal low pressure tank; (j) horizontal cylindrical pressure vessel; (k) spherical pressure vessel (Horton sphere); (l) vertical fixed roof refrigerated atmospheric tank (domed roof)*

Atmospheric tanks are designed to withstand an internal pressure/vacuum of not more than 1 psig (70 mbar). Further details are given below.

Horizontal cylindrical tanks have a relatively small capacity. Domed roof tanks go up to about 60 ft (20 m) diameter. Coned roof tanks are built up to 250 ft (76 m) diameter and 60 ft (20 m) height. Floating roof tanks may be 250 ft (76 m) in diameter and 72 ft (22 m) high.

In a floating roof tank, the roof floats on the surface of the liquid. There are different kinds of floating roof such as the pan, annular pontoon and double-deck types. The two latter have a double layer at the annulus and over the whole area, respectively, and therefore have greater buoyancy than a pan roof. Sealing between the floating roof and the tank wall is effected by a number of means such as spring-loaded fabric or rubber tube seals. In addition, a floating deck may also be used inside a fixed roof tank. Its main purpose is the reduction of vapour loss.

A traditional divide between the different sizes of storage tank is a nominal capacity of 12,000 UKgal (55m^3), which has corresponded to the approximate limit of shop fabrication. The design of petroleum storage tanks up to this capacity is governed by BS 799: 1972 – Oil Burning Equipment. Another applicable standard is BS 2594: 1975, which covers tank sizes both below and above 12,000 UKgal.

Large petroleum storage tanks are normally site erected and of mild steel welded construction. The design, fabrication, erection, inspection and testing of these tanks is specified in API Std 650: 1988 and BS 2654: 1989.

For fixed roof tanks, a traditional distinction (see BS 2654: 1961; J.R. Hughes, 1970) has been between 'non-pressure' and 'pressure' tanks. For tanks up to 128 ft diameter, non-pressure tanks were designed for an internal pressure of 3 in. WG (7.5 mbar) and a vacuum of 2½ in. WG (6 mbar) and pressure tanks for an internal pressure of 8 in. WG (20 mbar) and 2½ in. WG (6 mbar) plus superimposed load. The user was allowed to specify, however, an internal pressure greater than 8 in. WG. Pressure tanks up to 64 ft could be designed up to 21½ in. WG (54 mbar) provided the allowable stress did not exceed that given in the standard.

The designation of atmospheric storage tanks with a design pressure well below 1 psig as 'pressure' tanks is a possible source of confusion. As described below, there are other tanks designed for the low pressure range 0.5–15 psig which are termed 'low pressure'.

Non-pressure tanks are normally vented by an atmospheric vent and pressure tanks by a breather vent, as described below. Non-pressure tanks tend to have relatively high vapour losses from the 'breathing' of the vent. Pressure tanks with breather vents reduce these losses but are limited in diameter. Floating roof tanks provide an alternative which has low vapour losses and is available in large sizes.

The definitions of storage tanks now recognized in BS 2654: 1989 are somewhat different. The standards defines three categories of tank: (1) 'non-pressure' tanks designed for an internal pressure of 7.5 mbar (4 mbar for column-supported roofs) and a vacuum of 2.5 mbar; (2) 'low-pressure' tanks designed for an internal pressure of 20 mbar and a vacuum of 6 mbar and (3) 'high-pressure' tanks designed for an internal pressure of 56 mbar and a vacuum of 6 mbar. The maximum design pressure covered by the standard is thus 56 mbar (0.81 psi). BS 2654 also covers floating roof tanks.

(b)

Figure 22.4 *Large storage complexes, including: (a) cone roof and floating roof tanks and spherical pressure vessels (Chicago Bridge and Iron Co.); (b) cone roof tanks, spheroidal vessels and cylinderical pressure vessels (Chicago Bridge and Iron Co.)*

Atmospheric tanks are used for the storage of liquids at ambient temperature and also for the storage of refrigerated storage liquids, as described below.

22.3.2 Low pressure storage

Some typical low pressure storage tanks are shown in Figures 22.1(g–i). Figure 22.1(g) shows a horizontal cylindrical tank with dished ends. Figure 22.1(h) shows a vertical cylindrical hemispheroidal tank. Figure 22.1(i) shows a spheroidal tank which has the shape of a squashed sphere. The two latter types are also made in noded as well as plain versions.

Low pressure tanks are designed to withstand internal pressure in the range 0.5–15 psig. The design of low pressure tanks is governed by API Std 620.

Low pressure tanks are suitable for the storage of liquids which are too volatile for atmospheric storage. Gasoline is a typical petroleum product to which this applies. Use is also made of low pressure tanks in refrigerated storage, as described below.

22.3.3 Pressure and refrigerated pressure storage

Some typical pressure storage vessels are shown in Figures 22.1(j) and 22.1(k). Figure 22.1(j) shows a horizontal cylindrical pressure vessel and Figure 22.1(k) a spherical pressure vessel, or Horton sphere.

Pressure storage vessels are regular pressure vessels and can be designed to high pressures as required. The lower end of the scale for pressure storage is 15 psig.

In the United States, the design of pressure vessels is governed by the American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code*, Section VIII (1991) and by API Std 2510: 1989 *Design and Construction of Liquefied Petroleum Gas Installations (LPG)*. The British Standards for pressure vessel design were BS 1500: 1958 and BS 1515: 1965–, which have been superseded by BS 5500: 1991, introduced in 1976. Pressure vessels have been discussed in Chapter 12. Horizontal cylindrical vessels have a relatively limited capacity and for large quantities spheres are used.

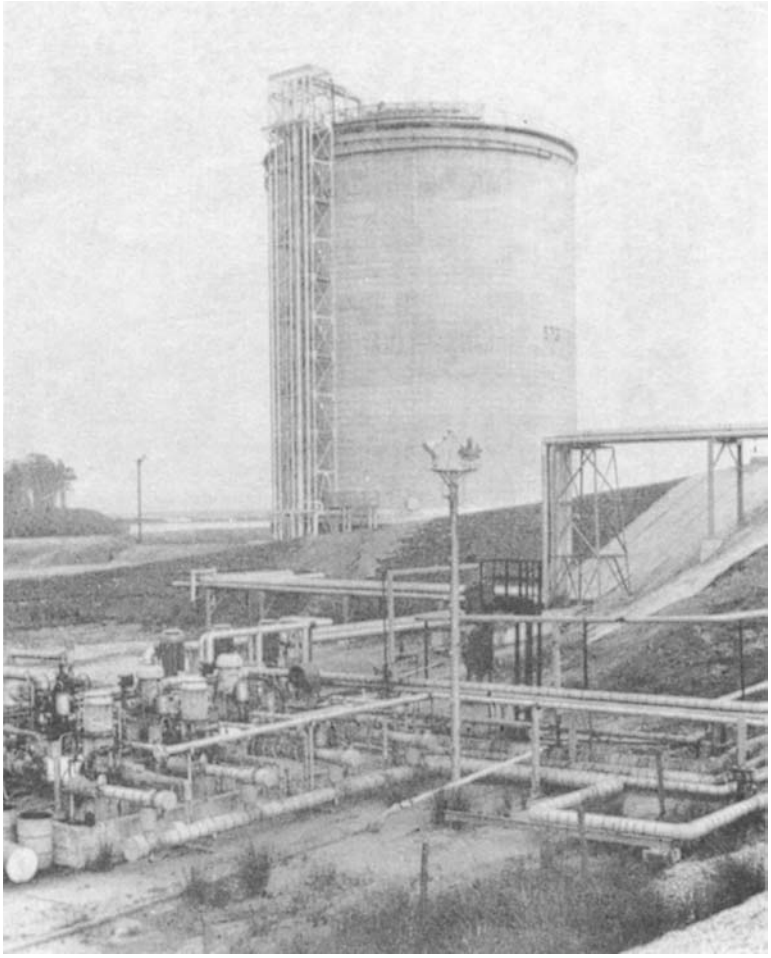

Figure 22.5(a) *Refrigerated atmosphere storage tank for liquid propane (Whessoe Ltd)*

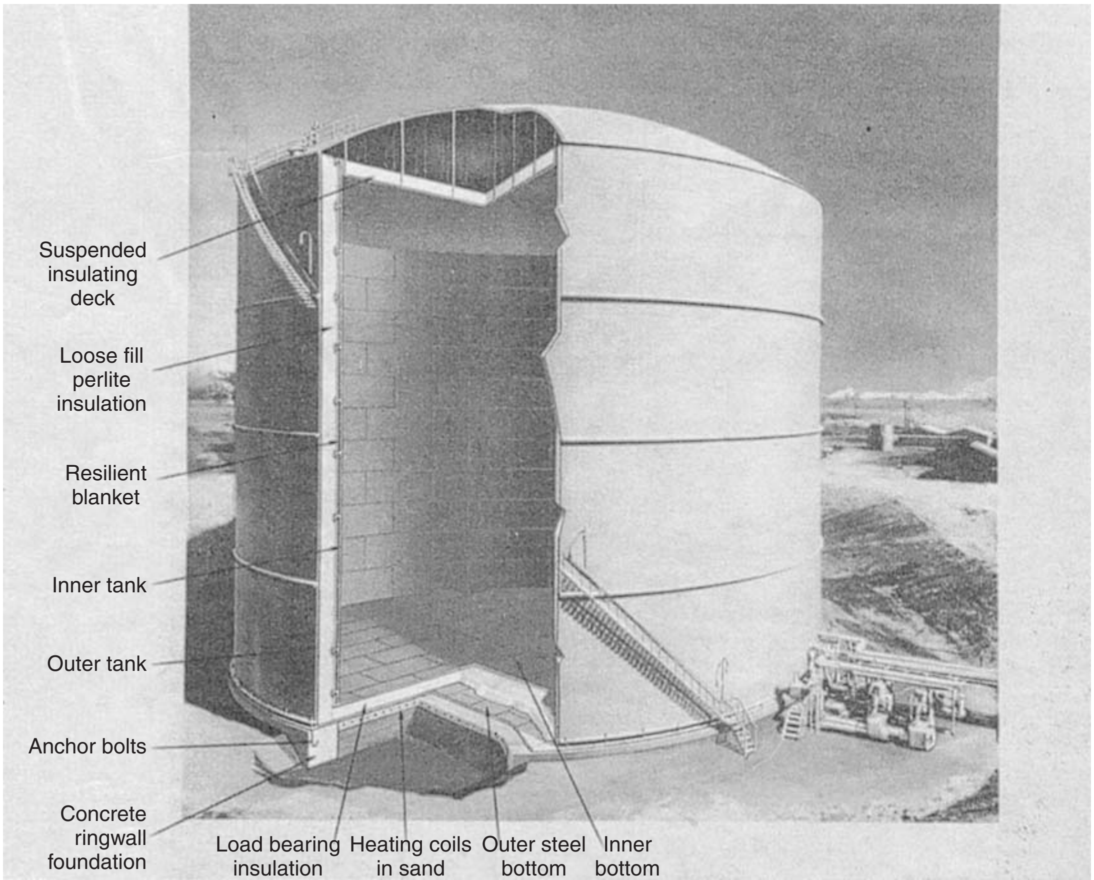

Figure 22.5(b) *Refrigerated atmospheric dome roof double wall tank for LNG (Chicago Bridge and Iron Co.)*

Spherical pressure vessels have a number of advantages. The surface to volume ratio is minimal and only 88% of that of a vertical cylindrical tank, which reduces heat leak. The foundation structure is simpler and there is no danger of soil freezing. The stresses under low temperature conditions are easily determined.

Pressure storage vessels are suitable for the storage of liquefied gases such as LPG and ammonia. Pressure storage vessels are also used for refrigerated pressure, or semi-refrigerated, storage.

22.3.4 Refrigerated storage

A typical refrigerated storage tank is shown in Figure 22.1(1). This is a domed roof, flat bottomed tank. It is essentially an atmospheric tank, with a design pressure below 1 psig. Low pressure tanks may also be used for refrigerated storage.

22.3.5 Concrete storage tanks

The need for very large storage capacities for LNG has led to the development of pre-stressed concrete storage tanks which are protected by an earthen embankment, or berm, and are internally insulated.

22.3.6 Underground cavity storage

Underground cavities may also be used for storage. Natural gas has been stored for many years in underground reservoirs, which are frequently depleted oil or gas fields. Use may also be made of such man-made cavities as worked-out salt formations or mined cavities to store gases. The well is usually operated with a brine system, but dry wells are possible also.

22.3.7 Earth pit storage

A method of storing LNG in pits, where a hole was excavated and the surrounding earth then frozen, was developed and used but the operating problems were such that it has fallen into disuse.

22.3.8 Gas storage

Gasholders are used to store gases such as hydrogen and acetylene close to atmospheric pressure. Storage of gas under pressure is usually done in gas cylinders or horizontal cylindrical pressure vessels. As already mentioned, gas may also be stored in underground cavities.

22.3.9 Glass reinforced plastic tanks

Widespread use is now made of vessels and tanks made of glass fibre reinforced plastic (GFRP), also known as glass reinforced plastic (GRP), fibre reinforced plastic (FRP) or fibreglass. GRP tanks are widely used to store corrosive materials. They are considered further in Section 22.23.

22.4 Storage Layout

The siting and layout of storage in relation to the process are discussed in Chapter 10. Here the layout within the storage area is considered.

As mentioned in Chapter 10, the storage, process and terminals should be suitably arranged relative to one another, an appropriate layout being one in which the storage is located between the process and the terminals. The storage should be built on ground able to support the heavy load involved and with ground contours and wind characteristics which minimize the hazard of flammable liquid or vapours from storage collected in hollows or flowing across to the process and finding an ignition source.

22.4.1 Segregation

The segregation and separation of materials within the storage area is largely based on classification of the materials stored, on secondary containment, on hazardous area classification (HAC) and on fire protection measures.

The classification of liquids is described in Chapter 10. Principal classifications are those given in the IP *Refining Safety Code* and in National Fireprotection Association (NFPA) 30.

Traditionally, the flashpoint classification has been used as a guide to segregation of liquids in storage. Using the earlier classification into classes A, B and C, the main distinction was between Classes A/B and C. This was the basis of the system used in the 1965 version of the IP *Refining Safety Code*. The current code places less emphasis on this type of distinction as far as concerns segregation.

It is convenient to segregate materials which require secondary containment such as bunding, from those which do not. Where the requirements for HAC are different, it may be convenient to segregate on this basis.

The fire protection which needs to be provided is a fourth means of classification. Fire protection is considered below.

22.4.2 Separation distances

Minimum recommended separation distances for storage are given in various codes and other publications. These were listed in Chapter 10. The separation distances for petroleum products given in the IP *Refining Safety Code* are shown in Table 22.3. The code gives a number of layouts illustrating these separation distances.

Table 22.3 *Minimum recommended separation distances for the storage of petroleum products: IP Refining Safety Code (Institute of Petroleum,1981 Refining Safety Code)*

Factor	*Type of tank roof*	*Recommended minimum distance*
(1) Within a group of small tanks	Fixed or floating	Determined solely by construction/maintenance/ operational convenience
(2) Between a group of small tanks and another group of small tanks or other larger tanks	Fixed or floating	10 m minimum, otherwise determined by size of the larger tanks (see (3) below).
(3) Between adjacent individual tanks (other than small tanks)	(a) Fixed	Half the diameter of the larger tank, but not less than 10 m and need not be more than 15 m
	(b) Floating	0.3 times the diameter of the larger tank, but not less than 10 m and need not be more than 15 m[a]
(4) Between a tank and the top of the inside of the wall of its compound	Fixed or floating	Distance equal to not less than half the height of the tank (Access around the tank at *compound* grade level must be maintained)
(5) Between any tank in a group of tanks and the inside top of the adjacent *compound* wall	Fixed or floating	Not less than 15 m
(6) Between a tank and a public boundary fence	Fixed or floating	Not less than 30 m
(7) Between the top of the inside of the wall of a *tank compound* and a public boundary fence or to any fixed *ignition source*	–	Not less than 15 m
(8) Between a tank and the *battery limit* of a process plant	Fixed or floating	Not less than 30 m
(9) Between the top of the inside of the wall of a *tank compound* and the *battery limit* of a process plant	–	Not less than 15 m

[a] In the case of crude oil tankage this 15 m option does not apply.

Notes: (1) Small tanks are those of up to 10 m diameter; (2) a group of small tanks with a total capacity of 8000 m^3 may be treated as one tank; (3) where future changes of service are anticipated, the layout should be designed for the most stringent case; (4) in order to allow access for fire fighting, the number of rows of tanks between adjacent access roads should be limited to two; (5) fixed roof tanks with internal floating covers should be treated for spacing purposes as fixed roof tanks; (6) where fixed roof tanks and floating roof tanks are adjacent, the spacing should be designed for the most stringent case; (7) where tanks are erected on compressible soils, the spacing should be such as to avoid excessive distortion; (8) for Class III(1) and Unclassified petroleum liquids, spacing of tanks is governed only by constructional and operational convenience.

Separation distances for flammable liquids are given in HS(G) 50 and HS(G) 52. Figure 22.6 shows a general layout given in HS(G) 52 and Table 22.4 lists the separation distances given in this guide. These separation distances are for flammable liquids with flashpoints up to 55°C. There are, however, certain relaxations for liquids with a flashpoint in the range 32–55°C, which are described in the guide.

22.4.3 Separation distances: fire models

An alternative approach is to base separation distances on engineering principles. Two main factors which should determine separation are (1) the heat from burning liquid and (2) the ignition of a vapour escape. These principles and their application were discussed in Chapter 10.

The application of such engineering calculations to the separation distances for storage tanks has been treated by Hearfield (1970) and R.B. Robertson (1976b). Calculations on separation distances related to heat effects are usually based on direct flame impingement and on heat radiation.

It is commonly assumed that in a storage tank fire, the tank is effectively a pool of liquid with a flame burning on this liquid and that on a tank of diameter D the height of the flame in still air is $2D$.

If there is a wind, however, the flame is distorted. At a wind speed of 2 m/s it has been observed that the flame is deformed to an angle of 45° to the horizontal and that on the downward side of the fire the flame hugs the ground for a distance of about $0.5D$.

For the heat radiated from the flame, it is usually assumed, for simplicity, that still-air conditions prevail. The heat radiated is calculated and compared with limit values.

An equation given by Hearfield and by Robertson for the heat radiated from the envelope of a flame burning on a liquid pool in a storage tank is:

$$Q = k_1 A r \rho C \qquad [22.4.1]$$

where A is the surface area of the pool (m^2), C is the calorific value of the liquid (kj/kg), Q is the heat radiated from the flame envelope (kW), r the liquid burning rate (m/s), ρ is the density of the liquid (kg/m^3) and k_1 is a constant.

The value of the constant k_1 generally used by these authors is 0.3. Robertson gives liquid burning rates of 0.083–0.17 mm/s (5–10 mm/min). Hearfield gives liquid burning rates of 0.1, 0.3 and 0.4 in./min for 1, 7 and 35 ft diameter pools, respectively.

The application of Equation 22.4.1 is described by Robertson as follows. It is assumed that the heat is radiated from the envelope of a cylinder diameter D and height D, and that in turn this is equivalent to radiation from a radiating area which is a vertical rectangular plane of width D and height $2D$. The heat flux received by another storage tank is obtained from the view factor method. He states that for most hydrocarbon flames, the heat radiation from the surface of the cylinder is approximately 170–240 kW/m^2 and suggests that a suitable limit for the heat received by an adjacent storage tank is 37.8 kW/m^2. Other limit values for heat radiation which are relevant to separation were given in Chapter 10.

It is pointed out by Robertson that the separation distances in some storage installations are less than ideal. For example, on many small chemical plants storage tanks approximately 6 m diameter and 6 m high are spaced 2 m apart. If a fire occurs when the wind direction is along the line of the tanks and the wind speed is 2 m/s, the fire would spread rapidly by direct flame impingement. It may not

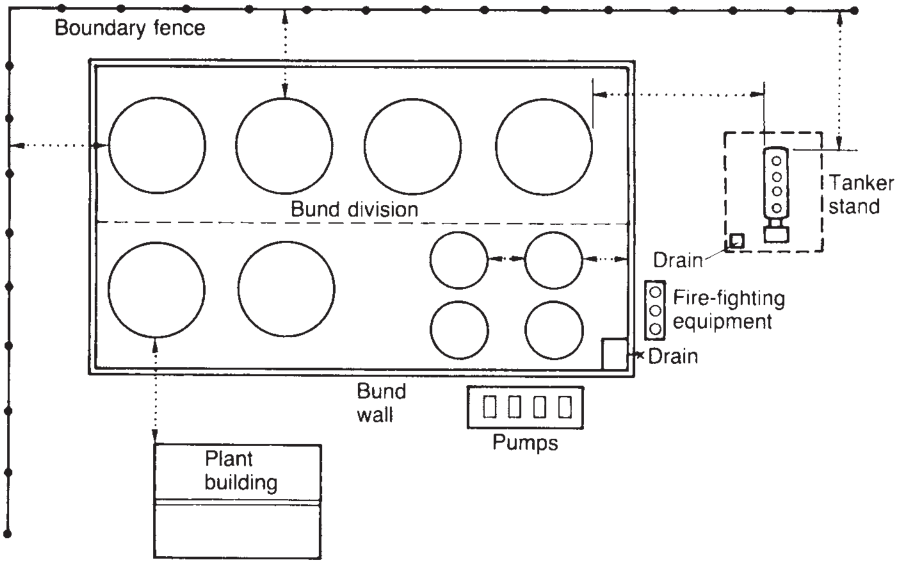

Figure 22.6 *Layout for storage of flammable liquids (Health and Safety Executive, 1991 HS(G) 52). The distances shown by dotted lines should be as in the text and Tables 1 or 2 of HS(G) 52. (Courtesy of HM Stationery Office © All rights reserved)*

Table 22.4 *Minimum recommended separation distances for the storage of flammable liquids: HS(G) 52 (Health and Safety Executive, 1991 HS(G) 52) (Courtesy of HM Stationery Office © All rights reserved)*

A Fixed roof tanks

Factor	*Minimum separation distance from any part of the tank* (m)
(a) Between groups of small tanks[a] (see note below)	15
(b) Between a group of small tanks and any tank outside the group	15
(c) Between tanks not being part of a group of small tanks	Half the diameter of the larger tank, the diameter of the smaller tank, or 15 m, whichever is least, but never less than 10 m
(d) Between a tank and any filling point, filling shed or building, not containing a possible source of ignition	15
(e) Between a tank and outer boundary of the installation, any designated non-hazardous area, or any fixed source of ignition	15

B Floating roof tanks

Factor	*Minimum separation distance from any part of the tank* (m)
(a) Between two floating roof tanks	10 m for tanks up to and including 45 m diameter; 15 m for tanks over 45 m diameter. The size of the larger tank should govern the spacing
(b) Between a floating roof tank and a fixed roof tank	Half the diameter of the larger tank, the diameter of the smaller tank or 15 m, whichever is least, but never less than 10 m
(c) Between a floating roof tank and any filling point, filling shed or a building not containing a possible source of ignition	10
(d) Between a floating roof tank and outer boundary of the installation, any designated non-hazardous area or any fixed source of ignition	15

C LPG storage[b]

	Distance from flammable liquid tank (m)	*Distance outside bund wall around a flammable liquid tank* (m)
LPG cylinders ($>$ 50 kg total capacity)	3 (3)	3 (0)
LPG vessel	6 (6)	6 (3)

[a] A group of small tanks, 10 m in diameter or less, may be regarded as one tank. Such small tanks may be placed together in groups, no group having an aggregate capacity of more than 8000 m^3. The distance between individual tanks in the group need be governed only by constructional and operating convenience but should not be less than 2 m.
[b] The figures in brackets relate to liquids with a flashpoint greater than 32°C.

always be possible to have the ideal separation, but the decision on the separation distance should be made with full awareness of the implications. A similar approach may be taken using the more recent models given in Chapter 16.

22.4.4 Secondary containment

Some types of liquid storage tank are normally surrounded by a bund, or dike, and/or provided with a pit to retain any spillage of the liquid, or impounding basin. Bunds are made of earth or concrete.

In general, bunds are provided for atmospheric storage tanks and for fully refrigerated storage tanks of liquefied gas, but not for pressure or semi-refrigerated storage of liquefied gas or for acid or alkali storage, although this generalization needs some qualification.

The object of bunding is to retain the liquid so that it can be dealt with in a controlled manner, by evaporation from a specially designed catchment/evaporation area, by foam blanketing or other measures.

Thus, the relatively weak atmospheric storage tanks are generally provided with full bunds, while pressure storage vessels may not be. Bunds tend not to be used for pressure vessels because these rarely fail, the emission when it does occur is mainly in vapour/spray form and the dispersion of small leaks and spillages is hindered. Even where a full bund is not used, however, a low wall may be provided which gives the vessel some protection from damage by vehicles. Low walls may also be used to keep flammable liquids from some external source from reaching a storage vessel.

It may be noted that experience shows that in most cases of tank rupture only a proportion of the liquid in the tank is lost and in many other cases most of the liquid is retained in the tank.

Some practical aspects of the design of bunds for flammable liquids have been discussed by Hearfield (1970). He draws attention to the fact that a leak in the side of a tank may form a horizontal jet and may jump the bund if the latter is too close to the tank, an effect known as spigot flow. The bund wall should be far enough from the side of the tank to prevent a jet jumping over or, alternatively, the bund should be surrounded by an impervious surface sloped inward to the bund drain area. The corners of the bund should be rounded and not at a right angle. It is difficult to extinguish a fire in a 90° angle corner because of the air compression effect.

The IP *Refining Safety Code* gives requirements for tank compounds. It states that Class I, II(1), II(2) and III(2) petroleum liquids should be completely surrounded by a wall or walls. Alternatively, the ground should be so sloped that spillages are directed to an impounding basin.

The *Code* gives the following restrictions on the total capacity of tanks in one bunded area: (1) single tanks: no restriction; (2) groups of floating roof tanks, 120,000 m^3 maximum; (3) groups of fixed roof tanks, 60,000 m^3 maximum and (4) crude tanks, not more than two tanks of greater individual capacity than 60,000 m^3. The figures for (2) and (3) may be exceeded for groups of not more than three tanks where conditions are suitable, that is there is no hazard to the public or risk of pollution.

The *Code* states that the net capacity of a tank compound should generally be equivalent to the capacity of the largest tank, but that a capacity of 75% will provide reasonable protection and may be used where conditions are suitable. The net capacity of the compound should be calculated by deducting from the total capacity the volume of all tanks, other than the largest, below the top of the compound wall and the volume of all intermediate walls within the compound.

For Class III(1) and Unclassified petroleum liquids, the code states that a low wall, which need not be more than 0.5 m high, should be constructed around the tankage, where conditions are such that the liquid could escape and cause damage or pollution.

Guidance on bunding for flammable liquids is given in HS(G) 50 and HS(G) 52. In respect of the restrictions on tankage within one bund and of bund capacity, the requirements are consistent with, but less detailed than, those of the IP *Code*.

HS(G) 52 states that the height of the bund wall should be restricted in order to ensure good ventilation, access for fire fighting and means of escape. It should not normally exceed 1.5 m, though it may go up to 2 m provided these factors have been taken into account.

For removal of rainwater, HS(G) 52 requires that where a bund drain is used it should have a valve on the outside of the bund with a system of work to ensure that the valve remains closed, and preferably locked, except when water is being removed. If the liquid stored is immiscible with water, there should be an interceptor to prevent flammable liquid entering the main drainage system. If the liquid is miscible with water, special arrangements are needed.

Guidance on bunds is also given in NFPA 30 and BS 5908. A further discussion of bunding is given in Section 22.21.

22.4.5 Hazardous area classification

Control of ignition sources in storage areas is exercised through the system of hazardous area classification (HAC). The principles of HAC have been described in Chapters 10 and 16.

Guidance on HAC for refineries, including storage, is given in API RP 500: 1991 *Recommended Practice for Classification of Locations for Electrical Installations* at *Petroleum Facilities*. This supersedes the separates RPs 500A, 500B and 500C, which covered refineries, offshore rigs and platforms, and pipelines, respectively. Guidance on HAC for storage is given in the *Area Classification Code for Petroleum Installations* of the IP (1990 MCSP Pt 15) (the IP *Area Classification Code*). The guidance of the Health and Safety Executive (HSE) is given in HS(G) 50 and HS(G) 52.

Figure 22.7 shows some HAC classification diagrams for petroleum storage tanks given in the IP *Area Classification Code*. Table 22.5 from HS(G) 52 gives some principles for the delineation of the zones around storage tanks in the HAC.

22.5 Venting and Relief

22.5.1 Atmospheric vents

A fixed roof atmospheric storage tank is connected to the atmosphere by some form of a vent, generally either a simple free flow atmospheric vent or a pressure/vacuum (PV) valve.

Vents for atmospheric storage tanks are dealt with in BS 2654: 1989 in appendix F and in API Std 2000: 1992 *Venting Atmospheric and Low Pressure Storage Tanks (Non-refrigerated and Refrigerated)*.

Since atmospheric tanks can withstand pressure/vacuum of only a few inches WG, it is essential that atmospheric vents should remain free. Blockage can occur accidentally due to debris, icing up, solids formation, polymerization, etc.

A flame arrester on the end of a vent also serves to keep out debris. If there is no arrester, a coarse wire mesh guard is usually provided. But there is a danger of blockage of flame arresters and guards. The use of flame arresters is considered further below.

The tank may also suffer overpressure or underpressure if the capacity of the vent is not sufficient. Pressure changes occur mainly during filling and emptying, but also in other circumstances.

Situations in which tank failures tend to occur due to accidental blockage or deliberate sealing off of a vent, or to lack of capacity in the vent, were described in Chapter 20.

22.5.2 Pressure/vacuum valves

A PV valve, also called a breather valve or conservation vent, actually has two vent valves – a pressure valve which opens to let vapour out and a vacuum valve which opens to let air in.

A fixed roof tank tends to breathe fairly heavily and appreciable vapour loss can occur through an atmospheric vent, particularly for a volatile liquid. A PV valve is effective in reducing this loss.

Avoidance of blockage and provision of adequate capacity are important for PV valves also. PV valves are subject to failure from icing up and deposition of material on the valve diaphragms or in the branch on the tank. The danger of ice formation is usually most severe just after the tank has been water tested, and the valve diaphragms are often removed for about 2 weeks until the water content of the liquid has reduced to normal, although the problem is less with newer diaphragm materials such as PTFE.

22.5.3 Flame arresters

If the vapour space above the liquid in a fixed roof atmospheric storage tank contains a flammable mixture, there is a possibility that it will be ignited via the vent. A flame arrester may be used to prevent this.

Flame arresters have already been discussed in Chapter 17. General accounts are given in *Guide to the Use of Flame Arresters and Explosion Relief* by the HSE (1965 HSW Bklt 34) and API Publ. 2028: 1991 *Flame Arresters in Piping Systems*. The discussion here is limited to the question of their use on storage tank vents.

The object of a flame arrester is to prevent a flame passing back through a vent to ignite a flammable mixture in the vapour space of the tank. Consideration needs to be given, therefore, to the conditions under which a flammable mixture can exist. The range of materials stored is such that for some the vapour mixture is below the lower flammability limit, while for others it is above the upper flammability limit, but for others again it is in the flammable range.

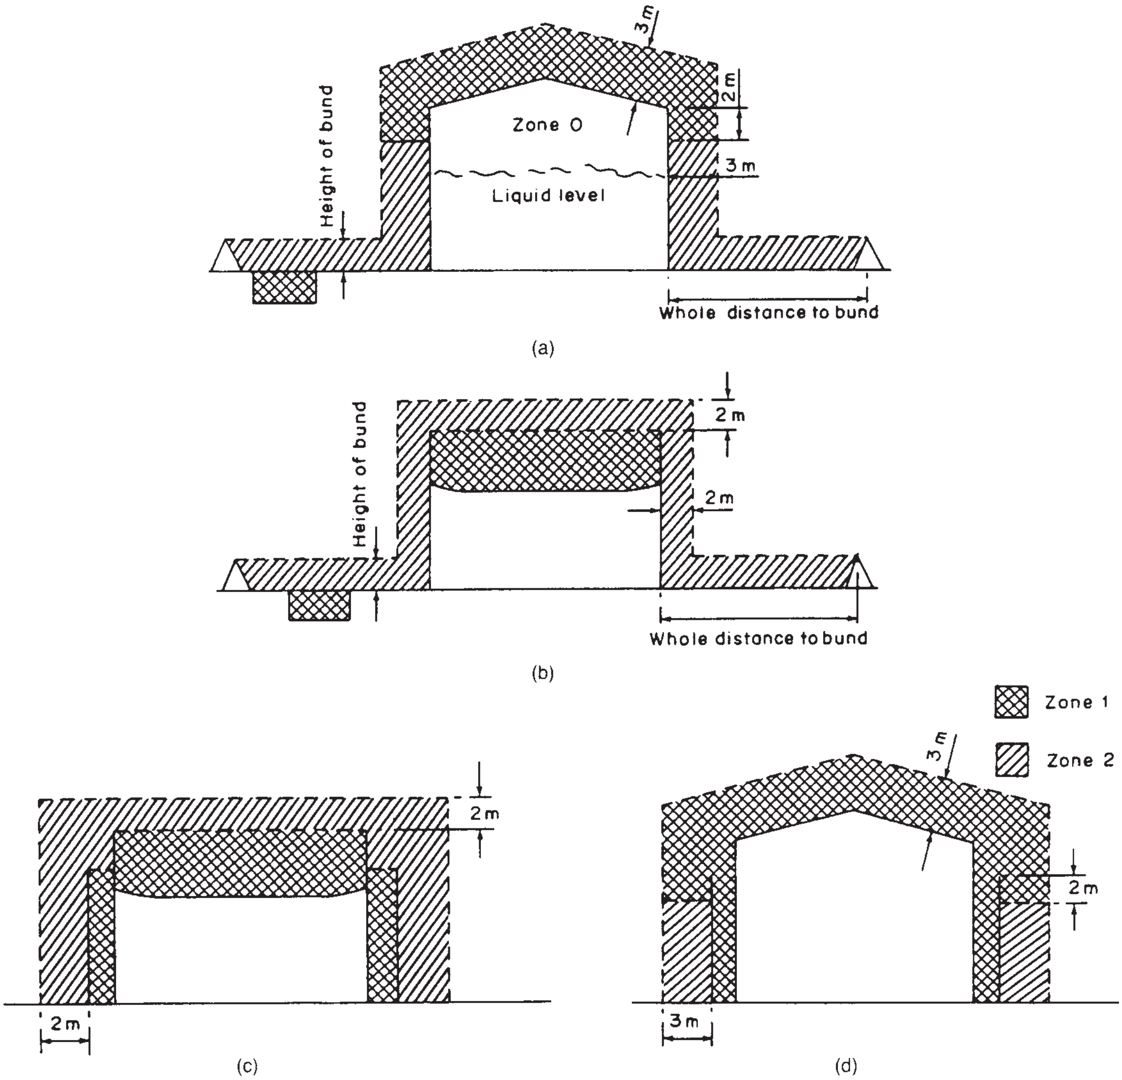

Figure 22.7 *Hazardous area classification of petroleum storage tanks: (a) cone or dome roof tank – Classes I, II(2) and III(2); (b) floating roof tank, where roof will not be grounded on its leg during operational cycle; (c) floating roof tank with outer protective wall; (d) cone roof tank with outer protective wall, for (a), because of the possibility of mist, spray or foam formation the ullage space of Class II(1) and III(1) tanks should also be regarded as Zone 0. It is recommended that the area surrounding any vents or openings on the roof of such a tank be regarded as Zone 1 to a diameter of 1 m (Institute of Petroleum, 1987 LPG storage Code; reproduced by permission)*

***Table 22.5** Guidelines for the hazardous area classification of the storage of flammable liquids (Health and Safety Executive, 1991 HS(G) 52) (Courtesy of HM Stationery Office. © All rights reserved)*

Item	*Extent of area*	*Classification*
Above-ground tanks	(a) Vertically from ground level to the height of the bund wall, and horizontally from the tank shell to 1 m outside the bund wall	Zone 2
	(b) Within 2 m of the tank shell	Zone 2
Underground tanks	Within any manhole chamber containing filling connections	Zone 0
Tank connections (all tanks)	Within a horizontal radius of 4 m from tank filling connections, and vertically from ground level up to 1 m above the connections	Zone 2
All tanks	Within the vapour space	Zone 0
Vent pipes	(a) Within a radius of 3 m in all directions of the open end of any vent pipe	Zone 1
	(b) The area below the Zone 1 area of any vent pipe, for a radius of 3 m around the discharge point and down to ground level	Zone 2
Pumps and sample points	Within a horizontal radius of 4 m and vertically from ground level to 2 m above the unit	Zone 2
Road and rail tankers (at loading/unloading points)	(a) Withn 300 mm in any direction of any opening on the tanker, and down to ground level	Zone 1
	(b) Within 2 m of the shell of the tanker	Zone 2
	(c) Within a horizontal radius of 4 m from tanker discharge connections and vertically from ground level up to 1 m above the connections	Zone 2
	(d) Within a radius of 1.5 m of any opening on the tank top, and down to ground level	Zone 1
	(e) On the top of the tank within the valence	Zone 1

Notes:

(1) Where an area is classified under more than one heading the more stringent classification should be adopted.

(2) Any pit, trench or depression in a Zone 1 or Zone 2 area should be considered a Zone 1 area throughout.

(3) Where tanks are mounded or buried in a hillside, etc., and access is by means of a tunnel or adit, typically 2 m or more in height, the space in the tunnel should normally be considered a Zone 1 area.

The situation is also affected by the use of a floating deck. This reduces the concentration of vapour, but does not necessarily eliminate flammable mixtures. The vapour space above the floating deck may in fact go from a mixture above the upper flammability limit near the deck to one below the lower flammability limit near the fixed roof.

It is also necessary to consider the conditions under which a flame can occur at the vent outlet. For this to happen the vent must be exhaling vapour. It may be assumed that it does this, on average, half the time. The situations which give rise to exhalation of vapour are, in particular, filling operations and temperature rises. Thus the conditions under which a flame may flash back and cause an explosion are when the vapour space in the tank contains an explosive mixture and the vent is exhaling vapour.

The desirability of using flame arresters has been a matter of some debate. Insurance companies have often recommended their use. Thus the Factory Mutual Engineering Corporation (FMEC, 1967) recommends their use on atmospheric vents for liquids with flash points below 110°F (43°C) and for liquids which may be heated above their flashpoints.

A discussion of the problem is given in API Publ. 2210: 1982 *Flame Arresters for Vents of Tanks Storing Petroleum Products*, though this is no longer listed. Flame arresters are a potential cause of vent blockage and tank collapse and their use needs to be justified.

The case for the use of a flame arrester in addition to a PV valve is less than clear. API Publ. 2210 suggests that where a PV valve is used, there is no good reason to put a flame arrester on.

The argument supporting this view is broadly on the following lines. Tank fires caused by lightning were a problem on the older wooden-roofed tanks, but with the advent in about 1920 of truly gas-tight steel roofs combined with PV valve, such fires are rare. The probability of tank fires via vents is low, because most oil industry stocks do not give a vapour mixture in the flammable range above the liquid, and ignition sources are excluded from the vicinity of vents. Moreover, it is notoriously difficult to keep flame arresters well maintained and this introduces the hazard of vent blockage and tank collapse.

API Publ. 2210 concludes: 'There is no supportable basis for requiring that an outdoor above-ground tank provided with a pressure–vacuum valve must also be equipped with a flame arrester. The use of flame arresters is discouraged unless the user is able to institute the maintenance necessary to ensure that the required venting capacity is maintained.'

API Std 2000: 1992 takes a similar stance, stating: 'A flame arrester is not considered necessary for use in conjunction with a PV valve because flame speeds are less than vent velocities through PV valves'. It does, however, go on to say: 'Open vents with a flame-arresting device may be used in place of PV valves on tanks in which oil with a flash point below 100°F (37.78°C) is stored and on tanks containing petroleum and petroleum products where the fluid temperature may exceed the flash point'.

The IP *Refining Safety Code* states that fixed roof tanks for Class I and II liquids are usually fitted with PV valves and tanks for Class III and Unclassified liquids with open vents. It further states that PV valves or open vents should not be fitted with fine mesh gauze, which is liable to clog.

HS(G) 50 and HS(G) 52 state that a flame arrester should normally be installed on an open vent on a fixed roof tank storing liquid with a flash point below 21°C. But a flame arrester is not necessary on a PV valve and should not be used where the liquid is liable to block the arrester by polymerization or otherwise.

22.5.4 Fire relief

It is also necessary for fixed roof storage tanks to provide for the effect of fire which heats the liquid, increases its vaporization and causes a rise in pressure. Tanks can normally withstand a pressure of only a few inches WG. It is normal not to size atmospheric vents or PV valves for fire relief but to provide for this by separate emergency venting.

Methods of providing emergency venting for fire are described in API 2210. They include larger or additional open vents, larger or additional PV valves, lifting manhole covers or hatches and a weak roof-to-shell connection.

This latter arrangement involves the use of a weak roof-to-shell attachment, otherwise known as a frangible joint or rupture seam. This involves making the seam between the shell and the roof deliberately weak so that it is the first to rupture, thus ensuring that the shell stays intact and contains the liquid. The incorporation of such a frangible joint as an emergency vent in accordance with API 2210 is allowed for in API Std 650. Not all companies consider it good practice to rely on a rupture seam for fire relief, although one may still be used to relieve explosions.

The methods given in API Std 2000 for the determination of the heat input into storage tanks in a fire, and hence of the venting capacity required, are described in Chapter 16.

22.6 Fire Prevention and Protection

Accounts of fire prevention and protection of petroleum storage are given in *Storage and Handling of Petroleum Liquids* by J.R. Hughes (1970) and *Fire Protection Manual for Hydrocarbon Processing Plants* by Vervalin (1964a, 1973a). Relevant standards and codes are API RP 2001: 1984 *Fire Protection in Refineries*, the IP *Refining Safety Code*, NFPA 30: 1990 *Flammable and Combustible Liquids Code*, BS 5306: 1976– *Fire Extinguishing Installations and Equipment on Premises* and BS 5908: 1990 *Code of Practice for Fire Precautions in the Chemical and Allied Industries*. HSE guidance is given in HS(G) 50 and HS(G) 52.

Fire prevention in and protection of storage has several objectives. These are (1) to minimize the risk to personnel, (2) to minimize loss due to the initial fire, and (3) to prevent the spread of fire to other vessels and equipment. Personnel are at risk principally from an explosion or sudden spread of fire.

Implementation of fire protection for storage takes the two forms (1) fighting the fire and (2) protecting the storage vessels. Methods of fire prevention and protection in general have been described in Chapter 16. The discussion there includes some treatment of storage, including the application rates of fire-fighting media.

A major contribution to fire prevention in storage is made by layout, as described in Section 22.4. Important aspects of storage layout are the practice of segregation, the provision of separation distances and HAC.

22.6.1 Inerting of storage tanks

An effective method of fire prevention in storage is inerting. This is widely used to reduce the hazard of fire in atmospheric storage tanks. The value of inerting in reducing fire/explosion in storage tanks was discussed in Chapter 16 and methods of inerting were described in Chapter 17.

22.6.2 Fire protection of storage tanks

There are two main effects of fire on an atmospheric storage tank. One is that those parts of the tank which are not cooled by the liquid inside may become hot and weaken. The other is that the liquid inside the tank is heated up and its vaporization is increased. In a fixed roof storage tank, this results in a pressure rise and, as explained earlier, relief of such pressure is now normally effected by the use of some form of emergency vent.

Fire protection for atmospheric storage tanks is provided by fixed water or foam sprays, which may be supplemented by fireproof thermal insulation, and by mobile water and foam sprays.

Fixed water sprays are effective in giving immediate cooling of exposed surfaces and are particularly useful where manpower is limited or access for mobile equipment is difficult. But the main water sprays are normally provided by mobile equipment and are used both to fight the fire and to cool exposed surfaces. There are also mobile water curtains which can be interposed to protect vessels if sufficient manpower is available.

For cooling of an unwetted tank surface a rate of application of water of 0.2 UKgal/ft^2 min (10 l/m^2 min) has been found satisfactory. It is desirable to cool the wetted surface also to minimize the rise in pressure, but the effectiveness of water cooling then depends on the boiling point of the stored liquid. If this is below the boiling point of water, the water does not vaporize and the cooling due to the latent heat effect is not obtained. If, however, the boiling point of the liquid is above that of water, then the water does vaporize and is much more effective.

Foam is used to extinguish fires rather than to cool surfaces. The type of foam used is normally mechanical foam. Fixed foam pourers are used to direct foam to the inside of the tank shell so that the foam flows over the liquid surface. Another fixed device which puts foam on the liquid surface is the Swedish semi-subsurface foam system. This consists of a hose which is connected through the tank shell to a foam supply and is normally at the bottom of the tank. Injection of foam inflates the hose, the top end of which rises to the liquid surface and sprays the foam.

Mobile foam-spraying equipment consists of mobile monitors and portable foam towers. A monitor projects jets of foam in a manner similar to that of conventional fire water jets. A portable tower is a light tube which is put upon the side of the tank and pours foam on the top of the liquid. There are various types, some assembled manually and others of telescopic design extended mechanically or hydraulically.

Mobile foam monitors are available with a foam output of 5000 UKgal/min and a range of 60 m (200 ft) in still air. For extinguishing fire, a rate of application of foam of 0.1 UKgal/ft^2 min (4.5 l/m^2 min) has been found necessary.

Fixed equipment such as foam pourers is very vulnerable to damage by explosion.

The application of foam from foam monitors requires some skill. An experienced operator can project foam so that it hits the inside of the tank on fire and runs down and blankets the burning liquid.

The amount of foam used is large and it is necessary to make arrangements for adequate supplies.

22.6.3 Pipework and fittings

Fire can also have a very damaging effect on pipework, which sometimes may withstand the fire for only about 10 min. Pipework is very vulnerable to fire and should be protected as far as possible. Fireproof insulation on pipework near storage vessels may be appropriate.

A small fire at a leaking flange can have a torch effect and this possibility should be borne in mind in designing pipework. A fire of this type was one of the causes considered at the Flixborough Inquiry.

22.7 LPG Storage

Some aspects of the storage of other fuels and chemicals are now considered, starting with LPG. The handling and processing of many of these substances were treated in Chapter 11 and the design of pressure systems in Chapter 12, and these topics are therefore not discussed here. However, attention is drawn to the fact that aspects such as the materials of construction, the pipework, the valves and the pumps are particularly important for these chemicals.

Propane and butane are referred to as LPG. They are described in *An Introduction to Liquefied Petroleum Gas* (LPGITA, 1974/1). A general account of LPG is given in Chapter 11.

Codes and standards for LPG were given in Chapters 10 and 11. HSE guidance on LPG storage is given in HS(G) 34 *The Storage of LPG at Fixed Installations* (1987). Other relevant codes are *Design, Installation and Maintenance of Bulk LPG Storage at Fixed Installations* (LPGITA, 1991 COP 1 Part 1) (the LPGA LPG Storage Code), NFPA 58 : 1989 *Storage and Handling of Liquefied Petroleum Gases* (also published as the *Liquefied Petroleum Gases Handbook*) and NFPA 59 : 1989 *Storage and Handling of Liquefied Petroleum Gases at Utility Plants*. The code *Liquefied Flammable Gases Storage and Handling* (ICI/RoSPA 1970 IS/74) (the ICI *LFG Code*), though out of print, contains much valuable guidance.

LPG is stored at petroleum storage terminals, at chemical works and at many non-chemical factories.

22.7.1 Regulatory requirements

The storage of LPG is governed by the Notification of Installations Handling Hazardous Substances (NIHHS) Regulations 1982 and the Control of Industrial Major Accident Hazards (CIMAH) Regulations 1984. The NIHHS notifiable inventory is 25 te for pressure storage and 50 te for refrigerated storage. The CIMAH inventory for either type of storage for which demonstration of safe operation may be required (Regulation 4) is 50 te and that which attracts a safety case (Regulation 7) is 200 te. An account of the regulatory requirements for LPG in Germany has been given by Ackermann (1986).

22.7.2 Storage conditions

Fully refrigerated storage is essentially at atmospheric pressure and at the boiling points of the substances concerned. For pressure storage, the temperature follows the ambient temperature and the pressure is the corresponding vapour pressure of the substance. The boiling point of pure propane is −42°C and that of pure *n*-butane is 0°C. The boiling point of commercial propane is −45°C and that of commercial butane is −2°C. At a pressure reference temperature of 38°C the vapour pressure exerted by commercial propane is 4.83 barg and that exerted by commercial butane is 14.5 barg.

22.8 LPG Storage: Pressure Storage

22.8.1 Storage vessels

Pressure storage of LPG is in horizontal cylindrical or spherical pressure vessels. The former are used for smaller quantities and the latter for larger ones.

The design of pressure vessels for LPG pressure storage is discussed in the Liquefied Petroleum Gas Association (LPGA) LPG *Storage Code*. The design pressures and temperatures should take into account the extreme ambient and service conditions to which the storage may be subject. The *Code* states that the design conditions should not be less onerous than the following:

	Commercial butane	*Commercial propane*	
		Liquid offtake	*Vapour offtake*
Maximum temperature (°C)	38	38	38
Maximum pressure (barg)	4.83	14.5	14.5
Minimum temperature (°C)	−18	−18	−40
Minimum pressure (mbarg)	−524	Zero gauge	Zero gauge

The values given for the maximum temperature, or pressure reference temperature, are for a vessel finished in white; a higher maximum design temperature and pressure should be used for a vessel in a finish which reduces normal reflection of solar radiation. A higher minimum temperature should be used only for dedicated service where controls are provided to limit the lowest fluid temperature to a value higher than that shown. A higher minimum pressure for butane should be used only if means are provided to ensure that an unacceptable vacuum does not occur or if the ambient temperature is such as to ensure that the fluid temperature will be higher than −18°C.

As the LPGA *Code* indicates, more stringent design pressures and temperatures may be appropriate. Some of the factors which bear on this are discussed in the ICI LPG *Code*. For the maximum reference temperature in the United Kingdom the *Code* suggests that the following temperatures be assumed for a hot summer day:

Temperature	*Tank capacity* (m^3)
47.5	<5
42.5	5–30
41	30–100
40	>100

The *Code* states that the design pressure at the top of the vessel should be set equal to the greater of (1) 110% of the maximum operating pressure or (2) the maximum operating pressure plus 1 bar (14.5 psi), and that the design pressure at the bottom of the vessel should be set equal to that at the top plus the static head of the product or water, whichever is the greater.

The choice of design pressure should also be considered in conjunction with relief and blowdown arrangements, since these can be expensive, and it may be economic to increase further the design pressure.

The maximum design temperature for pressure storage vessels is determined by the loss of strength in the metal at high temperatures. Increased temperature always leads to loss of strength, but the fall-off is much greater for a vessel designed to an advanced code rather than a conventional one. The ICI code states, for example, that the design stress for a vessel designed to BS 1500 does not reduce significantly until 400°C, whereas that for a vessel designed to BS 1515 falls off rapidly above 50°C, so that the maximum design temperature needs to be considered particularly carefully when using BS 1515. The maximum temperature reached by the metal is likely to be during a fire. The temperature of unprotected metal rises rapidly in a fire, but there are several features which may mitigate this. The metal is normally protected by fire insulation and water sprays, and metal in contact with the liquid inside is cooled by the liquid boil-off.

The minimum design temperature for pressure storage vessels is normally set by the loss of ductility and hence brittle fracture in the metal at low temperatures. There are several ways in which a low metal temperature may occur. The ambient temperature may be low, although in this case there is normally a time lag due to insulation. The metal may come in contact with low temperature liquid due to abnormal operating conditions in the process or loss of pressure and liquid boil-off in the vessel. This latter effect, however, is likely to signal its presence and the *Code* suggests that it may be assumed that for a vessel of reasonable size action would be taken before the temperature has fallen to that corresponding to atmospheric pressure.

The combinations of pressure and temperature which may occur should also be considered.

The material of construction of most storage vessels is carbon steel, but other materials may be used.

A classic set of general arrangements for pressure storage vessels is given in the ICI *LPG Code*. Figure 22.8(a) shows those for a horizontal cylindrical vessel and Figure 22.8 (b) shows those for a spherical vessel. Another set of general arrangements for such vessels given by Nazario (1988). Figure 22.9 shows the arrangements for horizontal cylindrical storage vessels given in HS(G) 34.

22.8.2 Separation distances

Separation distances for pressurized LPG storage are given in HS(G) 34, the IP *LPG Code* and NFPA 58.

Minimum separation distances for LPG pressure storage vessels given in HS(G) 34 are shown in Table 22.6. Guidance is also given on separation distances between LPG and storages of flammable liquids, toxic substances, LPG cylinders and cylinder filling buildings. For flammable liquids, the separation distance is 6 m to the bund wall for liquids with a flashpoint<32°C or 6 m to the tank and 3 m to the bund wall for liquids with a flashpoint of 32–65°C. For toxic or hazardous substances the separation distance is as given in Table 22.6 for buildings, etc., subject to a minimum value of 15 m. HS(G) 34 also gives the separation distances between LPG and liquid oxygen storages.

The approach to minimum separation distances in NFPA 58 is broadly similar. This code also gives separation distances between LPG and both oxygen and hydrogen storages.

The approach to minimum separation distances in Germany is described by Ackerman (1986).

22.8.3 Separation distances: fire models

As described earlier, an alternative approach to the setting of minimum separation distances is the use of models for vapour dispersion and fire radiation. An account of the application of this approach to petroleum storage is given in Section 22.4.

The separation distances for LFG given in the ICI *LPG Code*, and shown in Table 22.7, owe something to this approach, and are an early, if implicit, example of its use. Two methods of determining the heat received by pressure vessels are also presented in this *Code*, but these are not used there to determine separation distances, which are obtained from Table 22.7. The two methods are used to calculate the requirements for pressure relief and for drench water as described below. The modelling approach to separation distances is now entering mainstream codes. The minimum separation distances given in the IP *LPG Code* for LPG pressure storage are specified in terms of the thermal radiation flux from certain defined fires. These fires are jet fires from the vessel relief valve and spillages from the vessel, its associated equipment and other identified leak sources, with spillage possibly forming a pool in the bund or impounding basin. The *Code* gives guidance on potential leak sources and emission rates and on the thermal radiation from jet and pool fires. The minimum separation distances given in the code are shown in Table 22.8.

22.8.4 Secondary containment

For pressure storage vessels containing LFG a full bund is not used. It is true that an appreciable proportion of a spillage remains as liquid after the initial flashing off of vapour. For example, if liquid propane at 16°C escapes to atmosphere the theoretical proportion of liquid remaining after flashing off is 67%.

However, complete loss of containment from a properly designed, maintained and operated pressure vessel is rare, material is in any case ejected mainly as vapour/spray, and smaller spillages from valvework can be dealt with by other means. Moreover, it is essential to allow free circulation of air so that small leaks and spillages are safely dispersed.

The arrangement recommended in the ICI *LFG Code* is that there should be a diversion wall with only the vessel on one side and all the joints and valvework on the other. The only requirement on the vessel side of the wall, where the risk of spillage is remote, is that the ground should slope away from the vessel, but on the other side there should be not only sloped ground and a catchment area but also such diversion walls as are necessary to ensure that a spillage flows into the latter. In an existing installation or other installation in which it is not possible to eliminate joints and valvework under the vessel, these diversion walls should be put around the vessel.

The vessel and its pipework should also be protected against damage by vehicles, by the use of some form of crash barrier if necessary.

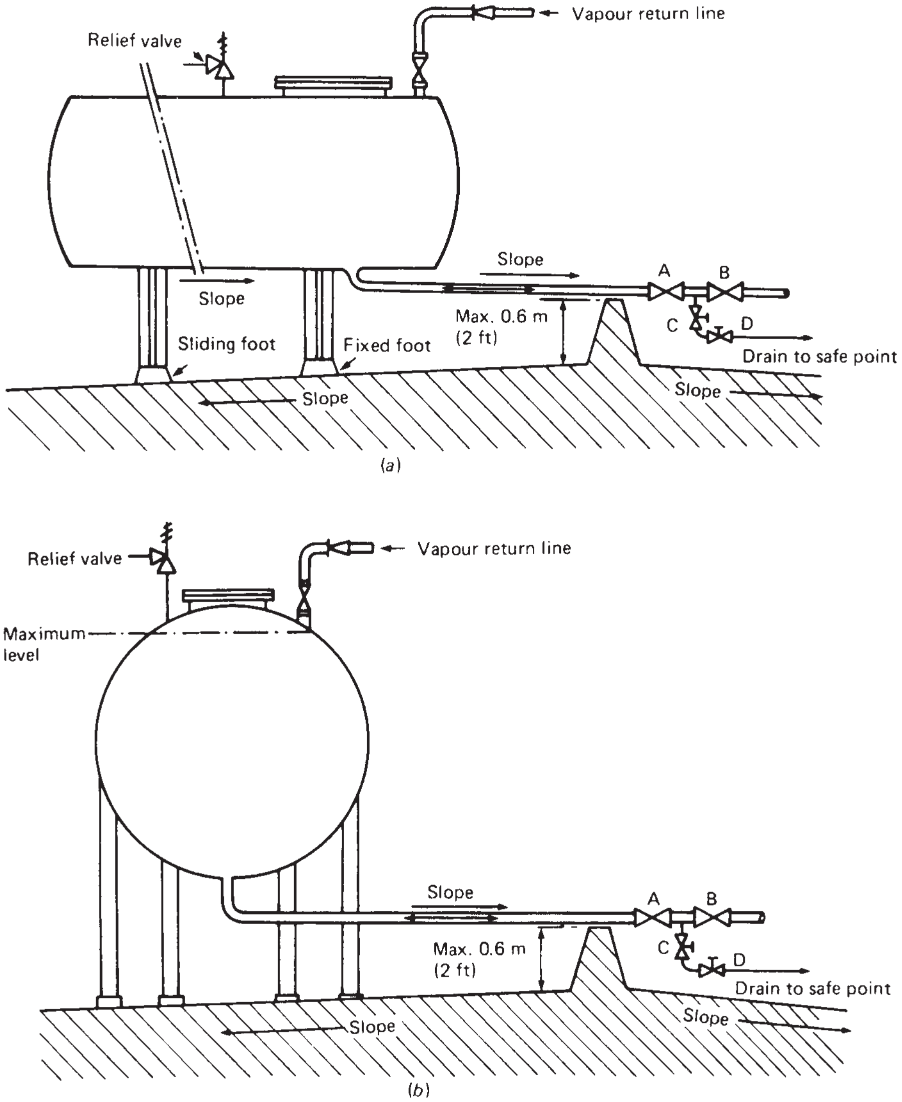

Figure 22.8 *General arrangement of LPG pressure storage vessels with special reference to piping: (ICI/RoSPA 1970 IS/74; reproduced by permission): (a) horizontal cylindrical vessel; (b) spherical vessel*

HS(G) 32 adopts a broadly similar approach, based on the principles of sloping the area under pipework connections, the use of diversion walls and an evaporating area, and the provision of a crash barrier against vehicle impact. It requires that the ground be impervious beneath the pipework connections, that the height of diversion walls should not exceed 0.5 m and that the evaporation area should be not less than 3 m from the vessel.

The IP *LPG Code* explicitly states that a bund is not normally required and its provisions are in line with the approaches just described.

The ICI *LFG Code* also considers pressure storage of non-hydrocarbon LFGs which are miscible with water and which it may be desirable to dilute. Thus, if the liquid can be rapidly diluted with water and rendered harmless, this is appropriate, and it is then not necessary to provide a catchment area for spillage. But some materials may need to be diluted for other reasons, for example toxicity. In this case, a full bund should be provided sufficient to take both the spillage and the dilution water. Walls should not exceed 2m (6 ft 6 in.) in height and they should have at least two access points.

22.8.5 Diversion walls and fire walls

Diversion walls can be used to divert large vapour flows to areas where they can be dealt with more safely.

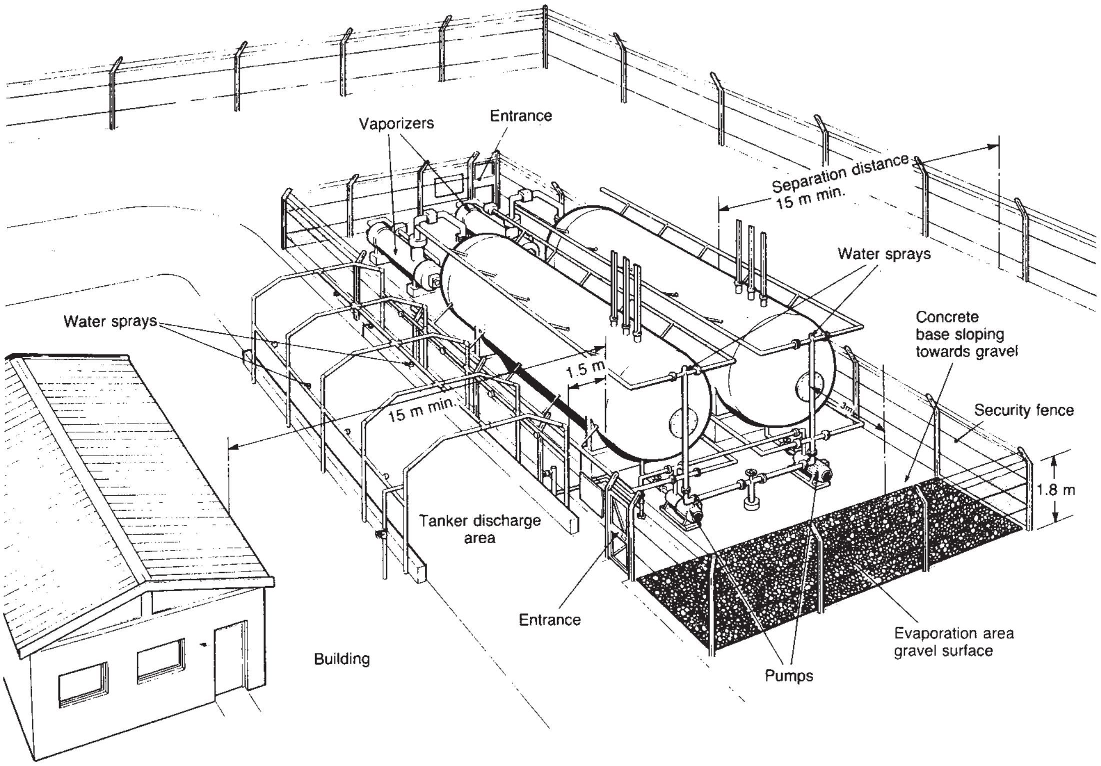

Figure 22.9 *General arrangement of LPG horizontal pressure storage vessels (Health and Safety Executive, 1987 HS(G) 34) (Courtesy of HM Stationery Office © All rights reserved)*

Table 22.6 *Minimum recommended separation distances for LPG pressure storage: HS(G) 34 (Health and Safety Executive, 1987 HS(G) 34) (Courtesy of HM Stationery Office © All rights reserved)*

Vessel capacity (te)		*Distance* (m)[a]		
Single vessel	*All vessels in a group*	*From buildings, boundary, property line or fixed fire source of ignition*	*With fire wall*	*Between vessels*
4–60	200	15	7.5	1.5
60–150	450	22.5	11	–[b]
>150	1000	30	15	–[b]

[a] These distances apply to above ground vessels. For mounded vessels the distances are as follows. The distances between buildings, etc., and the valve assembly are the same as those for above ground vessels with a fire wall; the distances between buildings, etc., and the vessel itself are 3 m in each case. The distances between vessels are 1.5 m for the lowest set of capacities quoted, but for the two higher sets the spacing should be determined by the site conditions and the requirements of installation, testing, maintenance and removal.
[b] One-quarter of the sum of the diameters of two adjacent vessels.

Steam curtains may also be considered as a means of maintaining separation from an ignition source, although they are actually used mainly around process plants.

Fire walls are utilized to give protection against flame or heat radiated from a fire.

Trenches leading from the storage area should be fire stopped at or near the boundary by barrier walls or bunds across the pipes. Drains with openings in the storage area should have means to prevent the transmission of insoluble flammable and noxious products to the general drainage system.

22.8.6 Hazardous area classification

Guidance on the HAC for LPG pressure storage is given in API RP 500, the IP *Area Classification Code*, and also in NFPA 58 and 59, the LPGA *LPG Storage Code* and HS(G) 34.

A table of guidelines for delineation of the zones round LPG pressure storage vessels for HAC is given in the LPGA *LPG Storage Code*. The virtually identical table given in HS(G) 34 is shown in Table 22.9.

***Table 22.7** Minimum recommended separation distances for LFG storage: IC1 LFG Code (ICI/RoSPA, 1970; reproduced by permission*

Minimum distance	*Material stored*					
	Hydrocarbons		*Non-hydrocarbons insoluble in water*		*Non-hydrocarbons soluble in water*	
Pressure storage$^{(1)}$						
To boundary, process units, buildings containing a source of ignition, or any other fixed sources of ignition	Ethylene	60 m (200 ft)	Methyl chloride	23 m (75 ft)	Methylamines	15 m (50 ft)
	C_3s	45 m (150 ft)	Vinyl chloride	23 m (75 ft)		
	C_4s	30 m (100 ft)	Methyl vinyl ether	15 m (75 ft)		
			Ethyl chloride	15 m (50 ft)		
To building containing flammable materials, for example filling shed		15 m (50 ft)		15 m (50 ft)		15 m (50 ft)
To road or rail tank wagon filling points		15 m (50 ft)		15 m (50 ft)		15 m (50 ft)
To overhead power lines and pipebridges		15 m (50 ft)		15 m (50 ft)		15 m (50 ft)
To other above ground power cables and important pipelines or pipelines likely to increase the hazard	(2)	7.5 m (25 ft)	(2)	7.5 m (25 ft)	See Note (3)	
Between pressure storage vessels	One-quarter of sum of diameters of adjacent tanks					
To low pressure refrigerated tanks	15 m (50 ft) from the bund wall of the low pressure tank, but not less than 30 m (100 ft) from the low pressure tank shell					
To flammable liquid$^{(4)}$ storage tanks	15 m (50 ft) from the bund wall of the flammable liquid tank					
Low pressure refrigerated storage$^{(5)}$						
To boundary, process units, buildings containing a source of ignition, or any other fixed sources of ignition $^{(6)}$	Ethylene 90 m	(300 ft)			Ethylene oxide	15 m (50 ft)
	C_3s	45 m (150 ft)				
	C_4s	15 m (50 ft)				
To building containing flammable materials, for example filling shed		15 m (50 ft)				15 m (50 ft)
To road or rail tanker filling point		15 m (50 ft)				15 m (50 ft)
To overhead power lines and pipebridges		15 m (50 ft)				15 m (50 ft)
Between low pressure refrigerated tank shells	One-half of sum of diameters of adjacent tanks					
To flammable liquid$^{(4)}$ storage tanks	Not less than 30 m (100 ft) between low pressure refrigerated LFG and flammable liquid tank shells, but LFG and flammable liquids must be in separate bunds					
To pressure storage vessels	As defined above under Pressure Storage					

Notes (to original table)

(1) Measured in plan from the nearest point of the vessel, or from associated fittings from which an escape can occur when these are located away from the vessel.

(2) If this distance cannot be achieved, the need for suitable fire protection of the cable or pipeline should be considered.

(3) The tanks containing water soluble non-hydrocarbons being bunded (see Clause 8.6.2), power cables and pipelines at ground level should be outside the bund and so protected by the bund from fire in the tanks.

(4) Flammable liquids are those with flashpoints up to 65.5°C (150°F).

(5) Measured in plan from the nearest part of the bund wall (see Clause 8.6.3), except where otherwise indicated.

(6) The Home Office *Code for Storage of LPG at Fixed Installations* recommends 45 m (150 ft) for C_4 as well as C_3, storage, which is considered to be unnecessarily conservative. The designer may be able to persuade the Licensing Authority of the adequacy of the ICI *Code* in this respect, in view of the significant difference in rate of vaporization of the respective materials.

Additional notes (communicated by ICI c. 1977):

(1) The separation distances quoted in this table are those within which leaks from pumps, valves, flanges, etc., will normally disperse to a safe level. They are not 'safety distances' for vapour cloud explosions.

(2) Refrigerated storage tanks are now often constructed with an outer wall of concrete which will retain any spillage. This design may permit the use of lower separation distances but no definite figure has been agreed.

Table 22.8 *Minimum recommended separation distances for LPG pressure and refrigerated storages: IP LPG Storage Code (Institute of Petroleum, 1987 LPG Storage Code)*

A Pressure storage

Site	*Maximum radiation flux levels*	
	(kW/m^2)	(BTU/h ft^2)
Equipment		
The outer surfaces of adjacent *pressure storage vessels* (1):		
Thermally protected (2)	44	13,750
Unprotected (3)	8	2,500
The outer surfaces of adjacent storage *tanks* containing *flammable* products (4) and process facilities:		
Thermally protected (2)	32	10,000
Unprotected (3)	8	2,500
Filling/discharge points	8	2,500
Personnel inside boundary		
Process area (5)	8	2,500
Protected work area (6)	8	2,500
Work area (7)	5	1,500
Critical area (8)	1.5	500
Plant boundary		
Remote area (9)	13	4,000
Urban area (10)	5	1,500
Critical area (8)	1.5	500

B Refrigerated storage

Site	*Maximum thermal radiation flux levels*	
	(kW/m^2)	(BTU/hr ft^2)
Equipment		
The outer surfaces of adjacent *refrigerated storage tanks:*		
Thermally protected (2)	32	10,000
Unprotected (3)	8	2,500
The outer surfaces of adjacent storage *tanks* containing *flammable* products (4):		
Thermally protected (2)	32	10,000
Unprotected (3)	8	2,500
The outer surfaces of adjacent LPG *pressure storage vessels* and process facilities (11)	8	2,500
Personnel inside boundary		
Process area (5)	8	2,500
Protected work area (6)	8	2,500
Work area (7)	5	1,500
Critical area (8)	1.5	500
Plant boundary		
Remote area (9)	13	4,000
Urban area (10)	5	1,500
Critical area (8)	1.5	500

Notes:

(1) The distance from an LPG *pressure storage vessel* to a *refrigerated storage tank* is determined by the requirement of Chapter 3 (see 3.3.1) and Table 2 of this appendix.

(2) Such facilities/areas are protected by means of water sprays, insulation, radiation screens or similar systems.

(3) Protection is provided by spacing alone.

(4) Special consideration should be given to the location of floating roof tanks containing high vapour pressure products since effective water cooling of their roof structures is impracticable.

(5) A normally unoccupied area occasionally manned by trained and suitably clothed persons familiar both with escape routes and opportunities for temporary shelter afforded by the process plant.

(6) A permanent building where personnel inside are shielded and/or have a shielded means of escape.

(7) An open area or small (e.g. temporary) building without a shielded means of escape.

(8) This is either an unshielded area of critical importance where people without protective clothing may be required at all times including during emergencies or a place difficult or dangerous to evacuate at short notice (e.g. a sports stadium).

(9) An area only infrequently occupied by small numbers of persons, for example moorland, farmland, desert.

(10) An area which is neither a remote area nor a critical area.

(11) The allowable thermal radiation flux level is restricted for these facilities in view of the potentially longer duration of exposure resulting from a *refrigerated tank/bund* fire.

Table 22.9 *Guidelines for hazardous area classification of LPG pressure storage (Health and Safety Executive, 1987 HS(G) 34) (Courtesy of HM Stationery Office © All rights reserved)*

Factor		*Area classification*
Storage vessels	(a) Within 1.5 m in all directions from the discharge orifice of fixed liquid level gauges, rotary or dip gauges, filler openings	Zone 1
	(b) Up to 1.5 m above ground level and within the distances set out for a fixed source of ignition in Table 2 column (a)[b]	Zone 2
Relief valve discharge	(a) Within direct path of discharge	Fixed electrical equipment should not be installed
	(b) Within 1.5 m in all other directions from point of discharge	Zone 1
	(c) Beyond 1.5 m but within 4.5 m, or the separation distance in Table 2 column (a)[b] in the case of vessels with a capacity not exceeding 2500 l, in all directions from point of discharge	Zone 2
Tanker loading and unloading	(a) Within 1.5 m in all directions from a point where connections are regularly made or disconnected for a product transfer	Zone 1
	(b) Beyond 1.5 m but within 4.5 m or the separation distance in Table 2 column (a)[b] in the case of vessels with a capacity not exceeding 2500 1, from point of connection or disconnection	Zone 2
Pumps, compressors and vaporizers other than direct fired		
(a) Outdoors in open air, at or above ground level[a]	(a) Within 1.5 m in all directions	Zone 1
	(b) Beyond 1.5 m but within 4.5 m in all directions or the separation distance in Table 2 column (a)[b] in the case of vessels not exceeding 2500 l capacity	Zone 2
(b) Indoor location with adequate ventilation	The entire room and any adjacent room not separated by a vapour-tight partition	Zone 1

[a] Where there is a high standard of maintenance of pumps and pump seals the area within 1.5 m in all directions from the pump may be classified as Zone 2.

[b] Of HS(G) 34.

Notes:

(1) Where any area is classified under more than one factor the higher classification should prevail.

(2) Any pit, trench or depression falling within a Zone 1 or Zone 2 area should be treated as a Zone 1 area throughout.

(3) The term 'outdoors in open air' includes pumps, compressors and vaporizers which are covered by a canopy.

For LPG storage during distribution, the IP *Area Classification Code* refers to the LPGA *Code*, whilst for storage under the more varied conditions which pertain in refineries and process plants it advises the use of the point source method.

22.8.7 Pipework and fittings

The pipework, valves and other fittings for storage systems should be designed in accordance with approved practice for such equipment. Pipework for pressure systems was described in Chapter 12 and the discussion here is limited to aspects particularly relevant to storage.

Pipework and fittings for LPG pressure storage are dealt with in the main LPG codes mentioned and also specifically in *LPG Piping System Design and Installation* (LPGA, 1990 COP 22) (the LPGA *Piping Systems Code*).

The types of consideration which should be taken into account in pipework for storage are illustrated by the following recommendations for pipework for LFG taken from the ICI *LFG Code*.

The minimum temperatures which may be attained by the piping should be carefully considered and materials of construction selected accordingly. Storage systems are subject to such operational conditions as rapid blowdown, which can result in low temperatures.

Allowance should be made in the pipework for stresses due to movement, expansion/contraction and vibration. In storage systems, typical causes of stress are shifting and settling of vessels and expansion/contraction due to temperature changes.

Joints should be welded or flanged. Welded joints are preferable and flanged joints should be kept to a minimum.

Valves should be of the wedge gate or ball type. Ball valves give a more positive shut-off than wedge gate valves and should be used on the critical filling/discharge and drain lines.

The ball valves should be dual directional, should be of the fire-safety type and should have antistatic protection. Ball valves welded into lines should be such that they can be maintained *in situ* by ‘top entry’.

With a ball valve, liquid can be trapped in the body cavity. In low temperature, LFG duties conditions can occur which cause the liquid to expand. Provision should be made for relieving this expansion which does not render the valve unidirectional.

The main filling/discharge line should have a minimum diameter of 4 in. The drain line should be 2 in., reducing to 3/4 in.

The preferred pipework arrangement for a horizontal storage vessel is shown in Figure 22.8(a). There are no flanges, valves or other fittings on the filling/discharge line on the vessel side of the separation wall, only a single butt weld. Valves A–C are butt-welded ball valves and valve D is a flanged, spring-loaded valve. Valve A is the main shut-off valve, which is remotely operated and has fail-safe action, closing on air failure.

There is also an alternative arrangement in which flanged joints are allowed on the vessel side of the separation wall.

The preferred pipework arrangement for a spherical storage vessel is shown in Figure 22.8(b).

If possible, the main filling/discharge pipe should be the only one below the liquid level. Another inlet may be provided at the top of the vessel if mixing of the liquid by pumping is necessary. There may also be a vapour return line to the vessel. With a horizontal cylindrical vessel, it is desirable to put the filling/discharge line and the vent at opposite ends to assist purging of the vessel.

The vessel branch sizes should be 4 in. minimum for the filling/discharge line and 1 in. minimum for all other branches.

Sections of pipe, such as those between shut-off valves, in which liquid may become trapped and may then undergo further expansion, should be provided with liquid expansion relief valves.

There should be good access to valves. Permanent access should be provided for valves which are operated or maintained regularly, or which may need to be used in an emergency.

The pipework should be protected against mechanical damage from external sources.

Pipework is very vulnerable to fire and should be protected as far as possible. Fireproof insulation on pipework near storage vessels may be appropriate.

A small fire at a leaking flange can have a torch effect and this possibility should be borne in mind in designing pipework. A fire of this type was one of the causes considered at the Flixborough Inquiry.

Remotely operated shut-off valves should be provided on all discharge or drain lines from storage vessels and these valves should be stable in fire conditions. Other valves in the storage area should be of fire-safe design.

Turning to the guidance on pipework and fittings in the main LPG codes, detailed treatments are given in the LPGA *LPG Storage Code*, the LPGA *LPG Piping Systems Code* and the IP *LPG Storage Code*. These codes cover materials of construction, pipe thickness, pipe joints, welding, flanges, gaskets, bolts, valves, pipe supports, etc.

The LPGA *LPG Storage Code* gives detailed requirements for the minimum set of fittings on an LPG pressure storage vessel. These are (1) a pressure relief valve on the vapour space, (2) a drain or other means of emptying the vessel, (3) a maximum level indicator, (4) a filling connection, (5) a service connection and (6) a pressure gauge on the vapour space on vessels of over 5000 l.

The *Code* requires the provision of a manual shut-off valve on all liquid and vapour connections, except on the pressure relief valve or very small diameter (<1.4 mm) connections.

Another requirement of the *Code* is that any connection on the vessel greater than 3 mm diameter for liquid or 8 mm diameter for vapour, except that for a relief valve, should be protected with an emergency shut-off valve (ESV). The types of ESV mentioned are excess flow valves, remotely operated isolation valves and back-check valves. The detailed applications of the three types are given in the *Code*.

A back-check valve is a spring-loaded non-return valve held in the closed position. The valve remains closed against reverse flow until the upstream pressure exceeds that of downstream, when the valve opens.

HS(G) 34 requires a remotely operated ESV on all liquid lines greater than 19 mm in diameter if they supply an activity which requires frequent making and breaking of connections or one where the general public have access or if the vessel is large (>225 m^3).

22.8.8 Water drainage facilities

As described in Chapter 20, small amounts of water tend to accumulate at the bottom on an LPG storage vessel and this water is commonly removed by the periodic action of an operator who drains it off manually. Loss of control by the operator can result in a breakthrough and escape of LPG.

Methods of dealing with this problem have been discussed by Klaassen (1980b), who describes valve arrangements for the bottom of LPG spheres designed to minimize the chances of such an escape. He describes a system with a 2 in. line coming out of the bottom of the sphere, reducing to 3/4 in. on the downstream part of the drain line. Basic principles underlying the system are: (1) a reduction in the line size, as just mentioned; (2) the installation of a first ball valve in the 2 in. line dedicated to isolation rather than manipulation, and preferably remotely controlled; (3) the provision of two further ball valves on the drain line, the downstream one being a spring-loaded valve; (4) a separation between the drain valve and the drain funnel and (5) the provision of an indication of water level which is visible at the point where the draining operation is performed.

Guidance on water draining arrangements is given in HS(G) 34 *The Storage of LPG at Fixed Installations* (HSE, 1987) as follows:

> 66. Drain connections should be less than 50 mm in diameter and fitted with two shutoff valves in series. The length of piping between the valves should be at least 0.5 m to minimize the risk of simultaneous obstruction of both valves by the freezing of any water present in the LPG. The piping downstream of the second valve should not discharge beneath the vessel. The second valve and piping should be adequately supported and secured to prevent mechanical damage or breakage by vibration or jet forces. Both valves on the drain systems should have means of actuation which cannot be readily removed or

moved from the closed position except by intentional operation.

67. Alternatively, a satisfactory arrangement for drain lines could be a single valve and a plug or blanking plate fitted on the discharge side of the valve. Additional pipework should be fitted, when required, in accordance with paragraph 66.

68. No drain lines should discharge within 6 m of any drainage system where this would be liable to create a hazard.

22.8.9 Ancillary facilities

The ancillary facilities required for LPG pressure storage include, in particular, pumps and vaporizers. It is important that these items, which effectively introduce a process element, should not hazard the storage. A pump should not be located directly under a vessel.

Pumps are a potential source of leakage of flammable vapours. This is particularly the case for pumps with packed glands. Pumps with mechanical seals are to be preferred. The type of pump used also has implications for the HAC.

A positive displacement pump needs to have a bypass or other appropriate protection against overpressure. The thermal expansion of LPG in a pump which is isolated and is then started up can be particularly damaging.

LPG storage is often provided with vaporizers. Descriptions of, and requirements for, vaporizer systems are given in NFPA 58 and 59, the LPGA *LPG Storage Code* and HS(G) 34. Vaporizers may be heated by direct firing or by an indirect heating medium such as steam or hot water. Some principal features of a vaporizer system include the vaporizer itself, drain connections, pressure relief and instrumentation. Direct fired and certain other types of vaporizer constitute ignition sources.

22.8.10 Instrumentation

An LPG pressure storage vessel should be provided with suitable measurements and alarms on liquid level, pressure and temperature. A discussion of instrumentation for LFG pressure storage is given in the ICI *LFG Code*. Instrumentation is essential to the safe operation of LPG pressure storage. It is important both that the instruments function correctly and that they do not themselves hazard the process.

Vessels should be protected against maloperation by alarm and trip systems. Overpressure is obviously one condition against which protection is necessary. It is often caused by overfilling, and so high level alarms and trips are important. But this is not the only condition requiring protection – overtemperature and undertemperature are important too.

The measurement of level in pressure storage may present some difficulties. In order to avoid leakage, it may be policy not to put additional branches on the vessel simply for level measurement, which rules out conventional differential pressure measurements. The *Code* recommends duplicate internally mounted level measuring instruments as the primary measurements with a magnetic float gauge or radioactive gauge as the secondary measurement. Separate high and low level switches are also required for the alarm and trip systems. Here the *Code's* recommendation is that the switch should be put in an externally mounted float chamber, the top connected to the top of the storage vessel and the bottom to the filling/discharge line between the ball valves and the manifold.

Debris from instruments should not create a hazard. It may be necessary to take precautions to prevent a loose float from a level measuring device blocking the branches to the relief valves.

For the measurement of temperature, a long thermocouple pocket is recommended. It should be inserted from the top and reach the bottom so that the temperature at any level can be measured. The bottom of the pocket should be guarded or supported in some way to reduce the risk of fracture by vibration.

Specific instrumentation requirements are contained in the main LPG codes, particularly in respect of level gauging. The LPGA *LPG Storage Code* requires the installation of a fixed maximum liquid level device, which should be of the type that allows vapour or liquid to be bled from a valve attached to a dip-tube to indicate when the maximum permitted level is reached during filling. The connection through the vessel should be no larger than 1.4 mm in diameter unless an excess flow valve is fitted. For a vessel of more than 5 m^3 capacity the *Code* also requires the provision of a pressure gauge connected to the vapour space. It requires that the connection be protected either by a tapping reduced internally to a bleed hole not larger than 1.4 mm or by a suitable excess flow valve or shut-off valve.

The provision of a contents gauge is also advised. The IP *LPG Storage Code* suggests that consideration be given to the installation of two independent level gauges in addition to the maximum level device.

Sampling is another aspect which merits careful attention, because it tends to be a source of leakage. The ICI *LPG Code* makes the following recommendations on this. Sampling should be done from pipelines rather than from vessels. If a representative sample is required from a vessel, the product should be circulated and a sample taken from the circulation line. Sample points should be carefully sited with respect to HAC, safe disposal of vented samples and access.

Sample connections should be limited, preferably to 1 in. reducing to 1/4 in. There should be double manual isolation with a 1 in. ball valve followed by a 1/4 in. valve. The valves should be close together but with a minimum separation of 1 m to avoid simultaneous blockage of both valves by ice or hydrate.

Operations involved in sampling were considered in Chapter 20.

Gas, flame and smoke detectors are another important aspect of instrumentation for storage. These have been discussed in Chapter 16.

22.8.11 Pressure relief

A pressure storage vessel should be protected against overpressure by a pressure relief valve. Pressure relief valves have been discussed in detail in Chapter 12. Only those aspects relevant to storage are considered here.

Pressure relief valves for LPG pressure storage vessel should be designed according to a recognized code such as BS 5500: 1991 or the ASME *Boiler and Pressure Vessel Code, Section VIII*. In this particular case, other appropriate codes are the LPGA *LPG Storage Code*, API RP 520 and NFPA 58 and 59.

Protection is required against overpressure due to (1) abnormal operating conditions and (2) fire exposure. It may be provided by a single pressure relief valve or by separate relief valves for each category.

Operational relief

A pressure relief valve for abnormal operating conditions should be designed to handle the most severe conditions which are likely to arise. Typical abnormal operating conditions include overfilling, high rundown liquid temperature and high tank temperature due to solar radiation.

Overpressure due to abnormal operating conditions may develop slowly or suddenly. The most common cause of a rapid increase in pressure is overfilling. The worst case here is obtained by considering the maximum liquid flow obtainable through the fully open control valve, and bypass if fitted, on the supply line.

Fire relief

A pressure relief valve for fire exposure should be designed to deal with the vapour generated by this. The vapour generated may be calculated from the latent heat of the liquid and from the heat input.

There are a number of measures which can, in principle, reduce the heat absorbed during a fire and hence the quantity of vapour to be handled. The most basic is to slope the ground under the vessel so as to ensure that any flammable liquid spill is drained away. Other measures to reduce heat absorbed include fireproofing, depressurization and water sprays.

A method of estimating the heat absorbed in a fire is given in API RP 520, Appendix D. For a bare surface two equations are given:

$$Q = 21{,}000\, FA^{0.82} \qquad [22.8.1]$$

and

$$Q = 34{,}500\, FA^{0.82} \qquad [22.8.2]$$

where A is the total wetted surface (ft^2), F is an environmental factor and Q is the total heat absorption (BTU/h). Equation 22.8.1 is applicable where there is adequate drainage and prompt fire fighting, and Equation 22.8.2 where these conditions are not met.

In this method, any credits allowed for other measures are incorporated in the environmental factor F. The value of F is unity for a bare vessel. No credit is given for depressurization or water application facilities, and even with these the value of F is still unity. Credit is given, however, for fireproof thermal insulation, provided it will resist dislodgement by fire hose streams. For a vessel furnished with fireproof insulation with a thermal conductance of 4 BTU/ft^{2}h °F the value of F is 0.3. Lower values of F are given for insulation with lower thermal conductances.

The LPGA *LPG Storage Code* and NFPA 58 and 59 give pressure relief valve capacities in tabular form and also give an equation for large vessels. The LPGA *Code* states that these capacities cover fire relief.

The pressure relief valve setting, both for operational and for fire relief, is considered in Chapter 12, and valve sizing is discussed in Chapter 15. For pressure storage, valves should be able to handle flashing, two-phase flow.

Combined relief

A single pressure relief valve may be used to provide both operational and fire relief. Alternatively separate valves may be used for operational and fire relief.

The arrangements are discussed in the ICI *LPG Code*. The *Code* states that where there is a single pressure relief valve, the relieving capacity should be at least equal to the greater of the individual capacities required for operational and fire relief, and that where separate operational and fire relief valves are provided the combined capacity of the two valves may be set against the fire relief requirement.

Fluid phase

A discussion of the fluid phase during pressure relief is given in API RP 520, although the account is not specifically concerned with storage. The IP *LPG Storage Code* states that for overfilling the relief discharge would be a flashing liquid, whilst for fire relief it treats the discharge as a vapour.

Relief disposal

A discussion of relief disposal for LFG storage vessels is given in the ICI *LFG Code*. The *Code* states that it is preferable that relief valves, whether for operational or fire relief, should discharge into a closed system.

An operational relief valve should discharge into a closed system which is led to an atmospheric vent or to a flare. The closed system should be designed to handle liquid discharge and to take the full flow from the valve. A fire relief valve should also discharge to a closed system. If this is not practical, it can be discharged vertically upwards to the atmosphere via a vent pipe.

Direct discharge to atmosphere should be done in such a way as to ensure that flammable material is diluted below its lower flammability limit before it reaches an ignition source, and toxic material should be below the appropriate exposure or odour limit before it reaches ground level outside the plant area.

These requirements for direct discharge are fairly readily met for vapours lighter than air which can be vented at a point above plant structures at low velocities, but for those heavier than air it is more difficult. The *Code* states that for vapours heavier than air it is necessary to use a velocity of at least 150 m/s (500 ft/s) to ensure jet mixing with air sufficient to give rapid dilution. The problem is discussed by Cude, who indicates that current experience is that this criterion can be reliably met only by the use of pilot-operated relief valves rather than ordinary relief valves. A fuller account of dispersion from relief valves is given in Chapter 15.

Most LPG pressure storage vessels are fitted with vertical vent pipes so that the relief discharge is directed upwards. The LPGA *LPG Storage Code* states that a vent pipe should have its outlet at least 1.8 m above the top of the vessel and should be not less than 3 m above ground level. HS(G) 34 gives similar requirements, but states that for large vessels the pressure relief system may discharge to the vent collecting system of a flare.

22.8.12 Vacuum protection

In severe cold weather the temperature of the contents of an LPG pressure storage vessel may fall below 0°C. For the storage of commercial butane in particular, this can cause the vapour pressure of the liquid to fall below atmospheric and thus create vacuum conditions.

This problem and the measures that can be taken to protect against it are discussed in the LPGA *LPG Storage Code*. The *Code* states that, in the absence of more specific information, a butane vessel should be designed for a minimum temperature of −18°C, which is the lowest ambient temperature recorded in the United Kingdom as sustained over a period of 12 h.

One approach is to design for full vacuum. Alternative approaches are (1) the prevention of unacceptable vacuum conditions, (2) the provision of high and low pressure alarms and (3) the use of methods based on product composition or vacuum breaking.

A low pressure alarm serves to give warning of the development of vacuum conditions.

Two methods of preventing an unacceptable vacuum are hot gas return and propane vapour pressurization. Hot gas return involves feeding hot butane vapour from a local vaporization source, and propane vapour pressurization involves connecting the vapour space of the butane vessel to that of a local propane storage vessel or to propane cylinders. Details of the procedures to be used are given in the LPGA *Code*.

In certain special cases, and by agreement with the supplier, the composition of butane to BS 4250: 1987 may be controlled so that the vapour pressure at the lowest service temperature will be above the minimum design pressure of the vessel. It should be confirmed that at this composition the vessel can withstand the vapour pressure at the reference temperature.

Other methods of limiting vacuum are the use of vacuum breakers or the introduction of inert gas. Both methods tend to lead to operating problems due to the introduction of air or inert gas and the first particularly is a specialist matter.

22.8.13 Vaporizers

LPG in vapour form may be obtained from a pressure storage installation using a vaporization facility. Vaporizers for LPG are treated in HS(G) 34.

LPG vaporizers may be heated with low pressure steam or hot water or heated electrically or by direct firing. The equipment should be located with suitable separation distances, in a well ventilated location and with the ground sloped to drain away any leak to a safe place.

HS(G) 34 gives the following minimum separation distances between vaporizers and the nearest important buildings or line of adjoining property. For vaporizers of capacity up to 36 kg/h, 3 m; of capacity >36 to 227 kg/h, 7.5 m; and of capacity >227 kg/h, 15 m. Separation distances between LPG vessels and direct fired or non-explosion protected electrically heated vaporizers are as given in column 3 of Table 22.6, which gives the distances for sources of ignition. The separation distance from LPG vessels for other types of vaporizer is 1.5 m.

Other features detailed in HS(G) 34 include the arrangements for draining, pressure relief and control of liquid level and temperature.

22.8.14 Fire protection

Fire prevention and protection of LPG pressure storage is dealt with in the main codes mentioned and also specifically in *Recommendations for Prevention or Control of Fire Involving LPG* (LPGA, 1972 COP 3) (the LPGA *Fire Code*). A further relevant standard is BS 5908: 1990. Other accounts include those by Kletz (1977d), Fullam (1987), Nazario (1988), Schoen and Droste (1988) and Schoen, Probst and Droste (1989).

The effect of fire on a pressure vessel is broadly similar to that on an atmospheric tank. The unwetted parts of the vessel become hot and lose strength. As a result the vessel may burst, even though it is below its design pressure. Overtemperature is just as serious as overpressure. The loss of strength is greater with vessels designed to advanced pressure vessel codes.

The other effect of fire is to heat the liquid in the vessel so that the pressure rises and causes the pressure relief valve to lift. Further heat input causes the liquid to vaporize without further rise in pressure, provided the valve has enough capacity to vent the vapour. If the valve fails to operate or has insufficient capacity, the rise in pressure may burst the vessel.

Failure of a pressure vessel in a fire may therefore be due to either overtemperature or overpressure. The failure of the vessel at Feyzin, for example, occurred due to overtemperature, even though the relief valve had lifted.

A discussion of fire prevention and protection is given in the ICI *LPG Code*. Some of the measures given in the *Code* have already been discussed, such as diversion and fire walls (see Section 22.8.5), fire protection of pipework and fittings (see Section 22.8.7) and fire and gas detection systems (see Section 22.8.10).

The ICI *Code* specifies measures to minimize spillages. The vessels and pipework should be made to give high standards of safety in both normal and emergency operations, by appropriate design calculation methods. The number of connections below the top liquid level should be kept to a minimum, preferably just one filling/discharge line if possible. The minimum size connections should be used for draining and sampling. The installations should be protected against external damage from such sources as vehicles and other plants. There should be good level measurement and other control instrumentation, and attention should be paid to the filling arrangements.

Measures for controlling spillages are also specified. The basic principle is that any vapour cloud resulting from a spillage should be safely diluted by air below its lower explosive limit before it can find a source of ignition. This dispersion should preferably be effected by air movement but, if necessary, some form of barrier may be required to contain and disperse the cloud.

Thus the installation should be sited with regard to factors such as ground contours and the prevailing wind. The provision of gas detectors should be considered. If necessary, consideration should be given to the provision of barriers or steam curtains to contain, direct or disperse the vapour cloud. Attention should be given to possible sources of ignition.

Finally, the *Code* specifies measures for controlling fire. The layout should ensure that liquid spillages are drained away from under vessels to a catchment area where they can be pumped out or burned. Vessels should be provided with water cooling or fireproof insulation and supports should be fireproofed. Consideration should be given to the provision of fire-fighting equipment to control and extinguish burning hydrocarbon liquids.

Figure 22.10 shows a classic diagram by Kletz (1977d) of the methods of fire protection for an LPG pressure storage vessel. They are (1) sloping of the ground beneath the vessel, (2) fire insulation, (3) a remotely operated depressurization valve, (4) water sprays and (5) a pressure relief valve.

Fixed water sprays are effective in giving immediate cooling of exposed surfaces and are widely used. On both horizontal cylinders and spheres there is a tendency for water to come off the vessel at the 'equator' and therefore sprays are usually provided both above and below this line.

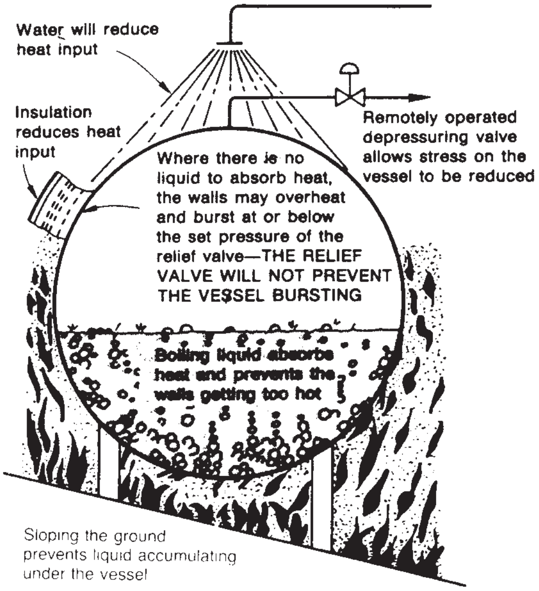

Figure 22.10 *Fire protection arrangements for an LPG pressure storage sphere (Kletz, 1977d) (Reproduced with permission from Hydrocarbon Processing, August, 1977)*

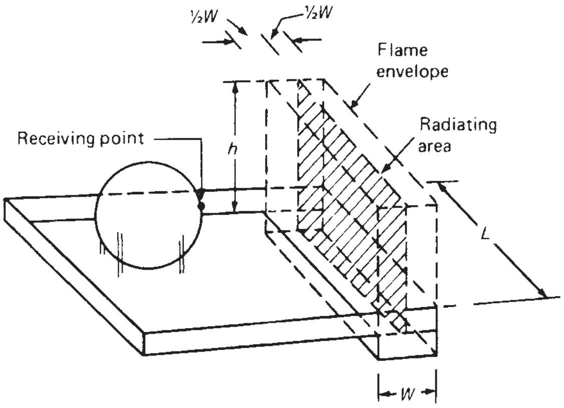

Figure 22.11 *Heat radiation from a fire burning in a catchment area to a pressure storage vessel (ICI/RoSPA 1970 IS/74; reproduced by permission)*

The ICI *LPG Code* gives the following method of calculating the amount of water required. For a vessel enveloped in fire the rate of application of water needed to remove the total heat input is 0.2 UKgal/ft^{2}min. But for a vessel designed to the *Code*, a lower rate of application in the range 0.06–0.2 UKgal/ft^{2}min is acceptable, provided the ground beneath the vessel is impervious and sloped away to a catchment area and the pipework is carried beyond the vertical projection of the vessel with no flanges or other fittings beneath the vessel.

The rate of application of water may be determined by heat flux calculations and from the rise in the temperature of the water from the mains temperature to a temperature close to boiling point at 100°C.

The *Code* gives the following method for the calculation of the heat flux. It is assumed that the separation distances given earlier in Table 22.7 are observed and that the fire is in the catchment area as shown in Figure 22.11. Then the heat radiated and the intensity of heat radiation from the flame burning on the liquid pool are calculated from the equations

$$Q = 5.1 \times 10^{-5} L W \rho C \qquad [22.8.3]$$

$$I = \frac{2.5 \times 10^{-5} L W \rho C}{(L + W)h + LW} \qquad [22.8.4]$$

where C is the net calorific value of the liquid in the pool (kj/kg), h is the height of the flame ($= 2W$) (m), I is the intensity of heat radiation from the flame envelope (kW/m^2), L is the length of the pool (m), Q is the heat emitted by fire (kW), W is the width of pool (m) and ρ is the density of the liquid (kg/m^3).

It is assumed that the heat is radiated from a radiating area which is a vertical rectangular plane through the centre line of the flame envelope cube prism parallel to the nearest point on the equator of the vessel, as shown in Figure 22.11. The heat flux received by this vessel is obtained by using the view factor method.

A fixed water spray system is normally maintained dry so that it cannot become frozen. When this system is required to operate, water is supplied by a deluge valve. This valve may be operated manually or automatically. If operation is manual, the valve should be in a place accessible during the fire. The preferred system, however, is automatic operation triggered by fire detectors.

Automatic detectors should be fast acting in order to protect the pipework in particular. Manual override control should be provided on an automatic system to allow sprays to be turned on to protect adjacent surfaces, even though the automatic controls have not brought them on.

It is desirable that, if possible, only those fixed sprays are activated which contribute to dealing with the fire concerned. Large installations should be subdivided to conserve water, which is likely to be needed to fight the fire. Again, the main water sprays are normally provided by mobile equipment and are used both to fight the fire and to cool exposed surfaces.

Fireproof thermal insulation may be used on pressure vessels as an alternative to, or in addition to, fixed water sprays. Such insulation reduces the rate of heat input from a fire to the vessel and this lag gives time in which fire-fighting measures such as mobile water sprays may be brought into play and the fire extinguished, or in the worst case an evacuation organized.

Fireproofing should be such as to provide protection for 2 h before the vessel becomes dangerously overheated. This insulation should be designed in conjunction with the arrangements for fire pressure relief. A fireproof insulation suitable for this purpose may be obtained by the use of vermiculite cement with a minimum thickness of 2 in.

Some of the measures described have their difficulties. The use of fire insulation is not straightforward. Some of the problems are considered by Fullam (1987). The use of such insulation inhibits inspection of the vessel. Corrosion and water ingress are liable to occur. There are potential problems with the durability of the insulation and its resistance to water jets. He states that these problems are serious enough to prevent the general adoption of this measure.

Likewise, the use of depressurization is controversial, as discussed by Nazario (1988). One problem is the time required to depressurize. Another is that the depressurization lowers the liquid level and increases the area of unwetted metal exposed to the fire. The approach described by Nazario is to use fire insulation as the preferred method for horizontal storage vessels, but not for spheres. On the other hand, water sprays and not insulation are used for spheres.

Turning to the guidance on fire prevention and protection in the main LPG codes, and also specifically in the LPGA *Fire Code*, detailed treatments are given in API Std 2510, AP RP 520, NFPA 58 and 59, the LPGA *LPG Storage Code*, the IP *LPG Storage Code* and HS(G) 34.

The LPGA *LPG Storage Code* gives a summary table of fire protection arrangements for storages of different sizes. For storages below 25 te it is generally sufficient to provide a water supply; for storages greater than 25 te but less than 50 te, fixed or portable water monitors should be available; and for storages greater than 50 te there should be a fixed water spray installation. This system should be automatic unless the plant is continuously attended.

With regard to the wetting rate required to effect protection for an uninsulated vessel, the *Code* states that a full film of water needs to be established over the whole vessel surface and supports at a rate of 7 l/m^2min, and that the typical design spray rate required to achieve this is 9.8 l/m^2min; the *Code* refers to the work of Billinge, Moodie and Beckett (1986). In some cases, one of these figures is quoted without the other; the IP *LPG Code* refers to the lower figure and HS(G) 34 to the higher one.

There should be adequate drainage to remove the fire water, and where necessary water sealed interceptors should be provided to prevent LPG entering the storm drains.

The LPGA *LPG Storage Code* recognizes fire insulation as an alternative to water sprays, provided it is capable of limiting the vessel temperature below 450°C for a period of at least 60 min in full fire engulfment. The *Code* requires, however, that the insulation should: (1) be non-corrosive to the vessel surface; (2) be impervious to water vapour, either by cellular construction or by provision of an effective vapour barrier; (3) be resistant to a hose directed jet; (4) be durable and easily repairable, and strong enough that minor mechanical damage will not destroy the vapour barrier; (5) be unaffected by environmental conditions and (6) not itself be a hazard, by spalling, spreading flames or emitting toxic fumes.

The LPGA *Fire Code* deals particularly with fire fighting of LPG fires.

HS(G) 34 gives guidance similar to that in the LPGA *LPG Storage Code*, again with a summary table of fire protection measures.

22.8.15 Inspection

Pressure storage vessels for LPG should be inspected in the manner and at the frequency given in the relevant codes, as described in Chapter 19.

22.8.16 Mounded storage

LPG is also stored in pressure vessels set in earthen mounds. Accounts of this method of storage are given in HS(G) 34 and by Bonnafous and Divine (1986) and Bellani, Cannalire and Beltrame (1992).

The arrangements for a mounded LPG horizontal cylindrical pressure storage vessel given by the HSE in HS(G) 34 are shown in Figure 22.12. The external surface of the vessel should be given an external coating to prevent corrosion. It should be placed on a firm foundation and installed so as to prevent movement or flotation. The backfill material should be inert and free of material likely to damage the external coating. The HSE advise that the depth of cover be at least 0.5 m.

Some of the installations of mounded LPG vessels are very large. Bonnafous and Divine describe mounded storages with horizontal pressure vessels of capacity 3500 m^3. In these systems the vessel is supported on a compacted sand bed in a 120° circular cradle. The depth of cover is one metre minimum.

Mounded storage offers enhanced protection against external fire, thus avoiding: a boiling liquid expanding vapour explosion (BLEVE); external explosion; impact from external threats such as vehicles or aircraft; and sabotage.

22.8.17 Hydrogen related cracking

In certain circumstances LPG pressure storage vessels are susceptible to cracking. The problem has been described by Cantwell (1989 LPB 89). He gives details of a company survey in which 141 vessels were inspected and 43 (30%) found to have cracks; for refineries alone the corresponding figures were 90 vessels inspected and 33 (37%) found to have cracks.

The cracking has two main causes. In most cases it occurs during fabrication and is due to hydrogen picked up in the heat affected zone of the weld. The other cause is in-service exposure to wet hydrogen sulfide, which results in another form of attack by hydrogen, variously described as sulpfide stress corrosion cracking (SCC) and hydrogen assisted cracking.

LPG pressure storage has been in use for a long time and it is pertinent to ask why the problem should be surfacing now. The reasons given by Cantwell are three aspects of modern practice. One is the use of higher strength steels, which are associated with the use of thinner vessels and increased problems of fabrication and hydrogen related cracking; the use of advanced pressure vessel codes, which involve higher design stresses and the greater sensitivity of the crack detection techniques available.

He refers to the accident at Union Oil on 23 July 1984 in which 15 people died following the rupture of an absorption column due to hydrogen related cracking (Case History Alll). Cantwell states: 'The seriousness of the cracking problems being experienced in LPG vessels cannot be overemphasized'.

The steels most susceptible to such cracking are those with tensile strengths of 88 ksi or more. Steels with tensile strengths above 70 ksi but below 88 ksi are also susceptible.

Cantwell also describes measures for the avoidance of the problem. For new vessels he recommends the use of lower strength steels which have controlled chemistry and welding and post-weld heat treatment and which have good toughness both at ambient and low temperatures. For existing vessels the recommendations centre on inspection techniques and intervals and on repair methods. A measure applicable to both cases is the elimination of breakthrough of wet hydrogen sulfide into LPG rundown.

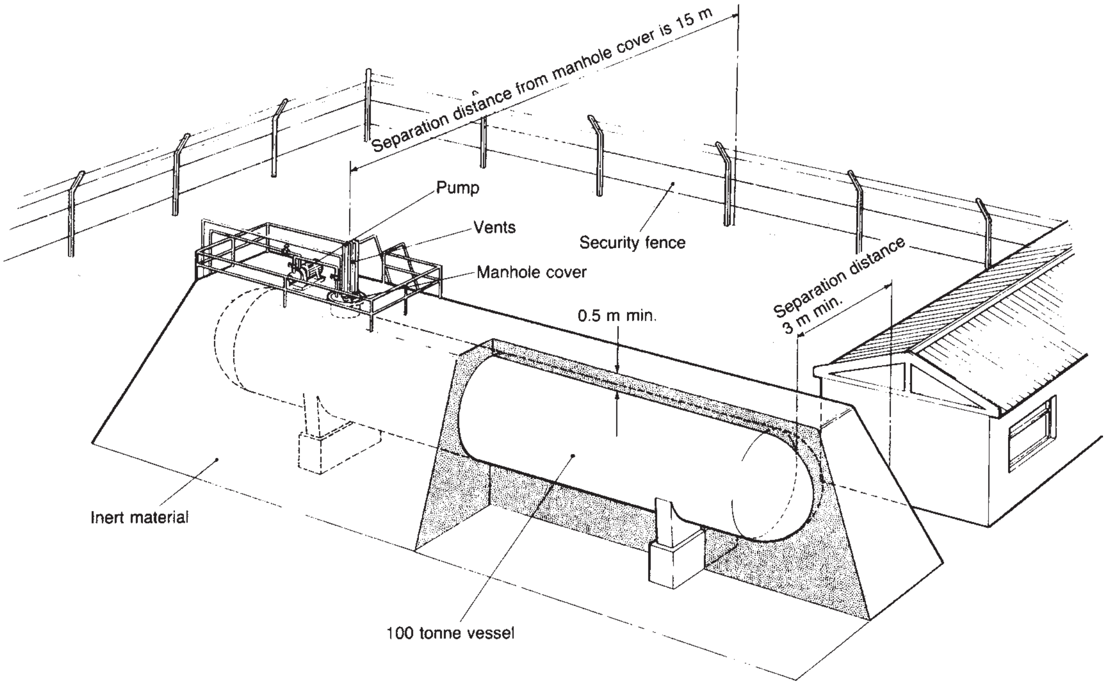

Figure 22.12 *General arrangement of LPG mounded pressure storage vessel (Health and Safety Executive, 1987 HS(G) 34) (Courtesy of HM Stationery Office © All rights reserved)*

22.8.18 LPG-air plants

LPG storage may be associated with an LPG–air plant, which is an installation for the production of LPG–air mixtures. Such plants are covered by the Recommendations for LPG–Air Plants (LPGA, 1972, COP 9). The main elements of such plant are pumps and vaporizers.

22.9 LPG Storage: Refrigerated Storage

Codes and standards for LPG deal mainly with pressure storage rather than with refrigerated storage, but the guidance in NFPA 59 does cover refrigerated storage. Other guidance is available which deals primarily with storage tanks for low temperature duty. Further information may be sought in codes for refrigerated storage of LNG.

22.9.1 Storage tanks

Tanks for the refrigerated storage of LPG and LNG have developed from those for atmospheric storage of petroleum products. A relevant British Standard is BS 4741: 1971 *Specification for Vertical Cylindrical Welded Steel Storage Tanks for Low-temperature Service: Single-wall Tanks for Temperatures down to −50°C.*

There is available a variety of tank systems which may be used for the storage of LPG or LNG. A more detailed account is deferred to Section 22.11 on LNG, and only a brief account is given here.

Tank systems for LPG have been described by Morand, Claude and Herbretau (1985). They distinguish the following tank systems: (1) single wall tank, (2) double wall tank, (3) double integrity tank and (4) membrane tank.

A single wall tank has a wall made of low temperature steel with external insulation covered by a vapour barrier. A double wall tank has an inner wall of low temperature steel and an outer wall of carbon steel with insulation in between. The outer wall is not designed to withstand the cold liquid, so that this system still gives only a single effective containment. A double integrity tank system has an inner tank of low temperature steel with a suspended deck and an outer wall either of low temperature steel or pre-stressed concrete, but in either design the outer wall also is capable of containing the cold liquid. The membrane tank consists of a pre-stressed concrete containment with an aluminium foil membrane. These four tank systems are shown in Figure 22.13.

Morand, Claude and Herbretau have given a detailed account of the GMS 2000 membrane tank system, adapted from the GMS membrane tank system developed for marine use. In such a membrane system, the functions of mechanical strength and leak-tightness are separated and are provided by separate features.

The minimum design temperature for refrigerated storage tanks should take account of the lowest temperature to which they may be subjected. The tank may be cooled down to the minimum temperature of the refrigeration system if there is little movement of the contents, or even lower if there is malfunction of the system.

22.9.2 Separation distances

Separation distances for refrigerated LPG storage are given in the IP *LPG Code* and NFPA 59, and also in the ICI *LPG Code*.

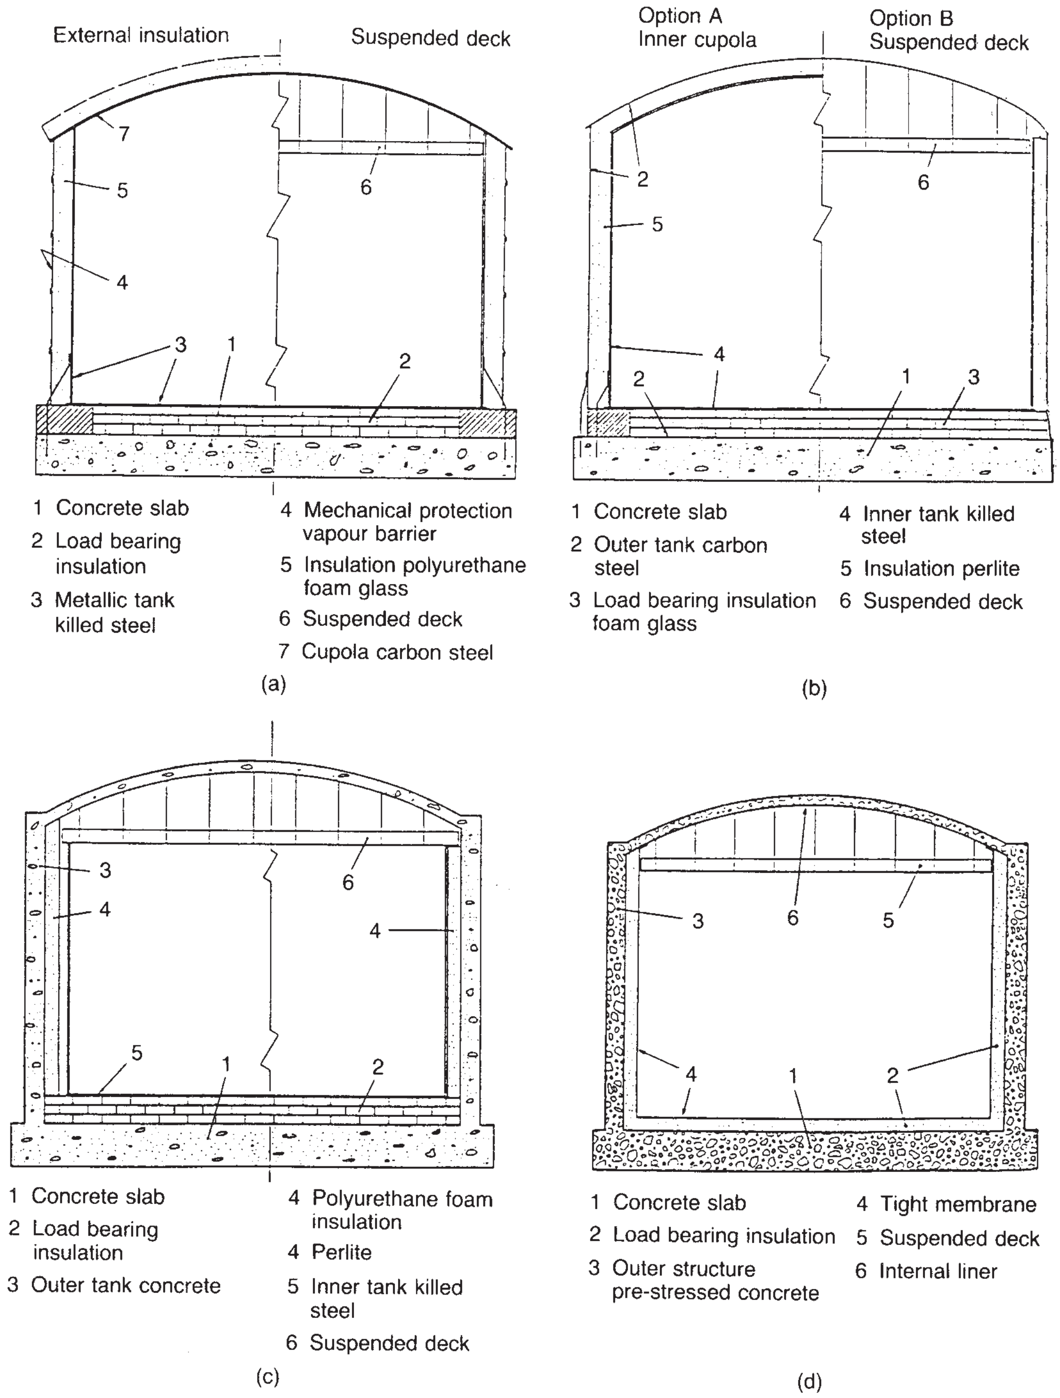

Figure 22.13 *LPG refrigerated storage tanks (Morand, Claude and Herbretau, 1985): (a) single wall tank; (b) double wall tank; (c) double integrity tank with concrete outer wall; (d) membrane tank (QMS 2000) (Courtesy of Gastech)*

22.9.3 Secondary containment

Secondary containment for refrigerated LPG storage tanks is treated in the same codes. An LPG storage tank should be provided with a full bund. The typical LPG refrigerated storage tank is sufficiently large to have its own bund, but in any event tanks containing other materials should not be located in the same bund as one holding refrigerated LPG.

If the topography is such, either naturally or by addition of diversion walls, that any spill can be contained and drained to an impounding basin, this provides an acceptable alternative to a bund.

Walls for full bunding should not be so high as to hinder fire fighting. The ICI *LPG Code* suggests a maximum height of 2 m (6 ft 6 in.) with an allowance of 0.15 m (6 in.) freeboard above the predicted liquid level. This leaves room for a foam blanket. There should be a minimum of two access points on opposite sides of the bund to allow safe access/escape in all wind directions. Access may be provided by steps over the bund.

22.9.4 Foundations

Refrigerated LPG storage tanks require good foundations and insulation for the bottom of the tank. The foundations need to be protected against 'frost heave'. The usual method of construction is to insulate the bottom of the tank and support it on a structure which has only limited contact with the ground and gives good air circulation. An account of foundation systems used for refrigerated storage tanks is given in Section 22.12.

22.9.5 Insulation

Refrigerated LPG storage tanks are insulated to reduce heat inleak.

On a single wall tank the insulation over the walls and roof is typically polyurethane foam (PUF). The insulation between the two walls of a double wall tank is usually perlite. The insulation between the walls of a double integrity tank may be PUF or perlite. A load-bearing foam glass insulation is used between the bottom of the tanks and the foundation.

Important features of the insulation on a single wall tank are the vapour sealing and the fire resistance. Vapour sealing of the insulation is necessary to prevent ingress of humid air and the consequent ice formation. The thermal insulation may also be given a degree of fire resistance, as described below.

22.9.6 Ancillary facilities

Ancillary facilities for refrigerated LPG tanks include the refrigeration system, the pumping facilities and vaporization equipment.

Reciprocating compressors are used for the direct re-liquefaction of vapour boiled off due to heat inleak. Use is also made of reciprocating compressors on refrigeration sets. Malfunction of a refrigeration set can cause the liquid refrigerated to be cooled below its normal temperature.

Reciprocating compressors can be a source of leakage of flammable vapour. They are subject to crankcase explosions and should normally be protected against this by an explosion relief valve.

Pumps should not normally be located inside a bund, where they introduce an additional hazard and are themselves at risk. It is desirable to locate them outside the bund. This also allows them to be used to pump down the storage tank during a fire.

22.9.7 Instrumentation

A refrigerated LPG storage tank should be provided with suitable measurements and alarms on liquid level, pressure and temperature and on boil-off gas flow.

Principal features of the instrumentation are the arrangements to prevent overpressure and overfilling. Pressure control is an integral part of the refrigeration system.

22.9.8 Pressure relief

The tank also requires pressure relief and vent disposal arrangements. There should be arrangements for both pressure relief and vacuum relief. Details of pressure relief systems are given in NFPA 59.

22.9.9 Vaporizers

Refrigerated LPG storage is commonly equipped with a vaporization facility to supply LPG in vapour form. An account of vaporizers for LPG has been given in Section 22.8.

22.9.10 Fire protection

Fire protection for refrigerated LPG storage tanks has much in common with that for other types of storage tanks for flammable products. The effect of fire on a refrigerated storage tank is basically similar to that on an ordinary atmospheric tank, but the heating and vaporization of the liquid are much more rapid.

Guidance on fire protection is given in NFPA 59. This refers to the need for HAC, for flammable gas detection and to a range of fire control and extinguishing systems such as water sprinkler, foam and dry chemical systems.

Passive fire protection for refrigerated LPG storage tanks is discussed in the ICI *LPG Code*. Tanks are provided with conventional thermal insulation, such as cork, polyurethane or perlite. Cork is combustible, but only burns slowly. In a fire risk area, it is usually vapour sealed with fire resistant mastic. Polyurethane is used in a similar way, and the 'high char' variety gives significant fire protection. Perlite is non-combustible, but needs to be contained in a steel jacket not easily damaged by fire. The conventional insulation, therefore, furnishes appreciable fire protection. A further fireproof finish may be added to bring the fire resistance up to a minimum of 2 h.

Such fire resistant thermal insulation provides a basic protection, which may be supplemented by fixed and mobile water sprays. Insofar as the insulation buys time for active fire fighting, automatic initiation of a fixed spray system may be less necessary.

22.9.11 Inspection

There is relatively little published on the inspection of, and inspection intervals for, refrigerated LPG storage tanks.

22.9.12 Underground storage

A number of installations have been built in which LNG is stored underground in an earth pit, as described in Section 22.10. The performance of these storages has been unsatisfactory and the method has essentially been abandoned. LPG may, in principle, be stored in a similar manner, but the same difficulties apply.

22.10 LNG Storage

22.10.1 Regulatory requirements

The storage of LNG is governed by the NIHHS Regulations 982 and the CIMAH Regulations 1984. The NIHHS notifiable inventory is 50 te. The CIMAH inventory for which demonstration of safe operation may be required (Regulation 4) is 50 te and that which attracts a safety case (Regulation 7) is 200 te.

22.10.2 LNG composition

LNG is not a homogeneous material. There are appreciable differences in composition between LNGs from different sources. Chatterjee and Geist (1972) give the properties of typical LNGs as follows:

Source	*Composition*								
	N_2	C_1	C_2	C_3	C_4	C_{5+}	SG	α	β (°F^{-1})
US	0.40	95.90	2.70	0.40	0.30	0.30	0.440	0.62	0.00164
Algeria	1.70	87.00	7.90	2.30	0.80	0.30	0.474	0.59	0.00151
Libya	0.40	68.60	24.20	9.40	2.00	0.40	0.538	0.50	0.00125

In the above table, c_4 denotes nC_4 and iC_4. The coefficients of expansion of the liquid with respect to concentration and temperature, α and β, respectively, are given by $\alpha = (1/\rho)(\delta\rho/\delta x)$ and $\beta = (1/\mathrm{p})(\delta\rho/\delta T)$, where T is the absolute temperature, x is the mole fraction of methane and ρ is the density of the liquid.

For LNGs having a molecular weight in the range 16–24, the specific gravity lies approximately in the range 0.42–0.54, respectively.

22.10.3 Storage conditions

LNG is generally stored fully refrigerated at −161°C and at atmospheric pressure.

22.11 LNG Storage: Refrigerated Storage

22.11.1 Storage tanks

As stated earlier, tanks for the refrigerated atmospheric storage of LNG have been developed from the conventional atmospheric storage tanks. The design of atmospheric storage tanks is governed by API Std 620: 1990 *Design and Construction of Large, Welded, Low-pressure Storage Tanks* and API Std 650: 1988 *Welded Steel Tanks for Oil Storage*. For refrigerated storage frequent reference is made to API Std 620, Appendix Q: *Low-pressure Storage Tanks for Liquefied Hydrocarbon Gases* and Appendix R: *Low-pressure Storage Tanks for Refrigerated Products*. A relevant British Standard is BS 5387: 1976 *Specification for Vertical Cylindrical Welded Steel Storage Tanks for Low-temperature Service: Double-wall Tanks for Temperatures down to* −196°C.

Tank systems for LNG have been described by Aarts and Morrison (1981), Nassopoules (1982), Closner and Wesson (1983), Collins *et al.* (1983), Steimer (1983), Gilbert *et al.* (1985), D.A. Jones (1985), Crawford, Durr and Handman (1986) and Morrison (1987). The following tank systems may be distinguished: (1) single wall tank, (2) double wall tank, (3) double integrity tank and (4) membrane tank.

A single wall tank has a wall made of low temperature steel with external insulation covered by a vapour barrier. A double wall tank has an inner wall of low temperature steel and an outer wall of carbon steel with insulation in between. The outer wall is not designed to withstand the cold liquid, so that this is still only a single containment system. A double integrity tank system has an inner tank with a suspended deck and an outer wall. Three permutations of materials of construction are used. In the first, both the inner and outer walls are of low temperature steel. In the second, the inner wall is of low temperature steel and the outer one is of pre-stressed concrete. In the third, both walls are of pre-stressed concrete. In all three of these designs the outer wall also is capable of containing the cold liquid. The membrane tank consists of a pre-stressed concrete containment lined with a stainless steel membrane.

Details of the internals of an LNG storage tank are shown in Figure 22.14. The construction of LNG storage tanks is discussed by Steimer (1983).

22.11.2 Separation distances

Separation distances for LNG storage are given in NFPA 59A.

22.11.3 Secondary containment

Where the tank itself provides only single containment, secondary containment may be provided in the form of a bund. The bund height may be low, intermediate or high. Since the bund has to contain the full contents of the tank; a low bund has to be located at some distance from the tank; a high bund can be located close to the tank; and the intermediate height bund can be located at an intermediate distance from the tank. Such bunds may be used with a single wall tank or a double wall tank. A high concrete bund should not be confused with the outer pre-stressed concrete wall of a double integrity tank. The latter is not structurally independent of the tank, whereas the former is. A high bund may, however, appear to be part of the tank, since it may be very close to it and may have its own roof.

22.11.4 Foundations

Foundations for LNG tanks are of two main types. One is an elevated pilecap foundation, with free air circulation. The second is a ringwall foundation with a heating system. An account is given by Steimer (1983).

The monitoring of the settlement of the foundations has been described by Morrison (1987).

22.11.5 Insulation

A typical insulation for a single wall tank is polyurethane with a metal jacket. For double wall tanks, use is made of perlite between the two walls. Insulation materials used for the suspended deck include perlite, mineral wool and fibreglass.

22.11.6 Ancillary facilities

Ancillary facilities for refrigerated LNG tanks include the refrigeration system and the pumping facilities. Accounts are given by Collins *et al.* (1983), Gilbert *et al.* (1985), Crawford, Durr and Handman (1986) and Morrison (1987).

An LNG storage is likely to be part of a terminal and vapour is generated from a number of sources, as described by Collins *et al.* Apart from those associated with the tank itself, these sources include superheated liquid rundown from process units, heat inleak into pipework and flash vapour formed during the loading of ships. The maximum vapour load may well occur during ship loading. Refrigeration facilities are provided to deal with these loads, but peak vapour flows are sent to the flare.

Pumping is required both for loading and for circulation, in order to prevent stratification. The tank system

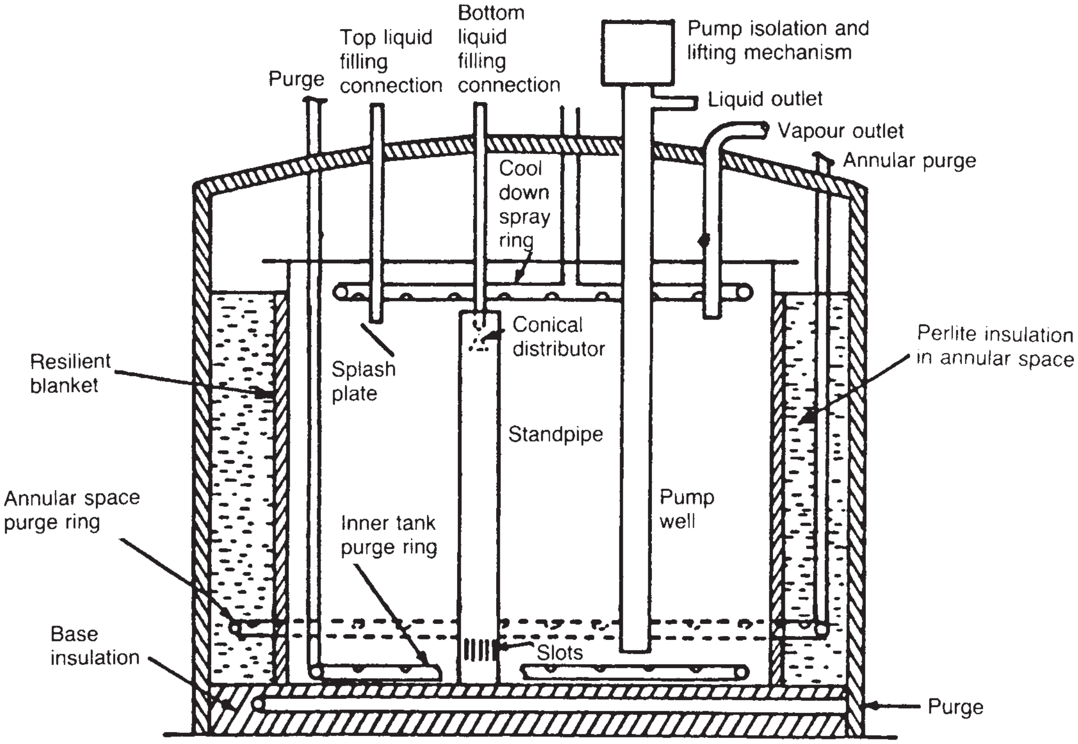

Figure 22.14 LNG refrigerated storage tank internals (Crawford, Durr and Handmann, 1986) (Courtesy of Gastech)

described by Morrison has six in-tank loading pumps and one circulation pump.

22.11.7 Instrumentation

A refrigerated LNG storage tank should be provided with suitable measurements of and alarms for the liquid level, the pressure and temperature in the tank and the boil-off gas flow.

Principal features of the instrumentation are the arrangements to prevent overpressure and overfilling. Pressure control is an integral part of the refrigeration system.

The monitoring of the movement of the inner tank has been described by Steimer (1983).

NFPA 59A requires that an LNG facility have an emergency shut-down system and gives details of the system to be provided.

22.11.8 Pressure relief

The tank also requires pressure relief and vent disposal arrangements. Accounts are given by Crawford, Durr and Handman (1986) and Morrison (1987).

Pressure rises may occur due to heat inleak into the tank, high liquid in-flows, the in-flow of superheated liquid, vaporization due to pumped recirculation, a fall in barometric pressure, failure of the pressure control system, heat input during a fire, or rollover. Causes of vacuum include high liquid withdrawal flows, the in-flow of subcooled liquid, and a rise in barometric pressure.

Pressure relief is provided by pressure relief valves and vacuum protection by vacuum breaker valves. In the system described by Crawford, Durr and Handman (1986), the pressure relief valves vent to atmosphere and the vacuum breakers admit air.

The pressure control system may be arranged so that if the vapour flow is too great for the refrigeration system to handle, vapour is vented to the flare before opening of the pressure relief valves occurs. Operation of the vacuum breakers may be forestalled by vacuum control, which admits fuel gas.

22.11.9 Fire protection

Fire protection of refrigerated LNG storage tanks has much in common with that for other types of storage tanks for flammable products. Guidance is given in NFPA 59A Further accounts are those by Closner and Wesson (1983) and Morrison (1987).

NFPA 59A refers to the need for HAC, for flammable gas detection and to a range of fire control and extinguishing systems such as water sprinkler, foam and dry chemical systems.

Closner and Wesson describe a number of fire protection measures. These are: (1) containment systems which limit the size of the pool, and hence of any fire; (2) protective coating systems; (3) foam systems and (4) water deluge systems.

The tank system described by Morrison is designed to withstand a collapse of the roof and the resultant tank fire. In these circumstances, the outer wall would be subject to hydrostatic pressure and severe thermal gradients from the flame, which is assumed to be tilted.

22.11.10 Annular space

In a double wall tank, some attention needs to be given to the annular space between the two tanks, and in particular to the entry of LNG into the space. One way in which this can occur is by condensation, caused by an increase in pressure in the tank. In some cases, the annular space is purged with nitrogen.

Another situation is that which results from a leak of LNG from the inner tank. If this is sufficiently large, the formation of vapour may generate a pressure sufficient to rupture the inner tank. An account of this problem in a double wall ammonia tank and its solutions has been given by Squire (1991), as described in Section 22.18.

22.11.11 Inspection

There is relatively little published on the inspection of, and inspection intervals for, refrigerated LNG storage tanks. An account of the design of storage tank internals to facilitate the decommissioning and recommissioning of the tank has been given by Crawford, Durr and Handman (1986), who describe these operations in detail.

22.11.12 Rollover

Under certain conditions, 'rollover' of the liquid in an LNG tank can occur, resulting in the rapid evolution of a large quantity of vapour with the potential to overpressure the tank.

Stratification can occur in an LNG tank if the density of the liquid 'cargo' charged to the tank is significantly different from that of the 'heel' already in the tank. As described above, there are in fact appreciable differences in density between LNGs from different sources.

A model of rollover in LNG tanks has been given by Germeles (1975b), who develops an earlier model by Chatterjee and Geist (1972). The liquid in the tank is assumed to be stratified into a number of 'cells' with heat inleak from the sides and from the bottom of the tank as shown in Figure 22.15. The model consists essentially of the unsteady-state heat and mass balance equations for these cells and of supporting correlations.

The model draws on previous work by J.S. Turner (1965) on the mass and heat transfer between the interfaces of cells in stratified layers of saline solutions of different strength. He defines an interface stability parameter R

$$R = \left|\frac{\beta\delta S}{\alpha\delta T}\right| \qquad [22.11.1]$$

where S is the concentration of the solute (mass fraction), T is the absolute temperature (K), α is the coefficient of expansion with respect to the temperature, T and β is the coefficient of expansion with respect to the concentration. The heat and mass transfer coefficients are given as functions f_1 and f_2 of R.

Another relation used in the Germeles model is the boil-off model by Hashemi and Wesson (1971). The boil-off rate b is given by

$$b = 0.328\ \frac{\rho_o C_p}{H_v}\ \frac{(g\alpha k^2)^{1/3}}{\rho\mu C_p^2}(T_n - T_s)^{4/3} \qquad [22.11.2]$$

where b is the boil-off mass flux, C_p is the specific heat of the liquid, g is the acceleration due to gravity, H_v is the latent heat of vaporization of methane, k is the thermal conductivity of the liquid, T_n is the absolute temperature of the top or nth cell, T_s is the absolute saturation temperature of methane in LNG, μ, is the viscosity of the liquid, ρ is the density of the liquid and ρ_o is the average reference density of the liquid.

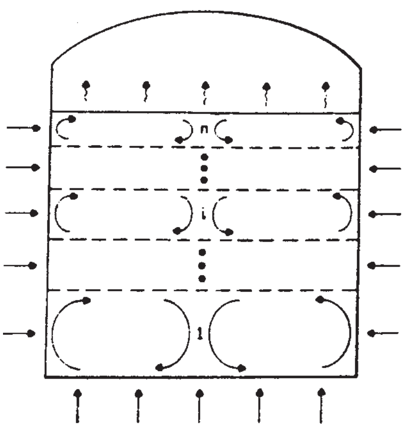

Figure 22.15 *An LNG storage tank with the liquid stratified into n cells (Germeles, 1975b)(Courtesy of the Plenum Publishing Corporation)*

In the Germeles model, equilibration of the liquid densities is taken as the necessary and sufficient criterion for mixing. In this aspect his model differs from that of Chatterjee and Geist, which requires equilibration of both temperature and composition.

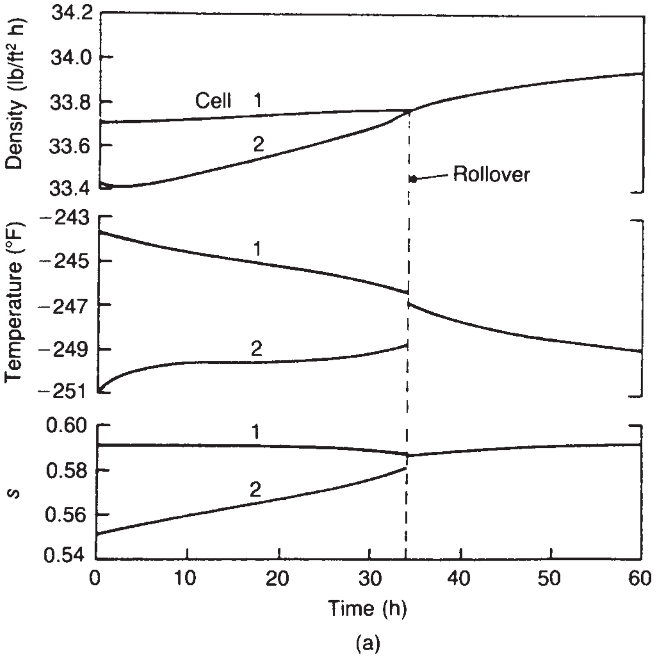
Some results from a simulation of the La Spezia rollover obtained by Germeles using his model are given in Figure 22.16. As Figure 22.16(a) shows, there is at rollover equilibration of density, but not necessarily of temperature or composition. Figure 22.16(b) shows the rapid increase in boil-off. The computed time to rollover is 34 h, which compares with a time of 31 h in the actual incident.

Further theoretical and experimental investigations of rollover in LNG tanks have been reported (e.g. Nakano *et al.*, 1983; Takao and Suzuki, 1983).

There are a number of measures which can be taken to reduce the risk of rollover. Accounts of such measures are given by Chatterjee and Geist (1972) and by Drake, Geist and Smith (1973). They include:

(1) limitation of the variation in LNG composition;
(2) mixing of the tank contents by the use of top and bottom filling points;
(3) mixing of the tank contents by pump recirculation;
(4) pressure control of the tank;
(5) monitoring of parameters related to stratification;
(6) provision of a high capacity vent.

In some cases it may be possible to limit the variation of LNG composition, but in others this is not attractive. Mixing of the tank contents may be effected during filling by using top or bottom filling to charge a cargo which is more or less dense than the heel. Mixing during filling may be enhanced by jet mixing devices. Mixing during and after filling by recirculation pumps may also be used, although this is a



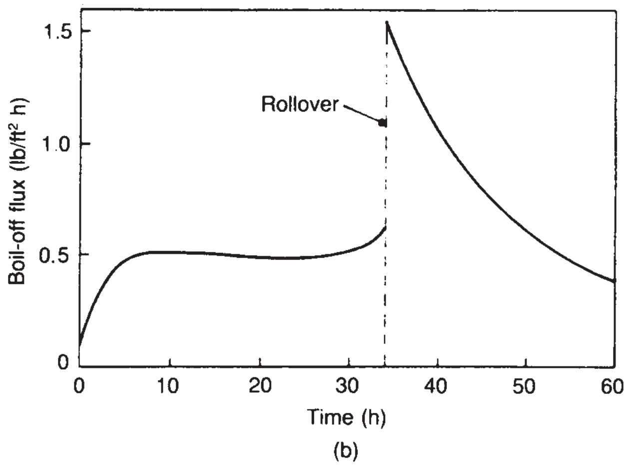


Figure 22.16 *Simulation of the rollover of LNG in the tank in the La Spezia incident (Germeles, 1975b): (a) density, temperature and impurity concentration S; (b) boil-off flux (Courtesy of the Plenum Publishing Corporation)*

slow method and it may take too long; it also increases the heat inleak. Control of pressure in the tank may be used to give controlled evolution of vapour from the liquid. There are several parameters which may be used to monitor stratification. One is the liquid temperature profile in the tank. Another is the difference in density between the feed and the tank liquids, a third is the vaporization rate in the tank. Protection of the tank if rollover occurs despite these other measures requires the provision of a high capacity vent. The peak vapour evolution rate resulting from a rollover is difficult to estimate and the vent needs to be generously sized.

The rollover hazard receives mention in a number of accounts of LNG tank systems, including those by Collins *et al.* (1983), Crawford, Durr and Handman (1986) and LeChat and Caudron (1987).

22.11.13 Particular installations

There are a number of accounts of particular refrigerated atmospheric storage installations for LNG.

The Montoir de Bretagne LNG terminal is described by Lechat and Caudron (1987). They discuss the potential for rollover due to differences in the composition of the LNG cargoes received, and the precautions taken.

An account of the LPG and LNG terminal at Das Island is given by Morrison (1987). He describes in detail the tanks, foundations, ancillary equipment, pressure relief and fire protection.

22.11.14 Storage vessels

Although an atmospheric storage tank is the norm for refrigerated land-based LNG storage, a pressure vessel may also be used, as described by Itoyama *et al.* (1989). The vessel is essentially an adaptation of the MRV storage sphere used on LNG carriers. It has an inner shell of aluminium, to ensure strength at a cryogenic condition, and an outer shell of mild steel.

22.11.15 Underground storage

A number of early LNG storages took the form of an earth pit. The ground around the pit was frozen by the cold liquid, thus providing a seal. One such installation was the 21,000 te LNG storage at the British Gas terminal at Canvey.

Experience with such earth pit storages, described by Ferguson (1975), was not good. Problems were experienced in making the containment leak-tight and waterproof and with fissuring of the ground. The heat inleak resulted in a boil-off rate which was uneconomic. Thus, whereas the boil-off for a good above-ground tank is of the order of 0.04% per day by volume, that for an earth pit storage is some 0.1–0.3%.

The abandonment of earth pit storage at Canvey meant that of some dozen such storages, by 1975 only one remained in use. However, the concept of underground storage remains alive. Conceptual designs for cavity storage of LPG and LNG have been described by Lagron, Boulanger and Luyten (1986).

22.11.16 Mounded storage

More success has been achieved with mounded storage in which the LNG pressure vessel is set in an earth mound. This method has already been described in relation to LPG storage.

The method has been used in Japan, as described by Collins *et al.* (1983). In some cases use has been made of a concrete tank with its roof at grade, whilst in others the tank has been constructed at ground level and surrounded by a full earth berm.

22.12 Hydrogen Storage

Hydrogen is stored both as a gas and as a liquid. Relevant codes are NFPA 50A: 1989 Gaseous Hydrogen Systems at Consumer Sites and NFPA 50B: 1989 Liquefied Hydrogen Systems at Consumer Sites. Also relevant are *The Safe Storage of Gaseous Hydrogen in Seamless Cylinders and Containers* (BCGA, 1986 CP 8) and *Hydrogen* (CGA, 1974 G-5). Accounts are also given by Scharle (1965) and Angus (1984).

The principal type of storage for gaseous hydrogen is some form of pressure container, which includes cylinders. Hydrogen is also stored in small gasholders, but large ones are not favoured for safety reasons. Another form of storage is in salt caverns, where storage is effected by brine displacement. One such storage holds 500 te of hydrogen.

A typical industrial cylinder has a volume of 49 l and contains some 0.65 kg of hydrogen at 164 bar pressure. The energy of compression which would be released by a catastrophic rupture is of the order of 4 MJ. There is a tendency to prohibit the use of such cylinders indoors.

Liquid hydrogen is stored in pressure containers. Dewar vessel storage is well developed with vessels exceeding 12 m diameter.

NFPA 50A requires that gaseous hydrogen be stored in pressure containers. The storage should be above ground. The storage options, in order of preference, are in the open, in a separate building, in a building with a special room and in a building without such a room. The code gives the maximum quantities which should be stored in each type of location and the minimum separation distances for storage in the open.

For liquid hydrogen NFPA 50B requires that storage be in pressure containers. The order of the storage options is the same as for gaseous hydrogen. The code gives the maximum quantities which should be stored in each type of location and the minimum separation distances for storage in the open.

Where there are flammable liquids in the vicinity of the hydrogen storage, whether gas or liquid, there should be arrangements to prevent a flammable liquid spillage from running into the area under the hydrogen storage. Gaseous hydrogen storage should be located on ground higher than the flammable storage or protected by diversion walls.

In designing a diversion wall, the danger should be borne in mind that too high a barrier may create a confined space in which a hydrogen leak could accumulate. Scharle (1965) draws attention to the risk of detonation of hydrogen when confined and describes an installation in which existing protective walls were actually removed for this reason.

Pressure relief should be designed so that the discharge does not impinge on equipment. Relief for gaseous hydrogen should be arranged to discharge upwards and unobstructed to the open air.

Hydrogen flames are practically invisible and may be detected only by the heat radiated. This constitutes an additional and unusual hazard to personnel which needs to be borne in mind in designing an installation.

22.13 Toxics Storage

The topic of storage has tended to be dominated by flammables. It would be an exaggeration to say that the storage of toxics has been neglected, since there has for a long time been a good deal of information available on storage of ammonia, chlorine and other toxic materials. Nevertheless, the disaster at Bhopal has raised the profile of the storage of toxics, especially in respect of highly toxic substances.

In the United States, in particular, there is a growing volume of legislation, as described in Chapter 3, for the control of toxic substances. Attention centres particularly on high toxic hazard materials (HTHMs).

Some of the factors which need to be taken into account in relation to storage of HTHMs are now considered.

22.13.1 Inherent toxic hazard

The starting point is the characterization of the toxic hazard. The toxicity of the substance is one aspect of this. Another is the inventory. But the potential for harm also depends very much on features of the substance and its storage which determine its emission and dispersion.

There are a variety of toxic exposure limits which have been devised for different purposes such as the threshold limit value (TLV) and the emergency exposure limit (EEL), but these tend to be of limited use in assessing the toxic hazard. Various attempts have been made to devise more appropriate indices such as the Dow Chemical Exposure Index (CEP). These exposure limits and indices are described in Chapter 18.

The most realistic approach to the characterization of the inherent toxic hazard, however, would appear to be some form of hazard assessment, which need not necessarily amount to a full risk assessment, but may be limited to consequence assessment.

22.13.2 Inherently safer design

As for other process activities, so for HTHM storage the principle of inherently safer design should be applied. In the case of HTHM storage this means in particular examining the products made and the whole series of processes used to make them, whether at the assessor's site or elsewhere, with a view to the use of more benign chemicals and to the reduction of toxics inventories throughout the production and transport chains. In particular, it should be an aim to eliminate intermediate storage. Illustrations of the application of inherently safer design with regard to toxics, including toxics storage, are given in Chapter 11.

Another aspect of inherently safer design in storage is the storage conditions. The choice between pressure and refrigerated storage is the obvious example. But storage can be made inherently safer in other ways also, such as choosing the storage temperature such that it reduces the load on the disposal system should it become necessary to depressurize.

22.13.3 Storage siting and layout

Storage for HTHMs should be sited so as to minimize the frequency and the consequences of any release. The consequences of a release may be reduced by the provision of separation distances between the storage and potential targets, exploitation of the terrain and provision of escape routes. Measures to reduce frequency include segregation from flammables, minimization of interactions with transport terminals and minimization of domino effects.

22.13.4 High integrity design

Plant used for the storage of HTHMs should be high integrity plant. The high integrity design features should cover, among other things, (1) plant layout, (2) vessels and tanks, (3) pipework, (4) loading and unloading facilities, (5) secondary containment, (6) instrumentation, (7) pressure relief and disposal systems and (8) contaminant control.

For the most part, the codes and standards which govern plant design are oriented to flammables rather than toxics. There is relatively little guidance on toxics specifically.

The American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code* does, however, recognize a category of 'lethal service', where the gases or liquids contained are of lethal toxicity. The ASME main piping code B31.3 has a Category M which is of similar purport.

The plant layout for HTHMs should include arrangements for the containment of liquid spillages by the use of bunds or other measures.

Pressure vessels and atmospheric tanks for HTHM storage should be built to high integrity standards. It is not usual to use double integrity tanks for HTHMs, though they are used for ammonia. But other measures to enhance integrity such as full radiography of welds, stress relieving and so on, should be used. Foundations and supports should also be of high integrity.

Likewise, pipework and fittings and equipment such as pumps should be to high integrity standards. Special attention should be paid to potential weak points such as nozzles, welds, flanges, gaskets and pipe supports. Events which might cause failure of pipework or equipment, such as hammerblow or vibration in the pipe or deadheading or cavitation in pumps, should be given extra consideration.

There are two quite separate aspects to pipework integrity. The measures just described are aimed at the prevention of serious failures. It is also necessary to aim for a high degree of leak-tightness in order to prevent fugitive emissions.

The disposition of the pipework into and out of the storage is another relevant feature. Lines connected below the liquid surface are a major source of large leaks and are to be avoided.

Provision needs to be made to shut-off or reduce leaks which may occur in the form of excess flow valves, remotely operated isolation valves, and so on.

Extra consideration should be given to external threats to the containment, whether due to impacts such as dropped loads or vehicles or to natural events.

Associated with storage are loading and unloading facilities which are another potential source of release. Features of such facilities which are not present in storage itself and which tend to increase the risk include: (1) a higher level of activity; (2) the involvement of personnel from different companies; (3) connections which are constantly made and unmade and which may be relatively fragile; (4) the movement of vehicles, including moving off whilst still connected and (5) the absence of secondary containment. The design should aim to minimize these problems.

The provision of secondary containment should be considered. Types of secondary containment include double integrity containments, double-walled pipes, dump tanks, bunds, drainage and sump systems and enclosures.

Some part of the instrument and control systems for HTHM storage may need to be high integrity. At the very least good practice should be followed in matters such as the use in critical applications of a sensor separate from that of the control loop for an alarm or a trip. It may be necessary in some cases to consider high reliability instrument systems based on the use of redundancy.

Systems for pressure relief on HTHM storage should receive extra attention. The relief and disposal system appropriate depends on the nature and quantity of fluid to be handled. Whatever system is selected, it too should be of high integrity.

A storage can be put at risk by the entry of a contaminant which either itself reacts with the material stored or catalyzes a reaction. For some chemicals it is necessary to include in the design features that prevent such contamination.

22.13.5 High integrity operation

High integrity in the design needs to be complemented by high integrity in the operation of the plant. It is not appropriate to rehearse here the various features of good practice in operation and maintenance, but a few salient points can be made.

Storage is not simply a passive adjunct to the main process plant. It too is actively operated by filling and emptying. These operations have the potential to cause destructive overpressure or underpressure and to cause overfilling, and they need to be carefully controlled.

The storage should be operated so as to exclude contaminants which might cause reaction of the material held. Likewise, operations should not result in serious depletion of any necessary stabilizer.

Where the HTHM is flammable as well as toxic, measures should be taken to control ignition sources, including procedures to prevent ignition by static electricity.

Activities in the vicinity of storage, such as lifting of loads or movement of vehicles, should be controlled so that they do not pose an impact threat.

Storage systems tend to have a quite large proportion of items for use only in an emergency and which tend to be neglected and are often found to be either in poor condition or in the wrong state. Examples are blocked pipes or closed valves on water spray systems or open valves on water drainage lines through bunds.

With regard to maintenance, some aspects of particular importance in HTHM storage include (1) the identification and ranking of critical features, (2) inspection to detect unrevealed failures, (3) preventive maintenance, (4) isolation procedures and (5) documentation.

The operating discipline should ensure that all protective features are maintained in operational condition, whether these be heating or cooling systems, instrumented protective systems, relief systems or fire protection systems.

22.14 High Toxic Hazard Materials: CCPS *Guidelines*

The Center for Chemical Process Safety (CCPS) has published guidance on the storage of HTHMs, and this is now described.

22.14.1 CCPS *Guidelines for Safe Storage and Handling of High Toxic Hazard Materials*

The CCPS *Guidelines for Safe Storage and Handling of High Toxic Hazard Materials* (1988/3) (the CCPS *HTHM Storage Guidelines*) cover a wide range of topics on HTHM storage. Many of these topics are dealt with in other parts of the present text. Table 22.10 gives an indication of the chapters or sections in which these topics are treated.

Table 22.10 *Some principal topics in the CCPS High Toxic Hazard Material Storage Guidelines and their treatment in this text*

22.15 Chlorine Storage

Storage of chlorine as a liquid is mainly either at chemical works or at installations where it is required for water treatment such as waterworks, power stations and swimming baths. Its boiling point is −34°C.

Guidance on the handling and storage of chlorine is given in HS(G) 28 *Safety Advice for Bulk Chlorine Installations* (HSE, 1986). This guidance is based on the earlier *Guidelines for Bulk Handling of Chlorine at Consumer Installations* (CIA, 1980/14) (the CIA *Chlorine Storage Guide*), which itself followed *Code of Practice for Chemicals with Major Hazards: Chlorine* (BCISC, 1975/1) (the CIA Chlorine Code). HS(G) 28 is the guidance now listed by the Chemical Industries Association (CIA).

Further guidance is given in the various publications of the Chlorine Institute, including *Chlorine Manual* (1986, Pmphlt 1), *Non-refrigerated Liquid Chlorine Storage* (1982, Pmphlt 5), *Refrigerated Liquid Chlorine Storage* (1984, Pmphlt 78), *Piping Systems for Dry Chlorine* (1985, Pmphlt 6), *Operation of Chlorine Vaporizing Equipment* (1979, Pmphlt 9) and *Chlorine Tank Car Loading, Unloading, Air Padding, Hydrostatic Testing* (1979 Pmphlt 66).

The account given here is confined to chlorine storage. Chlorine itself is discussed in Chapter 11, pipework for chlorine systems is discussed in Chapter 12 and chlorine unloading facilities are described in Section 22.26.

22.15.1 Regulatory requirements

The storage of chlorine is governed by the NIHHS Regulations 1982 and the CIMAH Regulations 1984. The NIHHS notifiable inventory is 10 te. The CIMAH inventory for which demonstration of safe operation may be required (Regulation 4) is 10 te and that which attracts a safety case (Regulation 7) is 75 te.

22.15.2 Storage conditions

Chlorine is generally stored under pressure at atmospheric temperature, but may also be stored fully refrigerated at −34°C and atmospheric pressure.

22.15.3 Storage systems

Chlorine should be stored in bulk only if it is used in quantities which make the use of drums impractical. A chlorine storage vessel should have a capacity appreciably greater than a full load from a road tanker or rail tank car. It is preferable to keep the number of vessels to a minimum in order to avoid complexity and proliferation of potential leak sources, but flexibility and continuity of supply require at least two vessels.

The *Chlorine Code* gives a well defined philosophy for the storage of chlorine. In view of the importance of the hazard of toxic release from storage, the *Code's* statement of the problem is of interest:

> Liquid stored in bulk is the potential source of the most serious incidents.
>
> Stored liquid could be released:
>
> (1) By failure of the vessel holding it.
> (2) By failure of pipework or equipment connected to that vessel.
>
> Stocks necessarily carried to conduct normal operation in the businesses are such that the techniques of design and operation of any storage must eliminate the risk of complete vessel failure leading to release of its contents.

(1) Liquefied gas storage can be designed, fabricated, inspected and maintained so that there is no possibility of a tank releasing its contents while it is kept within design conditions.
(2) Protective systems of quantified high reliability and availability can be designed to ensure that these physical conditions are maintained.
(3) Impurities can be controlled to obviate abnormal corrosion.
(4) These measures may be backed up by relief systems such that the combination of vessel design, protection, quality control and relief eliminates the possibility of complete vessel failure.
(5) Liquefied gas storages can be sited, or given protective barriers, such that they are fully protected from external damage other than civil commotion, sabotage, act of war or falling aircraft.

From these first premises it follows that, although the risk of some damage to a storage vessel cannot be totally eliminated, the main dangers derive from failure of pipework or equipment whether on producing or using plants or connected to storage.

The critical factors in preventing escapes are:

(1) Arrangements for isolation of stocks from all other equipment.
(2) Arrangements for isolation of process vessels from all other equipment.
(3) Protection from external damage.
(4) Means of maintaining design conditions and relieving abnormal conditions.
(5) Means for disposal of purged or vented material.
(6) The effect of chemicals and conditions in using processes on the design and operating requirements.
(7) Means for the retention of spillages near the point of origin and for their treatment. The capacity of the retention area shall be sufficient for, but need not be more than, the largest spillage which can reasonably be envisaged. The walls of the retention area shall, however, be sufficiently high to contain also any material used in treating the spillage.

22.15.4 Materials of construction

Materials of construction for chlorine handling are discussed in Chapters 11 and 12, and are therefore not dealt with in detail here, but there are a few matters which merit mention at this point. The normal material of construction for chlorine storage vessels is mild steel. Mild steel is satisfactory for the handling of dry gaseous or liquid chlorine, but not of wet chlorine. There are, however, upper and lower temperature limits for mild steel in chlorine which should not be exceeded.

22.15.5 Storage vessels

Chlorine pressure storage vessels are usually horizontal cylindrical vessels for the smaller capacities and spherical vessels for the larger ones. Pressure storage spheres up to 400 te capacity have been used for chlorine, but some large vessels have been taken out of use, thus reducing the hazardous inventory.

A chlorine pressure storage vessel should be designed to BS 5500: 1991 Category 1 or equivalent, but with the additional requirements of HS(G) 28.

HS(G) 28 states that a chlorine storage vessel should have a minimum design pressure of 12 barg (174 psig). The minimum design temperature should be −35°C, the temperature to which liquid chlorine will drop if completely depressurized. The normal design range for temperature is −35°C to 45°C.

With regard to the filling ratio, there is no standard equivalent to BS 5355: 1976 for transportable liquid containers. HS(G) 28 states that for chlorine the figure normally used is 1.25 kg of liquid chlorine/litre of capacity, which ensures that even at 50°C the volumetric fill does not exceed 95%.

The connections on a chlorine storage vessel should be held to a minimum and kept simple. Connections required are (1) a liquid chlorine inlet, (2) a liquid chlorine outlet, (3) vent and padding air lines, (4) a relief system and (5) instrument connections. Lines entering below the liquid level are to be avoided so that any release is of gas rather than of liquid. The preferred arrangement is that all the connections should be through a manhole located on the top of the vessel. Detailed design of these lines is described HS(G) 28.

The vent and padding air lines may have separate connections or may be through a single combined connection. The vent should go to the gas absorption system.

The arrangements given in HS(G) 28 for a chlorine storage vessel and the associated unloading facilities are shown in Figure 22.17.

Chlorine storage vessels should be located above ground and provided with a bund. The bund should be able to take the contents of the largest storage vessel with adequate freeboard. The ground under a storage vessel should be sloped to allow drainage into a sump. Provision should be made to remove rainwater over the bund wall rather than through it.

22.15.6 Ancillary facilities

Ancillary facilities required for chlorine storage include: an expansion vessel to take any chlorine vented in the event of overfilling; a gas absorption unit for the disposal of the vented material; equipment for the transfer of liquid chlorine from storage to consumer plants; and vaporization equipment to provide chlorine gas to consumer plants. These facilities are described below.

22.15.7 Instrumentation

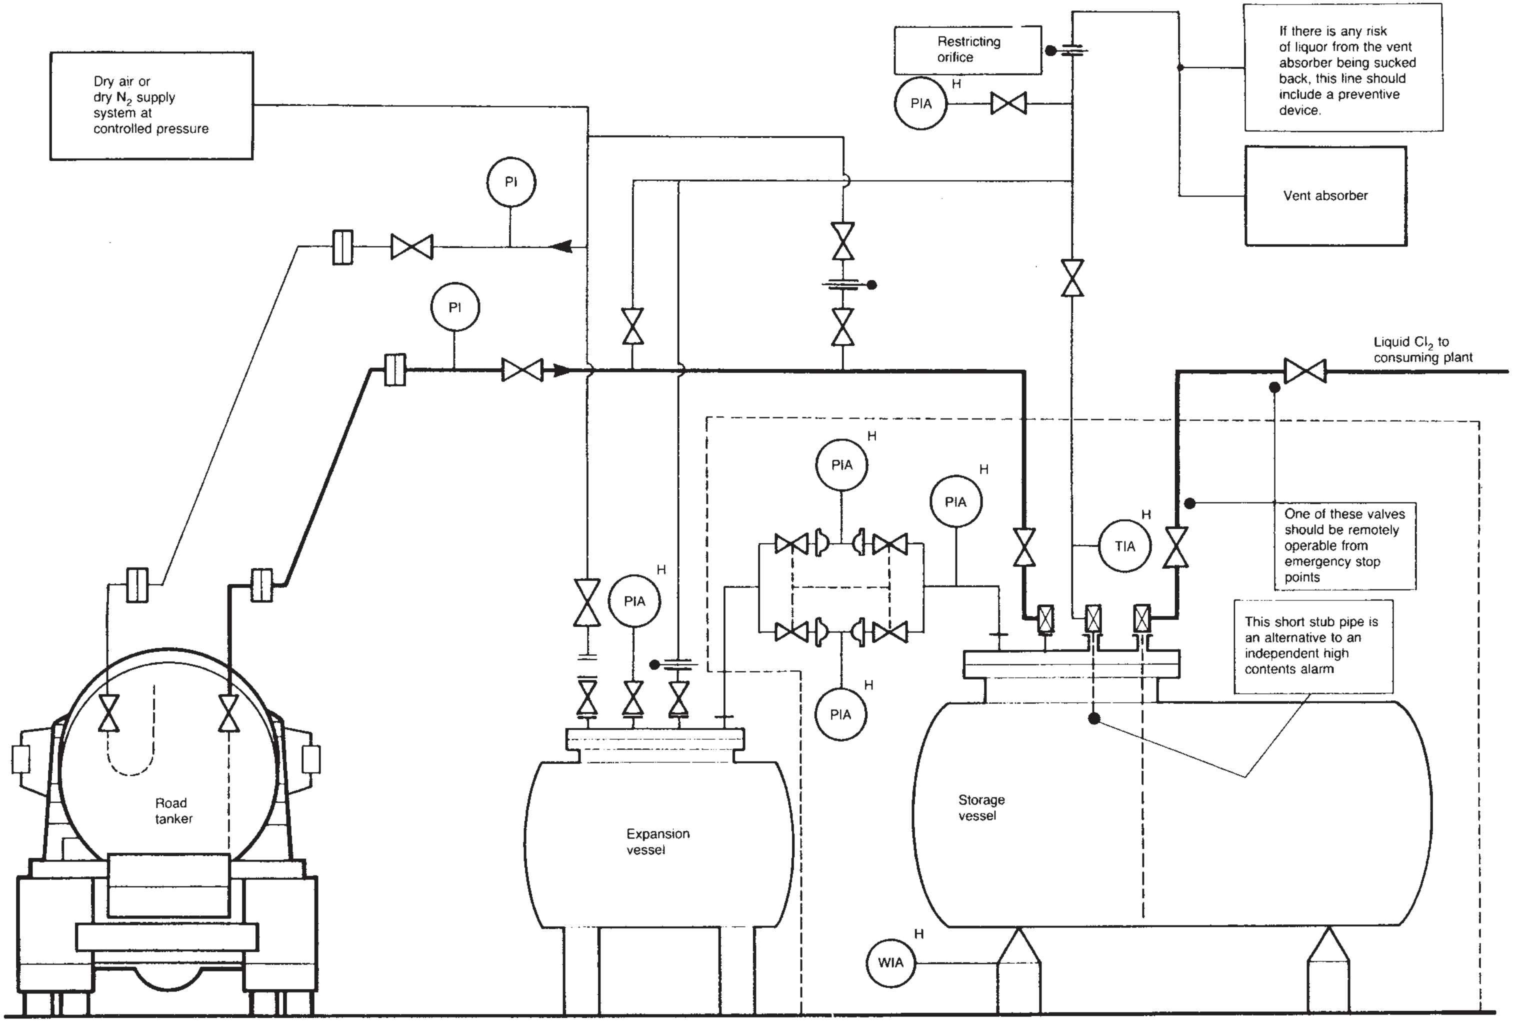
A chlorine storage vessel should be provided with suitable measurements and alarms on liquid contents, pressure and temperature. The measurement of the liquid contents should preferably be by means of load cells or a weighbridge.

Protection against overfilling should receive particular attention. As already stated, the vessel itself should be larger than the road tankers and rail tank car containers which deliver to it. There should be a high contents alarm, and possibly an extra-high contents alarm. A low contents alarm may also be appropriate. An ullage pipe may be provided on the vent line with a low temperature or other alarm to warn of entry of liquid chlorine into the line.

The storage should be provided with a chlorine gas detector system.

22.15.8 Pressure relief

For a chlorine storage vessel, pressure relief should be provided as an ultimate safeguard. HS(G) 28 requires that the pressure relief arrangements be a double stream system



The parts within the dotted line are repeated
on every storage vessel.

Figure 22.17 *General arrangement for a chlorine pressure storage installation and road loading facility (Health and Safety Executive, 1986 HS(G) 28). The original diagram contains cross-references to certain paragraphs in HS(G) 28. (Courtesy of HM Stationery Office © All rights reserved)* with isolation valves on the upstream and downstream sides of each stream, so that one stream can be operational whilst the other is under maintenance. There should be a safeguard against the risk of the simultaneous isolation of both streams, either by means of a mechanical interlock on the isolation valves or of a procedure for locking the valve.

For each relief stream, the relief devices should be either two bursting discs arranged back to back or a bursting disc followed by a pressure relief valve. Either way, there should be a pressure gauge on the space between the two devices. A pressure relief valve alone should not be used, owing to the risk of corrosion.

A single stream system with locked open isolation valves is in common use, but the arrangements described are the preferred ones.

An expansion vessel should be provided to receive the relief. It should be designed to the same standard as the storage vessels and should have a capacity about 10% of that of the largest vessel. It should be capable of being vented manually to the disposal system and should have its own high pressure alarm.

22.15.9 Absorption system

There should be suitable arrangements for the absorption of any chlorine vented. In some systems it is possible to arrange for the chlorine to be absorbed on a user plant, but normally a dedicated gas absorption system is required. As shown in Figure 22.17, the gas absorption system receives chlorine gas from normal venting and, via the expansion vessel, gas from the relief system.

The gas absorption system should be instrumented to ensure that the circulation of liquid and the concentration of absorbent are correct and to measure the concentration of chlorine in the outlet gas stream.

22.15.10 Transfer arrangements

The transfer of liquid chlorine from a storage vessel to consumer plants may be effected by vapour pressure alone, by padding gas pressure or by pumping. The first two methods are the most common.

The padding gas may be nitrogen or compressed dry air. Nitrogen for padding may be obtained from a liquid nitrogen vaporization unit. Compressed air should be dry to a dewpoint below −40°C and should be oil free. The padding gas should be held in a receiver with an operating pressure and with protective devices and instrumentation such that the storage cannot be over-pressured by the padding gas. Detailed arrangements are described in HS(G) 28.

For pumping, which may be utilized where a higher pressure is required or where the padding gas cannot be tolerated, use is made both of submerged pumps installed inside the tank and of external pumps. For the latter a special pumping system has been developed in which the liquid chlorine is first transferred from the storage vessel to a separate pumping vessel and then fed to the pumps.

22.15.11 Vaporizers

Where chlorine is required in vapour form, a limited supply may be obtained from cylinders or drums, but the supply of any appreciable quantity requires vaporization facilities. It is not good practice to draw the gas from the vapour space of a chlorine storage vessel, as this creates the risks that process liquid may be drawn into the vessel and that less volatile impurities such as nitrogen trichloride may become concentrated.

HSE guidance on chlorine vaporizers is given in CS 16 *Chlorine Vaporizers* (1985) and HS(G) 28.

Three heating media are in use in chlorine vaporizers: hot water, steam and heat transfer fluids. The most common method is the use of hot water at about 60–70°C. Where steam is used it should be saturated and pressure limited to prevent overheating.

Four main types of vaporizer are used, as shown in Figure 22.18. Type 1 has some form of vertical tube bundle, Type 2 is a coiled tube immersed in a heating bath, Type 3 is a concentric tube, or jacketed pipe, unit and Type 4 is a kettle, reboiler unit. HS(G) 28 discusses the characteristics of the different designs.

There are a number of potential problems and hazards associated with vaporizers. One is overpressurization. A vaporizer commonly operates at 70°C, at which temperature the vapour pressure of chlorine is some 21 bar. This pressure can be realized in the vaporizer if it is isolated whilst containing the hot liquid. It is not usual in the United Kingdom to fit a pressure relief valve to a vaporizer.

Overheating can result in more rapid corrosion and, in the extreme, the combustion reaction between steel and chlorine. A temperature limit of 120°C is normally observed. The pressure of steam used for heating is limited to 1 barg (15 psig), corresponding to a temperature of 120°C, with the steam saturated rather than superheated.

If the flow to the vaporizer is excessive, the heating is insufficient or the heat transfer surfaces are fouled, the chlorine vapour may lose superheat, liquid droplets may be entrained or the vaporizer may flood. It is even possible that ice may form on the heating surfaces. An indication of these problems may be obtained from the gas flow and temperature from the vaporizer. HS(G) 28 gives details of the controls required. A knockout pot may also be installed to remove liquid droplets.

If the chlorine becomes contaminated by water, whether by a pinhole leak of water or steam heating medium, or otherwise, rapid corrosion of mild steel can result. If vaporization of chlorine is partial rather than total, a concentration of impurities, notably nitrogen trichloride, can occur with the attendant risk of explosion.

Concentration of less volatile impurities such as nitrogen trichloride must be avoided. In some cases, the vaporizer itself is designed to ensure that the nitrogen trichloride is vaporized together with the chlorine. Otherwise a separate purge and vaporizer circuit may be required to deal with the impurity residues.

Reverse flow of a process fluid into the vaporizer may occur if the pressure at the vaporizer falls or the process pressure rises or if the chlorine vapour condenses, creating a vacuum and causing suck-back.

Precautions need to be taken against these various hazards. Detailed measures are described in HS(G) 28.

22.15.12 Inspection

HS(G) 28 requires that an initial inspection be made when the vessel is brought into service and that there should be a first thorough in-service inspection within 5 years of commissioning. Thereafter the inspection interval should be determined by the inspecting authority, but should normally not exceed 5 years.

The guide gives details of the procedures to be followed in decommissioning and recommissioning the vessel and of the features to be inspected and the methods of inspection.

22.15.13 Storage operation

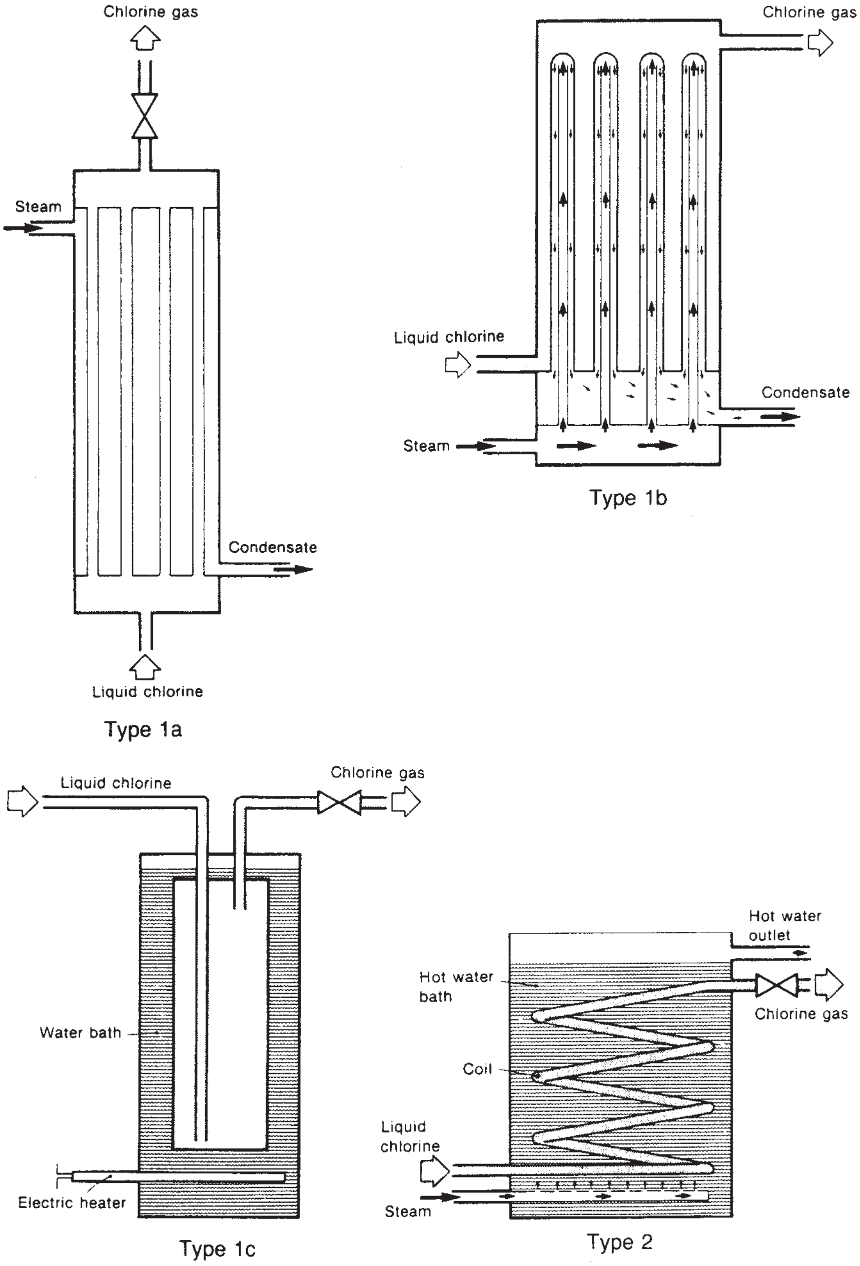
The principles governing the operation of chlorine storage are outlined in HS(G) 28.

22.15.14 Emergency arrangements

Emergency planning for chlorine storage is dealt with in HS(G) 28.

22.16 Ammonia Storage

Anhydrous ammonia is stored as a liquid, mainly either in chemical works or, particularly in the United States, in storage terminals supplying agricultural users. Its boiling point is −33°C.



Type 1a

Type 1b

Type 1c

Type 2

Figure 22.18 *continued*

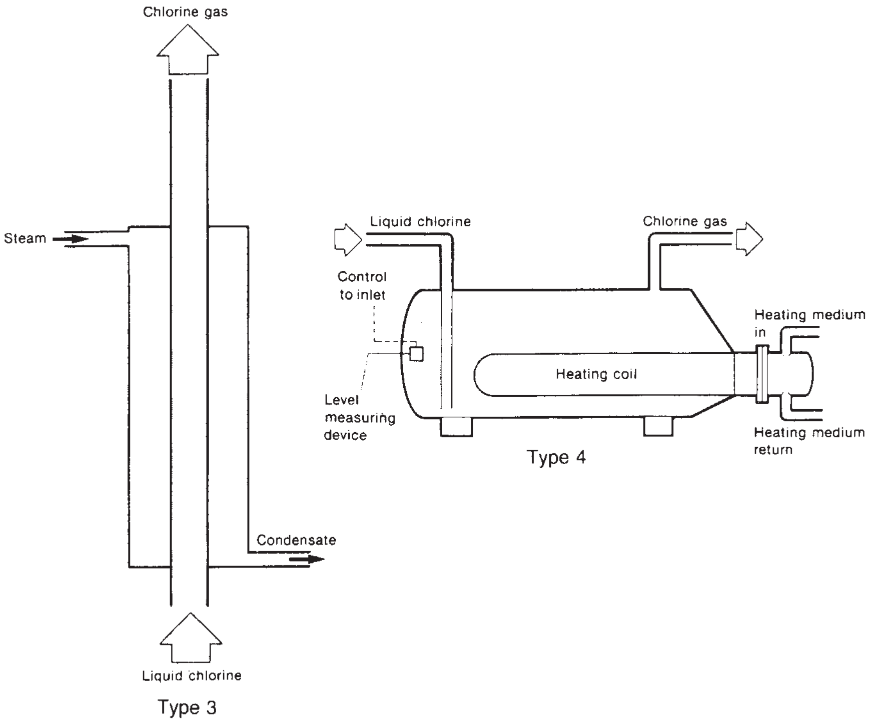


Figure 22.18 *Some types of chlorine vaporizer (Health and Safety Executive, 1986 HS(G) 28): (1a) shell and tube; (1b) steam bayonet; (1c) hot water bath; (2) coil tube immersed in heating bath; (3) concentric tube unit and (4) kettle type evaporator (Courtesy of HM Stationery Office © All rights reserved)*

The handling of ammonia, including its storage, has been a major preoccupation of the industry and this is reflected in the *Chemical Engineering Progress Series Safety in Air and Ammonia Plants* (American Institute of Chemical Engineers (AIChE) 1960–69/17–26) and *Ammonia Plant Safety (and Related Facilities)* (AIChE 1970–1994/31–52). The work of the industry storage committee has been described by Ball (1968b).

Guidance on ammonia storage is given in HS(G) 30 *Storage of Anhydrous Ammonia under Pressure in the United Kingdom* (HSE, 1986). Two CIA codes, *Code of Practice for the Storage of Anhydrous Ammonia under Pressure in the United Kingdom* (1975/13) (the CIA *Pressure Storage Code*) and *Code of Practice for the Large Scale Storage of Fully Refrigerated Anhydrous Ammonia in the United Kingdom* (1975/8) (the CIA *Refrigerated Ammonia Storage Code*), are no longer listed. A relevant US code is ANSI K61.1: 1989 *Safety Requirements for the Storage and Handling of Anhydrous Ammonia*.

The account given here is confined to ammonia storage. Ammonia itself is discussed in Chapter 11, pipework for ammonia systems in Chapter 12 and ammonia loading and unloading facilities in Section 22.26.

22.16.1 Regulatory requirements

The storage of anhydrous ammonia is governed by the NIHHS Regulations 1982 and the CIMAH Regulations 1984. The NIHHS notifiable inventory is 100 te. The CIMAH inventory for which demonstration of safe operation may be required (Regulation 4) is 50 te and that which attracts a safety case (Regulation 7) is 500 te.

22.16.2 Storage conditions

Ammonia is generally stored either under pressure at atmospheric temperature or fully refrigerated at –33°C and atmospheric pressure. A review of storage conditions has been given by C.C. Hale (1974).

22.16.3 Materials of construction

Materials of construction for ammonia handling are discussed in Chapters 11 and 12, and are, therefore, not dealt with in detail here, but there are a few matters which merit mention at this point. The normal material of construction for ammonia storage vessels and tanks is carbon steel. Ammonia reacts with copper and copper alloys, particularly if even traces of water are present, and they should not be used.

Materials of construction for ammonia handling need to be resistant to low temperatures and to SCC. High yield strength steels are more susceptible to SCC than lower yield strength steels, and an upper limit on strength may be specified. Austenitic steels are resistant to low temperature brittle fracture.

22.16.4 Storage statistics

Surveys of refrigerated ammonia storage with copious statistics have been given by C.C. Hale (1974, 1980, 1984) and

C.C. Hale and Lichtenberg (1990). The following subjects are among those covered, though not every subject is dealt with in every survey: (1) number of tanks, (2) size of tanks, (3) types of tank, (4) total storage capacity, (5) location of storage (by state), (6) siting of storage, (7) fill sources, (8) operating temperatures and pressures, (9) foundations, (10) insulation, (11) secondary containment, (12) vapour recovery systems, compressors and condensers, (13) flare systems, (14) inert gas purge systems, (15) utilities, (16) manning, (17) inspection, (18) downtime, (19) accident prevention programmes, and (20) emergency planning.

22.16.5 Storage policies

As for LPG and LNG, so for ammonia, the last decade has seen a considerable evolution of storage policy. Some accounts of these changes are given by W.G. Jones *et al.* (1989), J.R. Thompson and Carnegie (1989) and Squire (1991).

J.R. Thompson and Carnegie (1989) describe the policy of Dupont to replace pressurized storage of ammonia with high integrity refrigerated atmospheric storage.

The policy of ICI is described by W.G. Jones *et al.* (1989). There the policy is to retain in use existing pressure storage spheres, but for new storage to use small stress relieved cylindrical vessels and refrigerated atmospheric tanks.

22.16.6 Storage operation

The principles governing the operation of ammonia storage are outlined in HS(G) 30 and in the CIA *Refrigerated Ammonia Storage Code*.

The point was made earlier that in many of its aspects storage is not a low technology activity. This is illustrated by the comment of Squire (1991) in an account of the measures taken to ensure the integrity of a particular large refrigerated ammonia storage tank: 'Most, if not all, of the personnel associated with the ammonia tank did not understand the "technology of the tank"'.

22.16.7 Emergency arrangements

Emergency planning for ammonia storage is dealt with in HS(G) 30 for pressure storage and in the CIA *Refrigerated Ammonia Storage Code* and by C.C. Hale (1980). Hale describes an ammonia terminal emergency programme with emphasis on the properties and hazards of ammonia itself and on protective equipment for personnel.

22.17 Ammonia Storage: Pressure Storage

22.17.1 Storage vessels

Ammonia pressure storage vessels are usually horizontal cylindrical vessels for the small capacities and spherical vessels for the larger ones. It has been common practice to use pressure storage spheres with a capacity in the range 500 to 3000 te, but many spheres have suffered problems of SCC and some have been taken out of use.

An ammonia pressure storage vessel should be designed to BS 5500 Category 1, or equivalent, with due regard to Appendix D, which deals with low temperature steels, and taking into account the guidance given in HS(G) 30. HS(G) 30 gives separate treatments for cylindrical and spherical vessels, and this distinction is followed here.

22.17.2 Spherical vessels

HS(G) 30 states that an ammonia pressure storage sphere should be designed to withstand the stresses imposed when the vessel is full and the pressure in the vapour space is equal to the vapour pressure of ammonia at the maximum design temperature plus the partial pressure of any inert gases which may be present. The minimum design temperature should preferably be −33°C, which is the temperature to which liquid ammonia will drop if completely depressurized, but in any event should not be greater than −10°C.

The design should be such as to minimize the risk from SCC. The steel used should be not a high yield strength steel but one with a yield strength not exceeding 350 N/mm^2. The vessel should be fully stress relieved. These requirements apply to the design of a new vessel and are not necessarily met in existing vessels.

The inspection requirements given in HS(G) 30 include 100% magnetic particle inspection of all internal welds.

22.17.3 Secondary containment

It has been traditional to put bunds around all types of ammonia storage. But this practice has been questioned, for example by J.D. Reed (1974), in relation to pressure storage on the grounds that in this case sudden loss of containment tends to result in ejection of all the contents in the form of vapour, or spray, leaving no residual liquid.

HS(G) 30 recognizes this argument, but requires that an ammonia storage sphere should be provided with a bund. The bund should be able to take 20% of the capacity of the sphere, should be positioned outside the sphere radius and should be not less than 1 m high. The ground under the vessel should be sloped to allow drainage into a sump.

22.17.4 Ancillary facilities

The ancillary facilities required for ammonia storage include, in particular, pumps for the transfer of liquid ammonia from storage.

22.17.5 Instrumentation

An ammonia storage sphere should be provided with suitable measurements and alarms on liquid level, pressure and temperature. For level there should be at least two independent indicators. There should be a high level alarm independent of any indicators.

22.17.6 Pressure relief

HS(G) 30 requires that pressure relief on an ammonia storage sphere should be provided by means of at least two pressure relief valves. In addition, unless the sphere is designed for full vacuum, it should be protected by a vacuum break valve. Use may be made of separate pressure and vacuum valves or of the combined pressure/vacuum type.

There should be an isolation valve between each relief valve and the sphere, and a system should be incorporated to ensure that at any one time only one relief valve can be isolated.

22.17.7 Inspection

HS(G) 30 requires that an initial inspection be made when the sphere is brought into service and that there should be a first in-service inspection within 2 years of commissioning. A principal purpose of the inspection should be to detect any SCC which may have occurred, as described below. Provided the results of inspection are satisfactory, the inspection interval may be increased in steps of 2 years up to a maximum interval of not more than 6 years.

The guide gives details of the procedures to be followed in decommissioning and recommissioning the vessel and of the features to be inspected and the methods of inspection.

22.17.8 Stress corrosion cracking

Much of the treatment of operation and inspection in HS(G) 30 is concerned with SCC. This problem is considered at more length in Section 22.19, but the recommendations of the guide may be noted at this point. These are to the effect that the oxygen content of the liquid ammonia should not exceed 2.5 ppm when the water content is as low as 100 ppm, and that serious consideration should be given to maintaining the water content at 0.2% w/w.

22.17.9 Cylindrical vessels

As mentioned above, HS(G) 30 gives a separate treatment for cylindrical pressure vessels for ammonia storage. The guide states that an ammonia pressure storage cylinder should be designed for a pressure of at least 15.5 bars. The design temperatures given are essentially as for a storage sphere. The arrangements given in HS(G) 30 for a ammonia storage cylinder and the associated unloading facilities are shown in Figure 22.19. For a storage cylinder, the guide does not require a bund, but there should be protection against vehicle impact.

The inspection requirements given in HS(G) 30 include 100% radiography of all butt welds, and ultrasonic and/or magnetic particle inspection of all other welds.

22.17.10 Semi-refrigerated vessels

It is convenient to deal here with pressure vessels for the semi-refrigerated, or semi-pressure, storage of ammonia. These are normally pressure spheres and are treated in HS(G) 30 together with pressure spheres for storage at atmospheric temperature. Principal differences are that with semi-refrigerated storage it is necessary to allow for the heat gain and resultant boil-off by provision of suitable thermal insulation and refrigeration.

Insulation materials that may be used include foam glass and PUF. HS(G) 30 draws attention to the importance of a vapour barrier and to measures to prevent the integrity of the containment being impaired by the materials used in, or the attachment of, the insulation.

22.18 Ammonia Storage: Refrigerated Storage

22.18.1 Storage tanks

Refrigerated liquid ammonia is stored in atmospheric storage tanks. Accounts of such storage are given in the CIA *Refrigerated Ammonia Storage Code* and by Shah (1982), Blanken (1987), J.R. Thompson and Carnegie (1989) and Herbertsson (1992).

Tanks used for refrigerated ammonia have developed from conventional atmospheric storage tanks. The design of atmospheric storage tanks in general is governed by API Std 620: 1990 *Design and Construction of Large, Welded, Low-pressure Storage Tanks* and API Std 650: 1988 *Welded Steel Tanks for Oil Storage*. For refrigerated ammonia storage frequent reference is made to API Std 650, Appendix R.

There are now in use a number of tank systems similar to those used for LNG. The single wall tank has a wall made of low temperature steel with external insulation covered by a vapour barrier. A double wall tank has an inner wall of low temperature steel and an outer wall of carbon steel with insulation in between. The outer wall is not designed to withstand the cold liquid, so this is still only a single containment system. A double integrity tank system has an inner tank with a suspended deck and an outer wall. Both the inner and outer walls are of low temperature steel. Accounts of tank systems make little reference to the use of pre-stressed concrete for either the inner or outer wall or of membrane systems.

22.18.2 Foundations

The foundations of refrigerated ammonia storage tanks require be protected against 'frost heave'. The problem and its prevention have been discussed by Morrison and Marshall (1970). Two principal types of foundation are used. One involves a tank bottom slab on piling so that there is free air circulation. In the other, the bottom slab is provided with insulation and electrical heating.

Further descriptions of foundation systems are given in the CIA *Refrigerated Ammonia Storage Code* and by C.C. Hale (1980) and C.C. Hale and Lichtenberg (1990).

22.18.3 Insulation

A refrigerated ammonia storage tank requires thermal insulation. The type of insulation which is suitable depends on the tank system. Principal types of insulation for single wall tanks are foam glass, PUF, reflective multi-layered aluminium and Styrofoam. For doubled wall tanks use is made of perlite insulation. The suspended deck used in double wall tanks counts as another form of insulation.

Insulation failures on single wall tanks are not unusual. A common cause is the penetration of moisture. Insulation problems have been described by a number of authors, including Hoffman (1967) and C.C. Hale (1974, 1980). Loss of a section of lagging is undesirable, because it allows rapid heat leak into the tank with a consequent increase in vaporization; it may also cause 'bump boiling'.

Reviews of the failure rates of insulation systems have been made by C.C. Hale (1974, 1980). He found that double wall tank systems filled with expanded perlite and reflective multi-layer aluminium systems had a good record compared with foam glass, PUF and Styrofoam systems.

Further descriptions of insulation systems are given by C.C. Hale (1984) and C.C. Hale and Lichtenberg (1990).

Squire (1991) has discussed the effect of insulation in a double integrity tank system in the event of a leak from the inner tank into the annular space. Tests showed that as the ammonia vaporized, the perlite insulation behaved like a spouted bed, resulting in a pressure of 55–69 kPA (8–10 psi). Solutions were to vent to annular space or install block Styrofoam insulation. No satisfactory way was found of doing the former, and for the tank in question the latter solution was adopted.

22.18.4 Secondary containment

Refrigerated ammonia storage tanks may be provided with some form of secondary containment. Accounts are given by Comeau (1972), MacArthur (1972), C.C. Hale (1974, 1980), J.D. Reed (1974), Hendriks (1980), Shah (1982), Blanken (1987) and C.C. Hale and Lichtenberg (1990).

Escape from refrigerated ammonia storage results in immediate flashing of only about 2% of the liquid. Even a primitive secondary containment should hold some 90% of the liquid.

Bunds and other measures to prevent dispersion of ammonia from refrigerated storage have been discussed by Comeau (1972). It is not necessarily enough simply to catch the liquid released. If a low bund with a large surface area is used, the large quantities of ammonia vapour vaporized from the liquid will still present a serious hazard. It is

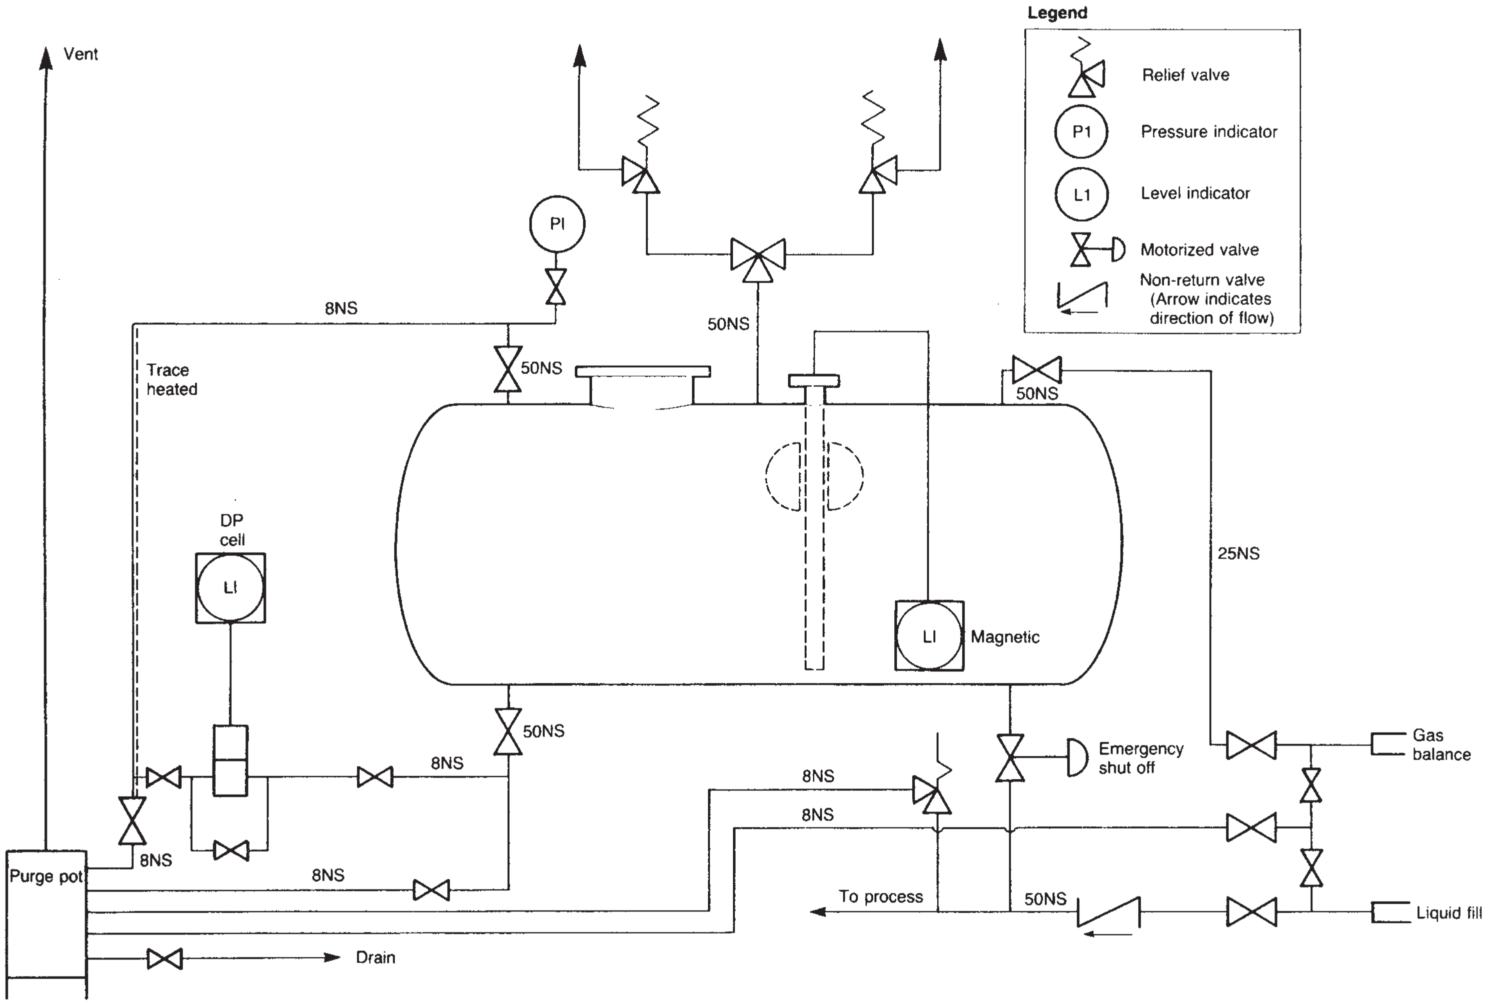

Figure 22.19 *General arrangement for an ammonia pressure storage installation (Health and Safety Executive, 1986 HS(G) 30) (Courtesy of HM Stationery Office © All rights reserved)*

therefore desirable to reduce the surface area. There are various methods of doing this. Use may be made of controlled drainage which runs the liquid off to a pit where its evaporation is reduced. Foam blanketing is another possibility, provided the area to be covered is not excessive. However, the most effective method of reducing the surface area available for evaporation is the use of a high bund.

The CIA *Refrigerated Ammonia Storage Code* requires that for a refrigerated atmospheric ammonia storage tank in the United Kingdom, means must be provided to contain the liquid safely in the event of failure of the main tank. The two methods which are acceptable are the use of a double integrity tank or the use of a concrete wall of approximately the same height as the tank wall. For the latter it is recommended that the width of the annulus is 1.5 m. The *Code* recognizes that in remote locations a low bund may sometimes be acceptable.

22.18.5 Ancillary facilities

Ancillary facilities for refrigerated ammonia tanks include refrigeration systems. Accounts are given by C.C. Hale (1980, 1984), C.C. Hale and Lichtenberg (1990) and Herbertsson (1992).

Refrigerated ammonia storage requires the provision of refrigeration facilities to liquefy vapour boil-off caused by heat inleak. Where the storage is part of an ammonia manufacturing plant, the main ammonia refrigeration facility may be used with just a backup set for storage, but generally the facility is a dedicated one. The principal elements are the refrigeration compressors and the ammonia condensers. There may also be a purge system to remove inerts from the ammonia condenser or receiver.

22.18.6 Instrumentation

A refrigerated ammonia storage tank should be provided with suitable measurements and alarms on the liquid level, pressure and temperature in the tank, and on boil-off gas flow.

Principal features of the instrumentation are the arrangements to prevent overpressure and overfilling. Pressure control is an integral part of the refrigeration system and there may also be a pressure control valve for emergency venting to flare.

In addition to the usual level instrumentation, use may be made of an interlock system to prevent overfilling by the operator.

In a double wall or double integrity tank system, instrumentation may be provided to detect any leak into the annular space between the two tanks.

22.18.7 Pressure relief

The tank also requires pressure relief and vent disposal arrangements. Accounts are given by C.C. Hale (1974, 1980), J.R. Thompson and Carnegie (1989) and C.C. Hale and Lichtenberg (1990).

Pressure relief is provided by a pressure relief valve. Most tanks also have vacuum relief. PV valves are a common method of providing both forms of relief.

Venting to atmosphere has been common practice, provided that the location is suitable and the venting is done at a safe height, but the trend is away from such venting. In the normal operation of refrigerated ammonia storage, however, there is very little venting. Vapour is reliquefied by the refrigeration set and returned as liquid to the tank.

The main requirement for venting is in an emergency. In many systems, flares are provided to handle emergency venting. The flares may be on the tank, or inside or outside the bund. Venting to the flare may be by a separate pressure control valve rather than the main pressure relieve valve. Complete combustion of the ammonia flared, and avoidance of odour, is assisted by the addition of fuel gas.

22.18.8 Inspection

The inspection of refrigerated ammonia storage tanks presents a number of problems and needs to be governed by a well thought out policy. Accounts are given by Truscott and Livingstone (1978), Shah (1982, 1987), P.P. Briggs, Richards and Fiesinger (1986), W.G. Jones *et al.* (1989), Conley, Angelson and Williams (1991) and Squire (1991). Inspection practice is one of the topics covered in the surveys by Hale.

One type of problem is the determination of an inspection interval. A difficulty here is that the opening up of the tank system is liable to introduce oxygen into it and may thus itself become a cause of deterioration. Another is that the outage period can be several months. A third difficulty concerns the degree of confidence which can be placed in the predictive techniques.

The problem may also come in the form of a need to decide whether to open up a tank on a particular occasion. An account of a review of a particular refrigerated ammonia storage tank, its features and its hazards, has been given by Squire (1991), who describes the reasoning behind a decision not to open up the tank for inspection.

There are also problems in the reliability of inspection techniques, as described below.

The stages of decommissioning a tank for inspection and recommissioning it after inspection have been described by Shah (1982) and P.P. Briggs, Richards and Fiesinger (1986). The latter give an account of the arrangements for continuity, emptying and purging, tank entry and cleaning, inspection and repair, and purging and refilling.

22.18.9 Rollover

There has been some concern that in refrigerated atmospheric storage tanks temperature stratification might occur, leading to ‘rollover’, which is defined as ‘a spontaneous and sudden migration of a substantial mass of liquid ammonia from the bottom of the tank to the surface’. The effect of rollover is to release large quantities of vapour which could overpressure the tank.

Rollover has been the subject of an investigation by the Ammonia Storage Committee, as described by Ball (1968b). Calculations showed that only a very small temperature gradient is required to initiate natural circulation and prevent temperature stratification. The calculations have been confirmed experimentally. It has also been shown, however, that there is a possibility of stratification in ammonia containing over 5000 ppm of water.

An account of conditions which might lead to what he terms ‘thermal overload’ has been given by Squire (1991). They include the introduction of contaminated or wrong material such as wet ammonia or even water; the introduction of warm ammonia; or a strong heat input such as might occur through loss of thermal insulation.

22.19 Ammonia Storage: Stress Corrosion Cracking

As already indicated, SCC has been a widespread problem in ammonia pressure storage vessels. Accounts have been given by W.D. Clark and Cracknell (1977), Truscott and Livingstone (1978), Lemoine *et al.* (1986), Loginow (1986), Stephens and Vidalin (1988), Byrne, Moir and Williams (1989), Appl *et al.* (1990), Burke and Moore (1990), Selva and Heuser (1990) and Conley, Angelsen and Williams (1991).

Although ammonia has been used without apparent problems in the chemical and refrigeration industries for many decades, the use of liquid ammonia for agricultural purposes, which began after the Second World War, saw a number of cases of failure in the vicinity of welds on the pressure vessels used. A survey by T.J. Dawson (1956) found that about 3% of these pressure vessels failed within 3 years of entering service. In the chemical industry, concern intensified in the 1970s. A 1982 survey by the AIChE, described by Blanken (1982) and referred to by Burke and Moore (1990), reported inspection results for 72 pressure storage spheres in 37 of which SCC had been found.

Extensive investigation, and in particular the work of Lunde (Lunde, 1984; Lunde and Nyborg, 1987, 1989, 1990) in the Kjeller Ammonia Stress Corrosion Project (KASP) has given a clearer picture of the conditions under which SCC occurs. This work has shown that (1) uncontaminated ammonia does not cause cracking, (2) contamination with oxygen at a concentration as low as 1 ppm promotes cracking and (3) 0.2% w/w water inhibits cracking in oxygen-contaminated ammonia in the liquid phase.

It is also necessary to consider the vapour phase. Even where the liquid ammonia contains water, SCC can occur in the vapour phase, where due to the vapour–liquid equilibrium relations the concentration of oxygen is some 650 times higher than that in the liquid phase, whilst the concentration of water is some 500 times lower.

The metallurgy of the steel is also a factor. SCC occurs more readily where stress relief has not been carried out and in high yield strength steels. Measures to prevent SCC are therefore the use of stress relief by post-weld heat treatment and of low yield strength steels.

With respect to crack growth, it has been found that under conditions typical of those known to cause SCC (3 ppm oxygen, 500 ppm water), crack growth rates are similar to those which occur in-service, of the order of 2–6 mm/year, depending on the stress intensity. Crack growth rates tend to be rapid initially, but to decrease markedly over time.

Whereas SCC has been widespread in ammonia pressure storage vessels, this has not been the case with refrigerated atmospheric ammonia storage tanks – as recently as 1987 it was largely discounted (Blanken, 1987). However, SCC has now been found in refrigerated ammonia storage tanks, as described below.

22.19.1 Inspection and repair

There are a number of accounts of the inspection of pressure vessels and of refrigerated tanks for ammonia storage in order to detect SCC. Inspections of pressure vessels have been described by R.S. Brown (1982) and by Guth and Clark (1985). They illustrate both the procedures for isolation, emptying, purging and entry, and bringing back on-stream such storages, and the procedures for inspection and repair.

Brown describes the inspection and repair in 1978 of two ammonia spheres installed in 1961 and 1962. Although the recommendation in 1962 to maintain the ammonia water content at 0.2% was followed, the spheres may have contained some ammonia which did not contain water. The inspection was performed using both magnetic particle and dye penetrant methods and significant cracks were found, which were diagnosed as being due to SCC. A maximum crack depth of 7.8 mm, or 25% of the shell weld cross-section, was found. Repairs were carried out in accordance with the ASME *Boiler and Pressure Vessel Code and the Compressed Gas Association* (CGA) *Guidelines for Inspection and Repair of Cargo Tanks*. Cracks were removed by mechanical grinding or arc gouging to sound metal. The area was then pre-heated and weld repaired. Further inspection and repair were conducted in 1980.

Another instance of cracking in two ammonia spheres in 1982 is described by Guth and Clark. Acoustic emission was used to detect the faults. In one sphere the repair method used was to grind down to the parent metal, repair the weld and hammer to relieve stresses. In the other sphere the crack was ground out and the welder then pre-heated the metal, repaired it, and peened it.

The discovery of SCC in a refrigerated ammonia storage tank has been described by Byrne, Moir and Williams (1989). The tank in question was a 12,000 te tank at Seal Sands, acquired by BASF from another company. The previous owners had relied on acoustic emission testing to extend the inspection interval for the tank and had detected no SCC. An inspection performed by the new owners using magnetic particle inspection discovered SCC. The SCC was found to occur mainly at the site of internal cleats and was attributed to defective welding procedures, the effect of which was aggravated by the use of high strength steel. A detailed account of the treatment of defects in this tank has been given by Selva and Heuser (1990).

Appl *et al.* (1990) have given an account of the inspection of two further refrigerated ammonia storage tanks owned by BASF. They describe in detail the taking out of service, preparation, magnetic particle inspection, repair and bringing back into service.

Principal techniques for the detection of cracks are magnetic particle inspection, dye penetrant testing and acoustic emission testing. The use of dye penetrant testing is described by Brown, but not by the other authors mentioned.

As already indicated, there is a view that acoustic emission testing is not a reliable method. Vessels with SCC may not produce significant acoustic emission. Furthermore, Conley, Angelson and Williams (1991) describe a case where it was found that acoustic emission activity was greater in a vessel which had been repaired than in one with SCC which had not been repaired.

The inspection technique mainly quoted is magnetic particle inspection. However, the same authors state that even this does not necessarily reveal all the defects and that different operators tend to produce different results.

22.19.2 Fracture mechanics

Fracture mechanics, described in Chapter 12, has been applied to SCC both in ammonia pressure vessels and refrigerated ammonia storage tanks.

Accounts of the application of fracture mechanics to ammonia pressure vessels have been given by W.G. Jones *et al.* (1989) and Burke and Moore (1990).

Byrne, Moir and Williams (1989) describe the application of fracture mechanics to the Seal Sands refrigerated ammonia storage tank. The task of removing all the defects found was enormous. The interest lay, therefore, in reducing this activity to an acceptable level. In many cases, it was possible to determine that the crack would exhibit leak-before-break behaviour. Those cracks for which this could not be demonstrated were removed. Further details of this fracture mechanics work are given by Selva and Heuser (1990).

The use of fracture mechanics to set the inspection interval for refrigerated ammonia storage tanks is described below.

22.19.3 Control policy

The maintenance of the integrity of ammonia storage requires a policy for the control of SCC. Accounts of such policies have been given by W.G. Jones *et al.* (1989), Appl *et al.* (1990), Squire (1991) and Conley, Angelson and Williams (1991).

W.G. Jones *et al.* (1989) describe the policy of ICI for the control of SCC in ammonia pressure vessels. As stated earlier, the overall ammonia storage policy is to move away from pressure storage spheres to smaller fully stress relieved pressure vessels and refrigerated storage tanks. They postulate two extreme scenarios for pressure spheres. An unpurged, unlagged sphere handling imported ammonia from a variety of sources at relatively high temperature and without vapour export may well experience a comparatively high level of SCC, whereas a purged, lagged sphere handling site-produced ammonia at a low temperature with continuous vapour offtake may experience little, if any. Operational measures to control SCC include purging to remove oxygen, maintenance of the water content, and cooling of the liquid.

An account of policy at Dupont for the control of SCC in ammonia pressure vessels has been given by Conley, Angelson and Williams (1991). The approach includes the use of fracture mechanics to predict the probability of failure and to determine inspection intervals.

Appl *et al.* (1990) of BASF rehearse some of the problems of controlling SCC in pressure storage vessels. There are difficulties in excluding oxygen and in keeping the oxygen content of the liquid ammonia below 1 ppm. There are some applications for which the ammonia is required to be dry and for which a requirement to maintain a water content of 0.2% w/w is highly undesirable. They state that stress relief by post-weld heat treatment appears to be the only reliable way to avoid SCC and that, whereas it has been necessary to scrap an older ammonia sphere due to SCC, a new stress relieved sphere inspected after 2 years of operation has shown no SCC.

22.20 Other Chemicals Storage

The storage of particular chemicals involves in some cases features which do not occur in the storage of the materials so far described. The general characteristics and handling of some of these chemicals are described in Chapter 11. The account given here seeks to highlight some features characteristic of the storage of individual chemicals; no attempt is made to give a comprehensive treatment of the storage of any given chemical, which is covered in the code cited.

Table 22.11 lists some topics on storage dealt with in codes and guidance for particular chemicals.

22.20.1 Acrylonitrile

Guidance on the storage of acrylonitrile (AN) is given in *Codes of Practice for Major Hazards: Acrylonitrile* by the CIA (1978 PAH) (the CIA Acrylonitrile Code).

AN has a boiling point of 77.3°C. It is typically stored in atmospheric fixed roof storage tanks. An AN storage tank should be provided with a suitable bund.

AN has a tendency to polymerize rapidly under certain conditions and in bulk storage it needs to be stabilized. The *Acrylonitrile Code* mentions three stabilizers. One is the methyl ether of hydroquinone (MEHQ), which is used when the AN contains dissolved oxygen. Another is ammonia, which combines with AN to form stabilizing compounds and thus in due course becomes depleted. The third stabilizer is water, which at a concentration of 0.2% w/w confers a degree of stabilization. Strong alkali or peroxides should be excluded.

Under certain conditions a flammable mixture can form in the vapour space of the tank. Precautions mentioned in the *Code* are the safe location of the vent, the installation of a flame arrester on the vent and the inciting of the vapour space.

Table 22.11 *Some topics on storage covered in certain codes of practice and guidance documents for particular chemicals*[a]

Terminals	9		2,20		19			15

[a] The entries give the page numbers. The documents referred to are as follows: acrylonitrile (CIA, 1978 PA11); ammonia (HSE, 1986 HS(G) 30); chlorine (HSE, 1986 HS(G) 28); ethylene dichloride (CIA, 1975 PA13); ethylene oxide (CIA, 1992 RC14); hydrogen fluoride (CIA, 1978 PA14); phosgene (CISHC, 1975/3); vinyl chloride (CIA, 1978 PA15). Aspects other than storage are considered separately in Chapter 11.

22.20.2 Ethylene dichloride

Guidance on the storage of ethylene dichloride (EDC) is given in *Codes of Practice for Major Hazards: Ethylene Dichloride* by the CIA (1975 PA13) (the CIA *Ethylene Dichloride Code*).

EDC has a boiling point of 84.4°C. It is generally stored, dry or water saturated, in atmospheric storage vessels, which may contain several thousand tonnes. An EDC storage vessel should be provided with a suitable bund.

Under certain conditions a flammable mixture can form in the vapour space of the tank. The *Ethylene Dichloride Code* advises that consideration be given to protecting the vapour space from ignition and requires that means be provided for preventing over- and underpressure, including explosion relief.

Fire protection of larger EDC storage vessels tends to be by water spray systems, and that of small vessels is by fire insulation.

22.20.3 Ethylene oxide

Guidance on the storage of ethylene oxide (EO) is given in *Guidelines for Bulk Handling of Ethylene Oxide* by the CIA (1992 RC14) (the CIA *Ethylene Oxide Code*).

EO has a boiling point of −17.8°C. It is stored as a liquefied gas, mainly in pressure vessels, although refrigerated storage is an option. The separation distances appropriate for EO are of the same order as those quoted in codes for LPG, but should not be less than 15 m.

An EO storage vessel should be provided with a suitable bund. Since an EO spillage is commonly dealt with by dilution, the bund and drain arrangements should be able to handle water used for this purpose as well as the usual fire-fighting purposes of equipment cooling and fire control.

Many EO bulk storages are associated with plants which use a catalyst to polymerize the EO. Stringent precautions are necessary to ensure that the catalyst is excluded from the bulk storage. Three ways in which contamination may occur are (1) backflow from user plants, (2) introduction by a diluent gas pressurizing system and (3) inadvertent contamination during supply offloading. Both design and operations measures are required to prevent contamination. The design measures are described in Chapter 11.

22.20.4 Hydrogen fluoride

Guidance on the storage of hydrogen fluoride (HF) is given in *Guide to Safe Practice in the Use and Handling of Hydrogen Fluoride* by the CIA (1978 PA14) (the CIA *Hydrogen Fluoride Code*).

HF has a boiling point of 19.5°C. Liquid HE is stored in pressure vessels of a few tonnes upwards.

The storage temperatures range from −5°C to 30°C, at which temperatures the vapour pressures of HE are 0.4 and 1.5 bars, respectively. Assistance is therefore required to effect transfer from storage, and this may be by the use of inert padding gas or, more commonly, by pumping.

The *Hydrogen Fluoride Code* lays particular emphasis on lines connected to the vessel below the liquid surface. Where these are unavoidable, it requires that there be a means of isolation integral to the vessel and independent of any external valve used for routine isolation and control, and that this external valve be capable of remote operation.

22.20.5 Oxygen

The storage of oxygen is the subject of two codes by the British Compressed Gases Association (BCGA) – *Bulk Liquid Oxygen at Production Plants* (BCGA, 1990 Code 20) and *Bulk Liquid Oxygen at Users' Premises* (BCGA, 1992 Code 19) – and of one by the NFPA – NFPA 50: 1990 *Bulk Oxygen Systems at Consumer Sites*.

The hazard posed by liquid oxygen is the reaction with combustible or flammable materials. The layout for the storage of liquid oxygen should include the use of non-combustible surfaces, the provision of separation distances between storages of liquid oxygen and flammable liquids, and the prevention of contact between the two through flows of liquids, by ground contour or diversion.

22.20.6 Phosgene

Guidance on the storage of phosgene is given in *Codes of Practice for Major Hazards: Phosgene* by the CIA (CISHC, 1975/3) (the CIA *Phosgene Code*).

Phosgene has a boiling point of 8.2°C. It is stored as a liquid in pressure vessels.

The *Phosgene Code* advises that the storage temperature be kept below 8°C so as to reduce the load on the disposal system if the vessel has to be depressurized.

Particular emphasis is placed in the *Code* on the integrity of the pressure vessel, with requirements such as 100% radiography of butt welds and exclusion of installed lifting devices in the immediate vicinity of the vessel.

The *Code* requires that all branches in the top of the vessel be fitted with dip pipes which protrude at least to the maximum liquid level under normal operating conditions to ensure that the tank cannot be accidentally overfilled. There should be no lines connected to the vessel below the liquid surface, but if this is unavoidable they should be provided with a remotely operated isolation valve.

22.20.7 Monomers

An important class of liquid chemicals which require to be stored are monomers. Accounts of the storage of monomers is given by Shelley and Sills (1969) and Bond (1985 LPB 65).

A problem in the storage of monomers is polymerization. One hazardous consequence of such polymerization may be heat release, which causes both a rise in pressure and an acceleration in the reaction, resulting in the extreme case in the explosion of the tank. Another hazardous effect may be the blockage of vents and pressure relief devices.

It is common practice to dose monomers with additives. A discussion of their use has been given by Bond (1985 LPB 65). Types of additive include (1) inhibitors, (2) stabilizers, (3) anti-oxidants, (4) preservatives and (5) stenching agents. The function of inhibitors and stabilizers is to prevent polymerization, while anti-oxidants prevent decomposition, preservatives prevent bacterial or fungicidal attack and stenching agents impart an odour.

Typically, an inhibitor is effective only in the presence of oxygen. The use of nitrogen to blanket the liquid can reduce the oxygen content both in the liquid and in the vapour space and render the inhibitor ineffective in both phases. The liquid monomer may polymerize in a runaway reaction and the monomer vapour may polymerize and block vents.

A fuller account of the storage of monomers is given in the IChemE training package *Safer Use of Chemical Additives*, described in Chapter 27. This package includes a list of chemicals which are commonly dosed with an additive, and gives the purpose of the additive, an example of the additive used, the quantity added and an indication of requirement for dissolved oxygen.

The interactions between the various factors are illustrated by the account given by Shelley and Sills (1969) of options in the storage of styrene in the late 1960s. They describe the use of *p*-*t*-butyl catechol (TBC) as the inhibitor. The TBC also acts as an anti-oxidant but it is effective as an inhibitor only in the presence of oxygen. Storage under air suffices to maintain an adequate concentration of oxygen in the liquid phase. However, there remains the problem of polymerization in the vapour phase on the internal surfaces of the tank. This is liable to occur in older tanks with rusty surfaces, but is largely eliminated by coating the surface. One policy for older, uncoated tanks is the use of a nitrogen blanket, since in the absence of oxygen polymerization in the vapour phase is much reduced. Where such a nitrogen blanket is used, separate measures are taken to maintain the oxygen content of the liquid.

22.20.8 Vinyl chloride

Guidance on the storage of vinyl chloride is given in *Codes of Practice for Chemical with Major Hazards: Vinyl Chloride* by the CIA (1978 PA15) (the CIA *Vinyl Chloride Code*), and also in *Precautions against Fire and Explosion: Vinyl Chloride* also by the CIA (1978/12). An account is also given by Shelley and Sills (1969).

22.21 Bunds

An important form of secondary containment is a bund, or dike. Accounts of bunding are given in *The Design of Bunds* (Barnes, 1990 SRD R500) and *Bund Overtopping – The Consequences Following Catastrophic Failure of Large Volume Liquid Storage Vessels* (Wilkinson, 1991 SRD R530).

Barnes discusses: the bunding recommendations given in codes and standards; the philosophy of, and practice in, bunding; the design of bunds; the effectiveness and failure of bunds; and the use of high bunds and double integrity systems. He gives case histories of storage, and particularly bund, incidents and some statistics on storage failures. He draws particularly on the report Liquefied Energy Gases Safety (GAO, 1978) and on a study by Buckley and Weiner (1978).

Common practice is to provide a bund for refrigerated atmospheric storage of LPG and other LPGs and for ammonia, but not for pressure storage of LPG or ammonia.

For atmospheric storage tanks, containing such hazardous chemicals as acids and alkalis, it is again not usual to have a bund. If there is a danger of spillage onto roads, pathways or working areas, or of hazardous interaction between spillages of two liquids, separation by distance is appropriate.

22.21.1 Code requirements

Barnes reviews the requirements for bunding given in a large number of codes, including not only those for oil, LPG and LNG, but also for ammonia, chlorine and the various chemicals covered by the CIA codes. The overall picture is of considerable arbitrariness and some inconsistency.

Codes differ, for example, in their requirements for features such as capacity and permitted wall height. They even differ as to whether or not a bund is required at all. Liquid ammonia and liquid chlorine have similar adiabatic flash fractions, at 16% and 18.3%, respectively, but Barnes identifies one code for ammonia which recommends a high bund, and another for chlorine which practically dismisses the use of a bund altogether. One code may set a maximum wall height to permit fire fighting in the bund, which would rule out the use of a high bund recommended in another code.

22.21.2 Philosophy of bunding

Barnes attempts, therefore, to develop a more coherent philosophy of bunding. He distinguishes between: liquids which are (1) flammable, (2) toxic, (3) corrosive and (4) reactive; liquids which are stored at a temperature (1) above the boiling point and (2) below it; and liquids which have (1) a high vaporization rate and (2) a low vaporization rate. Figure 22.20 shows his three decision trees for flammables, toxics and corrosives.

He takes a reactive material as being one which does not in its own right present a flammable, toxic or corrosive hazard, but which on contact with some other material, such as water or acidic or alkaline effluent, could produce a substance which does constitute a hazard. For this case he gives a simple two-branch tree, in which bunding is not required if the reactive material could not come into contact with another reactant but may be required if it could, depending on the assessed hazard.

22.21.3 Bund design

The elements of bund design, which Barnes addresses, are (1) bund capacity, (2) materials of construction, (3) wall design, (4) surface water drainage, and (5) common bunding.

Codes differ in their recommendations on bund capacity which vary between 75% and 110% of the nominal capacity of the container protected. Barnes also quotes data from the General Accounting Office (GAO) report which illustrate the capacity allowed in practice. For the nine storages for which information is given, the capacities range from 50% to 139%.

In the selection of materials of construction, factors which have to be considered are the mechanical strength, the vaporization rate and, for low temperature liquids, the resistance to thermal shock. The materials used both for bunded areas and for bund walls are mainly earth and concrete. Use is also made of insulating concrete.

A low bund wall facilitates firefighting, and up to about 1980 many codes set a maximum height for the bund wall, often of the order of 2 m. This restriction is now less common, reflecting a trend towards high wall bunds. Codes may also set a minimum height for a bund wall, such as the 1.5 m height set in the NFPA codes.

Most codes do not give clear guidance on the arrangements for the drainage of surface water. A major problem here is that if the arrangement for the removal of rainwater is through a drain hole with a valve on it which should normally be kept closed, the valve is liable to be left open, thus allowing any liquid released into the bund to escape from it.

The use of common bunding is widespread, but it is not regarded as good practice to co-bund incompatible materials.

22.21.4 Bund sizing

Relations for bund sizing have been given by Barnes, and reformulated by Wilkinson. Following the latter, for a cylindrical tank in a circular shaped bund

$$\pi R^2(H - h) = \pi(R + L)^2 h - \pi R^2 h \qquad [22.21.1]$$

whence

$$h \geq R^2H/(R+L)^2 \qquad [22.21.2]$$

where h is the height of the bund, H is the original height of the liquid, L the distance between the tank wall and the bund and R is the radius of the tank. For a rectangular bund

$$\pi R^2(H-h) = xyh - \pi R^2h \qquad [22.21.3]$$

whence

$$h > \pi R^2H/xy \qquad [22.21.4]$$

where x and y are the dimensions of the bund walls.

22.21.5 Vaporization from bunds

For many hazardous materials the magnitude of the consequences of a release depends largely on the rate of vaporization from the pool formed. In the main, this depends partly on the area of the bund and partly on the material of construction used.

A high bund gives a much smaller total area for vaporization. Another approach applicable with a low bund system is the use of a ditch within the bund, which for all but the largest releases, reduces the effective area for vaporization. There are a number of bund floor materials, such as insulating concrete, which give an appreciable reduction in the rate of vaporization. Another approach to the reduction of vaporization is to blanket the liquid surface, either with foam or with plastic spheres.

Vaporization from surfaces such as bund areas is discussed further in Chapter 15.

22.21.6 Spillage from bunds

With a low bund system in particular, if the release of liquid is sufficiently large it may flow as a wave which overtops the bund wall. Such overtopping has occurred in a number of cases. One of the most dramatic was at Qatar, where an LPG storage tank contained in a 50% capacity bund suffered a catastrophic failure. A 'tidal wave' of LPG overtopped the bund and caused massive destruction. Barnes quotes an estimate that, even if the capacity of the bund had been 100%, it would still have been overtopped by a wave some 5 m high.

Another major overtopping, from a bund that was 20% undersized, occurred at Moose Jaw, Saskatchewan, in 1980, following the catastrophic failure of an oil storage tank.

The GAO study gives results of modelling of bund overtopping by a tidal wave at a number of particular facilities. The six results for low bunds quoted by Barnes indicate overtopping in each case, with an average overspill of 58% of the tank contents.

Further work on overtopping of low bunds has been done by Greenspan and Young (1978), who derived an analytical model based on the shallow water equations, and by Greenspan and Johansson (1981), who performed model experiments. They correlated the fraction Q of the original liquid volume which spills over as function of the ratio h/H, where h is the height of the bund and H is the original height of the liquid in the tank, with the bund r radius and wall angle θ as parameters.

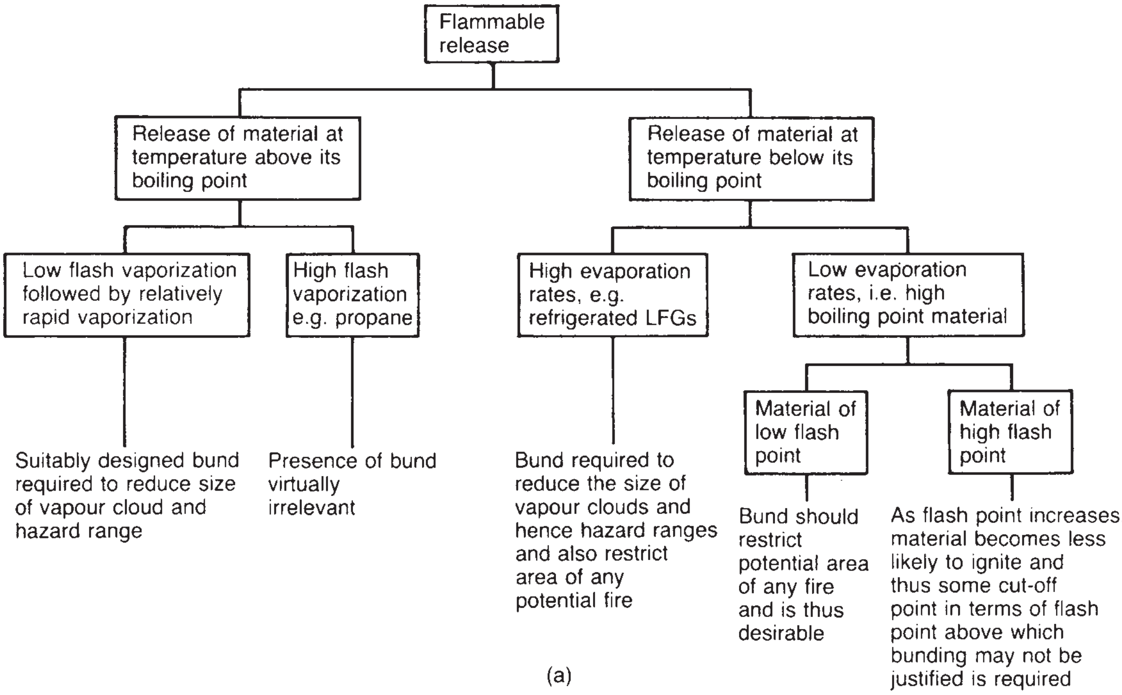

Figure 22.20 *continued*

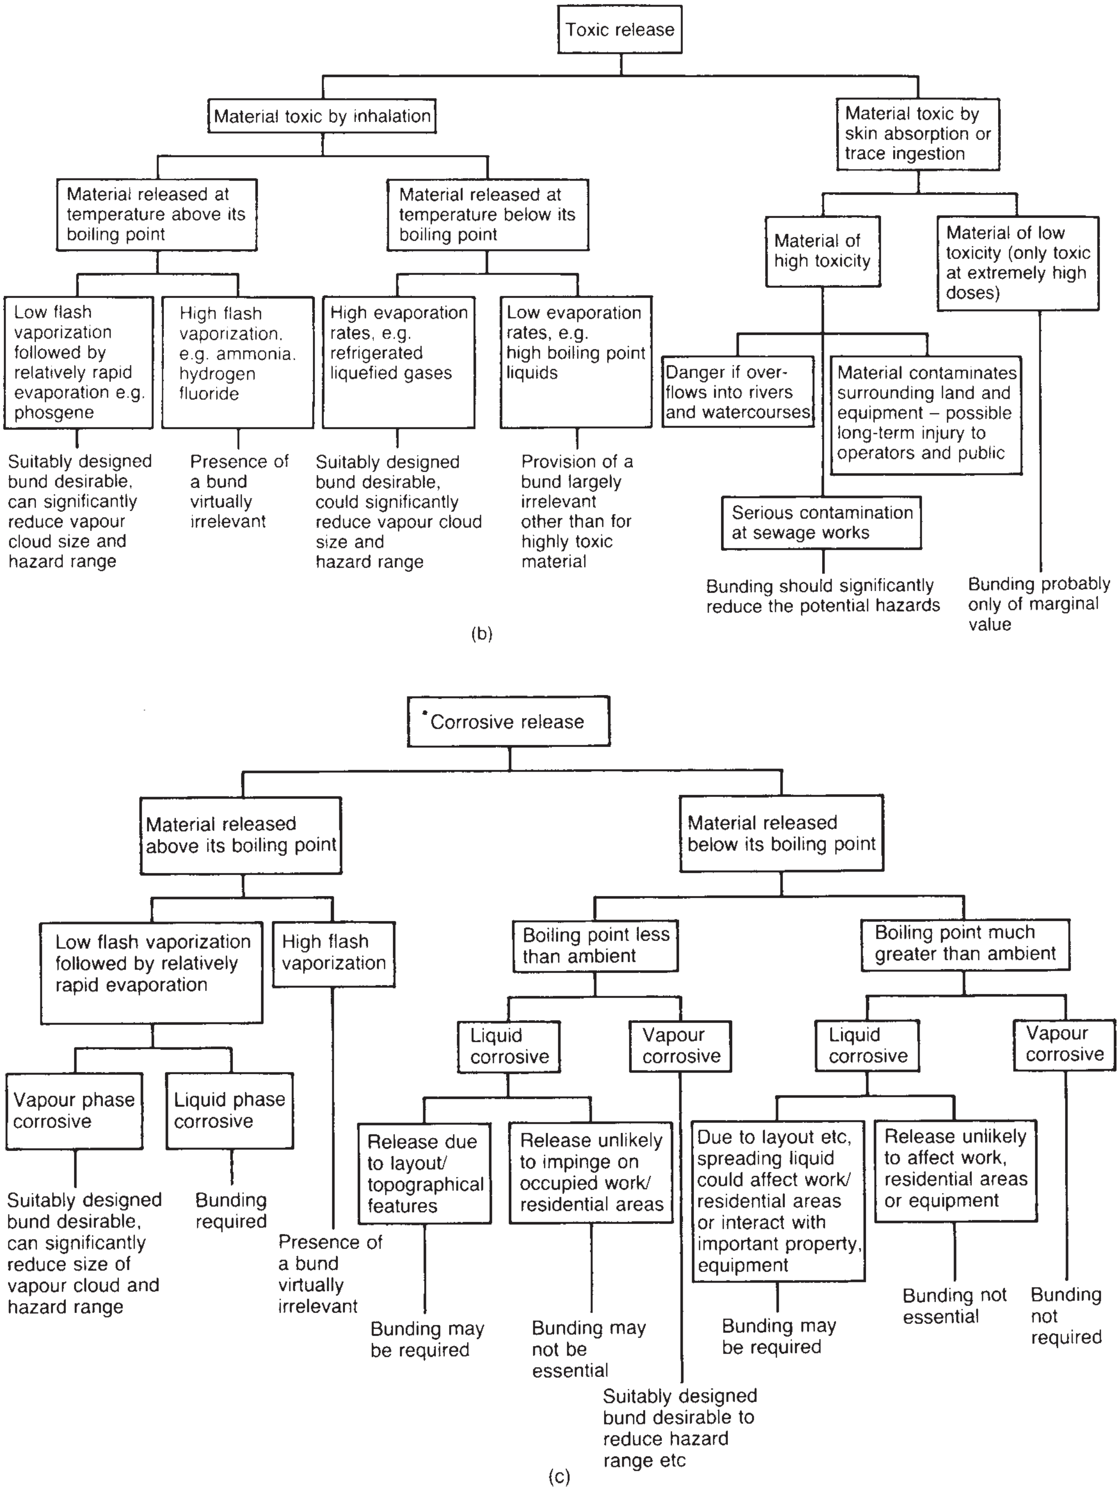

Figure 22.20 *Decision trees for the design of bunds (Barnes, 1990 SRD R500): (a) flammable material (b) toxic material; and (c) corrosive material (Courtesy of the UKAEA Safety and Reliability Directorate)*

Another form of escape from a bund is spigot flow in which the liquid issues from the containment as a jet which has a 'throw' sufficient to carry it over the bund wall. Spigot escapes also are dealt with in the GAO report.

22.21.7 High bunds

There is an increasing tendency to install high bunds, for which there are two main designs. In the first, the bund is some one-half to two-thirds the height of the tank wall and located about 7–8 m from it. In the second, the bund is the full height of the tank and separated from it by a distance of 3 m or less. There may be a weathershield between the tank and the bund so that the existence of a separate bund is not obvious. In both designs the bund is structurally independent of the tank.

Storage systems with bunds are to be distinguished from double integrity tanks which have two walls, both capable of containing the liquid, and in which the outer wall is concrete.

22.21.8 Dynamic loading of bunds

If a sudden, catastrophic failure of the tank wall occurs, and a large release of liquid occurs, the bund is subject to a dynamic load. It has been common to design bunds for the hydrostatic load of the liquid in the tank, but not for this dynamic load. Attention was drawn to the problem by Cuperus (1979, 1980), and it has subsequently been the subject of a number of studies.

Most of the work has been done in respect of double integrity tank systems rather than bunds. For such a system Cuperus concluded on the basis of modelling work that the impact loading was highly asymmetric and that the pressure at the base of the outer wall could be six times the hydrostatic pressure of the stored liquid.

Adorjan, Crawford and Handman (1982) have modelled the behaviour of the release allowing for the resistance of the insulation between the two walls. This modelling has been extended by Vater (1985) using the basic relation

$$h\rho - \frac{\rho u^2}{2g} = (M_\mathrm{f} + M_\mathrm{s})\frac{\mathrm{d}u}{\mathrm{d}t} - R(x) \qquad [22.21.5]$$

where g is the acceleration due to gravity, h is the initial height of the liquid in the tank, M_f is the effective fluid mass, M_s is the effective mass of the tank shell, R is the resistance to flow, t is the time, x is the distance, u is the velocity and ρ is the density of the fluid. Solution of the equation requires the determination of the initial acceleration $\mathrm{d}u/\mathrm{d}t$, for which the techniques of finite difference hydrodynamic analysis were used.

Finite difference studies on this problem have also been described by Trbojevic and co-workers (Trbojevic and Maini, 1985; Trbojevic and Gjerstad, 1989; Trbojevic and Slater, 1989). These authors have investigated both double integrity systems and bunds. Figures 22.21 and 22.22 show typical results for a high bund and a low bund, respectively.

Vater found that for the specific example which he considered the pressure at the base of the bund due to dynamic loading was some 2.65 times that due to hydrostatic load. The value obtained by Trbojevic and Gjerstad was 2.5. Higher load amplifications were found higher up the bund wall.

22.21.9 Consequences of spillage

A study of the consequences of spillage over a bund wall has been made by Wilkinson (1991 SRD R530). Predictions are given for the hazard ranges for various materials and scenarios using the GASP code for vaporization and the DENZ and CRUNCH codes for dense gas dispersion.

22.22 Underground Storage Tanks

Over the last 15 years there has come to prominence, particularly in the United States, the problem of leakage from underground storage tanks (USTs).

Underground storage tanks are treated in *Underground Storage Systems* (Schwendeman and Wilcox, 1987). Further accounts are given by Dwyer (1985), D.L. Russell and Hart (1987) and Semonelli (1990).

In the United States, the Resource Conservation and Recovery Act (RCRA) was amended in 1984 to extend the responsibilities of the Environmental Protection Agency (EPA) to underground storage tanks containing hazardous substances. Regulations on USTs came into force in 1988.

Various estimates have been given of the scale of the problem. The EPA has estimated that there are in the United States some 700,000 USTs of which about 25% are 'non-tight'. Evidence obtained by the EPA was to the effect that leaks came predominantly (84%) from loose tank fittings or faulty piping rather than from the tank itself.

The hazardous substances, to which the controls apply, are those given in the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) list. A tank is defined as a UST if more than 10% of the volume of the tank and its pipework are below ground.

The regulations require that: new UST systems for hazardous substances have a secondary containment such as a double-walled tank, an external liner or other acceptable system; the piping have secondary containment such as double-walled piping or trench lining; and pressurized piping have an automatic leak detection system. The requirement for secondary containment of tank and pipework does not apply to new UST systems for petroleum. For these the requirements are for: periodic monitoring to detect leaks on the tank; periodic leak-tightness testing or monitoring on the piping; and, on pressurized piping, an automatic leak detection system. There are less stringent requirements for existing tanks.

Secondary containment systems are required to contain any leak until it is detected and removed, to prevent any release to the environment, and to be monitored at monthly intervals. Where external liners are used, they should be such that they surround the tank completely and prevent lateral as well as vertical migration of a leak; can contain the whole contents of the tank; and prevent interference of rain or groundwater with the ability to contain and detect a leak.

Design of UST systems and methods of leak monitoring are discussed by D.L. Russell and Hart (1987). The designs include: a reinforced concrete tank with an external liner; a fibreglass tank with an external liner; and a regular horizontal tank placed in a reinforced concrete secondary containment.

The authors discuss the methods available for leak detection. Volumetric leak detection techniques rely on the change in level in the tank. Other techniques are based on detection of the leak itself. A further account of leak detection is given by Higgins and Byers (1989).

Methods used for decontamination of land where a UST has leaked are described by E. Johnson (1989a).

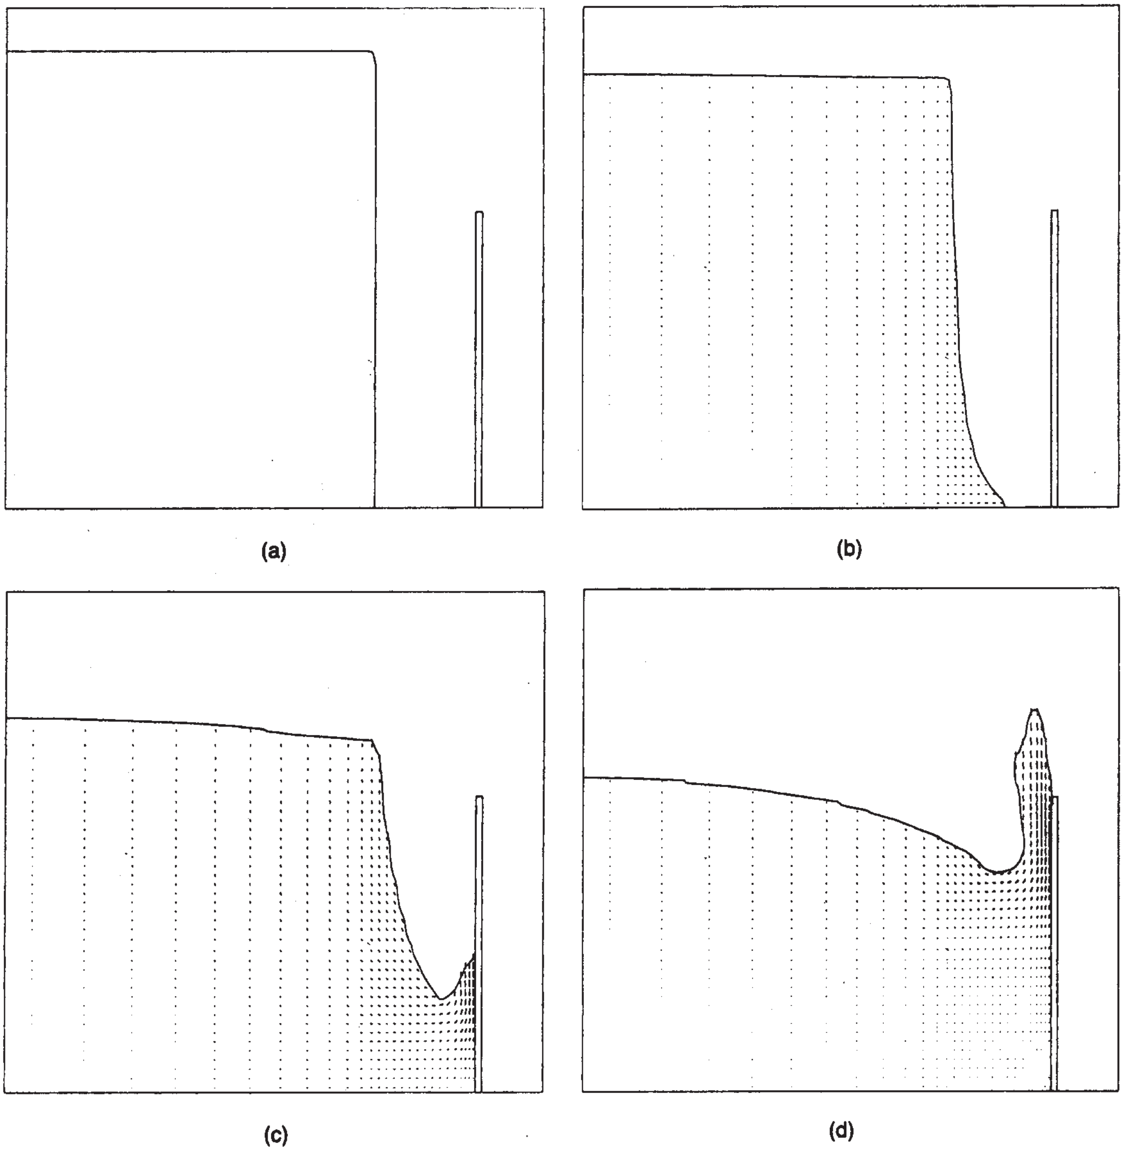

Figure 22.21 Simulation of liquid behaviour following the failure of a single wall storage tank inside a high bund (Trbojevic and Slater, 1989): (a) time t = 0 s; (b) t = 0.6 s; (c) t = 1.2 s; (d) t = 1.8 s (Courtesy of the American Institute of Chemical Engineers)

HSE guidance on underground storage tanks is given in HS(G) 52.

The environmental aspects of underground storage tanks are considered further in Appendix 11.

22.23 Glass Reinforced Plastic Storage

Most storage is constructed in steel but widespread use is also made of GRP, or FRP, containments.

An account of the use of GRP containers in the process industries is given in *Composite Materials Handbook* (Schwartz, 1991). HSE guidance on GRP containments is given in PM 75 *Glass Reinforced Plastic Vessels and Tanks: Advice to Users* (1991).

The design of GRP containment is governed by BS 4994: 1987 *Specification for Design and Construction of Vessels and Tanks in Reinforced Plastics*.

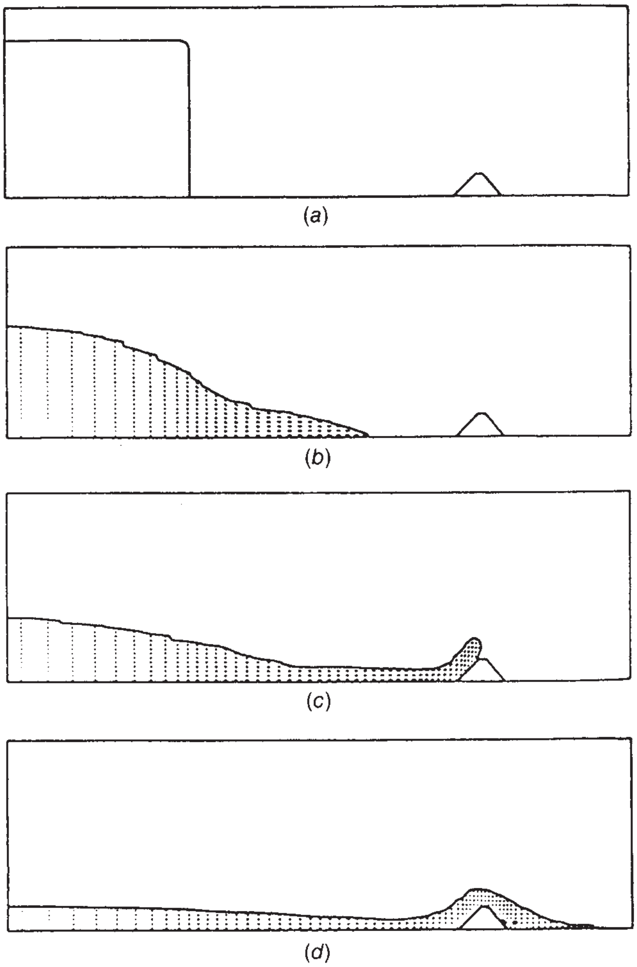

Figure 22.22 *Simulation of liquid behaviour following the failure of a single wall storage tank inside a low bund (Trbojevic and Slater, 1989): (a) time t= 0 s; (b) t= 1.5 s; (c) t= 2.5 s; and (d) t= 4.0 s (Courtesy of the American Institute of Chemical Engineers)*

GRP tanks and vessels are widely used to store corrosive materials. In addition to good corrosion resistance, they have the further advantage that they are readily fabricated into complex shapes. GRP does not suffer from external corrosion and it can have a suitable self-colouring. These factors minimize the maintenance costs of GRP storage.

However, GRP tanks are not without their hazards. In a small but significant number of instances tanks have failed. Some of these have been outright, or catastrophic, failures which have released the entire contents. The resultant tidal wave of liquid is capable of demo-lishing a bund wall, or, if the tank is indoors, a building wall.

GRP is subject to creep under sustained load, it is susceptible to chemical attack and some types may fail at temperatures below 100°C.

Typically, a GRP tank failure is due to environmental stress cracking in which the tank is subjected to excessive stress and crack propagation occurs, at first slowly and then with increasing rapidity. Prior to failure the tank often exhibits leaking or 'weeping'.

Resin rich layers are used to protect the glass reinforcement. Matrix cracking can expose the glass fibres to chemical attack.

Another cause of failure is excessive temperature. There have been cases where a GRP tank containing water has failed at 70°C.

As a material of construction, GRP has a number of features which distinguish it from steel. One is that it is anisotropic and thus has different strengths in different directions. The degree of difference depends on the fabrication, but it can be significant. Compared with steel, GRP is softer, it can only withstand much lower temperatures and it has a lower impact resistance but a coefficient of expansion three times higher.

Different GRP formulations are required for the containment of different chemicals. With an incorrect material deterioration can be caused by even small traces (ppm level) of impurity. This has obvious implications for the change of use of tanks and for the use of second-hand tanks.

GRP tanks are often provided with liners.

PM 75 describes the salient features of safety in the use of GRP storage, covering design, fabrication, installation and operation.

Design and fabrication should be to BS 4994: 1987, which grades GRP containments into three categories, Categories I–III. The strictest requirements are those for Category I, the application of which is governed by factors which include size, operating conditions and hazards.

Important features of the design are the use of the correct material and the limitation of the liquid temperature. PM 75 advises that the operating temperature should not exceed the design limits and should be no higher than 110°C.

The purchaser of a GRP tank should supply the manufacturer with a full specification of the tank duty. PM 75 reproduces from BS 4994 an appendix giving the suggested information.

Design and installation should ensure that the tank is not overstressed by providing good support for both the tank itself and the attached pipework. Care should be taken to avoid damaging the tank during erection.

In-service the tank should be subject to periodic inspection. Inspection techniques used include: ultrasonics to assess wall thickness, etc.; acoustic emission monitoring to detect defects; spark testing of welds and liner adhesion; and surface hardness testing and strain measurement.

22.24 Filling Ratio

The maximum permissible working capacity of a storage vessel, or permissible fill, is generally expressed either in terms of the filling ratio or of the maximum permissible volume. Other measures used are the filling density and the filling volume.

Filling ratios for transport of liquefied gases by road in the United Kingdom are given in BS 5355: 1976 *Specification for Filling Ratios and Developed Pressures of Liquefiable and Permanent Gases*. This standard gives formulae for the determination of the filling ratio, guidance on reference temperature for the United Kingdom and on maximum shade temperatures in other countries, and values of the filling ratio for the United Kingdom. It is considered further in Chapter 23. The formula used to calculate the filling ratio is generally of the form

$$\eta = \frac{\rho_{\mathrm{p}}}{\rho_{\mathrm{w}}}(1-\phi) \qquad [22.24.1]$$

where η is the filling ratio, ρ_{p} is the density of the liquid at the reference temperature, ρ_{w} is the density of water at 15°C and ϕ is the fractional free space. The formula may also include a term for the confidence limits on the density of the liquid. The reference temperature is the maximum temperature which the product should reach in-service.

For the United Kingdom, BS 5355: 1976 gives for low pressure liquefiable gases in vessels of volume greater than 5 m^3 a reference temperature of 38°C. The corresponding shade temperature is given as $<$ 35°C.

Filling ratios for LFG storage vessels are given in the ICI *LFG Code*. The *Code* takes for LFG a free space of 3% and a reference temperature of 38°C for vessels over 5 m^3. This yields the following filling ratios:

Propane	0.46
Propylene	0.47
n-Butane	0.54
Vinyl chloride	0.85

A formula for the maximum filling capacity of LPG storage vessels is given by the LPGA (1991 COP 1). This is

$$U_{\max} = 0.97\,\frac{g_i}{g_t}V \qquad [22.24.2]$$

where g_{i} is the specific gravity of the liquid at the reference temperature, g_{t} is the specific gravity of the liquid at its lowest likely temperature at filling, $U_{\max}$ is the maximum permissible volume and V is the internal volume of the vessel. The lowest likely temperature at filling is usually taken as 5°C.

It should be noted that while in Equation 22.24.1 the denominator is the density of water at 15°C, in Equation 22.24.2 it is the density, or rather specific gravity, of the liquid in question at the filling temperature.

Guidance on filling density is given for LPG in NFPA 59 and for LNG in NFPA 59A Guidance on the filling ratio for chlorine is given in the CIA *Chlorine Code*.

22.25 Loading and Unloading Facilities

Closely associated with bulk liquid storage are the arrangements for the loading and unloading of road tankers and rail tank cars. An appreciable proportion of accidents occur in the unloading and loading facilities.

Guidance on loading and unloading facilities is given for petroleum products in NFPA 30, the IP *Refining Safety Code* and HS(G) 50 and HS(G) 52; for LPG it is given in NFPA 58 and 59, the LPGA *LPG Storage Code*, the IP *LPG Storage Code* and HS(G) 34; and for toxic materials in general in the CCPS *HTHM Storage Guidelines*, for ammonia in HS(G) 30 and for chlorine in HS(G) 28. HAC is covered in the IP *Area Classification Code*. Further guidance is given by the Oil Industry Association (OIA, Pub. 711) and in the ICI *LPG Code*.

The account given here is concerned with the loading and unloading facilities associated with bulk storage in the main process industries, essentially at sites where the facilities and systems of work are those that are normal in these industries. It does not deal with facilities at small sites such as petrol filling stations.

It is convenient to consider first facilities in general terms, but with reference essentially to road tanker facilities for petroleum products, and then to deal with aspects specific to rail tankers and to particular chemicals.

22.25.1 Hazards

Before considering the facilities as such, it is worth reviewing some of the hazards which are characteristic of unloading and loading facilities. There are four broad categories of hazard at a tanker terminal. These are fire/explosion from leaks and spillages, fire/explosion of product in the tanker, toxic release and accidents arising from the transfer of the wrong products.

These hazards arise from: (1) overfilling of the container; (2) failure of the connection; (3) damage caused by movement of the vehicle itself; (4) vehicle movement whilst connected; (5) damage caused by impact by other vehicles; (6) ignition by static electricity; (7) equipment failures; (8) misidentification and (9) maloperation.

Overfilling of the tank during loading of the storage vessel is one of the most common accidents at such facilities, as witnessed by the extent of the measures taken to counter it. The temporary connections between the tank and the storage are a weak link, and again attract much effort to maintain their integrity. A particular cause of failure with some connections is a lack of flexibility to accommodate the normal movement of the tank on its suspension during the transfer operation.

Damage may be done to the fixed plant or to the vehicle itself as it moves to and from the loading bay. Releases also occur due to the movement of the vehicle whilst still connected to fixed system. This occurs most commonly when the vehicle is driven off, but other causes can be an unsecured vehicle on unlevel ground or impact by another vehicle. Impact by another vehicle may also lead to a release due to the rupture of the connections.

Any of the releases described may result in a fire, or occasionally an explosion. Another cause of fire/explosion is ignition of a flammable mixture in the tank of the vehicle.

22.25.2 Fire and explosion

A fire/explosion of the product during top loading constitutes a serious problem. The type of product which is the most hazardous is one which gives a flammable mixture in the vapour space. Liquids which give a lean mixture below the lower limit or a rich mixture above the upper limit of flammability are less troublesome.

Ignition of the product is usually due to static electricity. This may be generated if the liquid is allowed to fall free and splash from the filling pipe into the tank, so it is normal practice to position the tip of the filling pipe near the bottom of the tank. But charge may be generated at the start of the filling before the pipe is fully submerged. It is also possible for the liquid to acquire a charge before it reaches the tank. Build-up of charge due to flow in the pipe itself is usually not critical, but product filters with cotton, paper or felt elements are prolific generators of static electricity. It has usually been considered that a relaxation time of 30 s between the filter and the outlet of the filling pipe is necessary to dissipate this charge. Moreover, there has been a trend to purer, drier products for which the relaxation time tends to be in the range 100–500 s. A fuller account of the hazard of ignition by static electricity, including the specific case of tanker loading, is given in Chapter 16.

Fire/explosion also occurs due to spillage. Hose spillages are particularly frequent. Often they occur because a tanker is driven away from the gantry with the hose still connected. Also, hoses may burst because they are not strong enough.

22.25.3 Switch loading

A particularly hazardous situation occurs when a less volatile product is put in a tank which previously contained a more volatile one. This hazard is described by the OIA. There is often a tendency for the residue of the latter to form a flammable mixture, while the former does not readily dissipate static charge. According to the OIA, such 'switch loading' has accounted for some 70–80% of severe losses at loading bays. These appear to occur most often when compartments are one-quarter to one-third full and when temperatures are close to SOT (−1°C).

The IP *Refining Safety Code* states that, wherever possible, switch loading should be avoided.

22.25.4 Siting

Since loading and unloading facilities are areas of relatively high risk, their siting is important. A suitable approach is to locate the facility on the far side of the storage from the process, where this is practical. The location should also be chosen to allow good access for the vehicles to be loaded or unloaded, but to be as free as possible from any form of interference, particularly from other vehicles. Siting is considered in more detail in Chapter 10.

22.25.5 Layout

The layout of the loading and unloading facilities can make a major contribution to the elimination and minimization of incidents. Some aims of layout are to avoid releases, to minimize the size of any release, to prevent the ignition of a release, and to control any fire from an ignited release.

Some features of layout which contribute to these aims include: (1) minimum separation distances, (2) the general form of the loading/unloading bay, (3) ground slope and drainage, (4) ventilation, (5) access and escape, (6) lighting, (7) routing of pipelines, (8) protection against vehicle impact, (9) control of movements of vehicles, (10) control of the movement of personnel, (11) vessel, connection and equipment identification, (12) direct lines of sight, (13) control of ignition sources, including HAC, (14) fire protection and (15) emergency equipment.

Minimum separation distances for the loading and unloading facilities for particular materials are given in the codes for those materials, as described in Section 22.26.

There should be sufficient space so that congestion is avoided. It is desirable that vehicles are able to drive in and out without reversing. The ground at a loading/unloading bay should be firm and impervious. At the filling point it should slope away so that spillage does not collect under the tanker and there should be suitable drainage. Where top loading is practised, there should be a platform with good access, including access to the top of the tanker, and a means of escape. The facility should be well ventilated and well lit.

The layout should assure protection both of the fixed equipment and of the tanker from impact by another vehicle. Attention should be paid to the routing of pipelines connected to the facility. Damage from vehicles can largely be avoided by the provision of high kerbs around the loading island and also of barriers to protect equipment and by controlling the movement of vehicles. It may also be necessary, particularly where other persons may be passing, to provide barriers or other means to control vehicle movements.

Storage vessels, filling connections and other equipment such as pumps should be provided with a means of identification. The layout should provide direct lines of sight so that personnel conducting transfer operations can observe the effects of their actions.

Where a fire hazard exists, the control of ignition sources should be exercised through HAC and fire protection facilities should be provided. The HAC of loading and unloading facilities is considered in Section 22.25.6 and fire protection is discussed in Section 22.25.11.

Emergency equipment appropriate to the material handled should be available at the facility.

There should be arrangements at a filling point to run part or all of tanker's contents back to the storage vessel if necessary.

22.25.6 Hazardous area classification

Loading and unloading facilities are among the cases dealt with by the method of direct example in the IP *Area Classification Code*, which covers petroleum products. The code gives detailed recommendations for the HAC of road and rail transportation, dealing separately with loading and unloading, including the unloading of road tankers at petrol filling stations. The *Code* gives some ten figures showing the HAC zoning in plan and elevation for different facilities and situations.

Further guidance on the HAC for petroleum products is given in NFPA 30 and guidance on the HAC for LPG is given in HS(G) 34 and NFPA 58 and 59.

22.25.7 Filling arrangements and connections

There are three main types of connection used for the transfer of liquids between the fixed facility and the tank of the vehicle. These are (1) flexible hoses, (2) articulated arms and (3) flexible couplings. A description of the three types of system as used for chlorine is given in HS(G) 28.

Connection is frequently by means of a hose. Articulated arms with swivelled joints are used on installations with a high throughput. Flexible couplings are used for certain products such as chlorine.

Good practice in respect of hoses is illustrated by the guidance given in HS(G) 34 on flexible hoses for LPG. A hose should be designed and made to an appropriate standard such as BS 4089; it should be suitable for the product to be handled; it should be provided with means of identification; it should be protected both in respect of its end fittings against damage and ingress of foreign matter and, where necessary, in respect of external damage, using a procoil or similar device; it should be subject to a full system of maintenance and test, including inspection records, annual hydraulic testing, periodic examination for kinks, weakness and end fitting deterioration and electrical discontinuity; and it should be kept in a safe place when not in use and replaced or repaired when worn or damaged.

The filling of tankers is carried out through a pipe in the top or in the bottom of the tank, that is by top or bottom loading. Top loading is often done by a rigid arm system and bottom loading by a hose. Pipes should be arranged so that the line between the tanker and the plant can be emptied before the tanker is uncoupled. Incidents sometimes occur due to a failure of the hydraulic system on a filling arm which causes it to drop and foul a tanker, and a locking device should be provided to prevent this.

Vapour recovery systems are becoming more widely used, mainly to meet pollution requirements. These systems have a filling arm which makes a gas-tight fit over the tank hatch, a short pipe which gives splash filling and a float switch which cuts off the flow when the tank is full. There is a separate vapour line which goes to a compressor and gasholder. Loss experience with these devices is good.

22.25.8 Shut-off arrangements

There are measures which can be taken to avoid overfilling and a number of devices which can be used to effect rapid shut-off if a leak occurs due to overfilling, failure of a filling connection or otherwise.

These include (1) vessel identification, (2) vessel sizing, (3) ullage control, (4) pre-set filling meters, (5) pump trips, (6) high level alarms, (7) dead man's handle arrangements, (8) non-return valves, (9) excess flow valves, (10) remotely operated isolation valves, (11) remote control of pumps and (12) self-sealing couplings.

The marking of vessels to ensure correct identification is one elementary measure to prevent releases. The use of a storage vessel with a capacity at least that of the largest tanker from which transfer may be attempted is another: this is particularly important for chlorine facilities. Attention to the ullage in the container to which transfer is to be made is a third.

A pre-set filling meter may be used to ensure that the quantity transferred does not exceed the capacity of the container. The filling pump may be provided with a trip to stop the pump and preferably close a shut-off valve when the pre-set quantity has been delivered. There may also be a manual control for the pump and the shut-off valve at the loading point. On storage a high level alarm may be provided to warn if overfilling is occurring.

An arrangement which guards against an operator starting the filling and then having his attention diverted elsewhere is the use of a spring-loaded self-closing filling valve which remains open only as long as the operator's hand is on it, that is a dead man's handle valve.

Means are available for cutting off flow from a damaged or disconnected connection, for example non-return valves, excess flow valves and remotely operated isolation valves.

Whatever the other arrangements, means should be provided for stopping all pumps immediately if an incident occurs. This should be a manual control in an attended terminal and an automatic one in an unattended one.

As described below, another means of shutting off a leak, applicable to the case where the vehicle moves away whilst still connected, is the use of a self-sealing coupling.

22.25.9 Vehicle control

Likewise, there are a number of methods which can be used to prevent a vehicle from moving away whilst it is still connected to the fixed plant by a filling connection, and thus causing a release. These mostly involve some form of interlock. There are also devices to shut-off flow.

The measures used differ somewhat between road and rail, and those described here are those applicable to road tankers. The ground at the filling point should be level and chocks should be used to hold the tanker in position.

Movement of the vehicle may be prevented by the use of an interlock system. One method is the use of an interlocked barrier. Another is an arrangement which locks the vehicle's braking system when the delivery hose is taken from its stowage position and releases the system only when the hose is restowed. A third is a brake flap arrangement which must be moved aside to gain access to the filling branch, the action of which actuates the vehicle's braking system.

Flow may be cut off if the tanker moves by use of a self-sealing breakaway coupling. Other emergency shut-off devices have already been described.

22.25.10 Static electricity control

There are various precautions which may be taken against the hazard of ignition of product by static electricity.

An account of these measures is given by the OIA. Two measures which it considers very desirable, although they are not generally adopted, are the complete elimination of switch loading and the use of inerting of the tank during filling. The latter tends to be rather expensive and time-consuming.

Measures which are normally taken are earthing and bonding to dissipate static charges on the metal containment. The filling pipe, the product line and the gantry should be electrically continuous and earthed. The electrical resistance of the gantry should not exceed $10^4\ \Omega$ and should be checked periodically.

Bonding involves connecting the product line to the tank. This prevents static discharge between the filling pipe and the tank. It is usually done using a wire with alligator clips. It is considered adequate if the electrical resistance of the bond does not exceed $10^6\Omega$. The bond should be inspected and its electrical resistance checked periodically. The bond should be such as to avoid damage if the vehicle is driven off before the bond is disconnected. Devices which drop down from the gantry to touch the tank are not considered effective for bonding.

As mentioned in Chapter 16, however, it may be desirable to aim for lower electrical resistances than those just quoted in order to ensure that the latter are reliably achieved. The bonding should be attached before the filling pipe is inserted into the tank and it should remain in place until the operation is completed.

However, earthing and bonding do not immediately dissipate the charge on the surface of a non-conducting liquid in the tank. A relaxation time should be allowed after filling has been completed and before the filling pipe is withdrawn, to permit static charge on the liquid surface to dissipate to the pipe or tank shell. The minimum time is 1 min, but longer periods are advisable with some products, as indicated above.

Where switch loading is practised, there are various additional precautions which may be taken. These include the use of inerting, low filling rates, special filling tips and static neutralizing devices, and longer relaxation times. The initial filling rate should be 3 ft/s maximum, rising to 15 ft/s when the filling pipe outlet is fully submerged. Special filling pipe regulator tips are available to give this initial flow limitation. Static neutralizers may be installed in the product line. Longer relaxation times may be allowed before withdrawing the filling pipe.

Bottom loading does not eliminate the static electricity hazard, particularly in switch loading, and still requires earthing.

With vapour recovery systems, splash filling would theoretically appear to increase the hazard on switch loading. The OIA therefore recommends against their use in switch loading situations.

22.25.11 Fire protection

A loading/unloading facility should be provided with appropriate fire protection. The arrangements depend on the particular installation and especially on the product transferred, the amount of material and the number of tankers handled, the location of the terminal, and the potential for damage and business interruption.

Fixed water sprays may be provided to cool tankers at filling points. The failure of tankers in a fire can be relatively rapid. The OIA makes recommendations for fixed sprays of water, foam or dry chemicals for terminals for flammable liquids. It is particularly concerned with automatic systems for unattended terminals. It suggests that fixed sprays should be located both in the roof and along the loading island so that extinguishing media can be directed under tankers. For fixed water sprays, a rate of application of 0.25 USgal/ft^{2}min over the whole loading area is recommended.

The ICI *LPG Code* recommends fixed water sprays for terminals handling more than one tanker simultaneously or more than four tankers per day. The rate of application of water should be 0.2 UKgal/ft^{2}min of tank surface. In multi-bay installations, there should be arrangements to control the sprays selectively. Automatic operation is not essential, as it is assumed that the terminal is manned during transfer operations.

The *Code* also states that if fixed water sprays are not provided there should be fire hydrants capable of the same rate of application of water, but that if fixed sprays are installed the hydrant capacity can be reduced by 50%.

For LFG fires the method of extinction is to cut off the supply of fuel. Water from spray nozzles may be used to cool tankers and equipment, particularly to prevent direct flame impingement, to bend flames away from equipment and to cool the flames themselves. But putting water directly on an LFG spillage has the effect of increasing the evaporation rate and this generally makes the fire worse. In addition, it is undesirable to extinguish an LFG fire with water because of the danger of a subsequent explosion. Water should not be used, therefore, on LFG fires, except for very small spillages. Foam may be used to limit the evaporation rate, but it will not normally extinguish a fire and, as just stated, it is not desirable that it should.

Portable fire extinguishers and sand should be provided for dealing with small spillages or vehicle fires.

Drains should be provided which will handle flammable liquids and fire water, along the lines previously described.

Electrical cabling should be routed outside the high risk areas of the terminal or should be protected so that emergency services are maintained and any subsequent interruption minimized.

It is desirable that the tanker at a terminal have some degree of fire resistance. There are large aluminium tankers which may fail within only 1 min when exposed to intense ground fires and these represent a serious hazard.

The OIA draws attention to the increase in the number of unattended or 'keystop' terminals for flammable liquids. In such terminals there are problems of damage to loading equipment, of a lack of supervision of loading practices and of the absence of personnel to control fires.

22.25.12 Rail facilities

Most of the features of loading and unloading facilities for road apply also to rail, but there are some which are characteristic of the latter.

Rail tracks should be laid straight and level, though a small gradient can be tolerated. HS(G) 52 gives a limit of 1 in 400. The track and line-side equipment should be maintained to the appropriate British Rail standard.

There should be arrangements for the control of locomotives whilst filling is in progress.

There should be earthing and bonding to dissipate the static charges. Rails should be bonded together and to the product lines. A separate bond to the tank is necessary only if the earthing between the tank and the rails via the wheels is inadequate.

Stray currents constitute an additional hazard. These may arise from electrified main line tracks, rail circuit signal systems or cathodic protection systems. If the siding is part of an electrified system, it should be electrically isolated from the rest of the system and bonded to the site main earth. Precautions which may be necessary against stray currents are insulating inserts in the rails where they enter and leave the loading siding and an insulating flange between the product line and the filling pipe together with a flexible bond between the rail tank and the filling pipe.

22.25.13 Operation

As with other aspects of process installations, the safety of loading and unloading facilities depends as much on operation as on design.

A significant issue is the manning of the facility, which tends to vary and which has more than one aspect. One is control of the transfer. In some cases transfer is conducted by plant personnel and in others by the driver of the tanker. Another aspect is the back-up available if something goes wrong, such as the outbreak of a fire or a toxic release sufficient to overcome the person effecting the transfer.

Safe systems of work should be provided and enforced which cover all aspects of the operation, from the identification of materials, vessels, connections and equipment, through the transfer operations themselves, to the emergency procedures.

There should be a good standard of housekeeping at the facility.

During filling all ignition sources should be excluded from the area of the filling point, including road or rail traffic. The engines of road tankers should be turned off.

22.26 Loading and Unloading Facilities: Particular Chemicals

22.26.1 Petroleum products

As stated above, guidance on the loading and unloading facilities for petroleum products is given in NFPA 30, the IP *Refining Safety Code* and HS(G) 50 and HS(G) 52, and also by the OIA.

The account already given has been based largely on facilities for petroleum products and these may therefore be treated briefly. Features specific to such products given in the guidance just mentioned include: minimum separation distances; HAC; top and bottom filling arrangements; spillage disposal arrangements and fire protection.

22.26.2 LPG

For the loading and unloading facilities for LPG, guidance is given NFPA 58 and 59, the LPGA *LPG Storage Code*, the IP *LPG Storage Code* and HS(G) 34, and also in the ICI *LFG Code*.

For LPG, the requirements for minimum separation distances are different. Particular importance attaches to the arrangements for the control of ignition sources, including the control of static electricity; HAC and fire protection. The discussion of fire protection in Section 22.25 covers LPG facilities.

22.26.3 High toxic hazard materials

Guidance on the loading and unloading facilities for HTHMs is given in the CCPS *HTHM Storage Guidelines*. In essence, the *Guidelines* cover ground similar to that just considered, both in respect of the hazards and the measures taken to control them, at least as regards loss of containment, though the hazard from the flammability of the material may not apply. It is worth emphasizing, however, that the points which do apply do so with particular force to HTHMs and that for such materials the standards of integrity required are high.

The *Guidelines* point out that in the case of loading and unloading facilities it is not possible to apply the philosophy of secondary containment.

With toxic materials even the small release which occurs as the tank is filled with a high vapour pressure liquid may be unacceptable. In such cases use should be made of a dual transfer line system, with one line used for transfer of liquid to and from the container and the other line used for venting vapour during filling.

22.26.4 Chlorine

Guidance is given on the unloading facilities for chlorine in HS(G) 28. Some specific aspects include potential incidents, minimum separation distances, filling connections, padding gas arrangements and systems of work.

For chlorine, flexible couplings are the normal method of connection and HS(G) 28 gives details of their use. Methods of transfer of liquid chlorine described in HS(G) 28 are the use of dry compressed air or nitrogen or of chlorine vapour, obtained by recompression or vaporization.

The system of work should ensure that one person, the driver, is present throughout the unloading, and that a second is present during connection and disconnection and is available throughout the unloading operation.

22.26.5 Ammonia

General guidance on the handling of ammonia is given in HS(G) 30, but this does not give guidance on loading and unloading facilities comparable with that for chlorine just described.

Some of the issues arising in relation to loading facilities for ammonia are discussed by Lichtenberg (1987) the use of meters vs scales; the use of hoses vs articulated arms; blowing off vs the use of integral blowdown systems; and loading by the driver or by plant personnel.

Articulated systems include vertical articulated arm systems and also compact horizontal articulated arm systems with integral blowdown.

22.27 Drum and Cylinder Storage

Another type of storage is storage in drums and similar containers and in cylinders. Although such storage is, in principle, very simple, the hazards are not trivial.

HSE guidance on drum and cylinder storage is given in CS 4 *The Keeping of LPG in Cylinders and Similar Containers* (1986), HS(G) 40 *Chlorine from Drums and Cylinders* (1987) and HS(G) 51 *The Storage of Flammable Liquids in Containers* (1990). Another relevant code is *Storage of Full and Empty LPG Cylinders and Cartridges* (LPGA, 1967 Code 7).

22.27.1 Drum storage

Chemicals are stored in containers at supplier and user sites in the chemical industry and at depot and warehouse sites.

For flammable substances guidance is given in HS(G) 51. This supersedes earlier guidance given both in CS 2 and a Home Office code. HS(G) 51 does not cover reactive chemicals such as organic peroxides, LPG or large containers.

The containers considered in this guidance include drums, portable tanks and tank containers. Reference is made to containers of 200 l. A typical container in the United Kingdom is the standard 40 UKgal drum.

Relevant British Standards on container construction are BS 814: 1974– for steel drums and BS 3951: Part 2: 1978 – for freight containers.

The general approach to drum storage is broadly as follows. The preferred option is storage in the open. The storage should be in a defined area which should have an impervious surface and should be provided with a low bund or a drain and sump system. Where use is made of a bund, it is typically 150 mm high and should be large enough to hold 110% of the contents of the largest container. Within the storage area, the drums should be stored in stacks which should be marked off. The stacks should have good access and ventilation. There should be separation distances between occupied buildings, the boundary, process units, flammable liquid tanks and fixed ignition sources. There should also be a maximum stack size. Guidance is given on maximum stack sizes and minimum separation distances to the objects mentioned and to LPG storage. The area around the storage should be free of combustibles and tidy. The area should be fenced off, with one or two access gates, depending on the size of the site. The storage should have a HAC as a Zone 2 area. Firefighting facilities should be provided. If there is difficulty in providing the separation distances recommended, some relaxation may be obtained by the provision of fire walls or fixed water sprays systems.

Alternatively, storage may be in a separate building dedicated to that purpose or in a building used also for other purposes. The latter case requires additional fire resistant construction, particularly fire walls. A building used for such storage is essentially a warehouse, to which consideration is given in the next section.

Further guidance on drum storage is given by two anonymous authors (Anon., 1979 LPB 27, p. 68); Anon. (1979 LPB 28, p. 115).

22.27.2 Cylinder storage

As for other containers, chemicals are stored in containers at supplier and user sites in the chemical industry and at depot and warehouse sites.

For LPG guidance is given in CS 4. The basic principles are essentially the same as for drum storage, but there are differences of detail such as in the specific values of maximum stack size and minimum separation distances.

22.28 Warehouses

Warehouses constitute a quite different kind of storage. A wide variety of materials are stored in warehouses in many different forms. Material may be simply stored in a stockpile on the warehouse floor, but more often there are bays which hold discrete items such as paper, drums and spare parts. Chemicals in packages and drums are also stored in warehouses.

The Dangerous Substances (Notification and Marking of Sites) Regulations 1990 (the NMS Regulations) create a requirement for the notification and marking of sites which has particular relevance to warehouses. Guidance is given in HS(R) 29 *Notification and Marking of Sites. The Dangerous Substances* (*Notification and Marking of Sites*) *Regulations* 1990 (HSE, 1990).

HSE guidance on warehouses is given in HS(G) 51 *The Storage of Flammable Liquids in Containers* (1990), HS(G) 64 *Assessment of Fire Hazards from Solid Materials and the Precautions Required for their Safe Storage and Use* (1991) and HS(G) 71 *Storage of Packed Dangerous Substances* (1992). Further guidance is provided in *Guidelines for Safe Warehousing* by the CIA (1990 RC28) (the CIA *Warehouse Guide*).

Also relevant are NFPA 231: 1990 *General Storage* and NFPA 231C: 1991 *Racked Storage of Materials*.

22.28.1 Regulatory requirements

Sites which store large inventories of hazardous substances are covered by the NIHHS Regulations 1982 and CIMAH Regulations 1984. These regulations do not, however, apply to most warehouses. In a typical warehouse the quantity of any given chemical is below the threshold quantities which trigger these regulations. The necessity for the control of warehouses, however, has been highlighted by a number of incidents. The NMS Regulations 1990 were brought in to close this loophole.

In particular, the regulations are intended to provide the fire services with information to assist them in setting priorities for the inspection of sites and to warn firefighters arriving at an incident of the presence of dangerous substances.

Regulation 4 defines dangerous substances as those listed in Part 1A2 of the Approved List of the CPL Regulations 1984 and other substances with the characteristic properties set out in Schedule 2, Part 1, of those regulations. Notification is required if the warehouse stores a total of 25 te or more of dangerous substances. Regulation 5 gives requirements for access marking and Regulation 6 requirements for location marking.

There are a number of other pieces of legislation which are relevant to warehouses. In addition to those already mentioned, they include the Petroleum (Consolidation) Act 1928 (P(C)A), the Fire Precautions Act 1971, the Highly Flammable Liquids and Liquefied Petroleum Gases Regulations 1972 (HFLR), the Safety Signs Regulations 1980, the Control of Pesticides Regulations 1986, the Control of Substances Hazardous to Health Regulations 1988 (COSHH) and the current Building Regulations.

22.28.2 Management system

For the most part the companies which operate warehouses handling chemicals are not in the mainstream of the chemical industry and its culture. The operation of a chemical warehouse nevertheless demands a management system essentially similar to that in the industry.

Specifically, the management system should ensure that among other things there are formal systems which cover the identification, assessment and control of hazards; the use of suitable buildings; the storage and segregation of chemicals; the provision and maintenance of fire protection and the use of and training in suitable operating procedures.

The responsibilities of those involved in warehouse operation are outlined in the CIA *Warehouse Code*, which covers the supplier or owner of the goods, the warehouse keeper, the warehouse supervisor and the warehouse employee.

An essential aspect of the management system is good communications.

22.28.3 Warehouse siting and layout

The siting of warehouses is often far from ideal. Many existing warehouses are located in a built-up area and close to housing. Siting of new warehouses should be such as to minimize the risks to the surrounding area. Likewise, these risks should be taken into account when considering an extension to an existing warehouse. Fire and explosion are the events which are most likely to present a threat to the surrounding population.

Many warehouses are located on waterways where they serve as transit points. This increases the risk of pollution of these waterways by chemicals released during an incident.

The layout of the warehouse site should be such as to facilitate the movement of vehicles that are unloading or loading, with adequate access and parking. The layout should aim to minimize collisions and to allow incidents such as spillages or small fires to be readily dealt with.

The layout should also assist security. Access should be gained only through access gates. Each separate warehouse building should be capable of being securely locked.

22.28.4 Warehouse buildings

The construction of a warehouse building is subject to the Building Regulations. For industrial storage buildings there is an approved document which sets out standards for compartment size and fire resistance.

Some high fire hazard substances require separation distances between the building and the boundaries in excess of those specified in the Building Regulations. These include flammable liquids, oxidizing substances and organic peroxides.

A warehouse for dangerous substances should preferably be constructed in non-combustible materials. Where flammable substances are involved there may be specific regulatory requirements for fire resistance.

Guidance on warehouse building construction is given in the CIA *Warehouse Guide*. This guidance is intended to illustrate the approach which might be taken by a chemical company in constructing a new facility. The code deals with (1) frame, (2) infill, (3) floors, (4) roof, (5) ventilation, (6) drainage, (7) emergency exit doors, (8) internal doors, (9) internal partitions, (10) wall and roof linings, (11) fire protection, (12) special facilities, (13) lighting and (14) electrical installations.

Where the dangerous substances stored are liquids, floors should be impervious and resistant to the liquid. There should be bunds to contain the liquid and sills to prevent its spread through doorways. In areas where the risk of spillage is high, there should be a separate drainage system with sloped floor, a bund and a collection sump.

Rainwater should be taken away from the roof and outside areas in drains with roof downpipes sealed at ground level. The drainage arrangements should aim to prevent contamination of surface water by water used in fighting a fire in the warehouse.

22.28.5 Material identification

There should be a formal system for the identification and tracking of the dangerous substances handled. The system should be based on the classification systems for dangerous substances. Most such substances arriving on site will be marked with the conveyance labels specified in the Chemical Hazard (Information and Packaging) Regulations (CHIP) and goods in international transit should be labelled with the United Nations labels. The supplier should normally provide in addition the information required under the CHIP supply labelling system.

Some substances may require special storage conditions. These should be identified in advance by the supplier and accepted only if these conditions can be provided. Some substances may degrade or become unstable during prolonged storage. These too should be identified by the supplier.

All dangerous substances should be identified on receipt and their storage in and transfer from the warehouse documented. The documentation system should ensure both that records are made and that they are held securely.

22.28.6 Material segregation

The most serious incidents occur when a small event escalates and involves large quantities of material. The main cause of this is fire. An effective means of preventing such escalation is the segregation of materials.

One purpose of segregation is to separate dangerous substances from materials which may ignite or burn readily in the early stages of a fire. Another is to keep dangerous substances out of general storage where their presence is liable to aggravate the difficulties of firefighters.

Table 22.12 is the segregation table given in HS(G) 71. It is based on the conveyance labelling requirements of the CPL Regulations and is compatible with the *UN Recommendations for the Transport of Dangerous Goods*. The table does not include Class 1, Explosives, Class 6.2, Infectious Substances, or Class 7, Radioactive Substances, which are covered by separate guidance. The numbers in the table refer to the segregation of different classes of substance on the same floor of a building. Vertical segregation between different classes of material is not accepted except where there is an imperforate floor/ceiling with 1 h fire resistance. The general guidance given in the table is overridden where there is advice specific to a particular class of material.

The International Maritime Dangerous Goods Code may also be used as guidance, provided allowance is made for the different factors which apply to land storage.

22.28.7 Mechanical handling

Modern warehouses make full use of mechanical handling aids. There is also a trend towards automated warehouses under computer control. The mechanical handling facilities should accommodate the full range of packages to be stored, so that improvisation is avoided. Widespread use is made in warehouses of pallets and forklift trucks. Guidance on the use of forklift trucks is available (HSE, 1992 HS(G) 6). Forklift trucks are also considered in Chapter 21.

22.28.8 Storage operation

There are a number of basic operating principles which should be covered by formal operating procedures.

When a consignment is received, the substance should be identified and the integrity of the package should be checked. Damaged packages should not be accepted into store but dealt with by repacking or disposal.

Each location should have a specified storage capacity which should be adhered to. There should be maximum stack sizes and heights. The heights should take into account the potential for damage to the packages at the bottom and for fire spread. The racking used should be well constructed and should not be overloaded. Goods should not be stored so close to a wall as to interfere with ventilation or in gangways so that they inhibit access.

***Table 22.12** Segregation table for storage of dangerous substances in warehouses[a] (Health and Safety Executive, 1992 HS(G) 71) (Courtesy of HM Stationery Office. © All rights reserved)*

To be read in conjunction with Appendix 1[b]	*Class 2*			*Class 3*	*Class 4*			*Class 5*		*Class 6*	*Class 8*
	2.1	2.2	2.3		4.1	4.2	4.3	5.1	5.2		
2 Compressed gases											
2.1 Flammable	–	1	2	2	2	2	2	2	3	1	1
2.2 Non-flammable toxic	1	–	1	1	0	2	0	0	2	0	1
2.3 Toxic	2	1	–	2	1	2	1	0	2	0	1
3 Flammable liquids	2	1	2	–	1	2	2	2	3	1	1
4 Flammable solids											
4.1 Readily combustible	2	0	1	1	–	1	2	2	2	1	0
4.2 Spontaneously combustible	2	2	2	2	1	–	1	2	3	1	1
4.3 Dangerous when wet	2	0	1	2	2	1	–	1	2	0	0
5 Oxidizing substances											
5.1 Oxidizing substances	2	0	0	2	2	2	1	–	2	1	1
5.2 Organic peroxides	3	2	2	3	2	3	2	2	–	1	1
6 Toxic substances	1	0	0	1	1	1	0	1	1	–	0
8 Corrosive substances	1	1	1	1	0	1	0	1	1	0	–

[a] The table shows general recommendations for the separation or segregation of different classes of dangerous substance.
The miscellaneous dangerous substances in UN Class 9 and other dangerous substances in CPL have quite varied properties and no general advice can be given regarding segregation. Advice should be obtained from the supplier.

[b] Of HS(G) 71.

Key:

0 *Separation may not be necessary,* but suppliers should be consulted about requirements for individual substances. In particular, it should be noted that some types of chemicals within the same class may react violently, generate much heat if mixed or evolve toxic fumes.

1 *'Keep apart'.* Separate packages by at least 3 m or one gangway width, whichever is the greater distance in the store room or storage compound outdoors. Materials in non-combustible packaging which are not dangerous substances and which present a low fire hazard may be stored in the 3 m space. At least this standard of separation should be provided between substances known to react together readily, if that reaction would increase the danger.

2 *'Segregate from'.* These combinations should not be kept in the same building compartment or outdoor storage compound. Compartment walls should be imperforate, of at least 30 min fire-resisting construction and sufficiently durable to withstand normal wear and tear. Brick or concrete construction is recommended. An alternative is to provide separate outdoor compounds with an adequate space between them.

3 *'Isolate'.* This is used for organic peroxides, for which dedicated buildings are recommended. Alternatively, some peroxides may be stored outside in fire-resisting secure cabinets. In either case, adequate separation from other buildings and boundaries is required.

Where a particular material has the properties of more than one class, the classification giving the more onerous segregation requirements should be used.

Note: The table is to be read in conjunction with the following paragraphs from the text of HS(G) 71. Paragraphs 20 and 21 explain the logic behind the table and paragraphs 13, 15, 22 and 23 give certain caveats.

20 Often the first material ignited in a fire is not itself a dangerous substance. For this reason, stocks of combustible materials such as easily ignitable packaging should not be kept in store rooms with dangerous substances. Separate storage areas should be provided. Similarly, even small quantities of dangerous substances stored in a warehouse for general goods may seriously increase the consequences of any fire, and in particular add to the dangers for the fire brigade. Dangerous substances should preferably be stored in dedicated warehouses or compartments of warehouses which are effectively fire separated from the remainder of the building.

21 The intensity of a fire, or its rate of growth, may be increased if incompatible materials are stored together. In addition, a fire may grow and involve dangerous substances which of themselves are not combustible. In this way, toxic materials may be widely dispersed. To prevent this type of escalation a system of segregation is necessary in warehouses storing dangerous substances.

13 The conveyance labels alone do not give adequate information for all purposes associated with storage, and the supplier should normally provide at least the additional information required under the CPL supply labelling system. This includes standard risk and safety phrases. In most cases, drivers making deliveries of a dangerous substance are required to carry on the vehicle information about the hazards of the substance(s) being carried. This may be useful if safety data sheets are not already held for substances being delivered.

15 On arrival, the contents of each consignment or individual packages should be checked, identified and assessed against the shipment documents to verify acceptability. Dangerous substances should usally be identifiable by the conveyance labelling attached to the outer layer(s) of the packaging, and for most purposes can be assesed accordingly. The additional information obtained from the suppliers may identify specific examples of non-compatibility, and storage location should take account of this.

22 The table overleaf gives recommedations for the segregation of dangerous substances of different types. The classification scheme is based on the conveyance labelling requirements of the CPL Regulations, and is consistent with the United Nation *Recommendations on the Transport of Dangerous Goods*. The table excludes Classes 1, Explosives; 6.2, Infectious substances; and 7, radioactive substances for which guidnce is given elsewhere (see Appendix 3)[b]

23 Numbers in the Table relate to segregation of different classes of substance on the same floor of a building. Vertical segregation between different classes of material is not acceptable unless provided by an imperforate floor/ceiling of at least 60 minutes' fire-resisting construction.

Stock held for a prolonged period should be inspected for degradation. Where a substance has a maximum storage time this should not be exceeded. If this is close to occurring, the advice of the manufacturer should be sought.

There should be arrangements for dealing with spillages. This is partly a matter of building design, as already described, but it is also necessary to provide an absorbent and to have procedures for dealing with and disposing of the spillage.

Where appropriate, an operation should be governed by a permit-to-work.

22.28.9 Fire protection

The fire potential in a warehouse is high. The fire load is very high and the conditions for fire spread are nearly ideal, there being large amounts of combustibles close together and with good air circulation. In fact a large proportion of fire loss in storage is due to warehouse fires. The prevention of fires in warehouses is therefore extremely important.

Fire protection in warehouses includes the following measures: (1) building construction, (2) control of ignition sources, (3) fire detection systems (4) fire protection systems and (5) operational measures.

As already stated, the building should preferably be constructed in non-combustible materials and have a degree of fire resistance. The starting point is a concrete or steel frame. Other aspects of fire resistant construction are concrete protection of the steel supporting columns, separation of the arrival and dispatch areas from the storage area by fire resistant walls, and further separation by fire resistant walls within the storage area.

Whereas in process plant handling flammables the first line of defence is to remove the fuel by keeping the flammable material contained, in a warehouse storing flammable substances the fuel is to hand. Hence close control needs to be exercised over ignition sources.

The warehouse should be covered by HAC. Normally the appropriate classification is Zone 2 and the arrangements should then be such that no operation requires a more stringent classification.

Forklift trucks are a particular potential ignition source which require control. Where a HAC applies, only trucks suitable for use in that area should be used.

Fire detection systems are valuable in giving rapid warning of a fire. Whether detection is followed first by warning to personnel and manual fire-fighting methods or by immediate activation of automatic fire protection systems such as sprinklers depends on the circumstances. Problems with the latter include false alarms and water damage.

Sprinklers are the principal form of fire protection device used and are generally effective. For high warehouses, sprinklers on the roof may be insufficient and they may need to be provided at lower levels as well. Sprinkler protection is discussed further in Chapter 16.

There should be a working discipline, essentially similar to that required in a process plant, which ensures that procedures are observed. These include general good housekeeping, the avoidance of obstructions to corridors and fire doors and the elimination of ignition sources.

The HSE has developed a test, described in HS(G) 64 (HSE, 1991) and referred to as the HSE Test, which may be used to assess the need for particular forms of fire protection. Details of the test are given by Wharton (1990). The test characterizes a material in terms of (1) the maximum rate of vent temperature rise and (2) the total smoke evolution. For each of these two features the material is placed in one of two hazard categories according to the following scheme:

Category	*Temperature rise* (°C/min)	*Smoke* (m3 ODml)
HIGH	≥700	≥400
NORMAL	<700	<400

[a] OD, optical density – see Wharton (1990).

In some cases it may be a condition of a fire certificate under the FPA (1971) that certain precautions be taken for the storage of a HIGH fire hazard material. In any event it is desirable that a HIGH fire hazard material should be stored in a separate area, either in a separate building, a single storey extension of the main building or in the open air. Where it is not reasonably practicable to store such a material elsewhere than in the main building, it should be stored in an area separated from the rest of the building by a 30 min fire partition. A HIGH fire hazard material should not be stored in a basement or below an occupied floor. Exceptions to this are given in HS(G) 64 such as cases where the quantities are small or the risk is reduced by the type of packaging used or by some combination of spacing and active fire protection.

The problem of fire protection in warehouses is complex. The discussion of the problem, in relation to automated high bay warehouses, by the FPA (1970/9) outlines some of the difficulties.

Arson is a potential problem in warehouses. Guidance from the FPA also includes a treatment of the prevention and control of arson (1992 AR2).

22.28.10 Hazard assessment

Substances stored in warehouses may be hazardous by virtue of their being combustible, flammable, explosive, toxic, corrosive, unstable, reactive with air and/or water, pyrophoric or liable to spontaneous combustion or oxidizing.

There should be a system for the identification of the hazards. A checklist approach may in large part fulfil this function.

A hazard assessment should be performed, broadly on the lines of those made for process plant, but allowing for the characteristic features of warehouses. Initiating events may be associated with: liquid spillage due to leaks or the opening of valves; spillages of solid materials due to damage to packages or to repackaging operations; dust clouds; or small fires. Scenarios of escalation may include a major fire, a series of explosions, a release of toxic gases and vapour within the warehouse or beyond, a large smoke cloud (possible highly toxic) or the overflow of large quantities of contaminated fire water.

22.28.11 Emergency planning

There should be an emergency plan for the warehouse, adapting the basic principles described in Chapter 24 to warehouse conditions. The plan should be suited to the level of the assessed risk and should be developed in consultation with the local emergency services. Personnel should be trained in the plan and in their own role in it, and exercises should be conducted.

22.29 Warehouses: Particular Chemicals Storage

There are certain chemicals which are stored in warehouses that merit particular consideration.

22.29.1 Sodium chlorate

Sodium chlorate is a crystalline solid which is relatively stable and is a strong oxidant. It has a melting point of 248°C and starts to decompose at 265°C with the evolution of oxygen.

Guidance on the storage of sodium chlorate is given in CS 3 *Storage and Handling of Sodium Chlorate and Other Similar Strong Oxidants* (HSE, 1985). This guidance also applies to the several other strong oxidants listed.

There have been several warehouse fires, two of which are described below, in which the involvement of sodium chlorate has resulted in violent explosions.

One hazard of sodium chlorate is that it may become involved in a fire and explode, as just described. Another is that it may become mixed with a readily oxidizable material, such as a fuel. Such a mixture can be ignited by relatively mild stimuli and can burn with explosive violence.

Sodium chlorate should be stored in a secure and separate area. It should be segregated from combustible materials and contaminants should be excluded. Control should be exercised over ignition sources and measures should be taken to prevent the material becoming involved in a fire.

Storage for sodium chlorate may be in the open on a concrete pad, with or without a roof, but should preferably be fully enclosed. Any structure should be built of non-combustible materials and the floor should be smooth, impervious and non-carbonaceous. CS 3 gives maximum stack sizes and minimum separation distances for the storage of sodium chlorate.

Packaging of sodium chlorate is preferably in metal drums with a plastic liner. International agreements on transport also authorize the use of certain soft packaging materials such as flexible intermediate bulk containers.

Wooden pallets should not be used for the routine handling of sodium chlorate as they are liable to become impregnated with it, thus creating a fuel–oxidant mixture. CS 3 advises, however, that where wooden pallets do form an integral part of an International Maritime Organization (IMO) Code approved package and the wood is new, they may be allowed for one-off storage.

In view of the fact that the fires in the two warehouse incidents described in Section 22.30.7 were caused by outsiders, security assumes particular importance in the storage of sodium chlorate.

22.29.2 Organic peroxides

Organic peroxides are highly reactive and thermally unstable substances which undergo self-accelerating decomposition. They have oxidizing properties and some are also toxic.

Guidance on the storage of organic peroxides is given in CS 21 Storage and Handling of Organic Peroxides (HSE, 1991).

In the pure state some organic peroxides detonate. For commercial use organic peroxides are desensitized, but even so they are capable of runaway decomposition. Such decomposition may be caused by heating or contamination.

The self-accelerating decomposition temperature (SADT) of an organic peroxide is determined by test. The SADT tends to decrease with package size. A control temperature is specified which is the maximum storage temperature, and an emergency temperature at which emergency procedures should be implemented. The relationships between these two temperatures and the SADT are given in CS 3. Another aspect of temperature control is that in some cases an organic peroxide can separate out of solution if cooled, resulting in a concentrated peroxide which may be shock sensitive.

Organic peroxides should be stored in the original containers in a dedicated storage and segregated from other materials. They should be maintained within the specified temperature limits. Contaminants should be excluded.

Further detailed guidance on the storage of organic peroxides is given in CS 3. They are classified into four flammability types, Types 1–4. A distinction is made between storages up to 150 kg and above 150 kg. Minimum separation distances are given. A list is given of packaged organic peroxides by flammability type.

22.29.3 Ammonium nitrate

Ammonium nitrate (AN) is a crystalline solid with a melting point of 170°C which decomposes above 210°C. Most of the commercial material stored is some form of mixture.

Guidance on the storage of AN is given in CS 18 *Storage and Handling of Ammonium Nitrate* (HSE, 1986).

AN is an oxidizing agent. It is not itself combustible, but it can assist the combustion of other materials, even if air is excluded. It is insensitive to the friction and impact of normal handling, but it can be detonated under conditions of heat and confinement or by severe shock. The probability of explosion is much increased if the AN is mixed with organic matter. In a fire, molten AN may form and flow into areas, such as drains, where it becomes confined and/or contaminated, and it may then explode. Furthermore, when heated in a fire, AN gives off toxic fumes, mainly oxides of nitrogen.

The main requirements in the storage of AN are to avoid heating or involvement in a fire, serious confinement and contamination.

CS 18 makes a distinction between AN and AN fertilizers with $<28\%$ nitrogen and those with $>28\%$ nitrogen. It deals mainly with the latter.

Storage of AN with $>28\%$ nitrogen should be in a dedicated building constructed in materials which are not readily combustible and with good ventilation or in the open on a concrete pad. Measures should be taken to avoid the hazard of molten AN becoming confined or contaminated, particularly in drains.

AN in storage should be segregated from other materials. The storage should be located away from potential sources of heat, fire or explosion, including combustible and flammable materials. CS 18 gives maximum stack sizes and minimum separation distances.

Packaging of ammonium nitrate is typically in 50 kg bags of material impermeable to oil or water. Paper packaging should not be used. The bags should preferably be palletized. If wooden pallets are used, they should be uncontaminated.

With regard to AN fertilizers with $<28\%$N, whilst most are not combustible, a few are capable of self-sustaining decomposition with strong evolution of toxic fumes. These are known as 'cigar burners'.

AN storage should be provided with good security. CS 18 states that access should be prevented not only of unauthorized persons but also of animals. Whilst it does not elaborate, the point is presumably that an animal may not only damage packaging but may leave behind organic material.

22.30 Storage Case Histories

22.30.1 Oil storage

In the storage of petroleum products, there have been numerous cases of tank overpressure or vacuum collapse and of fire, and some cases of release from tanks.

A review of the failure of storage tanks containing oil and similar products has been given by Wilkinson (1991 SRD R530). He divides the incidents into mechanical and brittle fracture failures and failures following an explosion or bund fire.

On 30 August 1983, a fire started on the floating roof of an oil storage tank at a refinery at Milford Haven, Wales (Case History A106). The tank contained some 47,000 ton of light crude oils. There were fine cracks in the floating roof through which oil had seeped out. It is believed to have been ignited by hot carbon particles from the flare. The fire was massive, with three boilovers of burning oil. It was not extinguished until 2 days later.

On 2 January 1988, at Floreffe, Pennsylvania, a storage tank containing diesel oil suffered a sudden collapse (Case History A120). The tank split vertically and the force of the oil spurting out moved the tank 100 ft off its foundations. The tank cracked, collapsed and crumpled. A proportion of the oil flowed over the bund and entered the waterways. The tank had been reassembled after removal from another site and the failure occurred on its first filling after reassembly.

22.30.2 LPG storage

A review of LPG storage incidents has been given by Davenport (1986), who describes incidents at: Port Newark, New Jersey, on 7 July 1951; Feyzin, France, on 4 January 1966; Texas City, Texas, on 30 May 1978; and Mexico City, Mexico, on 19 November 1984. Accounts of these incidents are given in Case Histories A19, A38, A92 and in Appendix 4, respectively.

The Port Newark site had 100×115 m^3 horizontal pressure vessels for propane, in two groups, one of 70 vessels and the other of 30 vessels, separated by a distance of 106 m. A leak of unknown origin occurred in pipework near the vessels in the larger group. Within a few minutes the first vessel burst. Eventually all 70 tanks in the group ruptured with varying degrees of violence. None of the vessels in the smaller group failed.

At Feyzin, there were four 1200 m^3 propane and four 2000 m^3 butane pressure storage spheres. An escape of liquid propane occurred whilst water was being drained from the bottom of one of the propane spheres. The vapour cloud formed was ignited by a vehicle on a nearby road and the vapour cloud fire caused a series of BLEVEs which resulted in 18 deaths and the destruction of five of the spheres.

At both Texas City and Mexico City, the initiating event is believed to have been overpressure of a vessel which was being filled from a pipeline. At Texas City, there were three pressure storage spheres and a number of other pressure vessels. The hypothesis is that the sphere which was overpressured developed a crack and released material which found a source of ignition. It was reported that the vapour cloud fire then changed to a jet flame at the sphere. Within a short time the sphere failed, giving a huge fireball. This was followed by a series of explosions and fires, and the failure of the other two spheres.

The site at Mexico City contained four 1600 m^3 and two 2400 m^3 pressure storage spheres and 48 horizontal cylindrical pressure vessels for storing propane and butane. The leak gave rise to a vapour cloud which ignited at a neighbouring plant and, within a short time, one or possibly two of the spheres ruptured. There followed a series of explosions and fires, which killed some 500 people and destroyed many of the storage vessels.

Another significant incident is that of a 260,000 bbl refrigerated LPG tank at Umm Said, Qatar, on 3 April 1977 (Case History A88). A massive failure occurred and a wave of liquid propane swept over the bunds and inundated the process area of the associated NGL plant before igniting. The NGL plant was completely destroyed.

22.30.3 LNG storage

One of the earliest process industry disasters was the failure on 20 October 1944 of an LNG storage tank at Cleveland, Ohio (Case History A12). The cause of the rupture is believed to have been the use of a low carbon steel which was unsuitable for the low temperatures involved. A vapour cloud of LNG formed and ignited in the plant itself, whilst LNG liquid flowed into storm sewers, where it mixed with air and gave rise to a series of explosions. Some 128 people were killed.

A quite different case is the disaster at Staten Island, New York, in 1973 (Case History A67). Work was being done inside an empty LNG storage tank when flammable residues were ignited. Some 40 people died in the resultant fire.

A rollover incident occurred on 21 August 1971 at the SNAM LNG terminal at La Spezia in Italy (Case History A54). A sudden increase in pressure occurred in the tank, causing a discharge from the tank safety valves and tank vent. The release from the safety valves lasted for 75 min and that from the vent lasted 3 h and 15 min.

22.30.4 Ammonia storage

A review of the failure of ammonia storage failures has been given by Markham (1987b). He presents information on the ammonia concentrations as a function of distance in these incidents and on the physiological effects of ammonia on humans, animals and plants.

On 13 July 1973, a sudden failure occurred on a horizontal ammonia pressure storage vessel at Potchefstroom, South Africa (Case History A65). The cause of the failure was brittle fracture of the dished end. The ammonia spread as a dense gas cloud over the works and to an adjacent township. Eighteen people were killed.

On 16 November 1970, a 40,000 ton refrigerated atmospheric ammonia tank at Blair, Nebraska, was overfilled (Case History A47). The ammonia overflowed and formed a massive dense gas cloud which extended some 9000 ft. The area was sparsely populated and no one was killed.

In 1982, defects were observed on a 20,000 te refrigerated atmospheric ammonia tank at Arzew, Algeria (Martinez *et al.*, 1987). They included tilting, extensive degradation of the tank wall insulation and failures of the anchor bolts. The cause is not known, but two hypotheses were advanced. One is an earthquake – there were earthquakes nearby in 1980 and 1981. The other is frost heave, due to poor drainage, with the resultant accumulation of water in the aeration tubes and hence a reduction in the efficiency of the foundation heating.

On 2 October 1984, a 15,000 ton refrigerated ammonia storage tank at Geismar, Louisiana, suffered a catastrophic failure of the roof-wall weld two-thirds of the way around its circumference (Badame, 1986). There was some release of ammonia which gave a small cloud, but evidently had no serious consequences. The tank had suffered a mild overpressure of some 0.5 psi. The refrigeration compressors were down at the time. The relief valve opened but did not have the capacity to prevent the pressure from increasing. The weld had been subjected over the 17 years of the tank life to some 80,000 cycles and was held to have failed due to low cycle fatigue. It also showed extreme lack of penetration.

Another refrigerated atmospheric ammonia tank failure occurred on 20 March 1989 at Jonova, Lithuania (Case History A124). Some warm ammonia had been charged to the tank and in due course it erupted, causing a sudden increase in pressure. A massive failure occurred between the wall and the bottom of the tank and liquid ammonia rushed out. At the same time the tank was dislodged from its foundations and smashed violently through the containing wall on the far side from the escape, ending up 40 m away. A pool of liquid ammonia formed which in places was 70 cm deep. The ammonia suddenly ignited and the whole plant area was engulfed in flames. A burning conveyor belt transmitted the fire to a store of NPK fertilizer. Seven people were killed.

22.30.5 Pressure storage vessels

In 1986 a pressure storage vessel holding 25 te of carbon dioxide ruptured (Coleman, 1989). The report on the failure concluded that the steel was brittle at its service temperature and that inadequate leg attachments had created high local stress. The metallurgical evidence indicated that the heat treatment had not been properly carried out. There was also doubt whether the steel used in fabrication was the same as that on which the impact tests required had been performed.

22.30.6 Pressure storage vessels: decommissioning

Accounts of the decommissioning of pressure storage vessels also merit mention, even though in these cases no release occurred.

Squire (1991) records the case of an ammonia pressure storage vessel as follows:

> A bullet tank in refrigeration service had been cleverly made by turning a high-pressure distillation column on its side. While possessing considerable strength at ambient temperature, subsequent analysis showed no strength (<2 ft-lb) at 0°C. The bullet was immediately removed from service after identification. Great care was taken during the deinventory so as not to fracture the vessel.

Coleman (1989) describes an investigation into the state of a set of pressure vessels for the storage of carbon dioxide. The investigation was prompted by the carbon dioxide storage vessel failure just described. The company commissioned an investigation of its other carbon dioxide storage vessels, of which there were 24 vessels ranging in age from brand new to 26 years old. The work addressed in particular the risk of brittle fracture, and the methods used included visual examination, replica metallurgy and ultrasonic testing. The result of the investigation was that three vessels were taken out of service because it was found that their dished ends had been overheated during hot forming. Suspect metallurgy led to the withdrawal of a further six vessels, five of which had not only low toughness but also problems such as laminations and inclusions, weld defects and directly attached support brackets. All but one of these vessels were built before 1970, and most dated from before 1965.

22.30.7 Warehouses

On 4 January 1977, a serious fire and explosion destroyed a chemicals warehouse and adjacent whisky warehouse at Braehead and resulted in widespread window and roof damage within a 1 mile radius (Case History A85). Subsequent experimental investigation showed that explosions of this severity can be caused by the involvement of sodium chlorate under intense heat conditions. The warehouse had contained some 67 te of sodium chlorate in steel drums. The fire was started by boys who had built a ‘den’ beside the warehouse and had lit a fire there to warm themselves.

On 25 September 1982, a fire, followed almost immediately by an explosion, occurred in the warehouse of B&R Hauliers at Salford (HSE, 1983b) (see also Case History A85). The warehouse contained some 2000 te of chemicals, including 25 te of sodium chlorate. There was evidence that the original fire had been started outside the building by vandals and also that, earlier, persons had entered the warehouse where various containers were opened and chemicals mixed. The management had been unaware of the guidance issued by the HSE on sodium chlorate.

Another warehouse incident which involved a much smaller amount of sodium chlorate, some 2.45 te, but which nevertheless proved serious enough, occurred on 21 January 1980 at Barking, Essex (HSE, 1980a) (see also Case History A85). A fire started, probably caused by a domestic bar fire, possibly drying wet clothing and spread through packaging materials to involve various chemicals. There were three explosions, probably one was of an LPG cylinder and the other two of sodium chlorate. Nine firemen were injured.

22.31 Storage Risk

22.31.1 Historical record

The risks from the process industries arise from processes, storage and transport. The historical record shows that storage is a major contributor. Storage figures prominently in the case histories given in Appendix 1 and elsewhere in this book. An attempt to quantify the contribution made by storage to the overall risks from the process industries is given below.

22.31.2 Hazard assessment

Another approach to the estimation of the risks from storage is hazard assessment. Two major hazard assessment exercises in which storage figures prominently are the *Canvey Report* and the *Rijnmond Report*, which are described in Appendices 7 and 8, respectively.

An account is given below of hazard assessments of the storage of the principal hazardous substances: LPG, LNG and ammonia.

22.31.3 Storage vs process

Although the quantities of hazardous materials held in storage are much larger than in process, it is usually considered that process is the principal hazard. This view is reflected in the distinction made in the EEC Directive on Major Accident hazards between process and process associated storage on the one hand, and isolated storage on the other.

A study of the relative risks from process and storage has been made by Lees (1983d). He considered the following three principal sets of data:

(1) accidents involving 10 or more deaths;
(2) accidents involving 2 to 9 deaths;
(3) fire losses.

The data used in this study are given in Tables 22.13–22.15. The accidents listed in Table 22.13 were taken from the list given in Appendix 3 of the first edition of the present book. The table shows process and storage as the source of 14 and 9 accidents, respectively, making the latter 39% of the total. Table 22.14 shows the contribution of storage, rising from 13% for accidents involving 2 deaths to 36% for accidents involving 6–9 deaths. Of the fires given in Table 22.15, 195 were in process and 23 in storage. Storage was thus the source of 11% of the fires. However, 72% of the financial loss was attributable to storage.

Lees states:

> What the foregoing data appear to indicate is that the contribution of storage to deaths in multiple fatality accidents in the oil and chemical industries tends to increase with the number of fatalities and for accidents involving 5 or more fatalities to approach a figure of the order of 20–35%. Thus the idea that material in storage presents a much lower risk than that in process is a half-truth and cannot be accepted without qualification. As far as concerns multiple fatality accidents, and in particular large multiple fatality accidents, the contribution of storage is appreciable.

Since this study the accidents at Mexico City and Bhopal have occurred, both of which involved storage.

22.32 LPG Storage Hazard Assessment

Turning now to hazard assessment of storage, treatments fall into three groups: (1) overview, (2) generic study and (3) specific study. A particular form of the second group is the guidance issued by the HSE or industry associations on safety cases.

Table 22.13 *Some major accidents involving 10 or more deaths in the oil and chemical industries (Lees, 1983d) (Courtesy of Elsevier Science Publishers)*

Date	*Location*	*Deaths*	*Process/storage*
1926	St Auban	19	Storage
1928	Hamburg	10	Storage
1939	Zarnesti	c.60	Storage
1944	Cleveland	128	Storage
1944	Denison	10	Storage
1947	Rauma	19	Storage
1950	Poza Rica	22	Process
1959	Ube	11	Process
1960	Kingsport	15	Process
1962	Toledo	10	Process
1965	Louisville	12	Process
1966	Feyzin	18	Storage
	LaSalle	11	Process
1968	GDR	24	Process
1972	Brazil	37	Storage
	Weirton	10	Process
1973	Potchefstroom	18	Storage
1974	Czechoslovakia	14	Process
	Flixborough	28	Process
1975	Beek	14	Process
	Scunthorpe	11	Process
1976	Chalmette	13	Process
1977	Columbia	30	Process

Overviews of the hazard assessment of LPG pressure and refrigerated storage have been given in the *Canvey Reports* (HSE, 1978b, 1981a), and by Rasbash (1979/80) and Lyon, Pyman and Slater (1982). Generic hazard assessments of LPG pressure and refrigerated storage have been described by Considine, Grint and Holden (1982) and of pressure storage by Drysdale and David (1979/80), T.A. Smith (1985), Crossthwaite (1984, 1986) and Clay *et al.* (1988). Guidance on safety cases for LPG has been issued by the LPGA (1989 GN1). Specific hazard assessments of LPG pressure and refrigerated storage are given in the *Canvey Reports*, and of pressure storage by Khan (1990).

The hazard assessments of LPG given in the *Canvey Reports* are described in Appendix 7 and are therefore not considered further at this point.

The hazard assessments by Crossthwaite and Clay *et al.* are part of a generic methodology for the assessment of LPG, and by extension similar flammable materials, developed by the HSE; they are described in Chapter 9.

The studies by Drysdale and David and by Considine Grint and Holden are essentially generic risk assessments, the former dealing mainly with risk to plant personnel and the latter with risk to the public.

22.32.1 Pressurized storage

The classification of initiating events and hazard scenarios for the pressure storage of liquefied gas shown in Table 22.2 is broadly applicable to LPG. For a pressure storage vessel containing LPG principal hazardous events are catastrophic failure of the vessel, a major crack on the vessel,

Table 22.14 *Some lesser accidents involving two to nine deaths in the oil and chemical industries (Lees, 1983d) (Courtesy of Elsevier Science Publishers)*

	No. of deaths per accident				
	2	3	4	5	6–9
Process					
No. of accidents	26	13	9	4	11
Total no. of deaths	52	39	36	20	81
Storage					
No. of accidents	4	3	3	1	5
Total no. of deaths	8	9	12	5	46
Deaths from storage (%)	13	19	25	20	36

a major leak from the associated pipework, release due to overfilling of the vessel, a jet fire and an engulfing fire.

In the hazard assessment made by Drysdale and David (1979/80), the object considered is a 600 te propane pressure storage sphere with, at the four points of the compass, open sea at a distance of 50 m, a chemical plant at 150 m, a main road at 200 m and a loading bay at 50 m. They treat the following events: (1) a crack in the vessel, (2) a small leakage from the pipework and (3) a large leakage from the pipework. They consider the scenarios of a fire at the vessel, leading to a BLEVE, a vapour cloud flash fire and a vapour cloud explosion (VCE).

The authors give fault trees for the estimation of the frequency of: a fire at the sphere due to a small leak and for one due to a large leak; a BLEVE under fire conditions; and for a VCE. Some of the event frequency and probability estimates which they use are shown in Table 22.16, Section A. Many of these estimates are judgement figures and some differ from other literature values.

For ignition they assume the following probabilities for the presence of an ignition source: at the chemical plant, 1.0; at the main road, 0.5; and at the loading bay, 0.05. They further assume that the probability of ignition by the ignition source is 0.5 in each case.

With regard to consequences, these authors make the assumption that all the propane released evaporates. They use the Gaussian passive gas model to estimate the travel distances of the resultant cloud. The principal hazardous outcomes which they consider are a BLEVE and a VCE, the other outcomes being a vapour cloud flash fire and dispersion without ignition.

They assess the risks to the public as very low, but draw attention to the appreciable risk to firefighters from a BLEVE, a risk which was realized at Feyzin.

The object assessed by Considine, Grint and Holden (1982) is one of two 1500 te butane spheres. Two sites are considered, both a 500 m square site with the storage object located at one corner. The urban site is surrounded on all sides by population at 100 m from the site and the remote site by population at a radial distance of 1000 m in all directions. They treat the following scenarios: (1) a catastrophic failure of the vessel (explosive failure), (2) a catastrophic failure (equivalent to a 6 in. nozzle), (3) a fracture of a liquid line, (4) a fracture of a vapour line, (5) overfilling, (6) a serious leak from the pipework and (7) a leak due to a draining or sampling operation.

The authors consider the scenarios shown in Table 22.16, Section B, and give the event frequencies shown in that table.

Their model for ignition at source is as follows:

Release	*Probability of ignition*		
	Immediate	*Delayed*	
		Wind over site	*Wind not over site*
Large instantaneous	0.25	0.25	0.25
1000 te	0.25	0.25	0.1
250 kg/s, 50 kg/s	0.25	0.25	0.1
30 kg/s, 16 kg/s	0.15	0.15	0.05

The probability of ignition of a cloud reaching the edge of the populated area is taken as 0.7 and that of ignition over the populated area as 0.2.

For both for the pressure storage and refrigerated storage cases, Considine, Grint and Holden consider the following scenarios (1) immediate ignition at source, (2) delayed ignition at source, (3) ignition at the edge of the population zone and (4) ignition over the centre of the population zone.

For pressure storage, the immediate ignition at source of an instantaneous release is assumed to give rise to a fireball, and the immediate ignition of a continuous release is assumed to give rise to a jet flame, or torch fire. If ignition is not immediate, the cloud drifts. For an instantaneous release the assumption of complete vaporization is made and the gas dispersion is modelled using the DENZ dense gas dispersion code. The method used for the dispersion of the continuous releases is unclear, but appears to be the Gaussian model. For the three cases of delayed ignition the outcomes are flash fires and VCEs.

The authors assumed that catastrophic explosive failure of one of the spheres would cause failure of the other also. Furthermore, a proportion of torch fires are capable of causing a BLEVE of a sphere. The total frequency of torch fires was assessed as 3×10^{-3}/year and that of BLEVEs as 7.1×10^{-5}/year.

Thus the principal outcomes considered are: an explosive failure, generating missiles and causing failure of the other sphere; a fireball; jet flames; a BLEVE; a vapour cloud fire and a VCE. The authors outline the models used and the associated injury relations.

The risks estimated in this hazard assessment are given in Section 22.32.3.

It will be apparent from this description that different analysts tend to formulate scenarios in somewhat different ways, even where the events considered are similar.

22.32.2 Refrigerated storage

The classification of initiating events and hazard scenarios for the refrigerated storage of liquefied gas shown in Table 22.2 is broadly applicable to LPG.

For a refrigerated storage tank containing LPG the principal hazardous events are catastrophic failure of the tank, explosion in the vapour space of the tank, rollover, a major leak from the associated pipework and release due to overfilling of the tank.

The object assessed by Considine, Grint and Holden (1982) is a single refrigerated atmospheric fixed roof, single-wall storage tank containing butane positioned at the same location as the two pressure storage spheres already described. They treat the following events: (1) catastrophic failure of the tank, (2) rollover, (3) overfilling, (4) a fracture of a liquid line and (5) a leak from the pipework.

The authors consider the scenarios shown in Table 22.16, Section C, and give the event frequencies shown in that table. They use the same ignition model as for the releases from pressure storage.

As for the pressure storage case they consider the four cases of immediate ignition at the source and of delayed ignitions at the source, at the edge of and over the population zone.

For instantaneous release by catastrophic failure of the refrigerated storage tank, Considine, Grint and Holden take into account overtopping of the bund. Immediate ignition of an instantaneous release is assumed to give a pool fire. If ignition is not immediate, vaporization occurs, which the authors estimate using the SPILL code. Immediate ignition of a continuous release is evidently also assumed to result in

Table 22.16 Event frequency/probability estimates given in two LPG hazard assessments (after Drysdale and David 1979/80; Considine, Grint and Holden, 1982)

A Pressure storage sphere: Drysdale and David

	Frequency/probability (per year)
Crack in pipe	10^{-4}/year
Gasket failure	5×10^{-5}/year
Flange failure	4×10^{-5}/year
Valve seating failure	3×10^{-2}/year
Drainage/sampling valve not properly shut	10^{-4}/year
Pipe rupture due to:	
Vehicle impact	10^{-5}/year
Vibration	10^{-2}/year
Corrosion	10^{-4}/year
Repair whilst operating	10^{-4}/year
Excess pressure (blockage)	$10{\sim}^{7}$/year
Fatigue	10^{-4}/year
Creep	10^{-5}/year
Sabotage	2×10^{-3}/year
During filling operation:	
Operator fails to stop filling when correct level is reached	0.1
Operator fails to stop pump quickly enough when release occurs	10^{-2}
Fixed water spray inoperative because:	
Water shut-off	10^{-2}
Activation fails	2×10^{-2}
Water frozen	5×10^{-4}
Pipes completely blocked	10^{-4}
Low main pressure	3×10^{-3}
Sprinkler system damaged	10^{-5}
Fixed water spray system ineffective because:	
Pipes partially blocked	3×10^{-4}
Low mains pressure	2×10^{-3}
Some heads blocked	8×10^{-4}

B Pressure storage: Considine, Grint and Holden

Event	*Frequence*[a]*/probability*	*Flow*[b]
Catastrophic failure of vessel:		
Complete failure	3×10^{-6}/vessel-year	Instantaneous release of 1500, 2250 or 3000 te
Failure equivalent to 6 in. nozzle	7×10^{-6}/vessel-year	15 te/min
Fracture of 6 in. liquid line[b]		1 te, or 1 te + 50 kg/s
Pipework	3×10^{-7}/m-year	
Equivalent failure of fittings	5×10^{-6}/item-year	
Release due to overfilling[c]	10^{-4}/vessel-year	30 kg/s
Fracture of 2 in. vapour line	3×10^{-6}/m-year	1 kg/s
Serious leak from equipment or pipework (1 kg/s):		
6 in. pipework	6×10^{-6}/m-year	
2 in. pipework	6×10^{-5}/m-year	
Flange	3×10^{-4}/flange-year	
Pump seal	5×10^{-3}/seal-year	
Release in course of draining or sampling (1.5 kg/s):		
Release per operation	10^{-4}	
Draining operations	50/year	
Sampling operations	100/year	
Failure to recover during draining	10^{-1}	
Failure to recover during sampling	10^{-2}	

Table 22.16 continued

C Referigerated atmospheric storage: Considine, Grint and Holden[b]

Event	*Frequency*[a]	*Flow*[b]
Catastropic failure of tank	5×10^{-6}/tank-year	Instantaneous release of 1500, 2250 or 3000 te
Rollover[e]	10^{-5}/tank-year	Instantaneous release of 1500, 2250 or 3000 te
Overfilling[d, f], of which:	10^{-5}/tank-year	
With tank failure[e]	10^{-5}tank-/year	Instantaneous release of 1500, 2250 or 3000 te
Without tank failure[e]	9×10^{-5}/year	50 kg/s
Fracture of 6 in. liquid line	As Section B	50 kg/s
Leak from pipework, etc.	As Section B	1 kg/s

[a] Basic frequencies for a single vessel or tank.

[b] The flows given are complex; quantities quoted here are specimen values and in some cases are not sustained for more than 1 minute.

[c] Probability of emergency shut-off failure 0.2

[d] Based on protective system design.

[e] Probability of wall-base failure 0.25; probability of wall-roof failure 0.75.

[f] Probability that operator switches off pump and limits the event to a release into the bund rather than tank failure, 0.9.

a pool fire. The dispersion of releases which are not immediately ignited at source is modelled using the same method as for the pressure storage study. Outcomes of delayed ignition of these releases are pool fires, torch fires, vapour cloud flash fires and VCEs.

Further principal sources of information on the frequency or probability of events, on consequences and on assessed risk for LPG storage are the *Canvey Reports* and the *Rijnmond Report*.

22.32.3 Pressurized vs refrigerated storage

The study conducted by Considine, Grint and Holden was primarily directed at the comparison of the risks arising from the two types of butane storage in the two types of location. The comparative risks assessed by these authors for the specific configurations considered are:

Site	*Storage*	*Individual* ($\times10^{-6}$ year^{-1})	*Societal risk (casualties >N)* ($\times10^{-6}$ year^{-1})			
			>10	>100	>1000	>5000
Urban	Pressurize	102	159	84	76	40
	Refrigerate	35	66	7.1	7.0	1.6
Rural	Pressurize	12	76	76	76	36
	Refrigerate	0.26	2.0	2.0	0.08	–

22.33 LNG Storage Hazard Assessment

Overviews of the hazard assessment of refrigerated LNG storage have been given in the two *Canvey Reports* (HSE, 1978b, 1981a) and the *Rijnmond Report* (Rijnmond Public Authority, 1982) and by Kopecek (1977), R.A. Cox *et al.* (1980), Philipson (1980), Kunreuther and Lathrop (1981), Lyon, Pyman and Slater (1982), Nassopoules (1982), Philipson and Napadensky (1982), Valckenaers (1983), Wicks (1983), D.A. Jones (1985), Valk and Sylvester-Evans (1985), Napier and Roopchand (1986), D.F. Cooper and Chapman (1987) and Navaz (1987). Specific hazard assessments of LNG refrigerated storage are given in the *Canvey Reports* and the *Rijnmond Report* and by Philipson (1980), Dale and Croce (1985), D.A. Jones (1985), Setters, Luck and Pantony (1985), D.F. Cooper and Chapman (1987) and P. Roberts (1990).

The classification of initiating events and hazard scenarios for the refrigerated storage of liquefied gas shown in Table 22.2 is broadly applicable to LNG.

Considering some of the accounts mentioned, the treatment given by Kopecek (1977) is fairly general but includes a somewhat more detailed treatment than is generally found of the following natural events: (1) severe winds and tornadoes, (2) storm waves, tsunamis, (3) earthquakes and (4) meteorites.

R.A. Cox *et al.* (1980) deal with the hazard assessment of terminals rather than storage *per se*. The storage which they considered is a double integrity tank with inner steel and outer concrete walls and an earthen berm. They give for catastrophic failure of the inner tank leading to outer roof collapse and for partial fracture of the outer roof due to overpressure typical frequencies of 2×10^{-6} and 2×10^{-5}/year, respectively. They also give a typical failure frequency of 2×10^{-6}/year for catastrophic failure of a refrigerated ethane storage tank.

The accounts by Nassopoules (1982) and Closner and Wesson (1983) are concerned primarily with tank system designs, the former with a membrane system and the latter with double wall systems. Both give detailed consideration to the scenario of a tank fire in an adjacent tank. Closner and Wesson also consider a release from the inner tank, and earthquakes, missiles and blast.

D.A. Jones (1985) reviews refrigerated LNG storage systems, identifies five basic design concepts and summarizes the hazard assessments performed for installations embodying each of these concepts. Details of the assessments are sparse except for the Canvey studies. He does, however, give the following summary of the overall risks for exemplars of three of the five types of system:

Design	*Individual*	*Societal risk*
1. Single wall tank+low bund	2×10^{-6} 1.8×10^{-6}	9.3×10^{-6} 5.5×10^{-6}
2. Single wall tank+high bund	4×10^{-12} 8.5×10^{-9}	Negligible[a] 9×10^{8}[b]
3. Double integrity tank system	Nil	Nil

[a] No more than two offsite casualties.
[b] Risk for 100–1000 casualties.

The overview of hazard assessment methodology by Napier and Roopchand (1986) quotes the frequency estimates for LNG terminals given by R.A. Cox *et al.* and those of release duration on LNG plants given by H.H. West, Pfenning and Brown (1980). Napier and Roopchand also give information on models for vaporization, heavy gas dispersion, pool fires, flash fires and VCEs.

The account by P. Roberts (1992) refers to a hazard assessment of a double integrity LNG tank with a prestressed concrete outer wall. Failure of the tank roof was considered and the consequences found to be limited, provided the integrity of the tank walls was maintained. An analysis was undertaken to demonstrate the integrity of the outer wall. Consideration was given to the various initiating events such as earthquakes, severe impacts, frost heave, settlement and blast. The risk was assessed as negligibly low.

Further principal sources of information on the frequency or probability of events, on the consequences and on the assessed risk for LNG storage are the Canvey Reports and the Rijnmond Report.

22.34 Ammonia Storage Hazard Assessment

Overviews of the hazard assessment of ammonia pressure and refrigerated storage are given in the *Canvey Reports* (HSE, 1978b, 1981a) and overviews of pressure storage are given in the *Rijnmond Report* and by Resplandy (1967). Guidance on safety cases for ammonia has been issued by the CIA (1989 GN1). Specific hazard assessments of ammonia pressure and refrigerated storage are given in the *Canvey Reports*, of pressure storage in the *Rijnmond Report* and of refrigerated storage by Squire (1991).

The classification of initiating events and hazard scenarios for the pressure and refrigerated storage of toxics shown in Table 22.2 is broadly applicable to ammonia.

The hazard assessments of ammonia storage in the first *Canvey Report* and the *Rijnmond Report* are described in Appendices 7 and 8, but mention may be made here of the scenarios considered in those studies.

For the Fisons ammonia pressure storage sphere the First *Canvey Report* considers for the vessel occurrences of spontaneous failure, engulfment in fire, blast effects and missile impact. Ignition of the thermal insulation on the vessel was identified as a possible scenario, but was quickly discounted. The Shell refrigerated ammonia storage tank system was of the high bund type. For this tank the report considers the scenario of a fire engulfing the bund wall. Apart from this, the report states: ‘The concrete collar ensures that the failure of the main tank cannot create a major hazard. The actual consequence of inner tank failure with the bund intact is virtually zero’. Various events initiating release from pipework associated with the storage were also taken into account. By the time of the Second *Canvey Reports*, both the pressure storage sphere and the refrigerated storage tank were no longer in use.

One of the six objects studied in the *Rijnmond Report* was the UKF ammonia pressure storage sphere. Initiating events considered were catastrophic failure of the vessel, a major crack in the vessel and full bore fracture of the liquid and vapour lines on the vessel.

An account is given by Squire (1991) of measures for enhancing the integrity of a refrigerated ammonia storage tank, which includes reference to a hazard assessment. The site handles a number of toxic substances, but the ammonia tank was assessed as constituting 50% of the total risk. Scenarios considered included catastrophic failure and rollover, or at least thermal overload, of the tank, and release from large pipework.

As indicated, the main sources of information on the frequency or probability of events, on the consequences and on the assessed risk for ammonia storage are the First *Canvey Report* and the *Rijnmond Report*.

22.35 Notation

Section 22.4

A	surface area of pool (m^2)
C	calorific value of liquid (kj/kg)
D	diameter of tank (m)
k_1	constant
Q	heat radiated from the flame envelope (kW)
r	liquid burning rate (m/s)
ρ	density of liquid (kg/m^3)

Section 22.8

Equations 22.8.1 and 22.8.2

A	total wetted surface (ft^2)
F	environmental factor
Q	total heat absorption (BTU/h)

Equations 22.8.3 and 22.8.4

C	net calorific value of liquid in pool (kj/kg)
h	height of flame (m)
I	intensity of heat radiation from the flame envelope (kW/m^2)
L	length of pool (m)
Q	heat emitted by fire (kW)
W	width of pool (m)
ρ	density of liquid (kg/m^3)

Section 22.10

T	absolute temperature of liquid
x	mole fraction of methane
α	coefficient of expansion of liquid with respect to concentration
β	coefficient of expansion of liquid with respect to temperature
ρ	density of liquid

Section 22.11

Equation 22.11.1

R	interface stability parameter
S	concentration of impurity (mass fraction)
T	absolute temperature of liquid
α	coefficient of expansion with respect to temperature
β	coefficient of expansion with respect to concentration

Equation 22.11.2

b	boil-off rate
C_p	specific heat of liquid
g	acceleration due to gravity
H_v	latent heat of vaporization of methane
k	thermal conductivity of liquid
T_n	absolute temperature of liquid in top or nth cell
T_s	absolute saturation temperature of methane in LNG
μ	viscosity of liquid
ρ	density of liquid
ρ_o	average reference density of liquid

Section 22.21

Subsection 22.21.4

h	height of bund
H	original height of liquid
L	distance between tank wall and bund
R	radius of tank
x, y	dimensions of bund walls

Subsection 22.21.8

g	acceleration due to gravity
h	initial height of liquid in tank
M_f	effective fluid mass
M_s	effective mass of tank shell
R	resistance to flow
t	time
u	velocity of fluid
x	distance
ρ	density of fluid

Section 22.24

Equation 22.24.1 only

η	filling ratio
ρ_p	density of liquid at reference temperature
ρ_w	density of water at 15°C
ϕ	fractional free space

Transport

Contents

So far the loss prevention problems discussed have been principally those of fixed installations. It is necessary, however, to consider also the transport of hazardous materials.

Some aspects of this transport which need to be considered include:

(1) regulatory control;
(2) classification;
(3) packaging and labelling;
(4) transport containers;
(5) hazards;
(6) hazard assessment;
(7) emergency planning.

For each mode of transport, consideration has to be given to:

(1) controls and codes;
(2) hazard scenarios;
(3) design;
(4) operation.

In addition, the features particular to a mode must be considered.

A general account of regulatory controls and of codes applicable to transport internationally and in the United Kingdom has been given in Chapter 3. More detailed information on controls and codes is given in the following sections for road, rail, waterway, pipeline and sea transport.

A major source of information on transport and the associated hazards and risks is *Major Hazard Aspects of the Transport of Dangerous Substances* by the Advisory Committee on Dangerous Substances (ACDS, 1991) (the ACDS *Transport Hazard Report*). This report deals with marine, road and rail transport, and describes the regulatory regimes and transport environments as well as the hazards and risks. It considers in particular four substances which are both representative as well as themselves constituting a large proportion of the movements of dangerous substances: motor spirit, liquefied petroleum gas (LPG), ammonia and chlorine. The report also deals with explosives and ammonium nitrate. The ACDS *Transport Hazard Report* is described in more detail in Appendix 17.

Selected references on the transport of hazardous materials are given in Table 23.1.

Sources of Information on Transportation of Hazardous Materials

Because transportation regulations, requirements and best practices are changing constantly, the following is a list of reference websites which contain up-to-date information on regulatory and non-regulatory information concerning transport of hazardous materials.

International

www.iata.org

The International Air Transport Association (IATA) fosters safe and efficient air transport, including transportation of hazardous materials.

www.imo.org

The International Maritime Organization (IMO) is the United Nations specialized agency responsible for improving maritime safety and reducing pollution from ships.

Corrosion protection, cathodic protection: AGA (1979/29, 1990/67); British Gas (1992 GBE/ECP)

Plastic pipelines: British Gas (1985 Comm. 1281, 1986 BGC/PS/PL2); AGA (1989/12)

Trenchless technology: International Society for Trenchless Technology (1991); ACGIH (1992/86)

Sea

ICS (Appendix 27, 1974); IP (n.d.); NTSB (Appendix 28 *Marine Accident Reports);* OCIMF (Appendix 27); SIGTTO (Appendix 28); Wardle (n.d.); Minorsky (1959); Burgoyne (1965a); Rawson and Tupper (1968–); Comstock and Robertson (1969); Dickinson (1969); Dyer (1969); Advisory Committee on Carriage of Dangerous Goods by Sea (1971); DTI (1971); Lakey (1971, 1973, 1976); Neal (1971); Page and Gardner (1971); Stirling (1972); H.D. Williams (1972, 1973); F.A. Smith (1973); European Petroleum Organisations (1974); Kahn, Talbot and Woodward (1974); Mostert (1974); Boe and Foleide (1975); Chapman (1975); Eisenberg, Lynch and Breeding (1975); Swinbank (1975); Henderson, Srinivansan and Gower (1976); NPC (1976); JJ. Smith (1976); Davison (1977); IMCO (1977); Mullins (1977); Tanker Safety Group (1977); HSE (1978b, 1981a); ICS/OCIMF (1978); van Poelgeest (1978); Snow (1978); Planning Research Corp.

(1979); Bockenhauer (1980); Rutherford (1980); B.White (1980); Gardenier (1981); Gregory (1981); Aldwinkle and Slater (1983); van den Brink (1983); Georgas (1983); Hendrickx and Lannoy (1983); van der Horst and van der Schaaf (1983); Hough (1983); Preston (1983); Colonna (1984, 1986); Fleming (1984); Champness and Jenkins (1985); ACDS (1991); API (1991 RP 1140, 1993 RP 1139); DoT (1992); Janes Information Group (1993b); Paris Memorandum (1993); Donaldson (1994); Gilbert (1994); Hodges (1994); K James (1994); Jenkins (1994); Rawson (1994)

Codes, classification rules, regulation: AW. Clarke (1971a); DTI (1971); Lakey (1971, 1973, 1976); Kvamsdal (1973); R.K. Roberts (1973); International Chamber of Shipping (1974); IMCO (1977); Anon (1984r); R. Pearson (1984); J. Smith (1994)

Cargo compatibility: Flynn and Rossow (1970a,b); Flynn and Morrisette (1977); Morrisstte (1979)

Hazard information systems: DOT, CG (1974a–d); Butt (1975); Myatt (1975); Rappaport (1975); Willis and Cece (1975)

Human factors: Page (1971); Leeper (1973); Hooft, Keith and Porricelli (1975); D. Anderson, Istance and Spencer (1977)

Vessel design: Comstock (1967); Rawson and Tupper (1968); Barnaby (1969); J. Cox (1971); R.K. Roberts (1973, 1983); Hansen and Vedeler (1974); Chapman (1975); N. Jones (1976, 1983); Eyres (1978); HSE (1978b, 1981a); Kitamura, Okumoto and Shibue (1978); Bockenhauer (1982,1985); Clayton and Bishop (1982); Farrell (1982); Huther and Benoit (1983); Jean and Lootvoet (1983); Kinkead (1983, 1985 SRD R324); Betille and Lebreton (1986); Egge and Bockenhauer (1991)

Cargo tanks: Schampel and Steen (1975, 1976); Bockenhauer (1982)

Ship movement: A.G. Robinson (1971); Bovet (1973); Computer Sciences Corp. (1973); P.W.W. Graham (1973); US Coast Guard (1973); McDuff (1974); Eda (1976); J.W. Miller, Schneider and Varchok (1976); NPC (1976); Port of London Authority (1977); HSE (1978b, 1981a); Transportation Systems Centre (1978); ASCE (1980/11, 1983/14, 1986/28, 1989/37); Ligthart (1980); Brok and van der Vet (1984); Mankabady (1982); Technica (1985); ACDS (1991)

Collision, grounding: E. Chen (1975); Kinkead (1978 SRD R91, 1985 SRD R342); Vaughan (1978); Ligthart (1980); Poudret *et al.* (1981); Asadi and Vaughan (1990): ACDS (1991)

Ship–shore transfer: B.White (1980); Armitage (1983); T.B. Morrow *et al.* (1983); Bond (1986 LPB 71); Holtkamp and Keech (1989)

Emergency response, planning: Preston (1983); NFPA (1990 NFPA 1405); ACDS (1991)

Pollution: Stubberud (1973); European Petroleum Organisation (1974); Hann and Jensen (1975); Lakey (1976); Fleming (1984)

Tank purging, cleaning, inerting and flame protection: Page and Gardner (1971); Bang and Birkeland (1973); Boddaert (1975); Harth (1975); Savage (1975); Schampel and Steen (1975, 1976, 1977); Steensland, Askheim and Vossgard (1975); R.P.Wilson and Atallah (1975); Berkel (1982); Astleford, Morrow and Buckingham (1983); Anon. (1984s); Astleford, Bass and Colonna (1985)

Vapour emission, vapour emission control: T.B. Morrow (1980, 1982b, 1985); T.B. Morrow *et al.* (1980); API (1989/17, 1991 RP 1124, 1992/20); Lawrence and Cross (1994)

Fire, explosion: Burgoyne (1965a); Schb'n (1968); Page and Gardner (1971); Victory and Roberts (1971); Wilse (1974); Barreto (1975); Goland and Critelli (1975); Kitagawa (1975); J.H. Lee, Knystautas *et al.* (1975); Rushbrook (1979); Takeda (1988)

Static electricity: H.R. Edwards (1983); J.S. Mills and Oldham (1983); M.R.O. Jones and Bond (1984, 1985)

Fire protection: Page and Gardner (1971); Tanner (1976); Rushbrook (1979); Anon. (1980o, 1982k); Dicker and Ramsey (1983); Dimmer (1986); Wynne (1986); Gebhardt (1989); McKenna (1989); ACDS (1991); NFPA (1993 NFPA 306)

Containers, packing: Savi (1971); Stubberud (1971); Buschmann (1973); Kemler (1975); Swinbank (1975); Department of Trade (1977); UN (1991)

Ports, port storage

McKinley (1968); Meijer (1968); Dickinson (1969); Murdoch (1971); Siccama (1971); Bohlin (1973); J.R. Bradley (1973); Vossenaar (1975); Davison (1977); Hartlich (1977); HSE (1978b, 1980 HS(G) 7, 1981a, 1986 GS 40); ASCE (1980/11, 1983/15, 1986/29, 1989/38); Bryce (1980); Gebhardt (1980, 1989); P. Lewis (1981); NFPA (1990 NFPA 307); ACDS (1991)

Air

Pike (1975a,b); Civil Aviation Authority (CAA) (1977); K Warner (1981); Wilkinson (1989); Janes Information Group (1993a)

Particular chemicals

Ammonia: Heller (1965, 1981); Briley (1967); Inkofer (1969); Olsen (1969); Rohleder (1969, 1971); Medard (1970); Cato and Dobbs (1971); Caserta (1972a); C.C. Hale (1974); CIA (1975/9, PAI); Eisenberg, Lynch and Breeding (1975); Luddeke (1975); O'Driscoll (1975a); Sterling (1977); Fiber (1981); DCMR (1985); Josefson (1987); C.C. Hale and Lichtenberg (1988)

Chlorine: Chlorine Institute (Appendix 28, 1979 Pmphlt 66, 1981 Pmphlt 76, 1982 Pmphlt 60, 1984 Pmphlt 49, 79, 1986 Pmphlt. 1); Danielson (1964); H.P. Nelson (1964); R.L. Mitchell (1971, 1972, 1982); Mathiesen, Bakke and Boe (1973); Westbrook (1974); Eisenberg, Lynch and Breeding (1975); Macdonald (1977); DCMR (1985); Hunter (1988); J.L. Woodward and Silvestro (1988); Canadine and Purdy (1989); Rhyne (1990)

Explosives: P.A. Davies (1990, 1993); ACDS (1991); Sorenson, Carnes and Rogers (1992); Gilbert, Lees and Scilly (1994a–i)

LNG (*see* Table 11.23)

LPG: Faridany and Ffooks (1983); Jäger (1984); Puklavec and Lindenau (1985); Davenport (1988); Anon. (1990c)

Monomers: Butcher and Sharpe (1983); Kurland and Bryant (1987)

Petroleum: J.R. Hughes (1970); Page and Gardner (1971); F.A. Smith (1973); IP (1982 MCSP Pt 6)

Particular chemicals: other chemicals

Carbon dioxide: Brumshagen (1983)

Ethylene: Anon. (1962f); Waddams and Cann (1974); McKay *et al.* (1977); Backhaus and Olschlager (1985)

Lead additive: Associated Octel (1972 Bklt 23/72, 1975 Bklt 22/75)

Liquefied gases: Purdy *et al.* (1988)

Peroxides: Anon. (1984ee)

Polybrominated biphenyls (PBBs): Jacobs, Chou and Tiedje (1976); Kay (1977)

Radioactive materials: Pike (1975a,b); DoE (1975/5); Wilson (1981 LPB 42); Tuler, Kasperson and Ratick (1989)
Self-heating materials: Stone, Williams and Hazlett (1976)
Sulfur: Landry and Hiller (1975)
Vinyl chloride: Dowell (1971); Kogler (1971); O'Mara, Crider and Daniel (1971); Wheeler and Sutherland (1975); Mukerji (1977)

Fire (*see* Tables 16.1 and 16.2)
Spill control (*see also* Table A11.1)
R.L. Mitchell (1971, 1972, 1982); Baier *et al.* (1975); Brugger and Wilder (1975a,b); G.W. Dawson (1975); Pilie *et al.* (1975); Bulloff and Sinclair (1976); Froebe (1976, 1985); Temple *et al.* (1978); Thorne (1978a); Zadic and Himmelman (1978); R.E. Warren (1978); Tenzer *et al.* (1979); R.H. Hall *et al.* (1980); Norman and Dowell (1980); Temple *et al.* (1980); Anon. (1982h); Cumberland (1982); R.M. Hiltz (1982); R.L. Mitchell (1982); Scholz (1982); H.M. Freeman (1984); Neely and Lutz (1985); P.J. Warren (1985); Deckert (1986)
Leak control, sealing: Anon. (1977J); R.L. Mitchell (1982)

Hazard assessment
Buschmann (1968); Crouch (1968); D.L Katz (1968); Lindeijer (1968); McConnaughey (1971); Siccama (1971); McQueen *et al.* (1972); Coates (1973); Fortson *et al.* (1973); French and Richards (1973); Kneebone and Boyle (1973); McKinley (1973); Swalm (1973); Woodward-Lundgren and Associates (1973); Dunn (1974); Dunn and Tullier (1974); A.D. Little (1974); Philipson (1974b); Allan, Brown and Athens (1975); BDM Corp. (1975); Bohlman (1975); Domalski and Tsang (1975); Droppo and Watson (1975); Fedor, Parsons and de Coutinho (1975); Gardenier *et al.* (1975); Humphrey (1975); Philipson and Schaeffer (1975); Simmons (1975); Simmons and Erdmann (1975); Tihansky (1975); Frenkel and Hathaway (1976); USCG (1976a); Stoehr *et al.* (1977); Tanker Safety Group (1977); HSE (1978b,d, 1980c, 1981a); Napier (1979a); Jennsen and Larsen (1980): N.C. Harris (1982); Philipson and Napadensky (1982); Bello, Romano and Dosi (1983); Bergmann and Riegel (1983); van der Horst and van der Schraaf (1983); Lucas, Roe and Waterlow (1983); Windebank (1983); DCMR (1985); N.C. Harris and Roodbol (1985); Moffow (1985); Ackermann (1986); Allsop *et al.* (1986); D.A. Jones and Fearnehough (1986); Medland (1986); Purdy *et al.* (1987, 1988); van Aerde, Stewart and Saccomanno (1988); Cummings and Bradley (1988); Ormsby and Le (1988); J.L Woodward and Silvestro (1988); Abkowitz and Cheng (1989); Andreassen and Gjerstadt (1989); Canadine and Purdy (1989); Guy (1989); Hoftijzer, van der Schaaf and Lupker (1989); Hubert and Pages (1989); V.C. Marshall (1989a, 1991b); Sellers and Bendig (1989, 1990); Birk, Anderson and Coppens (1990); Ramachandran (1990b); Saccomano, Shortreed and Mehta (1990); J.R. Thompson *et al.* (1990); ACDS (1991); Brockhoff (1992); R.T. Hill (1992); Goh, Tan and Ching (1993); Medhekar, Gekler and Bley (1993); Purdy (1993); Romer *et al.* (1993); Song, Black and Dunn (1993); Tenniswood, Sharp and Clark (1993)
Comparative studies – modes of transport: Westbrook (1974); Beattie (1989); Saccamano *et al.* (1989); ACDS (1991)
Comparative studies – alternative routes: Rhyne (1990); ACDS (1991),
Comparative studies – transport vs fixed installations: Haastrup and Brockhoff (1990); Haastrup and Styhr Petersen (1992)
Explosives: Chapman and Holden (1987 SRD R412); P.A. Davies (1990); ACDS (1991)

Transport statistics, transport accident statistics
Hicks *et al.* (1973); Gay (1975); Department of Energy (1977b); Ichniowski (1987); ACDS (1991)
Road: North (1974); DoT (1982, 1985); CSO (1986); A. James (1986); Grime (1987); ACDS (1991); P.A. Davies and Lees (1991b, 1992)
Rail: ACDS (1991); P.A. Davies and Lees (1991a)
Rotorcraft: NTSB (1981)

---

www.unece.org

The United Nations Economic Commission for Europe (UNECE) provides links to all European nations's transportation regulatory websites.

www.cefic.be/Templates/shwStory.asp?NID = 27 &HID = 365

CEFIC is the European Chemical Industry Council (similar to ACC in the United States). The above link is to their Transport and Logistics section.

UK

www.hse.gov.uk

The Health and Safety Executive (HSE) website provides multiple references to transport safety, as well as links to other, related sites at the following link:

www.hse.gov.uk/spf/cdg/links.htm

US

Governmental Links:

www.dot.gov

The United States Department of Transportation (DOT) website provides information similar to the HSEs, specific to the United States. In particular, the following links provide useful information:

www.hazmat.dot.gov

This link provides information on general Hazmat safety, including links to the Research and Special Programs Administration (RSPA), which is responsible for coordinating a national safety programme for the transportation of hazardous materials by air, rail, highway and water.

www.geosbush.com/ctpat.htm

This is a link to the Customs-Trade Partnership against Terrorism (C-TPAT) website. C-TPAT is a joint government-business initiative to build cooperative relationships to strengthen border security.

www.hazmat.dot.gov/gydebook

This is a link to the on-line version of the *DOT Emergency Response Guidebook*, 2000 edition. A revised edition is due out in 2004.

www.fra.dot.gov

The Federal Railroad Administration (FRA) provides information specific to transport by rail in the US.

www.faa.gov/regulations

The Federal Aviation Agency (FAA) governs air traffic in the United States. The regulations section of their website lists both mandatory and non-mandatory guidance.
Non-Governmental Links:

www.transcaer.org/public/home.cfm

TRANSCAER is a voluntary national outreach effort that focuses on assisting communities to prepare for a possible hazardous materials transportation incident.

www.americanchemistry.com

The American Chemistry Council (ACC) represents the leading companies engaged in the business of chemistry. Council members apply the science of chemistry to make innovative products and services that make people's lives better, healthier and safer. The Council is committed to improved environmental, health and safety performance through Responsible Care, common sense advocacy designed to address major public policy issues, and health and environmental research and product testing.

www.chemtrec.org

Chemtrec, sponsored by the ACC provides a 24-h hazardous communications centre for member companies and associates.

www.chemtelinc.com

CHEM-TEL is a 24-h emergency response telecommunications service for industry.

www.umtri.umich.edu

The University of Michigan's Transportation Research Institute conducts research into transportation safety.

www.usroads.com

USRoads provides a compilation of links to commercial sites dealing with transportation issues.

www.aar.com

The American Association of Railroads (AAR) provides information, research and training on the control and response to hazardous materials incidents in transport by rail.

www.trucking.org

The American Trucking Association (ATA) provides information on truck transport in the United States.

Canada

www.tc.gc.ca

Transport Canada provides information in both French and English. It also provides the 2000 edition of the *North American Emergency Response Guidebook* on-line in French, English and Spanish.

www.tc.gc.ca/canutec/en/menu

Canutec provides hazard communications services in Canada similar to Chemtrec in the United States.

Australia

www.aph.gov.au/library/intguide/law/transportlaw.htm
The Australian Parliament provides links to transport law, as well as non-governmental informational links.

Mexico

www.aniq.org.mx/setiq/setiq.htm
SETIQ in Mexico provide similar services as CANUTEC and CHEMTREC provide in Canada and the United States.

23.1 General Considerations

The ability to transport the raw materials to and the products from the plant is very important in determining the viability of a project. This aspect was briefly considered in Chapter 1 in relation to ethylene plant economics.

The type of transport used may greatly affect the storage requirements. A mode of transport which involves larger but infrequent deliveries is, in general, likely to require more storage than one which gives continuous flow. Ship, rail, road and pipeline thus constitute a spectrum of modes of transport ranging from large discrete to continuous deliveries. The associated storage requirements have corresponding economic and safety implications.

In transport as in other aspects of loss prevention, training is of the greatest importance. It is essential that all personnel involved in the transport of chemicals are thoroughly trained in the properties of the chemicals and the associated hazards and in the normal operating and emergency procedures.

23.1.1 Modes of transport

The following modes of transport are used for the movement of hazardous materials:

(1) road;
(2) rail;
(3) waterway;
(4) pipeline;
(5) sea;
(6) air.

23.1.2 Transport movements

For the United Kingdom, information on the movements of hazardous materials is given in *Transport Statistics Great Britain 1991* by the DTp (1992b), which is part of an annual series.

Further data on the movements of hazardous materials by road and rail in the United Kingdom are quoted in the ACDS *Transport Report* and are given below in Sections 23.6 and 23.8, respectively.

For the United States, corresponding information is provided in the annual reports of the NTSB. The NTSB *Annual Report* for 1979 states that there were in that year some 250,000 hazardous materials shipments per day. Reports of accidental releases numbered about 16,000 and there were 19 fatalities and 942 injuries. The breakdown of fatalities by commodity was as follows: gasoline 32.5%, LPG 21.7%, chlorine 9.6%, corrosive liquids 9.6%, anhydrous ammonia 6%, aviation fuel 2.4%, compressed gas, 2.4% and others 15.6%. The *Annual Report* for 1991 quotes the same number of daily shipments of hazardous materials.

23.1.3 Transport conditions

The main sets of conditions for gas or liquid transport are:

(1) liquid at atmospheric pressure and temperature (atmospheric transport);
(2) liquefied gas under pressure and at atmospheric temperature (pressure transport);
(3) liquefied gas at atmospheric pressure and at low temperature (fully refrigerated transport);
(4) gas under pressure.

The behaviour of fluids released from such conditions has been described in Chapters 15 and 22. An account related specifically to transport is given by V.C. Marshall (1991b).

23.1.4 Transport hazards

The transport of hazardous materials may present a hazard to (1) the transporter, (2) the crew or (3) the public. The relative importance of these varies between the different modes of transport.

The hazards presented by the transport of chemicals are:

(1) fire;
(2) explosion;
(3) toxic release
    (a) conventional toxic substances,
    (b) ultratoxic substances.

As with fixed installations, so with transport, the most serious hazards arise from loss of containment.

Modes of transport such as road, rail, waterway and pipeline can give rise to release of flammable gas or vapour, which may result in a flash fire or a vapour cloud explosion, or of flammable liquid which may lead to a pool fire. Flammable liquid can also spread and then ignite, giving rise to a flowing fire. Jet flames may occur on the containers. The contained material may undergo a boiling liquid expanding vapour explosion (BLEVE) or other form of explosion. In general, a flammable fluid is more likely to give rise to fire than to explosion.

An explosion hazard also exists with substances that are to some degree unstable.

If the material is toxic, release may result in a toxic gas cloud. Toxic or corrosive materials may also spread as liquids.

With waterway and sea transport, the release of vaporizable materials onto the water is liable to give rise to very rapid vaporization, resulting in a large vapour cloud.

Transport accidents are particularly liable to cause pollution, since material spilled is often not recovered, but is dispersed into the environment.

The initiating factor in a transport accident may be (1) the cargo, (2) the transporter or (3) the operations.

The cargo may catch fire, explode or corrode the tank; the transporter may be involved in a crash or derailment or fire; the operations such as charging and discharging may be wrongly executed.

Thus, the events which can give rise to hazards include particularly (1) container failure, (2) accident impact and (3) loading and unloading operations.

Although the attention in transport of hazardous materials by moving vehicles focuses on the injury caused by release from containment, fatalities also occur due to the movement of the vehicles themselves. This should be taken into account also, particularly in comparative studies of different modes of transport, since although the deaths from this cause in any one accident tend to be small in number, they may in total equal or exceed those from the releases.

23.1.5 Size of units

As with fixed installations, so with transport, the question arises as to whether it is safer to handle a given quantity of hazardous material in a few large units or in many smaller ones. In particular, there is a wide range of possibilities with sea transport. The choice made affects not only the size of the ship but also that of the associated storage on land. In general, a small number of large units appears safer in the sense that the product of scale and frequency tends to be less. This is because, with fewer units, it is easier to achieve a more uniformly high standard of design and operation, and the frequency of incidents is less. The scale of the most serious accident, however, is greater. The problem has been considered by the Tanker Safety Group (1977), which has reviewed the historical experience with large crude oil tankers and supertankers.

23.1.6 Multi-use containers

The use of the same container to carry different chemicals is quite normal; it is fairly common practice in road tankers, barges, ships and pipelines. This not only creates potential problems of compatibility between materials carried, but also means that the carrier is less familiar with the substances he is transporting.

23.1.7 Loading and unloading

Many of the hazards associated with transport arise during loading or unloading. This aspect was treated in relation to storage in Chapter 22 and is considered only occasionally in this chapter.

23.2 International Codes

The transport of chemicals is an international activity and international codes assumes a dominant role. These codes govern not only the classification, packaging and labelling of substances, but also the transport containers. There are four main codes which are relevant here and these are now described.

23.2.1 UN Transport Code

A basic code for international transport is provided by the *Recommendations on the Transport of Dangerous Goods* (United Nations, 2001) (the UN *Transport Code*).

Topics dealt with in the code include: (1) classification, including testing; (2) packing; (3) labelling; (4) transport containers, including intermediate bulk containers and tank containers (IBCs) and (5) consignment procedures.

The classification of dangerous goods for transport given in the UN *Transport Code* provides a framework which is followed by other codes. The classification scheme, which is based on classification by class of substance, is shown in Table 23.2.

In addition to this classification, there is for Class 1, explosives, a further categorization by compatibility group. The compatibility groups are A–H, J–L, N and S. The general nature of these compatibility groups is illustrated by the following entries:

Group A	Primary explosive substance.
Group B	Article containing a primary explosive substance and not containing two or more effective protective features.

Dangerous goods of all classes other than Class 1, 2, 5.2, 6.2 and 7 are assigned for packing purposes to one of three groups according to the degree of danger which they represent:

Packing group

I	Great danger.
II	Medium danger.
III	Minor danger.

The *Code* contains a set of specimen hazard warning signs for the labelling of dangerous goods. Further details of the classification, packaging and labelling provisions of the code are given in Section 23.3.

The *Code* gives recommendations for the mechanical design, service equipment and pressure relief arrangements for transport containers, as described in Section 23.4. It also contains recommendations on consignment procedures, including packages and the provision of transport documentation. In addition to the general recommendations of the *Code*, there are special recommendations applicable to each class of substance.

Table 23.2 *UN Transport Code: classification of substances (United Nations, 2001)*

Class 10	**Explosives**
Division 1.1	Substances and articles which have a mass explosion hazard
Division 1.2	Substances and articles which have a projection hazard but not a mass explosion hazard
Division 1.3	Substances and articles which have a fire hazard and either a minor blast hazard or a minor projection hazard or both but not a mass explosion hazard
Division 1.4	Substances and articles which present no significant hazard
Division 1.5	Very insensitive substances which have a mass explosion hazard
Division 1.6	Extremely insensitive articles which do not have a mass explosion hazard
Class 2	**Gases**
Division 2.1	Flammable gases
Division 2.2	Non-flammable, non-toxic gases
Division 2.3	Toxic gases
Class 3	**Flammable liquids**
Class 4	**Flammable solids; substances liable to spontaneous combustion; substances which in contact with water emit flammable gases**
Division 4.1	Flammable solids
Division 4.2	Substances liable to spontaneous combustion
Division 4.3	Substances which in contact with water emit flammable gases
Class 5	**Oxidizing substances; organic peroxides**
Division 5.1	Oxidizing substances
Division 5.2	Organic peroxides
Class 6	**Poisonous (toxic) and infectious substances**
Division 6.1	Poisonous (toxic) substances
Division 6.2	Infectious substances
Class 7	**Radioactive materials**
Class 8	**Corrosive substances**
Class 9	**Miscellaneous dangerous substances**

23.2.2 European Road Carriage Agreement (ADR)

The European code for international transport is the *European Agreement Concerning the International Carriage of Dangerous Goods by Road* (ADR) issued by the DTp (2003a).

The document contains the Articles of the Agreement and two Annexes, Annex A and Annex B. Annex A, Provisions Concerning Dangerous Substances and Articles, has three parts: Part I on general provisions, Part II on special provisions for substances in the various Classes, and Part III a set of appendices. These appendices cover the following topics: A1, stability and safety conditions relating to explosive substances and articles, flammable solids and organic peroxides; A2, containers for Class 2 substances, including aluminium alloy containers and containers for fully refrigerated gases; A3, tests for substances; A5, general packing conditions; A6, intermediate bulk containers; A7, Class 7, radioactive materials; A9, symbols and labels. A4 and A8 are not used.

Annex B, Provisions Concerning Transport Equipment and Transport Operations, has two parts and a set of appendices; Part I dealing with general provisions and Part II with special provisions for the various Classes whilst the appendices cover the following topics: B1, containers including fixed and demountable tanks, tank containers and reinforced plastic tanks; B2, electrical equipment; B3 certificates of approval for vehicles; B5 list of substances; and B6, certificate of driver's training. B4 is not used.

The provisions for classification, packaging and labelling provisions are considered further in Section 23.3 and those for transport containers are discussed in Section 23.4.

23.2.3 International Rail Carriage Regulations (RID)

There have for some time been a set of Uniform Rules concerning the Contract for International Carriage of Goods by Rail (CIM) and there is a Convention concerning International Carriage by Rail (COTIF) of 1980. The international code for rail transport is the *Regulations Concerning the International Carriage of Dangerous Goods by Rail* (RID) issued by the DTp (2003b); it constitutes Annex 1 of the Uniform Rules.

The document, which is itself an annex, contains extracts from the Articles of the Convention and from the Uniform Rules, which are Appendix B of the Convention. It has three parts: Part I on general regulations, Part II on special regulations for substances in the various Classes, and Part III a set of appendices. These appendices cover the following topics: I, stability and safety conditions relating to explosive substances and articles, flammable solids and organic peroxides; II, containers for Class 2 substances, including aluminium alloy containers and containers for fully refrigerated gases; III, tests for substances; V, general packing requirements; VI, intermediate bulk containers; VII, Class 7, radioactive materials; DC, symbols and labels; X, construction, testing and use of tank containers; and XI, construction, testing and use of tank wagons. IV is not used.

The provisions for classification, packaging and labelling provisions are considered further in Section 23.3 and those for transport containers are discussed in Section 23.5.

23.2.4 International Maritime Dangerous Goods (IMDG) Code

For sea transport, the relevant code is the *International Maritime Dangerous Goods Code (IMDG Code)* issued by the IMO (2002 IMO-200). The classification for dangerous goods for maritime transport given in the *IMDG Code* is again virtually the same as that of ADR, as shown in Table 23.2.

23.3 Classification, Packaging and Labelling

There is a large international trade in dangerous goods and it is particularly important that the arrangements for the classification, packaging and labelling of these substances be accepted internationally.

23.3.1 Regulatory controls and codes

As already described, the international codes governing the transport of dangerous goods, namely the UN *Transport Code*, ADR, RID and the *IMDG Code*, give detailed recommendations on classification, packaging and labelling.

Classification, packaging and labelling is the subject of EC Directive 67/548 (the Dangerous Substances Directive). In the United Kingdom, this directive was implemented for the road transport of hazardous materials by the Classification, Packaging and Labelling Regulations (CPL) 1984. The associated Approved Codes of Practice (ACOPs) are COP 19 *Classification and Labelling of Substances Dangerous for Supply and/or for Conveyance by Road 1984*, Revision 1 (HSE, 1990) and COP 40 *Packaging of Dangerous Substances for Conveyance by Road 1984*, Revision 2 (HSE, 1990). Guidance is given in HS(R) 22 *A Guide to the Classification, Packaging and Labelling Regulations 1984* (HSE, 1985). Also relevant is COP 33 *Transport of Compressed Gases in Tube Trailers and Tube Containers* (HSE, 1989).

The Chemicals (Hazard Information and Packaging) Regulations 1993 (CHIP) now supersede the CPL Regulations.

These regulations are complemented by the Road Traffic (Carriage of Dangerous Substances in Packages etc.) Regulations 1992 and the Road Traffic (Carriage of Dangerous Substances in Road Tankers and Tank Containers) Regulations 1992, which are described in Section 23.5.

Guidance on cargo transport units (CTUs) for marine transport is given in HS(G) 78 *Container Packing* (HSE, 1992).

For explosives there are the Classification and Labelling of Explosives Regulations 1983 (CLER) and the Packaging of Explosives for Carriage Regulations 1991.

23.3.2 UN Transport Code

The classification scheme of the UN *Transport Code* has been given in outline in Table 23.2. The *Code* gives guidance on assignment to a class, or a division within a class. For some classes of substances, notably explosives and organic peroxides, there are specified tests. These tests, and the flow charts for assignment, are described in Chapter 8.

For Class 3, Flammable liquids, there is a hazard grouping based on boiling point and flashpoint. This is

Packing group	*Flashpoint (closed cup)* (°C)	*Initial boiling point* (°C)
I	–	<35
II	<23	>35
III	>23, <60.5	>35

For Class 6, Poisonous (toxic) substances, there are grouping criteria for solids and liquids based on oral toxicity and dermal toxicity, both characterized by an LD_{50} value (the lethal dose at the 50% level) and for dusts and mists by an LC_{50} value (the lethal concentration at the 50% level) for a 1 h exposure. For toxic vapours, the grouping criteria are shown in Figure 23.1. The *Code* gives a list of the dangerous goods most commonly carried. It also gives guidance on the assignment of a substance which is not in the list and which presents more than one hazard. The guidance is in the form of (1) a list of classes and divisions in the order of precedence and (2) a precedence table.

The UN *Transport Code* gives detailed definitions of forms of packaging and specifies requirements for testing and marking.

23.3.3 European Road Carriage Agreement (ADR)

The classification for dangerous goods for transport by road given in the ADR is shown in Table 23.3. The classification is similar, but not identical, to that of the UN *Transport Code.*

A special feature of ADR is that the classes are either restrictive or non-restrictive. The restrictive classes are Classes 1, 2, 6.2 and 7. For a restrictive class, only the goods specifically listed may be carried and goods not listed are prohibited. For a non-restrictive class, some goods, although not specifically listed by name, may fall under one of the generic descriptions in the class, and are then carried according to the provisions which apply to that group, whilst other goods which display the dangerous properties of the class, but are not listed either specifically or generically, may be carried free of ADR. However, there are for non-restrictive classes some goods which are prohibited.

ADR gives a further classification for Class 2, Gases, which is particularly relevant here. This is shown in Table 23.4.

23.3.4 International Rail Carriage Regulations (RID)

The classification for dangerous goods for transport by rail given in RID is the same as that shown Table 23.3, with the slight modification given in the footnote to that table.

23.3.5 CHIP Regulations 2002

Like the CPL Regulations which they replace, the (CHIP) Regulations 2002 deal with classification, packaging and labelling of chemicals.

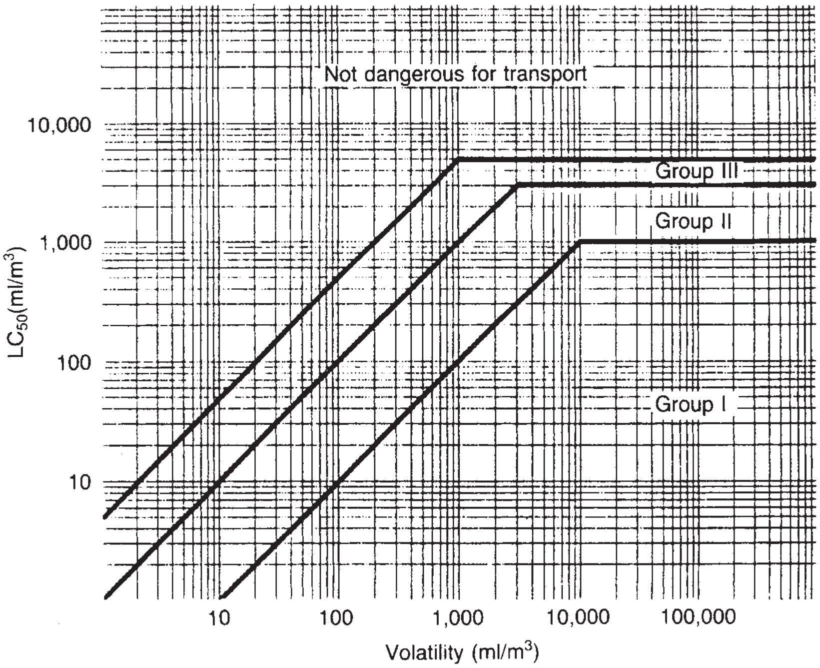

Figure 23.1 *UN Transport Code: grouping criteria for toxic vapours (United Nations, 1993; reproduced by permission)*

Table 23.3 *European Agreement for Road Transport (ADR): classification of substances*[a] *(Department of Transport, 2003a)*

Class 1	Explosive substances and articles
Class 2	Gas: compressed, liquefied or dissolved under pressure
Class 3	Flammable liquids
Class 4.1	Flammable solids
Class 4.2	Substances liable to spontaneous combustion
Class 4.3	Substances which give off flammable gases on contact with water
Class 5.1	Oxidizing substances
Class 5.2	Organic peroxides
Class 6.1	Toxic substances
Class 6.2	Repugnant substances and substances liable to cause infection
Class 7	Radioactive material
Class 8	Corrosive substances
Class 9	Miscellaneous dangerous substances and articles

[a] The classification given in the RID is identical with the above, except that very slightly different wording is used for Classes 4.3 (Substances which, in contact with water, emit flammable gases) and 6.2 (Infectious and repugnant substances).

There are three HSE documents issued in support of these regulations. Guidance is given in L38 *Approved Guide to the Classification and Labelling of Substances and Preparations Dangerous for Supply* (the *Approved Classification and Labelling Guide*) (2002). L37 (2002) gives guidance on materials safety data sheets. The third document is the *Approved Supply List*, described below.

The CHIP Regulations cover both supply and conveyance. The supply provisions are designed to provide protection to those who handle dangerous substances, the conveyance provisions protection to those concerned with their conveyance.

The regulations distinguish between substances and preparations, the latter being mixtures of substances. They also distinguish in classification between supply and conveyance. Regulation 4 defines two approved lists. The *Approved Supply List* is given in *Information Approved for the Classification and Labelling of Substances and Preparations for Supply* and the *Approved Carriage List* is given in *Information Approved for the Classification and Labelling of Substances and Preparations for Carriage.*

Regulation 5 requires that a substance or preparation dangerous for supply should not be supplied unless it meets the requirements of this regulation, which include that it is in the *Approved Supply List*, that it is a new substance classified in accordance with the Notification of New Substances Regulations 1982, or that it is classified in accordance with Schedule 1 of the CHIP regulations. Regulation 6 requires that the supplier should provide a safety data sheet. Regulation 7 requires that a substance or preparation dangerous for carriage should not be carried unless it has been classified by reference to the *Approved Carriage List* in the manner specified in the regulation.

Regulation 8 gives requirements for the packaging of substances or preparations dangerous for carriage or supply.

***Table 23.4** European Agreement for Road Transport (ADR): classification of Class 2, Gases (Department of Transport, 1993a)*

A Subclasses of Class 2[a]

A	Compressed gases having a critical temperature below −10°C
B	Liquefied gases having a critical temperature of −10°C or above
	(a) Liquefied gases having a critical temperature of 70°C or above
	(b) Liquefied gases having a critical temperature of −10°C or above, but below 70°C
C	Deeply refrigerated liquefied gases
D	Gases dissolved under pressure
E	Aerosol dispensers and non-refillable containers of gas under pressure
F	Gases subject to special requirements
G	Empty receptacles and empty tanks

B First subdivision, mainly relating to pure/gas or mixture

	Pure and technically pure gases	*Mixtures of gases*
A	1°	2°
B(a)	3°	4°
B(b)	5°	6°
C	7°	8°
D	9°	
Also		
E	10° aerosol dispensers; 11° non-refillable containers	
F	12° various mixtures of gases; 13° test gases	
G	14° empty receptacles and empty tanks, uncleaned	

C Second subdivision, relating to chemical properties

(a)	Non-flammable
(at)	Non-flammable, toxic
(b)	Flammable
(bt)	Flammable, toxic
(c)	Chemically unstable
(ct)	Chemically unstable, toxic

[a] These subdivisions are used in a hierarchy which may be illustrated by that of subclass A which is ordered: A; 1°; (a); (a t); (b); (b t); (c t); 2°; etc.

These requirements cover three main points. The package should be designed, constructed, maintained and closed so as to prevent the leakage of the contents when the overall package is subjected to normal handling. Any packaging material likely to come into contact with the substance should be compatible with it. The closure on a container which is repeatedly reused should be designed so that even after repeated use it will not leak. These requirements are essentially similar to those of the CPL Regulations.

Regulation 9 gives requirements for the labelling of substances and preparations dangerous for supply. These include the name and address of the supplier, information about the substance, symbols and risk and safety phrases. Regulation 10 gives requirements for the labelling of substances and preparations dangerous for carriage. These include the name and address of the supplier and the hazard warning sign.

Schedule 1 of the regulations gives three bases of classification: (1) physico-chemical properties, (2) health effects, and (3) environmental effects. Classification on the basis of physico-chemical properties is made using the headings: (1) explosive, (2) oxidizing, (3) extremely flammable, (4) highly flammable and (5) flammable. Classification on the basis of health effects is made under the headings: (1) very toxic, (2) toxic, (3) harmful, (4) corrosive, (5) irritant, (6) carcinogenic, (7) mutagenic and (8) teratogenic.

Schedule 2 gives the indications and symbols for substances and preparations dangerous for supply, and Schedule 3 the hazard warning signs for substances and preparation dangerous for carriage. Schedule 4 gives classification provisions for preparations dangerous for supply and Schedule 5 gives those for pesticides. Schedule 6 lists the headings under which particulars are to be provided in safety data sheets.

L38 gives guidance particularly on: (1) the classification by physico-chemical properties, health effects and environmental effects; and (2) labelling and risk and safety phrases. For the classification of substances, the data necessary are essentially those of the base set given in the Notification of New Substances Regulations 1982. The guide refers particularly to the test methods of EC Directive 84/449/EEC.

With regard to labelling, L38 gives two separate sets of formal phrases: the risk phrases and the safety phrases. A risk phrase which figures prominently in occupational hygiene is R45: May cause cancer.

Another risk phrase which occurs frequently in L38 is R48: Danger of serious damage to health by prolonged exposure. L38 gives detailed guidance on when R48 should be used. Other typical risk phrases are R23: Toxic by inhalation, and R35: Causes severe burns. Some typical safety phrases are S15: Keep away from heat, S22: Do not breathe dust, and S29: Do not empty into drains.

Detailed guidance on packaging is given in COP 40, an ACOP to the CPL Regulations. Aspects covered include: normal handling, dropping, stacking, abrasion and vibration of packaging and weather effects on packaging; packaging of liquids and venting of packages; and repeated use of packages.

A major feature of this code is the packaging of organic peroxides. It gives in Appendix A1, a list of such peroxides, in Appendix A2, a list of special provisions for these peroxides and in Appendix A3, a list of recommended packagings. It also gives in Appendix B, criteria for the packaging of organic peroxides not listed in Appendix A, utilizing the concept of the self-accelerating decomposition temperature.

As with classification, so with labelling, a distinction is made between supply and conveyance. In general, for supply there should be labelling on each discrete layer of packaging, while for conveyance, labelling is required only on the other layer.

For supply, the particulars to be shown are:

(1) designation of the substance;
(2) indication(s) of the general nature of risk and the
(3) corresponding symbols;
(4) risk phrases;
(5) safety phrases;
(6) name and address of the manufacturer, importer, wholesaler or other supplier.

For conveyance, the particulars are:

(1) designation of the substance;
(2) substance identification number;
(3) hazard warning sign;
(4) additional information, covering such matters as
    (a) nature of the dangers,
    (b) advice on first aid,
    (c) action in case of fire,
    (d) measures to deal with any spillage,
    (e) instructions about any safety equipment;
(5) name and address or telephone number of consignor or expert from whom advice on the hazard is available.

The CHIP Regulations are designed to be consistent with the international codes such as the UN *Transport Code*, ADR, RID and the *IMDG Code*.

23.3.6 Hazard warning symbols and signs

The hazard warning labels, that is, signs and symbols, are international. The UN *Transport Code* gives specimen labels. Hazard warning signs for supply (brown) and symbols for carriage (multi-coloured) are given in the CHIP Regulation 2002. Hazard warning panels for road tankers are given in the Road Traffic (Carriage of Dangerous Substances in Road Tankers and Tank Containers) Regulations 1992.

23.3.7 HAZCHEM system

The CIA operates the HAZCHEM scheme described in *Hazard Identification – A Voluntary Scheme for the Marking of Tank Vehicles and Dangerous Substances* (1975/X).

Top panel of the HAZCHEM shows the HAZCHEM code number (2PE), the UN classification number (1230), the emergency telephone number and the hazard warning sign.

The HAZCHEM guide gives information under the following letter code: A, emergency action code; B, substance identification number; C, hazard warning sign; D, specialist advice; and E, evacuation. The first character in the code number refers to A, the emergency action code. The numbers 1, 2, 3 and 4 refer to the firefighting methods to be used. The first letter P, R, S, T or W, X, Y, Z, refers to the spillage action to be taken. The second letter E is added where there is need to consider evacuation of the area.

There is also a European Transport Emergency Card, or TREMCARD, system operated by the European Council of the Chemical Manufacturers Federation (CEFIC) (CIA/1).

23.3.8 US arrangements

For the United States, accounts of controls on classification, packaging and labelling of dangerous substances are given in the *NFPA Handbook* (2003) and by Bierlein (1984). The regulating authority is the DOT.

NFPA 704 provides a labelling system based on the classification system given in that code. The National Fire Protection Association (NFPA) diamond is shown in Figure 23.2.

The DOT has a placard and labelling system. The system uses the United Nations (UN) hazard diamonds. Details of the system are given in the *NFPA Handbook*.

23.4 Transport Containers

23.4.1 Regulatory controls and codes

The containers used for transport, whether fixed on a vehicle or multi-modal, are the subject of detailed requirements in the UN *Transport Code*, ADR, RID and the *IMDG Code*. The general nature of the requirements for transport containers may be illustrated by considering those given in the UN *Transport Code* and in the ADR for road transport.

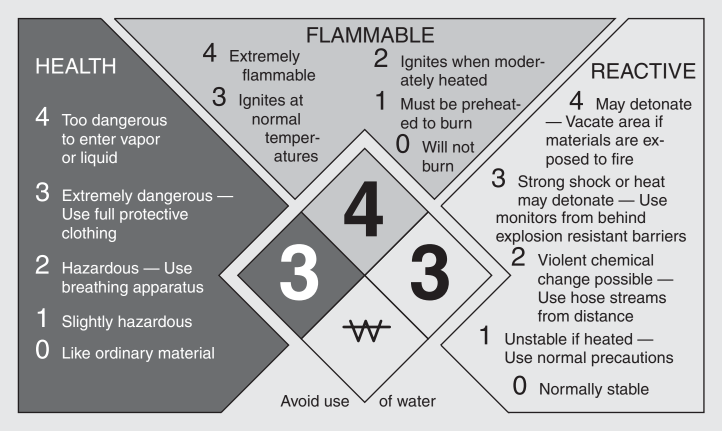

Figure 23.2 *NFPA 704 diamond (National Fire Protection Association, 2001), (Copyright © 2001 National Fire Protection Association Quincy, MA 02269. This warning system is intended to be interpreted and applied only by properly trained individuals to identify fire, health and reactivity hazards of chemicals. The user is referred to a certain limited number of chemicals with recommended classifications in NFPA 49 and NFPA 325M which would be used as a guideline only. Whether the chemicals are classified by the NFPA or not, anyone using the 704 system to classify chemicals does so at their own risk.)*

23.4.2 Types of container

The types of container used in the transport of dangerous goods include: (1) tanks fixed to road vehicles and rail cars; (2) multi-modal tank containers, which can be transported by several different modes of transport and (3) IBCs. There are also demountable tanks, which differ from tank containers in that they are not intended to be loaded and unloaded whilst fully charged.

The UN *Transport Code* defines a tank container as a tank having a capacity of not less than 0.45 m^3 whose shell is fitted with the items of service equipment and structural equipment necessary for the transport of dangerous liquids.

It defines an IBC as a rigid, semi-rigid or flexible packaging having a capacity of not more than 3 m^3 which is designed for mechanical handling and is resistant to the stresses produced in handling and transport, as determined by tests. Excluded from this definition are the forms of packaging dealt with in Chapter 9 of the code, which covers items having a mass of less than 400 kg or a capacity of less than 0.45 m^3.

Tank containers are treated in the UN *Code* in terms of requirements for pressure vessels. IBCs are treated rather in terms of the requirements for packaging, with emphasis on tests for such packaging. There are pressure test requirements, however, for certain metal IBCs such as drums.

The ADR contains provisions for fixed tanks, or tank vehicles, and for tank containers.

23.4.3 Tank containers

In the UN *Transport Code*, transport containers are mainly dealt with in Chapter 12 on multi-modal tank transport, which covers tank containers for Classes 3–9 and for non-refrigerated liquefied gases, and Chapter 17 on multi-modal tank containers for refrigerated liquefied gases. The treatment is under the following broad headings: (1) general requirements, (2) cross-sectional design, (3) minimum shell thickness, (4) service equipment, (5) bottom opening, (6) safety relief, (7) pressure relief devices, (8) setting and (9) capacity.

The treatment of transport containers in the ADR is mainly in Appendix A6 on IBCs and in Appendices Bla–c, dealing with tanks other than tank containers, tank containers, and tanks made of reinforced plastics, respectively. The treatment is under the headings: (1) general scope and definitions; (2) construction; (3) items of equipment; (4) type approval; (5) tests, (6) marking and (7) operation.

23.4.4 Road tankers

The other main type of tank of interest here is fixed tanks on road tankers and rail tank cars. The general principles are similar for the two modes of transport and it is road tankers which are now considered.

The requirements for road tankers, or tank vehicles, are treated in detail in the ADR. In the account that follows, the provisions quoted relate to the general requirements for tank vehicles. For some classes, there are also specific requirements.

23.4.5 Tank shell construction

The mechanical design of the tank shell on a tank vehicle is treated in detail in the ADR. The shell should be designed and constructed in accordance with a suitable code. The ADR gives certain minimum requirements covering, among other things, (1) the material of construction, (2) the minimum wall thickness, (3) the design pressure and test pressure and (4) the transport shocks.

23.4.6 Material of construction

The general requirement of the ADR is that the shell of a tank vehicle should be made of a suitable metallic material which is resistant to brittle fracture and stress corrosion cracking between −20°C and 50°C, except where another temperature range is prescribed for a particular class.

The usual material of construction for the shell is mild steel. Lined mild steel is also used. The usual linings are plastics and rubber. In this case, it is necessary to maintain the lining carefully, especially at the joints.

Other materials are used for tanks for particular chemicals. For example, aluminium alloy is utilized for hydrogen peroxide.

23.4.7 Minimum wall thickness

ADR gives the following formula for the calculation of the thickness of the cylindrical wall of the shell of a tank vehicle and of the ends and cover plates:

$$e = \frac{PD}{20\sigma\lambda} \qquad [23.4.1]$$

where D is the internal diameter of the shell (mm), e is the thickness of the metal (mm), P is the calculation pressure (bar), σ is the permissible stress (N/mm^2) and λ is a coefficient, not exceeding unity, which allows for any weakening due to welds.

There is also a minimum wall thickness. For a shell not exceeding 1.8 m diameter, this minimum thickness is 5 mm for mild steel, and for one of larger diameter it is 6 mm. For other metals, an equivalent thickness is applicable, determined from a formula based on the general relation:

$$e_1 = e_0\left(\frac{R_{m0}A_0}{R_{m1}A_1}\right)^{1/3} \qquad [23.4.2]$$

where A is the fractional minimum elongation of the metal on fracture under tensile stress, R_m is the minimum tensile strength, and subscripts 0 and 1 denote mild steel and the metal under consideration, respectively.

23.4.8 Design pressure

For the design pressure of the shell of a tank vehicle, the general provisions of the ADR define four categories of duty. The fourth covers shells for use with substances having a vapour pressure of more than 1.75 bara at 50°C. For this case, the calculation pressure should be 1.3 times the filling or discharge pressure, but in any case not less than 4 barg.

23.4.9 Transport shocks

The shell, and its fastenings, on a tank vehicle are required by the general provisions of the ADR to withstand the following forces:

(1) In the direction of travel: twice the total mass.
(2) At right angles to the direction of travel: the total mass.
(3) Vertically upwards: the total mass.
(4) Vertically downwards: twice the total mass.

23.4.10 Tank equipment

The ADR general provisions detail the equipment which should be provided on the shell of a tank vehicle. This includes shut-off devices on bottom-discharge shells and pressure relief devices.

A bottom discharge should be equipped with two mutually independent shut-off devices. The first should be an internal stop valve fixed directly to the shell and the second a sluice valve, or equivalent device, mounted in series, one at each end of the discharge pipe socket. In addition, the openings of shells should be capable of being closed by screw-threaded plugs, blank flanges or equivalent devices.

The internal shut-off valve should be operable from above or below, and its setting (whether open or closed), should if possible be verifiable from the ground. The valve should continue to be effective in the event of damage to the external control.

23.4.11 Pressure relief

The general provisions of the ADR require that a shell for carriage of a liquid with a vapour pressure exceeding 1.1 bara at 50°C should either be fitted with a safety valve or be hermetically sealed. A hermetically sealed shell is one with hermetically closed openings and without a safety valve, bursting disc or similar device, or one fitted with a safety valve preceded by a bursting disc.

The special provisions for Class 2, gases, state that a shell for gases in 1° to 6° and 9° may be fitted with safety valves. But they also state that for carriage of toxic gases in 1° to 9°, a shell should not have a safety valve unless it is preceded by a bursting disc. In this latter case, the arrangement should be satisfactory to the competent authority. These provisions also state that for shells intended for carriage by sea, the provisions of ADR do not prohibit the fitting of safety valves conforming to the regulations of the *IMDG Code*.

The fitting of a pressure relief valve to a road tanker is not a straightforward matter. It cannot be assumed that the fluid to be relieved will necessarily be vapour; in some cases, with the tanker lying on its side, the fluid may be liquid. He considers the problems which this poses.

23.4.12 Filling ratio

The general provisions of the ADR contain a number of formulae for the degree of filling (DF). These are of the general form:

$$\mathrm{DF} = \frac{\chi}{1 + \alpha(50 - t_{\mathrm{F}})} \qquad [23.4.3]$$

with

$$\alpha = \frac{d_{15} - d_{50}}{35 \times d_{50}} \qquad [23.4.4]$$

where d_{15} and d_{50} are the densities of the liquid at 15°C and 50°C, respectively, t_{F} is the mean temperature of the liquid at the time of filling (°C), α is the mean coefficient of cubical expansion of the liquid between 15°C and 50°C and χ is a proportion (%) which has values dependent on (1) the nature of the fluid and (2) the pressure relief arrangements, these values ranging between 95% and 100%.

23.5 Road Transport

23.5.1 Regulatory controls and codes

At the international level, codes for the road transport of dangerous goods are the UN *Transport Code* and the ADR.

In the United Kingdom, road transport is governed by three principal sets of regulations. The first set is the (CHIP) Regulations 2002, which cover these aspects as they apply to road transport. These regulations, and the associated ACOPs and guidance, have been described in Section 23.3.

The second set is the Road Traffic (Carriage of Dangerous Substances in Packages) Regulations 1992 (PGR). The regulations deal with: the design, construction and maintenance of vehicles; the marking of vehicles; loading, stowage and unloading; precautions against fire and explosion; information to be provided to the operator; information for, instructions to and training of drivers; supervision of parked vehicles; and information for the police. Regulation 11 places limitations on the carriage of certain substances. It contains requirements that an organic peroxide or flammable solid subject to self-accelerating decomposition be kept below its control temperature.

The third set of regulations is the Road Traffic (Carriage of Dangerous Substances in Road Tankers and Tank Containers) Regulations 1992 (RTR). The regulations deal with: the construction, maintenance and testing of tankers and tank containers; the marking of vehicles with hazard warning panels; loading, filling and securing of closures; information to be provided to the operator; information to be carried with the vehicle; precautions against fire and explosion; information for, instructions to and training of drivers; parking of vehicles and their supervision when parked; and information for the police.

Both the PGR and RTR give definitions of dangerous substances, referring in particular to the *Approved List*. The PGR also contains a schedule which gives criteria by which to determine whether a substance not in the list is to be classed as a dangerous substance.

The regulations which preceded these two sets of road traffic regulations, PGR 1993 and RTR 1993, namely PGR 1986 and RTR 1981, were supported by a number of ACOPs and guidance documents. The ACOPs are COP 11 *Operational Provisions of the Dangerous Substances (Conveyance by Road in Road Tankers and Tank Containers) Regulations 1981* (HSE, 1983); COP 14 *Road Tanker Testing: Examination, Testing and Certification of the Carrying Tanks of Road Tankers and Tank Containers used for the Conveyance of Dangerous Substances by Road (in support of SI 1981 1059)* (HSE, 1985); and COP 17 *Notice of Approval of the Operational Provisions of the Road Traffic (Carriage of Dangerous Substances in Packages etc.) Regulations 1986 by the Health and Safety Commission* (HSE, 1987). The guidance is HS(R) 13 *Guide to the Dangerous Substances (Conveyance by Road in Road Tankers and Tank Containers) Regulations 1981* (HSE, 1981) and HS(R) 24 *Guide to the Road Traffic (Carriage of Dangerous Substances in Packages etc.) Regulations 1986* (HSE, 1987).

These documents are currently in the process of being updated, with a single L series document replacing both ACOPs and the guidance. A single document will replace COP 11 and HS(R) 13, another will replace COP 14 and a third will replace COP 17 and HS(R) 24.

The design and construction of road tankers is covered in the following documents: L16 *Design and Construction of*

Vented Non-pressure Road Tankers used for the Carriage of Flammable Liquids (HSE, 1993); L17 *Design and Construction of Road Tankers used for the Carriage of Carbon Bisulphide* (HSE, 1993); L18 *Design and Construction of Vacuum Insulated Road Tankers used for the Carriage of Deeply Refrigerated Gases* (HSE, 1993); and L19 *Design and Construction of Vacuum Operated Road Tankers used for the Carriage of Hazardous Wastes* (HSE, 1993).

The road transport of explosives is covered by the Road Traffic (Carriage of Explosives by Road) Regulations 1989. The associated ACOP is COP 36 *Carriage of Explosives by Road* (HSE, 1989).

23.5.2 Hazard scenarios

The bulk of hazardous materials transported by road are carried as liquids or liquefied gases in road tankers. The main types of road accident associated with these are leaks due to tank puncture resulting from a collision or overturning or due to failure or maloperation of the tank equipment. Other causes of loss of containment are tank rupture due to overfilling, overheating or a defect and due to fire.

If the tank is ruptured by overfilling or overheating, a physical explosion may occur, giving rise to a blast wave and to missiles.

Material released from the tank by whatever cause may be flammable or toxic and in vapour or liquid form. A release of flammable vapour will form a vapour cloud which may ignite to give a flash fire or vapour cloud explosion. A flammable liquid spill may ignite to give a pool fire or flowing liquid fire. A toxic material will give a toxic gas cloud or toxic liquid spill.

A fire at the tank itself may cause rupture of the tank and, if the tank contains flammable liquid, may lead to a BLEVE, with its associated fireball. Road tankers do not, however, suffer BLEVEs as commonly as rail tankers, because there is not the torch effect from relief valves on other tanks which occurs in rail crashes.

Other hazardous materials are solids which are carried in goods vehicles. These include explosives and related substances. With these there is, therefore, the hazard of explosion.

There are several characteristics of road transport which bear on the nature of the hazard. The vehicle is moving through an environment over which the driver has relatively little control. If there is an accident, it may occur at a variety of points along the route with very different vulnerabilities. On the other hand, the quantity carried is limited, and it may be possible to move the vehicle to a less vulnerable location.

One important aspect of vulnerability is the number of people exposed at a particular location. The extent and composition of the population exposed varies widely with the location. Another aspect is the susceptibility to environmental pollution at that point. A road accident may pose a threat not only to life but also to the environment.

A feature of road accidents is that access for the emergency services is generally relatively easy compared with rail. On the other hand, the accessibility of a road accident increases the likelihood that spectators will gather.

23.5.3 Road tanker design

Requirements for the design of road tankers are given in the Road Traffic (Carriage of Dangerous Substances in Road Tankers and Tank Containers) Regulations 1992 (RTR). An outline of these requirements has been given in Section 23.5.1. Associated guidance is given in L16 for flammable liquids and L18 for deeply refrigerated liquids.

The RTR are essentially a set of goal-setting regulations and do not specify matters such as wall thickness or overpressure protection. In particular, the requirements of the RTR for design and for testing and examination, given in Regulations 6 and 7(1), respectively, are very general, and much less detailed than those given in the ADR. The RTR states in Regulation 8(5) that the aforementioned regulations do not apply to the carrying tank of a road tanker or to a tank container where that tank and its fittings comply with the ADR, RID or the IMDG *Code*. In other words, compliance with the ADR is in effect one way of meeting the requirements of the RTR.

There are also several industry codes which deal with the design and/or operation of road tankers. These include *Safe Handling and Transport of LPG in Bulk by Road* by the (LPGITA, 1974 COP2), *Code of Practice for Road Tank Vehicles Equipped with Bottom Loading and Vapour Recovery* (IP, 1987), *Road Transport of Dangerous Substances in Bulk* (CIA, 1990 RC26) and *Steel Containers for the Carriage of Hazardous Materials* (CIA, 1991 RC37).

For the more hazardous substances, it is common practice to use top rather than bottom connections and to provide the vehicle with additional features such as side protection.

23.5.4 Carriage tank fittings

The provision of suitable carriage tank fittings can make a major contribution to minimizing any loss of containment, both in road accidents and in loading and unloading. Good practice with respect to such provision is illustrated by the features specified in the ADR, some of which have been described in Section 23.4.

One particular feature is the arrangements for protection against overpressure. For flammables, the practice is to fit pressure relief. HSE guidance is given in L16, and L18. L16 for flammable liquids, requires each tank to be fitted with pressure relief devices, which it specifies. L18, for non-toxic, deeply refrigerated gases, likewise requires pressure relief devices on each tank, and specifies them.

For toxics, such provision is more controversial. In COP 38 on transportable gas containers, the HSE states that containers for toxic fluids should not normally be fitted with pressure relief devices.

23.5.5 Road tanker operation

The RTR also contains requirements for the operation of road tankers, which reflect some of the elements of good practice.

The documentation supplied should contain the information necessary for all the parties concerned, which include the consignee, the driver, the police and the fire service.

The driver should be well trained in and provided with the information that he requires. The training should cover: loading and unloading operations, including precautions against overfilling and measures to secure closures; arrangements at lorry stopover points; and handling emergencies, including both spillage and fire.

The vehicle, the carriage tank and its fittings need to be maintained to a high standard.

23.5.6 Filling ratio

It is essential that a tank should not be overfilled, with the consequent hazard of rupture due to expansion of the liquid. The permissible extent of filling is specified in terms of the filling ratio.

Guidance is given in the BS 5355: 1976 *Filling Ratios and Developed Pressures for Liquefiable Gases and Permanent Gases*. This standard, as amended in 1981, defines the filling ratio as:

> The ratio of the mass of gas introduced into a container to the mass of water (water capacity) at 15°C that fills the container fitted as for use, i.e. complete with valve, dip tube, float, etc. as necessary.

BS 5355 gives in Appendix A formulae for the filling ratio (FR). It distinguishes between a low pressure liquefiable gas, which has a critical temperature between −10°C and 70°C, inclusive, and a high pressure liquefiable gas, which has a critical temperature above 70°C. For single components, the FR formula is of the general form:

$$\mathrm{FR} = \frac{\chi \rho_1 (1 - C/100)}{\rho_{\mathrm{w}}} \tag{23.5.1}$$

where C is the confidence limits on the value of the liquid density (%), ρ_1 is the density of the liquid, ρ_{w} is the density of water and χ is a parameter which has the value 0.97 for low pressure liquefiable gases and 0.98 for high pressure liquefiable gases. The liquid density is to be evaluated at the appropriate reference temperature.

The standard also give values of the filling ratio in tabular form for a large number of gases.

23.5.7 Reference temperature

The reference temperature is the assumed maximum temperature which the tank contents could reach during carriage. It is used to determine the filling ratio and also the developed pressure.

BS 5355: 1976 gives reference temperatures for the United Kingdom and also information which allows reference temperatures to be determined for other parts of the world. It classifies areas according to the maximum shade temperature. The United Kingdom is classified as a climatic area with a shade temperature <35°C. In addition to Class UK, there are Classes A–E, with maximum shade temperatures of 37.5, 42.5, 47.5, 52.5 and > 52.5°C, respectively.

Then for the United Kingdom, the reference temperature for container volumes *(V)* over 1 m^3 are as follows:

Type of contents	*Reference temperature for filling ratio CO*		*Reference temperature for developed pressure CO*	
	$V = 1\text{–}5\ \mathrm{m}^3$	$F > 5\ \mathrm{m}^3$	$F = 1\text{–}5\ \mathrm{m}^3$	$F > 5\ \mathrm{m}^3$
Low pressure liquefiable gases	42.5	38	47.5	42.5
High pressure liquefiable gases			50	45

For low pressure liquefiable gases in winter, the standard gives a relaxation in reference temperature for filling ratio for volumes exceeding 5 m^3.

The choice of reference temperature is a very debatable subject. If a single reference temperature is used, simplicity is achieved, but the temperature selected has to be much higher than is necessary and economic for a large proportion of cases. Discussions of this point are given in the Home Office *Containers Report* and by A.W. Clarke (1971b). The latter states that reference temperatures as high as 65°C have been used in international codes.

The reference temperatures provide overall guidelines, but it is necessary also to observe any requirements of international transport and of the country of delivery.

23.5.8 Hazardous materials

For a given mode of transport, there are some hazardous materials which may not be conveyed. Road transport is a case in point. Writing in 1971, A.W. Clark (1971b) gave the following list of substances prohibited for road transport in West Germany:

Class 2 Gases: chlorine, hydrogen bromide, hydrogen chloride, hydrogen fluoride, hydrogen sulfide, phosgene, sulfur dioxide.

Class 3 Flammable liquids: carbon disulfide. Class 6 Poisons: acetone, cyanohydrin, acetonitrile, acrylonitrile, allyl alcohol, allyl chloride, aniline, epichlorohydrin, lead alkyls, organophosphorus compounds.

Class 8 Corrosives: bromine, fluoboric acid, hydrazine, liquid acid halides and liquid chlorides which give off acid fumes in contact with moist air (e.g. antimony pentachloride).

For certain chemicals which are transported by road special measures are required. These include:

(1) substances liable to polymerization;
(2) substances carried fused;
(3) hydrogen peroxide;
(4) organic peroxides;
(5) sulfur trioxide;
(6) bromine;
(7) lead alkyls.

Some chemicals, such as butadiene or ethylene oxide, have a tendency to polymerize. It is essential to prevent polymerization from starting, because if polymerization occurs heat is evolved and the reaction speeds up. One method of prevention is the use of an insulated tank, but this is increasingly being replaced by the alternative method, which is the use of polymerization inhibitors.

Some substances which are solids at ambient temperature, such as sulfur, phosphorus, alkali metals and naphthalene, are often carried in fused form in overdesigned and insulated tanks.

High strength hydrogen peroxide is transported in aluminium or special steel tanks. Materials which could react with the peroxide such as wood or valve lubricants are excluded from the vehicle. A water tank is carried to deal with any accident.

Organic peroxides are a somewhat similar case. They are sometimes carried in refrigerated insulated tanks to minimize the hazard due to their instability.

Sulfur trioxide is a solid at ambient temperatures and is carried heated in overdesigned and insulated tanks. It is stabilized to present polymerization. Bromine is usually transported in lead-lined steel tanks. Lead alkyls are carried in overdesigned and externally protected tanks.

23.6 Road Transport Environment

23.6.1 Road network and vehicles

The assessment of major hazards arising in the road transport of hazardous materials requires the use of a wide range of data on the road transport environment.

The road transport environment varies somewhat from one country to another. Accounts relevant to the United Kingdom have been given by Appleton (1988 SRD R474) and P.A. Davies and Lees (1992), and accounts relevant to North America have been given by Glickman (1988), Harwood and Russell (1989), Harwood, Russell and Viner (1989), Harwood, Viner and Russell (1990), Steward and van Aerde (1990a) and Gorys (1990).

As in hazard assessment generally, two situations can arise with respect to the estimation of the frequency of particular accident scenarios. Either it is possible to estimate the frequencies of these scenarios from historical data, or it is necessary to synthesize the frequencies, by methods such as modelling or fault tree analysis.

Thus, for scenarios such as release of materials which are transported in large quantities (e.g. gasoline and LPG), it may well be possible to obtain historical data. For other scenarios, such as a release of chlorine or an explosion of explosives during transport, it is much more difficult. Moreover, even where historical data exist, it may still be necessary to resort to modelling for reasons such as the need to adapt the data to the particular assessment or to explore the effect of possible mitigatory measures.

As will become apparent from the data given below, a large proportion of incidents involving hazardous materials are not due to traffic accidents, but to other causes. The prime concern here is with incidents which occur during transport rather than during loading and unloading or in temporary storage, but some of the data sets also cover the latter.

Hazardous goods are taken here to be goods defined as such under the United Nations classification and regulated by the Classification, Packaging and Labelling Regulations 1984 (CPL). These hazardous materials are mainly flammable and/or toxic liquids and liquefied gases, reactive chemicals and explosives.

The principal source of information on road transport and on road accident statistics is the DTp. Other important sources are the Home Office and the Transport and Road Research Laboratory (TRRL), which is part of the DoE.

Unfortunately, as so often happens, there are difficulties in relating information from one source to that from another. For example, DTp statistics are for heavy goods vehicles (HGVs) with unladen weights of not less than 1.5 te, whereas the principal TRRL study of HGV fatal accidents deals with HGVs with unladen weights not less then 3 te.

Road network

There are two classifications of roads used in Britain. Roads are generally classified as trunk, principal, secondary, etc., whilst in accident statistics, roads are described as A class, B class, and 'other'. Broadly speaking, trunk and principal roads are equivalent to A class roads, whilst secondary roads are equivalent to B class and 'other' roads (P.P. Scott, 1983). The length of the road network (km) in Great Britain in 1973 was given by H.D. Johnson (1981) as follows:

Length of road (km)						
BUA[a]			*Non-BUA*			
Trunk/principal	*Class II and below*[b]	*Total*	*Trunk/principal*	*Class II and below*[b]	*Total*	*Motorways*
13,874	117,052	130,926	32,383	163,587	195,970	1752

[a] BUA: built-up area.

[b] Of these totals, Class II roads are 8746 km in BUAs and 19,643 km in non-BUAs.

Heavy goods vehicles

Vehicles may be classed as HGVs, light goods vehicles (LGVs), cars, and motor cycles (MCs). HGVs may be subdivided according to the number of axles. The vast majority of hazardous materials are carried in HGVs. The most common HGV is the rigid two-axle vehicle.

The mass unladen of a typical two-axle HGV is some 7.5 te and that of a typical three-axle HGV is some 11.5 te, while that of an LGV is some 1.5 te. The maximum load of a two-axle HGV is some 12 te. Approximately, 50% of HGVs carry full load and 25% is empty, with the remainder carrying part loads. The load of an LGV is some 1.5 te.

A total of 435,000 HGVs were registered in 1986 (DTp, 1987b). The distribution of HGV weights for 1985 (JMP Consultants, 1986) was

Gross vehicle weight (te)	*Proportion of vehicles* (%)
<20	70
20–22	3
22–24	3
24–26	2
26–28	2
28–30	4
30–32	6
32–34	4
34–36	2
36–38	3
>38	1

Figure 23.3 shows some principal HGVs together with their classifications.

Recommended Description			Identifier	UK Maximum Gross Weight (tonnes)	Shape
LIGHT GOODS VEHICLES			2 axles	**3.500**	
LORRIES	**HEAVY GOODS VEHICLES** 1 Vehicles over 7.5 tonnes gross require a Heavy Goods Vehicle Drivers Licence.	SMALLER 2-AXLE LORRIES	2 axles	**Over 3.5 7.500**	
		BIGGER 2-AXLE LORRIES	2 axles	**Over 7.5 17.000**	
		MULTI-AXLE LORRIES	3 axles rigid	**24.390**	
			3 axles artic	**24.390**	
			4 axles rigid	**30.490**	
			4 axles artic	**32.520**	
			Vehicle and draw-bar trailer	**32.520**	
			5 axles c' more artic	**38.000**	

Figure 23.3 *Some principal goods vehicles*

Distances travelled

The journeys travelled by HGVs in 1986 are shown in Table 23.5, Section A, by body type and road type. HGVs travelled a total of 221×10^8 km (DTp, 1987b). The average annual distance travelled per vehicle is thus 50,800 km (221×10^8/435,000). Section B of the table gives a breakdown of the HGV distances travelled by road class.

Table 23.5 *Road transport environment in Great Britain: journeys by heavy goods vehicles in 1986 (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

A Distances travelled by body type and road type

HGV type	*Distance* ($\times 10^8$ km)		
	All speed limits	*Non-BUR*[a]	*BUR*
Rigid	152	103	49
Articulated	65	58	7
Total[b]	221	165	56

B Proportion of distance travelled on each road class

Road class	*Proportion of vehicles* (%)	
	Non-BUR[c]	*BUR*
A	87.0	61.0
B	6.0	11.5
Other	7.0	27.5
Total	100	100

[a] BUR, built-up road. Non-BUR includes motorways.
[b] Figures for rigid and articulated vehicles are for defined axle configurations. Total includes cases where the axle configuration was not reported.
[c] Non-BUR excludes motorways.

Speed in built-up areas

The severity of an accident depends on the speed of the vehicle(s). Of particular interest is the speed of vehicles in built-up areas (BUAs). Work on this has been done by the TRRL (N. Duncan, 1987). Their data for the speeds of good vehicles generally, LGVs as well as HGVs, are:

Time of day	*Average speed* (mph)	
	Small towns	*Large towns*
Peak period	13.1	20.5
Off-peak period	14.9	23.6

The figures refer only to the time when the vehicle is actually moving, the time spent stationary is discounted. With regard to the distribution of speeds, the assumptions made by TRRL are that the normal distribution applies and that the standard deviation is $1/5$ of the mean. Using these assumptions estimates may be made of the probability that a vehicle may be travelling at a particular speed.

More specific data on vehicle speeds at the moment of impact may be obtained from tachograph records, as described below.

HGVs conveying hazardous materials (HGV/HMs)

Some estimates are now made for HGVs conveying hazardous materials (HGV/HMs) in Great Britain.

It has been estimated by Kletz (1986J) that in 1986 there were some 14,000 road tankers in operation. The authors have confirmed that this approximate figure is still valid. Kletz also gives the annual distance travelled per tanker as 60,000 miles (96,500 km).

There are, in addition, HGVs other than tankers carrying hazardous materials. The number of such vehicles which at some time transport hazardous materials may be quite large, but what matters in the present context is the number of equivalent ‘full-time’ vehicles. There appears to be no reliable source of information for this figure. An estimate has therefore been made. The data for hazardous cargoes in the United States given in Section B of Table 23.20 (see below) indicate that the ratio of non-tank truck to tank truck HGV/HMs is about 0.6. Those given in Section B of Table 23.18 (see below) for significant spillages indicate that the ratio of non-tank truck to tank truck HGV/HM spillages is about 0.9. The former figure is regarded as a better guide. A roadside survey conducted by the authors is consistent with this estimate. The ratio of 0.6 is used for Great Britain also, which yields:

No. of tanker HGV/HMs $= 14{,}000$
No. of non-tanker HGV/HMs $= 0.6 \times 14{,}000 = 8400$
No. of HGV/HMs $= 14{,}000 + 8400 = 22{,}400$

Distance travelled by HGV/HMs

For the distance travelled by HGV/HMs, loaded and unloaded:

Distance travelled by individual vehicle $= 60{,}000$ miles $= 96{,}500$ km
Distance travelled by fleet $= 22{,}400 \times 60{,}000 = 13.4 \times 10^8$ miles $= 21.6 \times 10^8$ km

This figure is probably an upper bound, since non-tankers may well not travel as high an annual distance as tankers.

The ACDS figures given in Table 26.6 for that part of the tanker fleet carrying motor spirit, on relatively short journeys, imply an annual distance travelled, loaded and unloaded, of 1.64×10^8 km.

Proportion of route in built-up area

The severity of a road transport accident depends in part on whether it occurs in a BUA. The proportion of a route which passes through areas which are urban or suburban is typically of the order of 10–15%, but it varies. Detailed values for some particular routes are given in the ACDS report.

Movements of certain hazardous materials

The ACDS report of a detailed breakdown of the movements of the four materials considered is shown in Table 23.6.

23.6.2 Road accidents

Statistics on road accidents in Britain are given in the *Annual Abstract of Statistics* by the Central Statistical Office (CSO). Further information is given in the series *Road Accidents Great Britain* by the DTp.

An accident may be classified as a collision with other vehicle (COV) or a single vehicle accident (SVA). The latter may be subdivided into a collision with a stationary object (SVO) or overturning (OT).

Accident definitions

Accidents are commonly classified in the United Kingdom as personal injury (PI) accidents and damage-only (DO) accidents.

Road accident statistics derived from police records relate to personal injury accidents. The number of DO accidents generally has to be estimated from the number of PI accidents. For example, R.F.F. Dawson (1971) in a study of the cost of accidents gives the number of PI accidents in

***Table 23.6** Road transport environment in Great Britain: tanker capacities and movements for four hazardous materials (Advisory Committee on Dangerous Substances, 1991) (Courtesy of HM Stationery Office © All rights reserved)*

A Tanker capacities

Substance	*Tank capacity* (te)
Motor spirit	20–25
LPG	15
Ammonia	15
Chlorine	17

B Tanker movements

	Motor spirit	*LPG*	*Ammonia*	*Chlorine*
Total loaded movements (loaded tanker km/yr)	82×10^6	19.54×10^6	632,233	1,121,358
Total loaded journeys (loaded tanker journeys/yr)	1.3×10^6	63,667	2,974	9,871
Average loaded journey (km)	64	307	213	114

1968 as 264,200 and estimates the number of DO accidents as 1,583,000, giving a DO/PI accident ratio of 6. Appleton states that values of the ratio given in DoT and TRRL studies are in the range 6–12. He also states that a survey by the Safety and Reliability Directorate (SRD) of a small number of local authorities found a value of the DO/PI ratio of 2–3 but the reporting was not consistent. In any event, the problem of defining what constitutes an accident is more severe for DO than for PI accidents. Moreover, an accident severe enough to endanger the integrity of a load is likely to result in some personal injury. It is convenient, therefore, to work in terms of the PI accident criterion.

The main exception to the above is fires. Fire brigade records allow the derivation of fire statistics. Major studies of fires have been made by North (1974) and McLean (1981).

The significance of the definition of an accident depends on the use to which it is to be put in the hazard assessment. Broadly speaking, the definition is important if historical data on releases are lacking, but this is less so if such statistical information is available. The reason why is that, in the latter case, it is possible to work with a definition of an accident which is to a degree arbitrary and to work in terms of the probability of release given an accident so defined. If, on the other hand, data are not available and it is necessary to model the accident in order to determine the probability of release, the definition of what constitutes an accident becomes more significant, since it determines the accident frequency.

In the following, the UK accidents considered are injury accidents, except for fires.

Injury accidents

For vehicles generally, H.D. Johnson and Garwood (1971) found that the proportion of fatal accidents in the total of serious injury and fatal accidents for the period 1959–65 was in the range 5.1–9.2% for roads with speed restrictions of 30 or 40 mph and in the range 8.3–14.5% for other roads.

A study by the DTp (1987a) obtained for the ratio of fatal accidents to all injury accidents values in the range 0.018:1 to 0.025:1.

Some data on casualties in HGV accidents are given in Table 23.7. A study of fatal accidents involving HGVs in 1976 has been given by Riley and Bates (1980).

Grattan and Hobbs (1978) studied injuries to occupants of HGVs. In 1975, there were 3200 occupant casualties in HGVs, of which 800 were serious or fatal, the latter numbering 71. These casualties were usually the result of collision between two HGVs or between an HGV and a roadside obstacle. A 5% sample of the serious or fatal injuries was studied. All fatal injuries were associated with either massive intrusion of the cab structure or ejection of the occupant.

Hobbs, Grattan and Hobbs (1979) have examined various classifications of injury, in a study which relates the injury classifications to the length of stay in hospital.

Kletz (1986J) quotes figures given by Hills (1981) for the number of deaths from the road transport of hazardous chemicals in the United Kingdom in the period 1970–80 as 16 deaths overall, making an average of 1.23 deaths/year. From the context these are the deaths attributable to the load. Kletz also states that the average number of deaths per fatal accident is 1.5.

HGV accident frequency

In 1986, HGVs travelled 221×10^8 km and there were 13,429 accidents involving HGVs. A number of accidents involve more than one HGV. The number of HGVs involved in accidents is thus somewhat more than the number of accidents involving an HGV. The number of HGVs involved in accidents in 1986 was nearly 15,000.

Statistics on accidents involving HGVs are given Tables 23.8–23.11 gives, in Section A, the number of HGVs involved in accidents; in Section B, Table 23.8 the number of accidents involving HGVs by body type and road type; and in Section C, a breakdown of the road class on which the accidents occurred. Table 23.9 gives the number of HGV accidents in 1986, by the combination of vehicles involved. Table 23.10 gives the frequency of HGV accidents by body type, road type and road class. Table 23.11 gives the proportion of HGV accidents by junction type and by impact position.

The basic annual accident statistics for HGVs in 1986 are:

No. of accidents = 13,429/year
No. of vehicles involved in accidents = 15,000
Proportion of vehicles involved in accidents
 = 15,000/435,000 = 3.4%/year
Frequency of accidents = $134{,}297(221 \times 10^8)$
 = 0.62×10^{-6}/km

Impact accidents

A study of the impact speed of HGVs in accidents has been made by P.A. Davies and Lees (1991a,b) based on tachograph records. Table 23.12 gives the impact speeds obtained in this study. The accidents may be regarded as a biased sample in that the accidents were sufficiently serious for the police to have an interest and may tend therefore to give an overestimate of the impact speed in injury accidents generally.

Fire accidents

An investigation of fire in road vehicles was carried out by North (1974). Although reported in 1974, most of the data relate to 1971 and are therefore rather old. The study does, however, contain some information on certain special aspects of vehicle fires, which are given below after a consideration of the main fire statistics.

Information on the causes of fires in vehicles in 1985 has been given by the DTp (1985). In that year, out of some 248,000

***Table 23.10** Road transport environment in Great Britain: frequency of HGV accidents in 1986 (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

40–49	1	6	1
50–60	0	0	2
>60	0	0	1
Total	9	26	5

Table 23.13 *Road transport environment in Great Britain: causes of fires in road vehicles 1984 (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

Cause	*Number*	*Proportion* (%)
Deliberate ignition	7,434	22.0
Smokers' materials	1,165	3.4
Wiring of vehicle	8,980	26.6
Oil and petroleum in contact with hot components	8,475	25.1
Crash, collision	881	2.6
Other	4,042	12.0
Unknown	2,793	8.3
Total	33,770	100.0

accidents, there were some 33,000 fires. The causes of these fires are given in Table 23.13. It can be seen from the table that the vast majority of vehicle fires are non-crash fires.

Information from the Home Office quoted by Davies and Lees for goods vehicle fires specifically indicates that in 1986, fire brigades attended 7212 van and lorry fires. Not all of these were on a public highway.

Of the 2578 HGV fires, 2559 (99.3%) were non-crash fires and 19 (0.7%) were crash fires. No breakdown is available for non-crash fires by vehicle type, but for crash fires, the breakdown is as shown in Table 23.14, Section A. The causes of the HGV non-crash fires are given in Table 23.14, Section B.

The study by North gives some information on the location of vehicle fires. His data for lorries and tankers are given in Table 23.14, Section C. They show that for HGVs, some 82% of fires occur on roads. About another 10% occur in car parks, yards and garage forecourts, probably for the most part in BUAs.

North also gives information on the number of fatalities and on the damage caused in vehicle fires, which may help to determine the severity of such fires. In 1971, there were 241 vehicle fires, of which 16 were in lorries and 10 in tankers, and in two lorry fires there was one death in each fire and in two tanker fires one death in each. In 1972, there were 289 vehicle fires, of which 19 were in lorries and 12 in tankers and in one tanker fire there were two deaths, there being no deaths in the lorry fires. Thus, for lorries, out of 35 fires, 2 were fatal (6%) and, for tankers, out of 22 fires, 3 were fatal (14%).

North gives information on the resultant damage in a sample of car fires in 1971. Out of 200 fires, 73 caused minor damage, 44 damaged the original compartment, 24 damaged or severely destroyed the original compartment, 15 damaged more than one compartment, 2 damaged the exterior, 40 (20%) damaged or destroyed the whole car and 2 had no recorded result.

Table 23.14 *Road transport environment in Great Britain: fires in HGVs 1986 (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

A Number of crash fires

	Non-BUR	*BUR*	*All speed limits*
All HGVs	11	8	19

B Frequency of crash fires

	Frequency (fires/10^8 km)		
	Non-BUR	*BUR*	*All speed limits*
All HGVs	0.06	1.15	0.09

C Location of lorry and tanker fires (North, 1974)

Location	*Proportion of fires* (%)	
	Lorries	*Tankers*
Road or verge	71.7	67.4
Motorway	10.5	15.2
Field, open land	6.4	4.9
Car park, yard	10.1	9.7
Garage forecourt	0.7	0.5
Garden	0.1	0.5
Other (specified)	0.5	1.6
Total	100	100

From the above, the following annual estimates can be made for HGV fires:

No. of crash fires = 19
Crash fires as a proportion of accidents = 19/13,429 = 0.14%
No. of non-crash fires = 2559
Non-crash fires as a proportion of accidents = 2559/13,429 = 19%

Load-threatening accidents

Investigations of accidents which might threaten the load of a large HGV transporting radioactive waste have been made by I.A. James (1986) and by Allsop *et al.* (1986). The study by James is concerned with articulated, five-axled HGVs. For the determination of accident frequency, he assumes that only serious accidents, that is, those involving death or serious injury have the potential to threaten the load. Thus, James considers only accidents where the subject vehicle was an articulated HGV having a gross vehicle weight (GVW) of more than 1.5 tonne, where death or serious injury was involved, and where the accident either was a SVA or involved another HGV of GVW greater than 1.5 tonne. Table 23.15 shows his data for the number and frequency of such accidents.

Also shown in the table are the results obtained by Allsop *et al.* They considered all injury accidents involving either four-axle or five-axle HGVs in overturning or side damage. The accident frequencies obtained by these workers are appreciably higher. For motorways and A roads, their results are higher than those of James by a factor of 2–3. The factor is greater for B roads and other roads, but James' data show that the distance travelled by these large HGVs on the lower class roads is relatively small.

Chemical accidents

An account of the chemical accidents attended by the UK public fire service in 1980 has been given by McLean (1981). There were 983 special service calls in which dangerous chemicals were involved and 968 actual incidents. The incidents occurred at both fixed installations and in transport.

Table 23.16 gives the nature and number of these incidents. The principal chemicals involved, together with the number of incidents, were: hydrochloric acid (66), ammonia (65), LPG (42), sulfuric acid (34) and sodium hydroxide (30). There were 14 incidents involving petroleum and 10 involving ammonium nitrate. Of these incidents, 132 were fires in

Table 23.15 *Road transport environment in Great Britain: number and frequency of a certain type of load-threatening accident (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

Road type	*No. of accidents*	*Distance travelled* ($\times 10^6$ miles)	*Accident frequency*[a]	
			($\times 10^{-8}$ accidents/mile)	($\times 10^{-8}$ accidents/km)
Motorway	310	3202	9.68	6.0
A class	740	3855	19.2	11.9
B class	47	172	27.0	10.4
Total	1097	7229	15.2	9.4

[a] Allsop *et al.* (1986) give an accident frequency (accidents/10 km) as follows: motorways, 11.5; A roads, 36.5; B roads, 114; other roads, 83.1.

***Table 23.16** Road transport environment in Great Britain: nature of chemical incidents attended by the UK public fire services in 1980 (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

Nature of incident	*Number of incidents*	*Proportion of incidents* (%)
Chemical overheated	9	1
Spillage	419	43
Leakage	211	22
Vapour, gas escape	80	8
Potential spillage	11	1
Fire	173	18
Explosion	10	1
Chemical found	19	2
Other	20	2
Unknown	16	2
Total	968	100

which the presence of the chemical affected the firefighting to a significant degree, 18 were fires in which dangerous chemicals behaved in an abnormal manner and 25 were fires in which dangerous chemicals were present and gave rise to casualties.

For all transport incidents, both road and rail, there were 419 incidents, excluding cases in which chemicals were washed ashore. Of these, 105 (25%) occurred in rural areas, 187 (45%) in urban industrial areas, 113 (27%) in urban residential areas, and the remaining 14 (3%) in unrecorded locations.

As far as concerns the road transport incidents, there were 335 incidents, of which 21 (6%) were on motorways, 120 (36%) on A class roads, 56 (17%) on B class roads, 29 (9%) on unclassified roads, 96 (29%) occurred in a parking area off the public roads, and the remaining 14 (3%) were in unrecorded locations.

In 243 (73%) of the incidents, the vehicle was attended. Therefore, the number of incidents in which it was unattended was as high as 92 (27%).

In only 36 (11%) of the cases was an accident reported as the primary cause of the incident.

Background on accidents

A discussion of the UK accident statistics is given by H.D. Johnson and Garwood (1971). McBean (1982) attempts to assess the influence of road features on accident frequency and P.P. Scott (1983) that of traffic density, whilst Storie (1984) considers the effect of driver characteristics.

A study of HGV accidents was made in 1979 by Neilson, Kemp and Wilkins (1979), but the data given above are more up to date.

23.6.3 Road accidents: HGV/HMs

Accident frequency for HGV/HMs

HGVs carrying hazardous materials have a higher standard of design and operation, although the extent of this is variable. It may therefore be expected that the accident rate would be less. Information obtained by P.A. Davies and Lees (1992) for munitions vehicles indicates a reduction factor of about 0.1–0.33. For HGV/HMs, it seems doubtful whether such a large reduction is appropriate. The estimate used by Davies and Lees is 0.8.

M. Griffiths and Linklater (1984) found that the proportion of HGV/HMs suffering an accident was the same as for HGVs generally. Although a lower accident rate per unit distance travelled is assumed here for HGV/HMs, these vehicles travel a greater distance per year, and the net effect is to give them an annual accident rate comparable with or rather greater than that of other vehicles.

Taking the estimate:

Ratio of HGV/HM to HGV accident rates $= 0.8$

then for HGV/HM accidents

Frequency of accidents $= 0.8 \times 0.62 \times 10^{-6}$/km
$= 0.50 \times 10^{-6}$/km

No. of accidents $= 0.50 \times 10^{-6} \times 21.6 \times 10^{8}$
$= 1080$ accidents/year

No. of vehicles involved in accidents
$= (15{,}000/13{,}429) \times 1080 = 1206$

Proportion of vehicles involved in accidents
$= 1206/22{,}400 = 5.4\%$/year

For Ministry of Defence munitions vehicles (MVs), taking the estimate

Ratio of MV to HGV accident rates $= 0.2$

then

Frequency of accidents $= 0.12 \times 10^{-6}$/km

Release frequency and probability for HGV/HMs

An estimate of the frequency and probability of release given an accident can be made from the data given by Maclean. From his data:

No. of releases due to traffic accidents $= 36$

then

Frequency of release $= 36/(21.6 \times 10^{8})$
$= 0.017 \times 10^{6}$ releases/km $= 0.027 \times 10^{6}$ releases/mile
Probability of release given traffic accident
$= 36/1080 = 0.033 = 3.3\%$

These estimates are based on attendance by a fire brigade and should be regarded as lower limits.

These results may be compared with the US figures. Tables 23.18–23.20 (see below) give for the USA data on the probability of release and on the frequency of release per unit distance travelled. Again, in both cases, a distinction has to be made between releases occurring as a direct result of a traffic accident and releases due to other causes. The data given in Table 23.19 are particularly relevant in this regard.

Fatal accidents for HGV/HMs

Ratio of fatal accidents to injury accidents $= 0.022$
No. of fatal accidents $= 0.022 \times 1206 = 26.5$/year
No. of fatalities per fatal accident $= 1.5$
No. of fatalities from accidents $= 1.5 \times 26.5 = 39.8$, say 40

About one death per year is attributable to the load and the rest are due to traffic accidents.

23.6.4 Collision modelling: impact speed

The attempt to estimate the frequency of a particular type of event arising from an HGV collision will depend both on the probability of the event given a collision with a particular effective impact velocity, and on the frequency of a collision of sufficient severity with this impact velocity.

The effective impact velocity will depend on the closing, or impact, speed. For an SVA all that is required is the impact speed of a single HGV. Data which may be used to construct a probability density function for HGV closing speeds in accidents are given in Table 23.12. For an accident involving two vehicles, it is necessary to combine the probability density functions of the two vehicles. In such cases, the probability density function for the HGV impact speed may be used for both vehicles.

An approach to the determination of the probability of a given combined impact speed in a head-on collision of two HGVs is as follows. Given that there is available a distribution of HGV impact speeds such as that shown in Table 23.12, the distribution of the impact speeds of an HGV–HGV head-on collision and the probability that the speed lies within a certain range may be obtained as follows. Consider a normal distribution of HGV impact speeds $f(x)$ on built-up roads, where x is the impact speed, with a mean $\bar{x}$ and standard deviation σ. Then for the distribution $f(x_c)$ of the combined (i.e. summed) impact speeds

$$\bar{x}_c = 2\bar{x} \qquad [23.6.1]$$

$$\sigma_c^2 = 2\sigma^2 \qquad [23.6.2]$$

$$\sigma_c = 2^{1/2}\sigma \qquad [23.6.3]$$

The probability P that the combined impact speed x_c lies between x_{c1} and x_{c2} is then

$$P(x_{c1} < x_c < x_{c2})$$

$$= P\{[(x_{c1} - \bar{x}_c)/\sigma_c] < x_c < [(x_{c2} - \bar{x}_c)/\sigma_c]\} \qquad [23.6.4]$$

$$= P(a < x_c < b) \qquad [23.6.5]$$

$$= I(b) - I(a) \qquad [23.6.6]$$

$$= P \qquad [23.6.7]$$

where subscripts 1 and 2 denote bounding values of speed. Values of $I(a)$ and $I(b)$ can be obtained from standard tables of the normal distribution. As an illustration, consider the following example:

$$\bar{x} = 30.6 \text{ mph}$$

$$\sigma = 12.2 \text{ mph}$$

$$\bar{x}_c = 2 \times 30.6 = 61.2$$

$$\sigma_c = 2^{1/2} \times 12.2 = 17.3 \text{ mph}$$

The probability that the collision speed is between 110 and 130 mph is then

$$\mathrm{P}[(110 - 61.2)/17.3 < x_c < (130 - 61.2)/17.3]$$

$$= P(2.28 < x_c < 3.98) = 7(3.98) - 7(2.82)$$

$$= 0.9999 - 0.9976 = 2.3 \times 10^{-3}$$

This method provides a simple and rapid estimate of the probability of the combined collision speed, given a collision. The results are, however, only as good as the quality of fit of the distribution used. Specifically, the method utilizes the tail of the distribution. The fitting and use of tails is a common problem in the use of distributions. In some cases, it may be preferable to use alternative methods such as Monte Carlo simulation using the actual histogram data for collision speeds.

23.6.5 Collision modelling: impact consequences

There are several collision scenarios which may be relevant to the conveyance by road of hazardous materials. Loss of containment of hazardous liquids in bulk transport is the prime problem, but explosion of loads sensitive to shock may also be of concern.

The modelling of vehicle collision is discussed in *Handbook of Road Safety Research* (Grime, 1987).

For loss of containment of a hazardous liquid, there will be critical combinations of the impact velocities at which penetration of the tank occurs. For a frontal collision of two vehicles, by conservation of energy

$$\tfrac{1}{2}(m_1 v_1^2 + m_2 v_2^2) = \tfrac{1}{2}(m_1 + m_2)v^2 + E \qquad [23.6.8]$$

and by conservation of momentum

$$v = \frac{m_1 v_1 + m_2 v_2}{m_1 + m_2} \qquad [23.6.9]$$

where E is the energy absorbed in the collision, m_1 is the mass of the first vehicle, m_2 is the mass of the second vehicle, v is the residual velocity of the two vehicles after the collision, and v_1 is the initial velocity of the first vehicle and v_2 is that of the second vehicle. The mass of each vehicle is defined here as that of the vehicle plus its load which is assumed to be restrained. From Equations 23.6.8

$$E = \tfrac{1}{2}[m_1 v_1^2 + m_2 v_2^2 - (m_1 + m_2)v^2] \qquad [23.6.10]$$

Equation 23.6.10 may be used to determine the critical combination of velocities v_1 and v_2 which give the critical energy absorption E_{cr} for rupture of the containment. The latter factor is obtained from mechanical considerations for the particular tanker.

An early example of such an approach was the investigation by Westbrook (1974) of the comparative risks of chlorine transport by road, rail and pipeline. The study included a road tanker collision analysis to determine the probability of puncture given a crash.

A series of collision analysis studies for HGVs for US conditions is available in Gardner and Moffatt (1982).

For the explosion of a shock sensitive load, there will be some critical impact velocity of the load at which explosion occurs. For a frontal collision of a vehicle carrying such a load unrestrained with another vehicle as shown inFigure 23.4, by conservation of momentum, the residual velocity v of the two vehicles is given by Equation 23.6.9. This velocity may be positive or negative. Then the impact velocity v_ℓ of the load is

$$v_1 = v_1 - v \qquad [23.6.11]$$

Equation 23.6.11 may be used to determine the critical combination of velocities v_1 and v_2 which give the critical impact velocity v_{cr} for the load.

The treatment of ship collision, described below, presents close parallels to road collision analysis of the type just described.

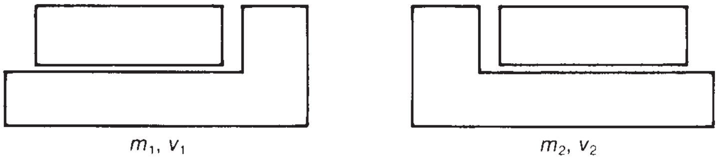

Figure 23.4 *Vehicle collision model*

Table 23.17 *Road transport environment in Great Britain: number of spills of motor spirit August 1980–August 1985*[a] *(Advisory Committee on Dangerous Substances, 1991) (Courtesy of HM Stationery Office. Copyright. All rights reserved)*

Initiating event	*Spill mechanism*	*Spill size* (kg)			
		<15	15–150	150–1500	>1500
Rollover	Puncture			1	4
	Equipment		1	1	3
	Not specified		2		
Collision	Puncture		1		2
	Equipment		1	1	
	Not specified		1		
Body material and equipment failure	Top hatch		1		
	Pipework	1	2		
	Material crack	1	2		
Total		2	11	3	9

[a] The period considered is given in tables 4 and 5 of the report as starting in August 1981, but in table 6 as starting in 1980. The latter fits the estimate given for motor spirit tankers on p. 235, para 32, of the report for the puncture frequency = 1.9×10^{-8} per loaded tanker km and is adopted here.

23.6.6 Releases

Moving on to accidents resulting in releases, the ACDS report considers two categories of accident: (1) the puncture of a tank wagon in an accident and (2) failure or maloperation of the tanker equipment.

It considers the four study materials in turn. For motor spirit

$$\text{Distance travelled} = 82 \times 10^6 \text{ tanker-km/year}$$

This figure, and the others quoted in this section, refer to loaded journeys only.

The number of spills of motor spirit in the 5-year period ending in August 1985 is shown in Table 23.17. The spills are classed as nuisance (<15 kg), small (15–150 kg), medium (150–1500 kg) and large (>1500 kg).

For spills of motor spirit due to punctures:

Frequency of spills due to punctures of motor spirit

$$\text{tankers} = \frac{8}{5} \times \frac{1}{82 \times 10^6}$$
$$= 1.9 \times 10^{-8}\text{/tanker-km}$$

The frequency of medium spills due to punctures is 1.4×10^{-8}/tanker-km and that of large spills 0.24×10^{-8}/tanker-km.

There were no punctures of LPG, ammonia or chlorine tankers in the observation period, if two incidents involving the transport of ammonia and LPG in improperly designed tankers are disregarded. However, from an ICI analysis of US data showing 12 LPG puncture incidents, the frequency of spills due to puncture of US LPG tankers was estimated as 8.1×10^{-9}/tanker-mile. Then, allowing for the higher frequency of level crossing incidents in the United States and for differences in tanker design, the frequency of spills due to puncture of UK LPG tankers was obtained as 4.8×10^{-10}/tanker-km. A similar value was assumed for ammonia, whilst for chlorine the frequency was estimated as 0.8×10^{-10}/tanker-km.

For motor spirit spills due to equipment failures, the frequency of small spills, including those with causes not specified, is 1.9×10^{-6}/journey, that of medium spills 3.0×10^{-6}/journey and that of large spills 4.5×10^{-6}/journey.

With regard to spill size, the average size of spill in six puncture incidents was 4015 kg and that in three equipment failure incidents was 3640 kg.

For the other three substances, the frequency of leaks due to equipment failure was obtained from fault trees which are given in the report. The results for all spills other than nuisance spills were as follows:

	Frequency of spill (spills/journey)
LPG	5.2×10^{-9}
Ammonia	7×10^{-9}
Chlorine	3.6×10^{-9}

23.6.7 Release ignition

For the probability of ignition of a spill of flammable material, the ACDS report states that none of the 25 spills considered ignited. It disregards the two nuisance spills (<15 kg) and obtains from the remaining unignited spills, an expected value of 0.7 ignitions in 23 spills, or an ignition probability of 0.033.

This value is lower than that adopted for rail spills, as described below. This appears surprising, since other vehicles are potential sources of ignition. The report gives as possible reasons the good drainage of roadways and the emergency action taken by tanker drivers. It also quotes expert judgement that a probability of ignition of 1 in 30 is about right.

23.6.8 Fires

The other main event which may give rise to an incident is fire. The frequency of fires on HGVs was considered in Section 23.6.2. With regard to fire, for HGVs, generally non-crash fires are much more frequent than crash fires. The Australian work indicates, not surprisingly, that this is less so for road tankers carrying flammable materials. Nevertheless, the figures suggest that even for such tankers, non-crash fires may be more significant.

23.6.9 Lorry stopover point incidents

The ACDS report also considers the hazard at lorry stopover points. These may vary from overnight lorry parks to points where the stopover is less than 1 h.

COP 11 states that when a vehicle is not being driven, it should be parked in a safe place or supervised at all times by the driver or other competent person. It recommends that for periods of parking in excess of 1 h, or for overnight parking, use should be made of a lorry park or some other place where the public do not have access.

The report states that UK records contain no puncture incident in a lorry stopover point. The authors therefore attempt to derive an estimate by adapting the *en route* puncture frequency data described above. These data, which are expressed as a frequency of puncture per tanker-km, are converted to a frequency of puncture per tanker-hour using a notional average speed of 60 mph. The data are corrected to allow for the low speed of vehicles in lorry stopovers by applying for motor spirit tankers and LPG tankers correction factors of 0.1 and 0.01, respectively. The frequency of punctures per journey is then obtained using appropriate values for the length of a stopover, taken as typically half an hour, and for the number of stopovers, taken as averaging 1.5 per journey.

For LPG, the *en route* frequency of puncture of a tanker is 4.8×10^{-10}/tanker-km and there are 63,667 journeys/year. Then, following the approach just described

Frequency of puncture of tanker

$$= 0.01 \times 60 \times 4.8 \times 10^{-10}/\text{tanker-km}$$
$$= 2.88 \times 10^{-10}/\text{tanker-h}$$

With 1.5 stopovers/journey and a stay of 0.5 h/stopover

Frequency of puncture of tanker

$$= 1.5 \times 0.5 \times 2.88 \times 10^{-10}$$
$$= 2.2 \times 10^{-10}/\text{journey}$$
$$= 63{,}667 \times 2.2 \times 10^{-10}$$
$$= 1.4 \times 10^{-5}/\text{year}$$

The frequency of leaks due to equipment failure was obtained from fault trees, one of which, that for LPG, is given in the report.

Using this methodology the results obtained for all four study substances in lorry stopover points are as follows:

	Frequency of puncture (punctures/journey)	*Frequency of spills due to equipment failure* (failures/h)
Motor spirit	2.9×10^{-9}	–
LPG	2.2×10^{-10}	2.6×10^{-9}
Ammonia	1.4×10^{-10}	3.9×10^{-9}
Chlorine	1.4×10^{-11}	1.3×10^{-9}

No evaluation of equipment failure frequency was made for motor spirit, since the consequences were judged to be minor.

23.6.10 Exposed population

The population exposed in a road transport accident is the *en route* population and the other road users together with the emergency services. Meaningful assessment of the societal risk from road transport requires the use of a reasonably refined population exposure model. The models used in the ACDS report are described in Appendix 17.

Population density and other characteristics

A study of the density and other characteristics of the population which might be exposed to hazardous materials has been made by Petts, Withers and Lees (1987). The information given includes data for the United Kingdom on population densities, both by day and by night, on the proportions of persons indoors and outdoors, and on the proportion of the population which may be considered particularly vulnerable.

There have also been specialist studies of the population density along routes taken in the transport of hazardous materials. These include the TRIP programme referred to in the Second *Canvey Report* (HSE, 1981a) and the study by Canadine and Purdy (1989) already mentioned.

High density targets

Of particular interest is the probability that any incident will occur at a location where large numbers of people are exposed. An estimate of this probability for BUAs may be made from V-2 rocket incidents. The distribution of the rockets which fell on London was effectively random. Analysis of the 517 V-2 incidents in London gives 8.9% which caused >10 deaths and 1.4% which caused >33 deaths.

Emergency services

In addition to the population that is normally in the area, emergency services personnel who attend the accident are also at risk. It is not uncommon in an incident involving the road transport of hazardous materials that a significant proportion of the casualties include such personnel.

A typical road accident involving injury and fire would probably be attended by one police patrol car (2 persons), one fire tender (4–5 persons) and one ambulance (2–3 persons). If the incident is considered serious and if time permits, additional fire tenders may attend.

23.6.11 Emergency services

Attendance times

In assessing the consequences of an incident, the time for the fire services to attend may be important. In accordance with Home Office guidance, fire brigades classify areas into different categories of risk. For each category there is a specified minimum number of pumps (i.e. fire engines) which are required to attend the scene and a maximum time for their arrival. A vehicle fire is normally attended by one fire engine. Information from the London Fire Brigade obtained by P.A. Davies and Lees (1992) indicates that a vehicle fire is normally attended by one fire engine and that for the type of area through which, for example, road transport of explosives takes place, the maximum attendance time is 20 min. The mean attendance time is between 10 and 15 min.

23.6.12 North American environment

There have been a number of studies in North America on the transport of hazardous materials. Several of the more recent studies are considered here.

A review of accidents involving, and releases from, vehicles carrying hazardous materials has been given by Glickman (1988). The data are based on the reporting system of the DoT, Office of Hazardous Materials Transportation. The basic data consist of the distance travelled by trucks carrying hazardous materials and the number of accidents involving a spillage.

The reporting system requires the recording of any unintentional release occurring during loading/unloading, transportation, or temporary storage. The author equates such releases to spillages. Spillages are treated as significant if they involve more than 5 US gallons or 40 lb of material. From these reporting requirements, from the data given by Maclean above and from other data given below, it would seem that most of these spillages do not in fact occur due to road traffic accidents on the public highway.

Some data from the study are shown in Table 23.18. The frequency of spillages is obtained by simply dividing the number of spillages by the distance travelled by the vehicles.

Table 23.18 *Road transport environment in North America: the distance travelled and the number and frequency of spillages for US trucks carrying hazardous materials in 1982 (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

A Distance travelled

Type of vehicle	*Distance travelled* (10^6 vehicle miles)
Trucks	
Private	6,416
For hire	9,804
Total	16,220
of which	
Tank trucks	
Private	4,121
For hire	307
Total	4,228

B Number of spillages

Type of vehicle	*No. of spillages*	
	Total	*Significant*
Trucks		
Private	357	233
For hire	5,314	1,434
Total	5,671	1,667
of which		
Tank trucks		
Private	248	178
For hire	936	692
Total	1,184	870

C Frequency of spillages

Type of vehicle	*Frequency of spillages* (spillages/10^6 vehicle miles)	
	Total	*Significant*
Trucks		
Private	0.0556	0.0363
For hire	0.542	0.146
of which		
Tank trucks		
Private	0.0602	0.0432
For hire	3.049	2.254

There are several points of interest in these data. One is the rather high ratio of the distance travelled by vehicles other than tank trucks to that travelled by tank trucks. Another is the rather lower ratio of the number of significant spillages for vehicles other than tank trucks to the number for tank trucks. Also of interest is the striking difference in the frequencies of spillage between private trucks and trucks for hire.

The overall frequency of significant spillages is

$$\text{Frequency of significant spillages} = 16{,}677(16{,}220 \times 10^6)$$
$$= 0.10 \times 10^{-6}\ \text{spillages/vehicle-mile}$$
$$= 0.062 \times 10^{-6}\ \text{spillages/vehicle-km}$$

Harwood, Russell and Viner (1989) have collated information on hazardous material (HAZMAT) accidents. This information was obtained from the DoT's RSPA Hazardous Materials Incident Reporting (HMIR) System database. The system is based solely on self-reporting by carriers. No minimum release quantity or damage level is specified and, technically, any release, however small, is reportable. The requirements apply, however, only to interstate transport, and carriers engaged solely in intrastate transport are not required to report HAZMAT incidents under this scheme.

Data were analysed for the period 1981–85. During this time, there were 28,433 HAZMAT incidents reported. Some data on these incidents are given in Table 23.19. As the table shows, the proportion of HAZMAT incidents due to traffic was 11%. However, the proportion of severe incidents due to traffic lay between 35% and 68%, depending on the definition of severity. The authors give one definition of a severe incident as one involving injury or death, a fire or explosion or more than US$50,000 dollars worth of damage.

The authors also give information from another database, the Motor Carrier Accident Report maintained by the FHWA Bureau of Motor Carrier Safety (BMCS), now renamed the Office of Motor Carriers. This database gives information on trucks involved in accidents, including

Table 23.19 Road transport environment in North America: hazardous material incident data from the US Department of Transportation RPSA database for 1981–85 (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)

A Location of incidents

Location	*Proportion* (%)	*Number*
On public highway	48	13,547
Off public highway	39	*c.*11,089
Unknown	13	*c.*3,797
Total	100	28,433

B Failure involved in incidents on public highway

Failure type	*Number*	*Proportion* (%)
Traffic accident	1,427	10.8
Body or tank failure	2,741	20.2
Valve or fitting failure	3,289	24.3
Cargo shifting	4,945	36.5

No. of deaths	273	53	326
No. of injuries	2514	441	2955

whether the truck was carrying hazardous materials and whether a release occurred. The reporting system applies, however, only to interstate carriers. Data from this source are given in Table 23.20.

An analysis of accident rates in three states (California, Illinois and Michigan) and of release probabilities overall in the United States has been given in a study by Harwood, Viner and Russell (1990), which follows on from the authors' earlier work (Harwood and Russell, 1989; Harwood, Russell and Viner, 1989). The data were obtained from the accident reporting systems of these states. Table 23.21 gives data on release frequencies and probabilities.

The accident frequencies differ appreciably between the different classes of highway. They also apparently differ appreciably between states. The probabilities of release given an accident, however, are relatively similar for rural highways as a group and for urban highways as a group.

An analysis of incidents in Canada in which there were releases of gasoline or LPG has been made by Steward and van Aerde (1990a). The incidents were those reported under the regulatory system as dangerous occurrences in the period 1986 to August 1987 (1.7 years). Thus, not all accidents were reported and the data are therefore not comparable with those reported under the US HAZMAT scheme.

There were 41 incidents involving gasoline. A proportion of these may not have been transport incidents. The proportion known to be transport incidents was 81%, leaving between 0% and 19% which may not have been. Table 23.22 gives the number of incidents by type of release.

The three major types of incident were collision, collision/overturn and overturn. The proportion of lading released in these cases was 30–40%. For fires, the release was large (98%) except in one case where it was very small (3%). Of these three types of incident, overturns caused most container damage. The authors suggest that in collision accidents, a large proportion of the energy is dissipated in other parts of the vehicle.

There were four evacuations of the public in the 41 incidents.

A similar analysis is given for the LPG incidents, but there were only nine of these.

Further more general data are given in the review of transportation of hazardous materials in Ontario by Gorys (1990).

Griffiths and Linklater (1984) have reported a study performed in 1980 of some 42 accidents involving road

Table 23.21 *Road transport environment in North America: probability and frequency of release of material in truck accidents in the USA (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

Freeway	0.062	0.14

tankers transporting flammable materials in New South Wales (NSW). In 1979, in NSW, there were some 3000 road tankers carrying flammable loads and some 100 pressurized tankers. The annual crash rate was 2.5%, which was the same as for all vehicles.

There were 42 accidents investigated, 11 involving non-articulated vehicles and 31 involving articulated vehicles. There were 18 rollovers, 5 for the non-articulated vehicles and 13 for the articulated vehicles.

In 24 cases there was no leakage of the bulk load but in three of these there was leakage of the prime mover fuel tanks. In 10 of the rollover cases, there was substantial leakage. In two of the non-rollover cases, the tank was punctured and burned out. Of the other non-rollover cases, one involved the loss of 'a lot' of product from a fractured pipe fitting, one a loss from a discharge pipe and two from vents.

The authors state that fire occurred in 5% of cases. This would seem to cover the two cases of burnout just mentioned and to imply that none of the other cases involved a fire.

The authors obtained data on the various factors which influenced the accident under the headings: mechanical, environmental, behavioural and general.

Factors causing rollover included high centre of gravity, 'soft' roll stiffness and sloshing of the liquid. None of the tankers appeared to have side baffles.

From these data, the following estimates may be made for crash fires:

No. of crash fires = 2

Crash fires as proportion of accidents = 2/42 = 4.8%

23.6.13 Individuality of accidents

It is easy in a preoccupation with incident statistics to lose sight of the individual nature of some of the accidents which have occurred involving the road transport of hazardous materials. Mention has already been made of the chlorine tanker crash with a lorry travelling down hill at 60 mph. Other incidents with rather unusual features include the San Carlos campsite disaster (Appendix 16), which may not have been initiated by either crash or fire and which involved a vulnerable target, and the explosion of an explosives lorry at Peterborough (Case History A125), which involved a fire rather than a crash and occurred off the road in a company yard.

Moreover, enough has been said to indicate that, even where historical data do exist, the data may or may not be directly applicable. A case in point is the provision of side protection on tankers. This is provided on the ICI chlorine vehicles but not on the Australian road tankers described. In such cases, it may be appropriate to modify any historical data to take account of the difference between the conditions to which those data apply and the conditions of the problem in hand. Again this may involve modelling and the use of data appropriate to that.

23.7 Rail Transport

23.7.1 Regulatory controls and codes

The international transport of dangerous goods by rail is the subject of the Convention Concerning International Carriage by Rail (COTIF) and is governed by the *Regulations Concerning the International Carriage of Dangerous Goods by Rail* (RID) (DTp, 1993b), as described in Section 23.2.

In addition, the International Union of Railways (IUR) issues information of an obligatory or recommended nature.

In the United Kingdom, British Rail (BR) has a number of internal regulations. There is no requirement on BR to accept dangerous goods for carriage. It has published the document *List of Dangerous Goods and Conditions of Acceptance* (LOG) (BR 22426) which lists the dangerous substances that it is prepared to accept and the conditions of such acceptance. The list is based on the United Nations (UN) classification. It incorporates relevant statutory requirements such as those for radioactive materials. The conditions cover maximum quantities, forms of packaging, labelling, documentation, etc., and conform as far as

Table 23.22 *Road transport environment in North America: tanker accidents involving release of gasoline in Canada (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

[b] One of these is classified as a spill/fire.

possible with UN recommendations. The Railways Act 1845 requires the consignor to give written indication of goods which are dangerous, and the Railways Act 1921 requires it to comply with the rules laid down by BR.

In addition to BR's general regulations, rules and procedures, for dangerous goods there are specific instructions to staff given in *The Working Manual for Rail Staff*, Part 3, *Handling and Carriage of Dangerous Goods* (BR 30054/3), commonly known as the 'Pink Pages'. This deals with the definition of dangerous goods and gives procedures for acceptance, marking, loading, unloading, marshalling and movement, and for incidents and fires.

In the United States, rail transport of hazardous materials is regulated by the DOT. The DOT Hazardous Materials Regulations (49 CFR Pt 179) apply to carriage by rail. The AAR complements the work of the DOT by setting standards.

23.7.2 Hazard scenarios

The hazard scenarios for rail transport of hazardous materials do not differ greatly from those for road described in Section 23.5. Thus, pool fires, torch fires, vapour cloud fires and explosions, and toxic releases may all occur in a broadly similar manner, as well as physical explosions and condensed phase explosions.

There are, however, a number of differences. One is that the energy in a train collision is much greater than that associated with a vehicle collision on a road. Another is that a train typically contains a number of tank wagons and these may be vulnerable to the initiating incident. A particular instance of this is that torch fires in which the flame from one tank wagon plays on another are much more significant. The rail environment also differs in respect of the population exposed to the event and of the access for the emergency services.

23.7.3 Rail tank wagon design

The RID gives requirements for the design of rail tank wagons which parallel those in the ADR for road tankers. For more hazardous materials, it is good practice to provide a strongly protected filling connection cover and buffer override protection.

Information on rail tank cars in the United States is given by Fitch (2003) in the *NFPA Handbook*. American rail tank cars are built to standards for freight cars generally and in addition must comply with the DOT Hazardous Materials Regulations and the *Specifications for Tank Cars* of the AAR. There are four main types of tank car:

(1) non-pressure tank cars;
(2) pressure tank cars;
(3) cryogenic liquid tank cars;
(4) other
    (a) high pressure service tank cars,
    (b) multi-unit tank cars.

Non-pressure tank cars have tank test pressures of 100 psi (6.89 bar) and pressure tank cars have test pressures of 100–600 psi (6.89–41.4 bar). Both types have capacities ranging from 4000 to 45,000 USgal (145–170 m^3). Cryogenic liquid tank cars carry liquids at −130 to −423°F (−90 to −253°C). The insulation is designed to protect the cargo for a 30-day period. Multiunit tank cars, or ton containers, carry demountable tanks which can be taken off the car for filling and emptying.

About 90% of the tank cars are constructed in carbon steel and most of the rest in aluminium. The regulations specify the following thicknesses of plate for the construction of tank cars: for non-pressure tanks, $^{7}/_{16}$ in. (11.1 mm) steel or $^{1}/_{2}$ in. (12.7 mm) aluminium, and for pressure tanks, $^{9}/_{16}$ in. (14.3 mm) steel and $^{5}/_{8}$ in. (15.9 mm) aluminium.

Tank cars may be provided with thermal insulation. The principal materials used are fibreglass and polyurethane foam. For cryogenic tanks, perlite is used. Some tanks are lined and some have heating coils.

The DOT has promoted a programme of protective measures to lessen the risk of tank rupture by overheating or puncture. These are:

(1) Thermal protection;
(2) Shelf couplers;
(3) Head shields.

The thermal protection is designed to protect the tank against a pool fire for 100 min or against a torch fire for 30 min. The shelf couplers are of a design which is less likely to disengage in a derailment. The head shields protect the lower part of the tank heads against puncture.

23.7.4 Rail system operation

The development of British practice in the movement of bulk chemicals by rail has been described by Sanderson (1981). The older method was to move small numbers of wagons through a series of marshalling yards; the newer method is to make up complete trainloads, or block trains, running between two points, so that rail transport becomes an integral part of the production line linking two works.

BR controls the movement of freight through the Total Operations Processing System (TOPS) computer system. This system makes it possible to keep track both of the movement of each individual wagon and of its position on the train. The system is particularly valuable in an emergency.

23.8 Rail Transport Environment

The basic sources of information on the rail transport environment in the United Kingdom are the Department of Transport and British Rail.

The *Transport Statistics Great Britain* 1976–86 (DTp, 1987b) and *Rail Safety – Report on the Safety Record of the Railways in Great Britain 1986* (DTp, 1987a) provide certain basic information. There are also available an appreciable number of accident reports.

Studies of the UK rail transport environment are given in the ACDS *Transport Hazards Report* (ACDS, 1991) and by P.A. Davies (1990). As already stated, the former considered four hazardous materials (motor spirit, LPG, chlorine and ammonia, and also explosives) whilst the latter was concerned with explosives, particularly munitions. Essentially these studies utilize two basic categories of information: (1) rail movements and (2) incident records.

23.8.1 Rail network and rolling stock

BR operates a rail network with 22,423 km of running line and 3601 km of sidings. There are some 70 marshalling yards.

In 1986, the distance travelled by freight trains was 54×10^6 km. In the year 1985–86, the distance travelled by loaded tank wagons containing both hazardous and non-hazardous chemical and petroleum products was 47.4×10^6 tank-wagon-km.

The ACDS report gives a detailed breakdown of the movements of the four materials considered, as shown in Table 23.23.

23.8.2 Rail accidents

Information on accidents involving freight trains generally is given in the study by Davies. The three main types of accident considered are collisions, derailments and fires.

The ACDS study deals mainly with accidents resulting in releases and with the ignition of releases of flammable materials.

From a study of general rail accident statistics, Davies gives the following breakdown of freight train accidents (FTAs) in 1986:

Type of accident	*No.*	*Proportion* (%)
Collision	113	35
Derailment	158	49
Fire	53	16
Total	324	100

Table 23.23 *Rail transport environment in Great Britain: tank wagon capacities and movements for four hazardous materials (after ACDS, 1991) (Courtesy of Elsevier Science Publishers)*

A Tank wagon capacities

Substance	*Tank capacity* (te) *2-axle*	*Bogies*
Motor spirit	32	75
LPG	20	40
Ammonia	–	53
Chlorine	29	–

B Tank wagon movements

	Motor spirit	*LPG*	*Ammonia*	*Chlorine*
Total movements (wagon-km/year)	10,199,095	13,90,590	1,348,080	313,668
Total wagon journeys (wagon-journey/year)	55,814	4,334	4,500	2,342

He also made a study of some 187 accident reports, of which 38 were for FTAs. This is referred to as the FTA study. In this study, he obtained the following breakdown of:

Type of accident	*No.*	*Proportion* (%)
Collision	26	68
Derailment	8	21
Fire	1	3
Other	3	8
Total	38	100

23.8.3 Collisions

In general, freight train collision accidents are more severe than derailments. For collisions in 1986, Davies gives:

Type of collision	*No.*	*Proportion* (%)
FTvsFT	8	7
FTvsPT	1	1
FT vs ECS	10	9
Buffer stop	55	49
Level crossing	6	5
Miscellaneous obstacles	22	19
Animals	9	8
Other	2	2
Total	113	100

where ECS denotes empty coaching stock, FT denotes freight train and PT denotes passenger train. The most severe collisions are with rolling stock. From the data just given, there were 19 such incidents (17%) which break down to give:

Type of collision with rolling stock	*No.*	*Proportion* (%)
FTvs FT	8	42
FTvsPT	1	5
FT vs ECS	10	53

From the FTA study, he found that some 70% of collisions with rolling stock were head-on or front/rear collisions and obtained for these the following breakdown:

Type of collision with rolling stock	*Proportion* (%)
Head on	40
Front on rear	40
Rear by front	20

The other 30% of collisions with rolling stock were side impacts or glancing blows.

The most frequent type of collision was with buffer stops but the speed at which these collisions occurred was generally 10 mph or below. This type of collision was considered sufficiently minor that in 1987 the practice of recording it was discontinued. It is worth noting, however, that a major disaster due to a collision of this type on a passenger train on the London Underground occurred at Moorgate station in 1975.

The number of collisions at level crossings involving freight trains was small, but for all trains the following breakdown was obtained:

Type of collision	*No.*	*Proportion* (%)
Train on car or van	18	78
Car or van on train	5	22
Total	23	100

The closing speeds at which collision accidents occurred are not known, but from an analysis of the FTAs in the FTAs survey, P.A. Davies and Lees (1991a) obtained the estimates shown in Table 23.24, Section A.

23.8.4 Derailments

Turning to derailments, these are generally less serious than collisions. The most severe derailments tend to be those which result in subsequent collisions. A study of derailments has been made by Taig (1980). He found that some 10% of derailments involve subsequent collision, 4% being with other rolling stock and 6% with other objects. Taig also presents a graph showing data on the speed at which derailments occur. These data are given in tabular form by Davies and Lees, as shown in Table 23.24, Section B.

23.8.5 Fires

As stated above, in 1986 there were 53 fires recorded on freight trains. Small fires are a not uncommon occurrence, but very few become severe.

Table 23.24 *Rail transport environment in Great Britain: accident speeds of freight trains (P.A. Davies and Lees, 1992) (Courtesy of Elsevier Science Publishers)*

A Freight train closing speeds in collisions with rolling stock[a]

Closing speed (mph)	*No. of collisions*	*Proportion of collisions* (%)
1–10	1	5
11–20	8	40
21–30	4	20
31–40	3	15
41–50	3	15
51–60	1	5

B Derailment speeds of freight trains[b]

Derailment speed (mph)	*Proportion of derailments*	
	On plain track (%)	*Not on plain track* (%)
1–10	15	54
11–20	20	20
21–30	6	6
31–40	18	4
41–50	26	4
51–60	9	4
61–70	3	4
71–80	2	4
81–90	1	0

[a] Estimated from accident reports. Sample size = 20.
[b] After Taig (1980). Sample size = 300.

Fires may be classified as crash fires and non-crash fires. In the 187 accident reports for all trains initially reviewed for the FTA study, only one involved a non-crash fire, which was not on a freight train. By contrast, in the 38 reports of FTAs, there were 6 crash fires. Four of these resulted from collisions and two from derailments. All 6 fires were quite severe. On this basis, the ratio of crash to non-crash fires is of the order of at least 6 : 1. Since there were 34 crashes (collisions and derailments) in the survey, the probability of a fire given a severe crash is 0.18 (= 6/34).

23.8.6 Releases

Turning to accidents resulting in leaks, the ACDS report considers two categories of accident: (1) puncture of a tank wagon by collision or derailment and (2) failure or maloperation of the tank wagon equipment.

It considers each of the four study materials in turn. For motor spirit

$$\text{Distance travelled} = 10.2 \times 10^6 \text{ tank-wagon-km/year}$$

There were four puncture incidents in a 6.25-year period, giving:

$$\text{Frequency of puncture of motor spirit tank wagon} = 6.3 \times 10^{-8} \text{/tank-wagon-km}$$

The report also mentions a BR estimate of puncture frequency of 10^{-8}/tank-wagon-km.

For the liquefied gases, it refers to a study by ICI on incidents with the possible potential to cause puncture of a chlorine or ammonia tank wagon. In the 7-year period 1980–86, there were on tank wagons generally seven puncture incidents. These all occurred on tank wagons with 'thin' (6 mm) walls. It was estimated that for such incidents the average probability of puncture of a chlorine tank wagon was 0.0385 and that for an ammonia wagon 0.103. Then utilizing the figure of 47.4×10^6 tank-wagon-km travelled by all laden tank wagons each year, the following estimates are obtained:

Frequency of puncture of chlorine tank wagon
$= 0.9 \times 10^{-9}$/tank-wagon-km

Frequency of puncture of ammonia tank wagon
$= 2.5 \times 10^{-9}$/tank-wagon-km

The frequency of puncture of an LPG tank wagon was taken as the same as that for an ammonia wagon.

The other leak mode is failure or maloperation of the tank wagon equipment. These leaks were assumed to be relatively small. Estimates of the frequency of such leaks per 10-h journey were made using fault trees, which are given in the report. The following results were obtained:

	Frequency of leak (leaks/journey)
LPG	0.83×10^{-8}
Chlorine	3.1×10^{-8}
Ammonia	1.3×10^{-8}

No evaluation was made for motor spirit, since the consequences were judged to be minor.

23.8.7 Release ignition

For the probability of the ignition of a leak of flammable material, BR incident reports showed that of five leaks over a period of 6.25 years, one ignited. The ACDS report bases its estimates partly on these data and data from fixed sites, and partly on judgement. It gives for small spills, whether of motor spirit or LPG, probabilities of 0.1 for immediate ignition, 0 for delayed ignition and 0.9 for no ignition. For large spills of motor spirit, the corresponding probabilities are 0.2, 0.1 and 0.7 and those for large spills of LPG are 0.2, 0.5 and 0.3, respectively.

23.8.8 Marshalling yard incidents

The ACDS report also considers activities in marshalling yards. BR operates some 70 such yards, but the majority of movements of dangerous goods are by block trains which do not enter marshalling yards.

In the 8-year period to the end of 1987, there were two puncture incidents. These involved methanol tank wagons punctured in collisions, one by a coupling hook and the other by a shunting engine. On this basis, the report obtains a generic value for the puncture frequency of 'thin' walled tank wagons:

Frequency of puncture $= 3.6 \times 10^{-3}$/yard-year

This implies similar levels of traffic at all yards.

For the four study substances, the proportions travelling by Speedlink service are: motor spirit, <1%; LPG, 28%; chlorine, 53%; and ammonia, >1% (occasional wagon load returned to its origin).

Based on arguments relating to the differences between thin- and thick-walled tank wagons, the probabilities of puncture given an incident of the type just described were estimated as 0.01 for LPG and ammonia tank wagons and 0.005 for a chlorine tank wagon.

One of the busiest marshalling yards was selected for detailed study. The substance principally considered there was chlorine. The yard handles some 78% of the Speedlink chlorine traffic, or some 1500 chlorine tank wagons per year. It was estimated that the yard handles a total of 7990 laden tank wagons of hazardous substances per year.

The frequency of a chlorine leak due to a puncture of a tank wagon at this particular yard was then obtained as:

Frequency of puncture of chlorine tank wagon

$$= 3.6 \times 10^{-3} \times 0.005 \times \frac{1500}{7990}$$
$$= 3.4 \times 10^{-6}/\text{year}$$

It may be noted that in deriving this figure for a busy yard, it is the generic figure for puncture frequency for all yards which is used.

For leaks due to failure or maloperation of equipment, use was made of the data obtained in the *en route* study, as given in Section 23.8.6. On the assumption that one-tenth of the total journey time is spent in the marshalling yard, the probability of a chlorine leak due to this cause was obtained as 3.1×10^{-9} journey. Then

Frequency of leak due to equipment failure of chlorine tank wagon $= 1500 \times 3.1 \times 10^{-9}$
$= 4.6 \times 10^{-6}$/year

The other main study substance passing through marshalling yards is LPG. The yard studied handles some 200 laden wagons per year. However, LPG tank wagons are not actually marshalled. In view of this, the generic puncture frequency was reduced by a factor of 5. Then, taking the probability of puncture of an LPG tank wagon in an incident which would puncture a thin-walled wagon as 0.01, as given above, the frequency of an LPG leak due to puncture of a tank wagon at this particular yard was then obtained as:

Frequency of puncture of LPG tank wagon

$$= 3.6 \times 10^{-3} \times \frac{1}{5} \times \frac{200}{7990}$$
$$= 4.6 \times 10^{-6}/\text{year}$$

23.8.9 Exposed population

The population exposed in a rail transport accident comprises the *en route* population and the other rail users, particularly passengers in other trains, together with the emergency services.

Meaningful assessment of the societal risk from rail transport requires the use of a reasonably refined population exposure model. The models used in the ACDS report are described in Appendix 17.

23.8.10 US environment

In the United States, the total railroad track mileage in 1981 was 327,000. From a survey of US and Canadian Class 1 railroads for 1983, the length of line surveyed was 145,881 which was 69.5% of the total track. This therefore gives for those two countries a total mileage of 209,900 for this class of track.

In 1986, there were in use in the United States some 183,000 tank cars, which comprised some 10% of the total fleet of freight wagons.

The NTSB *Annual Report* 1980 gives the railroad accident rate in 1979 for passenger and freight trains in the Unites States as 12.8 accidents per 10^6 train-miles. The 1981 *Report* gives for 1980 the following breakdown of causes of train accidents: track defects, 41%; mechanical/electrical failures, 17%; human factors, 28%; and other, 14%.

The main causes of accidents leading to loss of containment of hazardous materials from rail tank cars are derailments and collisions. One principal casue of such accidents is the state of the track and of the rolling stock.

23.9 Road and Rail Tunnels

Both road and rail systems include tunnels. In principle, differences may be expected from open routes with respect to both the frequency and the consequences of incidents, but there are certain common features between road and rail tunnels as well.

Accounts of tunnels tend to be either descriptions of incidents or hazard assessments. Case histories involving tunnels are described in Section 23.21 and hazard assessment is described in Section 23.26.

23.10 Waterway Transport

The extent of waterway movement of hazardous materials is small in the United Kingdom, but it is considerable in Europe and the United States. The Rhine and the Mississippi are major arteries. Accounts of waterway transport have been given by H.P. Nelson (1964), Backhaus and Janssen (1974) and Ligthart (1980).

In the United Kingdom, British Waterways bylaws apply to the transport of dangerous goods on canals. It issues a document on the terms and conditions of acceptance.

In the United States, the responsibilities of the US Coast Guard extend to inland waterways. The US Army Corps of Engineers is also involved through its responsibility for waterfront structures and embankments, canals, bridges and dams.

Backhaus and Janssen quote the maximum size of LNG barge which might be used on the Rhine as 108 m long × 11.4 m broad. Alternatively, use might be made of four barges with a push tug with total dimensions 185 m long × 22.8 m broad.

The construction of the barge tends to vary with the type of material which it carries. In the United States, for example, for petroleum, the barge shell is also the container wall, whereas for chlorine there are separate chlorine tanks within the barge structure.

A principal hazard of barge transport is collision. It is important to minimize the risk of this, not only when the barge is on the move but also while it is loading or unloading.

Another hazard of barge transport arises where barges are used to carry a variety of chemicals. While skilled people are generally available to assist at the loading point, the barge operator may well be on his own at the unloading point.

In the United States, the Coast Guard has attempted to improve the competence of barge crews by encouraging them to take specific training as chemical tankermen.

The NTSB annual reports describe measures to reduce collisions. In particular, efforts have been made to improve bridge-to-bridge communications.

A study of the hazards of transport of LPG on inland waterways has been described by Ligthart (1980). He states that serious risk arises only from collisions, although he qualifies this by excluding risks from cargo treatment, cleaning and repair.

23.11 Pipeline Transport

23.11.1 Regulatory controls and codes

The movement of hazardous materials by pipeline in the United Kingdom is regulated by the Pipelines Act 1962 and enforced by the Pipelines Inspectorate. The Act distinguishes between local pipelines (less than 10 miles long) and cross-country pipelines (greater than 10 miles long).

In the United States, pipeline transport is regulated by the DOT through the Natural Gas Pipeline Safety Act 1968 and related legislation for other hazardous materials. Relevant regulations include Pipeline Safety Program Procedures (Part 190) and Transportation of Natural and Other Gas by Pipeline: Minimum Federal Safety Standards (Part 192).

Some standards and codes for pipelines include BS CP 2010: 1970 – *Design and Construction of Steel Pipelines in Land*, the ASME *Code for Pressure Piping* B31.4: 1974 *Liquid Petroleum Transportation Systems* and B31.8: 1975 *Gas Transmission and Distribution Piping Systems*, the IP *Pipeline Safety Code* (1982 MCSP Pt 6) and IGE/TD/1 *Steel Pipelines for High Pressure Gas Transmission* (IGE, 1984).

23.11.2 Hazard scenarios

For a pipeline carrying flammable gas, some principal hazard scenarios are a jet fire and a flammable vapour cloud, leading to a flash fire or vapour cloud explosion, whilst for one transporting liquid, the scenario is a liquid spillage leading to a pool fire or flowing liquid fire. The main hazard scenario for a pipeline carrying toxic gas or liquid is a toxic vapour cloud.

23.11.3 Pipeline economics

The economics of pipeline transport have been discussed by Lennart (1964). The cost breakdown for pipelines is quite different from that for other modes of inland transport. At that time, for pipelines, the total costs were approximately 70% fixed costs and 30% variable costs, whilst for waterways, road and rail, the fixed costs were 30%, 15% and 5% and the variable costs 70%, 85% and 95%, respectively. Moreover, the cost index n relating the capital cost C to the throughput P

$$C = kP^n \qquad [23.11.1]$$

where k is a constant, is very low. Lennart gives the capital cost of a 6 in. line as only about 45% more than that of a 4 in. line. Thus, for the supply of an assured market at a fixed point, a pipeline is a very attractive mode of transport.

23.11.4 Pipeline systems

In Western Europe and North America, there are large pipeline systems carrying predominantly hydrocarbons.

For the former, statistics on the pipeline network are given in *Performance of Oil Industry Cross-Country Pipelines in Western Europe: Statistical Summary of Reported Spillages – 1991* (CONCAWE, 1991 4/92), which is part of an annual series.

In 1991, Western Europe had 210 service pipelines with a total length of 21,000 km. These pipelines carry some 593 million cubic metres of crude oil and refined products, giving a total movement of $101 \times 10^9\ \text{m}^3$-km. Maps showing the pipelines in Western Europe as a whole and in particular areas are given in the CONCAWE report.

Statistics on pipelines in the United States are collected by the Federal Energy Regulatory Commission (FERC). Periodic reviews are given in the *Oil and Gas Journal*. In the review of the 1984 figures by True (1985), the mileage of interstate pipelines is given as, for gas, 258,204 miles and, for liquid, 173,922 miles.

Sources of information on pipeline failures also often contain information on the size of pipeline systems.

23.11.5 Pipeline design and operation

Pipelines are usually buried about 1 m below ground. Their environmental impact is therefore usually minimal and they can be difficult to detect even by aerial survey unless there are sufficient marker posts.

The extent to which the temperature of the gas in a pipeline varies depends on the depth at which it is buried, but for most pipelines in the United Kingdom the variation is small, although this is not always so in other countries.

The standards of construction and protection of pipelines have improved markedly over the years. The older pipelines were of mild steel or cast iron. The former have often corroded, while the latter have often withstood conditions better. There are cast iron brine mains, for example, which have remained in good condition. But cast iron has a relatively low resistance to impact and is not an ideal material for pipelines for hazardous substances.

Mild steel is now generally used for pipelines, but it is of much higher quality, being more uniform and better extruded or seam welded. Welds on the pipeline are more carefully done.

Pipelines are also much better protected. The older pipelines had no specific external protection. Then the wrapping of lines was developed, culminating in the present practice of using a coal tar/glass fibre wrap. But this was not the whole answer, because corrosion still occurred at points where the wrapping was badly done or was damaged or where there were line joints.

This problem has been largely overcome by the use of cathodic protection. Corrosion of steel involves iron passing into solution as an ion. This process may be reduced by impressing on the pipe a suitable voltage. It is still necessary to wrap the pipe, because the currents required with unwrapped pipe are excessive. But cathodic protection gives effective protection at defects and gaps on a wrapped pipe.

The modern method of external protection, therefore, utilizes a combination of wrapping and cathodic protection. With this system, minimum external corrosion rates are obtained.

Internal corrosion depends on the material transported, but in many cases, it is very low.

Pipelines are regularly inspected for corrosion, both external and internal. The internal surface of the pipe may be checked by instrumentation transported through the pipe by an 'intelligent pig'.

A code of practice for pipelines is provided by the *Pipeline Safety Code* by the IP (1982 MCSP Pt 6). This deals with the design, materials, land and rights of way, construction, testing, cathodic protection, operation, maintenance and emergency procedures.

The internal pressure of the pipeline should not be less than the normal maximum working pressure plus any anticipated surge pressure. The minimum wall thickness for a straight pipe under internal pressure is determined by the formula

$$t = \frac{pD}{20 f_y a} \qquad [23.11.2]$$

where a is a design factor, D is the external diameter of the pipe (mm), f_y is the specified minimum yield strength (N/mm^2), p is the internal design pressure above atmospheric pressure (bar), and t is the design thickness of pipe wall (mm). The design factor a is taken as 0.72 for gas and liquid pipelines in remote areas.

Protective devices such as pressure relief devices and shut-down systems should be fitted to prevent the line pressure rising more than 10% above the internal design pressure and to deal with fluid expansion effects.

The Institute of Petroleum (IP) code describes a number of additional protective measures which may be provided to avert damage to a pipeline. They are: (1) increased earth cover; (2) increased coating strength; (3) an additional protective coating of concrete, provided this does not screen cathodic protection currents; (4) additional position markers on the surface; (5) increased pipe wall thickness; (6) provision of a casing sleeve and (7), for above ground pipelines, provision of impact protection.

In some areas, design of the pipeline against earthquakes assumes greater importance. Accounts of the seismic design of pipelines include those of Newmark and Hall (1975), Shinozuka, Takada and Ishikawa (1979) and Jinsi (1985).

Increasingly use is made of trenchless technology, in which a pipeline is installed, replaced or repaired without removing the earth above it. It is used particularly for water and gas distribution systems. An account of the set of technologies which come under this heading is given in *Introduction to Trenchless Technology* (International Society for Trenchless Technology, 1991). Whilst the techniques are applicable to distribution rather than transmission systems, they have been used for pressure piping and for quite large diameter pipes. Upsizing of pipes of 225 and 355 mm diameter is well established and pipes of up to 600 mm diameter have been done.

23.11.6 Hydrocarbon pipelines

The majority of pipelines carry flammable gases such as natural gas, ethylene or LPG or flammable liquids such as crude oil, oil products or NGL. It is to hydrocarbon pipelines that the account given so far mainly relates.

23.11.7 Ammonia pipelines

There are some very extensive liquid anhydrous ammonia pipeline systems, especially in the United States. The ammonia is mainly used by farmers in the corn belt as fertilizer.

Descriptions of the Mid-America Pipeline System are given by Rohleder (1969) and by Luddeke (1975) and of the Gulf Central System by Inkofer (1969).

The Gulf Central pipeline described by Inkofer has a 10 in. diameter trunk line 548 miles in length running south to north with two spur lines off it. One of these has 417 miles of 8 in. line and 235 miles of 6 in. line, the other has 234 miles of 8 in. line and 153 miles of 6 in. line. The design study was for a line operating at a pressure of 1440 psig (100 bar) and in the temperature range 35–75°F (2–24°C). Details of the design codes, materials and inspection methods are given by Inkofer.

The hazard of brittle fracture was given special consideration. Cases have occurred where brittle fracture has propagated along a pipeline at a velocity close to that of sound in the metal. Thus, a large length of line could be affected. The maximum transition temperature for the pipeline was set at 0°F (−17.8°C), which is well below the normal operating temperature range. Above the transition temperature, ductile shear failures may occur, but these were considered less serious.

The composition of the anhydrous ammonia is closely controlled to prevent attack on the pipeline. Impurities in ammonia, such as air or carbon dioxide, can cause stress corrosion cracking. This is largely inhibited, however, if the ammonia contains 0.2% water and this water content is specified as a minimum.

The pipeline has at approximately 10-mile intervals shut-off valves which can be closed manually. At the same points there are also check valves which prevent back flow from the line section ahead of the rupture point. At rather greater intervals there are pump stations with instrumentation that detects any sudden changes of pressure caused by a line break and stops pumps and closes automatic shut-off valves.

The situation arising in the event of a leak is considered by Inkofer. For a small leak, he suggests that, in theory, the ammonia should freeze the surrounding ground, but this was queried in the discussion, where it was pointed out that practical experience indicates that small leaks of ammonia actually tend to dissolve in water and generate heat.

With a large leak due a major pipeline rupture, the line break detectors would stop the pumps and shut the isolation valves at the upstream pump station and the suction pressure controls would stop the pumps at the downstream pump stations, so that the pipeline break would be isolated to a single section.

There would be an initial high pressure spurt of ammonia as the pipeline pressure vented. The line pressure would then fall to that corresponding to the vapour pressure of ammonia at the line temperature, that is, 107 psia at 60°F. Several other effects would further reduce the rate of discharge. Vapour locks would form at humps along the pipeline, and these would cause a back pressure due to the accumulated liquid heads created by each rise in the line ending in a vapour pocket. Flashing of vapour would cool the remaining liquid. The overall results of these effects would probably be that after the initial spurt of flashing liquid there would be a period of prolonged and spasmodic ejection of liquid and vapour.

The proportion of ammonia flashing off from saturated liquid at 60°F and 107 psia is approximately 10%. The remaining liquid would be cooled to −28°F and would form a pool. The evaporation from this pool would be in the range 1–7 lb/ft^2 h and thus fairly slow.

A 10-mile section of 10 in. line at 60°F contains 591 ton of ammonia and, assuming 90% of this forms a pool at −28°F, the resulting 24,990 ft^3 could form a pool of 12,495 ft^2 with a depth of 24 in., or one of 149,940 ft^2 with a depth of 2 in.

The pipeline is continuously monitored by a pipeline dispatcher. In the event of a line break, he will know the location between the particular pump stations. He then sends out a team to locate the break more precisely, to shut all isolation valves in the section affected and to open blowdown valves in order to encourage the formation of vapour locks. The basic procedure for containing the spillage is to dike around it. The line is then excavated and the rupture repaired. If necessary, stopple plugs are inserted into the line to shut off the flow.

The vapour from an ammonia line break is initially cold and heavier than air. It can travel in lethal concentration several miles. The dispersion of vapours from ammonia spillages was considered in more detail in Chapter 15.

The description given by Rohleder and by Luddeke of the Mid-America Pipeline system is broadly similar.

23.11.8 Chlorine pipelines

Pipeline transport of chlorine is much less extensive than that of ammonia. Chlorine lines are dealt with in *Chlorine Pipelines* (Chlorine Institute, 1982 Pmphlt 60). Further discussions are given by Danielson (1964) and H.P. Nelson (1964).

The chlorine may be transported either as vapour or as liquid. A vapour line should be operated with vapour phase only and a liquid line with liquid phase only. The situations which might give rise to mixed phase conditions should be identified and measures taken to avoid them.

The Chlorine Institute recommends that for any chlorine pipeline the maximum pressure should not exceed 300 psig (21 bar). However, this should not be construed as the design criterion. It recommends also that the maximum temperature at any section of the pipeline should not exceed 250°F (121°C).

The pipeline may be above or below ground. A line above ground is easier to monitor for external corrosion but an underground line may be safer in some circumstances. If the line is buried, consideration should be given to the frost line.

Internal corrosion is very low if the chlorine is dry, but is markedly increased by small quantities of water. It is essential, therefore, to design the line to facilitate drying out, to ensure that thorough drying is carried out and to keep the chlorine product dry.

Liquid chlorine has a very high coefficient of thermal expansion and it is necessary, therefore, to protect lines against hydrostatic rupture. The Chlorine Institute recommends the use of a pressure relief valve or bursting disc discharging to a receiver or safe area or, alternatively, the use of an expansion chamber. Nelson states that an expansion chamber should have a capacity of 20% of the line volume. If an expansion chamber is used, it should be properly operated and maintained, so that air in the chamber is not gradually replaced by chlorine.

The provision of a means for the control of line breaks is particularly important with a chlorine pipeline. Automatic shut-off valves may be installed for gas or liquid lines, while excess flow valves may be used as an alternative on liquid lines. A combination of both devices may be preferable for the liquid case.

23.11.9 Pipeline failures

For Western Europe, the publication *Performance of Oil Industry Cross-country Pipelines in Western Europe 1991* (CONCAWE, 1992 4/92), one of a continuing series, gives details of pipeline failures.

In the United States there appears to be no single body which regularly publishes information on pipeline failure. Pipeline operators are required to report leaks to the DOT. The DOT issues an annual report on natural gas pipelines. Major pipeline accidents are investigated by the NTSB. Both organizations periodically publish information on pipeline failures.

A survey on the *Safety of Interstate Natural Gas Pipelines* by the Federal Power Commission (FPC) (1966) gives information on failures in these pipelines in the $15\frac{1}{2}$-year period from January 1950 to June 1965. The length of transmission pipelines covered was 204,730 miles in 1964. The number of failures recorded in the period was 1058 line failures, 121 compressor or metering station or other facilities failures, and 1115 field testing failures. Employees suffered 35 deaths and 135 injuries, and non-employees 29 deaths and 87 injuries. Of the 64 deaths, 42 arose from failures in lines and 17 from failures in compressor or metering stations or other facilities. The causes of the line failures are analysed in Table 23.25. The relations between the number of failures and of casualties over the $15\frac{1}{2}$-year period and the pipe sizes are given in Table 23.26.

The *Annual Report on the Administration of the Natural Gas Pipelines Safety Act of 1968* by the DOT for 1974 states that in 1974 there were 335,000 miles of natural gas gathering and transmission pipelines, and that in the period 1970–74 there were 2093 failures. From these data, the failure rate for such pipelines was 1.25×10^{-3} per mile per year. In this period, there were eight fatalities to employees and the same number for non-employees. Causes of the 460 failures in 1974 are broken down as follows:

Cause	*Proportion* (%)
Damage by outside forces	59.5
Corrosion	17.0
Construction defect or material failure	17.6
Other	5.9

The annual report on pipeline failures up to 1976 by CONCAWE (1977 9/77) states that between 1972 and 1976, the combined length of oil industry pipelines increased from 15,800 to 18,100 km and that in the period 1972–76, there were 93 spillages. From these data, assuming an average of 17,700 km of pipeline over the period, the failure rate obtained for such pipelines is 1.05×10^{-3}/km-year. The causes of the 93 failures are categorized in Table 23.27, first column. The corresponding report up to 1991 by CONCAWE (1992 4/92) states that in 1991 there were some 21,000 km of pipeline and that in the period 1987–91 there were 50 spillages. Assuming an average of 20,000 km of pipeline over the period, the failure rate obtained is 0.5×10^{-3}/km year. The causes of the 50 failures are categorized in Table 23.27, second column.

Unknown or unreported	55
Total	1058

Table 23.26 *Failure of interstate natural gas transmission pipelines in the USA 1950–65: failures by pipe diameter (after Federal Power Commission, 1966)*

Pipe diameter (in.)	*No. of failures reported*	*Failures per* 1000 miles	*No. of casualties reported*
0–5.0	141	10.6	4
5.1–10.0	324	11.6	25
10.1–15.0	132	9.0	9
15.1–20.0	278	12.0	43
20.1–25.0	97	5.9	35
25.1–30.0	62	2.6	31
>30.0	5	2.8	11
Unreported	19	–	9

Further information on gas pipelines operated by the British Gas Corporation (BGC) has been given by Knowles, Tweedle and van der Post (1977). They state that since 1970, all faults on the transmission system have been recorded and that up to August 1977 there had been 309 repairable incidents, of which 73 were defined as 'lost gas' incidents. The following classification is given:

Mechanical interference (including coating damage)	204
Corrosion (internal and external)	32
Other faults (including faulty seal on pig trap door, leaking flanges, cathodic protection pad weld crack, etc.)	56
Girth weld	9
Pipe defect	5
Ground movement	3
Total	309

The interference incidents are further broken down as shown in Table 23.28. The total number of leaks includes broken connections and piercing of the carrier pipe, while the number of leaks due to excavating machinery covers piercing of the carrier pipe only.

A failure rate of 5×10^{-3}/mile-year for chlorine pipelines was used by Westbrook (1974) in his assessment of the hazard of this mode of chlorine transport, as described in Chapter 18.

A study of pipeline failure rates in which the prime concern was with failure of offshore pipelines in the North Sea has been described by de la Mare and Andersen (1981). The work draws on the data sources already mentioned, that is, the DOT for the United States, CONCAWE for Western Europe and British Gas for the United Kingdom, and also the USCG for the Gulf of Mexico, Gaz de France (GdF) and the E&P Forum for the Arabian Gulf. The authors quote the following failure rates: CONCAWE, for onshore crude oil and product pipelines in Western Europe 1966–76, 0.39×10^{-3}/km-year for crude oil, 1.11×10^{-3}/km-year for products, and overall 0.69×10^{-3}/km-year; British Gas, for its gas transmission network 1970–77, 0.65×10^{-3}/km-year; Gaz de France, for its gas transmission network 1967–77, 3.3×10^{-3}/km-year; USCG, for offshore pipelines (6–18 in.) in the Gulf of Mexico, for oil 17.4×10^{-3}/km-year and for gas 12×10^{-3}/km-year. The North Sea had recorded two failures, giving a failure rate of 0.7×10^{-3}/km-year, but with 95% confidence limits 0.067–2.5.

The authors conclude that: the failure rates of pipelines appear similar even where the fluid handled and the environment are different; that the failure rates of oil pipelines depend on the diameter; that about half the failures can be attributed to external factors; and that pipelines tend to exhibit wearout failure. On this latter point, they quote CONCAWE data for the times to the first, second and later failures, and analyse these data to demonstrate that wearout failure occurs.

Another study of pipeline failure, confined to oil lines, is that given by Blything (1984 SRD R326), who considers pipeline failures in the United States, Canada and Western Europe, using data from the DOT and NTSB, the Canadian Petroleum Association (CPA) and CONCAWE, but mainly from the latter. Some of their analyses of the CONCAWE data for Western Europe are given in Table 23.29. Section A of the table gives the number of failures by pipe diameter and cause, Section B, the overall frequency of failure by pipe diameter and Section C, the size of the defects and spills.

Section A shows that the most important causes of failure are third party activity (TPA) and external corrosion. Both are dependent on the diameter of the pipe. The other two causes are less significant and less diameter dependent. External corrosion is also a function of the fluid carried and is most frequent on lines conveying heavy fuel oil (HFO). This mode of failure is often by pinhole leaks and tends to have a low potential for major hazard.

Section B of the table shows that the overall failure rate of the pipeline decreases with increasing pipe diameter.

The data on size of defects were somewhat sparse. Some 21 incidents were found in the data for Western Europe and Canada where defect size was recorded. Of these, 15 were caused by TPA. The defects were either holes or partial penetrations which failed at a later date. For some of

these incidents, it was possible to estimate the size of the spill. Data for these incidents are given in Section C of Table 23.29. Details on each of the 21 incidents are given by Blything.

These two reports give a wealth of further information on pipeline failures. As described, the main cause of failure in pipelines is interference, or TPA. In particular, damage occurs to pipelines from earth-moving and excavating equipment. Most pipelines can be punctured by the tooth of a mechanical excavator with the possible exception of very large mains, which have a thickness of about $^1/_2$ in. In rural areas, this may arise particularly from ditching and land drain work; in urban areas from work on services such as water, gas, electricity and sewage. It is essential, therefore, for the pipeline operator to keep a close watch on activities which may give rise to the hazard and for him to liaise with the authorities involved with planning and utilities. Moreover, it should be borne in mind that the person who needs to know is the excavator operator, and the organizations concerned should understand their responsibilities to ensure this.

23.12 Marine Transport: Shipping

Marine transport is distinguished from the other modes of transport in a number of ways. These include its international nature, which has many aspects; the size of the cargoes carried; and the marine environment.

General accounts of marine transport are given in the ACDS *Transport Hazards Report* (1991), *Safer Ships, Cleaner Seas* (Donaldson, 1994) (the *Donaldson Report*) and *The Carriage of Bulk Oil and Chemicals at Sea* (Rawson, 1994), which may be supplemented by the references cited below.

23.12.1 Shipping industry

Marine safety needs to be viewed against the background of the shipping industry and its particular characteristics. An account of this background is given by Gilbert (1994). Since 1945, international trade has experienced an explosive growth. One consequence has been a massive increase in vessel size. Contrary to what might be expected, the industry is a ‘low entry’ one. As Gilbert states, ‘In boom times, banks and financial institutions have been only too willing to lend money to almost anyone who could submit a reasonable prospectus'.

Most ships are custom built. The owner identifies a particular market. Shipyards are then prepared to tailor the design to the owner's requirements. Ships are built with single or double hulls, single or twin screws, and slow or medium speed engines, in combination with a wide variety of cargo, ballast and fuel systems. This is in marked contrast, for example, with the situation pertaining to the design of aircraft.

Another characteristic feature is manning. Crews often contain many nationalities, some of whom may have difficulty in communicating with each other.

Shipping is vulnerable to the international economic cycle, so that in bad times large numbers of ships are laid up and sections of the industry are barely viable. This increases reluctance to incur expenditure on safety.

The international nature of the industry and the resistance of a large part of it to effective controls has meant that international agreements have tended to represent the lowest common denominator.

23.12.2 Hazard scenarios

A marine accident may pose a major threat not only to life but also to the environment.

A loss of containment of a material may occur due to damage to the cargo tanks or during loading and unloading operations. A serious hazard to life may arise from the release of a large quantity of flammable or toxic liquefied gas onto water, where it will vaporize rapidly, in or near a port. The USCG has commissioned studies of the hazard arising in this situation, such as the one by Eisenberg, Lynch and Breeding (1975). However, although much feared, this hazard has not so far been realized on a large scale.

Shipboard fire and explosion is another serious hazard and one which does occur periodically. The initiating event may be a fire in the engine room, the pump room, a cargo tank or elsewhere. Or it may be an explosion in the engine room or cargo tank. A particular hazard exists if the ship carries explosive substances. Some of the most devastating explosions have occurred from the explosion of ammonium nitrate cargo.

Loss of cargo also presents a threat to the environment. Here oil cargoes present a particular threat, since oil is carried in large quantities and is liable to do damage to the marine environment which it is difficult to prevent.

23.12.3 Ship design

Fundamentals of ship design are described in *Principles of Naval Architecture* (Comstock, 1967), *Basic Ship Theory* (Rawson and Tupper, 1968–), *Basic Naval Architecture* (Barnaby, 1969) and *Mechanics of Marine Vehicles* (Clayton and Bishop, 1982). Liquefied gas carrier (LGC) design is described in *Liquefied Gas Handling Principles on Ships and in Terminals* (SIGTTO, 1986/3). Accounts of ship design and construction with special reference to hazards are given in *Incidents Involving Aircraft, Shipping and Railways* (Home Office, 1985 *Manual of Firemanship* Bk 4) and in the *NFPA Handbook*.

A ship is essentially constructed as a box girder formed by the hull and the main deck and strengthened by members such as the keel, frames, bulkheads and other decks.

Cargo ships are of two broad types: (1) dry cargo ships and (2) bulk cargo ships. The first group is general purpose dry cargo ships carrying smaller quantities in packages, drums and tank containers, and includes general purpose ships, container ships, and roll-on/roll-off (RoRo) passenger (and cargo) ships. The second group is ships for the bulk transport of (1) crude oil, (2) petroleum products, (3) LNG, (4) LPG and other liquefied gases and (5) chemicals.

Figure 23.5 illustrates some typical vessel designs. Figure 23.5(a) shows a cargo vessel; Figure 23.5(b) an ore/bulk/oil (OBO) carrier; and Figure 23.5(c) a chemical tanker, or tank vessel. An oil tanker is broadly similar to the latter in respect of the layout of the holds, but tends to be very large. Figures 23.5(d) and (e) show two types of LPG carrier, and Figure 23.5(f) shows an LNG carrier.

Older tank vessels have pump rooms, one forward and one aft between the engine room and the last cargo tank. In newer vessels the pump rooms are eliminated by the use of deep well pumps.

A gas carrier, for liquefied gases, has cargo tanks which may operate at atmospheric pressure or higher pressure. Such tanks may be integral with the vessel or independent of it.

Further treatment of ship design is deferred to Section 23.16, where a description is given of liquefied flammable gas (LFG) carriers and chemical tankers.

An account of the influence of the chemicals carried on ship design and operation, as reflected in the provisions of the IMO codes, has been given by Farrell (1982).

23.12.4 Ship operation

The transport of hazardous materials by ship calls for an approach to loss prevention very similar to that required for land installations. The management and the systems and procedures are crucial. There should be identification and assessment of hazards. An effective instrument system, with trips where necessary, is required. There needs to be a variety of fire protection measures. Operations such as loading and unloading should be carried out in accordance with specified procedures. There should be an inspection system with appropriate record keeping akin to that used for pressure systems. The equipment should be well maintained and control exercised over modifications. There should be a permit-to-work system. Personnel should be thoroughly trained in all these aspects.

Operations of particular relevance here are the loading and discharge of cargo and the operations on cargo tanks. These are discussed in Sections 23.14–23.17.

Inspection of tanks is covered in *Guidance Manual for the Inspection and Condition Assessment of Tanker Structures* (ICS, 1986/5), *Guidelines on Surveys Required by the 1978 SOLAS Protocol, the IBC Code and the IGC Code Fire Test Procedures* (IMO, 1987 IMO-858), *Inspection Guidelines for Bulk Carriers* (OCIMF, 1989/8), *Inspection Guidelines for Ships Carrying Liquefied Gases in Bulk* (OCIMF, 1990/10) and *Condition Evaluation and Maintenance of Tanker Structures* (ICS, 1992/12)

23.12.5 Particular chemicals

An important category of substances moved by sea is liquefied gases. These are not confined to LNG and LPG or even other hydrocarbons, but include a number of other major chemicals.

A gas tanker is often designed to carry not only LPG but also ethylene, ammonia and vinyl chloride monomer as the principal cargoes, but the list of products may well be

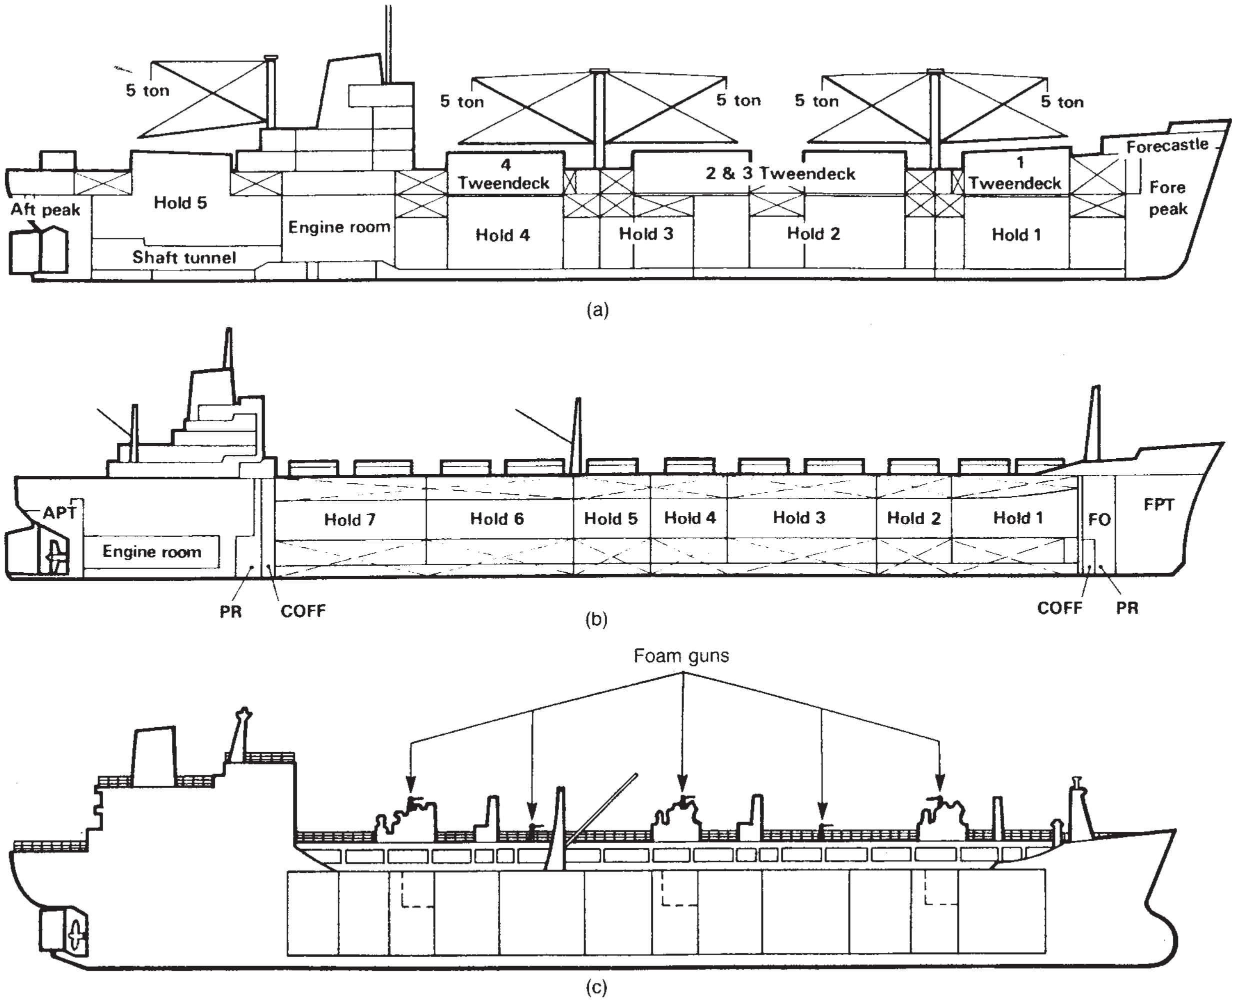

Figure 23.5 *continued*

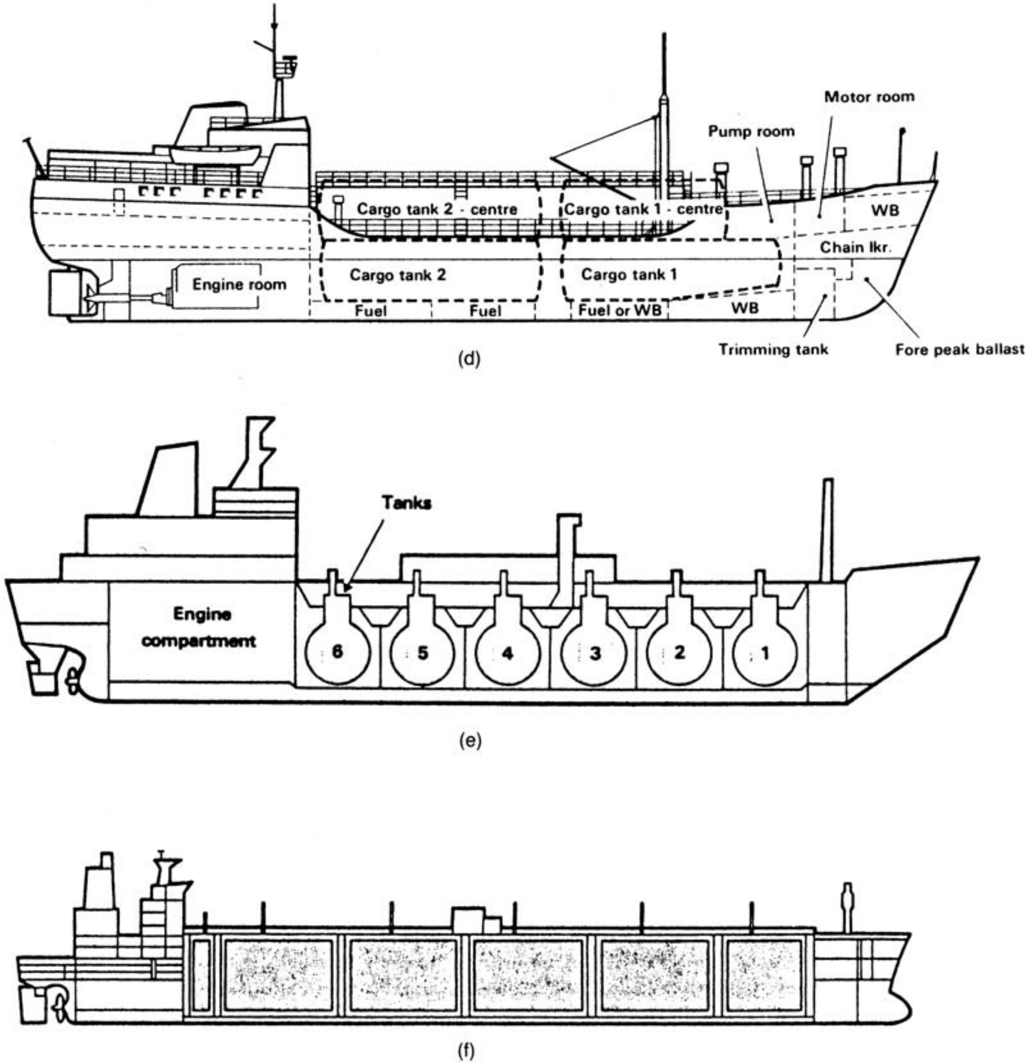

Figure 23.5 *Some typical vessels (Home Office, 1985 Manual of Firemanship Bk 4): (a) cargo ship; (b) oil tanker; (c) chemical tanker; (d) and (e) LPG carriers; and (f) LNG carrier (Courtesy of HM Stationery Office, © All rights reserved)*

more extensive. A cargo list for such a tanker is given by Puklavec and Lindenau (1985):

Ethylene
Ethane
Propene
Propane
Ethane/propane mixtures
Anhydrous ammonia
n-Butane, *i*-butane
Butadiene
Butylenes
Vinyl chloride monomer
Isoprene monomer
Propene oxide
Mixtures of ethylene oxide/propene oxide
Acetaldehyde
Monoethylamine
Methyl chloride
Dimethylamine
Diethyl ether

Other products are carried in general chemical tankers, or chemships.

The *Bulk Carrier Code* (IMO, 1996 IMO-100) has both ship type and additional requirements which are a function of the chemical carried.

An important class of chemical in sea transport is monomers. Monomers such as vinyl acetate need to be inhibited during transport. The effectiveness of inhibition depends on the oxygen concentration and problems can occur from polymerization due to low oxygen concentration. An account of inhibitors for vinyl monomers has been given by Douglas, von Bramer and Jenkins (1982) and of the specific problem of vinyl acetate inhibition by D.W. Butcher and Sharpe (1983).

Other accounts of the transport of particular chemicals include that of R.W. Macdonald (1977) on chlorine and that of Brumshagen (1983) on carbon dioxide.

23.12.6 Ship movement

The control of ship movement in restricted waters is necessary because the risk of collision or grounding is greater and the consequences may often be more serious. The arrangements for ship control vary in different countries, but many of the principal waterways have some form of movement control. This may vary from speed restrictions and a requirement for pilotage to a full system akin to that used in air traffic control.

There have been a number of studies of ship movement and of ship traffic control systems. The USCG has undertaken a programme of work on this topic. Table 23.30 shows typical ship movements in a major waterway as given by Sanders and Aldwinckle (1987). An account of ship movement at the approaches to Rotterdam has been given in a study of ship incident probabilities by Ligthart (1980). The speed restrictions required by the Port of London Authority as described in the *Canvey Reports* are discussed in Appendix 7.

The proportion of 'errant vessels' in traffic lanes on the UK continental shelf has been studied by Technica (1985). This report was a follow-up to previous work on ship–platform collisions, which showed that the main risk is from errant vessels. One of the main points made is that errancy is not restricted to particular vessels, crews or captains, but may occur at some time in any vessel, although the frequency of such periods will vary between vessels. The findings were that the proportion of vessels which are errant at a given time is about 1.6%, both with good visibility and with bad, but that the proportion likely to recover from being on an imminent collision course fell for vessels of <40,000 DWT from 78% in good visibility to 8% in poor visibility and for vessels of >40,000 DWT from 39% to 4%, respectively.

23.12.7 Factors enhancing risk

In recent years, there have been a number of developments which have combined to increase the risk of vessel failure. An account is given by Gilbert (1994). Among these developments are the massive increase in the size of vessels. This is not just a matter of increase in the hazard. Gilbert states 'Many of these cape-size vessels (100,000 to 170,000 DWT) have been lost over the last two years due to suspected structural failure'.

Structurally, important factors have been the reduction in scantlings, the use of high tensile steels or inferior coatings, increased stress caused by high capacity loading systems and poor lay-up provisions.

Gilbert describes the three main modes of vessel failure: fire, collision and grounding. He also draws attention to the risk from piracy, which in some regions is not negligible. He states 'In some instances, fully-loaded tankers have been left to steam at full speed in enclosed waters with no-one on the bridge, because pirates have locked up or otherwise restrained the crew'.

23.13 Marine Transport: Regulatory Controls

23.13.1 International regulatory controls and codes

The international marine transport of dangerous goods is the concern of the IMO (formerly the International Maritime Consultative Organization (IMCO)). This organization has a fairly complex structure of committees, which

Table 23.30 *Typical ship movements in a major waterway (Sanders and Aldwinckle, 1987) (Courtesy of Gastech)*

Ship size (× 10^3 GRT)	*Ship type*				
	Oil tanker	*Chemical tanker*	*Gas carrier*	*Other*	*All*
0–1	42	0	9	1,064	1,115
1–2	22	153	21	1,374	1,570
2–4	74	62	28	1,591	1,755
4–6	130	48	64	2,044	2,286
6–15	316	65	227	8,043	8,651
15–30	702	33	165	4,361	5,261
30–80	2,317	78	0	3,621	6,016
80>	537	0	0	556	1,093
Total	4,140	439	514	22,654	27,747

include the Maritime Safety Committee (MSC) and the Marine Environment Protection Committee (MEPC).

Other interested bodies include the International Chamber of Shipping (ICS), the Oil Companies International Marine Forum (OCIMF) and the Society of International Gas Tanker and Terminal Operators (SIGTTO), together with International Association of Ports and Harbours (IAPH), the International Petroleum Industry Environmental Conservation Association (IPIECA) and the International Tanker Owners Pollution Federation (ITOPF).

Accounts of the international controls and codes for the marine transport of dangerous goods are given in the *NFPA Handbook* (2003) and by the ACDS (1991).

Some principal international conventions and conferences include the International Convention for the Prevention of Pollution of the Sea by Oil 1954 (OILPOL), the International Conference on Revision of the International Regulations for Preventing Collisions at Sea 1972, the International Convention of Prevention of Pollution from Ships 1973 (MARPOL), the International Convention on the Safety of Life at Sea 1974 (SOLAS), the International Convention on Training, Certification and Watchkeeping for Seafarers 1978 (STCW), and the Convention on the International Maritime Organization 1984.

The resolutions of the periodic SOLAS conferences are a continuing source of provisions in the international system of control. The SOLAS Convention 1974 contains mandatory requirements concerning carrier safety. Chapter VII of the Convention deals with dangerous goods.

Some principal IMO codes include the *Code for the Construction and Equipment of Ships Carrying Dangerous Chemicals in Bulk* (the *BCH Code*) (IMO, 1993 IMO-772), the *International Code for the Construction and Equipment of Ships Carrying Dangerous Chemicals in Bulk* (the *Bulk Carrier Code*, or *IBC Code*) (IMO, 1996 IMO-100) and the *International Maritime Dangerous Goods Code* (the *IMDG Code*) (IMO, 1992 IMO-200).

There are three IMO codes for LGCs: the *Code for Existing Ships Carrying Liquefied Gases in Bulk* (IMO, 1976 IMO-788), the *Code for the Construction and Equipment of Ships Carrying Liquefied Gases in Bulk* (IMO, 1983 IMO-782) and the *International Code for the Construction and Equipment of Ships Carrying Liquefied Gases in Bulk* (the *Gas Carrier Code*, or *IGC Code*) (IMO, 1993 IMO-104). The first code applies to ships built up to 1976 and the second generally applies to ships built after 31 December 1976 and before 1 July 1986.

Guidance issued by the ICS and other bodies includes *Safety in Chemical Tankers* (ICS, 1977/1), *Safety in Oil Tankers* (ICS, 1978/2), *Safety in Liquefied Gas Tankers* (ICS, 1980/3), *Liquefied Gas Handling Principles on Ships and in Terminals* (SIGTTO, 1986/3), *International Safety Guide for Oil Tankers and Terminals* (*ISGOTT*) (ICS, 1991/11), the *Tanker Safety Guide* (*Chemicals*) (ICS, 1971/13) and the *Tanker Safety Guide (Liquefied Gases)* (ICS, 1993/14).

23.13.2 Paris Memorandum

The responsibility for enforcement of international agreements on marine safety lies with the state in which the vessel is registered (the flag state). Standards are variable and, as a secondary measure, the states at whose ports the vessel calls (the port states) are empowered to carry out inspections and to detain the vessel whilst repairs are done. This latter arrangement is governed by the Paris Memorandum of Understanding on Port State Control of 1982 (the Paris Memorandum, or Paris MOU). An account of this system is given in the *Donaldson Report* (Donaldson, 1994), described below, and its operation is reported in the annual reports of the Paris Memorandum.

23.13.3 Classification societies

In international shipping, an important role is played by the classification societies, of which the best known is Lloyds of London. An account of the work of Lloyds is given by McLean and Cripps (1986). The relationship of Lloyds to many of the international organizations mentioned is shown in Figure 23.6.

The classification societies operate a system of classification rules, as described below. In addition, the major societies are authorized by over 125 administrations to apply the requirements of specified IMO conventions and to issue certificates of fitness. The Lloyds Register requirements for gas ship construction and class maintenance are outlined in Figure 23.7.

23.13.4 Classification rules

Major sets of rules at Lloyds are the *Rules and Regulations for the Classification of Ships* and the *Rules for Ships for Liquefied Gases*.

An account of Lloyds' Classification Rules is given by J. Smith (1994). The hull of a ship must be able to withstand the forces due to still water and specified wave-induced loads. It must possess the local strength to resist buckling, fatigue, yielding and brittle fracture. In the Classification system, this is achieved by compliance with the Rule materials requirements, hull arrangements and scantling formulations. The Rules are intended to provide basic proven design methods whilst leaving freedom to innovate. They prescribe design methods for the ship's hull and certain other features and equipment. The system recognizes the principle of 'equivalence' and permits an alternative combination of arrangements and scantling, provided that it can be demonstrated to be of equal strength.

23.13.5 UK regulatory controls

In the United Kingdom, the transport of hazardous materials by sea is regulated by the Department of Trade (DoT) through the Merchant Shipping Act 1965 and succeeding Merchant Shipping Acts and through a series of regulations which include the Merchant Shipping (Cargo Ship Construction and Survey) Regulations 1984, the Merchant Shipping (Fire Protection) Regulations 1984, the Merchant Shipping (Gas Carrier) Regulations 1986, the Merchant Shipping (BCH Code) Regulations 1987, the Merchant Shipping (IBC Code) Regulations 1987 and the Merchant Shipping (Dangerous Goods and Marine Pollutants) Regulations 1990.

The DTp maintains a Standing Advisory Committee, which has for some years issued the *Recommendations for the Carriage of Dangerous Goods in Ships*, commonly known as the '*Blue Book*', covering variations from and additions to the *IMDG Code* judged appropriate for the United Kingdom. The 1990 edition of the *IMDG Code* with the 25th set of amendments provides comprehensive coverage of matters dealt with in the *Blue Book*, which is now superseded.

British law has held that the act of sending to sea an unseaworthy vessel is a misdemeanour. The Merchant Shipping Act 1979 replaced the wording 'unseaworthy' by 'dangerously unsafe'. The Merchant Shipping Act 1988, Section 30, gives powers to prosecute the owner and master

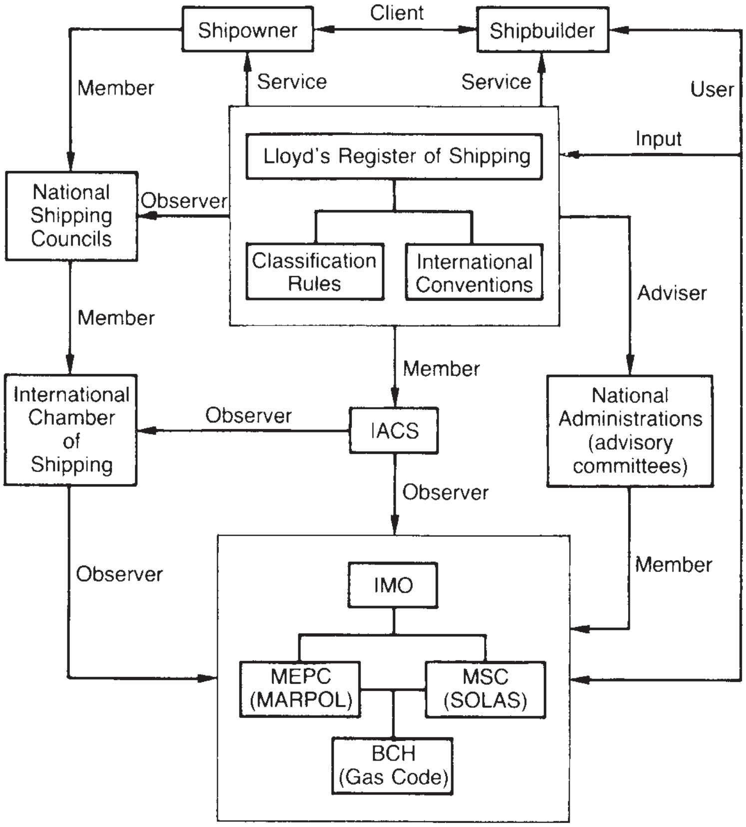

Figure 23.6 *Relationship of the Lloyds Register classification society with regulatory bodies and the liquefied gas shipping community (McLean and Cripps, 1986) (Courtesy of Gastech)*

of unsafe British ships in any port worldwide and of unsafe foreign ships in British ports.

In the United Kingdom, enforcement of the Paris Memorandum is the responsibility of the Marine Safety Agency (MSA). Accounts of the regulatory framework in the United Kingdom are given by Hodges (1994) and K. James (1994).

23.13.6 Seaworthiness

In British maritime law, an important concept in marine safety, as described by Hodges (1994), is that of the 'seaworthy' vessel, legally defined as one which is in 'a fit state as to repairs, equipments, crew and in all other respects, to encounter the ordinary perils of the sea'. The definition is thus limited to the perils 'of the sea' rather than 'on the sea'.

Aspects of seaworthiness which have been the subject of court judgements include: the ship's suitability to carry its cargo, or its cargoworthiness; its design and construction; its machinery, equipment and navigational aids; the sufficiency and competence of the crew; the sufficiency and quality of the fuel; and the stability and stowage of the cargo.

The seaworthiness of a ship is a particular aspect of its safety. For example, a deficiency in the medical supplies would detract from safety, but would not render the ship unseaworthy.

23.13.7 Donaldson Report

The *Braer* disaster in 1993 was the subject of an inquiry reported in *Safer Ships, Cleaner Seas* by Lord Donaldson (1994) (the *Donaldson Report*). The report reaffirms the duty of the flag state to enforce controls on the safety of vessels registered with it, but states that: There is clear evidence that some Flag States are failing in their responsibilities . . . '. It recommends various measures to strengthen the controls exercised by the port states.

23.13.8 Safety case

Following the Piper Alpha incident and the *Cullen Report*, the new UK offshore regulatory regime is based on formal safety assessment and the safety case. This has led some to advocate a similar regime for ships at an international level. The question of a regime for ships based on a safety case is discussed by J. Smith (1994).

The critique of a safety case for an individual ship has two main aspects, the potential benefits and the practical difficulties. With regard to benefits, the question concerns the extent to which the design and operation of the ship itself involves the type and degree of hazard for which the safety case methodology is suitable. The other question is the practicality of applying a safety case regime to international shipping, particularly given the difficulties

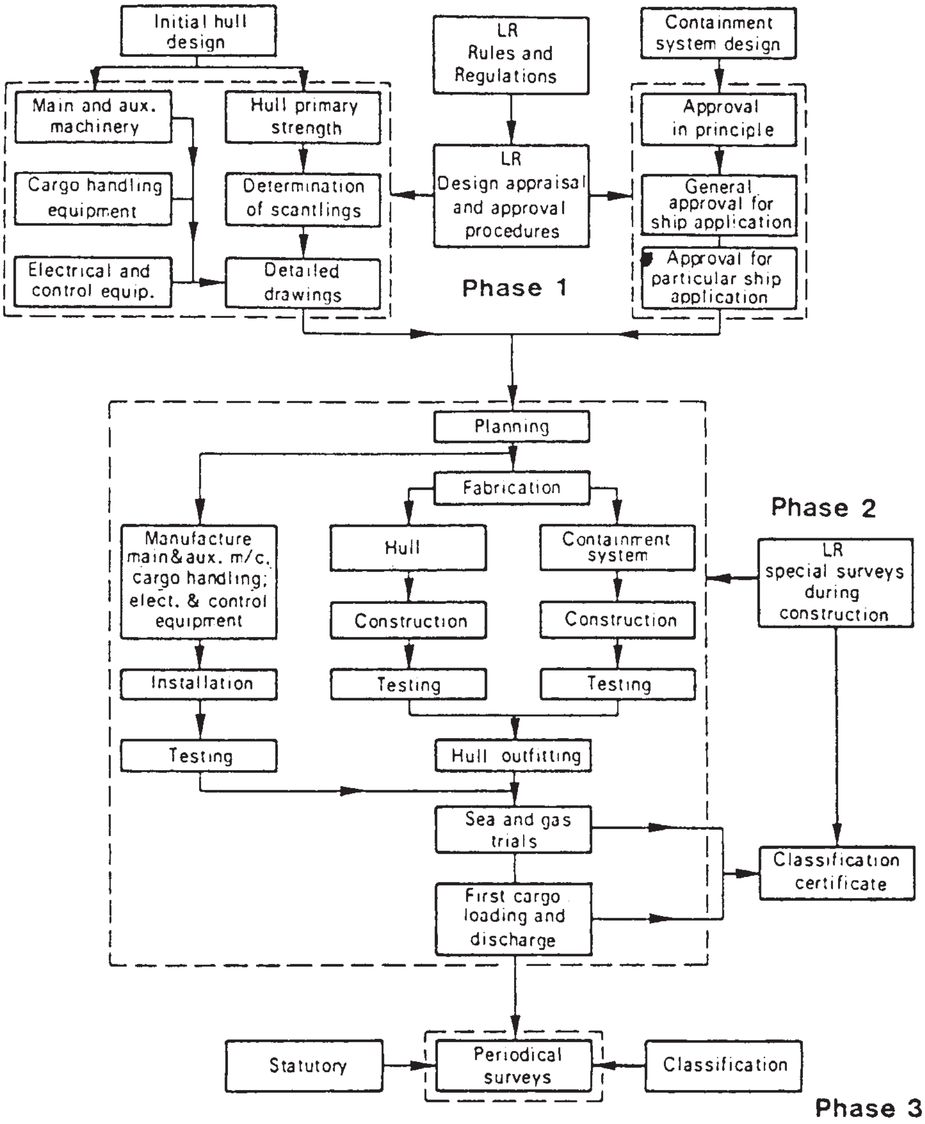

Figure 23.7 *Lloyds Register requirements for liquefied gas ship construction and class maintenance (McLean and Cripps, 1986) (Courtesy of Gastech)*

experienced in enforcing even a relatively straightforward prescription-based regime.

There may well be benefits to be had from generic formal safety assessment studies. The question of formal safety assessment of ports, sea lanes, etc., is another matter and is well established.

23.13.9 US controls

In the United States, ships trading in US waters have to meet the requirements of the USCG. The USCG have responsibility for ensuring the safety both of US vessels and US ports.

The USCG requirements for gas carriers are given in the Code of Federal Regulations, Title 46. The requirements for new ships are given in Part 154 and those for existing ships in Part 38. New ships are essentially those which meet the IMO *Gas Carrier Code* and existing ships are those which do not. An account of the USCG controls has been given by Rowek and Cook (1986).

The United States has now taken action to raise the standard of ships calling at its own ports. The Oil Pollution Act 1990 (OPA) provides that, from the year 2010, all such vessels must have double hulls.

23.13.10 Pressure for change

Shipowners are currently subject to a number of pressures to enhance the safety of vessels. Some of these are described by Rawson (1994). They include: IMO initiatives, unilateral legislation such as the OPA 1990 and the Paris Memorandum; the requirements of the classification societies and of the insurers, which are gradually tending to become more stringent; and the growth of litigation. Regulatory controls are thus increasingly being reinforced by economic pressures. There is, however, a long way to go.

23.14 Marine Transport: Ports and Harbours

23.14.1 Regulatory controls and codes

Ports and harbours are controlled through the Docks Regulations 1988 and dangerous substances are controlled through the Dangerous Substances in Harbour Areas Regulations 1987 (OSHA). Guidance is given in HS(R) 27 *A Guide to the Dangerous Substances in Harbour Areas Regulations 1987* (HSE, 1988) and GS 40 *The Loading and Unloading of Flammable Liquids and Gases at Harbours and Inland Waterways* (HSE, 1986). Also applicable are the regulations for fixed sites, including the Notification of Installations Handling Hazardous Substances Regulations 1982 (NIHHS), the Control of Industrial Major Accident Hazards Regulations 1984 (CIMAH), the Dangerous Substances (Notification and Marking of Sites) Regulations 1990 and the Planning (Hazardous Substances) Regulations 1992.

Interested organizations include the International Association of Ports and Harbours (IAPH) and the Independent Tank Storage Association (ITSA).

The OSHA Regulations are divided into 10 parts: (1) interpretation and application, (2) entry of dangerous substances into harbour areas, (3) marking and navigation of vessels, (4) handling dangerous substances, (5) liquid dangerous substances in bulk, (6) packaging and labelling, (7) emergency plans and untoward incidents, (8) storage of dangerous substances, (9) explosives, and (10) miscellaneous and general.

Some principal regulations of the OSHA Regulations are: Regulation 6 on the notice of entry of dangerous substances; Regulation 7 on harbour masters' powers of prohibition of dangerous substances, etc.; Regulation 18 on precautions against fire and explosion; Regulation 19 on the fitness of vessels; Regulation 20 on permission for transfer between vessels; Regulation 21 on safety precautions for loading, unloading and transfer; Regulation 26 on the preparation of emergency plans by harbour authorities; Regulation 27 on emergency arrangements at berths; Regulation 28 on untoward incidents; Regulation 29 on the storage of dangerous substances; Regulation 30 on storage tanks; Regulation 31 on the storage of freight containers, etc.; Regulation 32 on the parking of road vehicles; Regulation 34 on the need for an explosives licence; Regulation 37 on the security of explosives; Regulation 41 on deteriorated explosives; Regulation 43 on the power of harbour authorities to make bylaws; and Regulation 44 on enforcement. Regulation 28 deals both with the action in the event of untoward incidents and on reporting of such incidents. Regulation 34 defines the cases where there is need for an explosives licence; Regulations 37–42 on explosives apply irrespective of whether a licence is required.

HS(R) 27 contains in Appendix 3 guidance on emergency plans and in Appendix 4 a checklist of duties under the Regulations, covering some 18 categories of person, including: the harbour authority, berth owner and berth operator; the harbour master; the harbour and the berth explosives security officers; the masters of vessels; the operators of barges and harbour craft, road tankers, rail tank wagons, and storage; consignors; drivers; and employers and the self-employed.

COP 18 expands on some of these requirements, giving more details on aspects such as the information to be provided by incoming tankers, which includes the substances carried, the equipment available such as an inert gas system, defects on the ship and the expected time of arrival (ETA); the control of rail traffic in harbour areas; the ship–shore transfer of dangerous liquids; precautions against fire and explosion, which include the elimination of ignition sources and the provision of firefighting facilities; storage tanks for dangerous substances; the handling, storage and security of explosives; the discharge of harmful dusts and vapours to the atmosphere; and emergency planning, at both harbour and berth level. It contains an appendix giving a checklist for ship–shore transfer.

23.14.2 Port design and operation

Accounts of the handling of hazardous materials at ports have been given by Gebhardt (1980, 1989) and by P. Lewis (1981). Cargo is handled at a port in four basic modes:

(1) bulk materials;
(2) packaged goods;
(3) containers;
(4) roll-on/roll-off.

The characteristics of these modes are discussed by Lewis.

Some aspects of the design and operation of ports relevant to the handling of hazardous materials include:

(1) ship traffic control;
(2) ship–shore transfer;
(3) emission control;
(4) hazardous area classification;
(5) jetty fire protection.

Control of ship traffic is considered in Section 23.12, ship–shore transfer is considered in Section 23.14.3, and jetty fire protection is discussed in Section 23.14.4.

Some emission of flammable gas is unavoidable during loading operations. As with land-based plant, it is necessary to consider the dispersion of such gas. Similarly, it is necessary to have a hazardous area classification of the ship and the jetty.

23.14.3 Ship-shore transfer

The loading and discharge of cargo is a hazardous operation over which strict control needs to be exercised. Accounts are given in *Liquefied Gas Handling Principles on Ships and in Terminals* (SIGTTO, 1986/3), *Guidelines for the Alleviation of Excessive Surge Pressure in ESD* (SIGTTO, 1987/4) (the SIGTTO *ESD Surge Pressure Guidelines*) and *Recommendations and Guidelines for Linked Ship/Shore Emergency Shutdown of Liquefied Gas Cargo Transfer* (SIGTTO, 1987/5) (the SIGTTO *ESD Guidelines*) and by Gebhardt (1980), Armitage (1983), B. White and Cooke (1983), Holdsworth (1985) and Whitmore and Gray (1987).

Loading arms are covered in *Design and Construction Specification of Marine Loading Arms* (OCIMF, 1987/5).

There is also guidance on manifolds (OCIMF, 1987/7 and 1991/12) and on hoses (OCIMF, 1991/11).

Accounts of the development of the SIGTTO guidelines on ship–shore transfer and emergency shut-down (ESD) are given by Holdsworth (1985) and Whitmore and Gray (1987).

The transfer of hazardous materials between ship and shore during loading and unloading depends on the effective operation of a number of systems which include:

(1) mooring system;
(2) loading arms;
(3) pumping system;
(4) pressure relief.

Some hazards of ship–shore transfer are:

(1) ship movement;
(2) leakage;
(3) overfilling;
(4) overpressure;
(5) pressure surge.

Mooring systems have already been discussed. A good mooring is required to ensure that the ship does not break away during transfer. It is also desirable that the motion of the ship be minimal.

There are various arrangements for connecting the ship's cargo tanks to the land terminal. Types of loading arm in common use include Chiksan loading arms and Kvaerner arms.

In order to prevent leakage, pressure surge, overfilling or overpressure of tanks, it is necessary to design for these hazards and to establish a suitable link between ship and shore which allows orderly shut-down to be carried out.

There should be a trip system so that shut-off can be effected in the event of a serious leak. The operating pump should be interlocked to stop if the shut-off valve closes.

If shut-off is too rapid, pressure surge is liable to occur and can be very damaging. The prevention of pressure surge in this situation is an important feature of the SIGTTO arrangements (SIGTTO, 1987/4 and 5). It has been discussed by Armitage (1983).

Measures need also to be taken to avoid overfilling and overpressure. Particular consideration should be given to the relief arrangements at the receiving end in relation to the delivery flow and pressure in order to ensure that overpressure does not occur.

The operating arrangements, discussed by Gebhardt (1980), are equally important. The transfer operation should be planned. There need to be sufficient personnel available on ship and on shore. At each end there should be an engineer in charge of the transfer. There should be good communication between ship and shore and the principal tasks of the transfer operation should be coordinated.

The SIGTTO *ESD Guidelines* (SIGTTO, 1987/5) describe a standardized link connecting ship and terminal ESD systems to communicate and initiate ESD safely and rapidly. They give in an appendix a practical example of an intrinsically safe ship–shore ESD link system.

The SIGTTO *ESD Surge Pressure Guidelines* (SIGTTO, 1987/4) describe the hazards of surge pressures and give sets of guidelines common to ships and terminals and others specific to the ship or the terminal. The former cover (1) safe transfer rates, (2) valve characteristics and closure times, (3) pipeline design pressure and pipeline anchors, (4) linked ship and terminal ESD systems, and (5) operational factors. The guidelines also include an engineering treatment of surge as applied to loading systems and unloading systems and design approaches to alleviate surge pressures, including (1) pump shut-down/diversion of flow and (2) surge pressure relief.

A checklist for ship–shore transfer has been given by B. White and Cooke (1983).

Guidance on ship–ship transfer is given in *Ship to Ship Transfer Guide (Liquefied Gases)* (ICS, 1980/4) and *Ship to Ship Transfer Guide (Petroleum)* (ICS, 1988/7).

23.14.4 Jetty fire and fire protection

An account of fire and fire protection at jetties has been given by Dicker and Ramsey (1983). The minimization of the fire hazard at a jetty depends not only on the specific fire protection measures but also on the general standard of design, operation and maintenance. The ship–shore transfer systems are one important feature here. The arrangements for dealing with leaks and spillages are another.

The objectives of fire protection may be summarized as:

(1) prevention of fires and explosions;
(2) extinguishment of small fires;
(3) control of fires that cannot be extinguished;
(4) cooling of vulnerable equipment;
(5) protection to permit escape;
(6) protection to permit ship/shore access.

It may not always be possible to extinguish a fire, and in such a case, the fire should be controlled, and vulnerable equipment such as tanks, loading arms, pipelines and manifolds on shore or on ship should be kept cool.

The resources available on site should be such that an effective initial response to the fire can be mounted whilst the arrival of the outside fire services is awaited.

The approach to fire protection at a jetty is broadly similar to that on a plant. Basic elements include:

(1) control of leaks;
(2) control of ignition sources;
(3) fire control system;
(4) means of escape;
(5) means of access.

The fire control system includes:

(1) fire warning system;
(2) fire detection system;
(3) fixed firefighting system;
(4) mobile firefighting system;
(5) fire water supply system.

First consideration should be given to avoidance of leaks of flammable materials. Potential leak sources should be reviewed and appropriate action taken.

A source of flammables which is peculiar to jetties is flammable vapour vented from ship cargo tanks.

Most of the common sources of ignition may be present at a jetty. These include hot work, repair work, vehicles and smoking. There are also activities specifically associated with shipping which may cause ignition such as use of ship's galley equipment, repair work involving hammering or paint chipping, blowing of funnel uptakes or boiler tubes, or disconnection of ship–shore cargo pipelines.

Control of ignition sources should be based on a hazardous area classification. The *Area Classification Code for Petroleum Installations* by the IP (1990 MCSP Pt 15) gives guidance on hazardous area classification for jetties.

In this connection, Dicker and Ramsey deprecate the use of a blanket approach in which flameproof equipment is applied without detailed study. They suggest that there is benefit to be gained from the source of hazard method which gives a better understanding of the potential leak sources. These authors also state that it has to be accepted that complete elimination of all sources of ignition from hazardous areas is not practicable in all circumstances at jetties.

It is usual to provide a variety of means for fighting and controlling fire. For cargoes of crude oil or flammable liquids, the principal firefighting agent used is foam, which is applied by foam monitors. Low expansion foam is the most suitable for a jetty since it has a reasonable range. Fixed foam monitors may be used and may be remotely controlled. They may be supplemented with mobile monitors. Foam is usually not recommended for burning liquefied gas fires, since the gas tends to penetrate the foam blanket.

If the fire is on a gas or vapour leak, the preferred course of action is to stop the leak. Extinguishing the flame without stopping the leak risks allowing the creation of a flammable vapour cloud which may give a more violent flash fire or vapour cloud explosion.

Water monitors are used to cool exposed items, as already described. In the jetty situation, cooling of the gangways between the ship and shore is important for escape.

The capacity of the foam and water systems should match the firefighting requirements. For large vessels, these can be appreciable.

Effective fire control depends on coordination between shore and ship. One aspect of this is the compatibility between the ship and shore fire mains. It is necessary to ensure that connection of the ship's fire water system to that on shore does not result in overpressurization.

Another aspect is the responsibility for fire control in the early stages. Since in the event of fire the ship's crew need to attend to other actions, particularly the closure of pipelines and actions to prevent fire spread, it may be advantageous to control initial firefighting from the shore.

There should be good ship–shore communications. These are particularly important in the jetty situation, not only for firefighting but also for assisting escape. Regular exercises of the fire control system should be held.

Accounts available of the fire protection arrangements at major terminals include those of the arrangements at Rotterdam by Vossenaar (1975), at Wilhelmshaven by Hartlich (1977) and at Hamburg by Gebhardt (1980, 1989).

Vossenaar quotes for the port of Rotterdam traffic of 34,000 ships and 170,000 barges per annum. The area fire brigade has some 500 full time firemen who deal, each year, with about 5,000 fire and other emergencies. The fire brigade is equipped with high capacity pumps capable of delivering 4,000 l/min. There are also 14 fire boats, most of which have an output of 15,000 l/min and carry substantial quantities of foam, as well as a fire fort, a converted ferry, with a 30 m tower.

Hartlich gives a detailed account of the construction of the Mobil terminal at Wilhelmshaven and of the firefighting arrangements. There are separate fire water systems which draw on sea water and on the refinery fire water supply. The sea water pumps are protected against pack ice and freezing.

The foam supply is estimated to last 60 min, supplying 2 × 5,000 l/min and 3 × 800 l/min foam monitors. The monitors can be operated from the control building and also from other auxiliary control points. Use of the refinery mobile foam monitors extends the period of foam application to some 2 h.

The foam monitors have a range of 85 m. This is not enough to give coverage of the whole deck of a supertanker, but such ships have their own systems.

The foam induction rate is 5%. Devices are used to keep the induction rate constant at variable water flows. The foam compound is highly viscous and its flow velocity is low so that large diameter mains are necessary. These have a holdup of some 10,000 l of the compound.

There are water monitors with an output of 3,000 l/min for cooling ships' gangways and hulls. Dry powder systems also are provided for fighting fires on platforms and around manifolds.

Two of the jetties at this terminal are on an island. For this situation, it is necessary to provide facilities somewhat similar to those on an oil platform, such as lifeboats and fireproof shelter.

Somewhat similar arrangements at the Shell terminal at Kattwyk at Hamburg-Harburg are described by Gebhardt.

Evacuation of the ship in the event of a spillage of liquefied gas may be assisted by the use of a water curtain to reduce the level of thermal radiation to which the crew is exposed. A study of such a system has been described by S. Stephenson and Coward (1987).

Two principal scenarios are considered, the first, shown in Figure 23.8(a) being for a fire on deck, and the second, shown in Figure 23.8(b), for a fire on the sea. The fire considered in the first case was a pool fire with diameter equal to the width of the ship, and sufficient fuel for burning to be maintained and evacuation to be necessary, and the second case considered was a fire on a continuous spill onto the sea. A model for heat transmission through water curtains was developed and embodied in the computer program PRINCE, as described in Chapter 16.

The target heat fluxes for the two design basis fires are shown in Table 23.31. It is concluded that the water curtain considered would reduce the heat flux received by the human targets from 16 to 5 kW/m^2 and that this provides a significant contribution to safe evacuation.

23.15 Marine Transport: Shipboard Fire and Fire Protection

An account of fire and explosion on board ships of all kinds is given in *Fire Aboard* (Rushbrook, 1979). This work lists all recorded ship fires between 1800 and 1977 and describes in detail many of the principal incidents. It describes the general maritime legislation and that pertaining to fire-related aspects of ship design and construction. It covers fire protection aboard ship, including fire-proofing of ships, fire equipment on ships and firefighting on ships, and fire protection of ports and offshore structures.

The fire-proofing of ships is governed by the Merchant Shipping (Construction) Rules 1965 and, for cargo ships, the Merchant Shipping (Cargo Ship and Survey) Rules 1965. Rushbrook's account follows closely the requirements of these rules and covers watertight doors, fire resisting and fire retarding divisions, fire resisting materials, electrical equipment and installation, oil fuel installations, ship structure, and construction aspects such as means of

escape and facilities to shut-off forced ventilation. He also treats under this heading, fire detection systems and sprinkler systems.

Requirements for firefighting equipment on ships are contained in the Merchant Shipping (Fire Appliances) Rules 1965. Features covered by Rushbrook include: fire pumps and pump siting, fire water hydrants, fire hoses and hose reels, and portable fire extinguishers; fire fighter's breathing apparatus, including hose reel and trolley compressed air apparatus, and high pressure air charging equipment; fire smothering arrangements, including inert gas generators, funnel gas inerting systems, steam smothering systems and high pressure water sprays; fire detection and alarm systems; and certain special topics such as foam installations in mechanical spaces and crankcase monitoring.

Rushbrook emphasizes the need for training for the whole range of tasks required in ship operation. He quotes legal cases establishing the employer's obligation to provide training. Aspects of fire training mentioned include fire patrolling and firefighting, but the issue is much wider than this.

A detailed account of firefighting under different conditions is given by Rushbrook. Situations considered include fires in holds, in accommodation space, in refrigerated space, in fore and after peaks, and in engine rooms and machinery spaces.

He gives a detailed discussion of the problem of fires in holds. In general it is a golden rule of firefighting to hit the fire fast and hard, but this is not necessarily the right approach to a hold fire. There is a tendency to open up the hold too soon. It may often be better to develop a coherent plan of attack and make suitable preparations and, if there is an inerting system, to activate it and let it do its work. There are exceptions, however; immediate action is necessary when the cargo is nitrates, sulfates or explosives.

If quantities of water are pumped into the ship to fight a fire, they may lead to instability. Stability is determined by the relation between the ship's centre of gravity and its centre of buoyancy. The centre of gravity is the point at which its weight may be taken to act, in the vertical direction. The centre of buoyancy is the centre of gravity of the water displaced. If a vertical line is drawn through the centre of gravity of a body floating in a liquid and a second vertical line is drawn through the centre of buoyancy when the body is slightly displaced from its equilibrium position, the two lines meet at a point known as the metacentre. If the centre of gravity is below the metacentre, the ship is stable and will right itself, as shown in Figure 23.9(a), but if the centre of gravity is higher, the ship is unstable and tends to capsize, as shown in Figure 23.9(b). One solution to the problem of instability due to fire water is the use of an ejector, but this also has its limitations.

23.15.1 Cargo tanks

The problem of flammable cargoes and of the associated fire and explosion hazards is discussed in detail in *Petroleum Tankship Safety* (Page and Gardner, 1971).

Although oil tankers at any rate are now required to have inert gas systems to prevent tank fires, an understanding of such fires remains important.

A typical tank system for a petroleum cargo ship is shown in Figure 23.10. The tank is designed to operate at a pressure of about 1.17 bar (2.5 psig) and can withstand about 1.24 bar (3.5 psig). If this latter pressure is exceeded, the decks and bulkheads may give way.

The tank is fitted with an atmospheric vent which has a pressure/vacuum (PV) valve for normal operation and a bypass for loading. The PV valve is set to maintain the pressure within narrow limits, 0.14 bar (2 psi) above atmospheric and 0.035 bar (0.5 psi) below atmospheric.

During loading, the bypass is used, since the flow of gas necessary to equalize pressure is too great for the PV valve to handle. At other times, the bypass is kept shut.

It is important that vapour issuing from the vent during loading should not form a hazardous flammable or toxic cloud and it is desirable, therefore, for it to leave the vent at a velocity sufficient to promote mixing with the air. If loading is slow, the vapour may issue slowly and may accumulate. This problem may be overcome by fitting a minimum efflux velocity valve.

There may or may not be an inert gas system which is used to prevent the occurrence of a flammable mixture in the tank. If no such system is provided, there may be a flammable atmosphere during certain stages of the transport cycle. The air mixture found in the space depends on the volatility of the liquid.

Assuming that this is a volatile oil, which in this context means an oil above its flash point, then if the tank is clean and gas free, and contains only air before loading, the mixture in the vapour space will go from a too lean to a too rich mixture during loading. The diffusion of the vapour is slow, however, and a period of hours or even days may elapse before the space is saturated. Initially there may be a

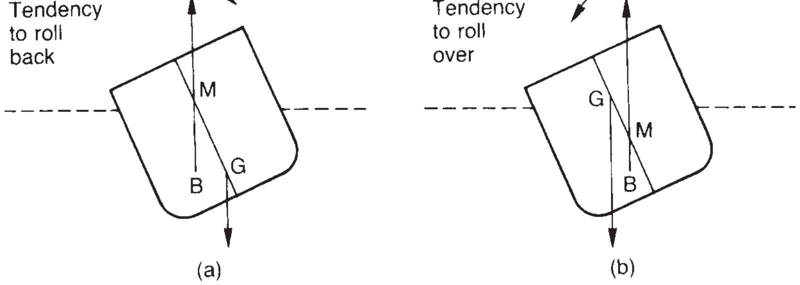

Figure 23.9 *Effect of the centre of gravity on ship stability: (a) tendency to roll back; (b) tendency to roll over. B, centre of buoyancy; G, centre of gravity; M, metacentre*

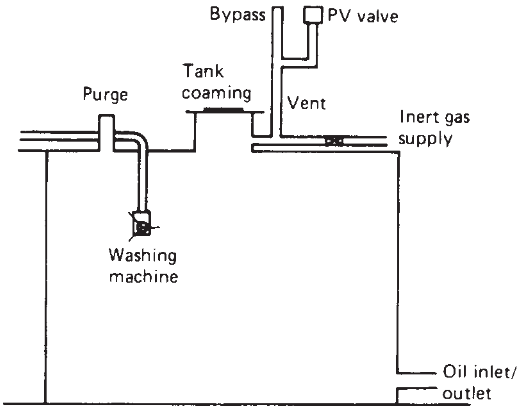

Figure 23.10 *Typical cargo tank system on a petroleum tanker*

range of conditions in the tank from a too lean mixture near the roof to a too rich mixture in the vapour layer just above the liquid. During loaded passage the atmosphere remains too rich. The vapour concentration falls again, however, during unloading. If the rate of unloading is high, the turbulence of the air entering tends to give a homogeneous atmosphere in the vapour space, while if it is too low, there may be layering. At the end of unloading, the atmosphere may be too lean, flammable, or too rich, depending on the volatility of the oil. The same applies if the tank is left empty but dirty during passage.

If the oil is involatile, then in principle a flammable mixture does not form, but this may occur if the oil is heated to assist pumping so that it rises above its flashpoint or if the tank contains traces of a volatile oil.

The pressure in the tank is maintained close to atmospheric by ejecting air through the vent bypass during loading, by the operation of the PV valve during loaded passage and by letting air in through the vent bypass during unloading.

In addition to loading and unloading operations, there are also those of tank cleaning and gas freeing. Tank cleaning is carried out by washing machines. If at all possible, it should be done with a too lean atmosphere. Gas freeing is effected by steaming out or by diluting the atmosphere with air drawn through it by extractor fans or steam eductors or blown in by windsails.

It is essential to eliminate all source of ignition. Some sources which are particularly relevant are as follows:

(1) direct heat
    (a) cigarettes,
    (b) welding,
    (c) hot soot;
(2) mechanical sparks
    (a) metal tools,
    (b) cigarette lighters,
    (c) heavy objects;
(3) chemical energy
    (a) metal smears,
    (b) spontaneous combustion,
    (c) autoignition,
    (d) pyrophoric iron sulfide;
(4) electrical equipment;
(5) static electricity.

Heavy objects which may produce a spark if they fall inside the tank include washing machines and anodes of cathodic protection systems.

Static electricity may arise from several causes. Charge separation occurs as the oil flows through the loading pipe. It also occurs if the oil is splashed or sprayed or if the turbulence of the oil raises up water droplets which then settle through the oil. Charge recombination may then occur due to an earthed probe such as a washing machine, the use of an ullage tape or the presence of a floating metal object such as a tin can or piece of wood with metal bolts. Precautions include the elimination of earthed probes and floating objects and the adoption of suitable ullage measuring arrangements.

The use of steam for tank cleaning may also involve a static electricity hazard, but this is minimized by using only fixed apparatus bonded to the ship's structure, keeping the steam velocity low and eliminating earthed probes.

Further details of the precautions necessary in loading and unloading and in tank cleaning and gas freeing are given by Page and Gardner.

If there is an inert gas system, this may be used to maintain an inert atmosphere in the tank. The inert gas produced with good combustion practice and after cooling and purification has a composition of approximately 3% oxygen, 13% carbon dioxide and 84% nitrogen. Under less ideal combustion conditions, the gas may contain carbon monoxide or more oxygen.

Prior to loading, the tank is purged with inert gas down to an oxygen concentration of about 5%, the purge gases being discharged through the purge pipe. During loading, the gas displaced by the liquid is discharged through the vent bypass. The pressure in the tank during passage is maintained by the PV valve. When the liquid is unloaded, more inert gas is allowed into the tank to prevent a vacuum developing. After unloading, the tank may be cleaned with its atmosphere still inerted.

An inert gas–vapour mixture is rather similar to a too rich mixture – it may become flammable if it is diluted with air. Situations in which this may happen include venting to atmosphere and rupture of the tank.

The types of explosion which can occur in a tank vary. One factor is the volume of flammable mixture. This is a maximum when there is no liquid in the tank and a flammable mixture fills the whole space, a situation which may occur after loading or during cleaning. Another factor is the power of the explosion. If the mixture is close to its flammability limits and the flame speed is correspondingly low, the explosion tends to be low powered and the pressure rise gradual, so that the tank ruptures and the burning gases escape without further pressure rise in the tank.

There are several situations in which a low powered explosion may give rise to a more powerful one. The initial explosion may overheat adjacent tanks. If the original mixture was close to the upper flammability limit, the explosion may cause dilution by air to give a more flammable concentration, while if the mixture was close to the lower limit, the explosion may vaporize more liquid to yield again a more flammable concentration.

Usually tanker explosions occur without prior warning, but sometimes the possibility of an explosion can be assessed from the nature of the flame issuing from the deck openings. A yellow-orange flame accompanied by black smoke indicates that the tank atmosphere is too rich and the flame will not pass back into it. A snapping, blue-red, nearly smokeless flame signifies that the tank contains a flammable mixture and that the flame may pass back. In this latter case, an explosion is imminent and the deck should be evacuated immediately.

A fire on deck does not usually cause a cargo tank to explode, provided that the tank is completely closed.

There is a trend towards the provision on tankers of an accommodation 'citadel' in which the crew are protected against fire in the cargo tanks, the cargo deck area, the engine room or the pump room. Measures are taken to reduce the risk of fire in the citadel itself. The ventilation system of the citadel and of the engine room should be such as to minimize the hazard from the entry of noxious gases.

23.15.2 Static electricity

Static electricity as a cause of ignition of flammable mixtures in cargo tanks has already been considered in general terms. Detailed studies of the hazard have been carried out in support of the chemical industry's case against compulsory inerting. Accounts of this work have been given by H.R. Edwards (1983) and by Jones and Bond (1984).

Edwards describes a series of experiments to determine whether the operations of loading, water washing and steam cleaning are capable of giving potentials sufficient to cause an incendive spark. Five trials were done on four vessels.

The minimum potentials required to produce incendive sparks were estimated as follows: for loading, the required potential was taken as 20 kV based on work by Rees (1981) and by Strawson and Lyle (1975b). For water washing, work by van de Weerd (1975) indicates a required potential of 15 kV, but a value of 10 kV was adopted. The same value of 10 kV was also taken as the required potential for steam cleaning.

In the loading experiments, the liquid used had a relatively low resistivity and high potentials were not obtained, the maximum surface potential being 3.4 kV. Estimates were made for other conditions using the method of Carruthers and Wigley (1962). It was estimated that the maximum surface value for a very high resistivity liquid (1 pS/m) would be 16.5 kV. The surface potential is a function, however, of tank size and this maximum value is obtained only with tanks smaller than those normally used. With such a liquid there is also the option of limiting the charge rate. It is concluded that loading is not likely to give rise to the potential required for an incendive spark.

Experiments on water washing in tanks up to 2500 m^3 gave a maximum potential of 7.9 kV except for certain esters. There are, however, certain features which would tend to increase the safety factor. One is that the potential was measured in the middle of the earth free volume, but an earthed probe is unlikely to exist at this point. Moreover, chemical tankers use washing machines which do not produce large slugs of water and probably in these conditions the potential required for an incendive spark exceeds 15 kV. It is concluded that in water washing also the potential required for an incendive spark is unlikely to occur.

The potential obtained in water washing for ethyl acetate, however, was 11.7 kV and that for methyl acrylate was also higher. These esters are therefore special cases.

The steam cleaning experiments gave a maximum potential of 18 kV in a 1200 m^3 tank. It is concluded that in this case an incendive spark could, in principle, occur. However, steam cleaning is used only after water washing so that a flammable atmosphere should not be present.

Further work on this topic is described by Jones and Bond, who define a tank centre space potential (TCSP) as the criterion to be considered. They develop a model to estimate the hazard threshold value of this potential. The model does not, however, predict the actual value of the potential which will occur in a given situation; this must be obtained by other means. They also give information on incidents and incident rates for cargo tank fires and explosions on chemical tankers, as described below.

23.15.3 Inert gas systems

One of the principal means of preventing fire on ships carrying flammable materials is the use of inerting. Inerting is treated in *Inert Gas Systems* (IMO, 1990 IMO-860) and by Rushbrook (1979), Gebhardt (1980), Berkel (1982), R.K. Roberts (1983), Anon. (1984r), Anon. (1984s) and Oellrich (1987).

An account of the methods available for generating an inert gas, usually nitrogen, and of its applications has been given by Oellrich (1987), who lists the following methods of generation:

(1) combustion processes;
(2) catalytic combustion of ammonia;
(3) pressure swing adsorption;
(4) permeation processes;
(5) cryogenerators;
(6) boiler flue gas.

These processes differ in various respects, including the required oxygen purity, energy consumption, convenient plant size and economics.

Some basic requirements of a nitrogen generation process are high purity oxygen, preferably <0.3%, high capacity and low space requirements.

There are several functions for which inert gas may be required. They include:

(1) gas freeing;
(2) inciting prior to loading;
(3) purging and padding.

Gas freeing is the purging of a tank with inert gas prior to purging with air for tank inspection. Purging and padding is carried out to render the gas space above the cargo in the tank inert and to keep it so.

Inciting is typically used to reduce the oxygen content of the space incited to below 5%.

There are certain problems and hazards associated with the use of inciting. These include:

(1) contamination of cargo;
(2) overpressure of tank;
(3) neutralization of inhibitors;
(4) asphyxiation of crew.

The use of inert gas such as boiler flue gas may contaminate the chemicals carried. The inciting operations may cause overpressure of the tank. Certain inhibitors used to prevent polymerization of monomers may be rendered ineffective unless there is sufficient oxygen in the atmosphere. An example is hydroquinone which is used as an inhibitor in vinyl acetate. The large quantities of inert gas required present a hazard of asphyxiation to the crew.

The IMO requirements for inciting are given in *Inert Gas Systems* (IMO, 1990 IMO-860), which covers oil tankers, product carriers and combination carriers and also deals with chemical tankers. As already described, there are also inciting requirements in the *IGC Code* and the *IBC Code*.

The use of inciting is an accepted practice for oil tankers, but has been controversial for chemical tankers. For oil tankers, the provision of an inert gas system has become mandatory. Under SOLAS 1974, it is required for tankers >100,000 DWTand under SOLAS 1978 for existing tankers >40,000 DWT, and new tankers >20,000 DWT.

The IMO has also considered a proposal for a requirement for chemical tankers, but there are certain problems and the proposal has been resisted. The problem has been discussed by H.R. Edwards (1983). Difficulties in the use of inert gas on chemical tankers are the facts that the most common method of inciting, that is, the use of inert gas from oil firing, is liable to contaminate the cargo and that inhibition of polymerization of monomers is less effective due to lack of oxygen. Given these difficulties, the relatively low number of incidents and the appreciable costs, it is argued that inciting is not justified.

The work by M.R.O. Jones and Bond (1984, 1985) on static electricity and on fires and explosions in chemical tankers may be regarded as a contribution to assessing the risks from these latter hazards. A study by Lloyd's Register showed that for chemical tankers, the use of inciting would lead to only a marginal reduction in the frequency of fire but an appreciable increase in the frequency of tank entry incidents (Anon., 1984s).

The IMO requirements for environmental control, or control of the atmosphere in the vapour space of the cargo tanks, are given in Chapter 9 of the *IBC Code*. This states that vapour spaces 'may require to have specially controlled atmospheres' and describes four methods, of which inerting is one.

23.16 Marine Transport: Liquefied Flammable Gas

23.16.1 Regulatory controls and codes

The controls and codes for ships carrying hazardous materials have already been described. For gas carriers transporting LFG, the *IGC Code* is of particular relevance.

23.16.2 Hazard scenarios

Principal hazards from gas carriers are spillage of a large quantity of LFG onto water, as a result of grounding, collision or leak during transfer, and a large fire or explosion on the ship, particularly in or near a port.

23.16.3 Ship design and operation

The design of LGCs is described in the *IGC Code* and in *Liquefied Gas Handling Principles on Ships and in Terminals* (SIGTTO, 1986/3). As stated earlier, gas carriers are designed with cargo tanks integral with the vessel or with separate tanks. Plate 29 shows a typical gas carrier, in this case one with separate spherical tanks.

Gas carriers fall into six groups: (1) fully pressurized carriers, (2) semi-refrigerated/semi-pressurized carriers, (3) semi-pressurized/fully refrigerated carriers, (4) fully refrigerated LPG carriers, (5) ethylene carriers and (6) LNG carriers. The first three groups are most suitable for smaller cargoes and the fourth for larger cargoes of LPG or ammonia.

The principal contents of the *IGC Code* are shown in Table 23.32, Section A, and illustrate many of the most important features of gas carriers.

The code specifies degrees of damage and flooding which the ship itself should be designed to survive.

The *Code* recognizes five types of cargo containment system: (1) independent tanks, (2) membrane tanks, (3) semi-membrane tanks, (4) integral tanks and (5) internal insulation tanks. Independent tanks are classified as Type A, B or C. Type A tanks are basically constructed of plane surface. Type B tanks may be constructed of plane surface

or as pressure vessels. For a Type B, tank, the stress analysis is more comprehensive than that for a Type A tank. Type C tanks are normally cylindrical or spherical pressure vessels. Figure 23.11(a)–(c) illustrates these three types. Figure 23.11(d) and (e) show two principal membrane systems, those of Gaz Transport and Technigaz.

The *Code* gives requirements for the pressure system, including cargo and process piping, type tests on piping components, piping fabrication and jointing details, testing of piping, cargo system valves, cargo hoses, cargo transfer methods and vapour return connections. It requires remotely operated emergency shut-down valves on each cargo hose connection, operable from at least two points on the ship.

The *IGC Code* contains a number of requirements for materials of construction, specifying a range of steels for successively lower minimum design temperatures down to −165°C, and for welding and non-destructive testing.

The *Code* gives detailed requirements for cargo tank venting, both pressure relief and vacuum relief, including settings and capacities. The pressure relief valve capacity should be able to handle the maximum capacity of the cargo tank inciting system or the fire exposure, whichever is the greater. There is also a requirement for an additional pressure relieving system for liquid level control. The *Code* gives the formulae for valve sizing.

Under the heading of environmental control, the code contains requirements for the gas freeing of cargo tanks, including for flammable gases the use of inert gas. There are also requirements for environmental control in the hold spaces for cargo containment systems other than Type C independent tanks and for the spaces surrounding tanks of this latter type.

In respect of fire protection, ships carrying products which are flammable or toxic are required by the *IGC Code* to have a water spray system for cooling, fire prevention and crew protection, and those carrying flammables are required to have dry powder systems. The *Code* specifies the areas and features to be protected by each system and gives equipment capacities and application rates.

Matters covered under the special requirements of the *Code* are: (1) materials of construction; (2) independent tanks; (3) refrigeration systems; (4) deck cargo piping; (5) exclusion of air from vapour spaces; (6) moisture control; (7) inhibition; (8) permanently installed toxic gas detectors; (9) flame screens on vent outlets; (10) the maximum allowable quantity of cargo per tank; (11) submerged electric cargo pumps; and (12) various chemicals, including chlorine, ammonia, ethylene oxide, propylene oxide/ethylene oxide mixtures and vinyl chloride.

The code gives a tabular summary of minimum requirements, covering (1) product name, (2) United Nations (UN) number, (3) ship type, (4) independent Type C tank, (5) control of vapour space in cargo tanks, (6) vapour detection, (7) gauging, and (8) special requirements.

One of the principal liquefied gases carried is LNG. Some features of LNG carrier design include (1) cargo tank design, (2) cargo protection, (3) cargo tank cooling, (4) cargo tank insulation, (5) boil-off, (6) reliquefaction and (7) propulsion.

For LNG carriers, there are three principal cargo tank designs in use. These are the Gaz Transport (GT) membrane, the Technigaz (TGZ) membrane and the Moss Rosenberg spherical tank. The three types have been described by Bouckaert and Cappoen (1984). An account of the GT design has been given by Jean and Bourgeois (1985) and of the Technigaz design by Ogawa *et al.* (1986).

Protection of the cargo tanks against grounding and collision is an important aspect of the tank design. Designs based on independent tanks have obvious advantages here, but membrane design has also given good protection in practice.

Since the LNG carried is very cold, it is necessary to ensure that its loading does not create a hazard due to thermal shock. The empty tanks may be sprayed with LNG before loading to cool them down or the tanks may be kept permanently cool. In the GT system, the solution adopted is the use of invar as the membrane material.

There must also be good thermal insulation. There are a number of different insulation systems in use. Accounts are given by Bouckaert and Cappoen (1984) and Bö ckenhauer (1987). The effectiveness of the insulation is such that the boil-off rate achieved is very low. The boil-off may be used as fuel for the ship's boilers. Alternatively, a reliquefaction system may be provided.

There is a trend towards the use of diesel engines as the propulsion system. Accounts have been given by Engesser *et al.* (1987), Grone and Pedersen (1987) and Terashima *et al.* (1987).

LPG carriers are often designed as flexible carriers able to handle not only LPG but also other liquefied gases. A typical cargo list for such carriers was given in Section 23.12. The design of flexible semi-refrigerated carriers has been described by Faridany and Ffooks (1983) and by Backhaus and Olschlager (1985), the first being for an LPG carrier with multi-lobe tanks and the second an ethylene carrier with tri-lobe tanks.

With respect to operation, Chapter 18 of the *IGC Code* treats the following topics: (1) cargo information, (2) compatibility, (3) personnel training, (4) entry into spaces, (5) low temperature cargoes, (6) protective equipment, (7) systems and controls, and (8) cargo transfer.

23.16.4 Terminal design and operation

A terminal for LFG is either an export or an import terminal and normally handles mainly either LPG or LNG. Some principal LFG terminals are listed in Table 23.33.

An account of LPG terminals in Europe has been given by de Sola (1985). Some principal export terminals are those at Sullom Voe (Shetlands), Flotta (Orkneys), St Fergus-Mossmorran, Grangemouth, Teesside (UK) and at Kaarstoe (Norway). Some principal import terminals are those at Canvey and Killingholme (UK), Rotterdam, Terneuzen and Flushing (Netherlands), Antwerp (Belgium) and Lavera (France).

The LPG terminal at Mossmorran has been described by Sellers, Luck and Pantony (1985). An account of the LNG terminal at Arzew, Algeria, has been given by Benazzouz and Abbou (1987). The authors give a description of the first 20 years of operation of the site. This includes a detailed listing of the principal failures and associated down-time.

Terminals differ depending on whether they are import or export terminals. An account of the differences for LNG has been given by R.A. Cox, Comer *et al.* (1980). The main elements of an import terminal are

(1) berth for LNG ships and handling facilities;
(2) LNG storage tanks;
(3) pressure control system for tanks;
(4) gas separation and dispatch system.

The main elements of an export terminal are

(1) gas liquefaction and fractionation units;
(2) LPG storage facilities;
(3) LNG storage tanks;
(4) berth for LNG ships and handling facilities; and sometimes
(5) slugcatcher.

These differences affect the hazards of the terminal.

23.17 Marine Transport: Chemicals

23.17.1 Regulatory controls and codes

The controls and codes for ships carrying hazardous materials have already been described. For chemical tankers, the *IBC Code* is of particular relevance.

23.17.2 Hazard scenarios

Chemical tankers tend to present different hazards from those of gas carriers. These hazards include those of a runaway reaction, an explosion, a toxic release and severe pollution.

23.17.3 Ship design and operation

It is convenient at this point to consider chemical tankers, or tank ships, which increasingly have come to share common features with gas carriers. Thus, as shown in Table 23.32, Section B, the headings of the *IBC Code* are very similar to those of the *ICG Code*.

Cargo containment systems are of four types: (1) independent tank, (2) integral tank, (3) gravity tank, and (4) pressure tank.

The cargo tank vent system is either an open vent or a controlled venting system using pressure/vacuum valves. The code gives requirements on the type of system for each product.

The *IBC Code* recognizes four types of environmental control system: inerting, padding, drying and ventilation. It gives requirements on the type of system for each product.

Matters covered under the special requirements of the *Code* include requirements concerning (1) acids, (2) toxic products, (3) inhibited cargoes, (4) high vapour pressure cargoes, (5) cargoes with a wide flammable range and low ignition temperature and (6) cargo contamination, together with requirements for a number of specific chemicals.

The *Code* gives a tabular summary of minimum requirements covering (1) product name, (2) UN number, (3) pollution category, (4) hazards, (5) ship type, (6) tank type, (7) tank vents, (8) tank environmental control, (9) electrical equipment, (10) gauging, (11) vapour detection, (12) fire protection, (13) materials of construction, (14) respiratory and eye protection and (15) special requirements.

With respect to operation, chapter 16 of the *IBC Code* treats the following topics: (1) tank filling, (2) cargo information, (3) personnel training, (4) opening of and entry into tanks, (5) stowage of cargo samples and (6) cargoes not to be exposed to excessive heat.

There are an appreciable number of chemicals to which the code does not apply, and these are listed in it.

23.18 Marine Transport Environment

23.18.1 Shipping

Information on the number of ships is available through Lloyds Register. The world fleet of oil tankers, chemical tankers and LGCs as given by Lloyds for 1986, quoted by Sanders and Aldwinckle (1987), is Further information on LGCs is given in Section 23.16.

Ship type	*No. of ships*	*Deadweight tonnage* ($\times 10^6$ te)
Oil tanker	5,985	240.2
Oil/chemical tanker	502	7.3
Chemical tanker	861	6.1
Gas carrier	770	10.1
Total	8,133	263.7
World fleet	75,266	647.6

23.18.2 Marine incidents

Lloyds Register also provides information on shipping incident statistics. Other sources of information are the *Interim Report of the Tanker Safety Group* (Tanker Safety Group, 1977) and *Analysis of Serious Casualties to Sea-Going Tankers* 1968–80 by the IMO.

Table 23.34 gives data from the Tanker Safety Group report. The accident rates are similar for all classes of ship. There is no evidence that very large ships, particularly very large crude carriers (VLCCs) are more liable to accidents. The yearly figures show no discernible trend with time.

For chemical tankers, information on fires and explosions has been given by M.R.O. Jones and Bond (1984), as shown in Table 23.35, which gives the number of fires and explosions, the size of vessel involved, the operation involved in each case and the source of ignition.

23.18.3 Substandard vessels

A study of the relation between the standards of ship design and operation and the probability of a ship accident has been reported in *Substandard Tankers* (van Poelgeest, 1978). In a comparison between 37 tankers owned by a Greek tanker operator and 37 oil company-owned tankers for the year 1973, this author found that whereas the latter ships were involved in some 10 incidents, mostly relatively minor, with a loss of 10 vessel-days, 28 of the former were involved in accidents, in many cases sustaining serious damage, and some in more than one incident, with a loss of 1072 vessel-days. The total of substandard tankers in the world tanker fleet of vessels of 6000 GRT and larger is estimated by van Poelgeest as approximately 450 vessels or 13–15% of the fleet.

Further information on substandard vessels is available in the 1993 *Annual Report* of the Paris Memorandum (1993). This gives statistics on the number of vessels, the number delayed/detained following inspection and the major categories of deficiency. In 1993, there were 17,294 inspections covering 112,523 ships, with 43,071 deficiencies and 926 detentions. The average proportion of vessels detained is about 8%, with some 10 states having at least double this proportion. The proportions for France, Germany, the UK and the USA are 4%, 3%, 2% and 0%, respectively. The proportion of the total delays/detentions attributable to different types of vessel includes 1.3% for gas carriers, 5.3% for chemical carriers and 10.7% for tanker/combination carriers, the proportions of each of these types detained being 6%, 8% and 7%, respectively. The breakdown of the major categories of deficiency is: life-saving appliances, 24.3%; firefighting appliances, 16.8%; general safety, 12.9%; navigational equipment, 11.6%; ship's certificates, 5.2%; MARPOL requirements, 4.7%; and other, 24.6%. The report refers to the 'increasingly ageing world fleet operating in a marginal market'.

23.18.4 Shipping: LPG

There is a large trade worldwide in LFGs. Accounts of this trade are given in *LNG Log* by SIGTTO (1986) and by Aprea (1983), Bouckaert and Cappoen (1984) and Glass (1987).

LNG Log contains statistical information on individual LNG carriers and terminals; on cargo containment systems; and on carrier movements, or voyages. In 1986, there were 963 movements of LNG carriers.

Further data on the number of LNG and LPG carriers are provided by Aprea (1983), Blything and Edmondson (1983), Bouckaert and Cappoen (1984) and Aldwinckle and

[a] Serious casualties are those involving loss of life, structural damage or pollution.

McLean (1985). Tables 23.36 and 23.37 give data on the world LNG and LPG fleets, respectively.

The number of LNG carriers (*c.* 1984) is given in Table 23.36, Section B, as 81. A vessel capacity of 125,000 m^3 has become the standard size for a modern LNG carrier. For LPG carriers, the number (*c.* 1984) given in Table 23.37, Section B is 708. Of these, 213 were >5000 m^3 capacity.

Only a proportion of the LPG fleet consists of refrigerated carriers, the rest being pressure carriers. Holdsworth (1985) states that a figure of 107 ships represents 44% of world capacity in refrigerated LPG ships, which suggests a world fleet of some 243 vessels.

The approximate worldwide deep sea movements per year of LFGs other than LNG and LPG are given by Glass (1987) as 370 for ethylene, 290 for propylene and 520 for butadiene.

23.18.5 Marine incidents: LPG

Incident statistics for LNG carriers are given by R.A. Cox, Comer *et al.* (1980) and Aldwinckle and McLean (1985), while Blything and Edmonson (1983) give data on fires and explosions. For LPG carriers, data on incident statistics are given by Aldwinckle and McLean (1985) and data on fire and explosion are given by Blything and Edmondson (1983).

Table 23.38 gives incident data for the world LNG and LPG fleets and, for comparison, for the world cargo fleet. These include incidents involving fire and explosion as well as grounding and collision. Further data on LNG carrier incidents is given in Table 23.39, which again provides information both on grounding and collision and on fire and explosion. Data on LPG carrier fire and explosion are shown in Table 23.40 and data an stranding and collision are given in Table 23.41. For the world LGC fleet, which includes both LNG and LPG carriers, data are given in Table 23.42.

These overall data on incidents and incident rates may be supplemented by data for specific waterways and ports. Incident data for the port of Rotterdam have been given by Ligthart. Figure 23.12 gives information on collision and stranding determined for this port.

For the Thames estuary, accident data are given in the two *Canvey Reports* as described in Appendix 7.

Table 23.35 *Fire and explosions on chemical tankers in the period 1973–83 (after M.P.O. Jones and Bond, 1984)*

A Number of incidents

Location	*No. incidents*
Cargo tank	14
Pump room	9
Engine room	34
Other	11

23.18.6 Ship collision

Two principal ship accident modes which may give rise to large loss of containment are collision and grounding. Both have been the subject of study. Studies of collision include those of Minorsky (1959), Kinkead (1978 SRD R91, 1980), Böckenhauer (1980) and F.S. Harris (1986).

The requirements for collision resistance are given by Harris as stability after collision, avoidance of spillage and energy absorption by the structure.

Minorsky presented a model of collision damage based on the equations for conservation of energy and momentum. These are respectively

$$\frac{1}{2}m_1v_1^2 = \frac{1}{2}(m_1 + m_2)V^2 + E \qquad [23.18.1]$$

and

$$V = \frac{v_1m_1}{m_1 + m_2} \qquad [23.18.2]$$

where E is the energy absorbed in the collision, m_1 is the effective mass of the striking ship, m_2 is the effective mass of the struck ship, v_1 is the speed of the striking ship before collision and V is the residual speed of the two ships after the collision.

Minorsky took the effective mass of the struck ship as the actual mass plus the added hydrodynamic mass δm, which he estimated as 0.4 m_2.

He defined a resistance factor R_T as

$$R_T = \sum P_NL_Nt_N + \sum P_nL_nt_n \qquad [23.18.3]$$

where L is the length of damage, P is the depth of damage and t is the thickness, and the subscripts N and n refer to the Nth member in the striking ship and the nth member in the struck ship.

From ship collision data, he obtained an empirical correlation between E and R_T, as illustrated in Figure 23.13. The relation may be expressed in the form:

$$E = mR_T + c \qquad [23.18.4]$$

where c and m are constants.

Table 23.37 World LPG fleet

A Blything and Edmondson (1983) – Date: 1981

Ship capacity (m^3)	*No. of ships*
<5,000	409
>5,000	159
Total	568

B Aldwinckle and McLean (1985): No. of ships

Ship capacity (m^3)	*Ship age* (year)							
	0–4	5–9	10–14	15–19	20–24	25–29	>30	*Total*
Unknown	6	3	1				2	12
<5,000	93	97	92	121	49	18	13	483
5,000–9,999	30	17	4	7	1			59
10,000–29,999	14	17	7	20	5		2	65
30,000–49,999	3	2	3	3	1	1		13
50,000–69,999	5	8	9	1				23
70,000–99,999	14	27	8	1				50
100,000–129,999		1	2					3
Total	165	172	126	153	56	19	17	708

Minorsky also defined an absorbed energy coefficient K and a ratio R of mass of the striking and struck ships:

$$K = \frac{m_2 + \delta m}{m_1 + m_2 + \delta m} \qquad [23.18.5]$$

$$R = m_1/m_2 \qquad [23.18.6]$$

Figure 23.14 shows the relation given by Minorksy between the two parameters. As $R \to 0, K \to 1$, and as $R \to 0, K \to 0$. The relationship is not very sensitive to the value of δm. Using this model, Minorsky was able to determine the critical impact speed of the striking ship required to cause a given degree of damage.

The following treatment by Böckenhauer (1980) for collision damage to a gas carrier is typical of analyses based on the Minorsky method. From Equations 23.18.1 and 23.18.2

$$E = \frac{m_1 m_2}{2(m_1 + m_2)} v_1^2 \qquad [23.18.7]$$

Then at the critical impact speed v_{cr} of the striking ship and at the corresponding critical energy absorption E_{cr}

$$E_{\mathrm{cr}} = \frac{m_1 m_2}{2(m_1 + m_2)} v_{\mathrm{cr}}^2 \qquad [23.18.8]$$

or

$$v_{\mathrm{cr}} = \left(\frac{2E_{\mathrm{cr}}(m_1 + m_2)}{m_1 m_2} \right)^{1/2} \qquad [23.18.9]$$

The critical energy absorption E_{cr} is given either as the sum of the energy absorptions of the striking ship E_2, and of the struck ship E_2:

$$E_{\mathrm{cr}} = E_1 + E_2 \qquad [23.18.10a]$$

or as

$$E_{\mathrm{cr}} \approx 2E_2 \qquad [23.18.10^*]$$

whichever is the lesser. The energy absorption E_2 is obtained from the resistance factor using an expression similar to Equation 23.18.3 but with a different definition of the resistance factor.

If the struck ship is moored at a jetty so that the residual speed V is zero

$$\tfrac{1}{2} m_1 v_1^2 = E \qquad [23.18.11]$$

$$v_{\mathrm{cr}} = \left(\frac{2(E_{\mathrm{cr}} + E_{\mathrm{f}})}{m_1} \right)^{1/2} \qquad [23.18.12]$$

where E_f is the energy absorption of the fender. This is taken as

$$E_{\mathrm{f}} \leq 0.3 \qquad [23.18.13]$$

Some critical impact speeds where the struck ship is an LNG or LPG carrier as obtained by Böckenhauer are given in Table 23.43.

Kinkead (1978 SRD R91) has studied the collision of LNG carriers using a method based on that of Minorsky but extended by a more detailed analysis of the energy absorbed in the processes causing damage, which he calls the substantiation analysis.

Figure 23.15 shows Minorsky-type curves obtained in this work. The dotted line is based on the more detailed substantiation analysis. Its principal feature is that it

indicates that for striking ships in the displacement range 15,000–30,000 ton, the critical impact speed is considerably less than the simpler analysis suggests.

Kinkead also gives a set of curves for the critical impact speed of the striking ship hitting an LNG carrier under different conditions, as shown in Figure 23.16.

23.18.7 Ship grounding

Of at least equal importance are ship groundings. Here there are two somewhat different scenarios which need to be considered. One is where the ship is moving at speed and its bottom is torn by a rock. Treatments of this situation have been given by Kitamura, Okumoto and Shibue (1978) and by Vaughan (1978). It has been shown by Poudret *et al.* (1981) that Vaughan's approach fits well such a grounding incident which occurred with the *El Paso Paul Kayser*, as described below.

The other scenario is grounding of the ship at low speed as a result of weather, currents, loss of control, etc. This is probably the situation which is most likely to occur in confined waterways. It has been studied by Johnsen and Jensen (1983) for the case of smooth rocks and by Kinkead (1983 SRD R 342, 1983) for that of sharp rocks.

The ships considered by Kinkead are LPG carriers in the capacity range 11,754–58,950 m^3. Grounding may occur with the ship moving forwards or sideways. For the ridged

rock formation considered, he obtains using a Minorsky-type analysis for a 15,495 m^3 carrier for forward grounding, a critical grounding velocity of 5.57 knot and for a 31,296 m^3 carrier one of 5.11 knot. The sideways critical grounding velocities for these two vessels obtained from Minorksy analysis are 3.82 and 3.23 knot, respectively. However, using a more detailed analysis the latter two values reduce to 2.69 and 2.86 knot, respectively. The analysis contains some conservative assumptions. One is that the rock is not friable, another that no energy is absorbed by other rock projections.

Kinkead states that imperfectly controlled manoeuvres during berthing of supply vessels at offshore platforms have occurred with sideways collision impact velocities of between 2.9 and 4.0 knot (between 1.5 and 2.0 m/s). Thus, the impact velocities which occur under imperfect control are of the same order as the estimated critical grounding velocities.

23.18.8 Piracy

A quite different kind of risk is that posed by piracy. The activities of pirates are monitored by the regional piracy centre of the International Maritime Bureau in Kuala Lumpur. Most attacks have occurred in the South China Sea, off Hong Kong and around Indonesia, and also off Somalia. In 1994, 60 vessels were boarded by pirates, almost twice as many as in the previous year. In several cases, ships were taken over and sailed to a port, where the cargo was unloaded and stolen. Most of the ships attacked were dry cargo vessels, but eleven oil tankers, four gas carriers and two chemical tankers were also involved.

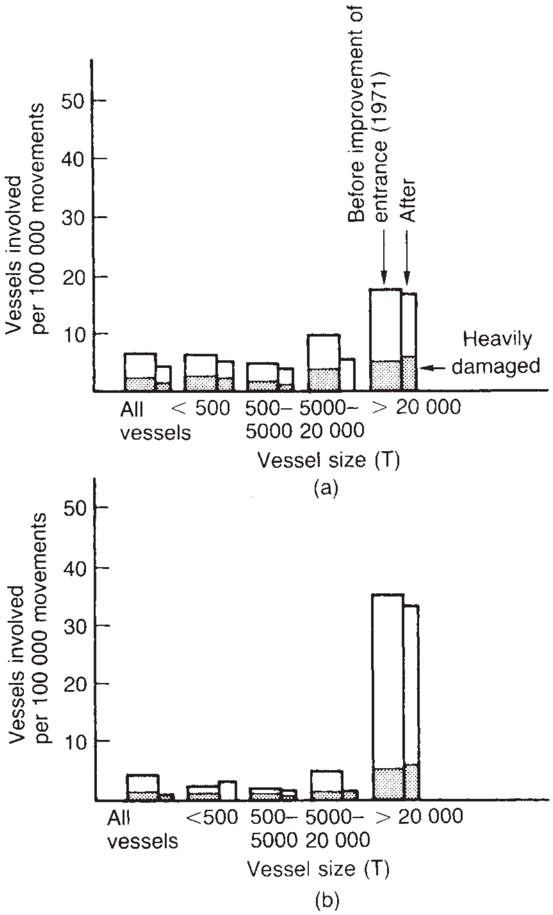

Figure 23.12 *(a) Collision ratio and (b) stranding ratio per tonnage class for vessels entering and leaving Rotterdam. T, gross registered ton (= 100 ft^3) (Ligthart, 1980) (Courtesy of Elsevier Science Publishers)*

23.19 Air Transport

Regulatory control of the carriage of hazardous materials by air has traditionally been the concern of the Restricted Articles Board of the International Air IATA. The IATA Restricted Articles Regulations have placed restrictions on the type and quantity of chemicals which are carried and specify requirements for packaging and labelling. These regulations are binding on IATA member airlines and are applied by many which are not members. They are also generally accepted by governments, who apply them to all aircraft registered with them.

In 1983, the International Civil Aviation Organization (ICAO) issued its *Technical Instructions for the Safe Transport of Dangerous Goods by Air* (the *Technical Instructions*). These introduced into air transport the UN system for the classification and packaging of dangerous goods. These *Technical Instructions* have largely superseded the IATA regulations.

In Britain, the Air Navigation (Dangerous Goods) Regulations 1985, and subsequent amending regulations, require dangerous goods to be carried in accordance with the *Technical Instructions*. The enforcing authority is the CAA.

The IATA continues to publish its Dangerous Goods Regulations. These are broadly compatible with the *Technical Instructions* and continue to be used by many operators.

The *Technical Instructions* give specific instructions for the packaging and set maximum quantities for carriage.

There are some substances the carriage of which is forbidden. These forbidden substances fall into three categories: (1) forbidden unless authorized by the state of origin; (2) forbidden unless authorized by all the states concerned; (3) forbidden in all circumstances. In the United Kingdom, requests for exemptions must come from the air operator and any exemption is issued to him.

The quantities of hazardous materials moved by air are quite large. In general, the quantities permitted for carriage are larger for cargo than for passenger aircraft. There has been, however, a steady decline in the proportion of cargo aircraft, so that increasingly carriage is in passenger aircraft.

The carriage of radioactive substances is governed by the IATA Regulations on Radioactive Materials, which embody the International Atomic Energy Agency (IAEA) Regulations on the Safe Transport of Radioactive Materials.

In general, the carriage of hazardous materials does not appear to be a significant cause of, or aggravating feature in, aircraft accidents. However, improperly packed and loaded nitric acid was declared the probable cause of a cargo jet crash at Boston, MA, in 1973, in which three crewmen died (Chementator, 1975 Mar. 17, 20).

Information on aircraft accidents in the United States is given in the NTSB *Annual report* 1984. In 1984, for scheduled airline flights, the total and fatal accident rates were 0.164 and 0.014 accidents per 10^5 h flown, respectively. For general aviation, that is, all other civil flying, the corresponding figures were very much higher at 9.82 and 1.73.

23.19.1 Rotorcraft

There is increasing use made of rotorcraft – helicopters and gyroplanes. Although these are used to transport people rather than hazardous materials, it is convenient to consider them here.

An account of accidents is given in *Review of Rotorcraft Accidents 1977–1979* by the NTSB (1981). In 64% of cases (573 out of 889), pilot error was cited as a cause or related factor. Weather was a factor in 17% of accidents. The main cause of the difference in accident rates between fixed wing aircraft and rotorcraft was the higher rate of mechanical failure in rotorcraft accidents.

The NTSB *Annual report* 1981 gives for rotorcraft an accident rate of 11.3 and a fatal accident rate of 1.5 per 100,000 h flown.

23.20 Transport Emergency Planning and Spill Control

23.20.1 Emergency planning

The transport of hazardous materials requires emergency planning, but the nature of the emergency plans depends on the mode of transport. Road transport is covered by the CHEMSAFE scheme. Accounts of emergency planning for transport include those in HS(R) 27 and in the ACDS Transport Report (Cooney, 1991) and those by Bosman (1980), Cumberland (1982) and Cooney (1985). The topic is discussed in Chapter 24 and treatment here is limited to two aspects not dealt with there: marine emergencies and spill control.

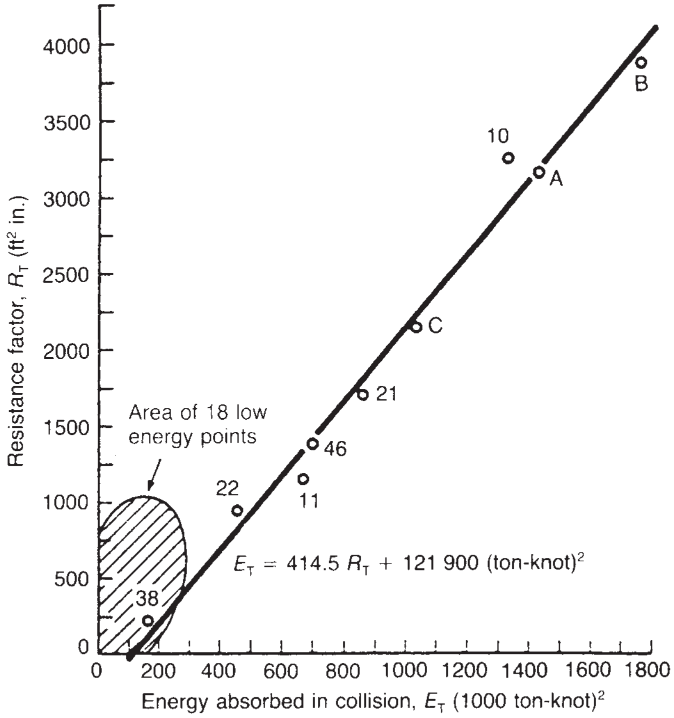

Figure 23.13 *Minorsky model of ship collision: empirical correlation between resistance to penetration and energy absorbed in collision (Minorsky, 1959) (Courtesy of the Journal of Ship Research)*

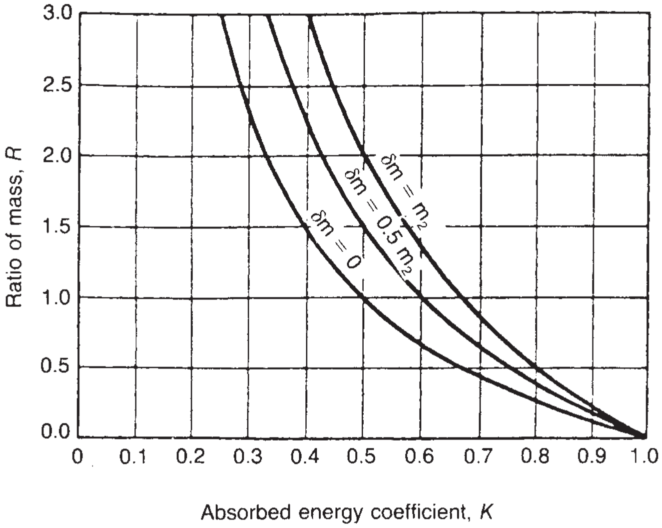

Figure 23.14 *Minorsky model of ship collision: effect of added virtual mass of water on energy absorbed in collision (Minorsky, 1959) (Courtesy of the Journal of Ship Research)*

[a] Values in brackets are for struck ship moored at jetty.

[b] Oil tanker fully loaded.

[c] Oil tanker in ballast.

23.20.2 Marine emergencies

The CIMAH Regulations 1984 contain a requirement for emergency planning for the fixed site to which they are applicable, which may include a port area. The DSHA Regulations 1987, Regulations 26 and 27, require ports handling hazardous substances to undertake emergency planning. HS(R) 27 gives in Appendix 3 detailed guidance for emergency planning in ports.

IMO guidance is contained in *Emergency Procedures for Ships Carrying Dangerous Goods* (IMO, 1991 IMO-254) (EmS). Other guidance is given in *Liquefied Gas Handling Principles on Ships and in Terminals* (SIGTTO, 1986/3), *Guide to Contingency Planning for the Gas Carrier Alongside and within Port Limits* (ICS, 1987/6), *Contingency Planning and Crew Response Guide for Gas Carrier Damage at Sea and in Port Approaches* (ICS, 1989/8), *Guide to Contingency Planning for Marine Terminals Handling Liquefied Gases in Bulk* (ICS, 1989/9) and *Guidelines for the Preparation of Shipboard Oil Spill Contingency Plans* (OCIMF, 1990/9).

Emergency shut-down of ship–shore transfer is covered in *Guidelines for the Alleviation of Excessive Surge Pressure in BSD* (SIGTTO, 1987/4) and *Recommendations and Guidelines for Linked Ship/Shore Emergency Shutdown of Liquefied Gas Cargo Transfer* (SIGTTO, 1987/5).

Firefighting is covered in *Cargo Firefighting on Liquefied Gas Carriers* (SIGTTO, 1986/2) and *Guide on Marine Terminal Fire Protection and Emergency Evacuation* (OCIMF, 1987/6).

Marine spill control is covered in *Guidelines for the Preparation of Shipboard Oil Spill Contingency Plans* (OCIMF, 1990/9).

23.20.3 Spill control

There are a number of basic techniques for spill control, but there are also some measures which are specific to the mode of transport.

Accounts of spill control are given in *Highly Hazardous Materials Spills and Emergency Planning* (Zadic and Himmelman, 1978) and *Hazards Materials Spills Handbook* (G.F. Bennett, Feates and Wilder, 1982) and by R.L. Mitchell (1971, 1982), R.H. Hiltz (1982), Scholz (1982), H.M. Freeman (1984) and Deckert (1986)

The ease of detection of a spill varies with the mode of transport. The driver of a road tanker will generally know at once. A spill on a rail tank wagon may not be appreciated immediately. A leak from a pipeline may remain undetected for a considerable time.

The general principles of spill control in the field are described by Scholz (1982). The spill may be a continuing escape or a complete spillage of the whole contents. In the former case, the first step is the termination, or at least reduction, of the discharge.

The measures which can be taken to effect this depend on the circumstances. If the leak is below the liquid level, it may be reduced by changing the orientation of the tank so that it is vapour rather than liquid which comes out; often, however, this is not practical.

If the source of the leak is a valve, measures may be taken to shut it off. If the leak is from a puncture of the tank itself, it may be possible to plug it. The liquid in the leaking tank may be transferred to another vehicle, either as the prime method of terminating the discharge or after that has been done by some other method. Resort has also been had to dumping the liquid in a pit and then 'neutralizing' it.

It may be possible to plug the leak by bolting on a patch plate. There are also special plugging devices such as the foam plugger developed by the EPA.

Following any measures to effect (1) termination of discharge, the other measures for spill control are (2) containment, (3) suppression of evaporation, (4) removal and (5) disposal.

Whether the spill is a virtually instantaneous release of the whole tank contents or a more gradual leak, the liquid will form a pool on the ground. Priorities are to prevent the liquid entering drains and sewers, and water courses, and to limit the size of the pool formed.

Depending both on the nature of the material spilled and the population exposed, there may be a need to reduce the rate of evaporation of the liquid pool. General methods of doing this are described below, but they may or may not be practical in a given case.

Methods of removal include pumping and use of sorbents. The pumps used must be able to handle the liquid with which they are presented, which will include not that originally spilled but any added to control evaporation with, possibly, earth and other solid matter. Sorbents include straw and synthetic sorbents. The material recovered is transferred to temporary storage and then passes to disposal.

Spill control measures which are available in principle may be impractical in many transport situations, because they require additional equipment or materials, or for some other reason. Accounts are available of measures actually used in the field, including those of R.L. Mitchell (1982) and Scholz (1982).

23.20.4 Spill control: evaporation

As just described, it may be necessary for highly hazardous materials to take measures to reduce the rate of evaporation. An account of methods available to do this is given by R.H. Hiltz (1982). They include the use of (1) liquid phase modification, (2) surface cooling, (3) mechanical covers, (4) films and foams and (5) sorbents.

For some liquids, the rate of evaporation may be reduced by modifying the liquid phase in some way. Some basic principles are dilution with water, reaction with another chemical and turning the liquid into a gel by use of a gelling agent.

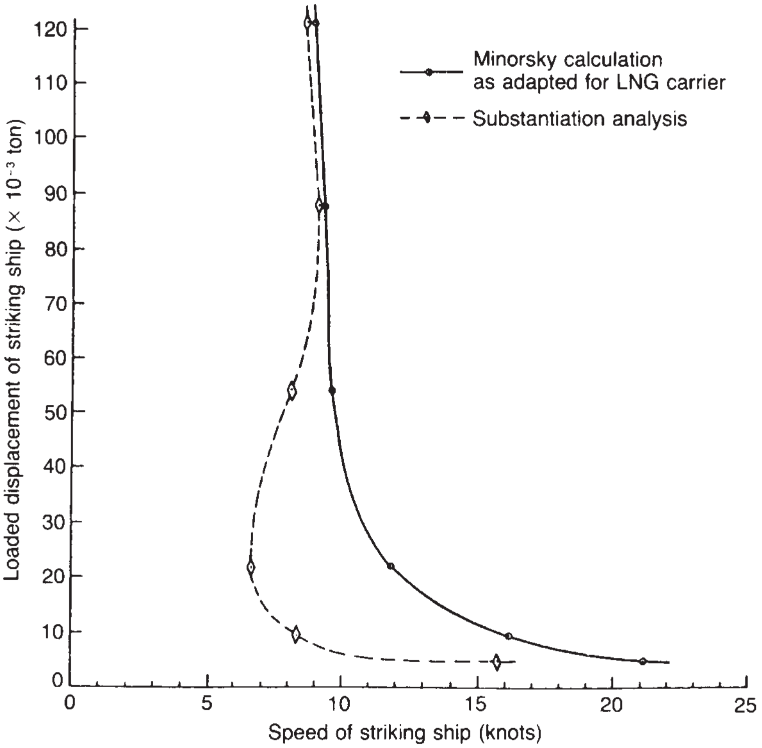

Figure 23.15 *Kinkead model of ship collision: comparison with Minorsky model for the case of a methane carrier stationary in mid-channel (Kinkead, 1978 SRD R391) (Courtesy of the UKAEA Safety and Reliability Directorate)*

Dilution with water can be effective in some cases, provided the spilled liquid is miscible with water and the pool is sufficiently well confined that addition of water does not cause it to spread.

There is available a Universal Gelling Agent which for a number of substances has been shown to be effective in forming a gel. These substances include water, gasoline and sulfuric acid. An account of this work is given by Pilie *et al.* (1975) and Baier *et al.* (1975/76) and the list of substances is quoted by R.H. Hiltz (1982). Hiltz states that although the formation of a gel may reduce the rate of evaporation, its value lies primarily in effecting immobilization of the spill. Further, the usefulness of the technique may be limited by the time taken for the gel to form. Few gels form within minutes and some take hours.

The vapour pressure of the liquid, and hence the evaporation, may be reduced by cooling the liquid surface, using ice, dry ice or liquid carbon dioxide. To be effective, this method requires good mixing of the coolant and the liquid.

One form of mechanical covers is cloth covers. Another is particulate covers such as small plastic spheres or the like. Sprays based on materials such as urethane are also sometimes classed as mechanical covers.

Films provide essentially a two-dimensional cover and foams a three-dimensional one. Surfactant films act partly by film resistance and partly by quiescence. They may be applied as a spray or in the form of a foam which rapidly collapses. There is a wide variety of foams and a good deal of work has been done to assess their suitability for the control of the evaporation of particular chemicals. Accounts include those of Baier *et al.* (1975), R.H. Hiltz and Friel (1976), Gross (1978), Norman and Dowell (1978), R.H. Hiltz (1982, 1987) and R.H. Hiltz and Brugger (1989). A matrix of foam suitability is given by R.H. Hiltz (1982). This shows high expansion surfactant foam as the best formulation for many of the substances listed, including gasoline, LNG, chlorine and ammonia.

Sorbents are used both to reduce evaporation and to remove spilled liquid. With regard to the former function, the sorbent needs to be continuously replenished. If it is simply allowed to become saturated, it may be ineffective in reducing, and, by increasing the surface area, may even promote vaporization.

23.20.5 Spill control: road transport

The control of a spill from a road tanker illustrates many of the basic principles of spill control. An account of the control of chlorine spills has been given by R.L. Mitchell (1982), with particular reference to the work in the United States of the Chlorine Institute.

The methods which he describes include: shutting off leaking valves; plugging or patching of punctures; transferring the load; and dumping the load into a pit and then neutralizing it.

A large proportion of cases involve leaking valves. The handling of a spill situation is greatly facilitated if the valves and manways are standardized. As Mitchell describes, for the carriage of chlorine in the United States, standardization of these items has been achieved for both rail tank cars and tank trucks. The Chlorine Institute has developed a number of emergency kits which include the equipment to assist in valve shut-off.

Some measures may be taken immediately by the tanker driver such as notifying the incident, clearing the area and, if possible, creating temporary diking to divert or contain the liquid spill. Others such as load transfer or dumping and neutralization require additional equipment and/or materials and need to be undertaken by a trained team.

23.20.6 Spill control: pipelines

For pipelines spill control is treated in *Methods of Prevention, Detection and Control of Spillages in West European Oil Pipelines* (CONCAWE, 1987 1/87) and spill clean-up in *Revised Inland Oil Spill Clean-up Manual* (CONCAWE, 1981 7/81).

CONCAWE 1/87 deals with causes of spillage, which are essentially: mechanical failure, operational failure, corrosion, natural hazards and TPA; prevention by design, construction and operation; detection by visual observation monitoring of pipeline parameters; control by operational measures; and emergency procedures.

Pipeline parameters which may provide an indication of a leak, and which may be monitored for this purpose, include pressure and flow. A leak may be detected by a fall in pressure or flow, or an excursion of the volume balance. Other methods of detection are based on negative pressure waves and on ultrasonic noise. Pipeline leak detection is discussed further in Chapter 19.

Emergency procedures for dealing with a pipeline spill include: notification of the leak; actions to reduce or stop the flow; location of the leak point; and measures to stop the hole.

Spill clean-up is treated in CONCAWE 7/81 under the headings of (1) behaviour of oil spills, (2) identification of contaminated zones, (3) clean-up strategy, (4) clean-up methods for oil on ground surfaces, (5) clean-up methods for subsoil, (6) clean-up methods for ground waters, (7) clean-up methods for surface waters, (8) clean-up methods in ice and snow, (9) integrated clean-up methods and (10) emergency kits for inland oil spills.

23.21 Transport Case Histories

23.21.1 Packaging and labelling

Misidentification of chemicals can have very serious consequences. This was highlighted by the *Firemaster* tragedy in Michigan in 1973, which has been described in *Bitter Harvest, The Poisoning of Michigan* (Egginton, 1980) and by Getty, Rickert and Trapp (1977), Kay (1977) and Selikoff (1979). A consignment of *Firemaster*, a fire-retardant chemical (polybrominated biphenyl, PBB), was dispatched from the Michigan Chemical Company instead of an animal feed additive which had a rather similar name. The consequences were a serious contamination of food eaten by animals and humans throughout much of the state. Cattle showed severe symptoms of poisoning. Somewhat similar symptoms were also found among residents of the state.

23.21.2 Road transport

Some principal incidents in the road transport of hazardous materials are shown in Table 23.44. Many of these incidents are described in Chapters 16–18 on fire, explosion and toxic release or are given in the case histories in Appendix 1.

In particular, attention is drawn to: the incidents at Deer Lake in 1959 (Case History A27) and Eagle Pass, Texas, in 1975 (Case History A76) involving BLEVEs and/or fireballs; those at Berlin, New York, in 1962 (Case History A30), at Lynchburg, Virginia, in 1972 (Case History A59) and at St Amand-les-Eaux, France, in 1973 (Case History A66), involving vapour cloud explosions; and those at Lievin, France, in 1968 and Houston, Texas, in 1976 (Case History A84), involving toxic releases.

On 14 July 1978, a road tanker carrying propylene ruptured near a camp site at San Carlos de la Rapita, Spain, and there was a flash fire which resulted in an eventual death toll of some 210 people (Appendix 16).

23.21.3 Rail transport

Some principal incidents in the rail transport of hazardous materials are shown in Table 23.45. Many of these incidents are described in Chapters 16–18 on fire, explosion and toxic release or are given in the case histories in Appendix 1.

In particular, attention is drawn to: the incidents at Crescent City, Illinois, in 1970 (Case History A50), Kingman, Arizona, in 1973 (Case History A63), Belt, Montana in 1976 and Waverly, Tennessee in 1978 (Case History A93), involving BLEVEs and/or fireballs; those at East St Louis, Illinois in 1972 (Case History A57) and at Decatur, Illinois, in 1974 (Case History A71), involving vapour cloud explosions; those at La Barre, Louisiana in 1961 (Case History A29) and at Cornwall, Ontario, in 1962, at Crete, Nebraska in 1969 and at Youngstown, Florida in 1978 (Case History A94), involving toxic releases; and that at Glendora, Mississippi in 1969 (Case History A43), involving a major evacuation.

On 10 November 1979, a freight train fire occurred in a BUA of Mississauga, Toronto (Case History A97). The fire was on a tank car containing flammable liquid, but the hazard was much increased by the fact that an adjacent tank car contained chlorine. A major evacuation took place. In fact, the emergency response was effective and the incident was contained, but the incident showed the importance of segregating flammable and toxic substances, so that a fire involving the former does not put the latter at risk.

A derailment of a freight train occurred on 28 September 1982 at Livingston, Louisiana (Case History A103). Some 43 cars were derailed and there was a massive fire. A cause of the accident was the misapplication of the brakes by an unauthorized rider in the locomotive cab, a clerk who was 'substituting' for the driver. The driver was found to have consumed a large amount of alcohol shortly beforehand.

There have also been incidents in tunnels. On 20 December 1984, a train conveying 835 te of petrol derailed in the Summit Tunnel, near Todmorden, Yorkshire (A. Jones, 1985). A spill occurred and was ignited, giving rise to a fire. One tank wagon suffered a BLEVE. The fire, which reached a mean temperature of 1300°C and 1530°C in places, destroyed the train and severely damaged the 2638 m long tunnel. Columns of flame and smoke rose high above the ventilation shafts.

23.21.4 Waterway transport

Some principal incidents in the inland waterway transport of hazardous materials are shown in Table 23.46.

A collision on the Seine, below Rouen, between the two product tankers *Foyoh Maru* and *Vitoria*, in ballast after discharging a cargo of gasoline, resulted in a violent explosion on the latter killing six of the crew. The vessel itself broke in two and was completely destroyed, whilst fragments from it fell over a wide area.

[a] L.N. Davis (1979).

On 30 August 1979, near Good Hope, Mississippi, the MV *Inca Tupac Yupanqui* lost steering and collided with the butane tank barge *Panama City* moored at a dock (Case History A96). The freighter's bow struck the barge amidships, cutting it in two and causing a fire and explosion which killed 12 people and did extensive damage to the dock. Half the butane barge drifted downstream and continued burning for about 24 h.

At St Louis on 2 April 1983, a four-barge tow pushed by the towboat *City of Greenville* hit a bridge, causing the breakway of three barges and an oil spill fire. The burning barges caused further fires along a 2-mile stretch of the river front. A year later on 24 April 1984, the same bridge was hit by a 12-barge tow of grain barges and a breakway of these barges resulted in a chain reaction of other barge breakaways along the waterfront until some 150 barges were adrift.

23.21.5 Pipeline transport

There have been a number of major accidents arising from the pipeline transport of hazardous materials.

One of the worst disasters in the process industries was a pipeline accident. On 24 February 1984, petrol leaked from a pipeline passing through a shanty town at Cubatao, Brazil, forming a large liquid pool which then ignited (Case History A108). The death toll is uncertain, but is believed to have run to some hundreds.

An explosion on a natural gas pipeline at Natchitoches, Louisiana, on 4 March 1965 caused a massive split in the pipe and killed 17 people (Case History A37).

1983, Apr. 2	St Louis	*City of Greenville* – collision with bridge	

[a] *Source*: NTSB *Annual Reports* 1979–84.

A leak of propane from a ruptured 8 in pipeline at Port Hudson, Missouri, on 9 December 1970, resulted in a massive vapour cloud explosion (Case History A52).

At Hearne, Texas, on 14 May 1972, a rupture on an 8 in. oil pipeline led to a flowing liquid fire (Case History A58).

A rupture of a 10 in. NGL pipeline at Austin, Texas, on 22 February 1973 resulted in the formation of a vapour cloud which ignited some 20 min later, killing six people (Case History A62).

On 13 March 1990, a gas cloud formed from a rupture of a liquid propane pipeline flowed downhill into the village of North Blenheim, New York (NTSB, 1991 PAR-91-01). The cloud ignited, flashing back to the pipeline rupture. Two people were killed.

Another major pipeline disaster occurred on 3 June 1989 at Ufa in Western Siberia (Case History A127). A leak occurred from a pipeline carrying mixed LPG near a railway line. A massive vapour cloud formed and ignited as two trains were passing. The strength of the explosion has been estimated as equivalent in the far field to 10,000 te of TNT. Initial reports put the death toll at 462, with many others severely burned.

An incident involving a vapour leak on an ammonia pipeline occurred on 6 December 1973 near McPherson, Kansas (Case History A64).

23.21.6 Marine transport

The case histories considered here may be classed as: collisions, groundings and driftings; lightning strikes, fires and explosions; and oil spillages.

On 9 November 1974, the oil/LPG carrier *Yoyo Marti* was in collision in Tokyo Bay with the cargo ship *Pacific Ares*. A 24 m gash was cut in the *Yoyo Maru's* hull and naphtha spilled out and ignited, giving a fire with flames 70 m high. The vessel also had LPG in other cargo tanks, but the LPG tanks and fittings withstood the fire, although LPG from the tank vents burned. Firefighting vessels were for some time unable to approach close due to the heat. The vessel was towed out to sea, where it continued to burn and was eventually sunk by air strikes. The death toll was 33.

In some cases, collisions occur while the vessels are proceeding at full speed. On 9 February 1982, off North Carolina, the barge carrier *Lash Atlantico* and the freighter *Hellenic Carrier* were in collision in thick fog as both vessels were at full speed. There were no injuries, but both vessels were badly damaged, the latter beyond repair. Ten days later, the barge carrier *Del Norte* and the freighter *African Pioneer* collided in the Gulf of Mexico, again both moving at full speed in thick fog. This time there were two serious injuries and again both ships were severely damaged.

On 21 August 1980, the tanker *Texaco North Dakota* travelling at full speed struck a partially constructed oil platform in the Gulf of Mexico (NTSB, 1981 MAR-81-04). The tanker was partly loaded with petroleum products, several cargo tanks were ruptured and fire broke out which gutted the vessel.

On 6 March 1982, the tankship *Golden Dolphin* exploded, burned and sank in the Atlantic 1000 miles to the southeast of Bermuda (NTSB, 1983 MAR-83–07). The vessel was in ballast and an empty cargo tank was being cleaned when a series of massive explosions occurred. An inert gas system had just been fitted but was not in use. The crew abandoned ship but nine died.

On 27 February 1984, in the Gulf of Mexico, the tanker *American Eagle* was wracked by an explosion and broke up (NTSB, 1985 MAR-85-06). Three crew died in the explosion, and two more died later and two were missing in the sinking.

Some shipboard fires and explosions are caused by lightning strikes. On 19 April 1979, the tankship *Seatiger* was hit by lightning while unloading oil at Port Neches, Texas (NTSB, 1980 MAR-80–12). Most of the cargo tanks exploded and the ship was destroyed. A similar explosion occurred on 1 September 1979 at Deer Park, Texas, when the tankship *Chevron Hawaii* exploded while unloading oil at a refinery (NTSB, 1980 MAR-80–18). Lightning ignited flammable cargo vapours on deck which propagated into an empty cargo tank, where the explosion occurred. Amongst the many fragments was a 15 m × 2.1 m section of hull which penetrated an onshore ethanol tank 250 m away. Burning cargo spread across the water and ignited the contents of three petroleum barges, which exploded and sank. Casualties are variously given as 3 or 4 killed and 9–13 injured.

Incidents of fires and explosions on chemical tankers with special reference to ignition in cargo tanks due to static electricity have been given by Jones and Bond (1984).

Some of the worst disasters due to chemicals have been shipboard explosions of ammonium nitrate. On 16 April 1947, a fire broke out on an ammonium nitrate vessel, the *Grandcamp*, in Texas City Harbor (Case History A16). After about an hour, the ship disintegrated with a tremendous explosion, killing all those in the dock. Fire spread to another vessel, the *High Flyer*, which also carried ammonium nitrate, and during the night this vessel too exploded. There were 552 deaths and over 3000 injuries.

On 8 January 1979, a large explosion and fireball occurred on board the *Betelgeuse* which was unloading at an oil terminal at Whiddy Island, Bantry Bay, Eire (Case History A95). All 42 members of the crew were killed as well as a crewman's wife and seven terminal operators.

Further case histories of fire and explosion on vessels in port are given by Rushbrook (1979) and by Dicker and Ramsey (1983).

Large-scale oil spills are a major threat to the environment. Major oil spills are those from the *Torrey Canyon* in 1967, the *Amoco Cadiz* in 1978, the *Exxon Valdez* in 1989 and the *Braer* in 1993. Further details are given in Appendix 11.

23.21.7 Marine transport: LPG

Some principal incidents to LFG carriers are given in Table 23.47. An account of incidents involving LNG carriers has been given by Lakey and Thomas (1983). L.N. Davis (1979) describes incidents with both LNG and LPG vessels.

On 29 June 1979, the LNG carrier *El Paso Paul Kayser* ran aground at Gibraltar. The bottom plating on the starboard side was ripped open but, although deformed, the Gaz Transport containment system, including both the primary and secondary containment barriers, remained liquid tight.

Another grounding of an LNG tanker occurred on 12 December 1980 when the *LNG Taurus* ran aground at Mutsure Anchorage, near Tobata, Japan. The initial damage in this case was less, but was aggravated during 4 days aground.

Worse damage than in either of these cases was sustained by the *El Paso Columbia* when it grounded on 16 December 1981 near Cape Sable in Nova Scotia. The engine room and, apparently, one cargo tank were flooded, but the vessel was in ballast.

In the autumn of 1968, the LPG carrier *Claude* collided with another vessel in Southampton Water. The crew abandoned ship and the vessel drifted until it ran aground. Another ship was chartered to remove the cargo of butane, but backed off when one of the unloading hoses sprang a leak, giving a vapour cloud. The leak was stopped by other boarders.

There have been a number of spills of LNG on the decks of LNG carriers. In 1965, fracture of the mild steel deck of the *Methane Princess* occurred due to a small LNG spill. In the same year, at Arzew another LNG carrier, the *Descartes*, also suffered deck fracture from an LNG overfilling.

LNG carriers have also experienced cargo tank rupture. On 17 November 1969, rupture of a cargo tank occurred on the *Polar Alaska* due to violent sloshing of the LNG liquid. In 1970, the LNG carrier *Arctic Tokyo* suffered cracking of a cargo tank due to sloshing.

On 30 June 1974, there was a pump room explosion and fire aboard the semi-refrigerated LPG carrier *MiUi* as she began unloading butylene at Grangemouth. A butylene vapour cloud estimated at 50 te spread around the area near the ship. The captain, who was in the pump room, died.

There have been several lightning strikes followed by fires on LNG carriers. On 25 December 1964, this occurred to the *Methane Progress* just after loading at Arzew. The next year the same ship again suffered a lightning strike and fire. In 1977, the *LNG Aquarius* unloading at Tobata, Japan, was struck by lightning followed by fire. Lightning strike and fire have also been experienced by the LNG carrier *Jules Verne*.

On 12 October 1984, the LPG tanker *Gas Fountain*, originally the *Gay Lussac*, was attacked by an Iranian aircraft in the Gulf. Three rockets hit the vessel. The crew abandoned ship and were rescued. One rocket caused a rupture of the pipework of No. 2 tank; propane escaped and caught fire. A second rocket penetrated the deck into the containment space of No. 3 tank and exploded near the cargo tank, creating a hole some 3 m × 2 m. Butane escaped and ignited giving a large fire on deck. It is estimated that some 130 te of butane may have escaped during this initial depressurization. The next day, a salvage vessel arrived, extinguished the fires using water jets, and took the vessel in tow. Extensive repairs were carried out. About a month later, most of the LPG cargo, some 17,200 of the original 18,400 te, was transferred to another vessel. An account of this salvage is given by J.A. Carter (1986).

23.22 Transport Risk

23.22.1 Historical record

The risks from the process industries arise from processes, storage and transport. The historical record shows that transport is a major contributor. Transport figures prominently in the case histories given in Appendix 1 and elsewhere in this book. An attempt to quantify the contribution made by transport to the overall risks from the process industries is given below.

23.22.2 Hazard assessment

Another approach to the estimation of the risk from transport is hazard assessment. A major hazard assessment exercise for transport is the ACDS *Transport Hazards Report*, which is described in Appendix 17. An account is given below of hazard assessments of transport by the principal modes of road, rail, ship and pipeline for the principal hazardous substances of LNG, LPG, chlorine and ammonia.

23.22.3 Fixed installations vs transport

A study of the relative risks from fixed installations and transport by road, rail, pipeline and waterway and sea has been made by Haastrup and Brockhoff (1990). They identified in the literature 1793 accidents in both fixed installations and transport. The breakdown of the accidents was as follows:

	No. of accidents	*No. of accidents with fatalities*
Fixed installations	998 (56%)	454 (67%)
Loading/unloading	104 (6%)	47 (7%)
Transport	691 (39%)	181 (27%)
Total	1793	682

and for the transport modes

	No. of accidents	*No. of accidents with fatalities*
Road	205 (30%)	54 (30%)
Rail	257 (37%)	41 (23%)
Pipeline	133 (19%)	56 (31%)
Inland waterway	38 (5%)	4 (2%)
Marine	58 (8%)	26 (14%)
Total	691	181

The authors quote the analysis of transport accidents in the Major Hazards Incidents Data Service (MHIDAS) database made by Appleton (1988 SRD R474), who found that 17% involved road, 36% rail and 21% pipelines.

The authors selected for study accidents occurring after 1959, which gave a total of 510 accidents with fatalities. They present a set of frequency-number curves, including one showing an overall worldwide curve for fixed installations and a corresponding curve for all transport modes. The transport curve lies somewhat above that for fixed installations, but for accidents with the number of fatalities exceeding four there was found to be no statistically significant difference between the two curves. Another of the graphs gives a set of separate curves for worldwide transport by road, rail and pipeline. The three curves lie very close to each other.

[a] R.A Cox, Comer *et al.* (1980); LN. Davis (1979); F.S. Harris (1986); Lakey and Thomas (1983).

[b] LPG vessels in incidents quoted by Harris were all refrigerated carriers.

Some major transport accidents include the ammonium nitrate explosions at Halifax, Nova Scotia, in 1917 and at Texas City in 1947, the road tanker fire at San Carlos in 1978, the pipeline rupture and fire at Cubatao in 1984 and the pipeline rupture and explosion at Ufa in 1989.

23.23 Transport Hazard Assessment

The hazards of transport tend to differ from those of fixed installations, whether process or storage, in a number of ways.

Disregarding pipelines for the moment, transport is characterized by the large amount of energy in the vehicles and vessels, both those carrying the hazardous materials and others. The order of increasing energy is road, rail and marine.

Another difference is the transport environment, which is much less subject to control by management. A transport vehicle or vessel is exposed to a variety of external threats to an extent that the situation is qualitatively different from that on fixed plant.

A third difference is in the variety of locations where an accident may occur and in the population exposed to any incident.

These last two points also apply to some degree to pipelines, but these are fixed installations and tend to have more in common with other fixed installations in the process industries.

The differences between transport and fixed installations are reflected in the hazard assessments. In the hazard assessment of transport, the characteristic features tend to be the incident scenarios, the associated frequency estimates and the population models. By contrast, the hazard models used to determine consequences are generally those developed for fixed installations, although there are some special cases such models for explosions in ship cargo holds or for events in tunnels.

As already mentioned, the most comprehensive hazard assessment for transport is the ACDS *Transport Hazards Report*, which is described in detail in Appendix 17. This deals with the risks from transport by road, rail and sea, though not by pipeline, for the set of four study substances motor spirit, LPG, chlorine and ammonia and also for explosives.

Some other hazard assessments of transport are now described.

23.24 Road Transport Hazard Assessment

The road transport environment has been described in Section 23.6. The account given there includes estimates made in the ACDS report of the frequency of release for the four study substances. The substance which has been most intensively studied is chlorine. Accounts of studies on the risks of chlorine transport include those of Westbrook (1974), Lautkaski and Fieandt (1980) and Canadine and Purdy (1989).

The work of Westbrook (1974) has been described in detail in Chapter 18. In this early study of chlorine transport in the United Kingdom, the author used data for road tankers generally and obtained the following estimate, which he then applied to chlorine tankers also:

$$\text{Frequency of accidents} = 0.63 \times 10^{-6}/\text{tanker-km}$$

The reference distance is for loaded journeys only. Westbrook then assumed that all tanker accidents are potentially spillage accidents. This approach is, therefore, very conservative.

Lautkaski and Fieandt (1980) in a study of the road and rail transport of hazardous materials in Finland made the following estimate for road tankers generally:

Frequency of releases $= 2 \times 10^{-8}$/tanker-km

It is unclear whether the reference distance is for loaded and unloaded journeys or for loaded journeys only. They state that some 15% of releases are due to valve failures and 85% to road accidents.

Canadine and Purdy (1989) describe a hazard assessment of the rail and road transport of chlorine. This study, which is evidently part of the background work preceding the ACDS report, does not explicitly quote release frequencies, although it does give some figures for societal risk. It does, however, provide insight into the factors bearing on a hazard assessment for chlorine road transport.

The principal producer of chlorine in the Unites Kingdom is ICI. The company has some 19 road tankers with payloads of 15–21 te. Over a 60-year period, there have been three leaks. Two were due to incompletely closed valves and were quickly rectified and the third was minor.

The frequency with which these tankers are involved in accidents is significantly lower than for commercial transport generally. The vehicles are fitted with various arrangements to reduce the accident rate, such as high quality suspension, anti-skid devices, anti-jack-knife systems, fuel cut-off devices, additional fire protection, and regular lights and fog lights. The tankers have their liquid and vapour valves protected in a recessed valve chest at the front of the vehicle. They have excess flow valves, and the two latest vehicles also have remotely operated shut-off valves.

Since 1976, the company has taken additional measures to reduce the consequences of any collision. Additional rear and side protection has been fitted to resist penetration, absorb energy and spread the load in the case of collision. The value of these measures was illustrated in 1985 when the most serious accident recorded to date occurred. A chlorine tanker was hit by a 38 te articulated lorry travelling at an estimated 60 mph down a hill near Baslow in Derbyshire. The vehicle veered diagonally across the road and hit the chlorine tanker on its front offside, stopping it dead and driving it sideways across the road. The side protection on the tanker absorbed most of the collision energy and spread the load as it was designed to do; there was no leak.

As described in Section 23.6, the ACDS report gives estimates for the road transport of chlorine which distinguish between releases due to punctures and those due to equipment failure. The frequency of the latter is expressed as releases per journey, but using the average journey length quoted, the following estimates for releases from chlorine tankers are obtained

Frequency of release due to puncture

$= 0.008 \times 10^{-8}$/tanker-km

Frequency of release due to equipment failure

$= 0.003 \times 10^{8}$/tanker-km

Frequency of release $= 0.011 \times 10^{-8}$/tanker-km

The reference distance is for loaded journeys.

23.25 Rail Transport Hazard Assessment

The rail transport environment has been described in Section 23.8. The account given there includes estimates made in the ACDS report of the frequency of release for the four study substances.

As for road transport, the substance which has been most intensively studied is chlorine. Accounts of studies on the risks of chlorine transport include those of Westbrook (1974), Lautkaski and Fieandt (1980), N.C. Harris and Roodbol (1985), Purdy *et al.* (1988) and Canadine and Purdy (1989).

The early study of Westbrook (1974), described in Chapter 18, on chlorine transport in the United Kingdom, used data for freight trains generally combined with a train model for the probability of a release given an accident and obtained for chlorine tank wagons the following estimates:

Frequency of accidents $= 1.18 \times 10^{-6}$/train-km

Probability of release $= 0.041$

Hence

Frequency of release $= 4.8 \times 10^{-8}$/train-kmn or

for an average of 4 tank-wagons per train

Frequency of release $= 1.2 \times 10^{-8}$/tank-wagon-km

The reference distance is for loaded journeys only.

In their study for Finland, Lautkaski and Fieandt (1980) made the following estimates for rail tankers generally:

Frequency of releases $= 0.41 \times 10^{-8}$/tank-wagon-km

The reference distance is unclear. This figure excludes releases due to valve failure, which the authors state amounts in the case of rail transport to 99.5% of all releases. They also say that the additional protective features of chlorine tank wagons were considered, but do not state what allowance, if any, was made for them.

N.C. Harris and Roodbol (1985) describe a hazard assessment of the rail transport of chlorine for the Netherlands. The accident and release estimates which they quote include the following values:

Country	*Event frequency*		
	Accident (train-km)	*Minor release* (tank-wagon-km)	*Major release* (tank-wagon-km)
UK	0.35×10^{-6}	1×10^{-8}	
Netherlands	0.88×10^{-6}	1×10^{-8}	0.1×10^{-8}
USA	6×10^{-6}	6×10^{-8}	1.5×10^{-8}

The reference distance is unclear.

Purdy *et al.* (1988) describe the hazard assessment of chlorine rail transport. This study, which is evidently part of the background work preceding the ACDS report, resembles the treatment given in the latter and is not therefore considered further here.

Another precursor to the ACDS report, the work of Canadine and Purdy (1989), deals with rail as well as road transport of chlorine. As for the road study, figures are given for societal risk though not for release frequency, but the account provides insight into the relevant factors.

The principal chlorine producer, ICI, operates some 40 braked tank wagons which take a 28 te load. This contrasts with the fleet of about 300 unbraked tank wagons of 14 te capacity in the 1950s. The company has never experienced puncture of a chlorine rail tank wagon or a major release.

The older type of tank wagon was involved in some major collisions, including one in which a loaded wagon travelling at 60 mph demolished a signal box, though it did not leak. Since the introduction of the larger wagons, accidents have been limited to minor derailments and collisions in marshalling yards.

The modern wagons have a number of safety features. They are fitted with top mounted needle valves, each with an internal excess flow valve, and protected with a heavily reinforced low profile dome. They are provided with buffer override protection consisting of a reinforced hollow steel section mounted below the buffers across the width of the tank.

As described in Section 23.8, the ACDS report gives estimates for rail transport of chlorine which distinguish between releases due to punctures and those due to equipment failure. The frequency of the latter is expressed as release per journey, but using the average journey length quoted, the following estimates for releases from chlorine tank wagons are obtained:

Frequency of release due to puncture
$= 0.09 \times 10^{-8}$/tank-wagon-km

Frequency of release due to equipment failure
$= 0.02 \times 10^{-8}$/tank-wagon-km

Frequency of release $= 0.11 \times 10^{-8}$/tank-wagon-km

The reference distance is for loaded journeys.

23.26 Tunnel Transport Hazard Assessment

Studies of road tunnel hazards include those of the Larson, Reese and Wilmot (1983) and Considine (1986), and several others referenced by the latter.

In the study by Considine (1986), the two principal events considered are spills and fires. For the estimation of the frequency of these events, the approach adopted was to extrapolate from open route data, the information on incidents in tunnels being inadequate. The author's estimates for road tankers are as follows:

Frequency of spills from tankers $= 5 \times 10^{-8}$/tanker-km

Frequency of fires on tankers $= 1 \times 10^{-8}$/tanker-km

He states that for vehicles carrying packages, the frequency of spills is about twice, and that of fires about half, the above figures. Many package spills occur when the package falls off the vehicle.

Events in tunnels may be initiated by a leak from a container, an explosion in a container, a fire of the load or an explosion of the load. The scenarios considered are fire, explosions (physical, condensed phase and vapour cloud) and toxic release.

The hazard models used to predict the consequences are for the most part adaptations of those developed for events in the open. For pool spread, a two-dimensional adaptation of the SPILL code was utilized. Gas dispersion is dominated by the tunnel ventilation. For heavy gas dispersion, use was made of a two-dimensional adaptation of the DENZ and CRUNCH codes for instantaneous and continuous releases, respectively, with the cloud advected at the ventilation velocity. For physical explosion the code GASEX was used. For condensed phase explosions, empirical correlations given in Christopherson (1946) were used to predict overpressure and impulse as a function of charge size, tunnel cross-section and distance. For vapour cloud deflagration, a simple combustion model was used based on a constant flame velocity and shock velocity, followed on completion of combustion by transition to a one-dimensional fluid flow code.

Four tunnels were studied. The data given include the following:

	Tunnel 1	*Tunnel 2*	*Tunnel 3*	*Tunnel 4*
Length (m)	1030	1483	1436	650
No. of tubes/lanes per tube	2/2	1/2	1/2	2/3
Lane width (m)	3.65	2.41	3.65	3.65
Headroom (m)	5.1	4.72	5.03	5.1
Ventilation system	Longitudinal	Semi-transverse	Semi-transverse plus section of longitudinal	Longitudinal
Construction	Submerged section	Driven tube	Driven tube	Cut and cover

An explosion may cause damage to the tunnel. In general, experiments indicate that damage in a large tunnel correlates better with mean overpressure than with transient peak overpressures. For the condensed phase explosions, peak overpressures were high, but the serious structural failures predicted were limited to two tunnels. These failures were of the roof and median wall in Tunnel 4 and of the road support in Tunnel 3 and were confined to a few tens of metres. The effects did not worsen dramatically for increasing charge sizes. The most damaging event was found to be deflagration of a vapour cloud filling the whole cross-section along an appreciable length. The effects obtained were comparable with those of a TNT explosion, but with a longer section sustaining damage. For injury from explosions, use was made of the injury relations given by Eisenberg, Lynch and Breeding (1975) and by W.E. Baker *et al.* (1979).

A fire in a tunnel differs in its effects from one in the open in that the flames, hot gas and smoke are confined and are thus much more lethal. Persons exposed are principally other road users and the general public.

The results of the hazard assessment included the following findings. The risks are mainly to other road users, those to the general public being typically an order of magnitude less. The dominant contributor (>70%) to these risks is flammable liquids.

At the lower end of the spectrum ($N > 1$ and $N > 10$), the factor mainly determining the societal risks to road users is traffic density rather than tunnel design. In this region, the risks are remarkably similar to those on the open road. The effect of tunnel design is seen, however, at the upper end of the spectrum ($N > 100$). This is illustrated by the following values of the ratio of the frequency for $N > 100$ to that for $N > 1$:

Tunnel 1	0.27
Tunnel 2	0.39
Tunnel 3	0.28
Tunnel 4	0.03

The low ratio for Tunnel 4 reflects the fact that it has a short length and a large cross-section, and the high value for Tunnel 2 reflects the fact that it carries two-way traffic and a small cross-section.

23.27 Pipeline Transport Hazard Assessment

A hazard assessment of a hydrocarbon pipeline is described in *A Safety Evaluation of the Proposed St. Fergus to Moss Morran Natural Gas Liquids and St. Fergus to Boddam Gas Pipelines* (HSE, 1978d).

The proposed natural gas liquids (NGLs) pipeline would run for approximately 200 km from St Fergus to Moss Morran. The pipe would be 16 in. (406 mm) diameter and would operate at a maximum pressure of 1000 psig (70 bar) and a minimum pressure of 246 psig (18 bar) with a typical fluid temperature of 10°C. The pipeline would transport up to 110,000 bbl/d (approximately 100 kg/s). The composition of the NGL would vary between summer and winter conditions. For the former, the NGL would contain approximately 50% ethane and 30% propane.

The failure rates of comparable pipelines and the factors influencing such failures are discussed in detail. The data considered include those of the US petroleum pipeline system, the European petroleum pipeline system and the UK gas transmission system, which have been described above. The report presents additional data on the UK petroleum pipeline system and on the UK gas transmission system.

The oil company pipeline system in the United Kingdom is only approximately 1500 miles long. In the period 1963–76, some 17 accidents were recorded. It was concluded that this is too small a number on which to base an estimate.

The data for the European petroleum pipeline system (CONCAWE, 1977 9/77) were analysed. Many of the types of incident recorded were considered inapplicable to the proposed pipeline. On the basis of applicable incidents, the incident rate of the pipelines was 2.32×10^{-4}/km year.

The data for the UK gas pipeline system were provided by the BGC. The applicable incident rate of the pipelines was again 2.32×10^{-4}/km year. This value was based on 31 faults. The distribution of rupture sizes of these faults was:

Equivalent diameter (mm)	*No. of faults*
>80	1 (3%)
20–80	3 (10%)
<20	27 (87%)

The hole sizes considered in the assessment were 80 and 20 mm equivalent diameters in the proportions 10% and 90%, respectively.

The emission rates from a rupture of the NGL pipeline were estimated as follows. Small orifices through which the maximum rate of emission as liquid would be less than 100 kg/s, the approximate maximum pump delivery rate, would release NGL as liquid. Orifices which could deliver more than 100 kg/s would give an initial liquid flow, followed by choked two-phase flow as the pressure fell locally to the saturated vapour pressure. At this lower flow the pressure would rise again and reversion to liquid flow would occur. There would follow an oscillation between liquid flow and two-phase flow. It was assumed for simplicity that the flow through this intermediate size of orifice would be 100 kg/s. The largest orifices would be able to deliver 100 kg/s or more with two-phase flow. For this latter case, the flow under two-phase discharge was calculated as the geometric mean of the flows of pure liquid and pure gas. The flows calculated for the 20 and 80 mm holes were 15.2 and 100 kg/s, respectively.

These estimates were made for the first 5 min after the rupture. It was assumed that after this time, the pumps would be shut off. The conditions after 5 min were not investigated, since it was considered that the leak would probably reach a critical phase in respect of ignition in less than 5 min.

The dispersion of the gas cloud from the pipeline was calculated assuming a neutral buoyancy gas and using the Pasquill equations. The effect of possible heavy gas behaviour was considered, but it was concluded that at the existing state of knowledge, it is not unreasonable to assume that the increased entrainment of air approximately compensates for the slumping effect.

The heat radiated from a flame ignited at the pipeline was calculated by the methods given in API RP 521: 1969. The three heat radiation levels considered were 1, 8 and 16 kW/m^2. These were chosen because they are, respectively, the level which is just tolerable to a clothed person, that which would result in death within minutes unless adequate shelter were found and that which causes spontaneous ignition of wood. Some of the data given in the report for these hazards are shown in Table 23.48.

The frequency of 'interactions' between the pipeline and the exposed populations was assessed. The most exposed population group considered was that at Glenfarg, which is 250 m from the pipeline. For this population the frequency of interaction for all releases up to 100 kg/s was

***Table 23.48** Hazards from the rupture of an NGL pipeline (Health and Safety Executive, 1978d) (Courtesy of the Health and Safety Executive)*

A Thermal radiation from burning vapours – distance from flame centre (m)

Release rate (kg/s)	*Radiation level* (kW/m^2)		
	1	8	16
20	128	45	32
100	282	100	70
250	450	160	112
1000	892	315	223

estimated as 4.4×10^{-5}/year. A further account of the approach taken in this work has been given by Bryce and Turner (1979).

Following a proposal to increase the diameter of this pipeline from 16 in. (406 mm) to 24 in. (610 mm), a reappraisal of the risks was undertaken (HSE, 1980c). Essentially the same methodology and data were used. The assessment found that the frequency of interactions remained highest for the population, at Glenfarg. For this population, the frequency of interactions for releases of 242 kg/s was estimated as 4×10^{-6}/year.

An treatment of the hazard assessment of pipelines from a broader perspective has been given by M.J. Turner (1980).

The hazard assessment of the British Gas pipeline in Morecambe Bay has been described by Considine (1983). The pipeline connects the offshore platform to the onshore terminal. It consists of a line about 40 km long and 36 in. diameter containing some 1774 te of gas and 612 te of liquid.

Scenarios for failure of the pipeline both on land and under water were considered. For the latter, there was uncertainty as to how the fluids released, particularly the liquid components, would behave. For the case of immediate ignition of the release, two scenarios were considered, one in which the release burns as a torch and the other in which it burns as a liquid pool on the surface with the gas confined to the area of the pool. For the case where the release does not ignite immediately, a gas cloud forms and drifts with the wind.

Consideration was also given to interaction with a passing ship. For this, three cases were envisaged: (1) the gas cloud drifts towards the vessel; (2) the vessel sails through the cloud; and (3) the vessel itself causes the release in some way such as by grounding or dragging its anchor.

23.28 Marine Transport Hazard Assessment

The mid-1970s saw a growing public awareness of the hazards from process installations and one manifestation of this was concern over ports and terminals, and the associated traffic, and in particular LNG terminals.

The USCG initiated an extensive programme of work on the hazards of ships carrying hazardous materials. One outcome was the vulnerability model developed by Eisenberg, Lynch and Breeding (1975) and their co-workers, which is described in Chapter 9. Other work performed or sponsored by the USCG and other bodies includes that of Fortson *et al.* (1973), Woodward-Lundgren and Associates (1973), Dunn and Tullier (1974), A.D. Little INC. (1974b), the National Materials Advisory Board (1974), Frenkel and Hathaway (1976), Stoehr *et al.* (1977) and the Planning Research Corp. (1979).

A scenario of particular concern was the spillage onto the sea of a large quantity of flammable liquid such as LNG or LPG. In the worst case, such a spill could be massive and could be expected to spread and to vaporize rapidly, giving rise to a very large vapour cloud. There were similar concerns over liquefied toxic gases, particularly ammonia.

Treatments of, and models for, the spill hazard were described by Burgess, Murphy and Zabetakis (1970 BM RI 7448), McQueen W. *et al.* (1972), Fay (1973), Kneebone and Boyle (1973), Kneebone and Prew (1974), Drake and Reid (1977) and Hogan (1982). This hazard also figures strongly in the Vulnerability model.

The frequency of realization of such hazards, particularly that of collision, was dealt with in other studies such as those by Horner (1974), Horner and Ecosystems Inc. (1974), Kahn, Talbot and Woodward (1974) and Ligthart (1980).

At the same time, studies were undertaken on particular projects, or project proposals, such as those for Staten Island, Los Angeles, Oxnard, Point Conception, Everett and Matagordo Bay. Studies include those by the Federal Power Commission (1974, 1976, 1977), Philipson (1974, 1980), Gratt and McGrath (1975a,b, 1976), Philipson and Schaefer (1975), Socio-Economic Systems (1977) and Nikodem (1978, 1980).

Accounts of the methodologies used in such work have been given by Philipson and Schaefer (1975), Kopecek (1977), Philipson (1978a,b, 1980), R.A. Cox, Comer *et al.* (1980), Lyon, Pyman and Slater (1982) and Philipson and Napadensky (1982).

More recent accounts of hazard assessments of particular terminals include those for Canvey (British Gas) by Lucas, Roe and Waterlow (1983), Horn *et al.* (1974) and Dale and Croce (1985), Mossmorran (Shell) by Sellers, Luck and Pantony (1985), St Fergus (British Gas) by Valk and Sylvester-Evans (1985), and an assessment by Bello, Romano and Dosi (1983).

Treatments of oil as opposed to LNG terminals are much less numerous. An example is that given by Bergmann and Riegel (1983) for the oil terminal at Galveston.

Aldwinkle and Slater (1983) have described the hazard assessment of a novel project, a process and storage ship (PASS).

More recent accounts of methodology include those of Valckenaers (1983), Valk and Sylvester-Evans (1985), Sellers and Luck (1986) and Navaz (1987).

The perspective of the HSE has been presented by Hough (1983), Wicks (1983), D.A. Jones (1985) and Crossthwaite (1986), while Considine and Grint (1985) have given a set of rapid assessment models, as described in Chapters 15–17.

23.28.1 Hazardous events

In marine transport, ships are at risk as the port approaches, in the port and during berthing, and whilst loading and unloading cargo. Accounts of scenarios of hazardous events during these different stages include the generic treatments by Solberg and Skramstad (1982), Hough (1983) and Cummings and Bradley (1988) as well as specific studies such as that of Lucas, Roe and Waterlow (1983). The studies by Aldwinckle and Slater (1983) on the PASS system and by Considine (1983) on the Morecambe Bay pipeline also contain relevant material.

The initial events fall into three broad categories: (1) release from cargo tanks, (2) release from a ship–shore transfer lines and (3) events associated with ship operations. The cargo which has been most studied is LNG and the following account refers primarily to this.

There are a number of events which have the potential to cause loss of containment of an LNG cargo. Two principal, and much studied, events are collision and grounding. Other events which have been examined as possible causes include: ship structural defects; liquid sloshing in a cargo tank; overpressurization of a cargo tank; a spillage on deck leading to brittle fracture; a fire on deck; a fire in a cargo tank; a fire on the sea; explosion in a cargo tank; an explosion in the engine room; and an explosion external to the vessel. Some of these rank as escalation events rather than initiating events.

A 125,000 m^3 gas carrier would typically have six 22,000 m^3 cargo tanks. The worst case scenario is a virtually instantaneous release of the ship's whole cargo of LNG, but this, whilst not physically impossible, is unrealistic. A more common, but still pessimistic assumption is a release from one cargo tank. More detailed assessments consider the extent of damage from the initiating event under consideration, such as collision or grounding, and estimate the flow through the aperture thus created.

A detailed treatment of release flows and spill sizes is given Solberg and Skramstad (1982). The flow from a damaged cargo tank depends on the location of the hole. The authors present a graph for LNG showing the flow from different cargo tanks as a function of hole location, hole size and time.

The location of the hole also affects the total size of the spill. The largest spill size is given by a tank penetration at sea level. Solberg and Skramstad give another graph showing the fraction of the cargo which is released as a function of the hole elevation.

A spill of LNG from a cargo tank may or may not be ignited immediately. Solberg and Skramstad mention as possible ignition sources in a collision: sparks; heating of steel above the methane ignition temperature due to absorption of collision energy; and ignition sources present in the bow of the striking ship.

For a spill onto the sea, if there is immediate ignition, a large release will give rise to a pool fire. If the release does not ignite immediately, a large flammable cloud will form. If this cloud is then ignited, the combustion will take the form of either a flash fire or a vapour cloud explosion. Alternatively, LNG may be spilled within the double hull structure of the ship and ignited, resulting again in either fire or explosion.

Solberg and Skramstad suggest that a fire occurring in the double hull structure of the ship is likely to be starved of oxygen, unless the opening is very large and the spillage massive. For a pool fire on the sea beside the ship, they give a detailed model, as described below.

This model indicates that, although a large pool fire will raise the temperature of both the outer hull and, after some delay, the inner hull, to a value at which some loss of strength will occur, this will not necessarily compromise the structural integrity of the whole ship. In this respect, a spill which is relatively small but prolonged may present the greater threat. A much larger fire may be of too short duration to induce tank failure.

The creation of a flammable mixture in the double hull structure may result in an explosion. The hull contains void spaces interconnected by openings of different size. An explosion propagating through these voids could be very destructive. For a case where the whole space is filled by a mixture within the flammable range, Solberg and Skramstad estimate the explosion overpressure as of the order of 5–10 bar.

For a vapour cloud explosion over the sea outside the ship's hull, they consider the effect of the overpressure at a distance of twice the radius from the centre of the cloud, which they take as about 0.1 bar. Treating the structural response as a quasi-static one, this overpressure is low compared with the strength of the hull and would not be expected to cause damage to the hull structure of the containment.

Another principal scenario for a massive spill is rupture of the ship–shore transfer system during loading or unloading. This event is considered by Lucas, Rowe and Waterlow (1983) and Cummings and Bradley (1988); the former authors also examine its escalation. Two possible causes of failure of the transfer system are failure of the expansion bellows and rupture of the transfer arm. A possible cause of transfer arm rupture is excessive movement between the ship and the jetty.

Estimates of the size of spill which could result from transfer system rupture is usually based on the full bore flow and the time to shut off the flow. Lucas, Rowe and Waterlow quote a transfer flow of 17 te/min and a response time to shut-down of 30 s or less.

These authors identify four ways in which, in principle, such a spill might escalate. If LNG is spilled on the deck of the ship, this may result in embrittlement and cracking of the steel. They conclude, however, that, given the low stresses, the cracks would arrest without extending beyond the embrittled zone.

More serious is the third path to escalation, that is, an explosion resulting from the entry of the liquefied gas into the ballast tanks. Lucas, Roe and Waterlow describe the estimation of the resultant overpressure. In a totally confined enclosure, the overpressure generated could be some 7 bar, which is well in excess of the pressure which most structures will withstand unless specifically designed to do so. However, commonly some weaker section fails and vents, thus reducing the pressure attained. Moreover, a high water level in the tanks tends to reduce the overpressure. The authors describe studies in which the overpressures calculated ranged from 0.07 bar for high water levels to 2 bar for nearly empty tanks, and other studies which indicated that in the absence of embrittlement by LNG such explosions would be unlikely to cause damage to the cargo tank.

The fourth path to escalation which these authors consider is an explosion in the engine room. In general, no scenario for engine room explosion was identified which could cause cargo tank failure other than entry of a large quantity of flammable gas. For the latter case, use was made of wind tunnel modelling and explosion simulation. It was concluded that in the worst case, the peak overpressure in the engine room could be some 6 bar, which compares with a cargo tank failure pressure of 3–4 bar.

Events which may occur associated with operations on the ship are described by Cummings and Bradley (1988). They include (1) ignition of a vapour plume from a cargo tank, (2) improper control of ballasting/deballasting operations and (3) rollover of LNG in the cargo tank.

The foregoing account has dealt with LNG. LPG presents a broadly similar set of hazards. Some relevant differences are that it is not so deeply refrigerated and that it is more likely than methane to give a vapour cloud explosion.

Other materials may have their own characteristic hazards. Thus, a monomer may undergo a runaway polymerization reaction. Monomers are stabilized using an inhibitor but Cummings and Bradley refer to work on the risk that delays at sea may cause the inhibitor to become exhausted.

23.28.2 Hazard models

As already mentioned, one of the first sets of hazard models for marine transport was the Vulnerability model (VM) of Eisenberg, Lynch and Breeding (1975) and of other workers. This included constituent models for evaporation of pools on water, gas dispersion, pool fires, flash fires and vapour cloud explosions.

Another set of hazard models which has been applied to marine transport is that of Considine and Grint (1985). These authors present convenient parameterizations of a number of models widely used in hazard assessment, including models for heavy gas dispersion, pool fires, flash fires and vapour cloud explosions.

Whilst such sets of hazard models constitute a basic toolkit, other models also are required for hazard assessment. Treatments of collision and grounding have been described in Section 23.18.

Models are also required for the effect of fire outside the ship's hull on the integrity of the cargo tanks. Such models have been described by Solberg and Skramstad. The set of models given by these authors covers: the size and duration of a pool fire beside the hull as a function of the size of hole in the damaged cargo tank; the heat flux from such a fire as function of the fire base diameter; the heat flux received by the ship's deck; and the unsteady-state temperature profiles of the outer and inner hulls.

Another group of models is that for explosions in confined spaces such as between the inner and outer hulls and in ballast tanks. These include both models for the overpressures generated in a confined explosion and for the damage caused by such an explosion. The former may be analytical models or explosion simulation codes.

23.28.3 Some hazard assessments

As already described, there have been a considerable number of hazard assessments for marine transport, covering shipping, ports and terminals.

An early generic study was that given in the vulnerability model by Eisenberg, Lynch and Breeding (1975), as described in Chapters 16–18.

A hazard assessment of marine transport at an oil terminal at the Deep Water Port, Galveston, Texas, has been described by Bergmann and Riegel (1983). The scenarios considered were collisions and groundings, giving rise to a fire or explosion.

The authors' estimates of the frequencies and probabilities of these events are as follows. The frequencies of collision and grounding are estimated, respectively, as 1.5×10^{-4}/movement and 3.5×10^{-4}/movement, and the probabilities, given collision, of spill, fire and explosion as 0.25, 0.33 and 0.1. They give the following figures:

Casualty type	*Frequency of casualty* (casualties/movement)	*Probability of spill* (spills/movement)	*Probability of fire* (fires/movement)	*Probability of explosion* (explosions/movement)
Collision	1.5×10^{-4}	4.3×10^{-5}	4.4×10^{-5}	1.6×10^{-5}
Dockside fire/explosion	1.4×10^{-4}	9.8×10^{-7}	1.0×10^{-5}	3.7×10^{-6}

They take as negligible the probability that, given a soft bottom with no hard underwater object, a grounding would result in a spill or fire.

The authors found that for collisions only one in 23 spills resulting in fire propagated into an explosion, but that all explosions had resulted in spill and fire. Records indicate that where an explosion occurs, between 29% and 94% of the cargo tanks become involved, but that where a fire occurs some 10–13% of the cargo is spilled and burned. They take the proportion of cargo involved as 36% for an explosion and 12% for a fire.

Bergmann and Riegel have developed event trees for the three scenarios of collision, grounding and dockside fire/explosion. They assess the effects of explosion using the methods of W.E. Baker *et al.* (1978), including correlations of overpressure vs scaled distance for a fuel-air explosive and of damage in terms of the pressure–impulse diagram. For fire, the treatment is largely concerned with firefighting and mitigatory measures, and appears essentially qualitative.

The two *Canvey Reports*, described in Appendix 7, cover marine risks, including collision, grounding and loading/unloading, and give a full assessment of individual and societal risks.

A further hazard assessment of marine transport at the British Gas LNG terminal at Canvey is described by Lucas, Rowe and Waterlow (1983). This study details the various hazard scenarios, as described in Section 23.28.1, and gives an engineering assessment of each one. As a result of this assessment, some postulated scenarios are rejected, whilst others are accepted and countermeasures are described. For example, it is concluded that failure of the bellows expansion units in the ship–shore transfer line would be manifested by a small crack rather than sudden rupture, and that the latter is not a credible failure mechanism. Likewise, major failure due to low temperature brittle fracture following LNG spillage on the ship's deck is discounted. Further, a fire on deck or on the sea is not expected to cause failure or overpressure of the inner hull. On the other hand, the authors do consider to be credible explosions in the ballast space or, with ingress of flammable vapour, in the engine room. They describe various measures taken to counter these hazards such as improved emergency shut-down, deck protection and engine room explosion relief.

One countermeasure described is to arrange that in operation the man-way hatches to each ballast tank are closed, though not secured. This, it was calculated, would allow sufficient pressure to build up as the first LNG entering the tank vaporizes that further entry of LNG through cracks would be inhibited. This is an example of the exploitation of the characteristics of the initial event to prevent escalation.

The authors comment that whilst a full quantitative risk assessment (QRA) has its place, in many instances, most of the benefits may be obtained from the detailed engineering analysis which should in any case be part of a good QRA. It is often more fruitful to put effort into discovering unidentified problems rather than into quantifying those already identified. This should be done in cooperation with the engineers involved in the design and operation of the system.

The ACDS *Transport Hazard Report* gives a set of hazard assessments for specific ports and utilizes this to obtain an assessment of national societal risks.

23.29 Transport Hazard Assessment: Comparative Risks

There have been a number of hazard assessments which have sought to determine the relative risks of different modes of transport, of the transport of different chemicals, or of transport in different countries.

An early study of this nature was that of Westbrook (1974), described in Chapter 18, on the risks of chlorine transport by road, rail and pipeline.

Ormsby and Le (1988) give frequency-number (FN) curves for the transport of natural gas, gasoline, LPG chlorine and ammonia in the United States, and also make comparisons with other parts of the world. For LPG, the dominant large event is the one that occurred at San Carlos. The study by Haastrup and Brockhoff (1990), described earlier, gives FN curves for transport in North America, Western Europe and other countries.

Sellers and Bendig (1989) have described a comparative study for transport by road and pipeline associated with two terminals.

The most comprehensive comparison of the risks of road vs rail is that given in the ACDS *Transport Hazard Report*. As described in Appendix 17, this study concludes that at least for the United Kingdom and for the four study substances, there is no basis for preferring one of these modes of transport to the other.

23.30 Security Issues

The US DoT issued HM 232 Final Rule, 'Transportation Security' on March 25, 2003.

23.30.1 Enhanced security requirements

September 11, 2001, brought home the reality of terrorism to all Americans. The terrible events of that day and the later anthrax scare, along with earlier bombings at the World Trade Center in 1993 and in Oklahoma City in 1995, mean that we all need to play our part in combating terrorism in order to maintain the type of lifestyle we enjoy. The DoT's RSPA is responsible for the safe and secure transportation of hazardous materials. Hazardous materials are essential to the economy of the United States and the well-being of its people.

Since 11 September 2001, RSPA has worked closely with hazardous materials shippers and carriers, as well as Federal, state, and local government agencies, to improve the security of hazardous materials in our Nation's transportation system. There are two strategies that are critical to managing transportation security risks. The first is to develop and implement security plans. The second is to assure that employees who handle and transport hazardous materials are trained to recognize and react to potential security problems. RSPA has established new security requirements that make use of these two strategies for hazardous materials transported in commerce.

20.30.2 Hazardous materials transportation enhanced security requirements

Companies must develop and implement a security plan if they offer for transportation or transport the following types or quantities of hazardous materials:

1. A hazardous material in an amount that must be placarded in accordance with the Hazardous Materials Regulations;
2. A hazardous material in a bulk packaging having a capacity equal to or greater than 13,248 'l (3500 gallons) for liquids or gases or more than 13.24 m^{-3} (468 cubic feet) for solids; or
3. A select agent or toxin regulated by the Centers for Disease Control and Prevention under 42 CFR part 73.

At a minimum, the security plan must include the following elements:

1. Personnel security;
2. Unauthorized access;
3. En route security.

The security plan must be in writing and must be retained for as long as it remains in effect and must be revised as necessary to reflect changing circumstances.

23.30.3 Training

Companies must provide training to their employees who are responsible for implementing the security plan. This training should cover the following topics.

20.30.4 Security plans

1. Company security objectives;
2. Specific security procedures;
3. Employee responsibilities;
4. Actions to take in the event of a security breach; and
5. Organizational security structure.

In addition, all hazmat employees – that is, employees who directly affect hazardous materials transportation safety – must receive training that provides an awareness of the security risks associated with hazardous materials transportation and methods to enhance transportation security. This training should also include a component that covers how to recognize and respond to possible security threats.

The following guidance should assist you in developing a security plan appropriate to your industry and operations. Even if you are not covered by the security plan requirements in the Hazardous Materials Regulations, you may want to review your current security programme and make any necessary adjustments to improve it.

Begin with a security assessment

To develop a security plan, a company should begin with a security assessment. List the materials they handle and identify those with the potential for use as a weapon or target of opportunity. Then, review their current activities and operations from a transportation security perspective. A security risk assessment model can be used to identify security risks and develop appropriate measures to reduce or eliminate those risks.

A Security Template found on RSPA's hazmat safety homepage (http://hazmat.dot.gov) utilizes the following steps:

1. Scoping – determine the scope of operations that should be subject to security risk management. Iden-

tify the types of hazardous materials handled and the modes of shipment used.

(2) Knowledge of operations – collect detailed information about the company's transportation operations: (1) quantities of material transported; (2) baseline security programmes; (3) current security procedures; and (4) related safety programmes and procedures.

(3) Assessment – analyse potential security threats and identify security risk control points. Risk control points are points in the transportation process where the company can make an impact by improving procedures or operations.

(4) Strategy – rank or group security risks, prioritize opportunities for security risk reduction, and decide on preventative actions. Create a written document summarizing these decisions which becomes the company's security plan.

(5) Action – implement the security plan.

(6) Verification – monitor implementation of the security plan.

(7) Evaluation – determine if goals are being met and benchmark strategy and results with other companies.

Suggested security measures

The following are specific security measures that could be considered for inclusion in a security plan. At a minimum, a security plan must include the following elements: personnel security, unauthorized access, and en route security.

Personnel security

Be aware of the possibility that an employee may pose a potential security risk. Establish a process to confirm the information provided by applicants on application forms or resumes, including checking with former and current employers, and personal references provided by job applicants. Such confirmation must be consistent with applicable Federal and State laws and requirements concerning employment practices and individual privacy. Employees can be one of the most critical assets for insuring the security of shipping or transportation operations. Under the new RSPA security requirements, employees must be familiar with the security plan and are properly trained in its implementation. Training should include company security objectives, specific security procedures, employee responsibilities, and organizational security structure. In addition, consideration should be given to taking one or more of the following actions:

(1) Encourage employees to report suspicious incidents or events.

(2) Implement routine security inspections.

(3) Convene regular employee/management meetings on security measures and awareness.

(4) Communicate with employees using an internal communication system to provide information on facts, trends and other security issues. Because Internet communications may be accessed by others, consider alternative methods for communicating sensitive information.

Unauthorized access

Access to hazardous materials in transportation and to a facility should be another security concern. Consider utilizing one or more of the following security measures to prevent unauthorized access:

(1) Establish partnerships with local law enforcement officials, emergency responders, and other public safety agencies with jurisdiction over the facility. Through such relationships, exchange information about threats, trends, and unsuccessful security programmes.

(2) Request a review of the facility and security programme by local law enforcement and fire safety officials.

(3) Restrict the availability of information related to the facility and the materials handled. Encourage authorities in possession of information about the facility to limit disclosure of that information to a need-to-know basis.

(4) Add perimeter security and increase off-hour security patrols. Request that law enforcement personnel increase off-hour patrols.

(5) Check the adequacy of locks and other protective equipment. Consider equipping access gates with timed closure devices. Conduct frequent inspections.

(6) Install additional lights, alarm systems, or surveillance cameras.

(7) Restrict access to a single entry or gate.

(8) Place limits on visitor access, especially when the Homeland Security Alert System raises its threat level; require visitors to register and show photo identification, and have someone accompany visitors at all times.

(9) Require employees to display identification cards or badges.

(10) Conduct security spot checks of personnel and vehicles.

(11) Upgradesecurity procedures for handling pick-ups and deliveries at the facility. Verify all paperwork and require pick-ups and deliveries be handled only by appointment with known vendors. Require that vendors call before a delivery and provide the driver's name and vehicle number. Accept packages and deliveries only at designated locations at the facility.

(12) Secure hazardous materials in locked buildings or fenced areas. Have a sign-out system for keys.

(13) Secure valves, manways, and other fixtures on transportation equipment when not in use. Lock all vehicle and delivery trailer doors when not in use. Secure all rail, truck, and intermodal containers when stored on site. Use tamper-resistant or tamper-evident seals and locks on cargo compartment openings.

(14) Periodically inventory the quantity of hazardous materials in order to recognize if a theft has occurred.

(15) Keep records of security incidents. Review records to identify trends and potential vulnerabilities.

(16) Report any suspicious incidents or individuals to your local Federal Bureau of Investigation (FBI) office and to local law enforcement officials.

En route security

Shippers and carriers should work together to assure the security of hazardous materials shipments en route from origin to destination. Shippers should assess the security of transportation modes or combinations of modes available for transporting specific materials and select the most appropriate method of transportation to ensure their efficient and secure movement. Know the carrier and have a system for qualifying the carriers used to transport hazardous materials. Consider implementing one or more of the following measures:

(1) Use carrier safety ratings, assessments, safety surveys, or audits, and ask the carrier to provide information on security measures it has implemented.
(2) Verify that the carrier has an appropriate employee hiring and review process, including background checks, and an ongoing security training programme.
(3) Verify the identity of the carrier and/or driver prior to loading a hazardous material.
(4) Ask the driver for photo identification and a commercial driver's license for comparison with information provided by the carrier.
(5) Ask the driver to tell you the name of the consignee and the destination for the material and confirm with your records before releasing shipments.
(6) Identify preferred and alternative routing, including acceptable deviations.
(7) Strive to minimize product exposures to communities or populated areas, including downtown areas; avoid tunnels and bridges where possible; and expedite transportation of the shipment to its final destination.
(8) Minimize stops *en route;* if you must stop, select locations with adequate lighting on well-travelled roads, and check your vehicle after each stop to make sure nothing has been tampered with.
(9) Consider using two drivers or driver relays to minimize stops during the trip. Avoid layovers, particularly for high hazard materials.
(10) Shippers and rail carriers should cooperate to assure the security of rail cars stored temporarily on leased tracks.
(11) If materials must be stored during transportation, make sure they are stored in secure facilities.
(12) Train drivers in how to avoid high jacking or stolen cargo – keep vehicles locked when parked and avoid casual conversations with strangers about cargoes and routes.
(13) Consider whether a guard or escort for a specific shipment of hazardous material is appropriate.
(14) Consider using advanced technology to track or protect shipments *en route* to their destinations. For example, you may wish to install tractor and trailer anti-theft devices or use satellite tracking or surveillance systems. As an alternative, consider frequent checks with drivers by cell phone to ensure everything is in order.
(15) Install tamper-proof seals on all valves and package or container openings.
(16) Establish a communication system with transport vehicles and operators, including a crisis communication system with primary and back-up means of communication among the shipper, carrier, and law enforcement and emergency response officials.
(17) Implement a system for a customer to alert the shipper if a hazardous materials shipment is not received when expected.
(18) When products are delivered, check the carrier's identity with shipping documents provided by the shipper.
(19) Get to know your customers and their hazardous materials programmes. If you suspect you have shipped or delivered a hazardous material to someone who may intend to use it for a criminal purpose, notify your local FBI office or local law enforcement officials.
(20) Report any suspicious incidents or individuals to your local FBI office and to local law enforcement officials.

Additional information

Up-to-date information is a key element of any security plan. Companys should consider methods to:

(1) Gather as much data as they can about their own operations and those of other businesses with similar product lines and transportation patterns.
(2) Develop a communications network to share best practices and lessons learned.
(3) Share information on security incidents to determine if there is a pattern of activities that, when considered in isolation are not significant, but when taken as a whole generate concern.
(4) Revise security plans as necessary to take into account changing circumstances and new information.

23.30.5 C-TPAT – Customs-Trade Partnership Against Terrorism

C-TPAT is a joint government-business initiative to build cooperative relationships that strengthen overall supply chain and border security. C-TPAT recognizes that Customs can provide the highest level of security only through close cooperation with the ultimate owners of the supply chain, the importers, carriers, brokers, warehouse operators and manufacturers. Through this initiative, Customs is asking businesses to ensure the integrity of their security practices and communicate their security guidelines to their business partners within the supply chain.

Businesses must apply to participate in C-TPAT. Participants will sign an agreement that commits them to the following actions:

(1) Conduct a comprehensive self-assessment of supply chain security using the C-TPAT security guidelines jointly developed by Customs and the trade community. These guidelines, which are available for review on the Customs website, encompass the following areas: Procedural Security, Physical Security, Personnel Security, Education and Training, Access Controls, Manifest Procedures, and Conveyance Security.
(2) Submit a supply chain security profile questionnaire to Customs.
(3) Develop and implement a programme to enhance security throughout the supply chain in accordance with C-TPAT guidelines.

(4) Communicate C-TPAT guidelines to other companies in the supply chain and work towards building the guidelines into relationships with these companies.

C-TPAT offers businesses an opportunity to play an active role in the war against terrorism. By participating in this first worldwide supply chain security initiative, companies will ensure a more secure supply chain for their employees, suppliers and customers. Beyond these essential security benefits, Customs will offer potential benefits to C-TPAT members, including:

(1) A reduced number of inspections (reduced border times).
(2) An assigned account manager (if one is not already assigned).
(3) Access to the C-TPAT membership list
(4) Eligibility for account-based processes (e.g. bimonthly/monthly payments).
(5) An emphasis on self-policing, not Customs verifications.

C-TPAT is currently open to all importers and carriers (air, rail, sea). C-TPAT membership will be made available to all sectors of the supply chain. Customs will be consulting with the trade community to develop the most effective approach for each sector to participate in C-TPAT. http://www.geosbush.com/ctpat.htm.

23.31 Notation

Section 23.4

Subsection 23.4.7

A_o	fractional minimum elongation of metal on fracture under tensile stress
D	internal diameter of shell (mm)
e	thickness of metal (mm)
P	calculation pressure (bar)
R_m	minimum tensile strength
λ	constant
a	permissible stress (N/mm^2)

Subscripts

0	mild steel
1	metal under consideration

Subsection 23.4.12

d_{15}	density of liquid at 15°C
d_{50}	density of liquid at 50°C
DF	degree of filling (%)
t_F	mean temperature of liquid at time of filling (°C)
∞	amean coefficient of cubical expansion of liquid between 15°C and 50°C
χ	parameter (%) (see text)

Section 23.5

C	confidence limits on value of liquid density (%)
FR	filling ratio
P_l	density of liquid
P_w	density of water
χ	parameter (see text)

Section 23.6

Equations 23.6.1–23.6.7

I	normal distribution parameter
P	probability
x	impact speed
x	mean impact speed
σ	standard deviation

Superscript

–	mean

Subscript

c	combined

Equations 23.6.8–23.6.11

E	energy absorbed in collision
m_1	mass of first vehicle
m_2	mass of second vehicle
v	residual velocity of two vehicles after collision
v_l	impact velocity of load
v_1	initial velocity of first vehicle
v_2	initial velocity of second vehicle

Subscript

cr	critical

Section 23.11

Equation 23.11.1

C	cost
k	constant
n	index
P	throughput

Equation 23.11.2

a	design factor
D	external diameter of pipe (mm)
f_y	specified minimum yield strength (N/mm^2)
p	internal design pressure above atmospheric (bar)
t	design thickness of pipe wall (mm)

Section 23.18

c	constant
E	energy absorbed in collision
E_f	energy absorbed by fender
K	absorbed energy coefficient
L	length of damage
m	constant
m_1	effective mass of striking ship
m_2	effective mass of struck ship
δm	hydrodynamic mass
P	depth of damage
R	ratio defined by Equation 23.18.6
R_T	resistance factor
t	thickness
v_{cr}	critical value of speed of striking ship before collision

V_1	speed of striking ship before collision
	residual speed of two ships after collision

Subscripts

cr	critical value
n	nth member in struck ship
N	Nth member in striking ship
1	striking ship
2	struck ship

Emergency Planning

Contents

There is a considerable body of work on disasters of various kinds, both natural and man-made, and, whilst much of this may be only marginally relevant to process plant emergencies, it is helpful to have some awareness of this background (Table 24.1).

Table 24.1 *Selected references on emergency planning*

Accounts of this work include *Emergency and Disaster Planning* (Healy, 1969), *Disaster Preparedness* (Office of Emergency Preparedness, 1972), *Disaster Technology* (Manning, 1976), *Disaster Planning* (H.D. Foster, 1980), *Types and Events of Disasters Organization in Various Disaster Situations* (Frey and Safar, 1980), *Disasters* (Whittow, 1980), *Disaster Policy Implementation* (May and Williams, 1986), *Accident and Emergency Management* (Theodore, Reynolds and Taylor, 1989) and *Hazard Management and Emergency Planning Perspectives in Britain* (D.J. Parker and Handmer, 1992).

In the United Kingdom, the Disaster Prevention and Limitation Unit (DPLU) at the University of Bradford is a specialist resource on disasters. Another is the Disaster Research Center, Ohio State University, and latterly the University of Delaware in the United States.

For the process industries specifically, relevant materials are *Highly Hazardous Spills and Emergency Planning* (Zadic and Himmelman, 1978), *Guide to Emergency Planning* (Society of Industrial Emergency Services Officers, 1986) and *Emergency Response to Chemical Accidents* (O'Reilly, 1987).

24.1 Introduction

Process safety of a chemical plant encompasses several layers of protection. Control measures, shut-down systems, release absorption, accumulation of releases by dikes, and protection by barriers. These layers of protection are intended to prevent an event from propagating into severe consequences because of deviations from normal operation conditions. Emergency response is the last layer of protection that is intended to control an event if possible, or to reduce consequences in cases of loss of control. However, a reliable response to an emergency event requires planning. The three components of emergency planning are presented in Figure 24.1.

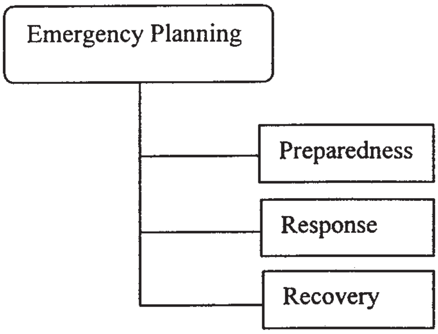

Figure 24.1 *Components of emergency planning*

Much of the material in the preceding chapters has been concerned with reducing the scale and frequency of hazards. Nevertheless, there remains for any hazard a finite possibility that it will be realized. It is necessary, therefore, to plan for such emergencies. Emergency planning is an integral and essential part of the safety and loss prevention strategy. Its objective is to mitigate the consequences of any incident that may occur.

The probability of the realization of a hazard is evaluated by a relatively sophisticated procedure, as already described. It is not then logical to assume that if this occurs, the worst consequences will necessarily follow. It is more appropriate to take a probabilistic approach to the evaluation of the consequences also.

There are two main types of emergencies with which the chemical industry is concerned. These are the works emergency and the transport emergency. They are somewhat different and require separate treatment. Whatever the type of emergency plan, the overall message is that it should be kept simple and flexible, but capable of being scaled up or down as circumstances demand.

24.2 On-site Emergency Planning

24.2.1 An overview

Unanticipated circumstances may yield emergency events. Emergency planning adds an additional layer of protection to circumstances where all of the other layers of protection failed to prevent the incident. Figure 24.1 demonstrates the three major components of emergency planning

Emergency preparedness process begins with identification of credible scenarios for which appropriate response strategies are developed. The analysis of resources and capabilities of facilities to respond to the emergency scenarios is part of the preparedness stage. This analysis examines the resources and the capabilities at the facilities, at neighbour sites, and the resources that are available at the local community. The development of resources is conducted according to the resources assessment and the potential of cooperation among site emergency responders, neighbouring facilities, and neighbouring communities.

As mentioned above, at least three separate parties are involved in emergency situations, in addition to the network within the facility. Therefore, communication systems are crucial to successful execution of emergency plans in real-time situations as well as in drills.

The complex nature of emergency events requires a very clear hierarchy of command, and a procedure without any ambiguities. It is extremely important that every position in the hierarchy is assigned to personnel with the appropriate skills and personality. Training and assessment of the potential collaboration among these three groups is also extremely important. It is not uncommon for preparedness programmes to be revised based on assessments of drill results.

The development of physical facilities infrastructure consists of the following:

(1) Development of shelters and safe havens.
(2) Establishment emergency operations centre (EOC).
(3) Development of emergency communication capabilities.
(4) Development of appropriate medical support infrastructure.

As shown in Figure 24.2, emergency systems are developed in parallel with the development of physical facilities. The list below consists of typical items in emergency systems; however, it can vary according to special circumstances:

(1) Emergency power supply
(2) Emergency water supply
(3) Communication systems
(4) Emergency management computer support system
(5) Site and community alert systems
(6) Adequate incident command transportaion
(7) Appropriate control room protection measures.

24.2.2 Identification of credible scenarios

The problem

A process hazard evaluation yields a large list of potential incidents. This list should be assessed to determine likelihood and consequences of each of the events, and then prioritized according to the risk associated with these events.

Preparedness for emergencies involving worst case scenarios requires enormous resources and may overwelm the business operability of the facility. Therefore, the outcome for each scenario should be evaluated based on the consequences and probabilities of the scenario. It is important to consider management controls in these evaluations. Incidents such as instantaneous loss of conainment are a major concern in the process industries. However, measures, such as control systems, overpressure reliefs, alarms, mechanical as well as non-destructive tests reduce the likelihood of development of such as scenario. Emergency planning may be effected by local regulations. The law may dictate the type of scenarios that emergency planning should be address.

The large number of chemicals along with the large number of equipment and the variety of potential incidents that can occur from the combinations of chemicals equipment lead to an enormous number of possible scenarios. As mentioned earlier, it is impractical to plan for all emergencies, and therefore it is neccesary to analyse and prioritize the scenarios. The process of scenario selection and prioritization is shown graphically in Figure 24.3.

Identification of process areas with high hazards

A large number of techniques are available for the identification of areas of major hazards. Dow Fire and Explosion Index (F&EI), and Dow Chemical Exposure Index (CEI) are examples of techniques that can be used to identify and evaluate hazards according to the nature of the substances, and other process physical conditions. The US National Fire Protection Agency (NFPA) Fire Hazard Indices is a classification methodology that classifies materials according to the reactivity, flammability and their possession of health hazards. The results of examination of the plant with these techniques will lead to a list of ranked areas that should then be analysed to identify credible scenarios.

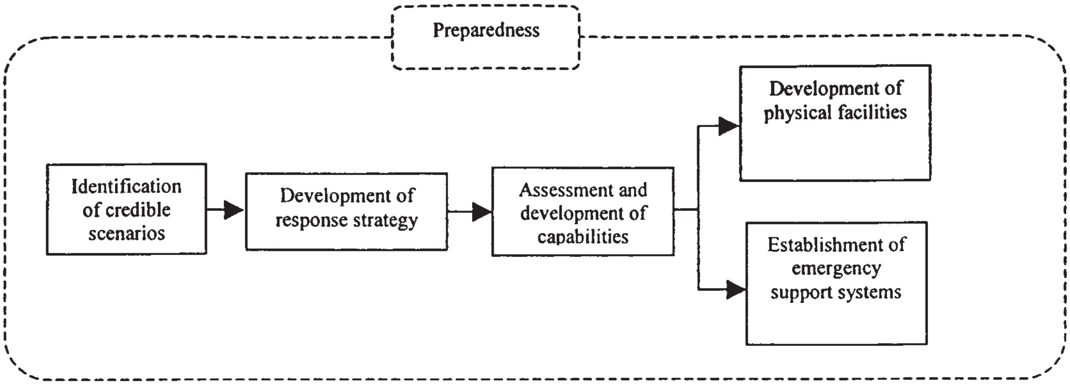

Figure 24.2 *Emergency preparedness flow chart*

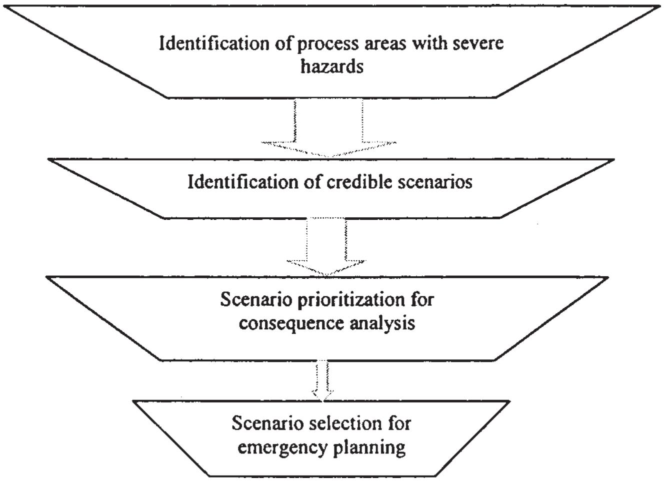

Figure 24.3 *Process of scenario selection for emergency planning*

Credible scenarios
A variety of techniques are available for identification of credible scenarios. The depth of analysis can vary from an informal review to a full Process Hazard Analysis session. The level of investigation is mainly dependent on the experience of the reviewers. Highly experienced reviewers are able to identify credible scenarios by an informal review only.

Consequence assessments
A preliminary screening of incidents is a helpful phase in reducing the number of consequence assessments, and in categorization of the incidents prior to the assessment stage. The following criteria could be helpful for the screening purpose:

(1) Incidents with only minor effects and low probability for escalation into a serious incident should be eliminated.
(2) Incidents with high similarity of discharge rates, locations, inventories and emergency response operations should be grouped.
(3) Two representative incidents should be grouped from each of the groups: (1) incident with high probability of occurrence, which may result in severe illness/injury or major property damage and (2) a credible worst-case scenario with critical/catastrophic consequences.

The screening procedure described above will establish a list of incidents for consequence assessment.

The common forms of incidents are fires, explosions and release of toxic material to the environment. Consequence assessment tools help in the estimation of the impact of these incidents on the employees, local communities, property and the environment. Source term modelling is used to estimate the release rate and quantity released. Explosion modelling, fire and thermal modelling, and dispersion modelling are applied for the assessment of the impact of the incidents. These are discussed in detail in previous chapters. The results of the consequence assessments lead to determination of areas that will be affected and the level of toxicity/thermal load/overpressure in these areas.

24.3 Resources and Capabilities

24.3.1 General

The development of strategy for emergency response requires consequence assessments of a list of credible incidents and data on resources and capabilities. Data should be gathered on the following:

(1) Emergency response equipment on-site.
(2) Emergency response equipment in neighbouring facilities.
(3) Emergency management service in local communities.
(4) On-site medical capabilities and medical facilities in local communities.

Appropriate resources and adequate capabilities are major factors in determining the severity of consequences of an incident. The following is a common list of physical facilities, equipment and systems that are useful in preparing for emergencies:

(1) shelters;
(2) safe havens;
(3) emergency power supply;
(4) adequate and alternate water supply;
(5) EOC;
(6) command post vehicle (CPV);
(7) emergency management computer system;
(8) media information centre;
(9) medical facilities;
(10) large-scale decontamination equipment;
(11) emergency evacuation transportation;
(12) communication centre;
(13) on-site and off-site alerting system;
(14) weather station.

The paragraphs below present the major components of the equipment and systems above that are relevant to emergency preparedness.

24.3.2 Facilities and equipment in emergency planning

On-site shelters and safe havens

Shelters and safe havens provide protection from toxic substances release incidents when an evacuation is not viable. While shelters provide passive protection by closing all air passages and shutting ventilation systems, safe havens consist of independent source of breathing air, such as compressed air bottles, or a specially designed active carbon filtration system. Because of the need to safely shut off (or control) critical systems, it is common to design control rooms as shelters, and sometimes as safe havens.

The process of emergency planning for shelters and safe havens should consider variables such as concentration of employees, distance from incident location, typical weather conditions, and alternate evacuation routes. Administration buildings are commonly used as shelters. When a building is selected as a shelter, the planner should verify that the spaces that are designated as shelter areas do not have holes and cracks, that doors and windows seal properly when closed, and that a ventilation system control (at least a shut-off control) is available.

Both shelters and safe havens should consist of support systems that are proportional to the estimated occupancy.

Emergency power supply

Emergency power supply is a critical system. Planners should verify that vital systems and locations have a power supply for all situations. Generators that are attached to internal combustion engines are most common as emergency supply systems. However, stored electrical energy as battery racks are used as well. *NFPA 110 – Emergency and Standby Power Systems, and NFPA 111 – Stored Electrical Energy Emergency and Standby Power Systems*, provide guidelines and codes for these systems.

Adequate and alternate water supply

Adequate water supply is extremely important for proper emergency response. Type of chemicals used in the plant, thermal load, demand of sprinkler systems, foam systems and hose streams are factors that should be considered in calculation of water reserves.

Alternate water supply is necessary to assure water delivery in an emergency. Ponds, lakes, reservoirs, and on-site tanks can be used as an alternate water source. However, for an adequate preventive maintenance programme, it is crucial to have the source as well as the equipment available. Moreover, heavy equipment is often required to access the alternate source of water, which will require hard surface pavement for the anticipated load. In case of extreme cold weather, measures should be taken to avoid freezing.

Emergency operations centre

It is not uncommon to designate a special room as an EOC. Location of the EOC should be carefully selected to minimize risk. The distance of EOC from processing areas and storage is an important variable in its functionality. The distance of the EOC from the normal residency of the management should be considered as well. The planner should designate an alternated EOC, which will be located opposite to the EOC in reference to the processing area. This will allow access to the alternate EOC in situations where access to the main EOC is not possible. An optimal EOC is one designed as a safe haven. *NFPA 101 – Life safety code*, consists of specifications for designing an EOC. An EOC should contain plans which facilitate the control of the emergency. Table 24.2 provides an example of a list of plans that should be available in the EOC. Documentation, material and equipment that may be necessary to monitor, administer and control the emergency should be provided. This includes the Emergency Plan and the list of personnel with their department, assembly point, home address, nearest relative, and telephone number, if applicable. Information from PHA studies scenarios should be available in an appropriate format so that the EOC personnel can carry out continuous speculative reviews of the possible development of the emergency. The EOC should be provided, as appropriate, with any equipment needed for dealing with the emergency, such as breathing apparatus, rescue gear, etc.

The EOC should be manned in an emergency by the senior emergency coordinator, nominated senior works personnel, senior officers of the outside services and any nominated assistants such as messengers. Other personnel should not be in the centre. If the hazard justifies it, the EOC may be manned continuously.

Command post vehicle

CPV allows the Incident Commander (IC) to control the efforts and activities in emergencies and be located at vantage points. The IC should be able to communicate with the management in the EOC, have access to essential documents, be able to document the scenario, and be able to monitor the environment. Therefore, the CPV should be selected to allow installation of all the equipment necessary and installation of power source that will be able to supply the consumption that this equipment demands.

Emergency management computation system

Emergency management computation systems (EMCS) are used for organization of information, estimation of severity of the incident by using source and dispersion models, data collection from the field if a network is installed, receiving monitoring data, etc. This information is essential to determine the magnitude of the event, and to make decisions as to announce an escalation and to determine the need of evacuation both on- and off-site. Modern wireless networks, computation capabilities, and mobilization of computation systems make these systems extremely useful. Advanced process safety management packages with well-developed emergency management, can be connected

(1) areas affected by hazard;
(2) areas evacuated;
(3) deployment of emergency teams and equipment.
(4) inventories of hazardous materials

to weather station, alarm systems, local, state and federal authorities.

Media information centre

A significant incident may have an impact on the organization's reputation. Sharing information and collaborating with the media could reduce the snowball effect that an emergency event may have. Moreover, media can assist by announcing the emergency, and increase the awareness of the general public in areas that might be affected.

A large room such as a conference room can be designated a media information centre (MIC). The MIC should be located at a distance that will assure the safety of the reporters and should be designed as a shelter or safe haven.

Medical facilities

On-site medical facility can have the capability of a first-aid room or a medical department. In general, the adequate capability is a function of parameters such as number of employees in the plant, capabilities of the local community medical centres, distance to these centres, and the anticipated consequences in an emergency. Coordination between emergency team, on-site medical facility, and local community medical centres may have major impact on the severity of consequences in cases of multiple casualty events, especially if decontamination is required. Local emergency centres should be made aware of the chemicals in the plant, and the estimated number of injuries that are expected in emergency. A procedure that enables evacuation of injuries by airlift is very common and can help in cases where the medical centre is too far, or in cases where the situation requires specialties that are not available in the local medical centre.

Communication system

The design of communication system should address the following:

(1) Maintain on-site communication.
(2) Establish communication with off-site agencies and neighbouring facilities.
(3) Allow communication among management, emergency team and responders.

Communication equipment includes announcement system, alert system, phones, secure phone system, cellular phones, radio system, wireless computing systems and cable TV.

Alerting and announcement systems serve both on- and off-site. Use of alerting system requires coordination between the plant and the local agencies. An audio alerting system requires that a code be well communicated with the general public. In general, alerting systems are used to alert on weather hazards such as a tornado. Since man-made hazards are rare, emergency plan should verify public knowledge with regard to audio alerting systems. Cable TV is a very effective tool to notify the general public in local community with regard to hazards, and to deliver behav-ioural guidelines and directions. It is recommended that the planner not leave the notification of the general public to the local agencies. A computer dial-up system can be used as a tool to contact the general public in emergency.

On-site response equipment and supplies consist of a variety of items. An inadequate equipment and supply can worsen the consequences of an event. Therefore, the planner must verify that equipment and supplies will meet the needs in an emergency.

Response equipment and supplies

The success of the response team in mitigating an incident is dependent on the availability of adequate equipment, and implementation of an adequate procedure of inspection, maintenance and replenishment of this equipment. Response equipment and supplies can be divided to three main categories:

(1) personal protection,
(2) fire fighting, and
(3) decontamination.

Personal protection equipment allows the response team to function in the affected zone in order to continue with the efforts to control the incident and minimize the consequence. Personal protection equipment consists of two major types:

(1) respiratory protection and
(2) thermal and chemical protection.

The circumstance determines the level of respiration protection that is needed. In many cases, a mask equipped with a canned active carbon filter may answer the needs. In other cases, a self-contained breathing apparatus (SCBA) is required. This apparatus usually consists of a full face protection mask and a regulator connected to a compressed air cylinder that is carried by the responder. NFPA standard 1981 *Open-Circuit Self-Contained Breathing Apparatus* determines the requirement of SCBA.

A supplied air respirator (SAR) is a system that supplies air from a source that is located in a distance from the affected area. This system is known as an airline respiration system as well. The air is supplied through an air-line hose to the responder. The major advantages of this system are that it allows the responder to stay longer in the affected area, and that the responders are not required to carry heavy systems as with SCBA. The major disadvantages are that the responder is not as mobile as with SCBA, and that the air-line hoses are vulnerable to mechanical, thermal and chemical damage and therefore this arrangement is not approved for Immediate Danger to Life and Health environment, unless an emergency escape SCBA is carried by the responder as well.

As for fire fighting gear, these systems supply reasonable thermal protection for most fires. In incidents in which excessive thermal load is expected, the responder should wear adequate clothing. An ice vest is used when high ambient temperature is imposed on the responders. The vest consists of pockets in which ice can be installed. The ice absorbs the thermal load, and enables the responder to stay longer in high-temperature environment, or to get closer to the source of the heat.

NFPA 1991 – *Standard on Vapor-Protective Ensembles for Hazardous Materials Emergencies*, and NFPA – 1992 *Standard on Liquid Splash-Protective Ensembles and Clothing for Hazardous Materials Emergencies* assist in determining the proper clothes according to the characteristics of the hazards.

Fire fighting and decontamination equipment consist of (but not limited to) the items in Table 24.3:

A planner should determine the necessity of integrating heavy equipment as dump trucks, earth movers, and cranes, and integrating these in the planning.

24.4 Developing an Emergency Plan

24.4.1 Overview

Regulatory agencies require preparation for emergencies and documentation of emergency plans. The emergency team will respond to incidents according to this plan and therefore the importance of the accuracy and comprehensiveness of the written plan. Emergency plan consists of the following major components:

(1) Establishment of a set of credible scenarios.
(2) Study emergency plans of neighbouring facilities and local community.
(3) Study availability of resources and capabilities, and determining needs.
(4) Study emergency-related regulations and emergency authorities' requirement and responsibilities.
(5) Development of tactics to respond to fires and explosions, release of hazardous materials, natural hazards, terrorist threats, rescue, evacuation, and plan for medical response and emergency mitigation.
(6) Development of procedures to assess level of emergency.
(7) Training of emergency teams, other employees and contractors.
(8) Development and execution of drills (include neighbouring facilities and local communities).
(9) Development of drill-based improvement procedure.
(10) Communication of the emergency plan on- and off-site.

Component (1), (2) and (3) in the list above were discussed in detail earlier in this chapter.

24.4.2 Emergency organizations and regulations

Emergency-related regulations, requirements and responsibilities are different in different countries. The planner should study the requirements and regulations and develop the plan to meet these requirements. An active Local Emergency Planning Committee (LEPC) in the United States can assist a great deal in coordinating between the plant and the local community authorities and responding agencies. A central entity such as the LEPC in the United States may have in hand emergency plans from other sites and the emergency plan of the local community. Moreover, a mutual agreement that establishes a net of emergency equipment and supplies may be available and thus reduce the costs involved in preparing the plant for emergencies.

Local community planning should include diverse government, volunteer and private organizations. Table 24.4 consists of examples of such organizations.

Table 24.4 *Organizations that may be involved in local community emergency planning*

Local community emergency preparedness organization
Emergency management services
Fire department
Police department
Traffic control agencies
Hospitals
Red cross
Salvation army
Department of Health
EPA and OSHA (US)/HSE (UK)
Coast guard
Media
Mayor

When establishing a mutual framework for efforts in emergency, the planner should identify each one of the personnel that the plant should interact with, and establish a dialogue that will create mutual trust and commitment.

24.4.3 Development of response tactic

Initial assessments and criteria for decision on escalation of emergency are major issues in responding to an emergency. The planner should establish procedures for assessment of severity of the incidents, and a set of criteria that will help in the decision to declare on escalation of the situation. The emergency team management must understand that the safety of the employees and responders is their first priority. Next is preventing the incident from escalating. Environmental concerns are next and finally the prevention of property damage is the last priority among these. The actions to be taken should be developed according to these priorities for both: fires and explosions, and release of hazardous material. In both cases, the initial efforts should determine work zones, in which the responders will be able to respond from.

Following the initial assessment, the IC should determine what the objectives of the response are, for example, should the responders try to extinguish the fire (aggressive response), prevent it form spreading or, respond just to allow safe evacuation of employees (defensive)? This decision should be made based on the risk associated with level of intervention.

Next, location for mitigation efforts to take place should be determined as well as entrance and exit routes, the time frame for the variety of actions, and who will carry out the variety of responsibilities.

The planner should develop procedures for the following indirect response components:

(1) Warning and alerting
(2) Communication
(3) Distribution of managerial responsibilities
(4) Emergency shut-down
(5) Identification of missing employees
(6) Mutual assistance with the variety of external entities
(7) Reporting
(8) Declaration of escalation
(9) Security
(10) Dealing with the media and
(11) Special notification.

Procedures for direct response efforts should include the following:

(1) Evacuation
(2) Medical mitigation
(3) Rescue
(4) Fires and explosions
(5) Release of hazardous materials
(6) Terrorism threats
(7) High winds
(8) Flood
(9) Freeze.

Procedures for training, drills, effectiveness measurements and post-drill change management should be considered part of the response stage as well as part of the preparedness.

24.5 Training

24.5.1 Background

Training is the foundation of the success of emergency planning. The training verifies that all employees are familiar with the alerting and warning codes, and the location of shelters and safe havens. Members of the response team are introduced to their responsibilities and its role in the 'big picture'. The frame for training for emergencies was mandated by the government in the United States. Occupational Safety and Health Administration (OSHA), Environmental Protection Agency (EPA), and the Department of Transportation require training for emergencies. Other organizations established standards and good practices that are very useful. OSHA requires that an employer will train his employees at least once in three years.

24.5.2 Fundamental training

The most fundamental emergency training is the use of fire extinguishing systems and equipment. It is common for all employees to be trained to use these systems. Additional training that all employees should receive is familiarity with alert codes, evacuation routes, and the locations of shelters and safe havens. These training include identification of hazards, the type of response that is appropriate, and to whom these hazards should be reported, and which communication system is to be used.

24.5.3 Operators training

Operations personnel are required to be familiar with the site emergency plan, and to be familiar in details with the relevant part of the plan that is related to their processes. This part requires knowledge of safe work practices and emergency shut-down procedures. The operators should be trained on the procedure, and to the criteria for proper shutdown. This type of training is extremely important, and more important is exercising it, in order to increase the correct decision-making, and to prevent wrong decision-making as was made in the Piper Alpha incident in the North Sea.

24.5.4 Response teams

Response teams are required to have high level of familiarity with the emergency plan. They have to understand the inherent hazards that are characterizing the plant, and the list of credible incident that the emergency plan was developed for, hierarchy of command, reporting system, responsibilities, communication systems and all other relevant information and procedures that the emergency plan consists of. The response teams are required to have knowledge and skills in several types of response categories:

(1) Fire fighting
(2) Release of hazardous material (in all phases: leak of liquids, rain of vapour and drops, gas)
(3) Terrorism threats
(4) Rescue (natural hazards, man-made hazards, confined places)
(5) Medical and
(6) Evacuation.

In most cases the teams are designated to one or more of the categories; however, they are expected to be able to perform in other teams as well.

Several of the emergency response personnel should be trained to deal with the media and public relations. This is a very sensitive duty because of the impact that the incident and the media covering the events may have on the image of the organization.

24.6 Essential Functions and Nominated Personnel

24.6.1 Incident Commander

It is the IC responsibility to proceed to the scene of the incident and to coordinate the efforts. The following list describes the IC's major responsibilities:

(1) As soon as the IC becomes aware of an incident, he should assess its scale against predetermined criteria or emergency reference levels, and decide whether a major emergency exists or is likely. If so he should immediately activate the on-site plan and if necessary the off-site emergency plan.
(2) Ensure that emergency services have been called.
(3) Direct the shutting down and evacuation of the other plant areas, etc., likely to be affected.
(4) Ensure that key personnel have been notified.
(5) Direct all operation at the scene.
(6) Control the rescue and fire fighting operations activities until the arrival of the fire brigade, when he should hand over control to a senior fire officer.
(7) Search for casualties.
(8) Evacuate non-essential workers to assembly areas.
(9) Set up a communications point with radio, telephone or messenger contact with the EOC.
(10) Give advice and information as requested to the emergency services.
(11) Brief the site emergency management and keep them informed of developments.

Where a fire is involved, the IC will direct fire fighting until the outside Fire Brigade officer or the Fire Services arrives, he will then hand over control of this aspect to the senior officer of the fire brigade. The IC should be thoroughly familiar with the works situation; a suitable person is the shift section manager. It is important that the IC be readily recognizable when he is at the scene of the incident. This is facilitated if he wears a distinctive garment such as a brightly coloured or luminous jacket or helmet. This garment should be known to all concerned and should be distinct from any which might be worn by others at the scene, including the outside services.

24.6.2 Emergency Operation Manager

The function of the Emergency Operation Manager (EOM) is to take overall control of the emergency operation activities from the EOC. The EOM controls the 'big picture' from the EOC, and takes an overall control of the scene. Among his responsibilities are the following:

(1) If he decides that a major scale emergency exists or is likely to be developed, then he should ensure that the emergency services have been called and the off-site plan activated.
(2) Ensure that key personnel are called in.
(3) Exercise direct operational control of those parts of the works outside the affected area.
(4) Continually review and assess possible developments to determine the most probable course of events.
(5) Direct the shutting down of plants and their evacuation in consultation with the IC and key personnel.
(6) Ensure that casualties are receiving adequate attention. Arrange for additional help if required. Ensure that relatives are informed.
(7) In case of emergencies that involve risk to outside areas from wind blown materials, contact the local meteorological office to receive early notification of impending changes in weather conditions.
(8) Liaise with chief officers of the fire and police services and provide advice on possible effects on areas outside the works, and ensure that personnel are accounted for.
(9) Control traffic movement within the works.
(10) Arrange for a log of the emergency to be maintained.
(11) Where the emergency is prolonged, arrange for the relief of site personnel and the provision of catering facilities.
(12) Issue authorized statements to the news media.
(13) Ensure that proper consideration is given to the preservation of evidence.
(14) Control rehabilitation of affected areas after the emergency.

The EOC should be familiar with the activities and should have the authority needed to take any necessary major decisions affecting these activities, the activities in the neighbouring facilities and the outside services. A suitable person is the shift manager. For both managers deputies should be appointed who can take over their duties if they are unavailable for any reason.

24.6.3 Other functions and personnel

There are numerous other functions that may have to be carried out in an emergency. Some of these functions are normal, though they can easily become overtaxed in an emergency, but most are specific to the emergency situation. Similar to the list of responsibilities of the IC and EOM, each of the key personnel should be familiar with all his responsibilities, all the relevant procedures, to whom he reports and who are those under his responsibilities, and to whom he reports if the primary person is not in duty for any reason.

24.7 Declaration and Communication of the Emergency

24.7.1 Raising the alarm

When a serious incident occurs, it is very desirable for the alarm to be raised as quickly as possible. Prompt action will in many cases forestall the development of a full emergency. Crucial aspects of raising the alarm are the authority to raise the alarm, the training of personnel and the alarm system. An efficient and widely practiced policy is to allow any employee to raise the alarm. Such a policy is more effective if personnel have been specifically trained in this aspect.

24.7.2 Declaration of the emergency

When the alarm has been raised, the emergency procedure is activated. The first stage is the decision as to whether the incident constitutes, or could develop into, an emergency. The IC should visit the scene of the incident. He then makes the decision whether to declare an emergency. The authority to declare an emergency need not be restricted to the IC; however, it is undesirable to allow the authority to be too widespread, but too close a restriction may introduce an undesirable delay into the declaration. Other competent personnel may therefore be vested with this authority.

24.7.3 Communication of the emergency

Once an emergency has been declared, it must be communicated to the following entities:

(1) EOM
(2) Personnel working within the areas affected
(3) Personnel that are needed to be called in from outside
(4) Off-site emergency services
(5) Key personnel on call-in
(6) Personnel in other threatened areas and facilities
(7) Police
(8) Medical services
(9) Media, and
(10) Headquarters.

As far as possible, the IC should be relieved of the task of communicating the emergency so that he can devote his efforts to dealing with it on site. However, the duties include communication of the emergency to interested parties until the EOM arrives. It may be appropriate to consider arrangements that assist the IC in this task.

It is desirable to work out in advance fairly formal procedures for the notification of an emergency. The order in which the different parties are to be notified is one obvious aspect. It is also necessary to avoid entering into lengthy explanations to personnel on call-in and, in such instances, use may be made of short pre-arranged messages. Personnel liable to call-in should be issued with identification which will allow them to pass through police barriers erected to control traffic and sightseers.

It is essential that the existence of an emergency be notified without delay to affected plants within the works, the emergency teams and the off-site services.

The emergency should be notified to any neighbouring firm that might be affected by it. This may be necessary if there is a threat to the firm's plant or personnel, if the firm's activities could compound the emergency, for example, create a traffic jam at a shift change, or if there are mutual assistance arrangements.

24.8 Cooperation and Drills

24.8.1 Planning cooperation with off-site services

The planning of cooperation and the development of understanding with the off-site services is vital to the success of response to emergency. The first step is obviously establishment of agreements to cooperate in emergencies. These agreements are established mainly by the senior managers of the organizations involved. But this needs to be followed up by active planning and drills by plant personnel.

The activities should be seen not as two disjoint activities, but as a single operation in which a growing weight of resources is brought to bear on the incident. The planning should aim to clarify not only what is to be done but also who is to do it.

Cooperation benefits greatly if there is a full-time liaison officer, and this can be justified in an area where there is large potential for emergencies. What is known in advance is the general location and nature of possible emergencies. Other factors will not be so well defined: time, weather, and number of people. Excessive detail in the planning should be avoided. The aim should be to plan broad areas of responsibility, chains of command and systems of communication.

Off-site services will require their own communications. On-site, the practice has been for the police, fire and medical services to be linked by radio to their own communications systems. The EOC should be available to them. Alternatively, they may wish to set up their own mobile control centres.

The off-site services will also normally need to tap into the on-site emergency internal communication. This should be allowed through the EOC. An alternative is to provide for their use portable radios as used by the emergency teams.

Each service should have its own emergency plans. The police have a Major Incident Plan that covers road, rail, aircraft and airports as well as industrial situations. The fire service probably has a number of emergency plans.

24.8.2 Emergency drills

Emergency drills are effective in familiarizing personnel with their functions. While drills with on-site personnel can be dictated by a routine, real-time simulation that involves all forces, on- and off-site are much more complicated to perform. However, the effectiveness of the plan, as well as the performance of each of the entities in the response stage can be assessed only in full-scale drills. It is common that full-scale emergency drill resulted in major changes in the plan, and sometimes it required conducting process hazard analysis in order to better understand the hazards, and the risks associated. In any case, the emergency plan should consist of a procedure for implementation of change management.

24.9 Public Relations

If a major incident occurs, it is important to provide the media with accurate information. To give no report in the press is not an option. All personnel should direct turns from the media to the spokesman. A good emergency plan will consist of a procedure that provides guidelines to answering questions. Several questions might be anticipated. The choice is between an attitude to the press that may foster informed and sympathetic reporting and one that almost guarantees ignorant and hostile comment. A company is unwise to expect sympathetic reporting unless over the long term it has built up with the press, as far as it is able, a relationship of trust based on openness about the hazards present and the preventive and protective measures adopted. It will normally be appropriate that the long-term handling of major hazard policies be done by the company's head office with reference to national policies and standards.

The following is a list of common questions that a media would query about:

(1) What happened and where?
(2) How it occurred?
(3) Was a hazardous material released and how much?
(4) What is the extent of the emergency?
(5) How long will the event last?
(6) Is the incident under control?
(7) What are the measures that are being taken to protect the public?
(8) Are there injuries and fatalities, and how many?
(9) On-going update on the emergency activities.
(10) Information on the criteria of declaring on escalation.

A periodic training of a spokesman can significantly improve the credibility and reliability of the firm's public relations.

24.10 Off-site Emergency Planning

Off-site emergency planning are developed within a jurisdiction, or a city, county or a region. An off-site emergency plan consists of procedures that address the following disciplines:

(1) Warning
(2) Communication
(3) Shelters and mass care
(4) Evacuation
(5) Fire fighting
(6) Spills of hazardous materials and petroleum products
(7) Law enforcement
(8) Health and medical services
(9) Hazard mitigation
(10) Public works
(11) Utilities
(12) Human services
(13) Search and rescue
(14) Transportation
(15) Donation management
(16) Terrorism threads.

The purpose of an off-site emergency plan is to outline strategic framework to respond to natural and man-made disasters. Since the terrorist attacks on the World Trade Center in New York on 11 September 2001, there is a significant emphasis on mutually supporting terrorism preparedness programmes, with the goal to enhance the capabilities by establishing a comprehensive programme for the full spectrum of terrorist threat and any other kinds of disasters.

The off-site emergency plan is similar in structure to the on-site emergency plan. However, coordination of off-site emergency plan requires much more energy and effort. While for on-site plans, the EOM has an authority to direct all the activities and disciplines in the plant, for off-site plans, the EOM may have partial authority only.

Warning procedures should use common channels of communication to advise the public on an emergency. However, some people who are directly threatened by the hazard may not hear and not understand the warning. It is necessary to address special needs groups such as sight and hearing impaired, and nursing home.

Communication system planning should assume that the hazards may neutralize the designated communication systems, and that additional communication equipment may be required.

Provision of shelters and mass care is a major responsibility, and a large number of parameters are involved in the process of designation of shelters. The efforts in the United States should be coordinated with the American Red Cross, which has been chartered under federal law to provide mass care in cases of natural disaster.

The characteristics of hazards, magnitude, intensity and anticipated duration are major factors in evacuation planning. Small- and large-scale evacuation should be addressed by the planner. The criteria for the decision of evacuation should be clear, and the planner should remove ambiguities from this procedure. A common assumption is that about 80% of the population at risk will respond to the first recommendation of evacuation. However, as the hazard becomes more obvious, more will respond. Some of the people will refuse to be evacuated under any circumstance. Some of them will demand that their pets be cared for too. All of these factors should be addressed, as well as the response rate at different parts of the day.

Large number of procedures, modular plans and templates are available for the disciplines listed above on the US Federal Emergency Management Agency and on states' Division of Emergency Management websites.

24.11 Transport Emergency Planning

24.11.1 Background

As described in Chapter 23, it is essential for hazardous chemicals to be transported in tanks and containers designed and maintained to high standards, for transport personnel to have any necessary training, for comparative studies of the different means of transport to be done and routes carefully selected, and for hazard studies to be carried out. Even so, it is still necessary to plan for possible transport emergencies.

As with safety in the transport of hazardous chemicals in general, so with transport emergency planning, the chemical industry has always tended to take the view that although strictly the responsibility lies with the shipper, it is very much in the interests and responsibility of the industry also to take measures to deal with transport emergencies. This attitude finds practical expression in companies' willingness to send emergency teams to situations in which their own products are not involved.

Transport emergency planning has something in common with works emergency planning, but there are some important differences. The main one is that even with careful routing, there is a vast range of locations at which the emergency can occur.

Transportation emergency planning includes the following elements:

(1) chemical data;
(2) information and labelling;
(3) incident control network;
(4) emergency procedures;
(5) emergency teams;
(6) outside services, and
(7) public relations.

The following paragraph discusses these elements.

Chemical data

Although the properties of chemicals that are shipped are usually understood well enough for most purposes, it is necessary that particular attention be paid to any property that is specially important in a transport emergency. In the Glendora incident described below, 30,000 people were evacuated because it was feared that lethal quantities of phosgene might be generated by burning vinyl chloride monomer (VCM). Although the manufacturer's expert on the spot discounted this hazard, the authorities proceeded with the evacuation. The incident led the industry to carry out research to determine more exactly the extent of the hazard from this source, which turned out to be small. Material Safety Data Sheet (MSDS) should be part of the delivery, to simplify the search for data.

Information and labelling

People involved in transportation incident need information about the chemical, but their needs differ. The amount of information required is different for the public, the personnel involved in the first few minutes and for those involved in longer term incident control and clearing up operations.

There are also different sources of information. The most accessible is the labelling of the container. Then there is usually more detailed information carried somewhere on the vehicle, if an MSDS is not reachable. The shipper and outside services, such as police and fire services, should have manuals that contain similar data. Finally, there is the manufacturer who may be contacted through the Federal Emergency Management Agency, EPA, and others. The UN classification code is commonly being used for labelling in transportation of hazardous materials.

Emergency procedures

There are certain priority actions that should be taken by the person at the scene of the incident. The priorities are as follows:

(1) keep people away;
(2) inform incident control;
(3) contain the chemical;
(4) avoid igniting the chemical, and
(5) obtain chemical data.

The communication with the EOC is important. The centre should be informed as follows:

(1) place and time of the incident;
(2) chemical involved;
(3) container condition;
(4) injuries or/and fatalities;
(5) the surrounding area (urban, rural);
(6) weather conditions;
(7) the assistance available (police, fire services), and
(8) the means of maintaining contact.

It is particularly important for the man on the spot to ensure that the control centre can keep in contact with him, by using a cellular phone or any other communication measure. If possible, the chemical should not be allowed to get into sewers. A pool of liquid may often be rendered safer by covering it with a blanket of suitable foam.

Ignition of the material should be avoided if at all possible. Sources of ignition should be kept well away.

Some chemicals that are transported have properties that may increase the hazard of the incident. These include low boiling points, capacity for spontaneous ignition, and reaction with water.

Emergency teams

The manufacturer of a hazardous chemical normally arranges for an emergency team to be available to be sent to the scene as soon as a transport emergency is notified. In some cases this involves mutual assistance schemes.

The personnel comprising the emergency team are usually thoroughly familiar with the chemical and are trained in handling incidents. In addition to the general incident control measures already described, the emergency team usually has expertise in dealing with leaks and fires and in emptying damaged containers and clearing up.

A leak or spillage should not be ignited. If a leak has ignited, however, it may be the best policy to let it continue burning. The danger of putting out a fire without eliminating the leak is that the amount of flammables may build up and, if re-ignited, cause a more serious fire or explosion.

If other containers are present, as it typically the case in rail incidents, it may be necessary to cool these with water to prevent their overheating.

The emergency team is sent as soon as possible on receipt of notification, but several hours are likely to elapse before it reaches the scene of the incident.

24.11.3 External services

The general role of the external services such as the police and fire services has already been described. Some additional points relevant to transport emergencies may be mentioned briefly.

A transport emergency differs from emergency activities on-site. There is therefore much less scope for advance cooperation between a manufacturer and the services in his local authority area. The variety of hazardous chemicals that the services may have to handle is much greater.

Another feature of a transport emergency is that it may well occur in an urban area. This means that measures to keep people away from the scene, to divert traffic, to maintain access for emergency vehicles and possibly to evacuate the population assume particular importance.

Decisions on the advice to be given to the public, whether this be to take shelter or to evacuate, are particularly difficult. In some situations where it is not strictly necessary to involve large numbers of people, the authorities may nevertheless have little choice but to order action, unless precise information is available to them on the hazards of the chemical, particularly the toxic hazards. Likewise, information on fighting fires of the chemical is important for the fire services. In particular, the latter need to know whether the chemical reacts violently with water.

24.11.4 Rail transport

The foregoing account has been concerned primarily with road transport, but most of it is applicable to rail road transportation as well. In this case, the railway authority establishes its own procedures and trains its own personnel. Again the prime requirement from the manufacturer is full information about the chemicals.

Emergencies involving hazardous chemicals on railways tend to have some special features. One is the problem of access, particularly for fire engines. The track is often blocked by derailed rail vehicles. Another aspect is that there are usually a number of tank cars involved, with the danger of a spread of the fire/explosion. Frequently there is a hazard to other transport, such as to trains on other tracks, or to nearby roads.

24.12 Spectators

An incident that lasts for any appreciable length of time is liable to attract spectators. This is true not only of transport incidents occurring outside the site, but also of incidents on-site that are visible outside.

The effect of spectators is two-fold. The number of people at risk may be considerably increased, and the passages for the emergency services can become congested, with consequent delays.

The problem of spectators has been investigated by Hymes (1985 LPB 65), who describes quite a large number of incidents in which spectators suffered injury. Some of the cases cited involve people who became exposed to the threat and stood watching it develop instead of making their escape, whilst in others they were attracted to the incident as sightseers. Some of the incidents that he describes are summarized in Section 24.13.

The control of spectators is therefore an essential part of an off-site emergency plan and of a transport emergency plan. The responsibility for such control rests with the police.

24.13 Emergency Incidents

24.13.1 Historical data

Some information on emergencies in the process industries has been obtained in the course of a study on human factors as a cause of pipe work failures by Bellamy, Geyer and Astley (1989).

For failures of mitigation, the number of incidents due to each cause were as follows: delay, 23 (45%); design deficiency, 14 (27.5%) and lack of resources, 14 (27.5%). Examples in the first category were lack of procedures for handling the incident and defective fire fighting equipment; in the second category, examples were a layout leaving insufficient space for fire water jets to be directed at the source of the fire and the inaccessibility of shut-down equipment due to the leak itself and in the third category, examples were lack of manpower and lack of equipment.

The information on the implementation of emergency plans and on evacuation in this study is ambiguous. On the one hand, there were 42 cases recorded in which an emergency plan was put into effect. In 27 of these cases, the plan implemented was the on-site plan and in 11 it was the off-site plan; in the 4 remaining cases, the plan was not specified. On the other hand, there were 30 cases in which there was evacuation, either on-site or off-site or both, with 13 on-site and 24 off-site evacuations.

24.13.2 Incidents involving evacuation and/or shelter

There have been a number of instructive incidents involving evacuation and/or shelter. They include those at

La Barre in 1961, Glendora in 1969, Potchefstroom in 1973, Houston in 1976, and Mississauga in 1979.

In 1961, a rail crash occurred at La Barre, Louisiana, involving a chlorine rail tank car, only 50 yd from a house. A father was looking after a baby in the house, the infant began to choke and gasp, and the frantic father carried it outside, where the gas concentration was higher still. The child died in hospital.

In 1969, a group of eight rail tank cars containing VCM were involved in a crash at Glendora, Mississippi, and one started to leak. That evening one of the tank cars ruptured, with subsequent ignition of the leak. A heavy fog was observed over the area and it was considered that it might be VCM. The responders stated that in a VCM fire, phosgene could be formed. Further advice was sought from the manufacturer's representative, who stated that the principal problem was likely to be HCl and smoke, and university chemists, who stated that burning VCM could create phosgene that was potentially dangerous up to a radius of 35 miles. An evacuation was initiated involving some 30,000 people.

In 1973, a sudden failure occurred in an anhydrous ammonia storage tank at Potchefstroom in South Africa. Workers in a building 80 m from the release survived, but people who left their houses 180–200 m from it died.

In 1976 at Houston, Texas, a tank truck carrying 19 tons of anhydrous ammonia ruptured at a highway intersection. The resultant gas cloud enveloped the Houston Post building but the workers inside were not affected. Outside, 94 people caught in the cloud were injured, of whom 5 died.

24.13.3 Mississauga

A very large evacuation occurred on Saturday, 10 November 1979 at Mississauga, near Toronto. At 23.52 p.m., a train crashed and several propane rail tank cars exploded. The train manifest was found, but it was in code. A strong smell of chlorine was detected. At 01.30 the next morning, a readable version of the manifest was obtained. A rail tank car containing some 90 te of chlorine was identified as being in the train and it was concluded that this car was amongst the burning wreckage. At 03.00, the decision was taken to evacuate the surrounding population. An evacuation was begun which involved a total of about 215,000 people. The chlorine tank car was identified by helicopter and found to have a visible hole in it. At 09.00 on Tuesday morning, an initial attempt was made to plug the hole, but this failed; a second attempt later was successful. The tank was subsequently emptied. During Tuesday afternoon 143,000 evacuees were allowed to return to their homes in the areas more distant from the crash. The rest returned only after a total absence of 6 days.

24.13.4 Incidents involving spectators

The following incidents have been described in the study of spectators. At Deer Lake, Pennsylvania, in 1959, a road tanker carrying LPG was struck by a following truck in a wet street. LPG was released and ignited, engulfing the rear of the tanker. Fire services arrived, but expended water on a nearby building, and in due course the tanker suffered a boiling liquid expanding vapour explosion (BLEVE). Fragments, which included most of the tank, killed 11 spectators and injured 10 more. Emergency services were hampered both before the rupture and after it.

At Meldrin, Georgia, in 1959, a rail tank car suffered a partial rupture near a picnic site. A large gas cloud spread and for some time did not ignite. When it did ignite, a flash fire occurred. There were 23 dead, many of whom were found in their cars. Emergency services were greatly hampered because the site was remote and served only by a dirt road congested by spectators and relatives of the casualties.

At Kingman, Arizona, in 1973, a rail tank car carrying propane developed a leak that ignited. Despite police discouragement, a large crowd of spectators jostled to get a view. In due course the tank car underwent a BLEVE and a huge fireball erupted. Some 90 spectators 300 m away suffered injury.

At San Carlos de la Rapita, Spain, in 1978, a road tanker carrying propylene past the Los Alfaques campsite ruptured with a small explosion. A flammable gas cloud began to spread through the site. Campers who did not appreciate that the full hazard from the burning tanker had yet to develop stood around bemused whilst escape was still possible. Many wore bathing suits or light beachwear. There followed a major explosion and flash fire. The eventual death toll was about 210, a large proportion from severe burns.

Other incidents in which many of the deaths occurred among spectators are those at Texas City in 1947, and Caracas, Venezuela, in 1982. In the Texas City disaster, a fire developed aboard a ship in the harbour. The ship was carrying ammonium nitrate. In due course the ship disintegrated in an enormous explosion, killing all those in the dock, including firemen and spectators. This explosion and a further one in another ammonium nitrate carrier killed 552 people and injured another 3000.

The Caracas disaster involved a fire in an oil tank sited on a hill. A boilover occurred and the burning oil flowed down the hill. Forty firefighters were killed, together with many civil defence workers and spectators, giving a fatality toll of 153 with 7 missing.

24.14 Recovery

A recovery from a major emergency event is a process that requires major efforts and takes a significant period of time. The extant of the efforts is a function of parameters such as the resources that are required to rebuild and renovate, requirements of the enforcing agencies, personnel commitment, length of process purchasing and delivery, and more. The most important factor in the recovery process is leadership, and therefore the recovery management should be selected carefully. Recovery process consists of a very large number of details. The recovery manager needs to establish a recovery team that will represents all the disciplines in the plant. The team should include representatives from engineering, maintenance, production, purchasing, ES&H, legal department and other, as the circumstances require.

Following the emergency phase, the site should be secured and preservation of evidence and data collection need to take place. Parallel to these activities, human resources should provide assistance to employees and victim families. Incident that resulted in fatalities will require professional psychological support as well. Portion of the efforts of assessment of the damage to the environment and property and incident investigation could be integrated to avoid repetition of some of the phases. Clean up activities should be coordinated extremely carefully to avoid removal of evidence. It is recommended to consider involvement of the media in the process in order to improve public relation, and recovery of the damaged image.

24.15 Regulations and Standards

24.15.1 Regulations

In the United States, the OSHA established the Process Safety Management (PSM) requirements, following the issuance of the Clean Air Act section 112(r). The US EPA followed by issuance of the Risk Management Program (RMP), for Chemical Accidents Release Prevention.

The Health and Safety Executive in United Kingdom established guidance for writing on- and off-site emergency plans 'HS (G) 191 Emergency planning for major accidents: Control of Major Accident Hazards (COMAH) regulations 1999'. OSHA PSM standard consists of 12 elements. CFR 1910.38 in the standard states the requirements for emergency planning. However, other OSHA requirements such as CFR 1910.156 that establish requirements for training Fire Brigades, and CFR 1910.146 that states the requirement for training emergencies in confined spaces are related as well.

EPA RMP rule is based on industrial codes and standards, and it requires companies to develop an RMP if they handle hazardous substances that exceed a certain threshold. The programme is required to include the following sections:

(1) Hazard assessment based on the potential effects, an accident history of the last 5 years, and an evaluation of worst-case and alternative accidental releases.
(2) Prevention programme.
(3) Emergency response programme.

On the other hand, EPA requires that the communities will put the efforts from their side. The EPA Emergency Planning and Community Right-to-Know Act (EPCRA) establishes requirements for the industry, Federal, State and local governments, on reporting on hazardous and toxic chemicals.

EPCRA consists of four parts:

(1) Emergency planning (Section 301–303),
(2) Emergency release notification (Section 304),
(3) Hazardous chemical storage reporting requirements (Sections 311–312) and
(4) Toxic chemical release inventory (Section 313).

The purpose of the EPCRA is to help increasing awareness in the public on chemicals at individual facilities, their uses and releases into the environment. The act states that every community in the United States must be part of a comprehensive emergency plan.

Both, the Department of Transportation and the Department of Energy, address emergency planning. Information is available on their websites.

24.15.2 Standards

A large number of standards that addresses process safety and are relevant to process safety are available. However, the NFPA published a variety of standards that are useful in emergency planning and training for emergencies. List of NFPA publications is given in Appendix A. Similarly, the National Institute of Safety and Health and the American National Standards Institute (ANSI) provide guidelines and standards that can be helpful in planning for emergencies.

Appendix A: NFPA Publications

NFPA 1	Uniform Fire Code
NFPA 10	Standard for Portable Fire Extinguishers
NFPA 11	Standard for Low-, Medium-, and High-Expansion Foam Systems
NFPA 11A	Standard for Medium- and High-Expansion Foam Systems
NFPA 12	Standard on Carbon dioxide Extinguishing Systems
NFPA 12A	Standard on Halon 1301 Fire Extinguishing Systems
NFPA 13	Standard for the Installation of Sprinkler Systems
NFPA 13D	Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes
NFPA 13E	Recommended Practice for Fire Department Operations in Properties Protected by Sprinkler and Standpipe Systems
NFPA 13R	Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height
NFPA 14	Standard for the Installation of Standpipe, Private Hydrants, and Hose Systems
NFPA 15	Standard for Water Spray Fixed Systems for Fire Protection
NFPA 16	Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems
NFPA 17	Standard for Dry Chemical Extinguishing Systems
NFPA 17A	Standard for Wet Chemical Extinguishing Systems
NFPA 18	Standard on Wetting Agents
NFPA 20	Standard for the Installation of Stationary Pumps for Fire Protection
NFPA 22	Standard for Water Tanks for Private Fire Protection
NFPA 24	Standard for the Installation of Private Fire Service Mains and Their Appurtenances

NFPA 25	Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems
NFPA 30	Flammable and Combustible Liquids Code
NFPA 30A	Code for Motor Fuel Dispensing Facilities and Repair Garages
NFPA 30B	Code for the Manufacture and Storage of Aerosol Products
NFPA 31	Standard for the Installation of Oil-Burning Equipment
NFPA 32	Standard for Drycleaning Plants
NFPA 33	Standard for Spray Application Using Flammable or Combustible Materials
NFPA 34	Standard for Dipping and Coating Processes Using Flammable or Combustible Liquids
NFPA 35	Standard for the Manufacture of Organic Coatings
NFPA 36	Standard for Solvent Extraction Plants
NFPA 37	Standard for the Installation and Use of Stationary Combustion Engines and Gas Turbines
NFPA 40	Standard for the Storage and Handling of Cellulose Nitrate Film
NFPA 42	Code for the Storage of Pyroxylin Plastic
NFPA 45	Standard on Fire Protection for Laboratories Using Chemicals
NFPA 50	Standard for Bulk Oxygen Systems at Consumer Sites
NFPA 50A	Standard for Gaseous Hydrogen Systems at Consumer Sites
NFPA 50B	Standard for Liquefied Hydrogen Systems at Consumer Sites
NFPA 51	Standard for the Design and Installation of Oxygen-Fuel Gas Systems for Welding, Cutting, and Allied Processes
NFPA 51A	Standard for Acetylene Cylinder Charging Plants
NFPA 51B	Standard for Fire Prevention During Welding, Cutting, and Other Hot Work
NFPA 52	Compressed Natural Gas (CNG) Vehicular Fuel Systems Code
NFPA 53	Recommended Practice on Materials, Equipment and Systems Used in Oxygen-Enriched Atmospheres
NFPA 54	National Fuel Gas Code
NFPA 55	Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks
NFPA 57	Liquefied Natural Gas (LNG) Vehicular Fuel Systems Code
NFPA 58	Liquefied Petroleum Gas Code
NFPA 59	Utility LP-Gas Plant Code
NFPA 59A	Standard for the Production, Storage, and Handling of Liquefied Natural Gas (LNG)
NFPA 61	Standard for the Prevention of Fires and Dust Explosions in Agricultural and Food Processing Facilities
NFPA 68	Guide for Venting of Deflagrations
NFPA 69	Standard on Explosion Prevention Systems
NFPA 70	National Electrical Code® National Electrical Codë
NFPA 70A	Electrical Code for One- and Two-Family Dwellings and Mobile Homes
NFPA 70B	Recommended Practice for Electrical Equipment Maintenance
NFPA 70E	Standard for Electrical Safety Requirements for Employee Workplaces
NFPA 72	National Fire Alarm Codë
NFPA 73	Electrical Inspection Code for Existing Dwellings
NFPA 75	Standard for the Protection of Information Technology Equipment
NFPA 76	Recommended Practice for the Fire Protection of Telecommunications Facilities
NFPA 77	Recommended Practice on Static Electricity
NFPA 79	Electrical Standard for Industrial Machinery
NFPA 80	Standard for Fire Doors and Fire Windows
NFPA 80A	Recommended Practice for Protection of Buildings from Exterior Fire Exposures
NFPA 82	Standard on Incinerators and Waste and Linen Handling Systems and Equipment
NFPA 85	Boiler and Combustion Systems Hazards Code
NFPA 86	Standard for Ovens and Furnaces
NFPA 88A	Standard for Parking Structures
NFPA 90A	Standard for the Installation of Air-Conditioning and Ventilating Systems
NFPA 90B	Standard for the Installation of Warm Air Heating and Air-Conditioning Systems
NFPA 91	Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids
NFPA 92A	Recommended Practice for Smoke-Control Systems
NFPA 92B	Guide for Smoke Management Systems in Malls, Atria, and Large Areas
NFPA 96	Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations
NFPA 97	Standard Glossary of Terms Relating to Chimneys, Vents, and Heat-Producing Appliances
NFPA 99	Standard for Health Care Facilities
NFPA 99B	Standard for Hypobaric Facilities
NFPA 99C	Standard on Gas and Vacuum Systems
NFPA 101	Life Safety Codë
NFPA 101A	Guide on Alternative Approaches to Life Safety
NFPA 101B	Code for Means of Egress for Buildings and Structures
NFPA 102	Standard for Grandstands, Folding and Telescopic Seating, Tents, and Membrane Structures
NFPA 105	Standard for the Installation of Smoke Door Assemblies
NFPA 110	Standard for Emergency and Standby Power Systems
NFPA 111	Standard on Stored Electrical Energy Emergency and Standby Power Systems
NFPA 115	Standard on Laser Fire Protection
NFPA 120	Standard for Coal Preparation Plants
NFPA 121	Standard on Fire Protection for Self-Propelled and Mobile Surface Mining Equipment
NFPA 122	Standard for Fire Prevention and Control in Underground Metal and Nonmetal Mines
NFPA 123	Standard for Fire Prevention and Control in Underground Bituminous Coal Mines

NFPA 130	Standard for Fixed Guideway Transit and Passenger Rail Systems
NFPA 140	Standard on Motion Picture and Television Production Studio Soundstages and Approved Production Facilities
NFPA 150	Standard on Fire Safety in Racetrack Stables
NFPA 160	Standard for Flame Effects Before an Audience
NFPA 170	Standard for Fire Safety Symbols
NFPA 203	Guide on Roof Coverings and Roof Deck Constructions
NFPA 204	Standard for Smoke and Heat Venting
NFPA 211	Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances
NFPA 214	Standard on Water-Cooling Towers
NFPA 220	Standard on Types of Building Construction
NFPA 221	Standard for Fire Walls and Fire Barrier Walls
NFPA 225	Model Manufactured Home Installation Standard
NFPA 230	Standard for the Fire Protection of Storage
NFPA 232	Standard for the Protection of Records
NFPA 241	Standard for Safeguarding Construction, Alteration, and Demolition Operations
NFPA 251	Standard Methods of Tests of Fire Endurance of Building Construction and Materials
NFPA 252	Standard Methods of Fire Tests of Door Assemblies
NFPA 253	Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source
NFPA 255	Standard Method of Test of Surface Burning Characteristics of Building Materials
NFPA 256	Standard Methods of Fire Tests of Roof Coverings
NFPA 257	Standard on Fire Test for Window and Glass Block Assemblies
NFPA 258	Recommended Practice for Determining Smoke Generation of Solid Materials
NFPA 259	Standard Test Method for Potential Heat of Building Materials
NFPA 260	Standard Methods of Tests and Classification System for Cigarette Ignition Resistance of Components of Upholstered Furniture
NFPA 261	Standard Method of Test for Determining Resistance of Mock-Up Upholstered Furniture Material Assemblies to Ignition by Smoldering Cigarettes
NFPA 262	Standard Method of Test for Flame Travel and Smoke of Wires and Cables for Use in Air-Handling Spaces
NFPA 265	Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls
NFPA 268	Standard Test Method for Determining Ignitibility of Exterior Wall Assemblies Using a Radiant Heat Energy Source
NFPA 269	Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling
NFPA 270	Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber
NFPA 271	Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter
NFPA 272	Standard Method of Test for Heat and Visible Smoke Release Rates for Upholstered Furniture Components or Composites and Mattresses Using an Oxygen Consumption Calorimeter
NFPA 273	Standard Method of Test for Determining the Degrees of Combustibility of Building Materials
NFPA 274	Standard Test Method to Evaluate Fire Performance Characteristics of Pipe Insulation
NFPA 284	Standard Test Method for Mattresses for Correctional Occupancies
NFPA 285	Standard Method of Test for the Evaluation of Flammability Characteristics of Exterior Non-Load-Bearing Wall Assemblies Containing Combustible Components Using the Intermediate-Scale, Multistory Test Apparatus
NFPA 286	Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth
NFPA 287	Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA)
NFPA 288	Standard Method of Fire Tests of Floor Fire Door Assemblies Installed Horizontally in Fire Resistance Rated Floor Systems
NFPA 289	Standard Method of Fire Test for Room Fire Growth Contribution of Individual Fuel Packages
NFPA 290	Standard for Fire Testing of Passive Protection Materials for Use on LP-Gas Containers
NFPA 291	Recommended Practice for Fire Flow Testing and Marking of Hydrants
NFPA 301	Code for Safety to Life from Fire on Merchant Vessels
NFPA 302	Fire Protection Standard for Pleasure and Commercial Motor Craft
NFPA 303	Fire Protection Standard for Marinas and Boatyards
NFPA 306	Standard for the Control of Gas Hazards on Vessels
NFPA 307	Standard for the Construction and Fire Protection of Marine Terminals, Piers, and Wharves
NFPA 312	Standard for Fire Protection of Vessels During Construction, Repair, and Lay-Up
NFPA 318	Standard for the Protection of Semiconductor Fabrication Facilities
NFPA 326	Standard for the Safeguarding of Tanks and Containers for Entry, Cleaning, or Repair
NFPA 329	Recommended Practice for Handling Releases of Flammable and Combustible Liquids and Gases
NFPA 385	Standard for Tank Vehicles for Flammable and Combustible Liquids
NFPA 402	Guide for Aircraft Rescue and Fire Fighting Operations
NFPA 403	Standard for Aircraft Rescue and Fire Fighting Services at Airports
NFPA 405	Recommended Practice for the Recurring Proficiency Training of Aircraft Rescue and Fire-Fighting Services

NFPA 407	Standard for Aircraft Fuel Servicing
NFPA 408	Standard for Aircraft Hand Portable Fire Extinguishers
NFPA 409	Standard on Aircraft Hangars
NFPA 410	Standard on Aircraft Maintenance
NFPA 412	Standard for Evaluating Aircraft Rescue and Fire Fighting Foam Equipment
NFPA 414	Standard for Aircraft Rescue and Fire Fighting Vehicles
NFPA 415	Standard on Airport Terminal Buildings, Fueling Ramp Drainage, and Loading Walkways
NFPA 418	Standard for Heliports
NFPA 422	Guide for Aircraft Accident Response
NFPA 423	Standard for Construction and Protection of Aircraft Engine Test Facilities
NFPA 424	Guide for Airport/Community Emergency Planning
NFPA 430	Code for the Storage of Liquid and Solid Oxidizers
NFPA 432	Code for the Storage of Organic Peroxide Formulations
NFPA 434	Code for the Storage of Pesticides
NFPA 450	Guide for Emergency Medical Services and Systems
NFPA 471	Recommended Practice for Responding to Hazardous Materials Incidents
NFPA 472	Standard for Professional Competence of Responders to Hazardous Materials Incidents
NFPA 473	Standard for Competencies for EMS Personnel Responding to Hazardous Materials Incidents
NFPA 484	Standard for Combustible Metals, Metal Powders, and Metal Dusts
NFPA 490	Code for the Storage of Ammonium Nitrate
NFPA 495	Explosive Materials Code
NFPA 496	Standard for Purged and Pressurized Enclosures for Electrical Equipment
NFPA 497	Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas
NFPA 498	Standard for Safe Havens and Interchange Lots for Vehicles Transporting Explosives
NFPA 499	Recommended Practice for the Classification of Combustible Dusts and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas
NFPA 501	Standard on Manufactured Housing
NFPA 501A	Standard for Fire Safety Criteria for Manufactured Home Installations, Sites, and Communities
NFPA 502	Standard for Road Tunnels, Bridges, and Other Limited Access Highways
NFPA 505	Fire Safety Standard for Powered Industrial Trucks Including Type Designations, Areas of Use, Conversions, Maintenance, and Operation
NFPA 520	Standard on Subterranean Spaces
NFPA 550	Guide to the Fire Safety Concepts Tree
NFPA 551	Guide for the Evaluation of Fire Risk Assessments
NFPA 555	Guide on Methods for Evaluating Potential for Room Flashover
NFPA 556	Guide on Methods for Evaluating Fire Hazard and Fire Risk of Vehicular Furnishing
NFPA 560	Standard for the Storage, Handling, and Use of Ethylene Oxide for Sterilization and Fumigation
NFPA 600	Standard on Industrial Fire Brigades
NFPA 601	Standard for Security Services in Fire Loss Prevention
NFPA 610	Guide for Emergency and Safety Operations at Motorsports Venues
NFPA 654	Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling of Combustible Particulate Solids
NFPA 655	Standard for Prevention of Sulfur Fires and Explosions
NFPA 664	Standard for the Prevention of Fires and Explosions in Wood Processing and Woodworking Facilities
NFPA 701	Standard Methods of Fire Tests for Flame Propagation of Textiles and Films
NFPA 703	Standard for Fire Retardant Impregnated Wood and Fire Retardant Coatings for Building Materials
NFPA 704	Standard System for the Identification of the Hazards of Materials for Emergency Response
NFPA 705	Recommended Practice for a Field Flame Test for Textiles and Films
NFPA 720	Recommended Practice for the Installation of Household Carbon Monoxide (CO) Warning Equipment
NFPA 730	Guide for Electronic Premises Security
NFPA 731	Standard for the Installation of Electronic Premises Security Systems
NFPA 750	Standard on Water Mist Fire Protection Systems
NFPA 780	Standard for the Installation of Lightning Protection Systems
NFPA 801	Standard for Fire Protection for Facilities Handling Radioactive Materials
NFPA 804	Standard for Fire Protection for Advanced Light Water Reactor Electric Generating Plants
NFPA 805	Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants
NFPA 820	Standard for Fire Protection in Wastewater Treatment and Collection Facilities
NFPA 850	Recommended Practice for Fire Protection for Electric Generating Plants and High Voltage Direct Current Converter Stations
NFPA 851	Recommended Practice for Fire Protection for Hydroelectric Generating Plants
NFPA 853	Standard for the Installation of Stationary Fuel Cell Power Plants
NFPA 900	Building Energy Code
NFPA 901	Standard Classifications for Incident Reporting and Fire Protection Data
NFPA 906	Guide for Fire Incident Field Notes
NFPA 909	Code for the Protection of Cultural Resources
NFPA 914	Code for Fire Protection of Historic Structures

NFPA 1000	Standard for Fire Service Professional Qualifications Accreditation and Certification Systems
NFPA 1001	Standard for Fire Fighter Professional Qualifications
NFPA 1002	Standard for Fire Apparatus Driver/Operator Professional Qualifications
NFPA 1003	Standard for Airport Fire Fighter Professional Qualifications
NFPA 1006	Standard for Rescue Technician Professional Qualifications
NFPA 1021	Standard for Fire Officer Professional Qualifications
NFPA 1031	Standard for Professional Qualifications for Fire Inspector and Plan Examiner
NFPA 1033	Standard for Professional Qualifications for Fire Investigator
NFPA 1035	Standard for Professional Qualifications for Public Fire and Life Safety Educator
NFPA 1041	Standard for Fire Service Instructor Professional Qualifications
NFPA 1051	Standard for Wildland Fire Fighter Professional Qualifications
NFPA 1061	Standard for Professional Qualifications for Public Safety Telecommunicator
NFPA 1071	Standard for Emergency Vehicle Technician Professional Qualifications
NFPA 1081	Standard for Industrial Fire Brigade Member Professional Qualifications
NFPA 1122	Code for Model Rocketry
NFPA 1123	Code for Fireworks Display
NFPA 1124	Code for the Manufacture, Transportation, Storage and Retail Sales of Fireworks and Pyrotechnic Articles
NFPA 1125	Code for the Manufacture of Model Rocket and High Power Rocket Motors
NFPA 1126	Standard for the Use of Pyrotechnics before a Proximate Audience
NFPA 1127	Code for High Power Rocketry
NFPA 1141	Standard for Fire Protection in Planned Building Groups
NFPA 1142	Standard on Water Supplies for Suburban and Rural Fire Fighting
NFPA 1143	Standard for Wildland Fire Management
NFPA 1144	Standard for Protection of Life and Property from Wildfire
NFPA 1145	Guide for the Use of Class A Foams in Manual Structural Fire Fighting
NFPA 1150	Standard on Fire-Fighting Foam Chemicals for Class A Fuels in Rural, Suburban, and Vegetated Areas
NFPA 1192	Standard on Recreational Vehicles
NFPA 1194	Standard for Recreational Vehicle Parks and Campgrounds
NFPA 1201	Standard for Developing Fire Protection Services for the Public
NFPA 1221	Standard for the Installation, Maintenance, and Use of Emergency Services Communications Systems
NFPA 1250	Recommended Practice in Emergency Service Organization Risk Management
NFPA 1401	Recommended Practice for Fire Service Training Reports and Records
NFPA 1402	Guide to Building Fire Service Training Centers
NFPA 1403	Standard on Live Fire Training Evolutions
NFPA 1404	Standard for Fire Service Respiratory Protection Training
NFPA 1405	Guide for Land-Based Fire Fighters Who Respond to Marine Vessel Fires
NFPA 1410	Standard on Training for Initial Emergency Scene Operations
NFPA 1451	Standard for a Fire Service Vehicle Operations Training Program
NFPA 1452	Guide for Training Fire Service Personnel to Conduct Dwelling Fire Safety Surveys
NFPA 1500	Standard on Fire Department Occupational Safety and Health Program
NFPA 1521	Standard for Fire Department Safety Officer
NFPA 1561	Standard on Emergency Services Incident Management System
NFPA 1581	Standard on Fire Department Infection Control Program
NFPA 1582	Standard on Comprehensive Occupational Medical Program for Fire Departments
NFPA 1583	Standard on Health Related Fitness Programs for Fire Fighters
NFPA 1584	Recommended Practice on the Rehabilitation for Members Operating at Incident Scene Operations and Training Exercises
NFPA 1600	Standard for Disaster/Emergency Management and Business Continuity Programs
NFPA 1620	Recommended Practice for Pre-Incident Planning
NFPA 1670	Standard on Operations and Training for Technical Rescue Incidents
NFPA 1710	Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations, and Special Operations to the Public by Career Fire Departments
NFPA 1720	Standard for the Organization and Deployment of Fire Suppression Operations, Emergency Medical Operations and Special Operations to the Public by Volunteer Fire Departments
NFPA 1851	Standard on Selection, Care, and Maintenance of Structural Fire Fighting Protective Ensembles
NFPA 1852	Standard on Selection, Care, and Maintenance of Open-Circuit SCBA
NFPA 1901	Standard for Automotive Fire Apparatus
NFPA 1906	Standard for Wildland Fire Apparatus
NFPA 1911	Standard for Service Tests of Fire Pump Systems on Fire Apparatus
NFPA 1912	Standard for Fire Apparatus Refurbishing
NFPA 1914	Standard for Testing Fire Department Aerial Devices
NFPA 1915	Standard for Fire Apparatus Preventative Maintenance Program
NFPA 1925	Standard on Marine Fire Fighting Vessels
NFPA 1931	Standard on Design of and Design Verification Tests for Fire Department Ground Ladders
NFPA 1932	Standard on Use, Maintenance and Service Testing of Fire Department Ground Ladders
NFPA 1936	Standard on Powered Rescue Tool Systems

NFPA 1951	Standard on Protective Ensemble for USAR Operations
NFPA 1961	Standard for Fire Hose
NFPA 1962	Standard for the Inspection, Care and Use of Fire Hose, Couplings and Nozzles; and the Service Testing of Fire Hose
NFPA 1963	Standard for Fire Hose Connections
NFPA 1964	Standard for Spray Nozzles
NFPA 1965	Standard for Fire Hose Appliances
NFPA 1971	Standard on Protective Ensemble for Structural Fire Fighting
NFPA 1975	Standard on Station/Work Uniforms for Fire and Emergency Services
NFPA 1976	Standard on Protective Ensemble for Proximity Fire Fighting
NFPA 1977	Standard on Protective Clothing and Equipment for Wildland Fire Fighting
NFPA 1981	Standard on Open-Circuit Self-Contained Breathing Apparatus for Fire and Emergency Services
NFPA 1982	Standard on Personal Alert Safety Systems (PASS)
NFPA 1983	Standard on Fire Service Life Safety Rope and System Components
NFPA 1989	Standard on Breathing Air Quality for Fire and Emergency Services Respiratory Protection
NFPA 1991	Standard on Vapor-Protective Ensembles for Hazardous Materials Emergencies
NFPA 1992	Standard on Liquid Splash-Protective Ensembles and Clothing for Hazardous Materials Emergencies
NFPA 1994	Standard on Protective Ensembles for Chemical/Biological Terrorism Incidents
NFPA 1999	Standard on Protective Clothing for Emergency Medical Operations
NFPA 2001	Standard on Clean Agent Fire Extinguishing Systems
NFPA 2010	Standard on Aerosol Fire Extinguishing Systems
NFPA 2112	Standard on Flame-Resistant Garments for Protection of Industrial Personnel Against Flash Fire
NFPA 2113	Standard on Selection, Care, Use, and Maintenance of Flame-Resistant Garments for Protection of Industrial Personnel Against Flash Fire
NFPA 5000	NFPA Building Construction and Safety Code

Personal Safety

Contents

The majority of injuries or deaths on process plants are the result not of high technology but of quite simple situations. The number of people involved in a single accident is usually only one or two. Thus, although loss prevention is particularly concerned with technical aspects, it is appropriate nevertheless to devote some consideration to hazards to the person and to their control.

Moreover, the loss prevention approach has a contribution to make in this area also. The same management discipline is required to deliver good performance in the personal safety area as in that of high technology. Three aspects appear particularly relevant: formal systems and procedures, hazard identification and hazard assessment.

In addition to injuries from accidents, workers may also suffer impairment of health which sometimes becomes apparent only over a long period. It is necessary, therefore, to make some mention of this type of hazard and its control by occupational health measures.

Personal safety is dealt with in a large number of texts, which include *Safety and Management* by the Association of British Chemical Manufacturers (ABCM) (1964/3), *Industrial Safety Handbook* (Handley, 1969, 1977), *Industrial Hazard and Safety Handbook* (R. King and Magid, 1979), *Safety and Accident Prevention in Chemical Operations* (H.H. Fawcett and Wood, 1982), and *Safety at Work* (Ridley, 1993–) and *Safety in the Process Industries* (R. King, 1990). Selected references on personal health and safety are given in Table 25.1.

The general nature of the problem may be seen from the injury figures given in the *Health and Safety Statistics 1990/91* (HSE, 1992b) and shown in Table 25.2. These data refer to general industrial accidents and need to be supplemented for the chemical industry by data for that industry. These are reported on an occasional rather than an annual basis. Some accident data given in the *Annual Report* of HM Chief Inspector of Factories for 1985 are shown in Table 25.3.

The overall approach in questions of personal safety should always be, in order of descending preference, (1) hazard elimination, (2) hazard control and (3) personal protection. The principle of hazard elimination and control before resort to personal protection is a recurring theme.

Another recurring theme in personal safety is the need for thorough training and for effective supervision. The objectives of training should include not only the ability to use equipment and perform tasks, but also the understanding and motivation to do the work properly and safely. In other words, the worker should be convinced as well as instructed. Most of the hazards and activities described in this chapter have some training implications. The importance of training cannot be overemphasized. Similarly, it is essential to have good supervision so that malpractices are stopped and procedures are enforced.

25.1 Human Factors

Much can be done to reduce accidents by proper design of the work situation. This is the province of human factors. An account of human factors in general and of its application to the job of the process operator in particular is given in Chapter 14. Discussion here is confined to those aspects which are particularly relevant to personal accidents.

Guidance on human factors aspects is given in HS(G) 48 *Human Factors in Industrial Safety* (HSE, 1989). Further accounts are given in *Human Factors Engineering* (McCormick, 1957b), *Human Engineering Guide to*

Equipment Design (C.T. Morgan *et al.*, 1963), *Human Engineering Guide for Equipment Designers* (Woodson and Conover, 1964), *Human Factors Evaluation in System Development* (Meister and Rabideau, 1965), *Ergonomics* (Murrell, 1965a), *Human Performance in Industry* (Murrell, 1965b), *Human Factors* (Meister, 1971), *Handbook of Human Factors* (Salvendy, 1987), *Applied Ergonomics Handbook* (Burke, 1992 ACGIH/76) and *Human Factors in Design and Engineering* (Sanders, 1993). Accounts of human factors with specific reference to safety are given in *Ergonomics Guides* (AIHA, 1970–/1), *Human Aspects of Safety* (Singleton, 1976b) and *Human Factors in Process Operations* (Mill, 1992) and by Hands (1969, 1977).

Human factors should be considered from the beginning of the project. Much of the contribution which it can make to accident prevention is in areas such as the allocation of function between man and machine. If it is brought in later for detailed equipment design or in a rescue role, many of the options for design are already foreclosed.

Much work in human factors is concerned with human error. In fact, error rates are one of the main criteria used in scoring human factors experiments. Where an error leads to injury or other serious effect, it becomes an accident.

Error is to a large extent a function of the work situation. As such it is amenable to reduction by better design of the work situation, including not only equipment design but also all other relevant factors. Some error is certainly attributable to the individual, and variations in error rates between individuals can be investigated. But management should concentrate primarily on the work situation, since this is not only the factor which is most important but also that which it can most readily alter.

Table 25.2 *Injuries to employees by nature of accident and of injury and by severity of injury in the year 1990/91 (after HSE, 1992b)*[a]

A Nature of accident and severity of injury[b]

Nature of accident	*Severity of injury*		
	Fatal	*Non-fatal major*	*Total*
Contact with moving machinery or material being machined	29	1,738	9,491
Struck by moving, including flying or falling, object	51	2,371	25,788
Struck by moving vehicle	53	733	4,631
Struck against something fixed or stationary	3	781	11,074
Injured whilst handling, lifting or carrying	–	1,257	55,477
Slip, trip or fall on same level	1	6,396	39,849
Fall from a height:			
Up to and including 2 m	8	1,964	9,261
Over 2 m	66	1,337	3,162
Height not stated	7	973	4,517
All heights	81	4,274	16,940
Trapped by something collapsing or overturning	24	204	776
Drowning or asphyxiation	10	22	58
Exposure to or contact with a harmful substance	14	806	5,336
Exposure to fire	5	109	690
Exposure to an explosion	8	90	318
Contact with electricity or electrical discharge	24	298	929
Injured by an animal	3	72	928
Other kind of accident	28	651	7,960
Injuries not classified by kind	12	94	808
Total	346	19,896	181,053

B Nature and severity of injury[c]

Nature of injury	*Severity of injury*		
	Fatal	*Non-fatal major*	*Total*
Amputation	–	1,392	1,463
Loss of sight	–	20	29
Fracture	46	14,108	27,035
Dislocation	–	30	1,146
Concussion and internal injuries	16	147	1,290
Lacerations and open wounds	3	617	12,453
Contusions	37	371	29,221
Burns	9	859	5,827
Poisonings and gassings	25	224	822
Sprains and strains	–	153	59,752
Superficial injuries	–	263	17,478
Natural causes	–	5	20
Other injuries caused by contact with electricity	19	80	318
Injuries of more than one of the other natures	37	261	2,738
Injuries not elsewhere specified	21	68	1,228
Injury not known	85	327	11,128
Total	298	18,925	171,948

[a] *Source: Health and Safety Statistics 1990/91* (HSE, 1992b). Section A is an extract from table 9 and Section B is an extract from table 15.

[b] Injuries reported to all enforcing authorities, including offshore injuries.

[c] Injuries reported to the Factory and Agricultural Inspectorates and to local authorities.

Table 25.3 *Incidents in the chemical industry in 1983 (after HM Chief Inspector of Factories, 1986b)*

A Incidents

Incident type	*No of incidents*	*Proportion of incidents* (%)
Releases of chemicals[a]	222	34.5
Machinery incidents	77	12.0
Process-related fires and explosions	66	10.3
Falls from a height	56	8.7
Falls at same level and striking against objects	39	6.1
Pressure system and other equipment failures[b]	24	3.7
Hit by falling objects	23	3.6
Failure or overturning of lifting equipment	22	3.4
Struck or trapped by vehicle	15	2.3
Affected by chemicals during work[c]	13	2.0
Runaway exothermic reactions[d]	9	1.4
Manual handling and strains	8	1.2
Non-process related fires and explosions	7	1.1
Confined space incidents – people overcome	5	0.8
Electric short circuits	5	0.8
Not elsewhere classified	52	8.1
Total	643	100

B Other information

1. 17 incidents involved clear failures of the permit-to-work system
2. There were 30 pipework failures in addition to 37 incidents involving flexible hoses or insecure temporary joints
3. Of the 222 releases of chemicals, 127 (57%) affected people directly or indirectly to some degree, 92 (41%) occurred during normal operation with no immediate direct involvement of workpeople, 64 (29%) occurred during normal operations with direct involvement of workpeople, 68 (30%) occurred during cleaning, maintenance or repair activities
4. 49 cases of ill health were recorded, mostly associated with the release of chemicals or with confined spaces
5. 17 incidents involved tanker vehicles or tank containers
6. 62 incidents (9.6%) involved personnel other than those employed by the occupier, ie. contractors, visitors, etc.

[a] Including 97 toxic; 51 corrosive; 45 flammable; 23 hot, and 6 other materials.
[b] Where main risk was not from chemicals released.
[c] Examples are decanting, charging, etc., without significant escape or spill.
[d] With no major release of chemicals.

Principal influences on the frequency of errors, and hence of accidents, include (1) equipment design, (2) working methods, (3) motivation and (4) stress.

There is now a wealth of data on the design of equipment. The equipment should be physically easy to use. Valuable guidelines here are given by anthropometry, which is the study of human measurements.

It is often possible to build into equipment a barrier to error. A simple example is to prevent a plug being put into the wrong socket by making the relative shapes such that this is impossible. More complex methods for achieving similar results include interlocks.

Correct identification is important if error is to be avoided. There should be clear and consistent coding and labelling. A valuable form of coding is by colour.

Much information is available on the ways in which humans receive information through the senses. Some account of this has already been given in Chapter 14 in relation to the design of displays and controls.

It is necessary to train the operator in the use of equipment. The training should deal not only with how the operation is performed but also with why it is done that way.

Although training is important, it is not always the correct solution. Sometimes error is inherent in the design of the equipment. In this case, it is better to redesign the equipment than to use training to overcome the defects.

It is important to pay attention to motivation in the use of correct and safe methods of operation, and this should be a major objective of training.

Human performance is much affected by stress. Some factors which cause this stress include poor environmental conditions, bad equipment design, lack of time, fatigue and anxiety. Although there tends to be some improvement in performance at moderate levels of stress, beyond a certain threshold (which is different for each individual), it causes severe deterioration.

Important aspects of the environment are air quality, thermal conditions, illumination and noise. The first two are considered in Section 25.3. The last two are treated by Ragsdale (1969) and Atherley and Purnell (1969). Noise is also dealt with in Appendix 12.

25.2 Occupational Health

Occupational health is an established branch of medicine. It involves not only the investigation of industrial disease but also the provision of health services at the place of work.

Accounts of occupational health are given in *Occupational Diseases and Industrial Medicine* (R.T. Johnson and Miller, 1960), *Diseases of Occupations* (Hunter, 1975), *Occupational Health and Safety Concepts* (Atherley, 1978), *Recognition of Health Hazards in Industry* (Burgess, 1981 ACGIH/5), *Occupational Health* (Harrington and Gill, 1983–), *Chemical Exposure and Disease* (Sherman, 1988 ACGIH/16), *Occupational Health Practice* (Waldron, 1989), *Occupational and Environmental Health Management* (Kavianan and Wentz, 1990 ACGIH/47), *Health Fundamentals* (Hansen, 1991 ACGIH/71) and *Industrial Health* (Peterson, 1991 ACGIH/65). Epidemiological aspects are treated in *Exposure Assessment for Epidemiology and Hazard Control* (Rappaport and Smith, 1991 ACGIH/56) and *Introduction to Occupational Epidemiology* (Hernberg, 1992 ACGIH/79).

Guidance on occupational health arrangements is given in HS(G) 20 *Guidelines for Occupational Health Services* by the HSE (1980).

25.2.1 Industrial medical services

A chemical works usually has a medical centre with facilities for medical tests and which is able to handle a small number of casualties. The centre is typically staffed by a doctor working part time and a nurse working shifts. Descriptions of such medical services and of their liaison with hospital emergency departments are given by Cameron (1969, 1977) and M.H. Hall (1969, 1977), respectively, and the work of an industrial nurse is described by Mort (1965).

The medical personnel should be familiar with the chemicals and processes used in the particular factory. Information such as that given on materials safety data sheets provides a useful starting point.

Information on the medical history of individual workers is equally important. Careful interviewing and record keeping can assist in diagnosing early symptoms or high susceptibility in individuals. It can also make a significant contribution to the epidemiological investigation of industrial disease.

25.2.2 Employment Medical Advisory Service

The Employment Medical Advisory Service Act 1972 and the Health and Safety at Work etc. Act (HSWA) 1974, Part II define the role of the Employment Medical Advisory Service (EMAS). Information on EMAS is given in *Employment Medical Advisory Service Act 1972 – Guide to the Service*.

The service acts as the medical arm of the HSC, does work on medical matters for which there are statutory requirements, provides medical advice to the Factory Inspectorate and to employers, and furthers research on the epidemiology of industrial disease.

It is able to advise on the effects of particular jobs on health, on the medical precautions to be taken in working with substances which are toxic or otherwise hazardous to health, and on medical examinations, investigations and surveys.

There is a series of guidance notes on medical topics (the Medical Series (MS)) and also series of leaflets (the MS(A) and MS(B) series).

25.2.3 National Institute for Occupational Safety and Health

An important source of information on occupational health is the NIOSH. Some publications of the Institute are listed in Appendix 28.

25.3 Occupational Hygiene

Industrial chemicals tend to be noxious substances. It is essential, therefore, to take appropriate measures of occupational hygiene to ensure that those who work with them are not exposed to unacceptable risks.

Occupational health and hygiene are the subject of the Control of Substances Hazardous to Health Regulations 1988 (the COSHH Regulations). These are described together with the HSE guidance in Section 25.4.

Other regulations frequently referred to in this chapter are the Control of Lead at Work Regulations 1980 (the CLAW Regulations) and the Control of Asbestos at Work Regulations 1987 (the CAWR).

In addition to that specifically related to the COSHH Regulations 1988, HSE guidance includes EH 22 *Ventilation of the Workplace* (HSE, 1988), EH 42 *Monitoring Strategies for Toxic Substances* (HSE, 1989), HS(G) 61 Surveillance of People Exposed to Health Risks at Work (HSE, 1990), HS(G) 27 *Substances for Use at Work: the Provision of Information* (HSE, 1991) and EH 40/94 *Occupational Exposure Limits* (HSE, 1994).

Guidance by the BOHS is given in *Controlling Airborne Contaminants in the Workplace* (the BOHS *Airborne Contaminants Guide*) by Piney *et al.* (1987 BOHS/TG7) and by the AIHA in *Basic Industrial Hygiene: A Training Manual* (AIHA, 1975/2), *Engineering Field Reference Manual* (AIHA, 1984/7), and *A Strategy for Occupational Exposure Assessment* (Hawkins, Norwood and Rock, 1991 AIHA/24). A computer-based system is described in *LOGAN Workplace Evaluation System* (Dupont, 1990 AIHA/20).

Guidance on occupational hygiene in the petroleum industry is given in *Guidelines for Recording Industrial Hygiene Data* (CONCAWE, 1983 7/83), *Health Aspects of Worker Exposure to Oil Mists* (CONCAWE, 1986 86/69), *Review of Strategies for the Evaluation of Employee Exposures to Substances Hazardous to Health* (CONCAWE, 1987, 87/57) and *API Exposure Classification Scheme for Collection of Industrial Hygiene Monitoring Data* by the API (1990).

Further guidance is given in *Employment and Reproductive Health* by the Chemical Industries Association (CIA) (1984 RC13).

Occupational, or industrial, hygiene is also treated in *Occupational Health and Safety Concepts* (Atherley, 1978), *Occupational Health* (Harrington and Gill, 1983–), *Case Studies in Industrial Hygiene* (Perkins and Rose, 1987 ACGIH/9), *Industrial Hygiene Management* (Garrett, Cralley and Cralley, 1988 ACGIH/23), *Fundamentals of Industrial Hygiene* by the NSC (1988/13), *The Risk Assessment of Environmental Hazards* (Paustenbach, 1989 ACGIH/37), *Quantitative Industrial Hygiene: A Formula Workbook* (Caravanos, 1991 ACGIH/74) and *Industrial Hygiene Workbook* (Burton, 1992 ACGIH/85). Engineering aspects are treated in *Health Hazards Control in the Chemical Process Industry* (Lipton and Lynch, 1987), *Industrial Hygiene Engineering* (Talty, 1988 ACGIH/22) and *In-Plant Practices for Job-related Health Hazards* (Cralley and Cralley, 1989 ACGIH/36).

Guidance for dusts specifically includes EH 44 *Dust: General Principles of Protection* (HSE, 1991), the *User Guide to Dust and Fume Control* (Muir, 1985) (the IChemE *Dust Control Guide*) and the BOHS *Airborne Contaminants Guide*.

The elements of occupational hygiene include:

(1) identification of noxious substances or effects;
(2) establishment of criteria;

(3) assessment of exposure;
(4) prevention of exposure;
(5) control of exposure –
  (a) enclosure,
  (b) ventilation;
(6) provision of PPE;
(7) monitoring of workplace atmosphere;
(8) monitoring of personnel;
(9) keeping of records.

This general approach is applicable to toxic and corrosive chemicals, noxious dusts, and ionizing and non-ionizing radiations.

In addition to vapours and dusts, it is necessary to deal also with skin disease and noise. Skin care is treated in Section 25.8 and noise is discussed in Appendix 12.

25.3.1 Noxious substances

Information on the health effects of industrial chemicals is available from a large number of sources. These include: *Dangerous Properties of Industrial Materials* (Sax, 1957–), *Hazardous Chemicals Handbook* (Carson and Mumford, 1994) and other compendia; *Chemical Safety Data Sheets* (Walsh, 1988, vol. 1) and (A. Allen (1988, other volumes); the series *Information Sheets on Hazardous Materials* by the FPA and other collections of such data sheets; and the Environmental Hygiene (EH) series and criteria documents (EH 64 and 65) by the HSE.

Information on hazardous chemicals, including materials safety data sheets, is discussed in Chapters 8 and 18, and materials toxicity in the latter chapter.

Some aspects of health effects in the petroleum industry are treated in *The Health Experience of Workers in the Petroleum Manufacturing and Distribution Industry* (CONCAWE, 1987 2/87) and *Survey of Exposure to Gasoline Vapour* (CONCAWE, 1987 4/87).

25.3.2 Airborne contaminants

A classification of airborne contaminants is given by the HSE (1993, HS(G) 37). The particle size ranges given are:

	Size range (μm)
Dusts	0.1–75
Fume	0.001–1.0
Smoke	0.001–1.0
Mist	0.01–1.00

These figures refer to: dust generated by natural fragmentation or mechanical cutting or crushing; fume formed as solid particles of condensed vapour, especially metals; smoke as aerosol formed by the incomplete combustion of organic matter; and mist as an aerosol of droplets formed by condensation from the gaseous state, or as a dispersion of the liquid state. For vapour, a single value of 0.005 μm is quoted. This refers to the gaseous state of materials which are liquid or solid at room temperature and pressure.

The *BOHS Airborne Contaminants Guide* gives for contaminants of occupational importance a size range of 0.01–150 μm for both dust and mist, and of 0.001–1.0 μm for fume.

The particle size of a contaminant is determined by the process by which it is generated. Oil mist generated by metal cutting has a larger particle size than that of oil fumes formed by the condensation of oil vapour.

The behaviour of an airborne particle may be characterized in terms of the settling velocity and the stopping distance. The latter is the distance which a particle with a defined initial velocity will travel before coming to rest. The BOHS *Guide*, quoting Hinds (1982), gives the following values for settling velocity and stopping distance:

Particle diameter (μm)	*Settling velocity* (m/s)	*Stopping distance* (m)
0.01	7.0×10^{-8}	6.8×10^{-8}
1.0	3.5×10^{-5}	3.6×10^{-5}
100	0.25	0.127

The particle density used is 10 kg/m^3 and the initial velocity for the stopping distance is 10 m/s.

Fine particles sediment out only very slowly and thus remain airborne for long periods. They move with the air.

Where particles are emitted from a source, the larger particles travel some distance, but the distance travelled by the finer particles is very short. Even if their initial velocity is high, their movement follows that of the air.

As far as the health effects caused by particles are concerned, there is an upper limit of size above which a particle tends to be deposited before it reaches the lungs. The particle size range of interest for harmful effects by inhalation into the lungs is discussed in the *BOHS Guide*, which gives the range as being from the submicron level to about 25 μm in diameter.

25.3.3 Generation of contaminants

There is a variety of ways by which a contaminant may enter the workplace atmosphere. Four principal routes are (1) a contaminant-generating process or operation, (2) a leak, (3) opening up of plant and (4) handling fabrics saturated with the material.

For a vapour contaminant, a principal determinant is the vapour pressure. If a liquid is being handled under conditions where there is a route to the atmosphere and it is at a temperature at which it exerts an appreciable vapour pressure, a significant amount may escape.

In relation to industrial hygiene, a significant measure is the ratio of the vapour pressure to the occupational exposure limit. A vapour hazard index (VHI) is defined as

$$\mathrm{VHI} = \frac{\text{Vapour pressure}}{\text{Occupational exposure limit}} \qquad [25.3.1]$$

where both the vapour pressure and the occupational exposure limit are measured in parts per million (ppm).

The conditions that must be met for a dust contaminant to enter the workplace atmosphere are that a route exists for it to do so and that it has imparted to it sufficient energy to follow that route.

Some conditions in which a contaminant, vapour or dust, may enter the atmosphere include (1) passage of air through the material, (2) free fall of the material, (3) pouring of the material, (4) agitation of the material, (5) transfer of the material, (6) opening of bags or drums of the material, (7) leak of the material, (8) opening up of plant containing the material and (9) handling of fabrics saturated with the material.

In addition, vapour generation may occur due to (1) the evaporation of a liquid or (2) the heating of a liquid; and dust generation may occur due to (1) vibration of a powder or (2) a size reduction of the material.

Typical equipment and activities where contaminants are generated include reactor charging, mixing operations, powder handling and packing processes, grinding mills, conveyors and elevators, storage silos, hoppers and bins, bag emptying operations, drum and bag filling operations, and plant maintenance.

The situations in which fumes and mists are generated tend to be highly specific.

25.3.4 Leaks of contaminants

A common source of contamination is leaks from the plant. A gross leak may be readily identified, but this may not be so where the leak is small, but still large enough to cause significant contamination.

With regard to leaks of gas, vapour and liquid, an account has been given in Chapter 15 of fugitive emissions, particularly of volatile organic compounds (VOCs). Although originally work on such emissions was driven largely by concern over environmental pollution, the information is generally applicable equally to emissions into the workplace atmosphere.

Leaks of dust can also occur. If the dust is fine, the leak may not be visible. Figure 25.1 shows a leak of asbestos dust from a gaiter, made visible only by the use of a dust lamp, as described below.

25.3.5 Air movement

As already described, most contaminants move with the air in the workplace. This air movement is therefore of great importance in developing controls.

There are available a number of methods for the investigation of air movements. One is the use of a smoke tracer. Smoke is introduced from a smoke generator and its movement is observed or filmed.

Methods exist for the visualization of the presence and movement of dust particles in air. The dust lamp, or Tyndall lamp, technique is widely used. This makes visible the dust cloud in a manner similar to that which occurs when a shaft of sunlight falls across a room where there is dust in the atmosphere. This method permits observation of dust clouds of particles too fine to be seen otherwise. The use of a dust lamp is illustrated in Figure 25.1. Accounts of the dust lamp technique are given by the HSE (1975 TON 35) and in the *BOHS Guide*.

There is also an infrared (IR) technique which permits the movement of a vapour to be followed.

25.3.6 Monitoring variables and criteria

There is a hierarchy of methods which may be used as the basis for the monitoring and control of noxious substances. These are the measurement and monitoring of (1) the concentration of airborne contaminants in the workplace,

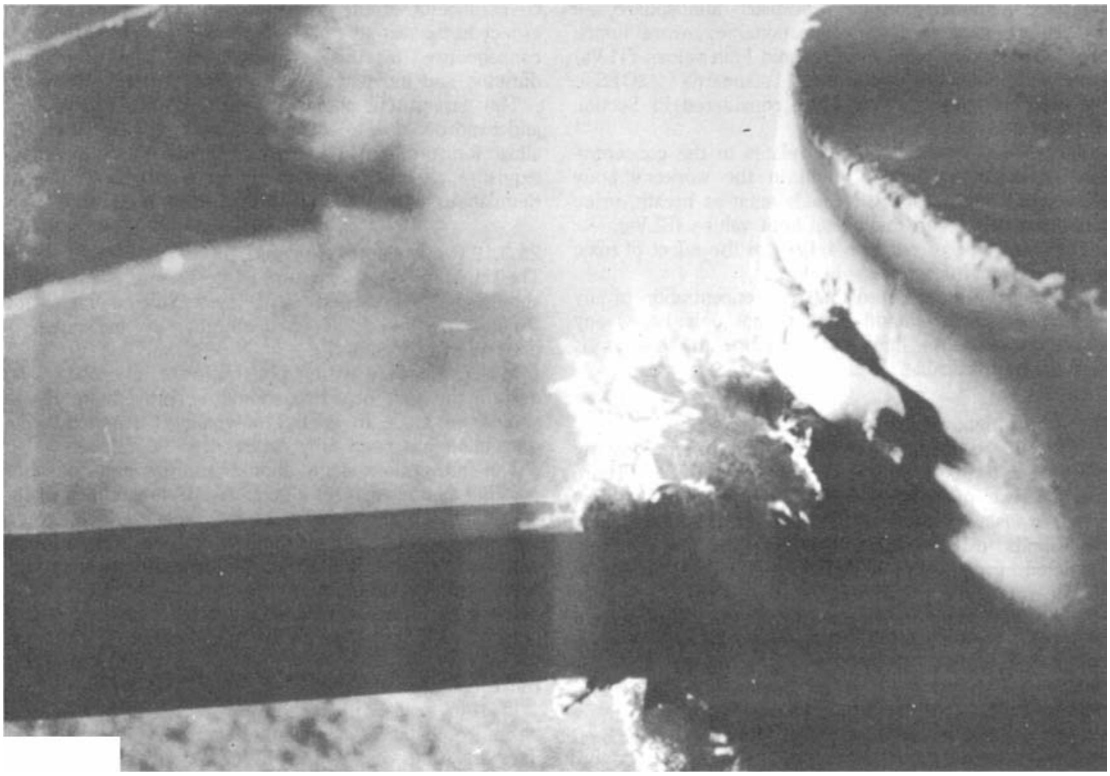

Figure 25.1 *Leakage of asbestos dust due to failure of a gaiter (HSE, 1975 TON 35) (Courtesy of HM Stationery Office)*

(2) their concentration in workers' body tissues and body fluids and (3) their effect on workers' health.

There are three corresponding types of criteria used in monitoring for occupational hygiene. For the concentration of contaminants in the workplace atmosphere, the criteria are expressed as occupational exposure limits. This type is exemplified by threshold limit values (TLVs) and occupational exposure standards (OESs). Occupational exposure limits are considered in Section 25.3.7.

The second type of criterion relates to the concentrations of toxic substances found in the worker's body tissues and fluids, especially fluids such as breath, urine and blood. These are biological limit values (BLVs).

The third type of criterion relates to the effect of toxic substances on the worker's health.

It should be emphasized that the concentration of any harmful substance should be kept not only below any maximum exposure limit (MEL) but as close to zero as is reasonably practicable.

25.3.7 Occupational exposure limits

In the United Kingdom, occupational exposure limits were formerly specified in terms of TLVs. There are now two main types of limit which apply: OESs and MELs. The latter apply to a relatively restricted group of chemicals which are listed in Schedule 1 of the COSHH Regulations 1988.

The larger group are covered by an OES. The current OES values are given in EH 40 *Occupational Exposure Limits 1994* (HSE, 1994). The basis of the limits is explained in EH 64 *Occupational Exposure Limits: Criteria Document Summaries* (HSE, 1993).

An account of the OES system is given in *Occupational Exposure Limits* (CIA, 1985 PA23).

Further guidance is given by the AIHA in *Workplace Environmental Exposure Level Guides* (AIHA, 1980–/4), *Occupational Exposure Limits – Worldwide* (Cook, 1987 AIHA/12), *Hygienic Guides* (AIHA, 1988/14) and *Odor Thresholds for Chemicals with Established Occupational Standards* (AIHA, 1989/17). The American Conference of Government Industrial Hygienists (ACGIH) guidance includes *Documentation of the Biological Exposure Indices* (ACGIH/1), *Documentation of Threshold Limit Values and Biological Exposure Indices* (ACGIH/3), *Guide to Occupational Exposure Values – 1992* (ACGIH/78) and *Threshold Limit Values and Biological Exposure Indices, 1992–1993* (ACGIH 1992/80). The ILO publishes *Occupational Exposure Limits for Airborne Toxic Substances* (ILO 1991/2).

25.3.8 Non-inhalation exposure

The account given so far has concentrated on exposure by inhalation. It is also necessary to consider exposure by ingestion and by skin absorption. The consumption of food and drink in contaminated conditions is one situation in which ingestion of a contaminant is prone to occur. Skin absorption is discussed in Section 25.8.

25.3.9 Assessment of exposure

If workers may be exposed to a noxious substance, an assessment needs to be made of the extent of the exposure. This assessment merits as much effort as is generally devoted to determining how noxious the substance is.

The foregoing account has indicated some of the processes, operations and activities which may cause contamination of the workplace atmosphere. The other aspect is the extent to which workers are exposed as a consequence of this contamination. The frequency, duration and intensity of exposure are all relevant.

The assessment should cover all modes of exposure and exposure due to activities as well as leaks. It should allow for foreseeable human behaviour. Assessment of exposure is an important aspect of the COSHH Regulations and is described further in Section 25.4.

25.3.10 Prevention of exposure

The minimization of exposure of workers to contaminants should be approached in a systematic manner and should be based on a hierarchy of measures of prevention and control.

In accordance with the philosophy of inherently safer design, the first objective should be prevention. Resort should be made to control only after the potential for prevention has been fully explored.

The prevention stage should address the following possible approaches: (1) elimination or substitution of the substance, (2) modification of the process, (3) segregation of processes, (4) elimination of leaks, (5) modification of operations and (6) arrangements for dealing with contaminated clothing.

Measures of prevention have two main objectives. One is to use substances which are less harmful. The other is to use processes and operations which are less prone to cause contamination.

In some cases it has proved possible to replace a harmful substance by substituting it by a less harmful one. In other cases, the harmful substance may be eliminated. This may occur by elimination of a harmful impurity or of a process, or process stage, in which the harmful substance is used. Modification of the process by alteration or substitution is another approach which has been used with success. A third method is to segregate the processes, or process stages, which are 'dirty' in respect of contamination from those which are 'clean'. Examples of these approaches are given in Chapter 11 and in the *BOHS Guide*.

Where leaks are a cause of contamination, measures should be taken to eliminate them.

Contamination of the working atmosphere may also arise from various activities on the plant, such as opening reactors, taking samples or opening up equipment for maintenance. This aspect may need to be controlled by specific procedures.

Workers may be exposed to contamination from work clothes or from protective clothing, and arrangements may need to be made to prevent this.

25.3.11 Control of exposure

When measures based on prevention have been exhausted, controls should be used to reduce exposure further. These controls are applied in a hierarchy which is broadly as follows:

(1) total or partial enclosure;
(2) LEV;
(3) general ventilation;
(4) limitation of exposure –
    (a) number exposed,
    (b) frequency and duration of exposure;
(5) PPE.

A further discussion of prevention and control is given in Section 25.4 in relation to the COSHH Regulations 1988.

25.3.12 Ventilation of workplace atmosphere

It is frequently necessary to use ventilation as one of the control measures taken to reduce exposure.

The siting of plant in the open air rather than in a building is often the most effective means of ventilation, since small leaks are then dispersed by the wind. But such open construction is not always appropriate, for various reasons, some of which were considered in Chapter 10. Moreover, as discussed below, it cannot be assumed that an outdoor location guarantees that exposure is negligible.

In most applications, the preferred method of indoor ventilation is LEV. The use of general ventilation tends to be less effective and more expensive. Where general ventilation is used indoors, it may be natural ventilation or mechanical ventilation.

An account of ventilation is given in Section 25.7.

25.3.13 Monitoring of workplace atmosphere

The monitoring of the workplace atmosphere involves identifying valid methods of sampling, measurement and evaluation, and the adoption of a suitable monitoring strategy.

HSE guidance on the measurement and monitoring of contaminants in the workplace atmosphere is given in EH 42 *Monitoring Strategies for Toxic Substances* (HSE, 1989) and in the series *Methods for the Determination of Hazardous Substances (MDHS)*. The series includes MDHS 70 *General Methods for Sampling Airborne Gases and Vapours* (HSE, 1990) and MDHS 71 *Analytical Quality in Workplace Air Monitoring* (HSE, 1991).

Further guidance by the AIHA is given in *Quality Assurance Manual for Industrial Hygiene Chemistry* (AIHA, 1988/15), *Direct-Reading Calorimetric Indicator Tubes Manual* (Perper and Dawson, 1993 AIHA/9), *The Industrial Hygienists' Guide to Indoor Air Quality Investigations* (AIHA, 1993/26), and *Manual of Recommended Practice for Combustible Gas Indicators and Portable Direct-Reading Health Survey Meters* (AIHA, 1993/27). ACGIH guidance includes *Methods of Air Sampling and Analysis* (Lodge, 1988 ACGIH/24), *Air Sampling Instruments* (ACGIH, 1989/27) and *Air Monitoring for Toxic Exposures* (Ness, 1991 ACGIH/51).

For petroleum products, the guidance available includes *The Identification and Measurement of Refinery Odors* (CONCAWE, 1975 8/75) and *Method for Monitoring Exposure to Gasoline Vapour in Air* (CONCAWE, 1986 8/86).

Strategies for measuring and assessing personal exposure are described in *Review of Strategies for the Evaluation of Employee Exposure to Substances Hazardous to Health* (CONCAWE, 1987 87/57).

25.3.14 Health surveillance

It may not be sufficient to monitor the working atmosphere. It is often necessary also to monitor the people who work in it by a system of health surveillance. HSE guidance on health surveillance is given in HS(G) 61 *Surveillance of People Exposed to Health Risk at Work* (HSE, 1990).

HS(G) 61 lists the sets of regulations which contain requirements for medical surveillance. They include the CLAW Regulations, the CAWR and the COSHH Regulations.

Health surveillance may be carried out at different stages of an employee's involvement with the company. HS(G) 61 distinguishes between the types of surveillance which occur during recruitment, on employment, during work and on detection of an adverse effect.

HS(G) 61 gives the following purposes of health surveillance at work: (1) to identify adverse effects early, (2) to identify inadequacies in control, (3) to inform those at risk as soon as possible of any damage to their health and (4) to provide an opportunity to reinforce health education on the risk present.

It also describes some of the practicalities. (1) There are some substances which are impractical to control to a level which protects all those who may be exposed, due to differences in the susceptibility of individuals. A person sensitized to a lung allergen may develop asthma at a concentration level three orders of magnitude lower than would affect a previously unexposed person. (2) Control may not be equally effective in protecting all groups of workers. Controls designed to protect plant operators may not cover well maintenance personnel. (3) The controls may not do all they were intended to do. Early controls on cotton dust did not prevent byssinosis because they did not remove fine particles. (4) The type of injury may not be foreseen. This was the case with lung cancers from asbestos up to about 1940 and with mesothelioma from vinyl chloride monomer (VCM) until about 1974.

Employees should be informed of possible consequences of health surveillance. One potential consequence might be that an employee is moved to another job.

As with monitoring of exposure to airborne contaminants, so with monitoring of concentrations of toxic substances in the body, the aim should be to keep the concentrations as low as is reasonably practicable.

Guidance on monitoring against BLVs is given by the ACGIH in *Biological Monitoring of Exposure to Chemicals: Organic Compounds* (Dillon and Ho, 1987 ACGIH/8), *Methods for Biological Monitoring* (Knelp and Crable, 1988 ACGIH/25) and *Biological Monitoring of Exposure to Chemicals: Metals* (Dillon and Ho, 1991 ACGIH/52). AIHA guidance includes *Biohazards Reference Manual* (AIHA, 1985/10).

25.3.15 Hot environments

The environment may also be injurious to health because it is too hot. This aspect is treated in *Hot Environments* (NIOSH, 1986 Publ.86-113) and by Bedford (1974) and Gill (1980a).

Depending on the situation, countermeasures for hot environments may include the provision of ventilation, the use of protective clothing and the limitation of the working period.

25.4 COSHH Regulations 1988

A requirement for a comprehensive system for the protection of workers based on industrial hygiene principles is given in the COSHH Regulations 1988 (the COSHH Regulations). The corresponding Approved Code of Practice (ACOP), which also deals with carcinogenic substances is L5 (formerly COP 29) COSHH and Control of Carcinogenic Substances (HSE, 1991). It is convenient to refer to these two parts of the ACOP as the COSHH Code and the *Carcinogens Code*, respectively. Further guidance is given in COSHH Assessments (HSE, 1988b), HS(G) 27 Substances for Use at Work: the Provision of Information (HSE, 1988), EH 42 Monitoring Strategies for Toxic Substances (HSE, 1989) and HS(G) 61 Surveillance of People Exposed to Health Risks at Work (HSE, 1990).

Guidance from the CIA is given in the series *COSHH – Guidance on Assessments* (Reg. 6) (CIA, 1989 RC9), *COSHH*

– *Guidance on Health Surveillance* (Reg. 11) (CIA, 1989 RC11), *COSHH – Guidance on Information, Instruction and Training* (Reg. 12) (CIA, 1990 RC 12), *COSHH – Guidance on Setting In-house Exposure Limits* (Reg. 7) (CIA, 1990 RC10), *COSHH – Guidance on Collection and Evaluation of Hazard Information* (Reg. 2) (CIA, 1991 RC39) and *COSHH – Guidance on Recordkeeping* (CIA, 1991 RC 38).

Further treatments are given in *The COSHH Regulations: A Practical Guide* (Simpson and Simpson, 1991) and by P. Lewis (1980), Blain (1987), Waterman (1987) and Boniface (1990b). The principal contents of the COSHH Regulations are given in Table 25.4.

Regulation 2 defines a 'substance hazardous to health' (SHH) as covering the following: (1) a substance which is listed in Part 1A of the Classification, Packaging and Labelling of Dangerous Substances Regulations 1984 and for which the general indication of nature of risk is specified as very toxic, toxic, harmful, corrosive or irritant; (2) a substance for which the MEL is specified in Schedule 1 of the regulations or for which the HSC has approved an OES; (3) a micro-organism which creates a hazard to health; (4) dust of any kind, when present at a substantial concentration in air and (5) any other substance which creates a comparable hazard to health.

The regulations cover substances which have chronic or delayed effects such as substances which are carcinogenic, mutagenic or teratogenic.

Under Regulation 3, an employer has towards an employee the duties of: (1) assessment; (2) prevention or control of exposure; (3) use of control measures and their maintenance, examination and test; (4) provision of information and training; and, where appropriate; (5) monitoring of workplace exposure and (6) health surveillance. So far as is reasonably practicable, the employer should regard himself as having similar duties towards other persons at the premises, except that there is no duty of health surveillance, and as having the first three duties listed towards others likely to be affected by the work. These duties are not confined to the occupier but apply also to contractors. Thus, the duties of an employer are owed by a contractor to his employees.

Table 25.4 *Principal contents of the Control of Substances Hazardous to Health Regulations 1988 and the associated Guidance*

Regulation 2	Interpretation
Regulation 3	Duties under these Regulations
Regulation 4	Prohibitions relating to certain substances
Regulation 6	Assessment of health risk created by work involving substances hazardous to health
Regulation 7	Prevention or control of exposure to substances hazardous to health
Regulation 8	Use of control measures, etc.
Regulation 9	Maintenance, examination and test of control measures
Regulation 10	Monitoring exposure at the workplace
Regulation 11	Health surveillance
Regulation 12	Information, instruction and training for persons who may be exposed to substances hazardous to health
Schedule 1	List of substances assigned maximum exposure limits
Schedule 2	Prohibition of substances hazardous to health for certain purposes
Schedule 3	Frequency of thorough examination and test of local exhaust ventilation plant used for certain processes
Schedule 4	Specific substances and processes for which monitoring is required
Schedule 5	Medical surveillance
Appendix	Health records

Regulation 4 places prohibitions on certain substances listed in Schedule 2 to the extent specified in that schedule. This includes a prohibition on: the manufacture and use of 2-naphthylamine, benzidine, 4-aminodiphenyl and 4-nitrodiphenyl; the use of benzene for any purpose other than in an industrial process; and on the use of sand for sand blasting.

Regulation 6 requires that the employer make 'a suitable and sufficient assessment' of the risks created by the work and of the steps which need to be taken to ensure compliance. The assessment should be reviewed if there is reason to suspect that it is no longer valid or if there has been a significant change in the work.

Regulation 7 requires that exposure to substances hazardous to health should be prevented or, where this is not reasonably practicable, adequately controlled. Further, it requires that so far as is reasonably practicable, this be done without recourse to personnel protective equipment, but, that, where necessary, such equipment should be provided. Where a substance has a MEL specified in Schedule 1, the exposure should not exceed this limit and should be reduced below it to the extent which is reasonably practicable. Where a substance has an OES, the exposure should not exceed this standard, but if it does, the employer should identify the reason and take action to remedy the situation as soon as is reasonably practicable. The exposure referred to may be any route, including inhalation, ingestion, absorption through the skin or contact with it.

Regulation 8 requires that an employer providing any control measure, PPE or other item, should take all reasonable steps to see that these are properly applied and that an employee should apply them and report any defects.

Regulation 9 requires adequate maintenance, examination and test of control measures. It refers specifically to LEV and to RPE. For the former it lays down a maximum interval for examination and test of 14 months or, for plant specified in Schedule 3, the interval given in that schedule. It requires that a record be kept of the examination and test, and of any repairs effected.

Regulation 10 requires that, where necessary to ensure control of exposure or prevent harm, monitoring of the workplace should be carried out using a suitable procedure. For certain substances given in Schedule 4, monitoring is required at the minimum frequency specified in the schedule. The regulation requires that records, or suitable summaries, be made and that where they are representative of the personal exposure of identifiable employees, they should be kept for 30 years.

Regulation 11 requires that, where it is appropriate for the protection of the health of employees who are liable to be exposed to a SHH, the employer should set up a system of health surveillance. The regulation is a long one, with some 12 sections. Regulation 11(2) states that health surveillance is appropriate where the employee is exposed to one of the substances and is engaged in one of the processes listed in Schedule 5, unless the exposure is insignificant, or where he is exposed to a substance so that an identifiable disease or adverse health effect may be related to the exposure, there is a reasonable likelihood that the disease or effect may occur given the conditions of his work, and there is a valid technique for detecting indications of the disease or effect.

Regulation 12 requires the employer to provide to an employee who does work which may expose him to a SHH such information, instruction and training as is suitable and sufficient for him to know the risks to health and the precautions to be taken. The information should include the results of any monitoring carried out in compliance with Regulation 10. If, in the case of a substance listed in Schedule 1, the MEL is exceeded, the employee should be informed immediately. The information should also include the collective results of any health surveillance carried out in compliance with Regulation 11, presented in a form where the data cannot be related to a particular individual.

Regulation 12(3) requires that any person, whether or not an employee, who carries out work in connection with the employer's duties under the COSHH should have the necessary information, instruction and training.

Regulation 6 requires that the person making the assessment be competent and refers to Regulation 12(3).

25.4.1 Substances hazardous to health

There are a number of factors mentioned in the ACOP which need to be borne in mind when considering whether a substance is hazardous to health. The same substance may be hazardous in one form but not in another. Thus, a substance in dust form may be hazardous but be safe in solid form. The fibrous form may also be hazardous. A substance may contain an impurity which is more hazardous than the substance which it contaminates. A substance may have been found by experience to be hazardous, even if the causative agent has not been identified. Some combinations of substances may have harmful additive, or synergistic, effects.

25.4.2 Suitable and sufficient assessment

The ACOP states that the purpose of the assessment is to obtain the information necessary to select suitable control measures. It also provides a demonstration that the relevant factors have been taken into account and the necessary measures taken.

A suitable and sufficient assessment should include an assessment of the risks to health, a determination of the measures which need to be taken to achieve control under Regulation 7, and an identification of any other action necessary to comply with Regulations 8–12.

The assessment of risks should identify the substances to which personnel are liable to be exposed, the effects of the substances on the body, the places where and the forms in which these substances are likely to be present, and the ways in which and the extent to which personnel could be exposed, allowing for foreseeable deterioration, or failure, of a control measure. It should include an estimate of the exposure given the engineering measures and systems of work adopted. This estimate should be compared with any available standards for adequate control.

If comparison indicates that control is likely to be inadequate, the assessment should go on to determine the measures which need to be taken to achieve adequate control. A record should be kept of the assessment, except in very simple and obvious cases which could be readily repeated and explained at any time.

The assessment should be reviewed if it is shown to be no longer valid by some new information, which may include: results from the periodic examination and test of the engineering controls; results from the monitoring of workplace exposure; results of health surveillance, or a confirmed case of occupationally induced disease; or new information on health risks. A review is also called for if there is a significant change in the work, including any change in the substances used, the process, the throughput, the work practices or the engineering controls.

Further guidance on the assessment is given in *COSHH Assessment*. The stages of the assessment are the gathering of information, the evaluation of the risks, the specification of the measures and precautions required and the recording of the assessment. Information needs to be gathered on the substances and their hazards and on the work and the working practices.

Evaluation of the risks from a substance involves assessing, on the one hand, the potential for harm from exposure to it and, on the other, the nature of any exposure. For the latter, it is necessary to determine the situations in which exposure may occur, the persons liable to be exposed, and the frequency and duration of exposures.

Where there is uncertainty about the magnitude or significance of the exposure in relation to the requirement for prevention or adequate control, exposure should be measured, provided there is a suitable method of measurement.

COSHH Assessment identifies five possible outcomes of the assessment, which may be summarized as:

(1) risks are insignificant now and for the foreseeable future;
(2) risks are high now, and not adequately controlled;
(3) risks are controlled now, but foreseeably could become higher;
(4) risks are uncertain – uncertainty concerns extent and degree of exposure;
(5) risks are uncertain – uncertainty due to lack of information.

Guidance is given on the action to be taken for each of these outcomes.

25.4.3 Competent person

COSHH Assessment also gives guidance on the competence required of the person who is to undertake the assessment. The guide distinguishes between basic skills and additional skills. The basic skills are an understanding of the regulations and the abilities to make a systematic assessment of the risks and the exposures, to specify the measures which need to be taken in light of the assessment, and to communicate the findings in a report.

The additional skills are qualifications, experience and training. The guide emphasizes particularly practical experience and an understanding of the behaviour of people as well as processes.

25.4.4 Occupational exposure limits

As already stated, the two types of occupational exposure limit mentioned in the regulations are the MEL and the OES. The MELs are listed in Schedule 1 and the OESs are contained in the List of Approved OESs. This is given in

EH 40 *Occupational Exposure Limits*, which is up-dated annually.

The status of these two exposure limits is described in the ACOP. A MEL is the maximum concentration to which an employee may be exposed by inhalation under any circumstances. The concentration is averaged over a reference period which is specified in Schedule 1. Further details of the application of MELs are given in the ACOP.

Where an OES is assigned, exposure should be reduced to that standard. However, if exposure by inhalation exceeds the OES, the control may still be deemed adequate provided the reason for the excursion has been identified and appropriate steps are being taken to comply with the OES as soon as is reasonably practicable.

Where a substance is not assigned an MEL or OES, the ACOP states that the concentration should be controlled to a level to which nearly all the population could be exposed, day after day, without adverse effects on health.

25.4.5 Measurement and monitoring

The ACOP states that compliance with an OES may be demonstrated by measuring and recording the exposure of employees in accordance with EH 42 *Monitoring Strategies for Toxic Substances* (HSE, 1989).

Guidance is given in the ACOP on those situations where monitoring is required. Paragraph 68 states that it is always required for substances in Schedule 4 and, in addition, unless it is immediately obvious that control is adequate or suitable procedures for monitoring do not exist and cannot be devised, the requirement exists (1) where failure or deterioration of the control measures could result in a serious health effect, either because of the toxicity of the substance or the extent of the potential exposure, or both, (2) where measurement is necessary to ensure that an MEL or OES or any self-imposed working standard is not exceeded or (3) an additional check is required on the effectiveness of any control measure required under Regulation 7.

EH 42 gives detailed advice on such monitoring, including sampling strategies and interpretation of results.

25.4.6 Prevention and control

The ACOP states that adequate control is achieved if certain standards set out in paragraphs 27–30 of the code are met. Paragraph 27 deals with substances assigned an MEL, paragraph 28 with substances assigned an OES, paragraph 29 with other inhaled substances and paragraph 30 with exposure by routes other than inhalation. Compliance with an OES may be demonstrated by monitoring, as just described.

As far as is reasonably practicable, prevention or adequate control of exposure should be achieved by means other than PPE. Circumstances in which it may be necessary to resort to the latter include those: (1) where it is not technically feasible to achieve adequate control by process, operational and engineering measures alone; (2) where a new or revised assessment necessitates the temporary use of personal protection until adequate control is achieved by other means; (3) where urgent action is required, such as that following a plant failure and (4) where routine maintenance operations have to be done. In deciding whether to use PPE, due allowance should be made for its limitations and the practicalities of its use.

The ACOP enumerates the measures which may be used for the prevention or control of exposure to a SHH. Prevention may be effected by elimination of the substance or by substitution of a less hazardous substance. Twelve measures are listed for control: (1) a totally enclosed process and handling system; (2) a plant, process or system of work which minimizes the generation of, or suppresses or contains, fumes, dusts, etc.; (3) a partially enclosed system, with LEV; (4) LEV; (5) sufficient general ventilation; (6) a reduction of the number of workers exposed and a restriction of access; (7) a reduction in the period of exposure; (8) regular cleaning of surfaces and walls; (9) the provision of a means of the safe storage and disposal of the substance; (10) suitable PPE; (11) prohibition of eating, drinking and smoking in contaminated areas and (12) provision of adequate facilities of washing, changing and storage of clothing, including laundry arrangements for contaminated clothing.

25.4.7 Personal protective equipment

PPE includes respiratory equipment, protective clothing, footwear and eye protection. The selection of such equipment for protection against a substance should take into account the ability of the material to resist penetration by the substance, the adequacy of the design of the clothing and its suitability for the intended use, the environment in which it is to be worn, and, in the case of dust, the dust release characteristics of the material.

25.4.8 Health surveillance

Guidance on health surveillance is given in the ACOP and also in HS(G) 61 *Surveillance of People Exposed to Health Risks at Work* (HSE, 1990). The ACOP describes the purposes of health surveillance, the type of surveillance suitable and the situations in which it should be undertaken.

The purposes of health surveillance are essentially the protection of the health of employees and the evaluation of health hazards and control measures. The surveillance should lead to action and, before it is undertaken, the options and criteria should be established.

The health surveillance procedures enumerated in the ACOP are: (1) biological monitoring; (2) biological effect monitoring; (3) medical surveillance; (4) enquiries about symptoms, inspection or examination by a suitably qualified person; (5) inspection by a responsible person and (6) a review of the records and occupational history during and after exposure. Biological monitoring is based on the measurement of agents or their metabolites in body tissues or fluids, whilst biological effect monitoring is based on the biological effects on the worker. In this context, a suitably qualified person is instanced as an occupational health nurse and a responsible person as a manager or supervisor. The latter might check, for example, for chrome ulceration.

Health surveillance is appropriate for any exposure which fulfils the criteria of Regulation 11(2). The judgement on the likelihood of disease or adverse effects should be related to the nature and degree of exposure and should take into account information on epidemiology, human exposure, human and animal toxicological data, as well as extrapolation from information about analogous substances or situations.

25.4.9 Schedule 5

Frequent reference has been made in the foregoing to Schedule 5. This contains in Column 1 the names of various substances and in Column 2 processes in which they are involved.

One substance listed in this schedule is VCM. The processes given in column 2 opposite this substance are manufacture, production, reclamation, storage, discharge, transport, use or polymerization.

25.4.10 Carcinogenic substances

The ACOP contains a second, separate section, or code, covering the control of carcinogenic substances (the *Carcinogens Code*). The *Carcinogens Code* covers scope, prohibitions, assessment, prevention and control, monitoring, health surveillance and information, instruction and training. Its structure thus reflects that of the COSHH Regulations and code. It is an amplification of the *COSHH Code* and not a replacement for it.

With regard to scope, the code applies to substances assigned the 'risk phrase' 'R45: May cause cancer' of the Classification, Labelling and Packaging Regulations 1984 and listed in Part IA1 of the approved list and to substances listed in Appendix 1 and substances arising from processes listed in that appendix. Certain substances are prohibited and these are listed in Schedule 2.

The guidance on assessment and on prevention and control largely follows that of the *COSHH Code*, but there are particular emphases and specific measures.

Exposure to a carcinogen involves risk of cancer. The risk increases with the exposure but there may be no short-term manifestation of adverse effects. The dose–response relation is quantal rather than graded.

In the case of carcinogens, particular importance is attached to prevention. The use of carcinogenic substances should be kept to a minimum, these should be clearly labelled, and the areas where they are used should be delineated and non-essential personnel excluded.

The first choice for control should be a totally enclosed system. Where this is not practical, alternative effective engineering measures should be taken including, where appropriate, the use of LEV. Care needs to be taken, however, that control measures do not aggravate the risk in the workplace or the outside environment.

Since exposure to carcinogens can result in a serious health effect, monitoring is normally required under paragraph 68 of the *COSHH Code*.

The *Carcinogens Code* states that, unless exposure is insignificant, health surveillance is appropriate for all carcinogenic substances. For substances in Schedule 5 of the regulations, medical surveillance is required. The code explains the objectives and limitations of surveillance. Surveillance has limitations in the identification of susceptible persons and in early recognition of cancer. It is largely restricted to the keeping of records to protect workers through the detection and evaluation of health risks.

In view of the nature of the risk, workers who may be exposed should be given full information about it and on the importance of prevention, control and hygiene measures. This should include information on the long-term risk and on the need for continued surveillance.

25.5 Dust Hazards

In general industry, dust is one of the most serious hazards to health. Even in the chemical industry, where there are many toxic vapours, dust remains a relatively important airborne contaminant.

The HSE guidance on dust hazards and their control is given in *Principles of Local Exhaust Ventilation* (HSE, 1975a), MS 4 Organic Dust Surveys (HSE, 1977), EH 44 *Dust: General Principles of Protection* (HSE, 1991) and EH 40/94 *Occupational Exposure Limits 1994* (HSE, 1994). Further guidance is given in *User Guide to Dust and Fume Control* (Muir, 1985) (the *IChem Dust Control Guide*), the *BOHS Airborne Contaminants Guide* and *Dust Control Handbook* (Mody and Jakhete, 1988 ACGIH/18) and by Bridgwater (1983).

25.5.1 Health effects of dusts

Some dusts have harmful effects, and some of the most harmful airborne contaminants are dusts. There are many dusts, however, which are inert, although they are unpleasant to breathe. Some account of the effects of dust on health and of exposure limits is given in Chapter 18.

EH 40 requires that, in the absence of a specific exposure limit for a particular dust, exposure should be kept below both 10 mg/m^3 8-h time-weighted average (TWA) total inhalable dust and 5 mg/m^3 8-h TWA total respirable dust. Respirable dust is the fraction of inhalable dust which penetrates the lung.

Much of the most important harmful effect from dusts is the various forms of fibrosis such as silicosis from silica or asbestosis from asbestos dust. Metals which are essentially harmless in bulk form may have dusts which are to some degree toxic and cause severe lung inflammation. Some dusts are associated with lung cancer.

25.5.2 Measurement of dusts

As described earlier, techniques exist for the visualization of dust clouds so that the presence and movement of dust in the workplace atmosphere may be followed. Such visualization is often sufficient to check the general state of the atmosphere, to detect leaks and to investigate the effectiveness of measures for dust suppression.

However, if the concentration of the dust is to be controlled in accordance with exposure limits, then a quantitative measurement of the total particle concentration is needed. It may also be necessary to measure the particle size distribution. The measurement of particle concentration and size distribution is a specialist matter.

Methods for the sampling and measurement of dust in air are described in the *IChemE Dust Control Guide*, the *BOHS Airborne Contaminants Guide, Particle Size Analysis* (Lloyd, 1987) and *Particle Size Analysis* (Stanley-Wood and Lines, 1992), and by Stairmand (1951), T. Allen (1975), Munns (1977), Kaye (1981), Vincent and Mark (1981) and Rood (1992a,b).

25.5.3 Minimization of exposure to dusts

The general approach to the minimization of exposure is similar to that taken for airborne contaminants generally and is described in Section 25.3, which makes frequent reference to dusts.

Section 25.3 describes the generation of dusts and methods for the prevention and control of exposure. Amplifying these as regards prevention, there are a number of industrial examples of the elimination of dust by such means as the substitution of different materials or a change of process. The substitution of metal shot for silica sand in shot blasting eliminates silica dust. The change from dry to wet processes for asbestos products largely eliminates asbestos dust.

Another important aspect of prevention is the suppression of dust fines. Here one approach is to prevent the generation of fines by a modification of material or process. This is exemplified by the use of spray drying or fluidized bed processes to produce granular products. Another approach is the use of a de-dusting agent. This finds application in the treatment of many pigments with very small amounts of liquid de-dusting agent.

Where exposure cannot be reduced sufficiently by prevention, it is necessary to resort to control. The methods of control available are described in Section 25.3. These include in particular enclosure and LEV. Indeed, accounts of LEV are couched mainly in terms of the control of dusts.

Good housekeeping and hygiene measures assume particular importance for dusts, especially highly toxic dusts. The objective of good housekeeping is to prevent dust from being carried back into the atmosphere. It includes the construction of buildings to eliminate dust-collecting surfaces and permit easy cleaning, the avoidance of dust spillages, the removal of dust piles and of pastes which form dust when dried, and the cleaning of dust-collecting surfaces. Arrangements to prevent contamination by dusty clothing may also be necessary.

25.6 Asbestos Dust

Asbestos dust is a particularly important hazard and occurs in the process industries. It is appropriate, therefore, to give it separate consideration. The effect of asbestos dust on health was described in Chapter 18 and it is principally the control of the dust which is considered here.

The relevant regulations are the CAWR 1987. There are two ACOPs, L27 (formerly COP 21) *Control of Asbestos at Work* (HSE, 1993) and COP 3 *Work with Asbestos Insulation, Asbestos Coating and Asbestos Insulation Board* (HSE, 1988).

Further guidance on asbestos dust is given in EH 10 *Asbestos: Exposure Limits and Measurement of Airborne Dust Concentrations* (HSE, 1990). There are a number of other guidance documents from the HSE, including MS 13 *Asbestos* (HSE, 1988), EH 41 *Respiratory Equipment for Use Against Asbestos* (HSE, 1985), EH 50 *Training Operatives and Supervisors for Work with Asbestos Insulation and Coatings* (HSE, 1988), EH 51 *Enclosures Provided for Work with Asbestos Insulation, Coatings and Insulating Boards* (HSE, 1989), EH 35 *Probable Asbestos Dust Concentrations at Construction Processes* (HSE, 1989), EH 52 *Removal Techniques and Associated Waste Handling for Asbestos Insulation, Coatings and Insulation Boards* (HSE 1989), EH 37 *Work with Asbestos Insulating Board* (HSE, 1989), EH 47 *Provision, Use and Maintenance of Hygiene Facilities for Work with Asbestos Insulation and Coatings* (HSE, 1990) and EH 36 *Work with Asbestos Cement* (HSE 1990).

A US viewpoint is given in *Asbestos: Medical and Legal Aspects* (Castleman, ACGIH 1990/39).

The principal contents of the CAWR are given in Table 25.5. It can be seen from this table that the general structure of the CAWR mirrors that of the COSHH Regulations, with requirements for the assessment, prevention or reduction of exposure, control measures, maintenance of control measures, air monitoring, health records and medical surveillance, and information, instruction and training. The CAWR also contains, however, a number of other provisions which are described below and which serve as an additional model for exposures of this general type.

Table 25.5 *Principal contents of the Control of Asbestos at Work Regulations 1987 and the associated Guidance*

Regulation 2	Interpretation
Regulation 3	Duties under these Regulations
Regulation 4	Identification of the type of asbestos
Regulation 5 and 5A	Assessment of work which exposes employees to asbestos
Regulation 6	Notification of work with asbestos
Regulation 7	Information, instruction and training
Regulation 8	Prevention or reduction of exposure to asbestos
Regulation 9	Use of control measures, etc.
Regulation 10	Maintenance of control measures, etc.
Regulation 11	Provision and cleaning of protective clothing
Regulation 12	Duty to prevent or reduce spread of asbestos
Regulation 13	Cleanliness of premises and plant
Regulation 14	Designated areas
Regulation 15	Air monitoring
Regulation 16	Health records and medical surveillance
Regulation 17	Washing and changing facilities
Regulation 18	Storage, distribution and labelling of raw asbestos and asbestos waste
Regulation 19	Supply of products containing asbestos for use at work
Schedule 1	Particulars to be included in a notification

Regulation 4 requires that the type of asbestos to which exposure may occur be identified.

Regulation 2 defines action levels and control limits. The action levels are 96 fibre-hours/ml of air where exposure is solely to chrysotile, and 48 fibre-hours/ml of air where exposure is to any other form of asbestos alone or in mixtures including mixtures of chrysotile with any other forms of asbestos. Where both types of exposure occur separately over a 12-week period, a proportionate number of fibre-hours per ml of air applies.

The control limits given in this regulation are for chrysotile (1) 0.5 fibres/ml of air averaged over any continuous period of 4 h and (2) 1.5 fibres/ml of air averaged over any continuous period of 10 min. For any other form of asbestos, either alone or in mixtures, including mixtures of chrysotile with any other forms of asbestos, the control limits are (1) 0.2 fibres/ml of air averaged over any continuous period 4 h and (2) 0.6 fibres/ml of air averaged over any continuous period of 10 min.

In general, the regulations apply to any exposure to asbestos at work, but some particular regulations are triggered only if exposure is liable to exceed the action level. These are Regulations 6, 14 and 16, relating, respectively, to notification, designated areas and medical surveillance.

Regulation 6 requires notification of work with asbestos unless the exposure is not liable to exceed the action level or the employer is licensed under the Asbestos (Licensing) Regulations 1983.

Regulation 14 requires that any area in which work on asbestos is carried out be designated as: (1) an asbestos area, where the exposure of a person working for the whole of his working time is liable to exceed the action level; or (2) a respirator area, where the concentration of asbestos is liable to exceed any control limit.

General guidance on air monitoring is given in EH 42 *Monitoring Strategies for Toxic Substances* (HSE, 1989) and guidance for asbestos specifically is given in EH 10 *Asbestos: Exposure Limits and Measurement of Airborne Dust Concentrations* (HSE, 1990). EH 10 gives detailed information on the determination of action and control levels and on the monitoring and measurement of airborne asbestos, including accredited quality control laboratories, measurement methods, sampling and interpretation. It also contains a schedule dealing with sampling methods. Also relevant is *A Guide to Monitoring Airborne Asbestos in Buildings* (Keyes and Chesson, ACGIH 1989/33).

Further guidance on measurement is given in MDHS 39/3 *Asbestos Fibres in Air* (HSE, 1990).

Quality control laboratories are accredited for airborne asbestos measurement under the National Measurement Accreditation Scheme (NAMAS). This supersedes the earlier NATLAS scheme.

Where a process has the potential to generate asbestos dust, the methods of eliminating or reducing the generation of dust described in Section 25.5 should be exploited as far as is reasonably practicable.

Leaks from plant handling asbestos dust can cause serious contamination of the workplace atmosphere but are often invisible. They may be detected, however, using a dust lamp. This is illustrated in Figure 25.1 above, which shows the visualization of asbestos dust using a dust lamp.

An important part of the asbestos dust problem in the process industries relates to lagging. In many applications, there are satisfactory substitutes and the industry has moved towards the use of these. Any use of asbestos should be confined to white asbestos. In practice, the use of asbestos is limited and it may not be easy to obtain.

Dust is particularly likely to be raised in removing lagging. The work should be segregated and workers should wear protective clothing and RPE. The area should be thoroughly cleaned after the work is complete.

Maintenance is particularly important in plant where asbestos dust may arise or in plant with asbestos lagging.

Where asbestos dust may be present, housekeeping measures assume particular importance. A high standard of cleanliness is necessary in the workplace. There need to be good facilities for washing and changing, and for cleaning protective clothing.

25.7 Ventilation

If an assessment of the air quality in the workplace shows it to be necessary, ventilation should be provided. Accounts of ventilation are given in *Exhaust Hoods* (Dallavalle, 1952), *Plant and Process Ventilation* (Hemeon, 1963), *Fundamentals of Industrial Ventilation* (Baturin, 1972), *Basic Principles of Heating and Ventilation* (Bedford, 1974), *Air Conditioning and Ventilation of Buildings* (Croome-Gale and Roberts, 1975), *Handbook of Ventilation for Contaminant Control* (McDermott, 1976), *Advanced Design of Industrial Ventilation Systems for Contaminant Control* (Goodfellow, 1985) and by Grandidge (1969, 1977), Gill (1980b), Goldfield (1980), Caplan (1982), Cassells (1986–) and Fanger and Christensen (1986). The HSE guidance is given in *Principles of Local Exhaust Ventilation* (HSE, 1975a), HS (G) 37 *An Introduction to Local Exhaust Ventilation* (HSE, 1987), EH 22 *Ventilation of the Workplace* (HSE, 1988) and HS (G) 54 *The Maintenance, Examination and Test of Local Exhaust Ventilation* (HSE, 1990). Further guidance is given in the *BOHS Air Contaminants Guide*, the *CIBSE Guide* by the CIBSE* (1977), *Ventilation Requirements* by the Building Research Establishment (BRE, 1981 Dig. 208), *Design of Industrial Ventilation Systems* (Alden and Kane, ACGIH 1982/6), *Heating, Ventilation and Air-Conditioning Analysis and Design* (McQuiston and Parker, ACGIH 1988/21), *Ventilation for Control of the Work Environment* (Burgess, Ellenbecker and Treitman, 1989 ACGIH/38), *Guide for Testing Ventilation Systems* (ACGIH 1991/58), *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 1991/67), *Industrial Ventilation Workbook* (Burton, 1991 AIHA/21), *Laboratory Ventilation Workbook* (Burton, 1991 AIHA/22), *Industrial Ventilation: Engineering Principles* (Heinsohn, 1991 ACGIH/66) and *IAQ and HVAC Workbook* (Burton, 1993 AIHA/25) and in the handbooks of the ASHRAE (1990/4, 1991/5, 1992/6, 1993/7).

A relevant code of practice is BS 5925, which is particularly relevant to natural ventilation. The 1980 version was BS 5925: 1980 *Design of Buildings: Ventilation Principles and Designing for Natural Ventilation* which is the current one for much of the ventilation literature quoted here. The current version is BS 5925: 1991 *Code of Practice: Ventilation Principles and Designing for Natural Ventilation*. The code for mechanical ventilation is BS 5720: 1979 *Code of Practice for Mechanical Ventilation and Air Conditioning in Buildings*.

The reasons for ventilation and ventilation rates for normal purposes are discussed in Chapter 10. Briefly, a degree of ventilation which maintains a suitable thermal environment commonly suffices for the other requirements also. BS 5925: 1980 recommends for factories a rate of 0.8 l/s per m^2 of floor area.

If there is airborne contamination, however, the situation is different. In this case, the air requirement may depend primarily on the reduction of the contaminant concentration below the control limit.

As described in Section 25.3, the design should exploit, to the extent practical, methods of keeping the workplace atmosphere free of contamination which do not rely on ventilation.

If ventilation has to be used, there are two main methods available. These are general ventilation, which relies on dilution, and sometimes also on displacement, and LEV, in which contamination is removed close to its source so that the main workspace is not affected.

25.7.1 Local exhaust ventilation

HSE guidance on LEV is given in *Principles of Local Exhaust Ventilation* (HSE, 1975a), HS (G) 37 *An Introduction to Local Exhaust Ventilation* (HSE, 1987) and EH 22 *Ventilation of the Workplace* (HSE 1988). Further guidance is given in the *BOHS Air Contaminants Guide*.

LEV removes contaminants from the source directly into a ventilation system. It does not rely on the dilution or displacement effects of general ventilation. It should be designed to remove the contaminant from around the source rather than from around the operator.

An LEV system may be considered in terms of the following elements: (1) contaminant source, (2) hood, (3) ducting, (4) air filtration plant and (5) fan.

---

* The Chartered Institute of Building Services Engineers has twice changed its name in recent years, the previous acronyms being Institution of Heating and Ventilation Engineers (IHVE) and Chartered Institute of Building Services (CIBS). The guide referred to is also known as the *IHVE Guide* and the *CIBS Guide*.

25.7.2 Contaminant source

The main problem in effecting LEV is the dispersion of the contaminant from the source. Once it has escaped from the immediate area of the source, it is very difficult to bring it under control. It is necessary, therefore, to obtain information on the behaviour of the contaminant leaving the source, such as its direction and velocity.

The air currents which influence the behaviour of the contaminant should also be studied. Air currents which are not essential to the process but are incidental or unconnected should be eliminated.

25.7.3 Enclosure and receptor hoods

It is usual to distinguish between two basic types of enclosure or hood systems used in LEV: (1) enclosures and receptor hoods and (2) captor hoods. Enclosures may be (1) total enclosures or (2) partial enclosures.

With a receptor hood, the emission source is either inside or at the mouth of the hood. The hood receives contaminated air brought into it by air currents. These are either hot air currents rising from the process or cold air currents induced by the process. The air currents from a furnace and from a grinding wheel illustrate the two processes, respectively. The function of the fan in this type of system is simply to suck away the air entering the hood.

Total enclosure is the most effective arrangement, but it is not always practical. It is used in the chemical industry and for the handling of radioactive materials. It may involve remote operation using manipulators.

Where a total enclosure is used, it needs to be air-tight so that it contains the vapour or dust handled, and strong enough to remain so. When such an enclosure is used, the space inside and the plant and equipment inside may be heavily contaminated. There is thus a need for measures to limit exposure when the enclosure has to be opened. These may include measures to remove the contaminant and measures such as procedures and/or interlocks to control access.

There are a number of types of partial enclosure, including (1) booths, (2) fume cupboards, (3) hoods over hot processes and (4) jet assisted hoods.

A partial enclosure should be no larger than is necessary for the purpose. The velocity of the air entering it should be high enough to overcome any tendency for the air inside to escape. Turbulence may be created within the enclosure by the working of equipment inside it and outside the enclosure by air currents. For a partial enclosure, the basic air flow required is given by

$$Q = AV \qquad [25.7.1]$$

where A is the area of the opening (m^2), Q is the volumetric air flow (m^3/s) and V is the inward superficial air velocity (m/s). The *BOHS Guide* states that whilst in quiet conditions an inward air velocity of 0.5 m/s may suffice, in more difficult circumstances, 2 m/s or more may be needed, and that for normal situations in factories, an air velocity of 1 m/s is often used. Depending on the nature of the enclosure, it may also be necessary to make an allowance for leakage at the joints of the enclosure. Guidance is given in the *BOHS Guide*.

A booth is a type of partial enclosure from which one side, or part of one side, is missing. It should be deep, since leakage due to eddies tends to occur round the edges of a shallow booth.

If the booth is large enough for an operator to work inside it, he should work at the front open face and not between the contaminant source and the air exhaust outlets.

A laboratory fume cupboard may be regarded as a special type of booth giving partial enclosure, but with a closure which can be closed to give almost total enclosure. There are many variations depending on the type of work to be done, but a fume cupboard usually takes the form of an open-fronted booth with a vertically sliding front window, or sash. The sash may be left open, partially closed or closed, and there are various arrangements designed to maintain a stable air flow and to ensure that air is drawn from both the top and bottom of the cupboard.

Relevant standards for fume cupboards are BS 7258: 1990 *Laboratory Fume Cupboards* and also BS DD 191: 1990 *Method for Determination of the Containment Value of a Laboratory Fume Cupboard*. Further guidance is given by D. Hughes (1980), Piney and Carroll (1983) and J.D. Cook and Hughes (1986).

Another receptor arrangement is a hood over a hot process. The design intent is that the hot gas rises from the process and flows into the hood. If the gas plume is not hot enough or if too much air is entrained into it, so that the total plume volume is too great and too cool, the hood may not operate as intended. The plume may miss the hood or may enter but may flow back out.

Methods are available for the design of such hoods. They include the plume models by Hemeon (1963) and Bender (1979) and methods of measuring plume volume and velocity, assisted by the use of cine or video film, developed by Bamford (1961) and Goodfellow and Bender (1980).

A further type of receptor arrangement is the jet-assisted, or push-pull, hood. This is used with an open surface such as a tank, where a jet of air is blown across the surface. The design intent may be frustrated if the jet is too powerful so that it carries the contaminant beyond the exhaust hood or if it strikes parts of the tank so that turbulence is created.

Models applicable to jet-assisted hoods of this type include those by Hemeon (1963) and Baturin (1972), whilst a practical application has been described by Huebener and Hughes (1985).

25.7.4 Captor hoods

The other main type of hood used in LEV is the captor hood. Whereas a receptor hood receives a flow of contaminated air carried into it, a captor hood draws the air flow in. The two types of hood may sometimes be similar in shape, but the principle of operation is different. A receptor hood operates on the push and a captor hood on the pull principle.

For a captor hood, the air velocity required depends critically on the distance between the hood face and the contaminant source. For a normal shape such as a circle, square or rectangle (although not for a slot), the air velocity at a point only one-hood face diameter from the centre of the hood face itself is typically only one-tenth of the face velocity. Thus, a broad rule-of-thumb for a practical system is that the contaminant source should not be more than one hood face diameter from the hood face.

A more scientific approach is based on the concept of a capture velocity, which is the velocity induced at the source sufficient to capture the contaminant. Whilst there is no real design alternative to the use of capture velocity, the concept has limitations. It is most applicable where the contaminant at the source has a low velocity, but tends to break down where the contaminant is directed away from the hood at an appreciable velocity. The *BOHS Guide* states that, although capture velocities as low as 0.25 m/s are sometimes quoted, a value of 0.5 m/s should be taken as a practical minimum, and it uses in a subsequent illustrative example a velocity of 0.75 m/s.

A relation for the superficial velocity of air entering the hood has been given by B. Fletcher (1977). This is

$$\frac{V}{V_0} = \frac{1}{0.93 + 8.58\alpha^2} \qquad [25.7.2]$$

with

$$\alpha = \frac{X}{A^{1/2}}\left(\frac{W}{L}\right)^{-\beta} \qquad [25.7.3]$$

$$\beta = 0.2\left(\frac{X}{A}\right)^{-1/3} \qquad [25.7.4]$$

where A is the face area of the hood (m^2), L is the length of the hood (m), V is the capture velocity at distance X (m/s), V_0 is the superficial velocity at the face of the hood (m/s), W is the width of the hood (m), X is the distance from the hood (m), and α and β are indices.

The performance of a captor hood may be enhanced by the use of flanges around the face inlet. The design of such flanges is treated in the *BOHS Guide*.

The volumetric flow of air required for a captor hood can be very much greater than for a receptor hood. The *BOHS Guide* gives a comparison of four systems. Of these four systems, the one most economical in air is a receptor hood with a small aperture in the face side, the second is a receptor hood with the whole face side missing, and the third is a captor hood with a large flange and the last a captor hood with no flange. The ratio of the volumetric air flow required by the last of these arrangements to that required by the first is 100 : 1.

25.7.5 Low volume, high velocity system

A particular type of captor hood arrangement for LEV is the low volume, high velocity (LVHV) system. This system utilizes a small hood (typically <6 cm^2) placed very close to the contaminant source and a high capture velocity ($\approx 50-100$ m/s). It may be used for vapour sources such as welding and for dust sources such as grinding. However, it is not easy to use and tends to be limited in application. Successful use requires that it be unobtrusive, correctly adjusted and properly maintained.

25.7.6 General ventilation

LEV is the preferred method of ventilation, but there are circumstances in which it is not applicable, and in such cases it is resorted to general ventilation of the work space. However, such general ventilation is usually regarded as a comparatively ineffective method of contaminant control.

Some processes are operated outdoors, and it is often assumed that an outdoor location ensures negligible exposure. This is not necessarily so, and each case should be treated individually.

In indoors there tend to be wide variations between the concentrations at different locations in the work space; the concentrations can differ by orders of magnitude. The enhancement of general ventilation may have little or no effect on the concentration at a particular point.

In general, the variability of the concentration of a contaminant at a fixed point outdoors tends to be very high. Indoors, the variability at a fixed point is much less.

General ventilation may have two effects. One is simply to reduce the concentration of contaminant by the introduction of more air. The other is to move the contaminant in a particular direction by displacement of air.

As described in Chapter 10, methods are available for the determination of the volumetric flow of air due to natural ventilation. Guidance is available in BS 5925: 1980. The *BOHS Guide* gives a worked example based on the BS 5925 method.

The concentration of contaminant resulting from general ventilation may be obtained on the assumption of perfect mixing in the work space, as described in Chapter 10. In practice, the concentration may be considerably higher. One approach to this problem is the method used by the ACGIH for the determination of concentration of a contaminant relative to the TLV. This method utilizes an empirical factor K which takes into account variations in the concentration with space and time, and allows for the toxicity of the contaminant. Values of K range from 3 to 10.

25.7.7 Air jets

Air jets are sometimes used as part of a system of general ventilation. They are of two types: those that draw air from within the work space and those that draw air from outside. In the first type, the jet is used to promote mixing in the space. In the second type, it may be used as a fresh air jet to provide a volume where the concentration of contaminant is low, but in this case it must be sufficiently near the point in question to effect this; otherwise, the jet is liable to become contaminated with air from the work space.

The following equation is given by the CIBSE (1977) for the centre line velocity of a jet:

$$X = \frac{KQ}{V_x(A_f C_d)^{1/2}} \qquad [25.7.5]$$

where A_f is the free area of discharge (m^2), C_d is the coefficient of discharge, Q is the volumetric flow (m^3/s), V_x is the centre line velocity at distance x (m/s), X is the distance along the centre line (m) and K is a constant. The value of C_d is taken as 1.0 for a well-rounded nozzle and 0.6 for a sharp-edged orifice and that of K as 7.0 for a round nozzle and 5.7 for a standard grill, where the outlet velocity is 4–8 m/s.

The use of air jets can cause problems if the jet is not well integrated with the overall system design. Typical effects are undesired dispersion of the contaminant, interference with existing LEV systems, the creation of vortices where the contaminant becomes concentrated, and discomfort due to cold draught.

Use is also made of air curtains to provide a barrier to the flow of contaminant. The use of such a curtain can result in dispersion rather than containment of the contaminant and careful design is needed. Another device sometimes used is an air douche in which air is discharged at low velocity above the heads of workers.

25.7.8 Air replacement

The air removed by the ventilation system has to be replaced. It is usually recommended that this replacement air should enter through properly designed inlets. Air which simply leaks in through open doors, windows and cracks, may cause unpleasant draughts and may also set up air movements which affect the operation of an LEV system.

25.7.9 Design of ventilation systems

In designing a ventilation system for the control of a contaminant, this ultimate purpose needs to be borne constantly in mind. It is not uncommon for this objective to be lost sight of and for the design to degenerate into the mere provision of the mechanical elements of the system such as the hood, ductwork and fan. The *BOHS Guide* gives a series of quotations, starting with J.B.S. Haldane in 1907 and continuing into the 1980s. The following, from Hemeon (1963), though not the most recent, perhaps puts the problem most clearly:

> It sometimes seems that engineers experience such sheer satisfaction in their ability to handle the design of duct work on a neatly quantitative basis, that they are led to slight the initial problem of selecting suitable exhaust or ventilation rates as though they were a minor detail to be covered as quickly as possible . . . whereas the part they slight is the essential of industrial ventilation.

For this reason, the *Guide* advocates design leadership by an occupational hygienist.

Accounts of the mechanical design of ventilation systems are given in the texts quoted. In particular, *Local Exhaust Ventilation*, the *BOHS Guide* and the *IChemE Dust Control Guide* give detailed treatments, dealing with overall system design, ductwork, fittings, multi-branched systems, fans, and air cleaning and disposal.

Guidance on the commissioning of ventilation systems is given in *Principles of Local Exhaust Ventilation*, BS 5720, the *Commissioning Code of CIBSE* (CIBS, 1977; CIBSE, 1978–), and the *BOHS Guide*.

Where the system is a multi-branched one, the balancing of the flows is of particular importance.

25.7.10 Maintenance of ventilation systems

It is important that any ventilation system for the control of contaminants be properly examined and maintained. HSE guidance is given in HS(G) 54 *The Maintenance, Examination and Test of Local Exhaust Ventilation* (HSE, 1990).

Inspections have found that the effectiveness of many industrial ventilation systems is low. Sometimes this is due to inefficient functioning of the mechanical items due to poor maintenance. But it is also possible for these items to be working as intended but for the ventilation achieved to be ineffective. This may arise, for example, if the contaminant source has been moved somewhat further from the hood.

The prominence given in regulations to maintaining the whole system so that it operates as intended reflects the problem. As described earlier, Regulation 9 of the COSHH Regulations requires that for an LEV plant, the maximum interval for thorough examination and test is 14 months, or as given in Schedule 3 to that regulation. The CLAW Regulations and the CAWR also contain requirements for LEV system maintenance.

Checklists for the maintenance of LEV systems are given HS(G) 54 and the *BOHS Guide*.

25.8 Skin Disease

Thus far, the discussion has dealt with toxic substances which are airborne. It is also necessary to prevent corrosive and toxic chemicals from causing irritation of the skin leading to skin disease, or dermatitis, and from entering the body through the skin.

Guidance on skin disease is given in MS 3 *Skin Tests in Dermatitis and Occupational Chest Disease* (HSE, 1977), EH 26 *Occupational Skin Diseases* (HSE, 1981) and MS 24 *Health Surveillance of Occupational Skin Disease* (HSE, 1991). Further accounts of skin disease are given in *Occupational Diseases of the Skin* (L. Schwartz, Tulipan and Birmingham, 1957) and *Manual of Contact Dermatoses* (Fregert, 1974) and by McCreaney (1969, 1977), Rycroft (1979, 1980, 1980 LPB 58) and Gadian (1983). Aspects of skin disease in the petroleum industry are dealt with in *Petroleum Hydrocarbons: their Absorption Through and Effect on the Skin* (CONCAWE, 1984 84/54) and *Factors Affecting the Skin Penetration and Carcinogenic Potency of Petroleum Products Containing Polycyclic Aromatic Compounds* (CONCAWE, 1990 90/55).

Occupational skin disease is the most common cause of disablement in industry. Statistics are given in the Health and Safety Statistics 1990–91 (HSE, 1992b). There are a number of different ways of arriving at a figure for such disease, but the number of new cases is of the order of 40,000 per year.

The types of chemical which cause skin disease are classified as (1) contact irritants, (2) contact sensitizers and (3) photosensitizers. Contact irritants cause direct damage to the skin. Contact sensitizers cause a specific allergic response to develop over a period.

Photosensitizers may be either irritants or sensitizers, but require the additional stimulus of sunlight or ultraviolet (UV) light.

Substances which are liable to cause skin disease are chemicals, cutting oils, degreasing agents, tar and pitch. It may also be caused by physical agents such as heat, cold, humidity, light and ionizing radiations.

Prevention of skin disease should be based on engineering measures to eliminate the causal agent, supplemented where necessary by personal protection. Where chemicals have to be handled, it is essential to use the proper methods and to wear the appropriate protective clothing, to observe the highest standards of personal hygiene, to change working clothes, including underwear, frequently and to take a thorough shower each day. Any break in the skin should be covered. Skin rashes should be reported, and wounds treated, promptly.

25.9 Physico-chemical Hazards

There are a number of physico-chemical effects which are very simple and familiar to the engineer, but which have implications often not fully appreciated, particularly by process and maintenance personnel.

An account of some of these effects has been given by Jennings (1974a,b). They include:

(1) density differences –
    (a) gases and vapours,
    (b) liquids;
(2) phase changes;
(3) vapour pressure;

(4) flashing liquids;
(5) nearly immiscible liquids;
(6) heat of mixing;
(7) exothermic reactions;
(8) impurities.

At constant pressure, the density of a gas or vapour ρ_g is proportional to the molecular weight M and inversely proportional to the absolute temperature T:

$$\rho_g \propto \frac{M}{T} \qquad [25.9.1]$$

Density differences can cause the gas or vapour to flow in unexpected ways.

In one case, a manhole in a reboiler containing benzene was left open. Some benzene vapour escaped and poured down so quickly into the base of the room that the operator was killed before he could put on a respirator.

Another incident involved a hydrogenation vessel which was shut-down for repair, but into which hydrogen continued to leak through a valve that was only partially closed. When the top manhole cover was taken off to admit a charge of carbon dioxide as an inert blanket, there was a flash of fire. Since the hydrogen was much less dense, enough air had presumably entered to form a flammable mixture.

Differences in liquid density can give rise to very high pressure in equipment and to layering. In one incident, the discharge and suction valves were shut on a pump full of ethylene glycol and the pump was left running. The liquid heated up and the volumetric expansion of the liquid generated a pressure sufficient to crack the pump casing.

The effect of layering due to the difference of densities of two liquids is illustrated by the following case. A mixture of liquid caustic soda and phenol was being prepared in a reaction vessel by an operator. The addition was made without agitation and the phenol formed a separate layer on top of the caustic soda. When the agitator was switched on, there was a violent reaction and about half the charge was ejected through the top opening, which had a hinged lid, onto the operator.

The volume changes associated with a change of phase, particularly changes between liquid and vapour, can produce violent effects. At atmospheric pressure, for example, one volume of liquid water vaporizes to give about 1600 volumes of steam.

A road tanker was being filled with hot tar at a temperature just below 100°C when the pump failed. In accordance with normal practice, the tar line was blown out with steam. Since the tank was only half full, the driver went on to another site to top up and so obtain a full load. Here the tar was at a temperature in excess of 100°C and a few seconds after the filling began, hot tar was ejected from the manhole. The cause was vaporization of the steam condensate left in the tank from the steam blowing operation at the first site.

Conversely, sudden contraction of vapour can create a vacuum and cause a vessel to implode or to draw in air. A particular important case is a situation which occurs when heat input is lost on the reboiler of a distillation column. Rapid condensation of the vapour in the column may create a vacuum which draws air in through the vent and may thus cause an explosive mixture to form. This may be prevented by the use of nitrogen injection.

Powerful effects are also produced by the variation of the vapour pressure with temperature. For a pure liquid, the relation between the vapour pressure and temperature may be represented by the Antoine equation:

$$p^\circ = \exp\left(A - \frac{B}{T + C}\right) \qquad [25.9.2]$$

where p° is the vapour pressure, T is the absolute temperature, and A, B and C are constants. For most liquids, the vapour pressure doubles over a temperature range of about 8°C. For ideal liquid mixtures, Raoulf's law applies:

$$p_i = p_i^\circ x_i \qquad [25.9.3]$$

where p_i° is the vapour pressure of the pure component i, p_i is the partial pressure of component i and x_i is the concentration of component i (mole fraction).

But, if instead the liquids are immiscible, then for each liquid

$$p_i = p_i^\circ \qquad [25.9.4]$$

In both cases, the total pressure P is given by Dalton's law:

$$P = \sum pi$$

In the general case, some of the components may be inert gases.

The effect of vapour pressure is illustrated by a case in a works producing chlorine by the mercury cell process where a worker was found to have persistently high mercury in his urine, even though he hardly ever went into the cellroom. His main work was the removal of ebonite lining from mild steel sections used in the cellroom equipment. The work involved the application of heat. This heat was sufficient to cause traces of mercury lodged in cracks in the ebonite to exert an appreciable vapour pressure.

A common phenomenon associated with vapour pressure is cavitation in pumps. This occurs if the suction pressure is low and the liquid temperature is high. Pockets of vapour form and collapse as the local pressure falls below or rises above the vapour pressure. The resultant erosion and pitting is extremely damaging to the pump.

A Dowtherm furnace started up and the pressure rose suddenly from 15 to 110 psi. Water had entered the system and both liquids were exerting their full vapour pressure. In this instance, the pressure relief valve operated and prevented an accident.

If a liquid at a given pressure is let down to a lower pressure such that the boiling point at the lower pressure is less than the original temperature of the liquid, liquid immediately flashes off until the lower pressure boiling point is reached, the amount of vapour formed being determined by the heat balance.

A tank had been cleaned by boiling water in it under pressure. The operator opened a vent to release the pressure, but loosened a manhole before the venting was complete. Large amounts of boiling water and steam issued out around the cover.

Liquid systems in which there are two separate liquid phases are loosely referred to as 'immiscible', although there is always some mutual solubility, so that 'nearly immiscible' would be a more accurate description. Consider a system with two nearly immiscible components A and B. At equilibrium, the phase which is nearly all A is saturated with a small quantity of B. If this phase has separated out, both A and B exert their full vapour pressure. If B has a high vapour pressure, a considerable proportion may be evolved.

An operator drained water from a tank in which there was a water layer covered with a benzene layer. The benzene in the water exerted an appreciable vapour pressure and the operator suffered benzene poisoning.

When two liquid chemicals are mixed together, there is a heat of mixing. Whilst this is zero for an ideal mixture and low for many mixtures, for others it is appreciable.

Owing to a failure of communication, a tanker of hydrochloric acid was unloaded into a storage tank used for sulfuric acid. When about half of the 3000 gal load had been transferred, there was a violent explosion, which raised the tank several inches off the ground and buckled it, and broke the inlet and outlet lines.

In another case, a violent explosion occurred when mixing took place between very strong caustic soda, which was lying on the bottom of a vessel and was covered by a solid crust, and weak caustic soda above it.

Reaction kinetic effects, especially in exothermic reactions, are discussed in Chapter 11.

A particular case of importance is situations in which there is inadequate agitation in a chemical reactor. The reactants are allowed to build up without agitation and then react explosively, either spontaneously or when agitation is started.

One incident involved a sulfonation process in which benzene and concentrated sulfuric acid were premixed before transfer to a reaction vessel. On one occasion, the agitator was not used and the reactants were transferred unmixed. The operator noticed this and quickly switched on the reactor agitator. There was a rapid reaction, benzene vapour was evolved, a flammable mixture was formed in the room and it ignited.

Impurities can cause violent reactions or severe corrosion.

An operator was transferring thionyl chloride by vacuum from a 55 gal drum through a stainless steel hose when the hose developed a leak. He obtained another hose, checked that nothing drained from it and substituted it for the first. When he opened the feed valve, the hose ruptured. The accident was caused by a small amount of water which was left in the hose and which reacted violently with the thionyl chloride, releasing large volumes of hydrogen chloride and sulfur dioxide. Calculation showed that one teaspoonful of water would be enough to generate a pressure of 2800 psig in the hose.

Corrosion not only reduces the strength of the equipment, but also generates gases.

An apprentice under training was erecting some pipework. He required a blank flange of a particular size and noticed one on some redundant pipework nearby. When he attempted to remove the blank, acid sprayed in his face. The pipework had been used previously for concentrated sulfuric acid and corrosion had generated hydrogen, which pressurized the pipe.

25.10 Ionizing Radiation Hazards

Materials and machines which give off ionizing radiation are widely used in industry. They are potentially very hazardous, but they may be handled safely by taking proper precautions.

The legislation covering the use of ionizing radiations is discussed in Chapter 3. That of principal relevance here is the Ionizing Radiations Regulations 1985. The associated ACOP is COP 16 *The Protection of Persons against Ionising Radiation arising from any Work Activity* (HSE, 1985).

Engineering aspects of ionizing radiations are described in *Radioactivity for Engineers* (Coombe, 1968) and health and safety aspects are described in *Radiation Hygiene Handbook* (Blatz, 1959), *Radiation Protection Standards* (L.S. Taylor, 1971), *Principles of Radiation Shielding* (Chilton, Shultis and Faw, 1984), *Industrial Radiation Hazards Deskbook* (Cheremisinoff, Cheremisinoff and Teresinski, 1987 ACGIH/12) and *Radiation Protection* (Shapiro, ACGIH 1990/48) and by H.H. Fawcett (1965c), Bennellick (1969, 1977), Brodsky (1978–), Doran (1980), Harrington (1980b), Dennis (1982) and Kielman and Fawcett (1982).

A code relevant to potential exposure to radioactive materials during a fire is NFPA 801: 1991 *Facilities Handling Radioactive Materials*.

The hazard from sealed sources, from machines designed to generate ionizing radiations such as X-rays and from machines which give off radiations adventitiously is one of external exposure, but unsealed sources present the further hazard of internal exposure arising from ingestion.

Ionizing radiations are a complex and specialist matter and only a very limited treatment is given here. A more detailed treatment of types and units of radiation is given in Appendix 20. COP 16 gives detailed coverage of a large number of industrial aspects.

25.10.1 Types and units of radiation

There are three main types of radioactive particle or ray: (1) α-particles, (2) β-rays and (3) γ- and X-rays. α-particles have a relatively large mass and short range, being stopped by an air gap of about 8 cm or a sheet of paper, and generally they present little external radiation hazard, but are dangerous if they get inside the body. β-rays (or particles) have a much smaller mass and greater penetrating power. Their range in air is about 10 m, but they are usually stopped by a few millimetres of solid material. γ-rays and X-rays are electromagnetic radiations which have a range of a few hundred metres, but can be stopped by a few millimetres of lead or by 0.5–1 m of concrete.

In the SI system, the units of radiation are: for activity, the becquerel (By); for absorbed dose, the gray (Gy); and for the dose equivalent, the sievert (Sv). The dose equivalent is the product of the absorbed dose and a quality factor (QF). The corresponding units in the older system are the curie (Ci), rad (rad) and rem (rem), respectively.

25.10.2 Effects of exposure

α-Particles destroy bone marrow so that the red corpuscles are not replaced. β-rays give rise to skin burns, skin cancer, dermatitis and eye disease. γ-rays and X-rays cause skin burns and cancer and ageing effects. Fairly severe exposure is required to cause sterility, but genetic effects are believed to be proportional to exposure.

25.10.3 Industrial applications

Industrial applications of ionizing radiations include the following:

(1) radioactive process materials;
(2) Radioactive auxiliary materials –
    (a) tracers,

  - (b) sorting aids,
  - (c) quality control aids,
  - (d) static eliminators,
  - (e) instruments;
- (3) γ- and X-rays –
  - (a) non-destructive testing,
  - (b) quality control;
- (4) irradiation –
  - (a) food preservation,
  - (b) cold sterilization,
  - (c) polymerization.

Some process materials, such as radioactive metals, are themselves radioactive.

Radioactive materials are commonly used as tracers. Examples are the use of ^{24}Na, ^{59}Fe and ^{60}Co in work on mixing, piston ring wear and refractory wear, respectively, and of various tracers in following the progress of pigs or of interfaces between products in pipelines and in detecting leaks in water and other pipe systems.

Items on which sorting or quality control is to be carried out may be tagged with a radioactive material. Radioactive sources are used to ionize the air and so dissipate static electricity. Instruments which use radioactivity include level measuring instruments that measure the height of the liquid surface and ionization chambers which detect the presence of smoke.

γ-Ray sources are used to detect flaws in castings. The castings are grouped around the source with photographic plates behind them. Similarly, the non-destructive testing of pressure vessels and components, and particularly welds, is carried out using X-rays. The latter are also used in X-ray fluoroscopy for the inspection of items on conveyor belts for quality control purposes.

Applications of irradiation in polymerization include the vulcanization of rubber and polymerization of high melting point polyethylene.

25.10.4 Measurement of radiation

Measurements of radiation are made both on the plant and on the personnel. In the first case, the objective is to check radiation flux levels and releases, in the second, to monitor exposure.

Portable devices for measuring the exposure of personnel include film badges and pocket ionization chambers. Both types measure β-, γ- and X-rays.

Radiation on the plant or from contamination is measured by instruments such as Geiger–Muller counters and scintillation counters. Except for scintillation counters, these instruments do not measure α-particles, but special α-measuring instruments are available.

25.10.5 Limits for exposure

Occupational exposure to radiation should always be kept as low as practicable. The established limits should be observed, but since any level of radiation may involve some risk, every effort should be used to minimize exposure.

Recommendations on limits for exposure are made by the ICRP. These recommendations are widely applied internationally.

In the United Kingdom, the National Radiological Protection Board (NRPB) makes recommendations to government on working limits, taking into account the ICRP recommendations.

The statutory limits for ionizing radiations are given in the Ionizing Radiations Regulations 1985 and are:

Adult workers: dose limit	50 mSv in any calendar year
Adult employees: investigation level	15 mSv in any calendar year
Members of public: dose limit	5 mSv in any calendar year
Members of public exposed over long periods: dose limit	1 mSv annual average

The following are the limits now recommended by the NRPB (1993):

Adult workers: dose limit	20 mSv in any calendar year
Adult employees: investigation level	15 mSv in any calendar year
Students and apprentices	6 mSv in any calendar year
Members of public: dose limit	1 mSv in any calendar year

0.3 mSv from any single source

25.10.6 Control of exposure

As in industrial hygiene generally, control of radiation exposure depends on deciding acceptable limits of exposure, designing the plant to minimize release, operating systems which minimize exposure and monitoring the personnel exposed.

Radiation may be contained within the equipment by shielding. This may take the form of lead a few millimetres thick. Protection of equipment giving off radiations may be provided by interlocks.

If some exposure is unavoidable, measures should be taken to minimize it. Since the dose is inversely proportional to the square of the distance and proportional to time, the distance from the radiation source should be as great and the time of exposure as short as possible.

Contamination from unsealed sources requires special measures for control and decontamination. These are discussed by Bennellick (1969, 1977).

All personnel who may be exposed to radiation should be monitored. Principal methods of monitoring include the carrying of personal radiation metres and the testing of blood. If tests indicate that a person is nearing the limit of exposure, he should be withdrawn temporarily or permanently from the work.

25.11 Non-ionizing Radiation Hazards

Ionizing radiation is not the only kind of radiation which may be hazardous. There are a number of types of non-ionizing radiation which can have harmful effects.

Accounts of non-ionizing radiation are given by Harrington (1980b), Kanagasbay (1980), Kielman and Fawcett (1982), McKinlay (1982) and Pilborough (1989). Guidance is available in the series *Nonionizing Radiation Guides* (AIHA, 1977–/3).

25.11.1 Electromagnetic spectrum

The electromagnetic spectrum is divided by wavelength into the following regions:

Cosmic rays	$<10^{-4}$ nm
γ-rays and X-rays	10^{-4}–10 nm
UV	10–400 nm
Visible region	400–700 nm
IR	700 nm–1 mm
Microwaves	1 mm–1 m
Radio waves	>1 m

The boundaries have developed by usage and are adopted by convention. Non-ionizing radiation is conventionally taken as that radiation which has a wavelength exceeding 100 nm, and thus starts within the UV region.

25.11.2 Artificial sources

Artificial sources of non-ionizing radiation include: in the UV region, welding; in the IR region, welding, furnaces and lasers; in the microwave and radio frequency (RF) regions, microwave ovens, communications equipment and radar.

25.11.3 Health effects

The health effects of exposure to non-ionizing radiation are felt mainly on the eyes and skin. UV, IR, and microwave and RF radiations can each cause damage to both these parts of the body.

Thermal injury occurs when the rise in the temperature of the tissue is more than a few degrees. Thermomechanical damage ensues when thermal expansion of tissue is at such a rate that it results in explosive disruption. Photochemical injury is caused by absorption of a greater dose of energy than the body's repair mechanism can handle.

25.11.4 Ultraviolet radiation

UV radiation is most harmful in the waveband 200–315 nm. Acute injury depends essentially on the total dose, whether this be received for a few seconds or over some hours.

The effect of overexposure on the eye is exemplified by such conditions as 'welder's flash' and 'snow blindness' a condition known as photokeratitis which is painful but generally reversible. The acute effect on the skin is erythma, or sunburn. Long-term overexposure of the skin leads to the chronic condition of skin cancer.

Guidance on UV radiation is given in *Ultraviolet Radiation* (AIHA, 1991/14a).

25.11.5 Infrared radiation

Visible and IR radiation entering the eye are focused on the retina and can cause damage, but this is usually averted. The reaction to a bright light is to avert the eye and this aversion response, occurring typically with 0.25 s, usually ensures that damage is avoided.

The main cause of injury to the skin from IR is thermal damage. A particularly hazardous form of IR radiation is that from a laser.

25.11.6 Laser radiation

A laser produces an intense monochromatic beam of non-ionizing radiation, either as continuous wave (CW), a single pulse or a series of pulses. The beam from some lasers can cause damage, particularly to the eye.

Guidance on lasers is given in PM 19 *Use of Lasers for Display Purposes* (HSE, 1980) and *Safety in Universities – Notes of Guidance*, Part 2:1 *Lasers by the Committee of Vice-Chancellors and Principals* (CVCP) (1992). A relevant code is BS EN 60825: 1992 *Radiation Safety of Laser Products, Equipment Classification and Users Guide*. Further guidance is given in *A Guide for the Control of Laser Hazards* by the ACGIH (1990/41).

Laser products are classified according to the maximum permissible exposure (MPE) of the eyes and skin, and to the associated accessible emission level (AEL).

Class 1 laser products are those which are inherently safe. Class 2 laser products are not inherently safe but have a power so limited that eye damage should not result over a duration of 0.25 s for a blink reflex. Classes 3A, 3B and 4 cover higher power products.

A laser may or may not produce a beam in the visible part of the electromagnetic spectrum, so that a person working with one which does not may be unaware that he has been exposed.

Personnel working with laser equipment should wear safety glasses appropriate to the class of laser concerned. A high level of ambient lighting is beneficial in that it restricts pupil size.

Since different classes of laser have very different power outputs, arrangements satisfactory for one class may not be so for a higher power class.

The use of lasers requires a safe system of work, the principal elements of which are control of access, warning notices and lights, and, possibly, interlocks.

Work with lasers should be subject to health surveillance.

25.11.7 Protection and control

The principles of protection from non-ionizing radiations have many similarities with those for protection against the hazards already considered. The first line of defence is engineering measures to eliminate or reduce exposure, the second is systems of work for the control of exposure and the third is PPE.

25.12 Machinery Hazards

Accidents caused by moving machinery have always been a serious problem in industry. The reduction of this type of accident has been one of the main concerns of industrial safety legislation. The development of this legislation has been described in Chapter 3.

Guidance on the hazards and safe use of machinery is given in two series of publications by the HSE, the HSW series (*Health and Safety at Work Booklets*) and the PM (*Plant and Machinery*) series. The former includes HSW 3 *Safety Devices for Hand and Foot Operated Presses* (HSE, 1971) and HSW 41 *Safety in the Use of Woodworking Machines* (HSE, 1970). The PM series includes PM 1 *Guarding of Portable Pipe-threading Machines* (HSE, 1984), PM 21 *Safety in the Use of Woodworking Machines* (HSE, 1981), PM 22 *Training Advice on the Mounting of Abrasive Wheels* (HSE, 1983), PM 23 *Photoelectric Safety Systems* (HSE, 1981), PM 41 *Application of Photo-electric Safety Systems to Machinery* (HSE, 1984) and PM 65 *Worker Protection at Crocodile (Alligator) Shears* (HSE, 1986). A relevant standard is BS 5304: 1988 *Code of Practice of Safety of Machinery.* Accounts of safe working with machinery are given by Haigh (1969, 1977) and Bramley-Harker (1969, 1977).

25.12.1 Machine guarding

The law on the safeguarding of machinery has become progressively stricter. Requirements are given in the Factories Act 1961, Sections 12–15. These sections state that prime movers and their flywheels should be securely fenced, as should electric motors and generators, transmission machinery and other dangerous machinery unless safe by construction or position, that devices for promptly cutting off the power from transmission machinery should be provided in every place where work is carried out, that efficient mechanical appliances should be provided to move driving belts to and from fast and loose pulleys and that driving belts should not rest or ride on revolving shafts when the belts are not in use.

Secure fixed fencing is the preferred method of guarding machinery. The fencing should be strong so that it fulfils its protective function and does not deteriorate as a result of frequent removal and replacement for maintenance. It should be secure and removable only by the use of tools.

The fencing should enclose the parts guarded completely. Many accidents occur on equipment where the fencing is incomplete and where a worker is liable to catch his hand between the moving part and the guard.

In some applications, however, complete enclosure by fencing is not possible, because it is necessary to feed material or components into the machine. In such cases, partial fencing may be used. The space left unprotected should be big enough to allow the required access for materials but should exclude the hand. Thus, complete fencing is normal for machinery such as revolving shafts, belt drives and gear wheels, but partial fencing is used on power presses and calenders.

Partial fencing may be complemented by distance fencing, which prevents the operator approaching too close to the machine.

If a fixed guard is not practical by reason of the nature of the operation, a permissible alternative for machinery other than prime movers or transmission machinery is a device which automatically prevents the operator from coming in contact with the dangerous plant.

Some other methods of providing protection on these lines are (1) feeders, (2) interlocks and (3) trips.

A feeder device such as a side, chute or roller is used to allow material or components to be fed into a machine without the necessity for a worker to put his hand in.

It is often necessary to have access to machinery for purposes such as maintenance. In this case, use may be made of an interlock which prevents access until the machine is stopped and prevents start-up while it is unguarded.

The stopping of the machine requires a braking system. The interlock should ensure that the machine has been completely stopped before access is possible.

With some machinery, fencing is not a practical solution. An alternative approach is the use of a trip. Trip devices include safety bars, photoelectric cells and proximity switches. Again a braking system is necessary to ensure that the machine stops quickly.

It is essential for there to be good maintenance both of the machine itself and of the fencing and other protective systems such as interlocks, trips and brakes.

Operators should be trained in the use of the machinery itself and in the protective systems. Likewise, maintenance personnel should have training in the maintenance of both machine and protective system. In some cases, this training is the subject of a specific statutory requirement. The Power Presses Regulations 1965, for example, specify the training required for the maintenance of such presses.

25.12.2 Running nips

A large proportion of the hazards on moving machinery arises from running nips. A running nip occurs when material runs onto or over a rotating cylinder. Running nips exist, for example, where a belt runs over a pulley wheel, a chain over a sprocket wheel, a conveyor over a roller or material over a drum, or where two rolls create an in-running nip. Running nips cause many accidents and the accidents are frequently serious.

An account of running nips is given by S.F. Smith (1969, 1977). One relevant code is BS 5667: 1979–*Specification for Continuous Mechanical Handling Equipment: Safety Requirements*, particularly Part 18 *Belt Conveyors – Examples of Guarding Nip Points* and Part 19: 1979 *Conveyors and Elevators with Chain Elements – Examples of Guarding Nip Points*. Another code is BS 7300: 1990 *Code of Practice for Safeguarding of the Hazard Points on Troughed Belt Conveyors*.

Typically accidents arise because an operator gets his clothing caught in a nip or slips and falls into one, because he tries to make some adjustment to the material running onto a cylinder or to remove foreign bodies or to clean rollers, or because the machinery is started up by mistake. Where material runs onto a roller, it is safer if it runs over the top so that the hazard is confined to the sides of the nip.

Most of the methods of protection described for machinery in general are applicable to running nips. The preferred method is complete fixed fencing, but partial fencing, distance fencing, feeders, interlocks and trips are also used. Again if interlocks or trips are used, it is essential that braking be such that it can stop the machinery sufficiently quickly. Often several measures are used in combination. Protection on a conveyor belt, for example, may use a combination of fixed fencing, distance fencing, interlocks and trip wires.

25.12.3 Inadvertent starts

Some accidents occur due to the inadvertent starting of machinery. A study of this type of accident has been made by Rouhiainen (1982), who investigated some 105 incidents involving inadvertent starting of machinery in a range of industries. Of the six incidents in the chemical industry, four involved presses and two involved guillotine shears, machinery not particularly characteristic of the industry. On the other hand, there were 14 accidents with conveyors, 8 with other transferring and lifting machines, and 3 with packaging machines.

The primary causes assigned included 24 intentional starts, 26 starts caused by human error, 21 starts caused by accidentally touching the start button, and 16 starts caused by the machine itself.

The author proposes measures to prevent inadvertent starts in both maintenance and normal operations. The former includes the disconnection of sources of electrical and mechanical energy, such as would be applied in a good permit-to-work system. The latter includes the use of barriers, interlocks and touch stopping devices.

The protective measures described in the guidance in Section 25.12.1 include protection against inadvertent starts.

25.12.4 Abrasive wheels

Accidents with abrasive wheels used for grinding are usually due to wheel failure. The number of accidents is small, but this is so only because great care is usually taken with grinding operations.

Relevant statutory requirements include the Grinding of Metals (Miscellaneous Provisions) Regulations 1925. Guidance is given in PM 22 *Training Advice on the Mounting of Abrasive Wheels* (HSE, 1983) and HS(G) 17 *Safety in the Use of Abrasive Wheels* (HSE, 1984). Accounts of abrasive wheels is given by Blackshield (1969) and Southwell (1977).

The main cause of wheel breakage is accidents, including damage to the wheel by mechanical shock and unchecked traverse of the work onto the side of the wheel.

Excessive rotational velocity is also dangerous. For a given wheel, a velocity is specified and should be adhered to. The velocity depends on the type of grinding. In high velocity grinding, the velocity is about twice that for normal grinding. It is essential to avoid using wheels made for normal velocity in high velocity work.

Other causes of breakage include excessive heating and excessive work pressure.

Safety measures in grinding work include selection and care of the wheels, proper mounting of the wheels, running at the specified speed and eye protection for the operator.

25.13 Electricity Hazards

Accidents in factories due to electricity are frequently associated with a failure to isolate or earth electrical equipment or to temporary or defective equipment.

The use of electrical equipment in factories is governed by the Electricity at Work Regulations 1989, which supersede the Electricity (Factories Act) Special Regulations 1908 and 1944. Guidance is given in HS(R) 25 *Memorandum of Guidance on the Electricity at Work Regulations 1989* (HSE, 1989). A further treatment is given in *Handbook on the Electricity at Work Regulations* (Marks, 1991).

HSE guidance on electrical safety is given in HS(G) 13 *Electrical Testing: Safety in Electrical Testing* (HSE, 1980), GS 27 *Protection Against Electrical Shock* (HSE, 1984), GS 37 *Flexible Leads, Plugs and Sockets* (HSE, 1985), PM 64 *Electrical Safety in Arc Welding* (HSE, 1986), PM 32 *Safe Use of Portable Electrical Apparatus (Electrical Safety)* (HSE, 1990) and GS 47 *Safety of Electrical Distribution Systems in Factories* (HSE, 1991). Further accounts are given in Electrical Safety Engineering (Fordham Cooper, 1986) and by Haigh (1969, 1977), Crom (1977) and Bales (1977a–c).

Some British Standards on electricity and electrical work are given in Appendix 27. One of particular relevance here is BS 2769: 1984 *Hand-held Electric Motor-operated Tools*. Part 1 of this standard gives general requirements for all types of tool and part 2, sections 0–14, describe requirements for some 14 types of tool.

Electrical equipment should be installed, inspected, tested and maintained only by competent electricians.

Equipment should be regularly inspected and serviced. Equipment on which repair is to be done should be disconnected from the supply until the work is complete. The importance of this instruction should be made clear to both electrical and other maintenance personnel. Defective equipment should be taken out of use and completely disconnected from the supply until it is repaired.

Temporary wiring should be avoided as far as possible, but if used should be to a safe standard and properly earthed. It should be regularly inspected and repaired as necessary and it should be replaced by a permanent installation as soon as possible.

Circuits should not be overloaded, as this increases the risk of fire. Loading should be carefully supervised and circuits protected by fuses or circuit-breakers.

Leads should have wires of the standard colours, which in the United Kingdom are brown for live, blue for neutral and green and yellow for earth. Leads of other colours on old or imported equipment should preferably be replaced.

A large proportion of electrical accidents involves portable tools. As described in BS 2769: 1984, the types of portable tool are (1) earthed tools and (2) all-insulated or double-insulated tools. It is essential to ensure that an earthed tool is not used unless it is properly earthed. All portable tools should be maintained and tested regularly.

Cables and plugs are vulnerable and require attention. Wear occurs particularly at the points where the cable enters the tool or plug. Cable grips reduce this problem. Flexible cables should be positioned so that they are not damaged by heavy equipment.

Tools with low voltage (110 V or, in damp conditions, 50 V) should be used wherever practicable. The plug/socket system for such tools should be such as to prevent their being plugged into the normal mains.

25.14 Other Activities and Hazards

The hazards associated with certain common activities are considered in this section. Other activities and hazards are treated in other chapters. Those associated particularly with maintenance, for example, are covered in Chapter 21.

25.14.1 Lifting and carrying

Handling, lifting and carrying activities are discussed in HSW 1 *Lifting and Carrying* (HSE, n.d.), *Work Practices Guide for Manual Lifting* (NIOSH, 1981 Publ. 81–122) and *Manual Material Handling* (Kroemer, McGlothlin and Bobick, 1989 AIHA/16) and by Halliday (1969, 1977), A.R. Hale (1984) and Kroemer (1992).

The Factories Act 1961 states that 'a person shall not be employed to lift, carry or move any load so heavy as to cause injury'.

According to the Health and Safety Statistics 1990/91 (HSE, 1992b), accidents involving the handling, lifting and carrying of goods were responsible for some 55,477 injuries, including 2 fatalities and 1257 non-fatal major injuries reported to the HSE. In many cases, such accidents result in permanent injury, such as back trouble or hernia, and in long periods of absence from work.

These activities are often treated in terms of sudden injury arising from a single incident. But, in fact, much injury occurs due to cumulative strain caused by incorrect practices over a long period.

The first essential is that the ergonomics of the handling task should be right. This means not only that the weight to be handled should not be excessive, but also that the adoption of awkward positions should not be necessary and that suitable aids such as handles, platforms, rollers, etc., should be provided and sufficient time should be allowed.

Then, it is necessary that workers doing handling work observe some basic principles relating to grip, the position of the arms, chin and feet, back posture and the use of body weight. The grip should be a full palm rather than a fingertip grip. The arms should be held close to the body and fully extended so that the weight is taken by the body itself rather than the arms. The chin should be kept in, which reduces the risk of spinal injury. The back should be kept flat. This prevents compression of the abdominal contents, which leads to hernia, and in conjunction with correct foot positioning gives better mechanical advantage. The feet should be positioned slightly apart to give good balance. The weight of the body should be used ballistically, avoiding jerky actions. The use of body weight is one of the principles underlying judo and allows large weights to be moved with minimum effort.

There are wrong and right ways of lifting a heavy object. If the object is lifted with the back curved, the effort required is great and is placed on the back and abdominal muscles, whereas if it is lifted with the legs bent and the back straight, the effort is less and is taken by the leg and thigh muscles. These basic principles have been summarized in the 'six-point drill' of the NSC.

The heights to which heavy objects have to be lifted can often be reduced by the use of a platform.

A heavy object should be carried with the arms straight, with the head close to the body and with a straight back. Changes of grip and twisting movements should be avoided. So should blind carrying, in which the load prevents the carrier from seeing in front of him. The floors or other surfaces over which the carrying is done should not be slippery.

Any protective clothing necessary for handling should be worn. In particular, the task often requires the use of safety shoes or gloves.

A single worker should not attempt to handle an object which is too heavy for him alone. He should obtain the assistance of others.

The maintenance of a fixed position is one of the most tiring tasks for the muscles. Thus, even a seated task may cause muscle strain if it requires the operator to adopt awkward static positions.

In addition to recognized handling tasks, the occurrence of handling operations in such tasks as maintenance should be considered.

Handling objects requires good muscle tone. A worker should therefore be given time to tone his muscles up before being required to lift the heaviest loads if he is not used to such work.

It is important to give training in matters of handling. This is so not least because people often feel they know how to do it correctly, when in fact they do not. People often attempt from misjudgement, zeal or bravado, to handle loads which are too heavy. They should be discouraged from doing this.

A study of the effectiveness of safety training has been made by A.R. Hale (1984), which includes a case study of the effectiveness of training in handling loads. The basic principles commonly taught are those of the NSC's six-point drill mentioned earlier. The study found that conventional training tended to concentrate on injuries to the back, to the exclusion of other handling injuries, that it did not actually result in correct handling actions, and that recognition of good and bad postures was more important than action drills.

25.14.2 Hand and power tools

The proper use of hand tools is clearly essential for safety. But injuries also arise from the use of defective tools. A split hand file handle may come off and allow the file to penetrate the hand. A 'mushroomed' head on a cold chisel may loose fragments which could injure the eye. Another cause of injury is the use of the wrong tools. It is necessary, therefore, to provide suitable tools for the range of tasks to be performed, to store them securely, to maintain them properly and to have them regularly inspected by a competent person.

Guidance on the use of portable hand-held power tools includes PM 14 *Safety in the Use of Cartridge Operated Tools* (HSE, 1978) and *Pneumatic Tools – Safety in Operation, Safety Recommendations for the Use and Operation of Portable Pneumatic Tools* and *Recommendations for the Proper Use of Hand Held and Hand Operated Pneumatic Tools* by the European Committee of Manufacturers of Compressors, Vacuum Pumps and Pneumatic Tools (PNEUROP) (n.d.a, n.d.b, 1986, respectively). A further account is given by Bland (1977).

25.14.3 Welding

Welding operations may involve hazards to the plant and the welder. The former have been dealt with in other chapters, particularly Chapter 21, and only the latter are considered here.

Guidance on welding is given in MS 15 *Welding* (HSE, 1978) and PM 64 *Electrical Safety in Arc Welding* (HSE, 1986). Further sources of guidance are the publications of the Welding Institute (WI), the American Welding Association (AWS), the AIHA and the API. These include *Health and Safety in Welding and Allied Processes* by Balchin (1991 WI/43); the *Welding Handbook* (AWS, 7th ed. 1976–/1, 8th ed. 1987–/2), the EWH series *Effects of Welding on Health* (AWS, 1979–/3, 4), *Fumes and Gases in the Welding Environment* (AWS, 1979/5) and *Fire Safety in Welding and Cutting* (AWS, 1992/13); *Arc Welding and Your Health* (AIHA, 1984/6) and *Welding Health and Safety Resource Manual* (AIHA, 1984/8); and *Safe Welding and Cutting Practices in Refineries, Gasoline Plants and Petrochemical Plants* (API, 1988 Publ. 2009). Further accounts are given by Sanderson (1969, 1977). A relevant standard is BS 1542: 1982 *Specification for Equipment for Eye, Face and Neck Protection Against Non-ionizing Radiations arising during Welding and Similar Operations*.

The principal method of welding considered here is electric arc welding, which may be done by manual, semiautomatic or fully automatic methods and may take place in a welding shop or on site.

Electric arc welding uses power supplied by transformers or motor–generator sets which are supplied by the factory electrical system or by a self-contained engine-driven generator set. The circuit has three electrical connections: the welding lead, the welding return and the welding earth.

During welding, the electrode and parts of the holder are electrically live and hot, the arc gives off high intensity visible light and both IR and UV radiation and fumes are evolved. It is necessary, therefore, to take suitable precautions so that the operation can be done safely.

All the welding connections should be capable of carrying the full welding current. The welding lead should be robust and flexible enough for this purpose. The welding return, which is often the most neglected part, should receive equal attention. It need not be as flexible and in a workshop may be a permanent installation. The welding earth should be as near the work as possible rather than at the source of supply, although this is not always practicable. All joints in these connections should be in good condition. Where it is unavoidable that the cables are laid over rough surfaces, there should be frequent inspection for defects.

The electrode holder should be of sufficient size and should be insulated. Gloves should not be relied on to achieve insulation. If work is temporarily interrupted, the safest procedure is to render the holder electrically dead.

In the United Kingdom, open circuit voltages up to 100 V are used for welding, but in certain situations, such as welding at height, in damp conditions or in vessels, this may be too high a voltage for safety. Low voltage devices can be fitted which reduce the open circuit voltage by about half. These restore the full voltage when the electrode is touched to the work so that the arc can be struck. The voltage across the arc then drops as usual to a much lower value.

Some portable welding sets, particularly semi-automatic gas shielded equipment, have hoses for gas and water supply. The equipment should not be pulled around by the cables and the hoses. Both the latter should be regularly inspected.

Proper protective clothing and equipment should be used for welding. This typically includes an apron or more extensive covering, leather gloves and a helmet which has suitable filter glass and which protects the back of the neck from other nearby arcs. Different filter glasses are required for different welding currents. A hand shield with filter glass may be used as an alternative for short periods.

Screens may be used to protect other people from the rays of the arc. Booths used for welding should have a matt finish to reduce reflected light. This is an important precaution, especially with heavy current welding and high density arcs.

There should be adequate ventilation, particularly when working in a confined space. One purpose of ventilation is to remove welding fumes. These are not particularly detrimental to health, although some fumes such as those from galvanized materials are more noxious, but exposures should be minimized. Ventilation is also needed to remove inert gases such as nitrogen, argon and carbon dioxide. The two latter are heavier than air and thus tend to accumulate in confined spaces. This is made more hazardous by the fact that the gases cannot be smelled and that the welder may be out of sight. The use of air-supplied BA is necessary in some cases.

In welding, care should be taken that hot metal does not damage equipment or set alight material, which may lead to a fire.

Since electric arc welding involves electricity, the statutory notice for electrical equipment should be posted.

25.14.4 Corrosive chemicals

Corrosive chemicals present two kinds of hazard. One is corrosion of the plant leading to failure and hence injury. The other is injury from direct contact with the chemical, usually during some operations or maintenance activity.

Accounts of the problem are given in *Safety and Management* by the ABCM (1964/3) and by Harford (1969) and E.L.M. Roberts (1977).

Chemical corrosion is hazardous if it causes leaks in the plant or a failure in features such as staircases and handrails. It is necessary, therefore, to design both the plant and the buildings or structures to resist corrosion.

The vessels and pipework of the plant itself should be designed so that they do not corrode excessively and so that the effects of corrosion such as leaks and blockages can be dealt with as easily as possible.

The plant should also have a suitable layout. Open vessels containing corrosive materials and similar hazardous features should be fenced off. Parts which may leak, such as pipe flanges, should not be located over walkways and should, if necessary, have handrails around them. Floors and other surfaces should be sloped to let spillages drain or be washed away and to avoid allowing corrosion of features such as stairways by spilled materials. The layout of the plant for corrosive materials is discussed more fully in Chapter 10.

There should be clear marking of equipment and pipework to minimize errors of identification.

The plant should be maintained to a standard commensurate with the corrosive hazard. Leakage of fluids at high pressure is particularly dangerous.

There should be regular inspection of buildings or structures which may become corroded. Items which are vulnerable or which may fail with serious consequences include stairways, ladders and handrails, high level walkways, anchor points and lifting tackle.

Adherence to systems such as the permit-to-work system and to procedures such as the procedures for line breaking or for sampling and the prompt repair of leakages and cleaning up of spillages are effective in reducing the hazard from direct contact.

The plant should be provided with showers, eye fountains, eye washes and other neutralizers as applicable.

25.14.5 Compressed air

Compressed air is widely used in plants and in workshops, and presents hazards which are often not appreciated. Guidance is given in HS(G) 39 *Compressed Air Safety* (HSE, 1990) and by Paterson (1969, 1977).

Compressed air is provided by air compressor systems and it is used in blow guns and pneumatic tools. Compressor systems are treated in Chapter 12 and pneumatic tools in Section 25.14.2.

Use is often made of compressed air from a blow gun to blow swarf, filings and chippings from equipment or machinery. The air blast needed to effect such cleaning is usually quite sufficient to blow debris into, and cause injury to, the eye.

Another practice is the use of compressed air to clean clothes or parts of the body such as the hair. This is a very hazardous procedure. Air may enter the bloodstream through cuts in the skin, possibly with fatal results, or it may cause injury to the eye, ears, nostrils or rectum. The pressure needed to burst the bowels is quite low, about 4 psig. Moreover, it is emphasized that clothing offers no protection.

Horseplay with compressed air is likewise extremely dangerous. Air lines put down the trousers or even up the rectum have caused fatal or near-fatal injury.

The nature of the hazard from compressed air is such that it may affect not only the operator but also other people nearby.

Guidance on safer types of blow gun is given in HS(G) 39. This states that only two types are suitable, those with reduced jet velocity safety nozzles and those with air curtain safety nozzles. Whilst not foolproof, these types greatly reduce the risk. Types of blow gun nozzle which consist simply of a reduced orifice in direct line with the supply hose can be extremely dangerous and should not be used unless preceded by a tamper-proof pressure regulator.

Compressed air may also cause dust deposits to rise and form a dust cloud, thus creating the risk of a dust explosion.

25.14.6 Oxygen

As already mentioned, an oxygen-enriched atmosphere greatly increases the flammability of many materials, including clothing. Oxygen leakage from the process or from oxygen cylinders can create a hazardous situation. A relevant code on this topic is NFPA 53M: 1990 *Fire Hazards in Oxygen-Enriched Atmospheres*.

Moreover, for this reason, oxygen should not be added to an oxygen-deficient atmosphere, such as that in a vessel, in order to make it breathable.

Oxygen is used in one type of self-contained breathing apparatus (SCBA). It should not be used in the alternative type which uses air.

Ozone is a hazard at very low concentrations, due to its powerful oxidizing effect, the OES being 0.1 ppm. Guidance is given in EH 38 *Ozone: Health Hazards and Precautionary Measures* (HSE, 1983).

25.14.7 Inert gas

Atmospheres of inert gases which do not support respiration are common in the process industries, especially in vessels and confined spaces.

Guidance on oxygen-deficient or inert atmospheres is given in *Oxygen-Deficient Atmospheres by the Compressed Gas Association* (CGA) (1983 SB-2) and *Guidelines for Work in Inert Confined Spaces in the Petroleum Industry* (API, 1987 Publ. 2217A).

Breathing equipment for use in oxygen-deficient atmospheres must have its own air supply. The air-purifying type is not suitable.

It should be appreciated that an oxygen-deficient atmosphere can occur outside the plant as well as inside it. Accidents have occurred in which a worker standing alongside a plant has been asphyxiated. The hazard is greatest if the plant has been opened up for some purpose such as repair.

25.15 Personal Protective Equipment

There are many tasks for which some form of PPE such as clothing or other equipment is necessary.

Accounts of PPE are given in *Chemical Protective Clothing* (CIA, 1986 RC7), *Guidelines for Selection of Chemical Protective Clothing* (Schweppe *et al.*, ACGIH 1987/10), *Chemical Protective Clothing Performance Index Book* (Forsberg and Keith, ACGIH 1989/30) and *Chemical Protective Clothing* (Johnson and Anderson, 1990 AIHA/18) and by H.H. Fawcett (1965b, 1982c), C.S. Nicholson (1969), K.R. Nicholson (1976), Riddell (1977), Crockford (1980), Parson (1988) and Preece (1988). Some British Standards and NFPA codes for protective clothing are given in Appendix 27.

A significant problem associated with PPE is the setting of the standards which the equipment is required to meet. This is discussed by Berry (1969, 1977).

Some tasks which may require PPE are (1) working with corrosive chemicals, (2) working with toxic chemicals, (3) working with dusts, (4) working in hot environments, (5) working in noisy environments, (6) welding, (7) fire fighting and (8) rescue.

Protective clothing should be regarded as a last line of defence. It is much preferable to remove or control the hazard, if this is practicable.

For some tasks there are specific statutory requirements that protective clothing should be worn. In the United Kingdom, such requirements were rare until the 1940s but they are now quite numerous. Even where specific statutory requirements do not exist, the use of protective clothing is often necessary to comply with the HSWA 1974, Section 2.

It is the responsibility of the management to specify when protective clothing and equipment are required and to provide them. The worker then has the duty to use them. If he is reluctant to do so, management is responsible for enforcing their use. The Factory Inspectorate has used the prohibition notice procedure on an individual worker to make him wear protective clothing.

According to the Act, Section 9, no charge may be levied on an employee for anything done or provided to meet a specific statutory requirement.

Some types of protective clothing and equipment are (1) body clothing, (2) gloves, (3) helmets, (4) shoes, (5) eye protection and (6) ear protection.

There is no point in providing protective clothing which is not used. In general, therefore, it is better to select practical clothing which offers a good level of protection rather than theoretically safer but more cumbersome clothing. But each case should be considered on its merits.

Protective clothing may be a general issue or may be issued to an individual. The latter policy is preferable wherever it is practicable.

For some substances, specific guidance is available, as exemplified by EH 27 *Acrylonitrile: Personal Protective Equipment* (HSE, 1981).

25.15.1 Eye protection

The eye is a vulnerable organ and the avoidance of eye injury is particularly important.

The Factories Act 1961, Section 65, states that eye protection may be specified in certain processes, and eye protection has been covered by the Protection of the Eyes Regulations 1974 which give a schedule of processes for which appropriate eye protection is required. These processes include various cleaning and blasting operations using shot, water jets and compressed air, various operations involving particular tools, especially power tools, and various processes with hot metal or molten salt. Of particular relevance here is item 11, which reads:

> The operation, maintenance, dismantling or demolition of plant or any part of plant which contains or has contained acids, alkalis, dangerous corrosive substances, whether liquid or solid, or other substances which are similarly injurious to the eyes, and which has not been so prepared (by isolation, reduction of pressure, emptying or otherwise), treated or designed and constructed as to prevent any reasonably foreseeable risk of injury to the

eyes of any person engaged in any such work from any of the said contents.

These regulations are now superseded by the Personal Protective Systems at Work Regulations 1992, which deal with all types of such protection, including eye protection. Requirements for eye protection are also contained in certain other regulations.

Guidance on eye protection is given in L25 *Personal Protective Equipment at Work* (HSE, 1992) and *Protection of the Eyes* (CIA, 1990 RC22) and by Guelich (1965), Barker (1969, 1977) and Wigglesworth (1974).

Flying objects, chemicals and radiations are the main hazards to the eye in the process industries. Flying objects come most often from the use of hand or power tools. Chemical splashes are typically caused by operations such as line breaking or sampling. Welding is the main source of injurious radiations.

The hazard to the eye from power tools such as grinding wheels is understood and the use of eye protection is normal. There is evidence that, as a result, injuries to the eye from hand tools are as frequent as those from power tools (Wigglesworth, 1974).

The general principle that personal protection should be used only if hazard elimination and control are not sufficient applies with particular force to eye protection. The main types of eye protection are spectacles, goggles and face shields.

Spectacles have either prescription or plain lenses, depending on whether the wearer does or does not wear glasses. The lenses are glass or plastic such as cellulose acetate, acrylic or polycarbonate material. For welding, filter lenses are used.

The most appropriate eye protection depends, in principle, on the task. A view which is not only widely held but is also supported by successful company systems is that the most effective approach is to issue safety spectacles to all personnel who need eye protection and to require their use. Although safety spectacles do not give total protection against all eye hazards, they do give perhaps 90% protection and are more likely to be worn than some other devices. In other words, a protection which is worn is better than a superior protection which is not worn. The objective of the system based on safety spectacles is to achieve a situation where these are worn as naturally as prescription spectacles. This means that the spectacles should be fitted individually.

The alternative approaches are systems based on eye protection areas, supervisor's orders or personal judgement.

Whatever system is adopted, there are tasks for which eye protection other than safety spectacles is required. In particular, some tasks require protection not only for the eyes but also for the whole face. This applies especially to persons handling corrosive chemicals or doing welding.

First aid for eye injuries is discussed in Section 25.17.

25.16 Respiratory Protective Equipment

There are a number of tasks in the process industries for which RPE, or breathing equipment, is necessary.

Guidance on RPE is given in HS(G) 53 *Respiratory Protective Equipment* (HSE, 1990) and also in *Respiratory Protection: A Manual and Guideline* (Colton, Birkner and Brosseau, 1991 AIHA/23) and by H.H. Fawcett (1965d, 1982d), Cheffers (1969, 1977), Vanchuk (1978), Crockford (1980), Louhevaara *et al.* (1986), Stull (1987a,b), Parson (1988) and Preece (1988). Some special applications are dealt with in EH 41 *Respiratory Equipment for Use against Asbestos* (HSE, 1985) and EH 53 *Respiratory Protective Equipment for Use against Airborne Radioactivity* (HSE, 1990).

Relevant standards are BS 4275: 1974 *Recommendations for the Selection, Use and Maintenance of Respiratory Protective Equipment* and BS 4667: Part 3: 1974 *Fresh Air Hose and Compressed Air Line Breathing Apparatus*.

25.16.1 Regulatory requirements

The Factories Act 1961, Section 20, and formerly the Chemical Works Regulations 1922, Sections 6–8, require the use of approved BA for work in vessels and confined spaces where the atmosphere may contain dangerous fumes or may lack oxygen. There are requirements for the use of RPE in the CLAW Regulations 1980, the CAWR 1987 and the COSHH Regulations 1988.

The use of RPE should not be a substitute for measures to maintain a breathable atmosphere. The regulations require that it be used only as a last line of defence in situations where it is not reasonably practicable to control exposure by other means.

The regulations deal not only with the situations in which RPE should be worn, but also with its suitability and specification. In essence, they require that it be suitable for use, in that it has a sufficient air supply, that it fits well and that it is worn properly. The regulations also require that the RPE should meet a laboratory test specification. For an application requiring a high level of protection, this means that the HSE must approve the equipment itself and issue an Approval Certificate. For a lower level of protection, it is sufficient that the equipment meet a laboratory test approved by the HSE.

25.16.2 Applications of RPE

As just stated, RPE should be used only where it is the only reasonably practicable approach. There are four main types of situation in which it is used. These are (1) temporary situations, (2) short duration situations, (3) maintenance work and (4) escape. Temporary situations are those which arise in non-routine circumstances such, as commissioning. An important particular case is for activities in emergencies. Short duration situations may arise routinely. It is not normal for a worker to wear RPE all the time, but he may wear it routinely for certain tasks, for example, sampling or vessel entry.

25.16.3 Types of RPE

There are two broad classes of RPE. One is the respirator, which takes in air from the workspace and filters or cleans it, removing noxious gases and vapours or dusts, before it is inhaled. It is not itself a source of air and is quite unsuitable for use where the bulk gas in the atmosphere is not breathable air but is an asphyxiating mixture.

The second class is air-supplied equipment which does have a source of clean air. This class may itself be subdivided into equipment to which air is supplied by a hose and BA. Air for equipment supplied by hose may be compressed air or from a fresh air source. BA may be of the compressed air line or self-contained type.

HS(G) 53 gives the classification of RPE shown in Table 25.6. It contains an appendix giving illustrated descriptions of the main types.

25.16.4 Air-purifying respirators

The disposable facepiece or the half-mask respirator fits over the nose but does not cover the whole face. A full face mask respirator does cover the whole face; the wartime 'gas mask' is of this type. A powered respirator has a fan to assist the flow of air through the filter.

Each type of respirator is available in three performance classifications. Thus, half-mask and full face mask respirators may be of the PI, P2 or P3 specification.

The filters available for respirators are of three types: (1) filters for particular gases and vapours only, (2) filters for dusts and other particulate materials and (3) combination filters for particular gases and vapours and for dusts and other particulates.

As already stated, the air-purifying respirator differs fundamentally from the air-supplied RPE in that it is not itself a source of air and is therefore of little use unless breathable air can be drawn through it from the surrounding atmosphere. It will not sustain breathing in an asphyxiating atmosphere.

The concentration of oxygen in normal air is approximately 21%. A person breathing air with an oxygen concentration of less than about 16% may manage to do light work for a few minutes, but is likely to exhibit symptoms ranging from laboured breathing to unconsciousness or death.

Table 25.6 *Types of respiratory protective equipment (after HSE, 1990 HS(G) 53)*

A Respirators

- A1 Filtering respirators
  - A1.1 Disposable filtering facepieces
  - A1.2 Half-masks + filters
  - A1.3 Full face masks + filters
- A2 Powered respirators
  - A2.1 Half-masks
  - A2.2 Full face masks
  - A2.3 Visors
  - A2.4 Hoods and helmets
  - A2.5 Blouses (half-suits)

B Air-supplied equipment[a]

- B1 Compressed air-supplied equipment
- B2 Fresh air hose equipment
  - B2.1 Unassisted
  - B2.2 Manually assisted
  - B2.3 Power assisted
- B3 Breathing apparatus
  - B3.1 Compressed air line apparatus: demand type
  - B3.2 Compressed air line apparatus: demand type with positive pressure
  - B3.3 Self-contained breathing apparatus: open-circuit compressed air type
  - B3.4 Self-contained breathing apparatus: closed-circuit compressed oxygen type

[a] HS(G) 53 classifies simple compressed air-supplied equipment in its figure 3 in terms of (a) blouses, (b) hoods, helmets and visors, (c) half-masks, and (d) constant flow equipment, but classifies fresh air hose equipment in terms of the assistance to the air flow.

Respirators are produced for military, fire fighting and industrial uses. In the former case, they are commonly referred to as 'gas masks'. A respirator intended for one type of application should not be used for another.

The purifying element may work in several ways. Usually it adsorbs the gas. Alternatively, it may act as a catalyst: carbon monoxide is oxidized catalytically to carbon dioxide.

The element is designed to protect against a particular chemical or group of chemicals and should not be used for other substances. There are a number of toxic gases for which a respirator is quite unsuitable. Respirators should not generally be used against gases which have a high odour threshold or no odour at all, since odour is the only warning of failure of the respirator.

Some toxic gases are irritant to the face and for these full face protection should be used.

It is essential that respirators be kept in good condition and not held too long in stock; otherwise, the air-purifying element and/or the facepiece may deteriorate. The purifying element should be replaced after use or after the elapse of a certain time according to a specified policy.

It will be apparent that, although respirators are the most convenient form of RPE and have many legitimate applications, they also have some serious drawbacks and the circumstances in which they are used should be carefully considered.

25.16.5 Simple compressed air-supplied equipment

Simple compressed air-supplied equipment is so called to distinguish it from compressed air line BA, described below. In simple compressed air-supplied equipment, the air is supplied through a hose from an independent source of compressed air. There are various types, utilizing a full face mask, half-mask, hood or blouse.

The air supplied should meet the air quality standard described below. It should come from a high quality source which is capable of meeting the foreseeable needs of those requiring to use it. It should not be drawn for the compressed air supply intended for general works use. There should be suitable pressure reducing and pressure relief arrangements to protect the wearer from overpressure.

The hose used should comply with BS 4667: Part 3: 1974. The air line should be secured by a sturdy harness. Its route should be carefully chosen to keep it short, to allow escape and to avoid fouling and damage and it should be kept free of kinks.

The simple compressed air-supplied equipment is not a BA and it should not be used in situations where there is immediate danger to life or health; in other words, it should not be used in circumstances where an unprotected person would be rapidly overcome.

25.16.6 Fresh air hose equipment

In fresh air hose equipment, the air is supplied through a hose from a fresh air source. There are various types, utilizing a full face mask, half-mask, hood or blouse.

The requirements for air quality and for hose quality and routing for compressed air-supplied equipment apply also to fresh air hose equipment like simple compressed air-supplied equipment, fresh air hose equipment should not be used in situations immediately dangerous to life or health.

25.16.7 Breathing apparatus

BA is of two types. One is compressed air line apparatus and the other is SCBA. BA, whether of the compressed air line or self-contained type, provides the highest degree of protection and is the only type suitable for use in an atmosphere immediately dangerous to life or health.

25.16.8 Compressed air line breathing apparatus

Compressed air line apparatus is used with a full face mask or a full enclosing suit. There are two different methods of supplying the air. One is negative pressure demand in which the suction in the face mask generated by inhalation opens a demand valve allowing air into the mask. The other is positive pressure demand. With the former, the pressure inside the mask is slightly below atmospheric, whilst with the latter it is mainly above atmospheric, although it can fall below at high inhalation rates.

25.16.9 Self-contained breathing apparatus

SCBA comes in two types. One utilizes compressed air on an open-circuit system and the other compressed oxygen on a closed- circuit system.

Open-circuit compressed air BA utilizes a full face mask to which air is supplied from compressed air cylinders carried on the wearer's back.

Closed-circuit compressed oxygen BA utilizes a full face mask to which oxygen is supplied from compressed oxygen cylinders carried on the wearer's back. Exhaled air is passed through a purifier which removes carbon dioxide and is recirculated.

SCBA offers the wearer mobility but requires him to carry on his back a bulky load.

Use of oxygen instead of air introduces certain problems. There may be physiological effects on the person breathing it. The flammability of the material is much increased in oxygen-enriched air.

The length of time for which breathable air is supplied by SCBA is typically $\frac{1}{2}$ and 1 h for both types, but the time for which an apparatus provides air depends on the breathing of the wearer. Heavy exertion may cause an apparatus to run out before the nominal period.

Exhaustion of the air supply is hazardous and may cause asphyxia. An adequate safety margin of time should be allowed. There is normally a timer which can be set to give warning when the time has run out.

SCBA is indispensable, but it is more complex to use than other types. Maintenance and training aspects are therefore especially important.

25.16.10 Escape breathing apparatus

A particular type of SCBA is that provided for escape. Such escape BA is intended for use over a short duration, typically less than 10 min, and should be used for this purpose only.

25.16.11 Air quality standard

There are air quality standards which apply to air supplied to any form of air-supplied RPE. Standards are given in BS 4275: 1974 and in HS(G) 53, Appendix 4. The latter states that: the air supplied should contain not more than 5 ppm of carbon monoxide and 500 ppm of carbon dioxide, with other impurities kept to a minimum; the air should be comfortable, being in the temperature range 15–22°C and with relative humidity no higher than 85%; and the air flow capacity should be a minimum of 120 l/min per person.

25.16.12 Selection of RPE

The procedure for the selection of a suitable RPE described in HS(G) 53 is a two-stage one. The first stage involves selection on the basis of the contaminant concentration and the second involves selection on the basis of work-related and personal factors.

The guide gives a set of charts formulated in terms of the maximum multiple of the occupational exposure limit for which a particular RPE is suitable. For example, the suitabilities of full face mask respirators for dusts and other particulates are shown as multiple values of about 5, 13 and 800 for filter classifications P1, P2 and P3, respectively. There are separate charts for respirators for gases and vapours, respirators for dusts and other particulates, and for simple compressed air-supplied and fresh air hose equipment.

In selecting a respirator, account should be taken of the suitability of the filter for the particular gas or vapour and of the time until 'breakthrough', when the filter becomes ineffective.

Work-related factors which need to be taken into account in the second stage of selection include the length of time for which the RPE is to be worn, the physical work rate, and the needs for mobility, visibility and communication.

Personal factors include medical fitness, face shape and size, facial hair and the use of spectacles. A worker should not be subjected to additional health risks by virtue of wearing an RPE. Persons with a respiratory disorder may find difficulty with respirators which rely on lung power to draw air through the filter.

A face mask should achieve a good fit to the face. Procedures for checking face fit are given in HS(G) 53, Appendix 5. A beard or even stubble is liable to prevent a good fit to a face mask. Where there is immediate danger to life or health, a wearer with facial hair should be provided with an alternative type such as a hood, blouse or air-fed suit.

For a wearer of spectacles, the side arms tend to interfere with the seal of a full face mask and an alternative should be used such as a hood or blouse. However, spectacles worn inside these may mist over or become dislodged. Spectacles should not be worn, therefore, where the wearer would be in immediate danger to health if he removed the equipment to adjust his glasses or would be unable to leave the contaminated area at once in case of a problem.

25.16.13 Procedures for using RPE

There should be written procedures covering the situations in which RPE should be used and the actual use of the equipment, and the use should be integrated in the permit-to-work system.

The use of RPE is liable to involve a degree of discomfort and the periods for which it is required to be worn should be set with this in mind.

For a respirator, an estimate should be made of the duration of the protection provided by the filter cartridge used.

The equipment should be used in accordance with the manufacturer's instructions. It should be checked before use and should not be used if it has not been cleaned or is defective. Equipment which relies on a face seal should be given a fit test on each occasion it is used.

Where the atmosphere in an area is immediately dangerous to life or health, only BA should be used. There should be continuous supervision of the wearer from outside the area of hazard. Either the wearer should be kept under continuous observation or should be in communication with the person supervising. Rescue equipment should be available.

Where contamination of the RPE is likely to occur due to dust or other substances hazardous to health, facilities for decontamination should be provided at the exit from the contaminated area, so that the spread of such substances is minimized.

25.16.14 Maintenance of RPE

There should be a system of records for RPE covering its storage and maintenance.

RPE for immediate use should be clean and free of defects before being put into storage and should be segregated from equipment awaiting maintenance. There should be an adequate stock of spares for items such as filters, head straps and batteries.

The maintenance required includes cleaning, disinfection, examination, repair and testing. HS(G) 53 gives details of good practice in maintenance and, in Appendix 6, of examination and testing.

25.16.15 Training for RPE

Persons involved in the use of RPE should be given suitable training. Management should have an appreciation of RPE, its applications, selection, use, maintenance and limitations. Wearers should be trained in the wearing and use of the equipment and its limitations. Maintenance personnel should receive training in the maintenance, repair and testing of the equipment.

Training should be both theoretical and practical. The former should include: the hazards of contaminants and asphyxiation and the use of RPE to control exposure; the operation, performance and limitations of the equipment; the operating procedures and permit systems which govern its use; the storage and maintenance of the equipment; and the factors which may reduce the protection which it provides.

Practical training should cover: practice in inspecting the equipment before use; obtaining a good fit to the face, where applicable; putting the equipment on, wearing it and removing it; cleaning it after use; storing it; and replacing parts such as filters and cartridges.

Training is particularly important for the types of RPE which are more complex and are used in atmospheres immediately dangerous to life or health such as SCBA.

25.17 Rescue and First Aid

Effective rescue and first aid arrangements are essential in the process industries.

The Factories Act 1961, Section 61, and formerly the The Chemical Works Regulations 1922, Sections 6–14, contain various provisions for rescue and first aid.

The responsibility for the provision of these services should be clearly defined. There are some features, such as rescue equipment, which might, in principle, come under either the safety, the fire or the medical department.

All rescue and first aid equipment should be located with care and properly maintained. Personnel should be fully trained in its use.

25.17.1 Rescue

An account of general rescue methods is given in *The Light Rescue Handbook* by the Ministry of Defence (MoD, 1989a) (the *MoD Rescue Handbook*). Rescue from confined spaces is treated in *Recommendations to Facilitate Rescue from Confined Spaces* (EEUA, 1962 Doc. 12). A further account is given by Walters (1977).

There should be a rescue system which is capable of handling all reasonably foreseeable situations which may arise on a process plant. Frequently this function is performed by the works fire services, supplemented if necessary by the local authority fire services.

Rescue apparatus such as stretchers should be provided at strategic points.

Arrangements for rescue are also part of certain routine tasks such as entry into vessels or confined spaces and of some special operations such as hot tapping.

The *MoD Rescue Handbook* is oriented to rescue tasks arising from both natural and man-made disasters such as earthquakes and hurricanes and road and rail crashes. It deals with: the aims of rescue; the organization of the rescue team; the responsibilities of the team leader; personal and rescue equipment; searching for casualties; the five stages of rescue (surface casualties, lightly damaged buildings, likely survival points, selected debris removal and general debris clearance); recovery of the dead; recovery of valuables; building construction; levering and jacking; strutting and shoring; repairs to utilities; rope and wire bonds; knots and lashings; and thermal image cameras.

25.17.2 First aid

Regulatory requirements for first aid are given in the Health and Safety (First Aid) Regulations 1981. COP 42 First Aid at Work. Health and Safety (First Aid) Regulations 1981 (HSE, 1990) is the relevant ACOP. The relevant manual is the *First Aid Manual* of the St John Ambulance Association (1992), the official manual of the three leading organizations in the United Kingdom in this field, the St John Ambulance Association, the St Andrews Ambulance Association and the British Red Cross. First aid is also treated in *First Aid Manual for Chemical Accidents* (Lefevre, 1989 ACGIH/32) and *Industrial First Aid: Reference and Training Manual* (ACGIH, 1991/64) and by Lord Taylor (1967), Cameron (1969, 1977) and McKenna and Hale (1981). Also relevant is *Emergency Care for Hazardous Materials Exposure* (Bronstein and Currance, 1988 ACGIH/19).

The requirements of the First Aid Regulations are largely contained in Regulation 3. This requires an employer to make provisions for first aid by providing suitable equipment and facilities and by appointing suitable persons. These appointed persons have to possess a first aid certificate from an organization recognized for this purpose by the HSE and receive refresher training at specified intervals.

The ACOP deals under Regulation 3 with: different work activities needing different provisions; the applicability of, and provision of first aider cover for, situations when access to treatment is difficult, employees work away from employer's premises or employees of more than one employer work together; provision for persons other than an employer's own employees and for trainees; first aid equipment and facilities, first aid boxes and kits, travelling first aid kits, supplementary equipment, first aid room and equipment; suitable persons; criteria for deciding adequate and appropriate provisions for first aiders; number of employees and appointed persons; the recruitment and selection of first aiders; appropriate training for first aiders; access to skilled advice; recording first aid treatment; approval of first aid courses and qualifications; refresher courses; first aid training where specific hazards exist; emergency first aid training; first aid trainers and examiners; first aid examinations; and training of first aid lay trainers.

The number of first aiders required is specified in the ACOP as a minimum of 1 per 50 employees, a figure which applies to low risk situations. In hazardous situations, the employer should assess whether a higher proportion of first aiders is required.

Subjects to be included in the syllabus for first aid training given in the ACOP include (1) resuscitation, (2) treatment and control of bleeding, (3) treatment of shock, (4) management of the unconscious casualty, (5) contents of first aid boxes and their use, (6) purchasing first aid supplies, (7) transport of casualties, (8) recognition of illness, (9) treatment of injuries to bones, muscles and joints, (10) treatment of minor injuries, (11) treatment of burns and scalds, (12) eye irritations, (13) poisons, (14) simple record keeping, (15) personal hygiene in treating wounds with reference to hepatitis B and human immunodeficiency virus (HIV) and (16) communication and delegation in an emergency.

It is necessary to have a first aid system which can deal with the types of injury likely to be encountered on the plant, and where there are special hazards, first aiders should also receive additional training in respect of these. Normally first aiders in process plants are drawn from the process and maintenance personnel.

First aid equipment which should be provided includes first aid boxes and resuscitation apparatus. There should also be showers and eye wash equipment to deal with injuries from corrosive chemicals.

Showers are effective provided they are used, but there are certain practical problems. Measures need to be taken to ensure that the water supply is not frozen or turned off at a hand valve. And the reluctance of workers to make use of showers when fully clothed may have to be overcome by drills.

Guidance on first aid for eye injuries is given in *Protection of the Eyes* (CIA, 1990 RC22). Eye wash equipment includes eye wash fountains, pre-packed sterile washes, and eye wash bottles. The last two are a last resort, and are not supported by the ACOP.

Eye injuries from corrosive chemicals should preferably be dealt with by irrigation with water, using plenty of water and continuing for a long time. If sterile washes or eye wash bottles are used, they should contain an adequate volume. The CIA recommends, for example, for these two types of wash volumes of at least 500 ml and 1 l, respectively.

Information is available also on first aid for particular chemicals. Materials safety data sheets may include such information. The *CIA Codes of Practice for Chemicals with Major Hazards* and related publications give guidance on first aid.

In some situations there is a danger that the first aider may himself be injured, and precautions should be taken to ensure that this does not happen. Cases mentioned in the ACOP include casualties from electric shock, chemical burns and gassing. It states that in a case of electric shock, the current should be switched off before the casualty is touched or, if this cannot be done, the first aider should stand on dry insulating material and free the casualty from the electrical source with a wooden or plastic implement. Where the casualty has a chemical burn, the first aider should avoid contaminating himself with the chemical. With a casualty who has been gassed, the use of suitable protective equipment is advised.

25.18 Notation

Section 25.7

Subsection 25.7.3

A	area of opening (m^2)
Q	volumetric air flow (m^3/s)
V	inward superficial air velocity (m/s)

Subsection 25.7.4

A	face area of hood (m^2)
L	length of hood (m)
V	capture velocity at distance X (m/s)
V_{o}	superficial velocity at face of hood (m/s)
W	width of hood (m)
X	distance from hood (m)
α, β	indices

Subsection 25.7.7

A_{f}	free area of discharge (m^2)
C_{d}	coefficient of discharge
K	constant
Q	volumetric flow (m^3/s)
V_x	centre line velocity at distance X (m/s)
X	distance along centre line (m)

Section 25.9

A, B, C	constants in the Antoine equation
M	molecular weight
p_i	partial pressure of component i
p°	vapour pressure
p_i°	vapour pressure of component i
P	total pressure
T	absolute temperature
x_i	concentration of component i (mole fraction)
ρ_{g}	density of gas

Accident Research

Contents

Accidents in chemical plants may harm the process, the personnel or both. Research on accidents is relevant, therefore, both to accidents which result in property damage and those which cause personal injury.

Accident research as a discipline tends to concern itself primarily with those accidents in which people are involved. It is primarily concerned, therefore, with injury to personnel. But it does involve the study of the total accident situation. Often it is a matter of chance whether this situation hazards the process or the people. Clearly accident research is closely related to work in other fields such as human factors and, in particular, human error.

Accounts of accident research include *Occupational Accident Research* (Kjellen, 1984), *Information Processing and Human-Machine Interaction* (Rasmussen, 1986), *Individual Behavior in the Control of Danger* (A.R. Hale and Glendon, 1987) and *Human Error* (Reason, 1990). Many of the classic papers in the field are given with commentary in the collection *Accident Research, Methods and Approaches* (Haddon, Suchman and Klein, 1964).

Much work on the subject is concerned with areas which are not of prime interest here, such as accidents to children, accidents in the home and traffic accidents.

In addition to work on personal accidents, it is convenient to deal here briefly with some principal research programmes on, and test sites for, major hazards.

Selected references on accident research are given in Table 26.1.

26.1 General Considerations

The development of accident research has shown that there are a number of serious pitfalls in the investigation of accidents. There is a tendency for a particular feature to be studied as a possible cause of accidents and there is frequently a bias in favour of this feature. Often no information is given on any work with a control group. This situation was contrasted with that in medical work in a classic paper by Gordon (1949), who suggested that the approach taken in epidemiology is applicable to accident

Bull and Strachan (1992); CMI (1992) research. The epidemiology model, which is described below, has been widely used in work on accidents.

26.2 Definition of Accidents

The question of what actually constitutes an accident is worth at least brief consideration. It has been considered by Suchman (1961), who distinguishes three defining characteristics: (1) degree of expectedness, (2) degree of avoidability and (3) degree of intention. An event is more likely to be classed as an accident if it is unexpected, unavoidable and unintended.

Other secondary characteristics are (1) degree of warning, (2) duration of occurrence, (3) degree of negligence and (4) degree of misjudgement. Classification of an event as an accident is more probable if it gives little warning and happens quickly and if there is a large element of negligence and misjudgement.

It is suggested, however, by Suchman that as knowledge increases an event is more likely to be described in terms of its causal factors and less likely to be classified as an accident.

26.3 Classification of Accidents

Much work on accidents is concerned with accident statistics. These statistics are based on an accident classification of some kind. Accident classifications are therefore quite important. Unless a classification contains a particular category which is of interest, there is no means of retrieving information on it.

There are a number of standard accident classifications. These include the classification used by the HSE in its annual *Health and Safety Statistics,* published in the *Employment Gazette* and that used in the annual *Yearbook of Labour Statistics* published by the International Labour Office. Relevant standards are the American National Standards Institute (ANSI) Z16 series.

26.4 Causes of Accidents

The main aim of accident research is to understand accidents so that they can be prevented. The attempt to understand an accident is often equated with the search for its cause.

The concept of the cause of an accident, however, has become somewhat discredited. In accident investigation an administrative requirement to report a single cause usually does not do justice to the complexity of the situation. In accident research, there has been much criticism of work which isolates and overemphasizes a particular factor.

It is more acceptable, therefore, to regard an accident as arising from a particular combination of factors rather than from a single cause. There is thus a tendency to consider relationships between variables rather than causes.

While this approach is undoubtedly correct in general, the danger is that the accident situation then appears incredibly complex and the attempt to understand it, hopeless. The work of Rapoport (1961) provides something of an antidote to this. As he points out, the scientific technique of isolating the influence of one variable by controlled experimentation has been enormously fruitful and it should not be lightly abandoned.

Rapoport distinguishes between specific and non-specific causes both in the field of disease and in that of accidents. Progress in control of disease has come both from specific factors (e.g. vitamins), and non-specific ones (e.g. public hygiene).

Although much work on accidents is of a statistical nature, the value of the descriptive approach should not be underestimated. The work of Sheldon (1960) on accidents to old people involving falls has been cited as a classic in this regard.

The investigation of accidents is dealt with in Chapter 27, which describes an illustration of an accident investigation given by Houston (1971). The investigation does not aim to find a single cause, but rather to discover the many factors which contribute to the accident.

26.5 Accident Models

Recognition of the complexity of accidents has led to the development of a number of accident models. A particular model of the accident situation is that derived from epidemiology, following the work of Gordon (1949). The factors involved in an accident are defined as follows: (1) host, (2) agent and (3) environment. Although this model derives from medical work, it has been applied in many other fields.

The main agent in an accident is usually some form of energy which inflicts physical damage. Accidents not accounted for by energy have as an agent a toxin, which is the other principal agent.

A distinction is made between an agent and the vehicle for that agent. In an accident from a falling spanner, the agent is energy and the vehicle is the spanner.

Another model of the accident situation, which draws both on Gordon's model this one and on fault trees, is that developed by Houston (1971, 1977). In this model a driving force is activated by a trigger so that through some form of contact process it causes injury or damage to a target.

A second group of models is based on the concept that it is possible to define for a system a 'normal operating state', and hence deviations from that state, and that such deviations are associated with danger. The models of G.L. MacDonald (1972) and Kjellen (1983) exemplify this group. Figure 26.1 by Hale and Glendon illustrates MacDonald's model.

A third group of models is based on human information processing. They include those of Surry (1969b), A.R. Hale and Hale (1970) and A.R. Hale and Glendon (1987). The models of Surry and of Hale and Hale are both formulated in terms of perception, cognition and physiological response, or action. That of Surry is in two parts, the first dealing with the danger build-up and the second with the danger release or emergency. Each part has a similar structure, that for danger build-up being:

Perception	Warning of danger build-up? Perception of warning?
Cognitive process	Recognition of warning? Recognition of avoidance mode? Decision to attempt to avoid?
Physiological response	Ability to avoid?

Another important model in this group is that of Rasmussen (1986) based on the distinction between knowledge-based, rule-based and skilled activity. As characterized by A.R. Hale and Glendon (1987), following Leplat (1985), these three levels of function correspond at the cognitive level to interpretation, identification and

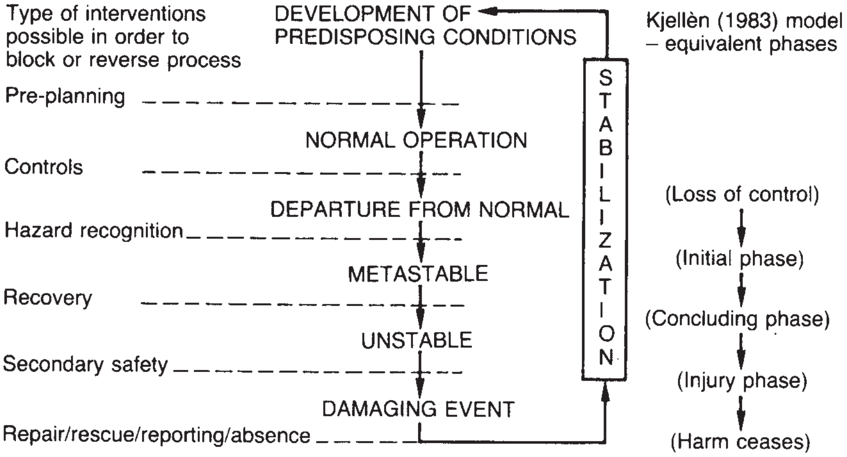

Figure 26.1 *Scheme illustrating accident models of MacDonald and Kjellen (A.R. Hale and Glendon, 1987 (reproduced by permission of Elsevier Science Publishers); after G.L. MacDonald (1972) and Kjellen (1983))*

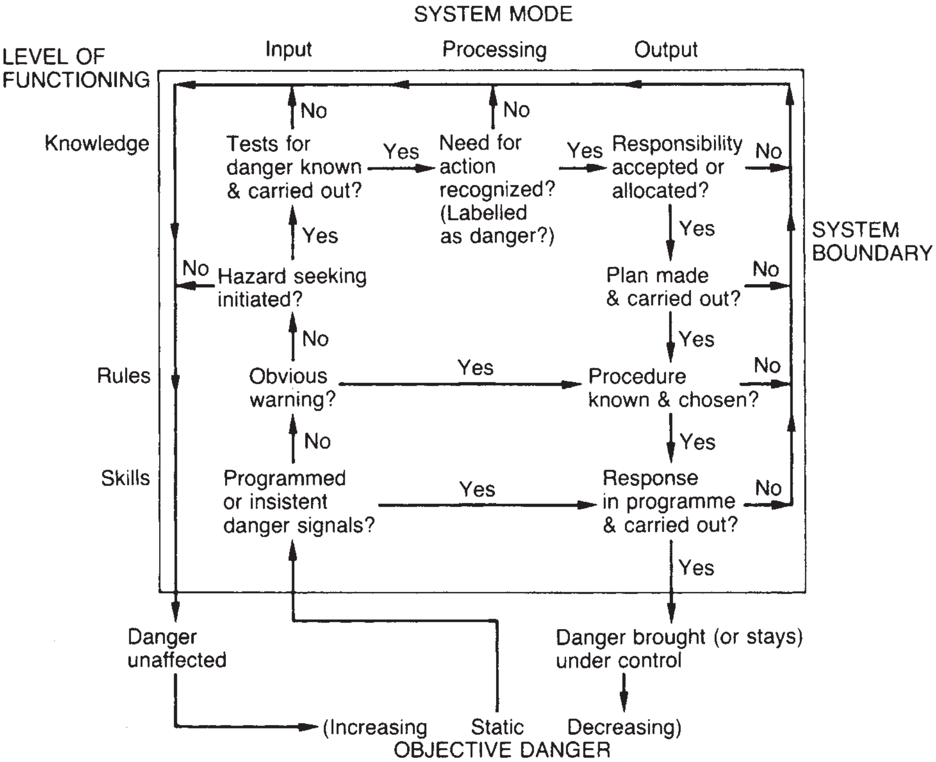

Figure 26.2 *'Behaviour in the face of danger' accident model (A.R. Hale and Glendon, 1987 (reproduced by permission of Elsevier Science Publishers))*

observation/activation and in terms of behaviour to evaluation/task definition, procedure and execution, respectively. The Rasmussen model is described in more detail in Chapter 14.

A model which draws on the foregoing models is the 'behaviour in the face of danger' model of A.R. Hale and Glendon (1987) shown in Figure 26.2. This has the general structure of Rasmussen's model but amplifies it using stages drawn from Surry's model. The model shows what has to occur if the danger is to be averted. In other words it is a prescriptive model. The text by Hale and Glendon is an exploration of the factors affecting this behaviour and of the extent to which the behaviour is likely to lead to a successful outcome.

Other models, reviewed by Mill (1992), include those of the Institut National de Recherche sur la Securite (INRS) in France, the Occupational Accident Research Unit (OARU) in Sweden and the International Loss Control Institute (ILCI) in Georgia. The INRS model represents an accident as a deviation in the normal work situation and has a fault tree structure. The OARU model is intended for investigation of single person injuries and represents the accident as a chain of deviations. The ILCI model is a five layer model which progresses from basic causes in management deficiencies and progresses through to the immediate causes.

A number of other accident models, drawn mainly from the literature on process safety rather from than the psychological literature, are described in Chapter 2.

The contribution of human factors, and in particular the work situation, to accidents is considered in Chapter 14.

26.6 Accident Proneness Plan

The idea that certain people are accident prone is quite an ancient one. In fact the accident prone individual is a classic comic character. Accident proneness as a concept in accident research, however, dates from the classic paper of Greenwood and Woods (1919) of the Industrial Fatigue (later Health) Research Board on accidents to industrial workers. The interwar period saw a number of publications on various aspects of accident proneness by investigators at the boards, in particular those by Newbold (1926) and E. Farmer and Chambers (1939).

The fact that an individual has an above-average number of accidents does not in itself necessarily mean anything. It can be shown from the Poisson distribution that on the basis of chance alone there will be individuals who have quite large numbers of accidents. It is accidents that cannot be explained in this way which have given rise to the concept of accident proneness.

The terminology associated with the problem of the variation in accident rate between individuals tends to be a source of confusion. Accident repetition describes the observed fact that an individual has suffered an above-average number of accidents and that this is statistically significant. Accident proneness refers to a higher than average susceptibility to accidents which arises from psychological factors and tends to be permanent. Accident liability is a broader term describing an above-average accident rate which may be due to many factors, including work situations and personal stresses and which tends to be temporary. It is emphasized, however, that authors in this field have been criticized (e.g. Arbous and Kerrich, 1953) for lack of definition and consistency in their use of terms.

Greenwood and Woods (1919) showed that some industrial workers have more accidents than would be expected from chance alone, using the Poisson distribution. In other words, they established the fact of accident repetition. They offered as an explanation a theory of unequal liability to accidents, but did not themselves go so far as to suggest one of accident proneness.

These findings were confirmed in further work by Newbold (1926), who suggested that there might be a psychological explanation for them.

The phenomenon of accident repetition has subsequently been confirmed by numerous workers, many of whom have gone beyond the original investigators' more conservative conclusions to develop a theory of accident proneness.

An activity which has been studied particularly is driving (e.g. E. Farmer and Chambers, 1939; Tillman and Hobbs, 1949; Cresswell and Froggatt, 1963; L. Shaw and Sichel, 1971). Farmer and Chambers investigated driver accidents and concluded that accident proneness was an established fact. Yet the only significant correlation obtained between accident rate and individual characteristics was in tests on aesthetokinetics rather than on personality.

The concept of accident proneness has been severely criticized by Arbous and Kerrich (1953), while Suchman and Scherzer (1960) have given an evaluation of its status. The conclusion drawn is that accident proneness is difficult to establish, but that accident liability is a more acceptable concept. Accident liability may be connected with such factors as the work situation or stress, is usually temporary and does not depend primarily on personality traits.

The investigation of accident liability may in fact be a fruitful way of reducing accidents. An example is the work of Viteles at the Cleveland Railway Company (Arbous and Kerrich, 1953). He identified 50 individuals with accident liability and, taking a clinical approach, analysed the cases individually. The prime causes of accident liability which he identified are shown in Table 26.2. Various measures, including medical treatment, systematic instruction and increased supervision, were taken. As a result, the accident rate was almost halved. This approach requires, of course, a great deal of effort. In a further review, Cazamian (1983) takes it as established that certain individuals do have repeated accidents, but treats this as an acquired susceptibility rather than an inherent predisposition. Individuals may enter and leave the group of accident repeaters. Some factors can be identified which increase the susceptibility to repetition. Accidents are more common among young

Table 26.2 *Prime causes of accident liability in an industrial investigation after Viteles*

Prime cause	*Percentage of cases*
Faulty attitude	14
Failure to recognize potential hazard	12
Faulty judgement of speed and distance	12

workers than mature adults, among those who lack training and experience and among those who are ill.

26.7 Human Error

Work on the psychology of human error is exemplified by the work of Reason, described in *Human Error* (Reason, 1990) and in other work (Reason, 1977, 1979, 1986, 1987a,b, 1991). One aspect of this work is the recognition that many accidents occur due to absent-mindedness and that, whilst in the vast majority of cases the consequences of such absent-mindedness are not serious, in a proportion of cases they are.

26.8 Risk-taking

Some accidents occur because people consciously take risks. In a given case the risk is generally judged to be small, but it is a finite risk nevertheless, and occasionally such behaviour results in an accident.

26.8.1 Risk homoeostasis definition? Maintaining an acceptable equilibrium

It is sometimes argued, particularly in relation to activities such as car driving, that there is a certain level of risk which people accept and that if physical measures are taken to reduce this risk, such as improved traffic engineering or vehicle crash resistance, the effect of these measures is cancelled by changes in individual behaviour so that the end result is that the risk remains the same.

A formal theory of risk homoeostasis has been given by Wilde (1978, 1982a,b, 1985, 1988). According to this theory, the loss due to road accidents per unit time is the output of a closed loop process in which the set-point is the target level of risk.

The concept of risk homoeostasis does not imply that all measures to improve road safety are doomed to failure. A distinction is drawn between physical and motivational measures. The latter act to influence the target level of risk and can indeed be effective. The theory is pessimistic, however, on the effectiveness of non-motivational measures.

A critique of the theory of risk homoeostasis has been given by McKenna (1975, 1985).

The measure of effectiveness in this debate is important. It is common ground that physical measures can reduce the accident rate per unit distance covered. It is argued, however, by Wilde that they have little effect in reducing the accident rate per unit driving time.

26.8.2 Risk judgement

Another type of situation which can also lead to accidents occurs when there is misjudgement of the risk. In relation to such accidents, a distinction has been drawn by J. Cohen, Dearnaley and Hansel (1956) between judgement and capability. They investigated the ability of bus drivers to drive a bus through a narrow opening. The work distinguished between lack of success due to misjudgement of the width of the opening and inability to drive the bus through it. In some cases, a generally capable driver would try to drive through an opening which was narrower than the bus itself. Obviously these two causes of failure have different implications for training.

An undesired outcome may occur either because the actions do not go as planned or because the plan is inadequate. It is with the first of these causes, 'actions-not-as-planned', that the work is concerned.

Reason conducted an experiment in which 35 subjects kept a diary of their actions-not-as-planned over a 2-week period. The classification of these errors and the proportion of errors in each main class are shown in Section A of Table 26.3, while Section B gives specific examples.

The classification is based on a computer program model of human activity. The discrimination errors are failures in classification of the inputs. The program assembly errors involve use of inappropriate subroutines. The test failures refer to failure to check on the progress of a sequence or to selection of an incorrect branch. The subroutine failures involve insertion into, omission from or mis-ordering within a sequence. The storage failures are forgetting or mis-recalling plans and actions.

Reason outlines a number of concepts which may help to explain the results obtained. Skilled performance involves switching between open and closed loop modes of control. Typically a large part of a task or series of tasks may be carried out under open loop control, but it is necessary to revert to closed loop control at certain critical decision points. A failure to make the necessary switch at the appropriate moment is likely to result in an error.

In some cases, a motor programme sequence shares a common subsequence with another sequence, but there is a critical decision point where it diverges from this second sequence. This is a situation particularly likely to lead to error.

Some motor programmes appear to acquire a strength which causes them to be activated contrary to the current plan. This is likely to apply particularly to a programme which has been used frequently or recently.

Reason goes on to propose certain hypotheses concerning such errors. He suggests that test failures occur when a critical decision point is reached while still under open loop control and where the strengths of the two motor programmes are markedly different, and that if an error occurs it is likely to involve the unintended activation of the strongest motor programme beyond the node.

Another hypothesis is that storage failures in the execution of a sequence are associated with some counting mechanism in the motor programme which checks off the actions as they are performed. It appears that on occasion this counter is unable to distinguish between planned actions and others which are similar in duration and degree of activity, so that if an interruption occurs the programme resumes at the wrong point.

In tasks such as maintenance, a large proportion of the errors involve omission. The practical application of the work described points to the provision of memory aids which assist the worker to remember which stage of the sequence he has reached.

This work leads to the distinction made by Reason (1990) between slips, lapses and mistakes. In essence, a slip is either an error in implementing a plan or an unintended action, a lapse is an error in which the intended course of action is not executed due to a failure of memory, and a mistake is an error in establishing the correct course of action.

26.9 Social Factors

The effect of physical features of the environment on accidents is readily appreciated. Less obvious, but often as important, is that of its social aspects. Social factors are effective in reducing accidents (1) if the socially approved

Table 26.3 *Classification and examples of actions-not-as-planned (after Reason, 1979)*

A Proportion of errors in each class

1. Discrimination failures (11%)
    - 1.1 Perceptual confusions (objects confused are physically similar)
    - 1.2 Functional confusions (objects confused are functionally similar)
    - 1.3 Spatial confusions (objects confused are close together)
    - 1.4 Temporal confusions (time is misperceived and inappropriate actions initiated)
2. Program assembly failures (5%)
    - 2.1 Behavioural spoonerisms (program elements are reversed)
    - 2.2 Confusions between currently active programs
    - 2.3 Confusions between ongoing and stored program
3. Test failures (20%)
    - 3.1 Stop-rule overshoots (actions proceed beyond intended end-point)
    - 3.2 Stop-rule undershoots (actions cease before their intended end-point)
    - 3.3 Branching errors (initial sequence of actions is common to two different routines and wrong branch is taken)
    - 3.4 Multiple side-tracking (subject is apparently diverted from original intention by series of minor side-steps)
4. Subroutine failures (18%)
    - 4.1 Insertions (unwanted actions are added to a sequence)
    - 4.2 Omissions (necessary actions are left out of a sequence)
    - 4.3 Mis-ordering (actions carried out are correct but in wrong order)
5. Storage failures (40%)
    - 5.1 Forgetting previous actions
    - 5.2 Forgetting discrete items in plan
    - 5.3 Reverting to earlier plans
    - 5.4 Forgetting the substance of plan

B Examples of actions-not-as-planned

1.1 ‘I put my shaving cream on my toothbrush’
1.2 There were two objects before me on the draining board: a cloth and a container of cleaning fluid which I normally keep in the bathroom but had brought into the kitchen to use. I decided to return the cleaning fluid to its place in the bathroom, but set off with the cloth in my hand instead’
1.3 ‘I turned on my electric fire instead of my transistor radio which was on the floor near it’
1.4 ‘When I got up on Monday morning, I found myself putting on Sunday’s sweater and jeans instead of my working clothes’
2.1 ‘I unwrapped a sweet, put the paper in my mouth and threw the sweet in the waste paper basket’
2.2 ‘My office phone rang. I picked up the receiver and bellowed “Come in” at it’
2.3 ‘I fetched a box of matches to light the electric fire’
3.1 ‘I brought the milk in from the front step to make myself a cup of tea. I had put the cup out previously. But instead of putting the milk into the cup, I put the bottle in the fridge’
3.2 ‘I was just about to step into the bath when I discovered that I still had on my underclothes’
3.3 ‘I intended to drive to Place X, but then I “woke up” to find that I was on the road to Place Y’
3.4 ‘I went upstairs to sort out and fetch down the dirty washing. I came down without the washing having tidied the bathroom instead. I went upstairs again to collect the washing, but somehow got side-tracked into cleaning the bathroom. I forgot all about the washing until I returned to the kitchen where the washing machine was pulled out in readiness’
4.1 ‘I came out of the sitting room in the daytime and flicked on the light as I left the room’
4.2 ‘I filled my electric kettle with water, plugged the lead into the back of the kettle and switched on the wall socket. When the kettle failed to boil I discovered I had not inserted the plug into the wall socket’
4.3 ‘Sitting in the car about to leave work, I realized I had put the car into gear and released the handbrake without first starting the engine’
5.1 ‘I started to walk home and had covered most of the distance when I remembered I had set out by car’
5.2 ‘I had intended to post a letter while I was out shopping but when I got home I found I still had the letter in my pocket’
5.3 ‘I decided to make some pancakes for tea. Then I remembered we didn’t have any lemons so I decided not to bother. Five minutes later I started getting together the ingredients for pancakes, having completely forgotten my change of mind’
5.4 ‘I went upstairs to the bedroom, but when I got there I couldn’t remember what I came for’

behaviour minimizes accidents and (2) if individuals adhere to that behaviour.

The effect of individual deviation from the approved standard has been considered by Paterson (1950). The basic argument may be illustrated by reference to Figure 26.3, which shows on the horizontal axis the strength of group conditioning, decreasing away from the origin, and on the vertical axis the number of people who exhibit that degree of conditioning. It is assumed that the optimal type of behaviour which minimizes accidents corresponds to that given by the highest degree of group conditioning. Curve A represents a highly disciplined society with a low mean. The

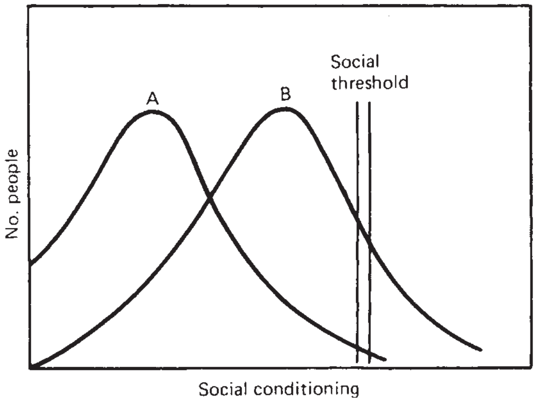

Figure 26.3 *Effect of social factors in behaviour affecting accident rates*

discipline may be due to the harshness of nature or to the social and political system. Curve B corresponds to a less disciplined society with a high mean. Also shown in the figure is the social threshold, which is the point at which the deviation from optimal behaviour results in marked increase in accidents. If the socially approved behaviour is optimal in reducing accidents, then clearly there will be more accidents in a society where there is greater individual deviation.

It cannot be assumed, however, that social pressures always tend to reduce accidents. On the contrary, the expectations of a small peer group may well run in the opposite direction and it is often this influence which is strongest. Thus the behaviour laid down in company safety procedures may be assumed to reduce accidents. But certain types of peer group pressure may increase them. Examples are neglect of permit-to-work procedures, failure to wear protective clothing and horseplay among apprentices.

26.10 Accident Prevention

Measures to prevent energy causing injury or damage may be based on the following four principles: (1) reduction of the energy available, (2) modification of the release of the energy, (3) separation by distance and (4) separation by a barrier.

Accident models such as that of Houston (1971, 1977) are useful in analysing potential accident situations and identifying appropriate preventive measures.

Accident prevention measures are not infrequently brought in without adequate understanding of the problem and without sufficient evaluation. Such measures are likely to be relatively ineffective. There is a tendency to believe that they must be better than nothing. But often they are an obstacle to progress, because they give the impression that something is being done about the problem.

This contrasts with the very thorough trials which are made on the effectiveness of drugs in countering disease. Proper evaluation is necessary for proposed accident prevention measures also. This again is in line with the more quantitative approach which characterizes loss prevention. The practical application of this principle is seen in the work of the Road Research Laboratory on the evaluation of road safety.

26.11 Safety Training

Most prescriptions for the prevention of accidents lay much emphasis on training, and rightly so. It is necessary, however, that the training be effective.

A study of the effectiveness of safety training by A.R. Hale (1984) found relatively little previous work on the topic. The essential finding of the study is that, unless effort is invested in analysing the problem and defining the training requirements, the training is liable to be ineffective and to get the activity a bad name. The author quotes the *Robens Report* (Robens, 1972) which states: 'Most people are agreed that safety training is of vital importance. There is no unanimity about what in practice should follow from that proposition'.

The requirements for training found in the legislation by the author are patchy, with power presses governed by a detailed training schedule whilst injection moulding machines have no specific provision. There are requirements of competence for drivers of coal mine face conveyors, but not for those of fork lift trucks.

26.12 Major Hazards Research

Research on major hazards is described throughout this book, particularly in Chapters 15--17 on emission and dispersion, fire and explosion. The treatment here is confined to an indication of some of the major experimental programmes and the sites where they have been conducted.

Large-scale experimental trials on dense gas dispersion have been conducted in the United Kingdom at Porton Down (Picknett, 1981a--c), Maplin Sands (Puttock, Colenbrander and Blackmore, 1983) and Thorney Island (A.G. Johnston, 1984, 1985; McQuaid, 1984b) and in the United States at China Lake, California (Ermak *et al.,* 1983), and at the Nevada Test Site (Koopman and Thompson, 1986).

Large-scale trials on fire phenomena have been performed at the Health and Safety Executive's (HSE) Explosion and Flame Laboratory at Buxton. This includes work on pool fires, fireballs and engulfing fires (A.F. Roberts, 1987; McQuaid, 1991).

Other work on fires has been done at Shell sites and at the British Gas sites at Fauld and at Spadeadam in cooperative projects involving a number of companies, including in particular trials on jet flames and on fire insulation. The Maplin Sands work on dense gas dispersion included trials on vapour cloud fires.

Explosion experiments on a large scale include those on condensed phase explosives such TNT and other military explosives at the Aberdeen Proving Ground (W.E. Baker, 1973) and other military sites. Buildings and equipment have been subjected to condensed phase explosions in Nevada (Glasstone and Dolan, 1980). Large-scale work on vapour cloud explosions has been done in the Netherlands at TNO (van Wingerden, 1989a).

In addition to the HSE laboratories just described other European centres include the Shell Thornton Research Centre (TRC) (D.C. Bull and Strachan (1992), the British Gas laboratories at Solihull, Loughborough and Killingworth and sites at Fauld and Spadeadam (Clerehugh, 1991), the Prinz Maurits Laboratory of TNO in the Netherlands (Groothuizen, 1988) and the Christian Michelsen Institute at Norway (CMI, 1992). UK centres specializing in fire include the Fire Research Station at Borehamwood and the Department of Fire Safety Engineering at Edinburgh University.

The European Community has had a wide-ranging programme of work on major hazards, particularly dense gas dispersion and vapour cloud explosions. This work is described by the Commission of the European Communities (CEC, 1989) and by Storey (1992). The commission maintains the Joint Research Centre QRC) at Ispra, Italy, which includes the European Laboratory for Structural Assessment (ELSA).

In the United States, research in many areas of process safety is conducted at the Mary Kay O'Connor Process Safety Center at Texas A&M University. In 2004, the Center had active research projects on Abnormal Situation Management, Aerosol Experiments and Modeling, Flammability Measurements and Modeling, Incident Database (Development, Analysis and Causation), Inherently Safer Design, Chemical Safety Assessment, Quantitative Risk Assessment, Reactive Chemicals (Thermal Analysis, Calorimetric Measurements, and Modeling) and Safety Performance Measurement Systems and Safety Metrics.

The work of many of these research centres is described in other chapters, mainly in Chapters 15--17.

27

Information Feedback

Contents

The feedback of information about incidents, accidents and failures, and about the performance of preventive measures, is a crucial aspect of the management system.

Some aspects of information feedback are considered here. Others are dealt with in other chapters, in particular Chapters 6, 8, 21 and 28.

Selected references on information feedback are given in Table 27.1.

27.1 The Learning Process

It is clearly essential that the industry should learn from its mistakes so that as far as possible it avoids repeating them.

This need to learn has long been recognized and is dealt with by a system of accident reporting and investigation.

On the basis of this information, accident statistics are compiled and an attempt is made to determine the trend in safety performance. Case histories are obtained and general lessons are derived. These lessons give rise to changes of practice, which are often embodied in standards and codes of practice or training programmes. These results are then publicized.

This system is essentially similar at company and at national level. There are statutory requirements for the reporting and investigation of accidents. Company requirements may be confined to these or may include other incidents. Accident statistics, safety performance trends and case histories are produced, changes in practice are made and publicity is given to these at both company and national level.

The effectiveness of this approach depends very much on the way in which it is implemented. There are wide differences, for example, in the quality of incident investigation and consequently in the benefit derived from it. There is also considerable variation in the extent to which the real lessons of case histories are appreciated and applied.

There are also other weaknesses in most systems for learning from incidents. One of the most fundamental has to do with the nature of the accident process itself. An accident normally occurs only when a number of conditions are fulfilled. If some of these conditions are not met, there may be instead an incident or 'near miss'. In general, the ratio of near misses to accidents is several orders of magnitude. This is seen most clearly in civil aviation, which is one of the few fields where there is a requirement to report near misses. Thus, in effect, a system based on reporting only of accidents reduces drastically the amount of information from which learning can take place.

The recognition of this fact is the basis of the total loss control approach, as described in Chapter 1. With total loss control there is a requirement for the reporting not only of personal injury but also of property damage accidents.

Not all near misses, however, result in property damage. Another important category of near misses is the operational incident. The aircraft near misses just mentioned are, in fact, mainly incidents associated with excursions outside operational limits rather than with damage to equipment. The chemical industry, however, does not appear to have a mechanism for learning from operational near misses.

Another weakness of the usual approach to learning stems from the nature of the hazards on process plants. It is a characteristic of complex technological systems that they allow very little scope for learning gradually by trial and error. Instead, it is necessary to try to eliminate failures from the start.

This is the reason for the growth in reliability engineering and it has implications for the learning process. It means that attention needs to be concentrated not only on the accidents but also on the failures within the system that in a proportion of cases result in an accident. The emphasis on learning shifts then to the assessment of system reliability and to the collection of data required on equipment failure and human error.

It is not enough, however, to discover the facts about accidents. It is even more necessary to make sure this information is used. A high proportion of accidents constitutes repetitions, with only minor variations, of accidents which have already occurred elsewhere and which are well understood by the engineering profession as a whole. It is not to be expected that the individual engineer should familiarize himself with all these. But he should make it his business to become familiar with some of the exemplary case histories and their lessons. In addition, he should make use of aids such as checklists and codes of practice that embody much of this experience in the most readily usable form.

If learning is to take place, therefore, it is necessary to have both a means of obtaining information, for example accident reporting and investigation, and a means of ensuring that this information is utilized, for example, checklists and codes of practice. It is desirable for the learning process to take place at both company and national level and the measures described are, therefore, necessary at both levels.

27.2 Incident Reporting

A system for reporting accidents and perhaps other incidents is necessary at company level. The minimum system is one limited to meeting the requirements for statutory reporting of accidents.

The national reporting requirements, which are described in Chapter 3, have been extended in recent years to cover certain types of event not previously included, such as leaks.

Such statutory requirements, however, are intended to assist the national learning process. The real object of a company reporting system should be to help the company to learn. It may be appropriate, therefore, for there to be a requirement for the reporting of additional types of incident. Events likely to be of particular interest in safety and loss prevention (SLP) include:

(1) leaks of flammable materials;
(2) leaks of toxic materials;
(3) leaks and/or fires at pumps;
(4) fires/explosions on burners;
(5) storage tank collapse;
(6) malfunctions of pressure systems items (relief valves, non-return valves, vents);
(7) incidents involving trip system malfunction or disarming;
(8) incidents involving alleged operator error.

It is necessary to define carefully the level of incident that is reportable. This can be done satisfactorily at company level so that the reporting is adapted to the particular circumstances and produces useful information.

A reporting system is not of much value unless the information that it generates is utilized.

It is also appropriate here to refer again to total loss control, which involves a system both of incident reporting and of subsequent action, although in this case the emphasis is on some form of damage.

27.3 Operations Monitoring

In addition to incidents that have some physical result, such as the leakage of flammable materials or the collapse of a storage tank, there are also other incidents, such as excursions outside the specified operating conditions. These operational incidents also may constitute near misses.

The monitoring of operations from this viewpoint, however, is not well developed. The instrumentation provides trend records of selected variables and the operator records certain types of incident or excursion. These may be analysed or discussed with him by the plant manager. With the advent of process computers there is also a record of the alarm excursions of a larger number of measurements and of the operator's interventions via the computer. This information is mainly used in *ad hoc* investigations.

The Court of Inquiry on the Flixborough disaster experienced some difficulty in extracting useful information from the process instrumentation, most of which was destroyed by the explosion and the collapse of the control room. The report (R.J. Parker, 1975) suggested, therefore, that consideration should be given to the creation of a statutory requirement for the installation on such plants of a 'black box' facility such as is carried on aircraft.

This facility in aircraft is governed in the United Kingdom by the Air Navigation Order 1972, Schedule 5, which requires that certain aircraft, essentially those involved in public transport, should be equipped with a flight data and cockpit voice recording system approved by the Civil Aviation Authority (CAA). A flight data recorder system is required which records a list of specified parameters (e.g. pressure, altitude, airspeed, compass heading, pitch and roll attitudes) with a specified logging interval, accuracy and reliability. A crash-protected recorder is also required which will retain a record of these parameters in the event of aircraft crash. This is the so-called 'black box', although it is actually more like a red football in appearance. As already mentioned, a cockpit voice recorder is also a requirement.

This system, therefore, gives a complete record of the flight, including the information on maloperations and near misses, the number of which exceed actual crashes by several orders of magnitude.

The information given by the cockpit voice recorder is very useful and in crash investigations can be as important as the instrument data.

It will be apparent that the aircraft black box is in effect a system rather than a piece of hardware. It works well for aircraft where the parameters that should be specified for recording are standard, where the correct flying behaviour is well defined, and where there is a single authority that can analyse the data. Its application to chemical plant is more open to question for several reasons. Chemical plants already have a considerable amount of recording, particularly those with computers. There is much greater variation in chemical plants, both in the instrumentation and in the operation. Any analysis of the operations recorded would almost certainly be practical only at company level. Furthermore, despite Flixborough, it is not very often that the process instrumentation is destroyed.

If the object is to further the learning process at national level, it would seem more profitable to concentrate attention on a more systematic approach to the analysis of process operations in order to learn about near misses rather than to provide protected recorders which are used only to assist rare Courts of Inquiry. There would seem to be considerable scope for the operations monitoring of process plants. This might be somewhat on the lines of the replay of the aircraft flight data record, but as always any system used would have to be adapted to the rather different characteristics of chemical plants.

Nevertheless, the provision of a facility akin to the aircraft black box system is quite practical on chemical plant, particularly where there is a process computer. The main requirements for such a system are the provision of a schedule of data to be recorded, the proper maintenance of the instruments and the protection of the system against fire/explosion.

27.4 Accident Models

Accident models, which have already been considered in Chapters 2, 8 and 26, are here considered again briefly from the viewpoint of accident investigation.

Not all accident investigators find it helpful to make use of an accident model, but some do. Work on accident models for use as aids in accident investigation has been described by Benner (1985) and the Center for Chemical Process Safety (CCPS) (1992/1).

27.4.1 Logic tree models

Perhaps the most widely used form of accident model is the logic tree, this term being taken here to cover fault trees and other methods with a tree structure.

The Management Oversight and Risk Tree (MORT) of W.G. Johnson (1980), described in Chapter 2, provides a methodology for either investigating an accident or assessing a situation. MORT gives an idealized safety system represented as a logic tree containing specific control factors and general management factors. There is a text commentary that helps to identify good and bad practice.

Another logic tree method, the causal tree, derives the work of Leplat (1978a, 1987). This model resembles a fault tree, but is applied to an event that has already happened and which therefore contains no OR gates, only AND gates. Construction of the tree is guided by simple rules that specify the event chains. The aim of the method is to identify those changes that can be made to break the chain of events.

27.4.2 STEP

A model which does not have a tree structure is the Sequentially Timed Events Plotting (STEP) procedure of Hendrick and Benner (1987 ACGIH/14). The elements of the model are actors, actions and events. An actor can be a person, equipment, substance, etc., whilst an action is anything brought about by an actor, and an event is the unique combination of an actor and one action. A structured procedure is used to create a model of the accident from these elements.

27.4.3 Kletz model

Kletz states that he does not find the use of accident models particularly helpful, but does utilize an accident causation chain in which the accident is placed at the top and the sequence of events leading to it is developed beneath it. An example of one of his accident chains is given in Chapter 2. He assigns each event to one of three layers:

(1) immediate technical recommendations;
(2) avoiding the hazard;
(3) improving the management system.

In the chain diagram, the events assigned to one of these layers may come at any point and may be interleaved with events assigned to the other two layers.

It is interesting to note here the second layer, avoidance of the hazard. This is a feature that in other treatments of accident investigation often does not receive the attention that it deserves, but it is in keeping with Kletz's general emphasis on the elimination of hazards and on inherently safer design.

27.4.4 Comparative studies

A comparative study of the characteristics of three accident models as applied to accident investigation has been made by Livingstone and Green (1992). They start from the perspective that investigations are generally too biased towards technical factors and take insufficient account of root causes. They identify three accident models as potentially useful: the causal tree model, MORT and STEP.

Livingstone and Green find that the causal tree method provides little guidance on how to collect the relevant information or identify the main events involved. It deals mainly with the direct causes, or trigger events, and does not deal so well with the root causes. They view STEP as well structured, but again as being of little assistance with root causes. They see MORT, on the other hand, as excelling in the identification of root causes, but as requiring the accident sequence to be identified separately.

These authors propose a hybrid model that combines STEP and root cause analysis.

27.5 Accident Investigation

Accident investigation is described in *Professional Accident Investigation* (Kuhlman, n.d.), *Modern Accident Investigation and Analysis* (Ferry, 1988), *Learning from Accidents* (Kletz, 1988h, 1994) and *Forensic Engineering* (Carper, 1989) and by Bulkley (1967), M.E. Lynch (1973), Kletz (1979g, 1984a), Burgoyne (1981/82, 1982) and Craven (1982).

Some accounts of accident investigation are concerned essentially with in-house investigations, whilst others describe the viewpoint of the consultant investigator. The account given here starts with a consideration of the selection of the investigator, either in-house or a consultant. It continues with a review of the purposes of investigation from the perspective of a consultant and then with the organization and conduct of an investigation, basically the technical aspects, again written from the viewpoint of a consultant, although the principles are equally applicable to an in-house investigation. Next, consideration is given to some particular types of investigation. The account then considers the investigation of the deeper causes of the accident and the recommendations for prevention, written largely from the viewpoint of the in-house investigator. The section concludes by considering a number of other topics related to investigations.

27.5.1 Selection of investigator

A formal system for the appointment of an accident investigator should be part of the emergency planning in a company. The selection of an investigator is discussed by Craven (1982). The choice is of particular importance if the accident is a major disaster. In this case it will usually be necessary to appoint a multi-disciplinary team, but the team will still require a leader. Craven considers the selection of the investigator under two headings: expertise and affiliation. Professional expertise and qualifications are factors to be taken into account, but personality and investigatory experience are also important. For small accidents, an in-house investigator may often be appropriate, but for a large accident it may be preferable to call in an outsider who is free of company involvement and is perceived as more independent.

27.5.2 Purpose of investigation

The usual purpose of an investigation is to determine the cause of the accident and to make recommendations to prevent its recurrence. There may, however, be other aims, such as to check whether the law, criminal or civil, has been complied with or to determine questions of insurance liability.

The situation commonly faced by an outside consultant is described by Burgoyne (1982) in the following terms:

> The ostensible purpose of the investigation of an accident is usually to establish the circumstances that led to its occurrence – in a word, the cause. Presumably, the object implied is to avoid its recurrence. In practice, an investigator is often diverted or distorted to serve other ends. This occurs, for example, when it is sought to blame or to exonerate certain people or things – as is very frequently the case. This is almost certain to lead to bias, because only those aspects are investigated that are likely to strengthen or to defend a position taken up in advance of any evidence. This surely represents the very antithesis of true investigation . . .

Ideally, the investigation of an accident should be undertaken like a research project.

It is, however, relatively rare for such investigations to be conducted in this spirit.

27.5.3 Organization of investigation

Often there will be separate investigations carried out by the company and by the regulatory body, which in the United Kingdom is the Health and Safety Executive (HSE). It is important, therefore, that the responsibilities of the investigation teams and of the individual investigators be clearly defined, and that people who may be affected by their activities be informed.

The investigation should start as soon as possible after the incident, while memories are still fresh and evidence is undisturbed. In particular, photographs, measurements and similar evidence should be taken on the site as early as possible.

The precise procedure for an investigation cannot be rigidly defined in advance. It may involve assessment of damage and interviewing of personnel and may include laboratory work such as metallurgical examination and simulation work such as the operation of equipment under simulated process conditions.

27.5.4 Conduct of investigation

The form taken by an investigation depends somewhat on the accident, but is likely to be broadly as follows: (1) remit, (2) preliminary site visit, (3) collection of background information, (4) examination of damage, (5) interviewing of witnesses, (6) research and analysis and (7) final report.

The purpose of the investigation should be clearly defined from the outset and a clear remit obtained. If in the course of the investigation it proves to be necessary, the remit should be renegotiated. The investigator should also ascertain the general circumstances of the accident.

The preliminary site visit should be made as soon as possible. The first matter to be considered is the potential hazards. The situation pertaining after a large accident particularly is, in the nature of the case, an uncontrolled one.

Some of the hazards enumerated by Burgoyne (1982) are: mechanical hazards, such as falling through collapsing structures or due to unsafe access, falling objects such as lifting gear, striking and crushing by collapsing structures, and collision with dangerous objects; thermal hazards of hot surfaces and fluids, and concealed fires; chemical hazards from corrosive, flammable or toxic materials, present as spills or in confined spaces or giving rise to sprays; and electrical hazards from live circuits and equipment.

At this stage, the site should not be disturbed. Photographs of the site are, however, invaluable. Colour photographs are preferred, since they give much more information, particularly on fire damage. A record should be kept of the location and viewpoint of each photograph. Sketch plans, sketches and notes should be made as appropriate. It may be helpful to obtain an overview of the site by viewing it from a distance, perhaps from the window of a nearby building.

During this visit, the names should be obtained of eyewitnesses and of others who may have relevant information. Witnesses should be encouraged to write down their experience whilst it is fresh and, if possible, before they have talked to other witnesses.

The investigator needs to familiarize himself with the details both of the process and of the plant equipment.

Examination of the damage caused by the accident usually yields much useful information. Some of the detailed features of fire and explosion damage are considered below.

The interviewing of witnesses is another important source of information but requires some care. Information should be sought on the situation immediately before as well as during and after the event. Allowance needs to be made for the fact that the account given by a witness may be defective by reason of the initial observation, memory or descriptive powers. Accounts of sudden, short and violent events in particular tend to be unreliable. The interviewer should avoid the use of leading questions and should seek to cross-check accounts given.

There follows a period of analysis and research. The danger of jumping to a conclusion and the need to keep an open mind are often emphasized. Burgoyne argues that the use of a working hypothesis, possibly with variants, is necessary, provided it continues to be treated as no more than that. The working hypothesis is then tested and adjusted, typically by an iterative process.

There may be some issues that can be resolved only by physical tests. In some cases, small scale tests are adequate, but frequently the only tests capable of providing results that will carry conviction are relatively large scale, time-consuming and expensive. One reason for the time and expense may well be the hazards of the work required. The decision as to whether to call for tests is often one of the most difficult which an investigator has to take.

There comes a point where further work is subject to the law of diminishing returns and the investigator has to come to a conclusion, even if, as is usually the case, there are loose ends.

A report is then written. This may well be best cast in the form of a chronological account of the steps by which the investigator came to his conclusion. The elements of an accident report are described by Craven.

27.5.5 Findings of investigation

An investigation is expected (1) to determine what happened and why it happened and (2) to propose how it might be prevented from happening again. These two outcomes constitute the findings and the recommendations of the investigation.

It is common for reports of accident investigations to draw conclusions, and make recommendations, which are concerned almost entirely with technical matters, and which fail to delve deeper into the more fundamental causes.

This characteristic of the conclusions of an accident inquiry is often virtually guaranteed by the way the investigator is chosen. Management assumes that the causes are technical and appoints to investigate them the person who seems to have the best technical qualifications for the task. He in turn assumes that he has been appointed to discover the technical cause(s).

In fact, accidents are typically the result of a combination of failures, technical and human, both of which are outcomes of management failure. Various aspects of this have been described elsewhere, notably in Chapters 2, 6, 9 and 14.

This characteristic of accidents is now common ground in the literature on accidents and their investigation. Different aspects are emphasized by different authors. For example, Reason (1991) stresses the prior presence of latent failures, or resident pathogens; Swain (1972) emphasizes the work situation and the associated performance shaping factors; and Bellamy (1984) stresses communication failures.

The need for a ‘layered’ accident investigation which strips off the surface layers and delves down to these deeper causes is a persistent theme in the work of Kletz on accident investigation and of learning from accidents; he calls it ‘peeling the onion’. Some authors use an accident model and/or taxonomies of causes as an aid to laying bare the structure of the accident.

The basic message of such work is that, at the end of the day, it is management that has the responsibility of ensuring that the deficiencies and failures of equipment and humans are so controlled that accidents are avoided and that recommendations for preventing a recurrence must start from this perspective.

However, the proposition that accidents are always in some sense attributable to management is not in itself especially constructive. It is much more helpful to identify the particular failings which repeatedly contribute to accidents.

Most workers on accident investigation give their own classifications of these failings. For example, the classification given by Reason in relation to near misses is quoted in Section 27.16.

Another classification is that of Kletz, which, as already mentioned, treats the accident in terms of the three layers (1) immediate technical recommendations, (2) avoiding the hazard and (3) improving the management system.

Kletz makes a number of suggestions for things to avoid in accident findings. It is not helpful to list ‘causes’ about which management can do very little. Cases in point are ignition sources and ‘human error’. The investigator should generally avoid attributing the accident to a single cause. Kletz quotes the comment of Doyle that for every complex problem there is at least one simple, plausible, wrong solution.

Increasingly, the findings of accident investigations are presented in terms of the root causes. The concept of root causes has been discussed in Chapter 8 and is considered further in Section 27.8. It underlies the family of techniques described by Wells and co-workers, the audit methodology being developed by the HSE and the approach suggested by the CCPS. The findings should identify the specific root causes and the recommendations should then address each of these in turn.

27.5.6 Recommendations of investigation

As just indicated, the recommendations should arise out of the findings of the investigation. The investigation should aim to match each root cause with a corresponding appropriate recommendation.

A recommendation will generally address one of three aspects of the accident situation: (1) reduction of frequency, (2) reduction/mitigation of consequences and (3) limitation of exposure of people.

In terms of the fault tree representation, the aim is to insert a new, or to strengthen an existing, AND gate at each critical point in order to prevent escalation up the demand tree.

It is urged by Kletz that technical proposals for prevention should aim for defence in depth and, therefore, should give due weight to the earlier as well as the later lines of defence. In fault tree terms, there should not be excessive concentration on the upper levels of the tree just below the top event.

Lines of defence which Kletz lists, some applicable only to flammables are (1) limitation of inventory, (2) inspection of construction, (3) gas detectors, (4) leak warning system, (5) leak isolation, (6) leak dispersion by open construction and fluid curtains, (7) elimination of ignition sources, (8) passive fire and explosion protection, (9) active fire fighting measures and (10) separation distances.

Kletz identifies as recurring themes in general recommendations in his own analyses of accidents: (1) design of user-friendly plants, (2) hazard identification by hazard and operability (hazop) studies, (3) control of plant modification and (4) inspection and testing of protective equipment.

Another recurring theme is management, which has a number of aspects, including (1) organizational memory and (2) training.

Recommendations may seek to exploit the concept of hazard warning outlined in Chapter 9. From this viewpoint, the existence, or insertion, of an AND gate in the fault tree means that the events below that gate, if observable, may be monitored and treated as warnings.

It is good practice to draw up draft recommendations and to consult on these before final issue with interested parties. This contributes greatly to their credibility and acceptance.

It is relevant to note that in a public accident inquiry, such as the Piper Alpha inquiry, the evidence, both on managerial and technical matters, on which recommendations are based is subject to cross-examination.

The recommendations should avoid overreaction and should be balanced. It is not uncommon that an accident report gives a long list of recommendations, without assigning to these any particular priority. It is more helpful to management to give some idea of the relative importance. The King's Cross Report (Fennell, 1988) is exemplary in this regard, classifying its 157 recommendations as (1) most important, (2) important, (3) necessary and (4) suggested.

In some instances, plant may be shut-down pending the outcome of the investigation. Where this is the case, one important set of recommendations comprises those relating to the preconditions to be met before restart is permitted. These recommendations may well involve process and/or plant modifications and, if so, should be subject to the established systems for management of change.

There should be full documentation of the recommendations, covering those considered and rejected as well as those accepted.

27.5.7 Report of investigation

The investigation is documented in the final report. If it is a lengthy one, it may also be appropriate to issue an interim report.

The final report should include: an executive summary; an outline of the accident; a statement of the scope of the inquiry; the background, which will often need to cover relevant aspects of the management systems, the process, the plant and its operational history; a narrative of the events prior to and comprising the accident; an account of the investigation itself; a listing of the findings, with supporting evidence; and a listing of the recommendations, with clear links to the findings.

The requirements for follow-up of the report should also be specified in writing, whether in the report itself or otherwise. These include dissemination of the report's contents and action on it recommendations.

27.5.8 Experimental work

It is necessary in some investigations to undertake experimental work. Two main types of investigation are tests on failed equipment and experiments undertaken to test a hypothesis.

The damage survey in the field is often complemented by laboratory examination of failed equipment. Figure 27.1 illustrates the procedure used at the time for examination of equipment failure by the Safety in Mines Research Establishment (SMRE), an HSE 'in-house' facility. Some of the inspection techniques have been described in Chapter 19.

An account of the approach taken in experimentation done to test a hypothesis is given by A.R. Baker (1982). Simulation experiments are done for three basic purposes: (1) to confirm or demonstrate, (2) to identify a mechanism or (3) to determine an initial condition. Thus, an experiment may be carried out to confirm or demonstrate convincingly that a particular event or sequence of events could have occurred under appropriate conditions. The relevance of such work depends on the extent to which the conditions of the accident can be simulated. Failure to reproduce even one of these initial conditions to which the results are known, or expected, to be sensitive may vitiate the work. In other causes, the initial conditions and the results are known, but the mechanism is not understood. There may be several candidate mechanisms. In yet other cases, the aim is to determine the initial condition(s) that caused the event of interest. Where there is a sequence of events, it is often impractical, and unnecessary, to simulate the whole sequence; it may be sufficient to simulate just one of these events.

It is generally easier to show that something could happen than that it could not. For the former a single positive result suffices, whereas for the latter the experimental space to be explored may be very large.

In many cases, a small scale experiment is not adequate, but large scale experimentation may be problematic, and is often potentially hazardous. It is likely to be expensive and time-consuming.

Where experiments are carried out, it is good practice to make a full photographic record.

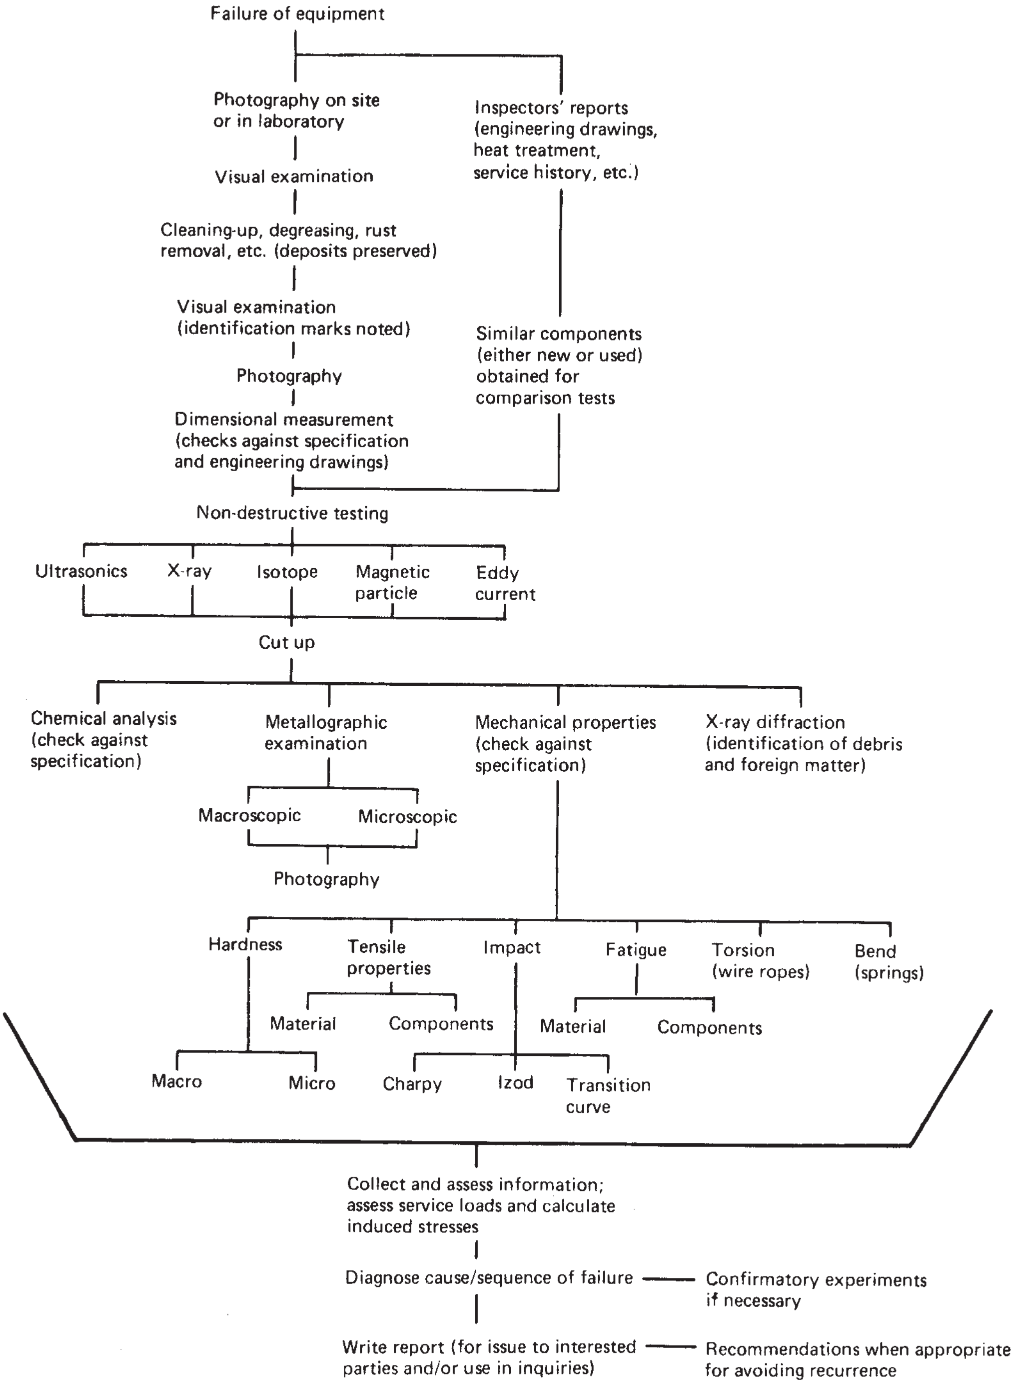

Figure 27.1 *Sequence of events in the examination of faulty equipment (Safety in Mines Research Establishment, 1971, Engineering and Metallurgy 4; reproduced by permission. The sequence may be modified and stages omitted according to the type of failure)*

Baker describes some seven different experimental investigations, including work on the bellows assembly at Flixborough and on a gas explosion in a building.

27.5.9 Some types of investigation

The account given so far has considered accident investigations conducted either in-house or by a consultant investigator. As mentioned earlier, accident investigations may also be carried out to check compliance with the law or to determine insurance liability. Where a crime is suspected, the police will be involved and may draw on resources such as those of the Home Office Forensic Science Laboratories. Where a violation of health and safety legislation is at issue, the HSE will be involved and may choose to conduct their own investigation, as described below. Where there is a question of the applicability of an insurance policy or the possibility of a transfer of liability to another party, one or more of the parties concerned may conduct their own investigations. It can occur, therefore, that there is more than one investigation of the accident going on at the same time.

27.5.10 Regulatory investigations

In the United Kingdom, a proportion of the more serious accidents are investigated by the HSE. It is the normal practice to publish the report. HSE reports in the *Investigation Report* series, listed in Appendix 28, include the following: *Explosion at Laporte Industries, Ilford, 5 April 1975* (HSE, 1976b), *Explosion at Appleby Frodingham Steelworks Scunthorpe, 4 November 1975* (HSE, 1976a), *Explosion at Dow Chemical Factory, King's Lynn, 27 June 1976* (HSE, 1977b), *Fire and Explosion at Braehead Container Depot, Renfrew, 4 January 1977* (HSE, 1979b), *Leakage of Propane at Whitefriars Glass Limited, Wealdstone, Middlesex, 20 November 1980* (HSE, 1981c), *Fire and Explosions at B&R Hauliers, Salford, 25 September 1982* (HSE, 1983b), *Abbeystead Explosion, 23 May 1984* (HSE, 1985a), *Summit Tunnel Fire* (HSE, 1985e), *The Fires and Explosion at BP Oil (Grangemouth) Refinery Ltd, 13 March, 22 March and 11 June 1987* (HSE, 1989a) and *The Peterborough Explosion of a Vehicle Carrying Explosives, 22 March 1989* (HSE, 1990b).

Likewise, in the United States of America if an accident is sufficiently serious, an investigation is conducted by the Occupational Safety and Health Administration (OSHA). The report *Phillips 66 Company Houston Chemical Complex Explosion and Fire* (OSHA, 1990a) is a case in point.

Investigations into transport accidents in the United States of America are conducted by the National Transportation Safety Board (NTSB). Some of their reports are listed in Appendix 28.

27.5.11 Public inquiry investigations

The *Flixborough Report* (R.J. Parker, 1975) together with its associated daily transcripts and the documents submitted to the inquiry remains perhaps the most comprehensive account of an accident investigation in the chemical industry. References to some of the large number of reports are given in Table A2.1. Accounts by individual investigators include those by Tucker (1975), J.I. Cox (1976b) and Gugan (1976). Further details of the Flixborough investigation are given in Appendix 2.

The *Piper Alpha Report* (Cullen, 1990), with its associated transcripts and the papers published subsequently, is another illustration of a major accident inquiry. References are given in Table A19.1. Accounts of individual investigators include those of Bakke (1989), R.A. Cox (1989a), M.E. Davies (1989), S.M. Richardson (1989) and Savffle (1989). Further details of the Piper Alpha investigation are given in Appendix 19 and an account of the inquiry is given in Section 27.9.

27.5.12 Illustrative examples

There are available in the literature a large number of reports and other accounts of accident investigations which serve as illustrative examples. At the top level there are the reports of public inquiries such as the *Flixborough Report* and the *Piper Alpha Report*. At the next level down are the accident investigation reports of the HSE and the NTSB, to which reference has just been made.

The work of Kletz gives a large number of accounts of accidents, each with an analysis that is an illustration of the principles of investigation that he advocates, together with explicit statements of those principles.

An account is now given of two further illustrative examples of the techniques of accident investigation.

27.5.13 Illustrative example: choked vent

An account of the investigation of accidents in process plants has been given by Houston (1971). This work was referred to earlier in Chapter 2. The approach taken is illustrated by an example that he gives of a hypothetical accident (see Figure 27.2):

> One end of a storage drum was blown out seriously injuring three men who were working nearby.
>
> The drum was used to store an organic liquid with a relatively high melting point. Steam tracing on the feed line was not very effective and chokes were common. Because of this it was customary to blow the line clear with air at 100 lbf/in^2 before and after each transfer.
>
> On this occasion the operator realized that the vent was not blowing and assumed that the line was blocked. In fact it was the vent that was blocked and when the pressure reached an estimated 30 lbf/in^2 one end of the vessel failed. Debris, particularly hot residual product from the last batch at 120°C, was blown some distance and three men who were working about 15 ft away were seriously injured.

The analysis of this accident using a model accident analysis form is shown in Table 27.2. The method has several important features. It does not report a principal cause, but

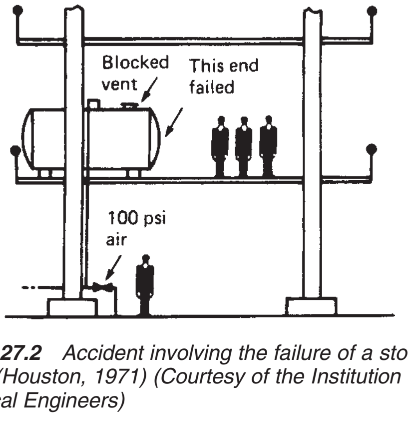

Figure 27.2 *Accident involving the failure of a storage vessel (Houston, 1971) (Courtesy of the Institution of Chemical Engineers)*

Table 27.2 *Model analysis of storage vessel accident (Houston,1971) (Courtesy of the Institution of Chemical Engineers)*

	What was the immediate cause?	*What else made an accident possible?*	*What form of energy or poison was involved?*	*What was done to prevent an accident?*	*What was the point of no return?*	*What effect did the locality have?*	*What was done to reduce the severity?*	*Did the accident have any further repercussions?*
Please describe what happened	Turning on $100\ \mathrm{lb_f/in.^2}$ air	Blocked 4 in. vent	$40\ \mathrm{m^3}$ of air at $\sim 30\ \mathrm{lb_f/in.^2}$ – the calculated bursting pressure	Nothing	When vessel shell failed	Product at 120°C sprayed on three maintenance men who were 15 ft away across platform	Injured given first aid in control room. Fire and ambulance services called. Area washed down	Loss of this vessel restricted plant output for 3 months at cost of £18,000
Why did it happen?	To prove feed line was clear before transfer (history of blockages)	Product (m.pt = 105°C) sprayed on cold vent by air blowing. Vent not normally inspected (poor access)	$50–100\ \mathrm{lb_f/in.^2}$ need to clear blocks $\sim 30\ \mathrm{lb_f/in.^2}$ could build up in tank in ~5 min	Operator knew vent was not blowing but assumed line was at fault (no PI or bursting disc provided)	Excess pressure designed only for $15\ \mathrm{lb_f/in.^2}$	Tank had residue of product after transfer. Men on routine maintenance job	A/F and crew heard bang and came running	Delay caused by tank cleaning due to more frequent grade changes on other storage tank
Has this or anything similar happened before?	Daily for 8 years; also done on discharge line	Nothing proven. A tank was sucked in due to vent restriction 2 years ago – suspect that was lesson not properly learned	See safety adviser's file on overpressure incidents	Instructions do not call for vent inspection as blockage not anticipated	See safety adviser's file on over-pressure incidents	Men must be in this area approximately 1% of time	–	No
What should be done to prevent a recurrence?	(1) Investigate use of internal steam tracing	(2) provide heated 8 in. vent on replacement tank (3) Arrange for registration and routine inspection of all critical vents	(4) Write up piece on vents in next safety bulletin and discuss with training manager	Bursting disc not needed if vent modified (5) Draft works standing order on use of $100\ \mathrm{lb_f/in.^2}$ air, etc., for line clearing	–	(6) Consult Engineering Dept on known modes of failure on location of access ways	–	–
MAIN RESULTS				FOLLOW-UP	*Recommendation*	*Action*	*Completion*	
Men off 6, 9 and 30 days with burns				1	Plant Engr			
				2	Plant Engr			
Vessel destroyed – replacement cost £15,000				3	Asst Wks Mgr			
Product lost – 5 ton valued at £1500				4	Safety Adviser			
				5	Asst Wks Mgr			
Contingent loss £18,000				6	Safety Adviser			

A/F, assistant foreman; PI, pressure indicator.

rather a chain of events that might be broken in several places. It identifies both the advance warnings and the preventive measures that might be utilized to prevent recurrence, and it yields recommendations that are capable of practical implementation.

27.5.14 Illustrative example: ethylene oxide plant explosion

An illustration of the investigation of a quite different kind of accident is that undertaken following the explosion at the ethylene oxide/glycol plant of BASF on 7 March 1989 at Antwerp (Anon., 1991 LPB 100, p. 1). The incident involved an explosion on a distillation column separating ethylene oxide (EO) and acetaldehyde. The investigation found that probably a small leak of EO had led to an accumulation of auto-oxidizable polyethylene glycols (PEGs) in the insulation of the column.

The account referenced describes the organization of task forces to (1) secure the damaged plant, (2) repair the equipment, (3) document the damage, (4) assemble information and (5) search for the cause.

A thorough review was made of the chemistry of the process and of the potential sources of ignition. The explosion event was reconstructed from an analysis of the damage, the examination of materials, the statements of eye-witnesses and the recorded information from nearby plants, and the probable chain of events leading up to the explosion reconstructed.

The location of the first explosion was identified as the acetaldehyde column K303 from the fact that a manhole cover from this column had left an imprint on nearby column K205. The damage to the trays of the column indicated that the explosion occurred in the lower part of the column, probably at the bottom.

Alternative sources of ignition included chemical reaction of the bottom products, static electricity and EO decomposition in an overheated pump, but these were eliminated. The only ignition source that could not be discounted was a fire within the insulation. It was confirmed that this was a feasible mechanism. EO itself is a low boiling liquid that does not generally accumulate on insulation, but it reacts with water to give PEG, a reaction which normally requires a temperature of 180°C but which was shown to proceed in direct contact with mineral wool at 100°C. The PEG is high boiling and can support self-heating of the insulation.

27.5.15 Disputed investigations

A large proportion of accidents are investigated by the fire services for the purpose of records and statistics, and the investigation is relatively short. Even where it is rather fuller, time and resource constraints still apply.

In some cases, a later investigator comes to a different conclusion as to the technical causes. Three such cases are given by Ursenbach (1980, 1983). In the first, the ignition of a vapour cloud from a plant leak was ascribed to a non-explosion-proof electric cart, but subsequent modelling of the vapour dispersion showed that a flammable mixture could not have reached the vehicle. In the second, an explosion was attributed to a defective acetylene cylinder, but a later study of marks on the cylinder indicated that the damage to it had been caused by compression of an oxygen cylinder onto it by the collapsing roof. In the third case, it was reported that the damage was due to an explosion of solvents evaporating from a massive ink spill caused by the failure of a ball mill at ground level, but a further investigation found that other explosions had occurred on upper floors which could not have been due to the heavier-than-air vapour on the ground floor.

27.6 Fire Investigation

Accounts of the investigation of fire are given in *Fire and Arson Investigation* (J. Kennedy, 1962) and *Fire Investigation* (Dennett, 1980) and by Burgoyne (1981/82, 1982) and Craven (1982).

The overall conduct of an investigation has been described above. The general account given of the preliminary site visit, the examination of damage, the interviewing of witnesses, etc., is applicable, but in addition there are a number of considerations which apply specifically to fire investigation.

The preliminary site visit serves to identify the area of origin of the fire. Further work is aimed at establishing the material first ignited, the source of ignition and the general features and pattern of the fire and thus identifying the cause.

27.6.1 Fuel involved in fire

Some pointers to identifying the fuels involved in a fire or explosion are given by C.H.H. Willis (1981).

27.6.2 Temperature attained by fire

The temperature of a process plant fire does not normally rise much beyond 1000°C. This is so whether the material undergoing combustion is a flammable liquid or a solid material such as wood, plastic or paper. On the other hand, it is usually sufficient to cause significant deterioration of steelwork, which occurs in the range 550–600°C. Jet flames can give rise to temperatures appreciably higher than 1000°C.

Some indicators of the behaviour of the fire are charring of wood, melting of metals, damage to vessels and damage to structural steelwork. Charring of wood can be expected to be deepest where the fire has burned longest. Most types of wood are charred to a depth of about 2.5 cm within 40 min, whatever the fire, as long as the flame is the diffusion flame normal in a fire.

Copper has a melting point of 1080°C and usually does not melt but its alloys brass and bronze do; their melting points being in the range 800–1000°C. So does aluminium with a melting point of 650°C.

The paint on a vessel containing liquid may be blistered above the line of the liquid level but not below. If the original liquid level is known, this can be used in conjunction with an assumed heat input rate to estimate the duration of the fire. Craven suggests values for the heat input rate of 110 kW/m^2 typical and 170 kW/m^2 maximum, in the absence of a jet flame.

The temperature at which structural steelwork distorts is attained in most process plant fires, and the damage can be spectacular, but generally it is not a very helpful indicator.

Fire temperature indicators are also described by Guenther *et al.* (1976), Guenther, Goodwin and Brininger (1978) and McIntyre (1981). The latter gives an account of the use of common materials as temperature indicators. He divides such indicators into two classes: time independent and time dependent. Some indicators which are essentially independent of, or only weakly dependent on, time are the melting of metals, the charring of wood, the high temperature scaling of steel and the recrystallization of copper. He gives a list of some 25 temperature indicators which may be observed by one of three methods: visual examination, hardness testing or metallographic examination.

27.6.3 Electrical short circuits

Fires of electrical origin are of considerable interest to fire investigators. A relevant code is NFPA 907M.

Accounts of the treatment electrical short circuits in fire investigations are given by Levinson (1977), Ettling (1978), Beland (1981, 1982), Delplace and Vos (1983) and D.A. Gray, Drysdale and Lewis (1983).

An electrical short circuit is a potential source of ignition. It is accompanied by an electric arc. Such an arc causes damage to the electric wiring and leaves a visible mark. The problem is to determine whether in a given case the short circuit is a cause or an effect of the fire.

The differentiation of cause from effect is addressed by Delplace and Vos (1983) and experimental work to this end is described by D.A. Gray, Drysdale and Lewis (1983). Delplace and Vos also state that there is a close parallel between the pattern left by a fire and the location of the short circuits and that this can be exploited in fire investigation.

27.7 Explosion Investigation

Accounts of the investigation of explosions are given in *Unconfined Vapour Cloud Explosions* (Gugan, 1979), *Explosion Investigation* (Yallop, 1980) and *Investigation and Control of Gas Explosions in Buildings and Heating Plant* (R.J. Harris, 1983) and by V.J. Clancey (1972b, 1981), W.E. Baker (1982) and Craven (1982).

27.7.1 Types of explosion

There are a number of different types of explosion on process plant which the investigator may need to consider. They include:

(1) condensed phase explosion;
(2) physical explosion –
    (a) hydraulic,
    (b) pneumatic;
(3) confined gas explosion;
(4) vapour cloud explosion;
(5) boiling liquid expanding vapour explosion;
(6) dust explosion;

It may also be necessary to distinguish between deflagration and detonation.

Explosions may occur with buildings; gas explosions in buildings are of particular importance.

27.7.2 Condensed phase explosions

Explosions of a condensed phase explosive such as TNT are of less interest for process plant than are some of the other types, but on the other hand the methods of investigation are well established and accounts more comprehensive, so that it is convenient to start with them. Accounts include *Explosion Investigation* (Yallop, 1980) and that by V.J. Clancey (1972b). The effects of condensed phase explosions, which are well documented, are described in Chapter 17 and the information given there may be used for diagnostic purposes.

The text by Yallop covers (1) explosion accidents and the explosion investigator, (2) fundamentals of explosives, (3) the approach to the scene, (4) the observation and assessment of damage, (5) identification of the explosive, (6) causes of initiation, (7) explosions in moving vehicles, (8) injury to persons, (9) examination of suspects, (10) analysis of witness statements, (11) unlikely occurrences, (12) negative evidence and (13) drawing the conclusions.

Yallop's treatment of the observation and assessment of damage covers (1) the importance of damage, (2) the type of explosive and explosion damage, (3) the value to be attached to damage observations, (4) the importance of the site of the explosion centre, (5) the determination of the site of the explosion centre, (6) the significance of pressure, (7) the application of pressure observations, (8) the phenomenon of fragmentation, (9) information from fragments, (10) craters and (11) ground shock. Some of the relationships given by Yallop, and also by Clancey, are among those used in Chapter 17, which also draw on his accounts of explosives and of their initiation.

Observable damage falls into three categories: (1) permanent distortion of objects, (2) displacement of objects and (3) flame and heat effects. Permanent distortion may itself be subdivided into (1) plastic deformation, (2) fracture and (3) fragment attack. In general, permanently distorted objects are generally quite reliable indicators, whereas displaced objects are much less dependable.

Modes of plastic deformation considered include: (1) bending of long metal objects such as structural members, rails, window frames, pipes, and nails, screws and bolts; (2) dishing of metal plates, including tanks; and (3) movement of piles of particulate matter. The author states, however, that observations cannot be made on a container that is full of liquid, which inhibits distortion. Fracture may be observed of the structural elements of buildings, the contents of buildings, and objects outdoors. Fragment attack take the form of surface attack, giving dents or small craters, or penetrative attack. The latter can be useful in locating the explosion centre by projecting back the lines of the penetration holes.

Flame and heat effects are melting and decomposition. The contact between the hot gas of the blast wave and surrounding objects is generally too short for much heat transfer to occur, but metal surfaces close to the explosion centre can exhibit 'gas wash', which is characterized by partial melting of the surface layers, giving a ripple effect. In some cases, heat transfer is sufficient to cause decomposition, such as the charring of organic materials or the discoloration of painted surfaces.

This information may be used to prepare a direction/damage diagram. Yallop describes a diagram made for the gas explosion in the flats at Ronan Point in 1968 with a detailed explanation of some 19 items.

The author gives a detailed account of the determination of overpressures from plastic deformation and from fractures. These may be used to determine the charge weight of the explosive using the usual scaling laws.

It is a basic principle of explosion investigation to recover as many primary fragments as possible. Fragments can give information on the nature of the exploding object and on the site of the explosion, and possibly the charge weight.

A further account is given by W.E. Baker (1982). He advises for the determination of explosion yield the use of the pressure-impulse method. He draws attention to the need to allow in the far field for meteorological effects due to possible focusing of inversions and wind shear.

27.7.3 Physical explosions

Physical explosions are often the result of overpressurization during a fire. Depending on whether the vessel is full of liquid or not, the explosion may be hydraulic or pneumatic. The mode of failure is determined by the weakest feature of the containment. A pneumatic explosion is the more violent and gives rise to a large number of missiles.

The estimation of the energy released in, and of the effects of, a physical explosion are described in Chapter 17.

27.7.4 Confined gas explosions

The behaviour of an explosion of gas confined within a plant depends on the nature of the space concerned. With a single volume such as a vessel the explosion can be expected to be a deflagration with a stress essentially uniform over the containment. With a multi-compartment volume there is scope for run-up to higher flame speed and for pressure piling. Damage is likely to be at a maximum at the point most remote from the source of ignition. With a pipeline the flame speed may accelerate to give a detonation.

Slow deflagration of a gas mixture tends to give a pure ductile failure at a pressure corresponding to the static strength of the container. The bursting of a cylindrical container in such a deflagration is usually taken to occur when the pressure causes the stress to exceed the hoop stress.

Where the flame speed in a gas mixture runs up to detonation, which can occur in a vessel of high aspect ratio or a pipeline, bursting may occur at a higher pressure than that for static loading. The bursting of a cylindrical containment in a detonation may be taken to occur at a pressure corresponding to a stress that is about twice the hoop stress.

Detonation in a pipeline gives rise to a characteristic longitudinal tear, or ribbon. This may be repeated at points along the pipeline where the explosion is relieved and then starts again the run-up to detonation.

Interpretation is complicated by the fact that a ductile failure due to a slow deflagration can create a tear that accelerates into a brittle fracture. Conversely, detonation does not necessarily cause brittle fracture.

The investigator usually seeks to determine the point of initiation of the failure. Where the failure is ductile, the point of initiation tends to correspond to that of maximum thinning. Where the failure is brittle, there tend to be characteristic chevron marks on the tear that point back to the point of initiation.

With regard to source of ignition, little can be deduced from the pattern of bursting of a single vessel, but for a multi-compartment configuration the maximum damage tends to occur remote from the source of ignition.

27.7.5 Failure analysis

Failure analysis seeks to determine the details of the failure of the containment and generally involves the collection of the fragments generated by the explosion within it. An account is given by Craven, who describes the piecing together of the fragments to reconstruct the original containment and to take measurements of the thickness.

Another account of failure analysis is that of Beyers (1980), who describes the investigation of a massive explosion at a group of spherical and cylindrical storage vessels. Utilizing information on the necking of the vessels, crack propagation and fracture mechanics, it was possible to determine the order of failure of the vessels and to establish that failure had occurred because both a level measuring device and a safety relief valve had failed, so that pumping was allowed to continue when the vessel was full and the resultant overpressure was not relieved by the safety relief valve.

27.7.6 Vapour cloud explosions

The main effect of a vapour cloud explosion that is used for diagnostics is the blast. Vapour cloud explosions tend not to give a crater and the missiles from such explosions usually yield less information than do those from confined explosions.

The characteristics of a vapour cloud explosion are described in Chapter 17. They are generally less well defined than those of a condensed phase explosion and consequently more uncertain in their application for diagnostic purposes.

A detailed survey of the damage done by the blast from the vapour cloud explosion at Flixborough has been described by Gugan (1979), who also gives an account of the interpretation of this damage to estimate the yield of the explosion. Features considered include the crushing of vessels and the bending of lampposts.

27.7.7 BLEVEs

A boiling liquid expanding vapour explosion (BLEVE) is another type of explosion which occurs in accidents in the process industries. A BLEVE tends to generate a number of fragments, but the overpressure of the blast wave is slight. There is usually relatively little difficulty in establishing that a container has undergone a BLEVE.

27.7.8 Ignition sources

It is usually more difficult to identify the source of ignition for a vapour cloud than for solid materials and in many cases of vapour cloud explosion no ignition source is identified.

27.7.9 Injury to humans

Injury to humans, whether deceased or surviving, is another potential source of information. The information that may be obtained from this source is considered by Yallop. A treatment of injury from different explosion effects is given in Chapter 17.

27.7.10 Gas explosions in buildings

An account of the investigation of gas explosions in buildings with particular reference to natural gas has been given in *Investigation and Control of Gas Explosions in Buildings and Heating Plant* (R.J. Harris, 1983). Some treatment of the topic is also given by Yallop. The account by Harris is concerned particularly with explosions following leaks of natural gas in consumers' premises.

Investigation of a gas explosion in a building proceeds by trying to establish (1) the nature of the explosion and, assuming it is a gas explosion, (2) the type of gas, (3) the source of gas, (4) the quantity, concentration and distribution of the gas, (5) the ignition source, and frequently, (6) the pressure generated and the distribution of pressure damage.

The investigation may start by determining whether the damage has been caused by fire or explosion. Here a useful indicator is damage to windows that may have been caused by pressure or by heat. The pattern of failure of a glass window under pressure is quite different from that of failure due to heat. Pressure failure gives a large number of fragments with visible stress marks, whilst failure by heat gives fewer fragments and no stress marks. Pressure failure causes fragments to travel further and they could be found at distances of over 5 m from the window.

An explosion due to gas may be distinguished from that of a bomb by the fact that the former gives a slow pressure rise and causes damage that is omni-directional, whereas the latter gives a fast pressure and damage is greatest at the location of the bomb.

With regard to the type of gas, the principal clue is whether the gas is lighter or heavier than air, which may often be determined from a 'tide mark' of scorching.

The search for the source of gas depends on the building and the potential gas sources in it.

The quantity of gas may be estimated from the damage done both within the building and outside. Again, the behaviour of the windows provides important information. The pressure inside the building may be estimated from that required to break the windows and from the distance travelled by the fragments. The correlations used are those of M.R. Marshall, Harris and Moppett (1977) given in Chapter 17. The other indicator is damage to windows of other buildings. Here use is made of the relation for the pressure outside a vented enclosure, which decays according to a modified inverse square law, as given in Chapter 17. The pressure on these outside windows is assumed to be the reflected pressure at normal incidence, or twice the incident pressure.

The author enumerates some of the ignition sources found in consumers' premises, but states that often the ignition source is not found.

27.8 Accident Investigation: CCPS *Guidelines*

Guidance on incident investigation is given in *Guidelines for Investigating Chemical Process Incidents* (CCPS, 1992/10) (the CCPS *Incident Investigation Guidelines*).

The *Guidelines* are concerned with process safety incident investigation (PSII). They cover (1) introduction, (2) basic incident investigation techniques, (3) investigating process safety incidents, (4) practical investigation considerations (gathering evidence), (5) multiple cause determination, (6) recommendations and follow-through, (7) formal reports and communications issues and (8) development and implementation. They contain a number of appendices, including: a review of major accidents such as Bhopal, Mexico City, Piper Alpha and Pasadena; examples of the causal tree method (CTM) and multiple-cause, systems orientated incident investigation (MCSOII) method; an example incident investigation; and examples of root cause analysis.

27.8.1 Types of investigation

The CCPS *Guidelines* distinguish between three types of investigation:

Type 1	Traditional, informal investigation carried on by immediate supervisor.
Type 2	Committee-based investigation using expert judgement to find a credible solution of cause and remedy.
Type 3	Multiple-cause, systems-oriented investigation that focuses on root cause determination, integrated with an overall process safety management (PSM) programme.

The Type 3 investigation is the preferred method.

27.8.2 Investigation management system

The *Guidelines* advocate that the company should have in place a management system for PSII. They describe the elements of this system, including the systems for incident reporting, incident classification, activating an investigation, selecting and training the investigation team, documenting the inquiry, disseminating its findings and following through its recommendations.

It is desirable that the approach to PSII be one that chimes with the methods of process safety review already in use for plant design and operation. This is met by the multiple cause analysis, or Type 3, approach, utilizing logic tree and related techniques.

The *Guidelines* give a detailed account of the measures necessary to set up a PSII management system, including the training requirements.

27.8.3 Investigation techniques

The *Guidelines* review some 18 investigation techniques which include: (1) fault tree analysis (FTA); (2) the CTM taken up by Rhone-Poulenc (Leplat, 1978a; Boissieras, 1983); (3) the MORT method of W.G. Johnson (1980); (4) the MCSOII developed by Rohm and Haas (Dowell, 1990; S.E. Anderson and Skloss, 1991); (5) the Accident Anatomy Method (AAM) developed at the Riso National Laboratory (Bruun, Taylor and Rasmussen, 1979); (6) Action Error Analysis (AEA) described by J.R. Taylor (1979); (7) the Cause-Effect Logic Diagram (CELD), developed by the Electrical Power Research Institute (EPRI) (Mosleh *et al.*, 1988) among others; (8) hazard and operability (hazop) analysis; (9) the Accident Evolution and Barrier (AEB) technique in development at the Swedish Nuclear Power Inspectorate (Svenson, 1991a); (10) Work Safety Analysis (WSA) developed at the Technical Research Centre in Finland (VTT) (Suokas, 1981; Soukas and Rouhiainen, 1984); (11) Human Reliability Analysis (HRA) developed at Sandia National Laboratories (B.J. Bell and Swain, 1983; Swain and Guttman, 1983); (12) Multi-linear Events Sequencing (MES) developed by the NTSB (Benner, 1975); (13) the STEP procedure described by Hendrick and Benner (1987); and the Systematic Cause Analysis Technique (SCAT) developed by the International Loss Control Institute (ILCI) (1990).

Of these methods hazop, FTA, MORT, and AEA have been described in Chapters 2, 8 and 9, HRA in Chapter 14 and STEP in Section 27.4. CTM essentially utilizes a stripped-down fault tree that is applicable to the particular accident and contains only AND gates. MCSOII is also a fault tree adaptation in which the events at the level just below the top event are the presence of the injurious factor, the presence of the target and a contact duration sufficient to cause harm. AAM utilizes a tree that, like the one in MORT, is generic, but which resembles a cause–consequence diagram and which is then developed to represent the features of the particular accident. AEB describes the incident in terms of a series of events in two parallel systems, the human and the technical, and of barrier functions that should prevent escalation. WSA utilizes a proforma in which are analysed the work step, hazard, causative factors, priority ranking and corrective actions. MES charts the events in a time sequence and is a forerunner of STEP. SCAT treats the incident as a domino effect and involves describing successively the loss, the contact between the injurious factor and the target, the immediate causes, the basic causes and the failure of control.

The *Guidelines* also describe other aids such as the fact–hypothesis matrix and simulation/recreation.

27.8.4 Multiple root cause analysis

Two strong themes in the *Guidelines* are that accidents have multiple causes and that the investigation should delve down to the root causes. The preferred approach is termed 'multiple cause analysis', but might equally well be called 'multiple root cause analysis'. The account given of the conduct of such an analysis relies heavily on the use of logic trees.

The *Guidelines* illustrate the application of this approach to major accidents such as Flixborough, Challenger and Piper Alpha, as well other incidents involving fire/explosion, compressor failure and vehicle collision.

27.8.5 Recommendations, reports and follow-up

The *Guidelines* discuss the recommendations of the investigation, dealing with the distinction between findings and recommendations, the correspondence between root causes and recommendations, the attributes of good recommendations, the layers of recommendations, the types of recommendation, the process of feedback on draft recommendations, the documentation of the recommendations, the recommendations on restart of plant, the documentation of the recommendations and the follow-through of the recommendations. They also treat the reporting of the incident from the initial verbal report through the interim report to the final report. The approach taken to these topics is broadly in line with that described in Section 27.5.

27.9 Public Accident Inquiries

In the United Kingdom, certain accidents are investigated by official bodies. The system varies with the industry, but in the case of a major disaster there is likely to be some form of public inquiry.

Reports of such accident inquiries include *The Flixborough Disaster* (R.J. Parker, 1975), *The Windscale Inquiry* (R.J. Parker, 1978), *MV Herald of Free Enterprise. Report of Court* (Sheen, W87), *Investigation into the King's Cross Underground Fire* (Fennell, 1988), *Investigation into the Clapham Railway Accident* (Hidden, 1989) and *The Public Inquiry into the Piper Alpha Disaster* (Cullen, 1990). The two major disasters in the process industries which in recent years have been the subject of a public inquiry are thus Flixborough in 1974 and Piper Alpha in 1988.

In the process industries, a proportion of accidents are investigated by the HSE. Until the mid-1970s the reports of these investigations were not generally published as such, although reference was often made to them in the annual report of Chief Inspector of Factories. Following the Flixborough inquiry in 1974, the HSE have conducted a number of major accident investigations and have published their reports, as described in Section 27.5. Thus, the number of public inquiries is very small and even quite major accidents are now mainly dealt with by an HSE investigation and report.

27.9.1 Procedure at public accident inquiries

A public accident inquiry is appointed by the government minister responsible and is presided over by a judge. There is some variability in the precise form taken, but the broad pattern is that the evidence is brought forward by the counsel to the Crown who is assisted by consultants to the inquiry. The judge himself is assisted by two or three technical assessors. The terms of reference are usually to establish the cause and to make recommendations for the prevention of any recurrence.

The judge receives requests from parties who wish to be represented and then gives a ruling on who the parties are to be. Typical parties might be the operator, other industrial companies, government bodies, trades unions and representatives of survivors and relatives. Each party is represented by a barrister, typically a Queen's Counsel (QC), who is supported by a solicitor and usually by experts.

Witnesses are brought forward by Crown counsel and by other parties and can be cross-examined by the parties. In this sense, the procedure resembles the adversarial process in the law courts.

27.9.2 Critique of public accident inquiries

The Flixborough inquiry (R.J. Parker, 1975) found that the disaster was due to a large release of hot, flashing cyclohexane from a 20 in. pipe, which gave rise to a massive vapour cloud explosion. This pipe was an inadequately supported bypass assembly consisting of a dog-leg pipe between two expansion bellows. The inquiry also found that this release was caused by pressure and temperature conditions in the pipe itself more severe than those that had previously prevailed. An alternative theory was put to the inquiry by Gugan and Cox that the assembly failed following prior rupture of a nearby 8 in. line, but the inquiry rejected it. A third theory was advanced at the time by R. King (1975a) that the cause was superheating of water in the reactor upstream of the pipe, but the inquiry did not pursue this hypothesis. The inquiry left proponents of these last two hypotheses dissatisfied with the way in which the technical evidence had been handled, and this gave rise to some debate in the engineering press at the time.

In consequence a view emerged and gained some support in the engineering profession that a public inquiry, with its adversarial legal process, is not the best forum in which to arrive at the truth about engineering matters. This view was urged after the Flixborough inquiry by Mecklenburgh (1977) and has been argued again with reference to the same inquiry by R. King (1990).

The critique given by King is broadly as follows. Many of the legal representatives at the inquiry are retained by interested parties. The presumption must be that the latter are concerned to protect their interests. A party may have an interest in ruling out a given cause and/or establishing another one. This situation is liable to lead to the investigation of improbable theories urged by particular parties at the expense of more probable explanations and thus to an imbalance in the investigation. Some persons whose impartial expertise would be valuable may not be called to give evidence because they are prevented by their employers or counsel or by the inquiry procedures. The inquiry itself is not accountable and there is no means of reopening it if its conclusions are subsequently found to be incomplete or incorrect.

The alternative model for technical investigation urged by Mecklenburgh draws on the procedure used in civil aviation. Aircraft accidents are investigated by the Accident Investigation Branch (AIB) of the Department of Trade. The AIB is directly responsible to the minister and is not part of the CAA. The Chief Inspector of Accidents presents a report directly to the minister. The investigations of the AIB are inquisitorial not adversarial. The inspectors have considerable powers to obtain evidence and inspect wreckage. Provision is made for persons whose reputation may be affected, such as the pilot, to make representations before the report is submitted.

The Flixborough inquiry handled the investigation of certain technical aspects by using a management committee that organized meetings of technical experts. This work went on in parallel with the main inquiry. Mecklenburgh argues that it would have been both practical and preferable for the technical investigation to have been completed before the public inquiry proper. This technical investigation would have dealt with the theories concerning the cause of the rupture of the 20 in. pipe. Mecklenburgh recognizes that there are usually human and management reasons for an accident. These he considers proper subjects for a public inquiry. He does not suggest that the latter be dispensed with but only that it should start only after the technical investigation has been completed. He, therefore, proposes that it should be required by regulation that the public inquiry be preceded by a technical investigation conducted by a specialist unit within the HSE. The technical inquiry could, of course, be dispensed with if the technical reasons for the accident are clear. This would leave the inquiry free to concentrate on the human and management aspects.

On the other hand, several engineers who have been involved as technical assessors on public inquiries have spoken in their favour. Davidson (1984), who was an assessor on the Flixborough inquiry, states:

> I do not share the view, expressed widely, that an engineer or a scientist, or a committee of them, would form a more effective Court of Inquiry than the existing type. As part of the Flixborough Inquiry there was a management committee to oversee tests and discuss the scientific side of the Inquiry. Representatives of the major parties were included. This committee was useful but very difficult to manage: everyone had preconceived ideas as to tests and how they should be run. There was not the well-established framework of rules evolved by lawyers over the centuries for orderly cross-examination. Of course some accident inquiries – e.g. for railways, mines and aircraft – are run by engineers or scientists. But such investigations have quasi-legal powers: the chairmen have by long experience become engineer/judges and conduct their inquiries much like a court of law. On balance I was impressed by the procedure at the Flixborough Inquiry and felt that an inquiry is best run by lawyers.

Support for the present system is also expressed by Crossland (1991), an assessor on the King's Cross inquiry.

27.9.3 Piper Alpha inquiry

The nature of a public inquiry into a major disaster may be illustrated by considering the Piper Alpha inquiry (Cullen, 1990). This was a large inquiry, as shown by some of the statistics. The inquiry sat for 180 days extending over 13 months. It heard evidence from 260 witnesses and had some 842 documents before it.

Piper Alpha involved a release of flammable gas, which ignited and exploded, and initiated a long and complex chain of escalation. The resultant emergency had many facets, including the assembly in the accommodation module and the escape and rescue. It was therefore a very different type of accident from Flixborough.

The assessors to the inquiry were an experienced oil man who had just retired as managing director of a large oil company, the production director of a large petrochemical company, and an academic specializing in SLP but with 13 years industrial experience. The team was thus well balanced, containing two industrialists and one academic or, viewed from another angle, one from the oil industry and two from outside it.

The inquiry was in two parts. Part 1 dealt with the accident itself, its causes, its escalation and the emergency to which it gave rise, whilst Part 2 dealt with the deeper causes. Prior to Part 1, the judge announced that the inquiry would be considering in Part 2 the following subjects with a view to making recommendations: (1) the location and protection of accommodation, (2) the means of mitigating the effects of explosions, (3) the means of ensuring the integrity of emergency systems, and (4) the means of ensuring full and safe evacuation. As the evidence in Part 1 unfolded, he added (5) permits-to-work, (6) control of the process, (7) risk assessment and (8) the offshore safety regime.

The assembly of the evidence was a major logistical exercise. The inquiry was seeking to determine the cause of an explosion that could have come from a leak through a hole of no more than a few square millimetres. But with most of the platform at the bottom of the sea, it was necessary to decide whether to recover the process equipment; the inquiry decided against doing this. The main accommodation module had, however, been lifted from the seabed. A major, and almost archaeological, exercise took place to recover the documents in this module. The documents believed to be relevant to the inquiry were specified and assembled by the consultants to the inquiry who created a library available to the parties.

The interviewing of the witnesses and the preparation of witness statements was another major activity. Evidence was given to the inquiry by 58 of the 61 survivors, and the other three gave written statements. The inquiry also heard from 38 witnesses to the emergency, 5 eye-witnesses who observed and photographed events, 8 persons from other nearby installations, 32 current and former employees of the operating company on a variety of technical and management matters, 14 current and former employees of other companies, 35 expert witnesses and 6 witnesses on behalf of regulatory and other bodies.

The evidence given in Part 1 by the witnesses not called as experts covered a range of topics: the practices of the company; the activities on the platform in the preceding days; the activities and events immediately prior to the explosion; the explosion itself and its effects; the escalation of the events from the initial explosion to the abandonment of the platform; the behaviour of the communications systems and of the emergency systems for shut-down and fire fighting; the development of and response to the emergency on the platform; the escape from the platform; the response of the fire fighting vessel *Tharos* which was near the platform at that time; the response of personnel on the nearby, linked platforms; and the rescue. In many cases, a single witness had significant evidence on a number of these topics.

The interim report by the Department of Energy indicated two principal hypotheses for the leak of hydrocarbons. One was that a leak occurred from the end of a relief line on a condensate pump where a pressure relief valve had been removed, because the blind flange at that point was not leak-tight or was missing altogether.

The other was that liquid condensate had backed up into a reciprocating compressor and caused damage and a leak.

The inquiry began to hear expert evidence at a quite early stage, interleaved with evidence from the expert witnesses. This covered, among other things, the interpretation of eye-witness evidence on the site, fuel, nature and strength of the initial explosion; the damage to and behaviour of the emergency power and shut-down systems; the gas cloud which formed in the module; the pressures generated by and general behaviour of this gas cloud; the damage to the walls of the module; the missile effects from the explosion; the pressures and flows in the gas and oil pipelines into and out of the Piper platform; the behaviour of hydrates, with special reference to the conditions on the platform; and various aspects concerning the relief line on the condensate pumps.

As an illustration of the mix of witnesses, the first eight called were: (1) a diver (survivor), (2) a detective inspector, (3) a former deputy offshore installation manager, (4) a manager at Lloyds Register, (5) a lead maintenance technician, (6) an expert on explosion modelling, (7) an expert on gas detectors and (8) an electrician (survivor).

In public inquiries, generally, the chairman is able to exercise control and ensure balance by indicating those topics in which the inquiry is interested and those in which it is not. A degree of latitude may be allowed to parties to explore particular issues. In making these decisions the chairman is advised by the assessors. At the end of the day, the final report is that of the judge alone. Nevertheless, it is the assessors' responsibility to advise him on the technical issues. In this sense, an assessor has ownership of the problem. This concentrates the mind and is a strong incentive to try to make sure that evidence is as balanced and complete as possible and that the arguments are in place to support both the positive and negative conclusions. It can occur that different hypotheses for the cause are entertained until a quite late stage or that some hypotheses are discarded but fresh ones are taken on board.

Firm control was exercised in the Piper Alpha inquiry. The inquiry does not appear to have been seriously criticized either for omitting matters which ought to have been considered or for examining particular matters, and especially matters raised by interested parties, to the point of imbalance. The report shows that there was an examination of a wide range of hypothetical leak scenarios, many prompted by non-expert witness evidence, and that several fresh scenarios were given consideration, notably one in which the leak was the result of a chain of events initiated by hydrate blockage and another in which pipework suffered overpressure from a methanol injection pump. But there is little evidence of the pursuit of issues arising from special pleading by parties.

The inquiry did make use of the system of meetings of technical experts, but only on two occasions. Each was chaired by an assessor. The topics at the two meetings were flows in certain pipelines and the scenario of condensate entry into a reciprocating compressor. The purpose of the meetings was to define the areas of agreement and disagreement. In both cases, there were technical reports to consider but the meeting did not deal with experimental work. At the second of these meetings, the experts reached the agreement that the scenario involving ingestion of liquid condensate into a reciprocating compressor could be ruled out. This conclusion was given in evidence to the inquiry and its report accepts this view.

A considerable amount of experimental work was presented in evidence. The inquiry heard about work commissioned by the operating company on the nature and strength of the initial explosion, which included explosion simulation, on the explosion damage to the fire walls, on missiles from these walls, on the failure of the Tartan gas riser and on the leak potential of various configurations of blind flange and on further explosion simulation work done for the Department of Energy. The inquiry itself commissioned wind tunnel tests to determine the gas cloud which might be expected to form given various leak scenarios and the consistency of this with the gas detector evidence. It also commissioned a single explosion simulation for a scenario of a leak at the pressure relief valve site, due either to a non-leak tight blind flange or to a hydrate-initiated event.

The *Piper Alpha Report* concluded that, on balance of probability, the leak occurred from the site of the missing pressure relief valve where the blind flange was not leak-tight. An explanation of this scenario was given which showed that it was possible to tie up quantitatively the leak rate from a non-leak-tight blind flange, the gas detector and wind tunnel evidence of a main leak preceded by a small leak, the size of the flammable gas cloud, the overpressure generated by explosion of that cloud, the damage done by the explosion and the effects experienced in the control room from that explosion.

Among the recommendations made in the report were a change in the regulatory authority and a requirement for submission of a safety case, with a safety management system and quantitative risk assessment.

27.9.4 Role of public accident inquiries

The account given above makes clear that most accidents are in fact investigated outside the forum of a public inquiry. The HSE investigations appear in large part to accord with the intention of the system proposed by Mecklenburgh. The residual issue, therefore, concerns those process industry disasters that are on a scale sufficient to attract a public inquiry. Such disasters are rare events. They are likely to differ greatly one from another and the public inquiries held into them may, and probably should, differ also.

The experience of the Piper Alpha inquiry is instructive. The most striking thing is that the technical issues and the human and managerial issues were interwoven in several ways. In many cases, a witness had evidence to give on both aspects. Witness evidence led to the consideration of fresh leak scenarios. A given scenario often involved both technical and human and managerial aspects.

Timing is another important feature. Time is required to decide on, schedule and obtain the evidence, both in documents and from witnesses, and to allow the experts to prepare their evidence, which often constitutes a mini-research project and may involve physical or computer simulation. The chairman and the assessors need time to digest the evidence and come to a settled view. The interweaving of the technical with the other evidence provides this time.

A third feature is the authority of a public inquiry. The inquiry can require the company involved to furnish documentation that may bear on the accident. The documents may be large in number, some may be hard to locate and some may be sensitive. It can require the attendance of witnesses. Once at the inquiry these witnesses are on oath. Most have probably never been in a court of law, let alone a major accident inquiry.

This authority also allows the inquiry to exercise control to try to ensure that the treatment is as balanced and complete as possible. This control is needed in respect both of interested parties and of technical experts.

Another aspect of authority relates to the fate of its report. Acceptance of the findings of the cause and of the recommendations to prevent recurrence depends in large part on the perception of the inquiry by government, the industry and the public. A public inquiry is better positioned to establish its authority than a technical investigation. This is doubly necessary where an inquiry recommends major changes in the regulatory regime or in the industry.

These considerations suggest that proposals for some form of separate technical investigation are unlikely to improve on the current form of public inquiry. What may be beneficial, however, is to recognize that there is considerable variability in the accidents which occur and that the public inquiry procedure needs to be flexible enough in its way of working to accommodate this variability.

27.10 Organizational Memory

Experience shows that the investigation of accidents is not in itself sufficient to ensure that the lessons are both learned and retained in the collective memory. It is necessary to take specific measures to ensure that this occurs. The problem is considered here from the viewpoint of a company. The arrangements necessary at national level are described elsewhere in this chapter.

Approaches to the problem are discussed in *Lessons from Disaster* by Kletz (1993b) and (1980g, 1982J, 1993c), R.W. Fawcett and Kletz (1982) and Hancock (1989, 1992).

The reduction of accidents is to a large extent a matter of applying what is already known. Unfortunately, within an organization this knowledge often decays. Sometimes it is an individual who is unaware, even though the matter is well known in many parts of the organization. Sometimes the organization as a whole appears to have forgotten. In Kletz' words 'Organizations have no memory'.

Kletz has also put the matter even more graphically. During his time as a safety adviser, he was often tempted to tell a manager on whose plant a familiar accident had happened: 'Don't bother to write the accident report. I'll send you a copy from my files'.

The first step in countering this problem is to ensure that the right lessons are drawn about the accidents that have already occurred, in the company and elsewhere. The need to get down to the fundamental causes was the main theme of Sections 27.5 and 27.8.

Measures aimed at making sure that the lessons are not forgotten but remain fresh in the collective memory are described by Kletz (1993b). Starting from receipt of the report, they may be summarized as follows. The immediate actions should be to (1) follow up the recommendations and (2) publicize the lessons. In order to keep the accident fresh in the memory, steps should be taken periodically to (3) hold workshops in which it is discussed and (4) describe it in the company SLP newsletter. Measures may also be taken to (5) introduce a reference to the accident in any code that contains provision derived from it and (6) create a database of accident case histories that gives company personnel easy access to them. Management should (7) avoid turning a blind eye to unacceptable work practices and (8) before removing equipment or ending a procedure, find out what its original purpose was.

There are a number of recurring themes in accident investigation and it is helpful to be aware of these. Some themes which run through the work of Kletz and which he has highlighted explicitly are shown in Table 27.3.

27.11 Case Histories

Case histories are critical to the learning process. Without this lifeblood, the process would soon shrivel and die. Case histories, and their sources, are described in Appendix 1.

27.12 Information Exchange

Learning can take place only if information on accidents and accident investigations is made freely available by the publication of reports and by schemes for information exchange.

27.12.1 Loss Prevention Bulletin

A principal information exchange scheme is that operated by the Loss Prevention Panel of the Institute of Chemical Engineers (IChemE). The Loss Prevention Bulletin (LPB) published by the panel contains articles on various aspects of SLP, but above all it gives case histories of accidents with accompanying analyses. The titles of the articles in the bulletin are listed after the references given at the end of this book.

Table 27.3 *Some recurring themes in accident investigation (after Kletz)*

A Some recurring accidents associated with or involving
Identification of equipment for maintenance
Isolation of equipment for maintenance
Permit-to-work systems
Sucking in of storage tanks
Boilover, foamover
Water hammer
Choked vents
Trip failure to operate, neglect of proof testing
Overfilling of road and rail tankers
Road and rail tankers moving off with hose still connected
Injury during hose disconnection
Injury during opening up of equipment still underpressure
Gas build-up and explosion in buildings
B Some basic approaches to prevention
Elimination of hazard
Inherently safer design
Limitation of inventory
Limitation of exposure
Simple plants
User-friendly plants
Hazard studies, especially hazop
Safety audits
C Some management defects
Amateurism
Insularity
Failure to get out on the plant
Failure to train personnel
Failure to correct poor working practices

27.12.2 Trend in publication

According to Kletz (1993b), the number of accident case histories published is diminishing. Unless this trend is reversed, the industry's learning process will be severely impaired.

Kletz deals in detail with the justification for the publication of accident reports, the reasons for the fall-off and the measures that should be taken to counter it.

27.13 Accident Databases

The accessibility of accident case histories is much enhanced by the creation of accident databases, particularly computer-based databases.

27.13.1 Major databases

There are a number of major accident databases such as the Major Hazard Incidents Data Service (MHIDAS), the Explosion Incidents Data Service (EIDAS) and the Environmental Incidents Data Service (EnvIDAS) of the Safety and Reliability Directorate (SRD); the Failure and Accident Technical Information System (FACTS) of TNO; the Major Accident Reporting System (MARS) of the Commission of the European Communities (CEC); and World Offshore Accident Database (WOAD) of Veritas Offshore Technology. An account is given in Appendix 1.

27.13.2 Company databases

A number of companies have developed their own accident databases, either confined to accidents that have occurred in the company or extended to include other accidents. An account of such a database in ICI has been given by R.W. Fawcett and Kletz (1982).

27.14 Safety Performance Measurement

Turning from accident investigation to the feedback of information about safety performance in a company, the first requirement is for methods of measuring it. Accounts of safety measurement are given in *Managing Safety* (HSE, 1981d) and *Techniques of Safety Management* (D. Petersen, 1989).

27.14.1 Safety performance metrics

The safety performance criteria that is appropriate to use are discussed in Chapter 6. For personal injury, the injury rate provides one metric, but it has little direct connection with the measures required to keep under control a major hazard. For the latter, what matters is strict adherence to systems and procedures for such control, deficiencies in the observance of which may not show up in the statistics for personal injury. However, as argued in Chapter 6, there is a connection – this is that the discipline which keeps personal injuries at a low level is the same as that required to ensure compliance with measures for major hazard control.

There needs, therefore, to be a mix of safety performance criteria. Those, such as injury rate have their place, but they need to be complemented by an assessment of the performance in achieving safety-related objectives. Safety performance criteria are discussed in detail by Petersen. Different criteria are required for senior management, middle management, supervisors and workers. He lists the desirable qualities of metrics for each group.

Any metric used should be a valid, practical and cost-effective one. Validity means that it should measure what it purports to measure. One important condition for this is that the measurement system should ensure that the process of information acquisition is free of distortion.

Qualities required in a metric for senior management are that it is meaningful and quantitative, is statistically reliable and thus stable in the absence of problems, but responsive to problems and is computer-compatible.

For middle management and supervisors, the metric should be meaningful, capable of giving rapid and constant feedback, responsive to the level of safety activity and effort, but sensitive to problems.

A metric that measures only failure has two major defects. The first is that if the failures are infrequent, the feedback may be very slow. This is seen most clearly where the criterion used is fatalities. A company may go years without having a fatality, so that the fatality rate becomes of little use as a measure of safety performance. The second defect is that such a metric gives relatively little feedback to encourage good practice.

A safety performance metric may be based on activities or results. The activities are those directed in some way towards improving safety practices. The results are of two kinds, before-the-fact and after-the-fact. The former relates to the safety practices, the latter to the absence or occurrence of bad outcomes such as damage or injury.

Metrics for activities or before-the-fact results may be based on the frequency of some action such as an inspection or the frequency of a safety-related behaviour, such as failure to wear protective clothing. Or, they may be based on a score or rating obtained in some kind of audit.

27.14.2 Some incident-based metrics

There are numerous metrics that can be devised based on incidents such as damage or injury. The first requirement for such a measure is a clear definition of the events to be recorded.

The incidents measured may include various forms of injury event and reportable accidents. Types of injury event include first aid treatments, lost time accidents, serious injury accidents and fatalities. Types of reportable accident are those for which there are statutory reporting requirements and those for which there is, in addition, a company reporting requirement.

Some metrics commonly used in the United Kingdom include

$$M_1 = n_{\mathrm{ra}}/N_{\mathrm{p}} \qquad [27.14.1]$$

$$M_2 = N_{\mathrm{lta}}/N_{\mathrm{h}} \qquad [27.14.2]$$

$$M_3 = n_{\mathrm{hl}}/N_{\mathrm{h}} \qquad [27.14.3]$$

where M_1, M_2 and M_3 are metrics, n_{hl} is the number of hours lost, n_{lta} is the number of lost time accidents, n_{ra} is the number of reportable accidents, N_{h} is the number of hours worked and N_{p} is the number of persons at risk.

27.14.3 Organization of measurement

There needs to be a formal system for the measurement of safety performance. This may be organized in various ways. In particular, systems differ in the division of responsibility between line management and the safety function.

It is normal for line management to measure, and report on, production performance and it may well do the same on safety performance. This is the preferred method in the arrangements described by the HSE (1981d). If it is adopted, its operation should be subject to audit by the safety function.

The HSE states 'The most frequently encountered difficulty in applying measuring schemes is for a manager to separate his own performance as an individual from that of his team'. The way in which this problem is resolved depends on the culture of the particular company.

27.15 Safety Performance Monitoring

Given that performance is to be assessed by measuring events, such as failures or accidents, then probability theory may be used to determine whether there has been an improvement or deterioration in performance as between two situations.

27.15.1 Statistical measures

An account of the methods that may be used to detect changes of performance has been given by Wynn (1950). If over a given reference period in a population of size n the observed number of events x has been sufficiently large that the expected number of events, μ ($=x/n$) is firmly known, then the Poisson distribution is applicable

$$P(r) = \exp(-\mu)\frac{\mu^r}{r!} \qquad [27.15.1]$$

where $P(r)$ is the probability of r events. The application of Equation [27.15.1] is facilitated by the use of Figure 27.3, which gives the observed number of events vs the expected number of events. It should be noted that although the curves drawn are continuous, the events to which they apply are integers.

As an illustration of the use of Figure 27.3, consider the case where the expected number is 8. If the observed number is 10, the difference is not significant, but if the observed number is 15, this is significant at the 95% level.

The use of the Poisson distribution in this way is permissible only if the expectation μ is known. The confidence with which the expected number of events is known depends on the observed number of events in the reference period. The determination of the confidence limits for the frequency of an event for use in the exponential or Poisson distribution was described in Chapter 7. Tables of the confidence limits of the Poisson distribution have been given by Woodcock and Fames (1970 UKAEA AHSB(S) R179).

If there is no firm expectation, the Poisson distribution is not applicable, but the problem may be treated using the chi-square distribution. This distribution may be used to test the hypothesis that there is no difference between a reference period and a test period where the population size and the number of events in the reference period are n_1 and x_1 and those in the test period are n_2 and x_2, respectively. For this case, the following chi-square table is applicable:

	No. affected by event	*No. unaffected by event*	*Total*
Population 1	x_1	$n_1 - x_1$	n_1
Population 2	x_2	$n_2 - x_2$	n_2
Totals	$x_1 + x_2$	$n_1 + n_2 - x_1 - x_2$	$n_1 + n_2$

A particular formulation of chi-square for this case (Moroney, 1956, p. 255) is

$$\chi_2 = \frac{[x_1(n_2 - x_2) - x_2(n_1 - x_1)]^2(n_1 + n_2)}{n_1 n_2(x_1 + x_2)(n_1 + n_2 - x_1 - x_2)} \qquad [27.15.2]$$

$$\approx \frac{(x_1 - kx_2)^2}{k(x_1 + x_2)} \qquad n_1 \gg x_1, \quad n_2 \gg x_2 \qquad [27.15.3]$$

with

$$k = \frac{n_1}{n_2} \qquad [27.15.4]$$

The system described here has one degree of freedom, and for this the values of the chi-square are:

Confidence level (%)	χ^2
90	2.706
95	3.841
99	6.635

The application of Equation [27.15.3] is facilitated by the use of Figure 27.4, which gives the group $(x_1 - kx_2)$ vs the group $k(x_1 + x_2)$.

As an illustration of the use of Figure 27.4, consider the case where in the reference period the population size is 1000 and the number of events is 55, and in the test period the corresponding values are 1000 and 45. Then, the values of k and of the groups $(x_1 - kx_2)$ and $k(x_1 + x_2)$ are 1, 10 and 100, respectively. This difference is not significant, but if the numbers of events in the reference and test period are 60 and 40, respectively, the difference is significant at the 95% level.

The chi-square method becomes inaccurate if the number of events in the cells of the chi-square table falls too low. The number should exceed about 20, or for approximate work about 5.

It should be noted that the quantity investigated using the methods just described is the number of events, not the event rate. It is also emphasized that the validity of any conclusions drawn depends on the correct choice of the variable that describes the population size. If in a particular case, for example, it is assumed that the number of maintenance accidents depends on the number of maintenance personnel, whereas in reality it depends on some other factor such as the number of maintenance tasks done, then incorrect conclusions may be drawn.

27.15.2 Vigilance against rare events

The more serious accidents are rare events, and the absence of such events over a period must not lead to any lowering of guard. There needs to be continued vigilance.

The need for such vigilance, even if the safety record is good, is well illustrated by the following extract from the 'Chementator' column of *Chemical Engineering* (1965 Dec. 20, 32) Reproduced with permission of *Chemical Engineering*:

> The world's biggest chemical company has also long been considered the most safety-conscious. Thus a recent series of unfortunate events has been triply shattering to Du Font's splendid safety record.

Latest incident occurred earlier this month when a dust explosion and flash fire in a dyestuff drying machine at the company's immense Chambers Works, Deepwater, N.J., caused some $50,000 damage, claimed two lives and injured nine more, three seriously. Ironically, in August of this year the plant had received an award from the governor of New Jersey for achieving 16,771,355 man hours worked without a single lost time accident.

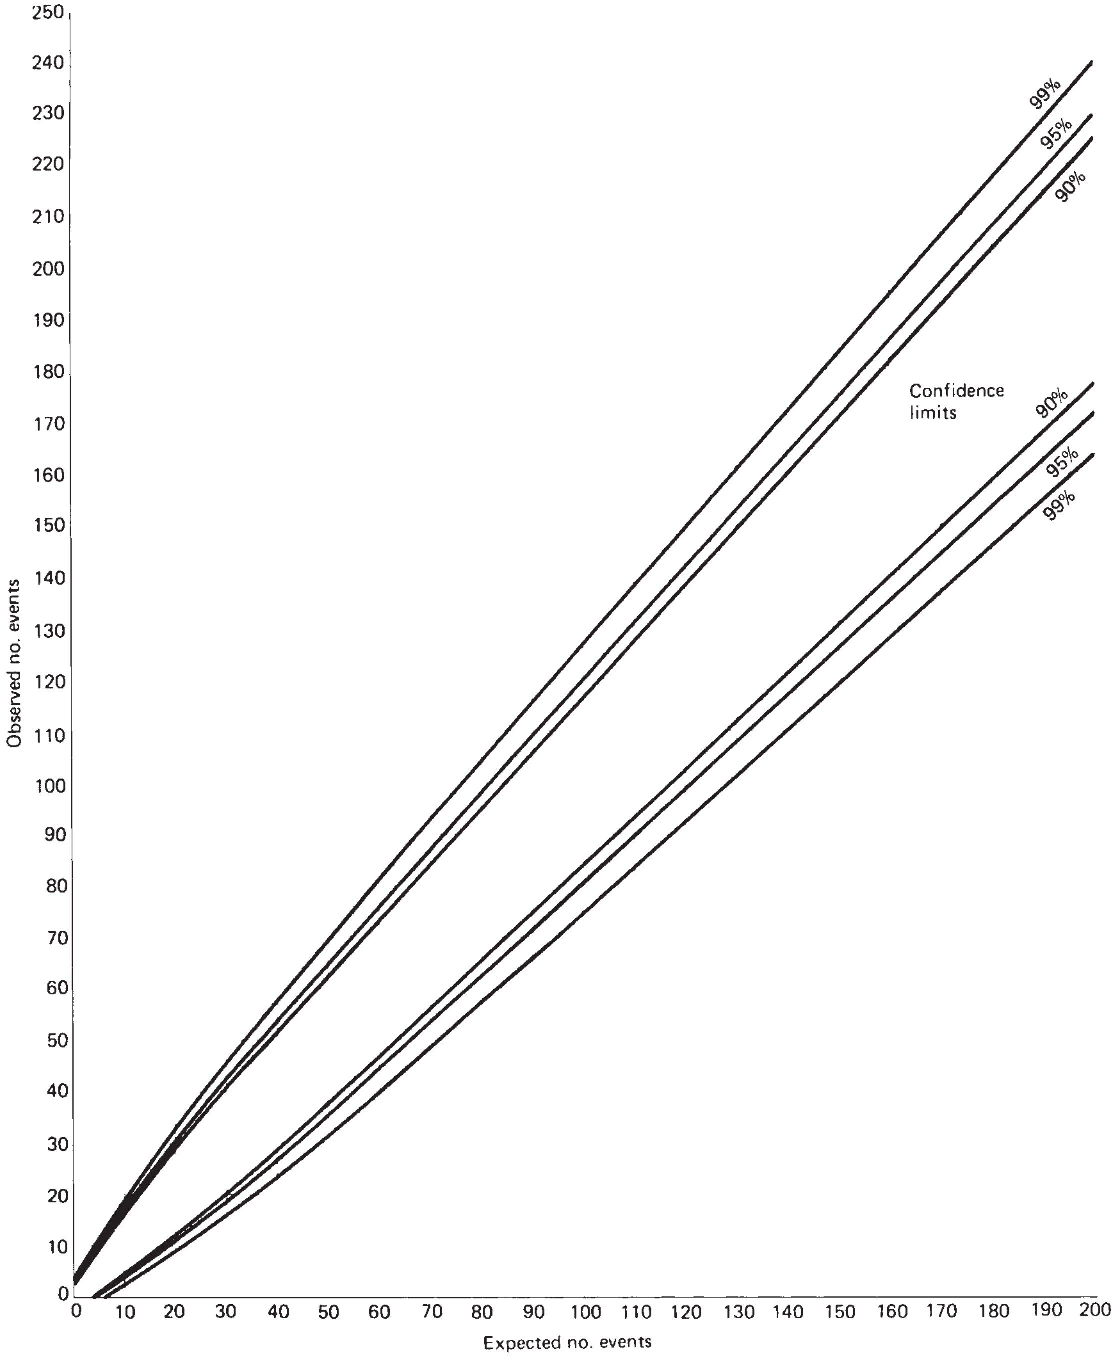

Figure 27.3(a) *Graph (coarse scale) for the determination of trends in safety performance: Poisson distribution (after Wynn, 1950)*

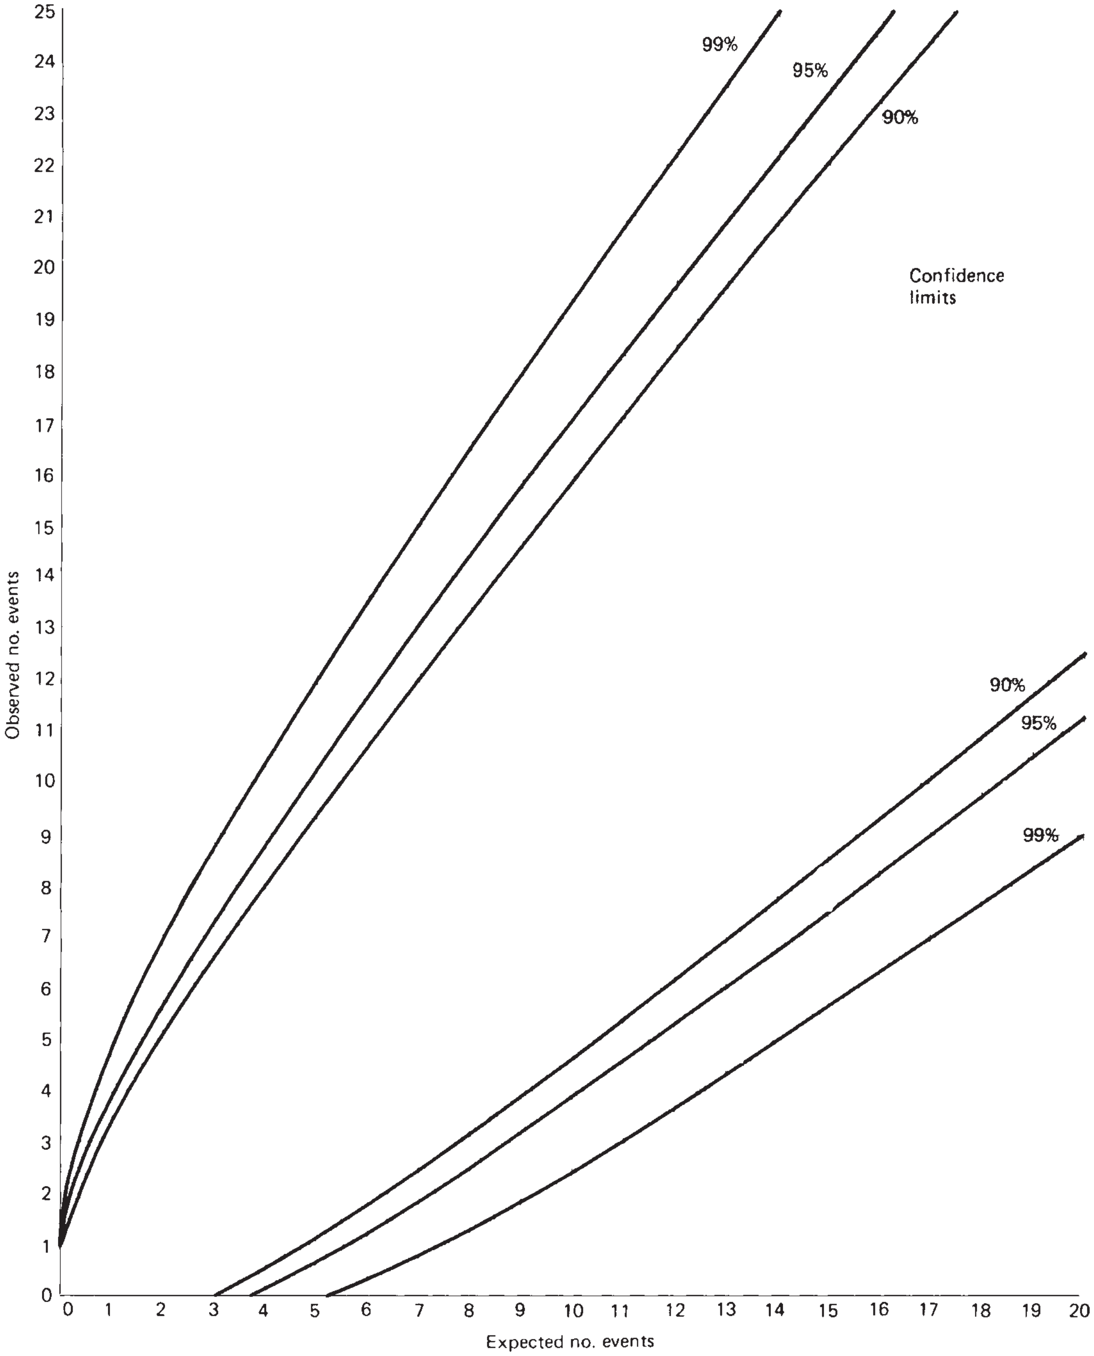

Figure 27.3(b) *Graph (fine scale) for the determination of trends in safety performance: Poisson distribution (after Wynn, 1950)*

In late November, a flash fire swept the drying room of the company's Carney Point, N.J., gunpowder plant. Damage was relatively light but four workmen perished. In operation before the turn of the century, the plant had had no fatal accidents since before World War I.

The earliest of the triple tragedies was a blast and fire at the firm's Louisville plant in August. Claiming 11 lives

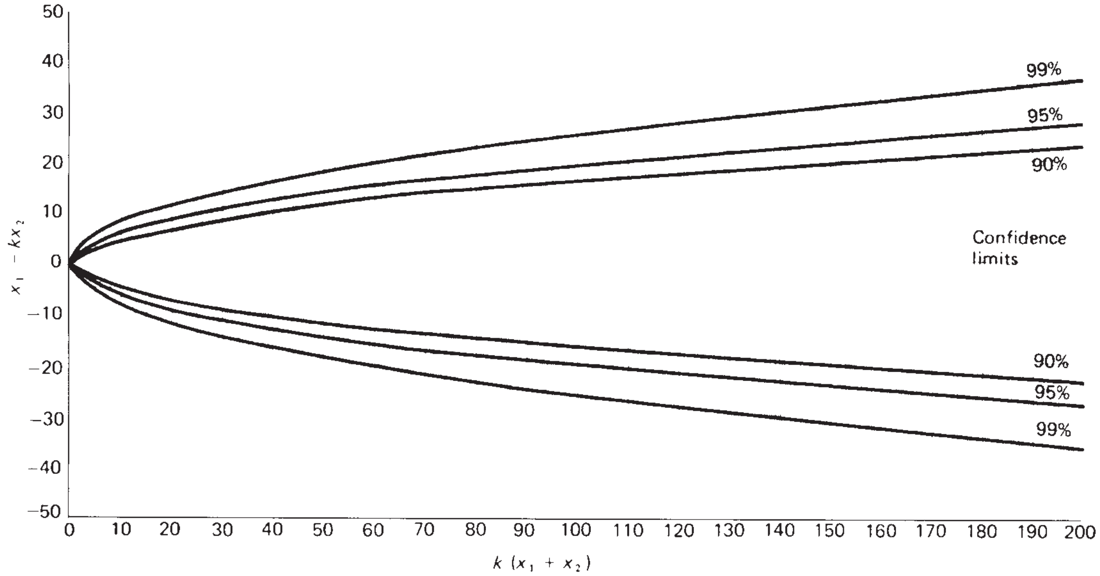

Figure 27.4 *Graph for the determination of trends in safety performance: chi-square distribution (after Wynn, 1950)*

and causing \$5 to \$10 million damage, the accident's magnitude was without precedent in the company's history.

27.16 Near Miss Reporting

It has long been appreciated that for every accident there are many lesser events, some with less material effect and others with no effect at all, and that is desirable to learn from these 'near misses'.

Accounts of the monitoring of and learning from near misses are given in *Near Miss Reporting as a Safety Tool* (van der Schaaf, Lucas and Hale, 1991) and by N. Carter and Menckel (1985).

Near Miss Reporting contains in effect a debate on the subject and poses the question of the purpose of such reporting.

27.16.1 Licensee Event Reports

One of the main public sources of information on near misses is the Licensee Event Reporting system of the Nuclear Regulatory Commission. Analyses of Licensee Event Reports (LERs) have been given by Rasmussen (1980b), who has also used the information given in these reports in his development of a methodology for the handling of human error.

27.16.2 Models for reporting

A system of near miss reporting must specify in some way the events to be reported and must, therefore, be based, explicitly or implicitly, on some form of model. Three principal forms of model are (1) the engineering system, (2) human behaviour and (3) the managerial and organization factors. Each type of model is represented in the account that follows.

27.16.3 Aims of reporting

It is suggested by van der Schaaf (1991c) that near miss reporting may be undertaken for three different purposes: (1) modelling (qualitative insight), (2) monitoring (quantitative insight) and (3) motivation (maintaining alertness).

If the aim is modelling, the interest centres on reporting of 'new' types of near misses, whereas if it is monitoring, the implication is that it is known types that are reported. The third aim, motivation, differs from the other two in that it is essentially a by-product of the reporting, albeit an intended one. The activity of reporting near misses makes people more conscious of them.

The author gives an account of a near miss management system which is aimed at monitoring rather than modelling, but which should have as a by-product an increase in motivation amongst those involved in the reporting.

27.16.4 Near miss management system

A description is given by van der Schaaf (1991b) of a near miss management system (NMMS). The concepts underlying this are that its sole function should be as a means for the organization to learn from near misses, that is should have as comprehensive a coverage as possible of the inputs and outputs, that it should be based on a suitable model of human behaviour and that it should be integrated into, rather than grafted onto, the organization. The modules of the framework for the NMMS are:

(1) Detection: recognition and reporting.
(2) Selection: according to purpose(s).
(3) Description: all relevant hardware, human and organizational factors.
(4) Classification: according to a socio-technical model.
(5) Computation: statistical analysis of large database of incidents to uncover certain (patterns of) factors.

(6) Interpretation: translation of statistics results into corrective and preventive measures.
(7) Monitoring: measuring the effectiveness of proposed measures after their implementation.

Further features of the NMMS are described by van der Schaaf (1991a) in an account of its application in a chemical plant, and specifically in the central control room. The detection module is essentially a redesigned version of an existing near miss reporting system. The selection module allocates the event to the modelling or monitoring mode. The description module utilizes a form of fault tree, termed an incident production tree, which contains as elements not only faults and errors but also recoveries, as described elsewhere by van der Schaaf (1988). The classification module is based on Rasmussen's Skills-Rules Knowledge (SRK) model of human behaviour. The classification proceeds in two stages. In the first stage, a rough classification is made into (1) technical factors, (2) organizational factors and (3) behavioural factors. Each element in the incident production tree is then examined according to the following procedure. It is first considered for classification as a technical factor, and if it is such, it is assigned to a subcategory such as engineering, construction, etc.; if this does not apply, it is considered for classification as an organizational factor; if this also does not apply, then and only then is it considered for classification under the third category as a behaviour factor.

27.16.5 Computer aid for reporting

The practicalities of near miss reporting and a computer-based aid influence diagram analysis (IDA) for such reporting are described by A.R. Hale *et al.* (1991). This work complements that of van der Schaaf just described and utilizes the same framework modules.

A problem with near miss reporting is that if a proforma is used, most of the entries are not relevant to a given event. This can be overcome by the use of a computer aid in which the user is prompted to enter information interactively.

The accident model used in this case is a hybrid derived partly from the energy barrier concept found in MORT (W.G. Johnson, 1980) and partly from the concept of deviation from normal conditions (Kjellen, 1983; A.R. Hale and Glendon, 1987).

27.16.6 Critiques of reporting

A critique of near miss reporting has been given by Reason (1991), who argues that current reporting schemes, where they exist, tend to be relatively ineffective in supporting safety management.

He distinguishes between active failures that have an immediate adverse effect, and latent failures which lie as dormant, enabling conditions until the accident is triggered by an active failure. He likens latent failures to resident pathogens in the human body. He argues that the most effective approach to the prevention of accidents is to identify and neutralize these pathogens.

Reason utilizes an accident model in which a distinction is made between failure types and failure tokens. In essence, the failure types are general classes of managerial and organizational failure, whilst the tokens are specific failures of individuals. The latter are categorized as slips and lapses, mistakes and violations.

He considers five channels for system safety information. These channels are (1) accident and incident reporting systems, (2) unsafe act and near miss reporting systems, (3) precursors of unsafe acts, (4) failure type indicators and (5) stylistic or cultural indicators. The precursors of channel 3 are described in terms similar to those applied to performance shaping factors. The failure types of channel 4 are the classes of managerial failure. The cultural indicators of channel 5 are described in terms of a seven-point ranking scale, which ranges from a condition where safety practices are at the barest industry minimum to one where good practice is followed.

The general failure types are (1) hardware defects, (2) design failures, (3) poor maintenance procedures, (4) poor operating procedures, (5) error-enforcing conditions, (6) poor housekeeping, (7) incompatible goals, (8) organizational failures, (9) inadequate training and (10) inadequate defences.

Reason argues that the key to effective safety management lies in appreciating what is controllable and what is not. He contrasts the situation in respect of accidents with that pertaining in production. Most of the factors that affect production are under the control of management. Accidents are different. They arise from a complex interaction between latent failures and local triggering events. There is little management can do about the latter. It should concentrate on the former, and any near miss reporting system should reflect this. What should be reported are failures at the level of channels 4 and 5.

The need to base near miss reporting on an appropriate model is echoed by Lucas (1991), who proposes reporting based either on the man-machine interface or on system-induced error.

27.16.7 Hazard warning structure

Another approach to near miss reporting is the hazard warning structure developed by Lees (1982b, 1983b, 1985). The basic concept is that the undesired event is modelled using a hazard warning tree, a specialized form of fault tree, so that the place of lesser events in the hazard warning structure can be seen. An account of hazard warning structure with examples is given in Chapter 9.

The hazard warning concept is intended to be used first in the design of plant and to be then carried through into its operation. If at the design stage an analysis has been made of the hazard warning structure for the undesired events of interest, it is then possible to use the analysis to locate lesser events as they occur in the structure, to assess their significance and to take measures to control them.

The hazard warning structure approach is based on, and oriented to, fault trees for engineering systems. By comparison with the near miss reporting just described, it has the following distinguishing characteristics. The events to be monitored are decided in advance and are relatively well defined. Other events not included are not monitored, at least not as part of this particular exercise. The method does not address human errors as such but rather the effects of such errors on the engineering system.

The incident production tree described above evidently has features in common with the hazard warning tree.

27.17 Education

The education of engineers normally includes some material on safety. In chemical engineering, this has traditionally tended to cover aspects such as legal requirements and personal safety. There has also generally been some coverage of the engineering aspects, particularly in design projects, but overall the treatment has been variable.

The occurrence of disasters such as Flixborough, Seveso and Bhopal has highlighted the need for greater awareness of and knowledge about SLP. These three accidents have had particular impact in the United Kingdom, Continental Europe and the United States of America, respectively. The trend has been for industry to urge universities to teach SLP and for professional bodies to introduce a requirement that SLP be part of the curriculum.

Accounts of the treatment of SLP in university courses in chemical engineering have been given by Mewis (1984), Talty (1986), Kaufmann (1987), Kletz (1988l, 1990a), Crowl and Louvar (1989), Nolan (1989), V.C. Marshall (1991c), Crawley and Scott (1992) and Lemkowitz (1992a,b).

The inclusion of SLP in chemical engineering curriculum requires justification. The ACMH in its *Third Report* (Harvey, 1984) stated:

> It is important that students be introduced to the concept of inherently safer design and that they realize that safety in plant operation must be considered right at the start of the design study. Process safety must be taught in a rigorous, stimulating way by staff of appropriate experience. Departments that initially do not have this expertise may need to use the services of experts from other universities, industry and consulting firms. By virtue of the nature of processes that give rise to major hazards, it is the chemical engineer who often fills the position of responsible person in the design or operation of plant, (paragraph 124)

Support for this view is given by Kletz (1981), who advances three principal arguments. One is the importance of treating safety from the outset as an integral part of the design of plant and of aiming for inherently safer design. Another is that whatever use he may make of other subjects taught at university, any practising chemical engineer will be involved in safety matters. He has a moral and legal responsibility and will probably be faced with safety issues from the first day. The third is that SLP involves basic principles.

SLP involves the application of a quantitative approach and encourages numeracy. It is based on a structured approach that involves the identification of hazards, an estimation of their frequency, an estimation of the consequences and decision-making based on defined criteria.

The need for an engineer to take a wider view of the task in hand is emphasized by Crawley and Scott (1992). Industry requires someone who is capable of reasoning and is aware of the factors involved and of the pitfalls. For example, in a design the student may well be able to calculate a flow in a pipe, but fail to give consideration to erosion, vibration, noise or isolation for maintenance.

The need to achieve a cost-effective design is another factor. There is often almost no end to the safety measures that might be taken. The engineer needs a tool which assists in deciding how far to go.

The view exists that even if the need for education in SLP is accepted, it is better done when the engineer first enters industry. However, the chemical engineer may well enter a firm that lacks the means of bringing him up to the level of SLP awareness and capability achievable at university, or one that does not have a safety culture. Even larger companies generally favour its inclusion in the university course. This does not, of course, obviate the need for the company to carry out its own training in SLP, particularly for new entrants.

The extent to which SLP ranks as a mainstream subject in chemical engineering has been examined by V.C. Marshall (1991c). He argues that to qualify, a subject must meet the following criteria. It should (1) be acknowledged as such by the academic culture, (2) be recognized as relevant by students, (3) be intellectually demanding, (4) comprise a well established corpus of knowledge, organized on clearly defined unifying principles, (5) be highly quantitative and thus capable of being subjected to mathematical analysis, (6) possess a content and unifying principles set out in authoritative textbooks, (7) be taught by specialists, (8) be a compulsory subject which must normally be passed and (9) be examined formally. He goes on to consider the extent to which SLP now meets these criteria. V.C. Marshall (1987, 1989c, 1990d) has also attempted to develop the unifying structure which he calls for.

Some objectives to be attained in teaching SLP and means used to achieve them include:

Awareness, interest	Case histories
Motivation	Professionalism
	Legal responsibilities
Knowledge	Techniques
Practice	Problems Workshops
	Design project

There has been considerable debate as to whether SLP should be taught by means of separate course(s) or as part of other subjects. The agreed aim is that it should be seen as an integral part of design and operation. Its treatment as a separate subject appears to go counter to this. On the other hand, there are problems in dealing with it only within other subjects. It cannot be expected that staff across the whole discipline will have the necessary interest, knowledge and experience and such treatment is unlikely to get across the unifying principles. These latter arguments have weight and the tendency appears to be to have a separate course on SLP but to seek to supplement this by inclusion of material in other courses also. It is common ground that SLP should be an essential feature of any design project. In 1983, the IChemE issued a syllabus for the teaching of SLP within the core curriculum of its model degree scheme. This syllabus was:

> *Safety and Loss Prevention*. Legislation. Management of safety. Systematic identification and quantification of hazards, including hazard and operability studies. Pressure relief and venting. Emission and dispersion. Fire, flammability characteristics. Explosion. Toxicity and toxic releases. Safety in plant operation, maintenance and modification. Personal safety.

In 1988, the IChemE issued further suggestions for the teaching of SLP. The background to these is given by Nolan (1989) and Crawley and Scott (1992), who also give an outline of the material proposed.

The topics highlighted by Kletz (1988l) as core material in SLP are inherently safer design, hazop, hazard analysis, human error and maintenance and modification.

The emerging pattern in the introduction of SLP into undergraduate courses appears to be an elementary treatment, perhaps within an overview course on chemical engineering, early on followed at some later point by a dedicated course on SLP. This is the approach described by Crawley and Scott and by Lemkowitz (1992a,b).

Another subject that has many similarities to SLP is environmental protection. These similarities include the engineer's moral and legal responsibilities, the concept of inherently cleaner design and a structured approach to environmental risks. There is a discernible trend, therefore, to treat environmental protection in a manner broadly similar to, and sometimes in the same course as, SLP.

The inclusion of SLP within a university chemical engineering course is not without its problems. One is the allocation of time within the timetable. The order of contact hours typically mentioned is some 4 hours for elementary treatment early on and 20 hours for a later dedicated course.

The other main problem is the availability of staff able and willing to teach SLP. Such teaching requires both industrial experience and knowledge not only of the specific discipline of SLP but of a number of core subjects. Only a small proportion of departments contain staff specializing in the subject. It is recognized, therefore, that there is need for support for staff teaching SLP. Two principal forms of support are the use of engineers from industry to complement the academic teaching and the provision of teaching material on the subject.

SLP can serve as an integrating factor in a course. In this respect, it has much in common with a design project. Some of the regular chemical engineering subjects on which the teaching of SLP draws are:

(1) mathematics;
(2) thermodynamics;
(3) fluid mechanics;
(4) mass transfer;
(5) heat transfer;
(6) reaction engineering;
(7) particle science and technology;
(8) process instrumentation;
(9) process dynamics and control;
(10) human factors;
(11) computer methods;
(12) management;
(13) engineer in society.

Table 27.4 illustrates some of the links between SLP topics and regular chemical engineering subjects.

Accounts of practice in particular courses are given by Kaufmann (1987), Kletz (1988l) and Lemkowitz (1992a,b). Kaufmann describes the use of a number of mini-courses, taking some 10–15 min. The treatment described by Lemkowitz involves an integrated treatment of SLP and environmental protection and has three main parts. In the first, early part a problem is taken from the media or the literature and becomes a project for investigation by the student, which involves interviewing industrial personnel about it. The second part is a dedicated course of lectures taking some 24 hours. The third part is a safety report that is submitted prior to starting on a laboratory project.

Table 27.4 *Some links between safety and loss prevention and other subjects in chemical engineering*

SLP topic	*Regular subject*
Inherently safer design:	
Chemical reactors	Reaction engineering
Separation processes	Mass transfer
System failure	Reliability engineering
Failure rates	Probability theory
Pressure vessels	Properties of materials: Strength of materials Fracture mechanics
Chemical reactors:	
Reaction runaway	Reaction engineering
Instruments	Instrumentation
Venting	Fluid mechanics: two-phase flow
Trip systems:	Instrumentation
Trip failure	Reliability engineering
Trip response	Process dynamics
Process operator	Human factors
Emission:	
Relief valve discharge	Fluid mechanics: gas flow
Flashing liquid	Fluid mechanics: two-phase flow
Vessel burst	Mixing processes
Vaporization:	
Volatile liquid	Simultaneous heat and mass transfer
Cryogenic liquid	Unsteady-state heat transfer
Dispersion	Turbulence theory
Fire	Radiant heat transfer
Explosion:	
Explosion energy	Thermodynamics
Adiabatic flame temperature	Thermodynamics
Toxicity:	
Toxicity testing	Probability theory
Computer aids:	
Plant design	Expert systems
Fault tree synthesis	Graph theory
Valve sequencing	AI techniques
Pressure systems management	Management
Risk criteria	Engineer in society

27.18 Teaching Aids

There are available a number of teaching aids of various kinds, suitable for use in the education of engineers at universities and/or of engineers and other personnel in industry.

Short introductions to SLP are given in *Flowsheeting for Safety* (Wells, Seagrave and Whiteway, 1976) and *A First Guide to Loss Prevention* (McCrindle,1981) and more substantial texts include *Industrial Safety Handbook* (Handley, 1977), *An Introduction to Loss Prevention* (Wells, 1980), *Industrial Hazard and Safety Handbook* (R. King and Magid, 1979), *Safety and Accident Prevention in Chemical Operations* (H.H. Fawcett and Wood, 1982), *High Risk Safety Technology* (A.E. Green, 1982b), *Major Chemical Hazards* (V.C. Marshall, 1987), *Chemical Process Safety* (Crowl and

Louvar, 1990) and *Safety in the Process Industries* (R. King, 1990), as well as the present book.

A series of books by Kletz includes *Cheaper, Safer Plants* (Kletz, 1984d), *Learning from Accidents in Industry* (Kletz, 1988h), *What Went Wrong?* (Kletz, 1988n), *Improving Chemical Engineering Practices* (Kletz, 1990d), *An Engineer's View of Human Error* (Kletz, 1991e), *Plant Design for Safety* (Kletz, 1991g), *Hazop and Hazan* (Kletz, 1992b) and *Lessons from Disaster* (Kletz, 1993b).

The IChemE has been active in the production of a variety of aids. Table 27.5 lists a computer simulation, open learning modules, slide modules and video training modules on various topics. Other aids include the information exchange scheme of the *Loss Prevention Bulletin*, the publications listed in Appendix 28, and many of the books by Kletz just mentioned.

Another source of material is the CCPS of the American Institute of Chemical Engineers (AIChE). Specifically, educational material from this source includes *Safety Health and Loss Prevention in Chemical Processes: Problems for Undergraduate Engineering Curricula – Instructor's Guide* (CCPS, 1990).

There are available a number of films and videos, both on the process industries generally, and on SLP in particular. Some of these are listed in Table 27.6.

Safety Management Systems

Contents

Safety and loss prevention depend primarily on the overall management system, as described in Chapter 6 and also in other chapters. The people who carry the main responsibility for safety are the line managers rather than the safety specialists. At managerial, as at other levels, safety is everyone's responsibility. There remains a need, however, within the management system for a specific safety organization and for safety personnel. The quality of this safety system can have a significant effect on safety performance.

Selected references on process safety systems are given in Table 28.1.

28.1 Safety Culture

It is crucial that senior management should give appropriate priority to safety and loss prevention. It is equally important that this attitude be shared by middle and junior management and by the workforce.

A positive attitude to safety, however, is not in itself sufficient to create a safety culture. Senior management needs to give leadership in quite specific ways. Safety publicity as such is often a relatively ineffective means of achieving this; attention to matters connected with safety appears tedious or even unmanly. A more fruitful approach is to emphasize safety and loss prevention as a matter of professionalism. This in fact is perhaps rather easier to do in the chemical industry, where there is a considerable technical content. The contribution of senior management, therefore, is to encourage professionalism in this area by assigning to it capable people, giving them appropriate objectives and resources, and creating proper systems of work. It is also important for it to respond to initiatives from below. The assignment of high priority to safety necessarily means that it is, and is known to be, a crucial factor in the assessment of the overall performance of management.

A fuller discussion of management leadership in creating a safety culture is given in Chapter 6.

28.2 Safety Organization

28.2.1 Safety department organization

It is normal for there to be a separate department responsible for safety and loss prevention. Titles vary, but generally include some combination of those two phrases.

Managers involved in safety work are generally referred to as safety managers, safety advisers or safety officers. The head of a larger department is typically designated as safety adviser and other staff as safety officers.

A large department may have staff who specialize in areas such as engineering, safety systems and manuals, training, and so on.

Other areas which may come within the safety department include occupational health, industrial hygiene, process safety, medical matters and environmental protection.

The safety department needs to be, and be seen to be, independent, and the organizational structure should reflect this. In particular, the department should be independent of the production function.

28.2.2 Safety responsibilities

In broad terms, it is the responsibility of the safety organization to: participate in the formulation of safety policy; ensure that safety systems are created, maintained and adapted; ensure compliance with the regulatory requirements; review plants and procedures; identify, assess and monitor hazards; educate and train in safety; assist communication and promote feedback in safety matters; and contribute to technical developments in safety. Thus, safety personnel are concerned with the development and maintenance of the overall safety system and with its application to particular works and to plants.

As already stated, it is line management which has the executive responsibility for safety, as it does for production; the role of the safety function is advisory. This means that in many areas of safety it is line management which undertakes an activity, but with assistance from the safety function. Accident investigation is a case in point.

In many instances, the safety department will monitor and will intervene only if necessary. For example, the plant emergency procedures manual should be revised periodically. The safety department will recognize a responsibility to see that this is done. If necessary, it will prompt line management to undertake the revision and may provide support.

Turning to the specific areas for which safety department typically takes some responsibility, these include:

(1) advice to senior management, including –
  (a) overall safety policy,
  (b) safety management system,
  (c) compliance with regulatory requirements,
  (d) safety performance measurement,
  (e) technical aspects of safety,
  (f) litigation support,
  (g) hazard insurance reviews,
(2) creation, monitoring and revision of safety management system, including –
  (a) personnel selection criteria,
  (b) process safety reviews, hazard studies,
  (c) safety auditing,
  (d) emergency planning,
  (e) accident investigation,
  (f) safety documentation,
  (g) safety training,
  (h) compliance with regulatory requirements,
(3) oversight and prompting of safety-related activities, including those in (2);
(4) safety training, exercises and drills;
(5) communication, including –
  (a) developments in regulatory requirements,
  (b) developments in technology,
  (c) good practice in safety,
  (d) accident investigation and case histories.

The safety department has a responsibility to ensure that there exists a safety management system which is appropriate and comprehensive, to monitor its implementation and operation, and to undertake period audits and reviews and to make proposals for revision as necessary.

On safety matters, the department should be the company's window to the outside world, monitoring developments, whether in legislation, technology or good practice.

For large projects, the safety department will need to plan ahead in some detail, to ensure that the various process safety reviews and hazard studies are scheduled and resourced.

Increasingly, safety personnel are involved in technical matters. Typical areas where safety personnel have had a strong technical input in recent years include inherently safer design, trip systems, isolation arrangements, hazard identification techniques, hazard analysis, quantitative risk assessment and emergency planning.

The safety department will have a substantial commitment to education and training. This includes such essential aspects as: induction and refresher training on safety matters; and exercises and drills for emergencies such as a fire or toxic gas release and for fire fighting. But its activities should also go beyond this and should extend in two further directions in particular. One is the creation of the safety culture and the dissemination of good practice. The other is training for new safety-related techniques. Examples of techniques introduced in recent years are hazop studies and quantitative risk assessment. In both cases, safety personnel have taken the lead in introducing the techniques and training engineers to apply the methods themselves. Safety training is considered further in Section 28.7.

Many of the activities described involve some form of communication. This is considered in more detail in Section 28.8.

28.2.3 Safety professionals

Personnel involved in work on safety and loss prevention tend to come from a variety of backgrounds and have a variety of qualifications and experience. It is possible, however, to identify certain trends. One is increasing professionalism. The appeal to professionalism is an essential part of the safety culture, and this must necessarily be reflected in the safety personnel. Another trend is the involvement in safety of engineers, particularly chemical engineers. A third trend is the extension of the influence of the safety professional.

The addition of a process safety course in many university chemical engineering curriculum has increased dramatically the safety awareness of recent graduates.

In the following section, an account is given of the role of a typical safety officer. Discussion of the role of the more senior safety adviser is deferred until Section 28.6.

28.2.4 Safety officer

The role of the safety officer is in most respects advisory. It is essential, however, for the safety officer to be influential and to have the technical competence and experience to be accepted by line management. The latter for their part are not likely persistently to disregard the advice of the safety officer if he possesses these qualifications and is seen to be supported by senior management.

The situation of the safety officer is one where there is a potential conflict between function and status. He may have to give unpopular advice to managers more senior than himself. It is a well-understood principle of safety organizations, however, that on certain matters, function carries with it authority.

The safety officer should have direct access to a senior manager, for example, works manager, should take advantage of this by regular meetings and should be seen to do so. This greatly strengthens the authority of the safety officer.

Much of the work of a safety officer is concerned with systems and procedures, with hazards and with technical matters. It should be emphasized, however, that the human side of the work is important. This is as true on major hazards plants as on others, since it is essential on such plants to ensure that there is high morale and that the systems and procedures are adhered to.

Although the safety officer's duties are mainly advisory, he may have certain line management functions such as responsibility for the fire fighting and security systems, and he or his assistants often have responsibilities in respect of the permit-to-work system.

28.2.5 Associated areas

Safety is commonly associated with one or both of two additional areas: (1) occupational health and (2) environmental protection.

The association of safety with occupational health is a long-standing one. In some cases the two have operated as separate, parallel functions, whilst in others one has been subsumed into the other. An account of the relationship between the two has been given by Kilian (1982). The increasingly strict requirements for industrial hygiene have resulted in a substantial expansion in occupational health, which mirrors that in safety and loss prevention.

As environmental protection has grown in prominence, it has become increasingly linked with safety. There appear to be a number of reasons for this. One is that it may be a matter of chance whether an incident results in injury to people or in acute damage to the environment. Another is that the loss prevention approach is broadly applicable also to environmental protection. A third is that it is often convenient to combine the safety and environmental functions.

28.2.6 Safety roles

A study of the role of safety specialists in industry from the viewpoint of the social scientist has been described by S. Dawson, Poynter and Stevens (1985).

They identify the three main activities of safety personnel as (1) processing and generating information, (2) giving advice and participating in problem solving and (3) taking direct action. These activities may be undertaken at any one of five stages of the technical control of hazards, namely (1) identification of hazards, (2) assessment of risk, (3) development of controls, (4) implementation of controls and (5) long-term monitoring and adaptation of risk and standards. They illustrate the matrix, which arises from this schema, as shown in Table 28.2.

With regard to the sources of influence to which the safety specialist has access, the authors identify: (1) formal

Table 28.2 *Safety specialist activities in relation to technical control of hazards (S. Dawson, Poynter and Stevens, 1985) (Reproduced by permission of Elsevier Science Publishers)*

Safety specialists' activities	*Stage of technical control*				
	Identification of hazards	*Assessment of risk*	*Development of controls*	*Implementation of controls*	*Longer term monitoring and adaptation*
A Processing information	Keeping accident statistics. Processing hazard information	Calculating accident frequencies, etc. Processing information on hygiene standards	Processing equipment manufacturers' information and lists of products, etc.	Processing orders for safety equipment	Comparing accident statistics over time
B Giving advice/problem-solving					
B1 Passive adviser	Looking at work operations, on request. Investigating complaints	Answering questions about severity of hazards	Commenting on available controls which have been suggested	Commenting on effectiveness on request	Investigating accidents. Inspecting. Providing feedback on request
B2 Active adviser	Taking initiative in looking for hazards	Lobbying for appropriate standards, control limits	Recommending controls	Identifying shortfalls and improvements	Making recommendations for update/review of systems
C Taking direct executive action					
C1 Jointly with line management	Doing joint inspections and audits	Jointly deciding on standards	Jointly drawing up codes of practice	Joint supervision and approval or disapproval to jobs	Participating in reviews of arrangements
C2 Alone	Doing own inspections and audits	Deciding unilaterally what is safe/unsafe	Issuing instructions. Specifying controls to be followed	Supervising job. Exercising veto. Physically stopping people working	Modifying procedures, etc., on own initiative

organizational position; (2) managerial dependence on specialist expertise; (3) patronage by senior management; (4) direct role in the control process; (5) internal coalitions, for example, with the workforce; (6) external coalitions, for example, with the HSE; and (7) personal qualities.

In respect of the dependence of senior management on safety specialists, they see the relationship extending from one in which the safety function is required to assure compliance and to deal with external agencies to one in which it has increasing relevance to core managerial objectives and activities.

28.3 Safety Policy Statement

In both Europe and the United States, legislation has decreed that the company must protect workers from hazards of the plant.

The US Occupational Safety and Health Administration has a general duty clause. The general duty clause, Section 5(a)(1) of the Occupational Safety and Health Act of 1970, applies to all employers and requires each employer to provide employees with a place of employment which is free of recognized hazards that may cause death or serious physical harm.

The Health and Safety at Work etc. Act (HSWA) 1974, Section 2(3), states:

> Except in such cases as may be prescribed, it shall be the duty of every employer to prepare and as often as appropriate revise a written statement of his general policy with respect to the health and safety at work of his employees and the organization and arrangements for the time being in force for carrying out that policy, and to bring the statement and any revision of it to the notice of all his employees.

It is suggested, however, that in large or complex undertakings, it may be appropriate to divide the policy statement into two parts. The first should be a single document giving a concise statement of general policy, organization and arrangements, and the second a more detailed document, or collection of documents, including manuals of rules and procedures.

28.4 Safety Representatives

A system of safety representatives with responsibility for their fellow workers at a particular workplace has long existed in chemical works.

A safety representative is appointed by a trade union. He represents in the first instance, the employees who are members of that union, but may by agreement represent other employees also. The functions of the safety representative are to represent the employees in consultation with the employer.

His specific functions, typical of both the United States and European Regulations, are as follows:

(1) to investigate potential hazards and dangerous occurrences at the workplace (whether or not they are drawn to his attention by the employees he represents) and to examine the cause of accidents at the workplace;
(2) to investigate complaints by any employee he represents relating to that employee's health, safety or welfare at work;
(3) to make representations to the employer on matters arising out of sub-paragraphs (1) and (2) above;
(4) to make representations to the employer on general matters affecting the health, safety or welfare at work of the employees at the workplace;
(5) to carry out inspections in accordance with Regulation 5, 6 and 7 below;
(6) to represent the employees he was appointed to represent in consultations at the workplace with inspectors of the Regulatory Authority and of any other enforcing authority;
(7) to receive information from inspectors; and
(8) to attend meetings of safety committees where he attends in his capacity as a safety representative in connection with any of the above functions.

The safety representative should keep informed on the hazards of the workplace, the relevant legislation and the employer's safety policy, organization and arrangements. The employer's duty to disclose information is particularly important in relation to safety representatives. The Regulations require an employer to make available to safety representatives information which is within the employer's knowledge and which the representatives need to enable them to fulfil their function.

The information which the employer makes available should include:

(1) information about the plans and performance of their undertaking and any changes proposed insofar as they affect the health and safety at work of their employees;
(2) information of a technical nature about hazards to health and safety and precautions deemed necessary to eliminate or minimize them, in respect of machinery, plant, equipment, processes, systems of work and substances in use at work, including any relevant information provided by consultants or designers or by the manufacturer, importer or supplier of any article or substance used, or proposed to be used, at work by their employees;
(3) information which the employer keeps relating to the occurrence of any accident, dangerous occurrence or notifiable industrial disease and any statistical records relating to such accidents, dangerous occurrences or cases of industrial notifiable disease;
(4) any other information specifically related to matters affecting the health and safety at work of his employees, including the results or any measurements taken by the employer or persons acting on his behalf in the course of checking the effectiveness of his health and safety arrangements;
(5) information on articles or substances which an employer issues to homeworkers.

Another important right of the safety representative is to inspect the workplace. The guidance notes refer to the following types of inspection:

(1) safety tours – general inspections of the workplace;
(2) safety sampling – systematic sampling of particular dangerous activities, processes or areas;
(3) safety surveys – general inspections of the particular dangerous activities, processes or area.

The safety representative also has the right to carry out inspections following notifiable accidents, dangerous occurrences and notifiable industrial diseases.

The safety representative should act as a channel of communication between the management and the workforce on safety matters. The arrangements outlined create the conditions for a concerned individual to make a major contribution to the safety of his fellow workers.

The relation between safety representatives and safety committees is a flexible one. Safety representatives are not appointed by or responsible to safety committees, or vice versa. There are provisions to protect safety representatives from both civil and criminal legal action arising from the discharge of their duties.

28.5 Safety Committees

Feedback from works personnel on safety matters is often most effective through such informal channels as direct contact with a foreman or manager. The formal system consists of safety representatives and safety committees.

The most common practice requires the employer to establish a safety committee if requested to do so by at least two safety representatives. The guidance notes suggest that the objectives of a safety committee are to promote cooperation between employers and employees and to provide a forum for participation by employees in matters of health and safety and that specific functions might include:

(1) the study of accident and notifiable diseases statistics and trends, so that reports can be made to management on unsafe and unhealthy conditions and practices, together with recommendations for corrective action;
(2) examination of safety audit reports on a similar basis;
(3) consideration of reports and factual information provided by inspectors of the enforcing authority under the Health and Safety at Work Act;
(4) consideration of reports which safety representatives may wish to submit;
(5) assistance in the development of works safety rules and safe systems of work;
(6) a watch on the effectiveness of the safety content of employee training;
(7) a watch on the adequacy of safety and health communication and publicity in the workplace;
(8) the provision of a link with the appropriate inspectorates of the enforcing authority.

The existence of a safety committee does not in any way relieve management of its responsibility for safety, but such a committee can fulfil a valuable function in complementing the work of the professional safety personnel.

The response of management to suggestions made by the safety committee is very important. This does not mean that suggestions should always be accepted. But where they are not, a reasoned explanation should be given.

28.6 Safety Adviser

The safety department is led by a safety adviser. The approach taken by the safety adviser may well have a crucial influence on safety and loss prevention in the company. In the process industries, the work of the safety adviser is likely to have a large technical content. As loss prevention has grown in importance, so has the function of the safety adviser.

The role of the safety adviser is to a considerable extent what the person appointed makes of it. The approach taken by one safety adviser is illustrated by the work of Kletz, which is referred to frequently in this book. Some of the technological developments with which he is associated include: inherently safer design; hazop studies; hazard analysis, and the adoption of a quantitative approach generally; human factors; emergency isolation valves and trip systems; incident investigation; and safety education and training. Kletz has described his work in a number of books the titles of which are given in Chapter 27.

The work of other safety advisers mentioned in this book includes that of W.B. Howard (1983, 1984), Lynskey (1985) and Searson (1982, 1983).

28.7 Safety Training

Training in safety is important both for management and for workers. Some of the general principles which should govern such training are outlined in Chapter 14. The discussion here deals primarily with the content of training.

Guidance on safety training includes the many books issued by the AIChE Center for Chemical Process Safety, and the Safety series of the IChemE. Managers require training, particularly in technical aspects of safety and in the loss prevention approach, in company systems and procedures, in the division of labour between the company's specialist safety personnel and themselves, and in training workers. Some topics in safety training for managers are listed in Table 28.3.

Any of the usual methods of training may be used, but particular mention should be made of case studies of incidents, which have proved especially effective. A number of case studies, often with audio-visual material have been

Table 28.3 *Some topics in safety training for managers*

Managerial responsibility for safety and loss prevention
Legal requirements, in particular the Health and Safety at Work etc. Act 1974, the Factories Act 1961, the CIMAH Regulations 1984 and the COSHH Regulations 1988 and the work of the Health and Safety Executive
Principles of safety and loss prevention
Company's management system in relation to safety and loss prevention
Company safety policy, organization and arrangements, including safety personnel, safety representatives and safety committees
Hazards of the particular chemicals and processes
Accidents and accident prevention, including accident statistics and case studies
Pressure systems
Trip systems
Principle of independent assessment
Plant maintenance and modification procedures, including permits-to-work and authorization of modifications
Fire prevention and protection
Emergency planning arrangements
Training of personnel
Information feedback
Good housekeeping
Sources of information on safety and loss prevention, including both people and literature
Case histories

produced by ICI and the IChemE. These include some of the case histories given in Appendix 1.

In addition, managers should also be familiar with the material which workers need to know. Workers require training particularly in recognition of hazards, in systems of work, in the use and location of safety equipment, and in actions to be taken in particular situations. Some topics in safety training for workers are listed in Table 28.4.

For process operators, the list given in Table 28.4 is complementary to that in Table 14.11, which covers more general aspects, but includes many which have a large safety content. In particular, aspects such as the identification of equipment are very important. Table 28.4 makes reference to various kinds of equipment such as those for personal protection, fire fighting, first aid and rescue. It is important that the training covers all aspects of its use, including when to use it, how to use it and where to find it.

Safety training should be included in the initial induction course so that the worker does not endanger himself and his fellows when he first goes onto the plant.

This initial training should be supplemented as soon as possible by more thorough safety training.

The supervisor, or foreman, has a particularly important part to play in training workers.

Training needs to be supported by documentation of various kinds. The plant design and operating manuals are key documents for training. In particular, the use of task analysis to assist in the development of operating procedures and operating manuals has been described in Chapter 14 and the writing of operating manuals in Chapter 20.

There is also a need for documentation more specifically concerned with safety in aspects such as company safety rules and procedures, procedures in the case of fire and information on chemicals. Data sheets describing the properties and handling of individual chemicals are issued by various bodies.

Table 28.4 *Some topics in safety training for workers*

Workers' responsibility for safety
Legal background, in particular the Health and Safety at Work etc. Act 1974 and the Factories Act 1961
Company safety policy, organization and arrangements, in particular general safety rules, safety personnel, safety representatives and safety committees
Hazards of the particular chemicals and processes
Fire/explosion hazard (flammable mixture, ignition source). Ignition sources and precautions, including hazardous area classification, static electricity, welding, smoking. Fire spread, fire doors. Action on discovering fire or unignited leakage.
Toxic hazard. Action on discovering toxic release
Emergency arrangements, including alarm raising, alarm signals, escape routes, assembly points
Protective clothing, equipment use and location
Fire fighting methods, equipment use and location
Rescue methods, equipment use and location
First aid methods, equipment use and location
Lifting and handling
Permit and handover systems
Security, restricted areas
Good housekeeping
Accident reporting
Health, medical aspects
Case histories

See also Table 14.10

Again case studies of incidents are an especially effective training technique. Atherton (1971) has described an interesting variation of this method in which the case study material consisting of slides and voice recordings was itself developed by a team comprising managers and workers. The incident selected for reconstruction was a real accident, in which a fitter removed a blank from a sulfuric acid line and received chemical burns. Extracts from the dialogue and points arising are shown in Table 28.5.

28.8 Safety Communication

A major aspect of the activity of safety personnel is communication in its various forms. This follows from the advisory role of the safety function. For the most part, communication takes place as a result of the participation of safety personnel in the various activities such as process safety reviews and hazard studies, emergency planning, safety training and safety cases. Such participation can be an effective means of creating and maintaining the safety culture.

In addition, it should be one of the aims of the safety department to exploit a range of communication techniques

Table 28.5 *Extracts of dialogue from an accident case history reconstructed for training purposes (Atherton, 1971) (Courtesy of the Institution of Chemical Engineers)*

(a) Start of incident

Dialogue

Maintenance foreman: In the morning, Len, I want to put B2 pump in on the weak circulation tank in C.D.
Process foreman: O.K., George, I'll have a clearance ready for you. There's no need for me to be there, you know the job. I'll put a chalk mark on the flange where the blank has to be removed. Just tell the fitter to be careful but he'll know what he is doing.

(b) The fitter is about to remove the blank

Dialogue

Fitter: Right, can you pass me the 5/8 in. spanner, Chris?
Apprentice: O.K.
Fitter: I'll start on these back bolts first. By hell These are tight.
Apprentice: How long have these been in?
Fitter: They look like originals, don't they?
Apprentice: Aye.
Fitter: I think we'll start on these front ones first, they look a bit easier.

Points arising

1 Poor attitude by supervisor
2 Poor identification of equipment
3 Assumes the fitter knows the properties of the chemicals with which he will come into contact
4 No mention of any specific instructions
5 Question clearance procedure

Points arising

The man knows the correct procedure, but takes a short cut (a common theme of many accidents) to inform and motivate people at all levels in the organization. Matters on which it will wish to communicate include developments in regulatory requirements, developments in technology, and good practice in safety.

There are a variety of techniques which are used to do this. There is commonly a safety newsletter. Table 28.6 shows some of the topics dealt with in issues of the *ICI Safety Newsletter*. Important features are that the topics are matters of concern and that the comments made are clear, practical, reasoned and authoritative.

Incident investigations and case histories, and the lessons drawn from these, provide concrete illustration of the principles. Incidents within the company are likely to make most impact, but it should be the case that these are not numerous enough to transmit the message, so that it is necessary to draw also on case histories from elsewhere. A detailed account of incident investigation and of the approach to drawing the lessons is given in Chapter 27.

The potential of case histories is not exhausted by recounting them in a newsletter. As described above, they should also be used in workshops, in which the group is invited to carry out its own analysis of the lessons to be learned and to formulate its own recommendations.

In addition to providing general reinforcement of the safety culture, such communication addresses two specific problems. One is raising the safety awareness of fresh and inexperienced personnel. Another is arresting the decay of procedures whose purpose is liable be forgotten if some time has elapsed since an incident occurred.

Another form of communication is to draw the attention of management to deterioration in the operation of systems and procedures and to malpractices. This is effective but requires a certain skill.

Table 28.6 *Some questions I am often asked (after ICI Safety Newsletter)*

1	66/8	Do we spend more on safety than other companies?
2	67/4	Would two small plants be safer than one big one?
3	68/7	How can we change people's attitude to safety?
4	69/4	What is our policy on safety?
5	70/5	Men are unreliable so should we try to make out plants fully automatic?
6	71/9	Who should take the decisions on safety matters – the manager or the safety officer?
7	72/5	How can we keep alive the memory of incidents that have happened on the plant when the staff change every few years?
8	73/1	How will the new Health and Safety at Work Act affect us?
9	74/6	Is there any easy way to get people interested in the plant safety book?
10	75/6	How often will an operator act correctly when an alarm sounds?
11	76/6	Most of our checking will show nothing wrong – so what is our incentive to continue?
12	77/7	Why does the Petrochemical Division board issue so few directives on safety?
13	78/12	Can you recommend some books which will give me some background information on loss prevention?
14	79/5	Are we expected to learn the lessons of accidents which have occurred somewhere else?
15	80/8	How long should a manager spend on a plant?
16	81/9	Why don't 'they' do more about safety (or plant tidiness or training)?
17	82/8	Do you put forward minimum standards? Can you go further than you suggest as long as you do not do less?
18	84/7	Flixborough has been described as the price of nylon – is it worth it?
19	85/6	How does our safety record compare with other companies?
20	86/4	In our designs, should we assume that people make mistakes?
21	87/5	What should we do to old plants when standards change?
22	88/6	How can I find out quickly and easily what has been written and recommended about subjects I am interested in at the moment?
23	91/8	Do we really need to do an operability study as this is only a very simple project (or it is very similar to the last one)?
24	92/6	What should we do to improve the safety record?
25	94/6	Are we willing to give information on safety to other companies?
26	95/5	Which airline should I fly?
27	96/5	What is the difference between operability studies and hazard analysis?
28	97/8	Is the *Safety Newsletter* issued free?
29	98/9	Do we spend too much money and effort on the problems that the press and TV publicize?
30	99/8	Can we get the money needed for safety?
31	100/6	What, in six words of one syllable, is the biggest single cause of accidents?
32	102/9	Can I be prosecuted if there is an accident on a plant which I work on or which I have designed?
33	108/7	What's new?
34	117/2	Does ICI add on more protective equipment than other companies?
35	119/5	How does ICI compare with other companies?
36	121/7	What should I do if a Factory Inspector asks me to do something which I think is unnecessary or even unsafe?
37	123/2	If we install a lot of automatic trips and controls on our plant, will we turn operators into zombies?
38	124/6	Has all the money and effort put into technical safety in the last 10 years produced any results?

28.9 Safety Auditing

A major aspect of the work of the safety department is auditing. Audits are the periodic examination of the functioning of the safety system. Accounts of auditing are given in *Safety Auditing* (Kase and Wiese, 1990) and by D.Williams (1971), Madhavan and Sathe (1987), Madhavan and Kirsten (1988), Madhavan and Landry (1988), Monk (1988), Tweeddale (1992), Ozog and Stickles (1992), D. Scott and Crawley (1992), J. Lockwood (1993), Sankaran (1993), Hurst and Ratcliffe (1994) and Hurst, Hankin *et al.* (1994).

28.9.1 Types and time-scales of audit

The overall system of control and auditing needs to operate at three levels, which correspond to increasingly long time-scales:

Level	*Time-scale*
1	Monitoring of outputs of systems and procedures Short term, essentially continuous
2	Audit of implementation of systems and procedures. Medium term
3	Audit of functioning and appropriateness of systems and procedures. Long term

Subjects of audit at both Levels 2 and 3 should be (1) the safety management system of the company, (2) the safety management system and operation of the plant and (3) special features of the plant.

Some of the audit activities of a safety officer are shown in Table 28.7, which is adapted from a more detailed table on safety audits given by D.Williams (1971). Important points illustrated by this table are the involvement of management at all levels, the training of both management and workforce, and the role of systems and procedures.

28.9.2 Company audits

The overall safety management system of the company should be subject to audit. At Level 2 the audit should check that the systems established are being operated and at Level 3 that these systems are still appropriate.

28.9.3 Plant audits

At plant level, there should be a post-commissioning audit carried out soon after a plant has been commissioned. Audits should then be repeated at intervals throughout the life of the plant. Plant audits should cover the safety management system of the plant, including operation, maintenance and control of change.

A structure for the conduct of the audit of a safety management system is available in the STATAS method described in Chapter 6.

28.9.4 Special feature audits

These general audits may be supplemented by audits in which some particular feature is examined in greater depth. Typical topics for such special feature audits might be the fire protection system or the permit-to-work system.

28.9.5 Audit aids

The conduct of a plant audit is assisted by the use of aids such as checklists. A structured set of checklists related to the root causes of accidents is typically used. This is described in Chapter 8.

28.9.6 Audit procedure

The effectiveness of an audit is highly dependent on the technique used. There is some guidance available on these practical aspects of auditing.

Tweeddale (1990, 1993) describes an approach to the auditing of a typical management system, taking as an illustration the auditing of a procedure for maintenance work permits. He sets four questions, or hurdles:

(1) Do you have a procedure for. . .?
(2) What are the main objectives of that procedure?
(3) How do you know whether that procedure is being properly applied in your area?
(4) Do you have to report to anyone about how well that procedure is being applied?

He shows how much these relatively simple questions can reveal.

28.9.7 Audit quality

Considerable effort is expended on audits in the process industries, but much of it is relatively ineffective in discovering defects in the systems examined. The quality of audit is crucial.

The point is illustrated by the audits conducted on Piper Alpha. Audits of various kinds were quite frequent, but none had picked up the numerous defects in the permit-to-work system. Yet once the Inquiry began, these defects were quickly laid bare in the evidence of the witness on this topic (Lockwood, 1989). This evidence repays study. The Piper Alpha Report is critical of the quality of the audits carried out.

28.10 Safety Rating

Some companies utilize as part of the safety system a safety rating system. Use may be made of a system developed in-house or of one of the proprietary systems. Three systems are described below – the ISRS, MORT and MANAGER systems – as illustrations of the types of system available.

A number of the accounts of audits referred to in Section 28.9 also contain rating schemes of various kinds.

28.10.1 Management and oversight risk tree

One such system is the Management and Oversight Risk Tree (MORT) described in MORT Safety Assurance Systems (W.G. Johnson, 1980). This system has been mentioned earlier in Chapters 2 and 27.

MORT provides a methodology for assessing a situation which may lead to an undesirable outcome such as injury or damage. The basic logic tree of MORT is shown in Figure 2.3. This MORT tree contains in structured form many of the basic concepts of safety management and engineering, including the concepts of: vulnerable targets, harmful energy, precursor events, barriers to escalation, mitigation of consequences, management policy formulation, management policy implementation and risk assessment.

28.10.2 International safety rating system

The International Safety Rating System was developed by Bird and co-workers at the International Loss Control Institute (ILCI) at Georgia State University. The philosophy

***Table 28.7** Some safety audit activities (after D. Williams, 1971) (Courtesy of the Institution of Chemical Engineers)*

Activity		*Interval* (month)
Plant safety review	Review of adequacy of operations, equipment and building safety	12
Job safety analysis	Reviews of standard operating procedures. Update where necessary	12
Operator review	Check for deviation from standard operating procedures and on work habits	6
Supervisors' safety meetings	Education, training, drills, follow-up	3
Management development seminar	Development of managerial competence	1
Supervisory training	Training of foremen for supervisory role	1
Safety committee	Motivational safety suggestions	1
Plant manager's meeting	Communication, education, training, innovation, follow-up	1
Foremen's meeting	Communication (vertical, horizontal), motivation, education, training	1
Critical incident technique	Observation of unsafe acts, conditions. Reports of near misses	1 Plus continuous observation
Central plant safety	Safety policy	As needed
Safety review committee	Review of safety of new processes and/ or equipment	As needed
Works safety procedures review	Review of work safety procedures	As needed

underlying the system is given in *Practical Loss Control Leadership* (Bird and Germain, 1985). The evolution of the system has been described by Bond (1988 LPB 80).

The system developed as the Five Star Rating System, was refined jointly with the South African Chamber of Mines to yield the International Mining Safety Rating System, and was finally generalized to give the ISRS. There are several versions of the system, including one for petrochemicals. The elements of the system are given in Table 28.8.

An account of the application of the system in a refinery has been given by Arnold, Redfearn and Maaren (1992) and of its application elsewhere by Eisner and Leger (1988) and Pringle and Brown (1990).

***Table 28.8** Elements of International Safety Rating System*

1. Leadership and administration
2. Management training
3. Planned inspections
4. Job analysis and procedures
5. Accident/incident investigation
6. Planned job observation
7. Emergency preparedness
8. Organizational rules and regulations
9. Accident/incident analysis
10. Employee training
11. Personal protective equipment
12. Health control and services
13. Programme evaluation system
14. Purchasing and engineering control
15. Personal communications
16. Group meetings
17. General promotion
18. Hiring and placement
19. Records and reports
20. Off-the-job safety

28.10.3 MANAGER system

The MANAGER system described by Pitblado, Williams and Slater (1990) and outlined in Chapter 9 was developed to assist in estimating the effect of the quality of management in quantitative risk assessment. A feature of the method is that it seeks to take account of all areas shown to be important in accident causation and of the incorporation of widely accepted management principles in all key elements of the safety management system.

28.10.4 Critique of rating systems

As mentioned in Chapter 6, a critique of safety rating, or packaged audit, systems has been given by D. Petersen (1989). He cites studies indicating that most packaged audit systems do not contain many of the elements found to be critical to safety performance and, on the other hand, that they do contain elements which fail to correlate with safety performance.

29

Computer Aids

Contents

The use of computers in the design and control of process plants is now widespread. The use of safety-related computer aids is described briefly in this chapter. A more general discussion of chemical engineering computer software is contained in Lees 2nd edition; however, the availability of software is changing too fast to simply develop a list. The list would be out dated before publication. The World Wide Web with its concomitant search capability has made published software lists out dated.

Rather than provide exhaustive lists, the generic type of available software, as it applies to loss prevention will be described herein. However, reference has already been made in a number of chapters to various specialist computer codes pertinent to the technology under discussion, such as those for consequence analysis and hazard analysis.

29.1 Computer Aided Process Engineering

Some of the principal codes for process plant design in CAD, or computer aided process engineering (CAPE), are now reviewed, considering first individual programs and then integrated packages.

29.1.1 Process selection

The selection of the process is perhaps the most fundamental problem in process design and it is a tough one. An account of the developments in the computer aiding of process route selection is given in Chapter 30.

29.1.2 Physical, thermodynamic and phase equilibrium properties

A package that furnishes physical, thermodynamic and vapour–liquid equilibrium properties is an essential service package for process design. Some of the packages are part of a suite of programs, typically supporting a flow sheet simulator.

29.1.3 Flow sheet simulation

Flow sheet simulation, handling the mass and energy balances, is the heart of the process design package. Much theoretical work has been done to produce codes that are efficient, particularly in handling features such as recycles. The core of a system for process plant design is the program, which performs the steady-state mass and heat balances, also called the process simulator. There are two main types of process simulators. The sequential modular (SM) simulator consists of a sequence of modules for the various unit operations performed. A basic set of modules is a mixer, a divider and a reactor. The equations of each unit operation are solved sequentially. The equation oriented (EO) simulator, by contrast, solves the equations of the whole system simultaneously. An SM simulator can accommodate more readily a variety of types of model in the modules, including user configured models, whereas the EO simulator scores for features which span a number of units such as recycles, control systems and constraints.

The process simulator forms the core of an integrated CAPE system. This core program draws on programs offering other facilities. These include physical properties, equipment sizing, cost and economics, and dynamic simulation packages. An important feature of a fully integrated CAPE system is the database. The database may contain files on a wide variety of aspects of the design, from flows, pressures and temperatures to material take-offs. Different CAPE systems start from different starting points. One may start from a graphics facility, another from a process simulator. Consequently, the systems have different strengths and weaknesses.

The degree of integration in current CAPE systems is not always as advanced as might be assumed. Typically a two-dimensional package will have its own database, which allows it to draw symbols representing plant units, but it does not identify the symbols as units such as vessels or heat exchangers, and does not have associated information about the units. In other words, it is purely a drawing package. This means that it cannot readily be used to capture the data about the units required for a package to perform a function such as fault tree synthesis.

CAPE systems typically have the capability to perform the following project functions:

(1) analysis of layout designs –
    (a) conceptual designs,
    (b) detailed designs;
(2) checking of designs against standards;
(3) control of project information;
(4) generation of documents and listings;
(5) archiving of project information.

29.1.4 Piping and instrument diagrams

Closely linked to the flow sheet simulation is the generation of the process flow diagram (PFD) or piping and instrument diagram (P&ID).

29.1.5 Process synthesis

Closely linked to the mass and energy balances is the thermal economy. These include computer programs for heat exchanger network design and for process synthesis using pinch technology.

29.1.6 Cost and economic estimates

Another essential service package is a program, which furnishes cost data and can be used to estimate the costs of designs.

29.1.7 Engineering units conversion aids

Aids for conversion between different chemical engineering units will always be necessary until a global standard is widely utilized.

29.2 Pipework and Fluid Flow

Programs for pipework are of several different types. One group performs the fluid flow calculations for piping and piping networks. Programs of this type include:

(1) two-phase flow;
(2) flash-off and flash drums;
(3) unsteady-state flow;
(4) flow through control valves;
(5) flow through rotating machinery;
(6) pipeline leak detection.

29.3 Unit Operation and Equipment

There are a number of programs for the design of unit operations and equipment of various types. Programs exist not just for shell and tube heat exchangers but also for air-cooled heat exchangers, thermosyphon reboilers, furnaces and heat exchanger networks:

(1) chemical reactors;
(2) distillation columns;
(3) fired heaters;
(4) solid–liquid separation;
(5) flare systems;
(6) steam systems;
(7) pumps and compressors.

29.4 Databases, Bibliographies and Indexes

Physical, chemical and toxic properties: there are a number of databases, or data banks, for the physical, chemical and toxic properties of materials. The databases are often associated with a government agency or technical society, such as the following:

Registry of Toxic Effects of Chemical Substances (RTECS), supplied by the National Institute for Occupational Safety and Health (NIOSH);
HSDE created by the NLM as part of its Toxnet data system;
Oil and Hazardous Materials Technical Assistance Data System (OHMTADS), supplied by the Environmental Protection Agency (EPA); and
Chemical Hazard Response Information System (CHRIS) supplied by the US Coast Guard.
NIOSHTIC, supplied by the NIOSH;
HSELINE, supplied by the Health and Safety Executive (HSE);
CISDOC, supplied by the International Occupational Safety and Health Information Centre of the International Labor Office (ILO);
MHIDAS, covering hazardous incidents, supplied by the Safety and Reliability Directorate;
TOXLINE, supplied by NLM;
RISKLINE, supplied by the National Chemical Inspectorate of Sweden;
BIOSIS, CAS, IPA and TOXBIB. PEST-BANK, supplied by the National Pesticide Information System, gives the key registration data of all US registered pesticides.
European Inventory of Existing Commercial Chemical Substances (EINECS) is an inventory of European commercial chemicals.
International Nuclear Information System (INIS) is supplied by the IAEA Medical databases, which include MEDLINE and CANCER.
Another set of databases is those from Microinfo. They include HAZARDTEXT (safe handling and incident response), INFOTEXT (regulatory listings), MEDITEXT (evaluation of exposed individuals) and SARATEXT (toxicity, Sara Title III)
The Bretherick Reactive Chemical Hazards Database is the database version of the *Handbook of Reactive Chemical Hazards* (Bretherick, 1990b).
CHEMSAFE and CHEMTOX are, respectively, compendia of the flammability and toxic properties of a large number of substances.
A number of specialty databases on medical subjects are available from Elsevier Science Publishers, including the *Excerpta Medica* database EMBASE.
IRIS is a database of monographs in support of the assessment of the risk from a large number of chemicals.

There are three incident data banks operated by SRD. MHIDAS is the Major Hazard Incident Data Service. The other two are the Explosion Incidents Data Service (EIDAS) and the Environmental Incidents Data Service (EnvIDAS). In addition to MHIDAS, AEA Technology offers the AIRS code for the recording of incidents in the workplace.

Another computer-based incident data bank is FACTS, of TNO.

29.5 Compliance Management

There are quite a large number of programs to assist with compliance with regulatory requirements, mainly for the United States.

29.6 Computational Fluid Dynamics

Codes for computational fluid dynamics (CFD) find widespread use both in design and in hazard assessment.

29.7 Hazard Identification

There are a number of codes available to assist in the conduct of the various techniques for hazard identification. Aids for hazard and operability (HAZOP) analysis are particularly valuable with the housekeeping and follow-up aspects. Computer codes exist for a number of hazard models, and indeed for the more complex models this is the only practical method of use. Some of the principal subjects are as follows: jets; vapourization from pools; pool fires; fire engulfment; flame impingement; explosion in, and explosion relief of, large enclosures; vapour cloud explosions.

29.7.1 Fault tree analysis

Details of aids to fault tree analysis. These cover the determination of the minimum cut sets, analysis for common cause failure, assessment of importance and sensitivity, quantitative analysis and uncertainty analysis.

29.8 Pressure Relief Devices Sizing

29.8.1 Reactor venting

The SAFIRE code for the venting of reactors, which implements the design methods developed by the Design Institute for Emergency Relief Systems (DIERS) as part of its design package for emergency relief.

29.8.2 Blowdown

Programs that calculate the emission flows from vessels, pipes and pipelines are:

BLOWDOWN (Imperial College)
BLOWSIM (UCL)

An account of BLOWDOWN is given by Haque, Richardson and Saville (1992).

29.8.3 Gas dispersion

One of the most important topics covered by such codes is gas dispersion, particularly dense gas dispersion. An account of gas dispersion models was given in Chapter 15. Different models are used for passive and dense gas dispersion.

Passive gas dispersion

Models for passive gas dispersion were described in Chapter 15. Manual calculation is possible with the simpler forms of model, but for most practical applications, particularly in air pollution modelling, use is made of computer codes.

There are now a large number of codes for specific situations such as multiple sources, complex terrain, urban conditions, and coastal and offshore locations.

The EPA advises certain codes as 'preferred' codes for air pollution modelling. The codes are listed with full details by Zannetti (1990). Zannetti also lists the codes advised by the EPA as 'alternative' as well as a large number of other programs.

Dense gas dispersion

Models for dense gas dispersion, also described in Chapter 15, have tended to be much more complex than those for passive dispersion, and for most such models, a computer program is essential.

Jets

The computer codes model jets of different density or buoyancy, jets with high and low velocity, jets with vertical, horizontal or angled orientation, jets in ambient wind and turbulent conditions, jets with two-phase flashing behaviour, and jets with airborne aerosol effects.

Vapourization from pools

Several computer codes for vapourization from pools have been developed.

Fire events

Programs for the calculation of the thermal radiation from a jet flame, a pool fire or a boiling liquid expanding vapour explosion (BLEVE) are widely available.

Condensed phase explosions

There are a number of programs that have been developed by the military to determine the effects of explosions, nuclear explosions and condensed phase explosions, including weapons.

Vapour cloud explosions

There are several computer codes for, or applicable to, the estimation of the blast from vapour cloud explosions.

29.8.4 Explosions in large enclosures

Codes for the simulation of explosions in large enclosures play an important role in the design of fire and explosion protection of offshore platforms. These programs solve the fundamental equations of fluid flow taking into account turbulence and combustion. The three-dimensional Navier–Stokes equations, suitably augmented to include the effects of turbulence and combustion, are cast in discrete form, employing a finite volume technique, and are solved implicitly. Turbulence is modelled in terms of eddy viscosity, and combustion is modelled in terms of a turbulent, mixing-limited reaction. The space modelled is divided into a grid of 'boxes' of 1 m^3 volume. Normal assumptions are that the gas cloud is a stoichiometric homogeneous, quiescent mixture. Ignition is modelled by assuming that at time zero, half the flammable mixture in one of the boxes has undergone combustion.

29.9 Hazard Assessment Systems

Some computer codes for hazard assessment systems are described here:

ARCHIE

The ARCHIE code of the Federal Emergency Management Agency (FEMA), from Hazmat America, contains a set of models for a variety of scenarios cast in a tree structure, which at the first level down include pressurized gas release, liquid release followed by vapourization from the pool, a closed tank engulfed in fire, and a condensed phase explosion, and at lower levels extend to events such as jet flame, flash fire, vapour cloud explosion and BLEVE. It is described in the *Handbook of Chemical Hazard Analysis Procedures* (FEMA, 1989).

SAFETI

The SAFETI code was developed for the Dutch Ministry of Housing, Physical Planning and Environment. This is a major code for the conduct of a complete probabilistic risk assessment (PRA). The development of the code was prompted by the Rijnmond PRA described in Appendix 8. The program performs a complete PRA for a fixed installation. It is designed for ease of input, speed of processing and transparency of results, both intermediate and final. It is also designed for minimum loss of detail, and allows the level of detail to be varied.

Details of the plant are entered into the PLANT program. A plant is organized in terms of 'units', which are linked by connecting 'pipes' to 'vessels'. Vessels and pipes have associated with them a set of 'equivalent discrete failures' (EDFs), essentially leaks and ruptures. Each failure is assigned a failure frequency, for which default values are supplied. Other input information includes the population density, defined by a grid; the density of ignition sources; and the meteorological conditions. There are databases for the failure frequencies, population, ignition sources and meteorology.

A set of eight release scenarios is used. These are: (1) an instantaneous release (by vessel rupture) of a flammable material; (2) a continuous pressurized release (from vessel or pipe) of a flammable material; (3) the vapourization of a refrigerated flammable liquid; (4) a pool fire; (5) a fireball or BLEVE; (6) an instantaneous pressurized release (by vessel rupture) of a toxic material; (7) a continuous pressurized release (from vessel or pipe) of toxic material and (8) the vapourization of a refrigerated toxic liquid. The program handles the development of these releases utilizing a set of four event trees, for which the starting events are one of the four possible combinations of instantaneous vs continuous and aerosol vs no aerosol in the cloud. The nodes in these event trees include the following queries: (1) Rainout? (2) Evapouration? (3) Pool left behind? (4) Pool of limited duration? (5) Essentially instantaneous? (6) Behaves as a free jet?

The hazard models used are described in Chapter 9. There are four gas dispersion models together with a set of models for vapourization from a pool, jet flames, fireballs, BLEVEs and vapour cloud explosions and probit equations for injury and damage.

The outcomes of the event trees for flammable releases are events that are then modelled, using the set of hazard models and probit equations. The results can be output in a variety of forms, including as risk contours, individual risks and frequency-number curves.

There are interactive facilities which permit the user to: bypass some or all of the automatic generation of EDFs and to replace them with alternative releases or events; replace a default failure frequency with an alternative value; and replace a standard hazard model with an alternative one.

WHAZAN

A rather simple code is WHAZAN, developed by Technica for the World Bank. It is described in the *Manual of Industrial Hazard Assessment* (Technica, 1986). WHAZAN provides a facility for the user to explore the consequences of a set of release scenarios. The core of the program is a set of hazard models. The program does not make estimates of the frequency of the scenarios or of the risks. WHAZAN is a much more modest package than SAFETI and was developed to run on a PC in the first instance.

RISKAT

The HSE has developed its own hazard assessment program entitled initially the Risk Assessment Tool (RAT), and latterly RISKAT. The essential features of this program have been described in Chapter 9 in connection with the HSE guide assessments for liquefied petroleum gas and chlorine.

29.10 Emergency Response Simulation

An aid to training personnel in the handling of emergencies is available in the form of the handling emergencies simulation system of the IChemE. The trainee assumes the role of the main incident controller and is responsible for controlling all personnel, and issuing operational commands. The program contains nine incident scenarios involving fire, toxic release and a combination of both. It uses a preplan entered by the trainee to determine how the scenario develops. The scenario highlights weak points in the preplan. In order to assist post-mortem analysis, a log is provided of events during the incident and of actions taken. There are several packages for the simulation in real time of the development of an emergency using suitable hazard models. The essential concept is that, in an emergency, the system is provided with certain key pieces of information, such as the material released, estimates of the location and size of the leak and the meteorological conditions, and gives a VDU display of the phenomenon such as plan and elevation contours of gas concentration.

One such system is SAFER (Dupont Safer Emergency Systems). The core of the code is a gas dispersion program together with data on the chemicals handled in the plant and their properties. The computer is provided with a network of instruments that measure meteorological conditions such as wind direction and speed. In an emergency, data are furnished to the computer both by these instruments and by operator inputs. SAFER is more than a computer code. It is essentially an emergency response system built around the computer package.

29.11 Transport

Hazard assessment systems for transport are not well represented. Transportation Risk screening programs, which support evaluation of the risks from different chemicals, transport modes and routes, typically are proprietary to special consultancy companies.

30

Artificial Intelligence and Expert Systems

Contents

This chapter deals with artificial intelligence, expert systems and certain other advanced developments in computer aiding. The aim of the chapter is to provide an overview of the field and an appreciation of the sorts of problem which are tackled, the types of technique developed, the terminology used and the applications made.

Accounts of artificial intelligence (AI) include *Artificial Intelligence* (Winston, 1984), *Introduction to Artificial Intelligence* (Charniak and McDermott, 1985), *Introduction to Knowledge Based Systems* (Frost, 1986), *Introduction to Artificial Intelligence and Expert Systems* (Patterson, 1990), *The Elements of Artificial Intelligence* (Tanimoto, 1990) and *Encyclopaedia of Artificial Intelligence* (Shapiro, 1992).

An important area of AI is expert systems. A large proportion of the AI applications in the process industries are of this nature. Expert systems are therefore given particular attention in this chapter.

Most accounts of AI are written in a style that makes extensive use of lines or sections of computer programs. For the most part this practice has not been adopted here. The aim has been to couch explanations in natural language. Some limited use has been made of program-type material, however, purely in order to give a feel for the approaches taken. The expressions principally used are related to the predicate calculus. This has influenced the order of treatment of the subjects in the chapter. The account of programming languages is placed after the account of predicate logic but before most of the other topics where program-type material may be used.

Selected references on AI and on expert systems are given in Table 30.1.

***Table 30.1** Selected references on artificial intelligence, expert systems and advanced aids*

30.1 Knowledge Representation

30.1.1 Knowledge

Knowledge is of many kinds and this is reflected in the forms of knowledge representation used.

One distinction commonly made is between data and information. Other distinctions made about knowledge are domain-independent vs domain-specific, exact vs *fuzzy*, and procedural vs declarative knowledge. Some types of knowledge include: facts; models; distinctions; relationships; constraints; procedures and plans; and rules-of-thumb, or heuristics.

The extent of the knowledge required varies greatly between problems. In certain limited worlds, such as the 'blocks world' extensively studied in AI, the world knowledge required is quite limited. In real-life, or mundane, situations on the other hand, the human comes to the problem possessed of a massive store of knowledge. He draws from this information not only about facts but also about other aspects such as constraints.

30.1.2 Natural language

By far the most widely used and most expressive form of knowledge representation is natural language. As a method of representation in AI work, however, natural language has a number of deficiencies.

There are a number of fundamental problems of natural language in this respect. It tends to be ambiguous. Its syntax and semantics are not well understood. There is considerable diversity in the structure of sentences. In some cases the meaning depends on the context.

Work in AI tends to involve the use of structured knowledge and natural language is not an obvious method for this purpose.

30.1.3 Databases

By contrast, in databases structure is a principal feature of the knowledge representation. In large part this structure is oriented to data retrieval, but it may also represent relationships between the objects stored, and databases generally have certain facilities for certain elementary transformations on the data. Databases are considered further in Section 30.2.

30.1.4 Classical logics

Logic is a formal method of reasoning and provides a sound theoretical basis for the reasoning process. This is particularly important for computer-based approaches.

There are two principal logics in common use. One of these classical logics is prepositional logic (PL) and the other first order predicate logic (FOPL). Prepositional logic is the earlier form, is simpler and is generally the starting point in teaching.

Predicate logic has been developed to overcome some of the limitations of prepositional logic. It is a more general logic of which prepositional logic may be regarded as a special case. It is predicate logic which is most widely used in AI and which is used in 'logic programming'.

Prepositional logic has a number of serious limitations. It cannot readily describe properties of entities or express relationships between them. Predicate logic has been developed as a form of logic with enhanced expressiveness. It replaces propositions with predicates and utilizes functions, variables and quantifiers. This makes it possible to reason about entities in terms of their classes and of their relationships.

In defining the syntax of a logic use is frequently made of the Backus–Naur form (BNF).

Prepositional logic and predicate logic are described in Sections 30.3 and 30.4, respectively.

30.1.5 Non-classical logics

Classical logic has severe limitations in its ability to handle real-world situations. It deals with statements that are either true or untrue and does not accommodate information which is incomplete, vague, contradictory or unbelievable. It does not readily handle uncertainty and inconsistency. It is a feature of classical logic that it is monotonic. The conclusions once derived are valid deductions and remain so. The set of facts and inferences can only increase; it cannot decrease. This does not accord well with real life, in which it is necessary to revise conclusions reached as more information becomes available.

Common-sense reasoning is therefore not well served by classical logic and there have been developed a number of non-classical logics that address particular deficiencies. Many of these deal with uncertainty and inconsistency, but other aspects such as time are also accommodated.

These non-classical logics are considered in Section 30.7.

30.1.6 Probabilistic reasoning

Much knowledge relates in some way to uncertainty. The methods just described are not well adapted to representing knowledge under uncertainty, but other methods do exist for this purpose. Foremost among these are probabilistic reasoning and fuzzy logic.

Methods for handling uncertainty are described in Section 30.8 and those of probabilistic reasoning and fuzzy logic are described in Sections 30.9 and 30.10, respectively.

30.1.7 Structured knowledge

AI possesses a rich repertoire of methods for the storage of knowledge in structured forms. The creation of structure has a significance that goes far beyond simple ease of retrieval. It imposes a discipline that ensures that the entities and their relationships are formally defined and it facilitates basic operations such as search and matching. Structured knowledge is considered in Section 30.12.

30.1.8 Graphs, trees and networks

A form of knowledge representation widely used by humans is diagrams in the form of graphs, trees and networks. There are a large number of such diagrams in common use and a number that have been developed in the course of AI work. These diagrams may be mapped into program structures and in many cases there are standard techniques available to do this. An outline of some of the graphs, trees and networks in use in AI is given in Section 30.22.

30.1.9 Programming languages

The programs of interest here are those that both contain representations of knowledge and perform operations on them. Such programs are most effectively implemented in programming languages of the declarative rather than the procedural type, the principal languages being LISP and Prolog. The strength of these languages is their ability to combine representation of knowledge in the forms required in AI work and support for various modes of reasoning. Programming languages are described in Section 30.11.

30.2 Databases

A widely used form of knowledge representation is the database. Databases are a major topic but may be treated here quite briefly.

Accounts of databases are given in *An Introduction to Database Systems* (Date, 1977), *Principles of Database Systems* (Ullman, 1982), and *The Theory of Relational Databases* (Maier, 1983). Data bases in the context of AI are discussed by Frost (1986) and Tanimoto (1990).

A database stores and provides ready access to data. It imposes a discipline on the classification and storage of data. It is a natural form for the storage of knowledge about certain types of relationship between data.

A rich variety of data structures are available, including: arrays, lists, strings, queues, stacks, bit maps and records; direct access, sequential, inverted and transposed files; hash tables; graphs and trees; and multi-lists, inverted lists and bit lists.

Aids to the design and implementation of databases exist in the form of database management systems (DBMSs) that provide a collection of procedures, documentation aids, languages and programs.

Corruption of the database must be avoided and various formal systems are required. By controlling access a privacy subsystem protects against unauthorized alteration of the database. An integrity subsystem protects against invalid alteration by imposing a discipline on those authorized to make changes. A back-up and recovery subsystem provides a facility for rebuilding the database after corruption has occurred.

30.2.1 Relational databases

A form of database suited to the handling of large data sets with regular structure is the relational database. The term ‘relation’ is applied to a set of ordered n-tuples, or ordered sets each containing n items. An n-ary relation has n fields. The first field is referred to as the primary key. A field possesses a domain, which comprises the set of entities from which elements in the field may be drawn. A name is assigned both to the relation and to its fields. The following table is an illustration of a 3-ary relation.

	PIPE		
Section	*Diameter* (in.)	*Material*	*Supplier*
Straight	3	Copper	X
Straight flanged	3	Mild steel	Y
90° bend	4	Stainless steel	Y
T-section	4	Stainless steel	Y

The relation is PIPE, the primary key is *Section*, the other fields being *Diameter, Material* and *Supplier.*

Some elementary operations that are supported by relational database programs include selection, projection and joining. Selection is the creation from an existing relation of a new, more specialized relation by selection of a subset of rows which have some common property. Projection is the creation from an existing relation of a new, more specialized relation by excision of some of the fields. Joining is the creation of a new relation by the fusion of two existing relations.

30.3 Prepositional Logic

30.3.1 Propositions

Prepositional logic deals with the relationships between propositions. Typical propositions are:

(1) The valve is open.
(2) The valve is open and the pipe is full of liquid.

The first of these is a simple proposition and the second a compound proposition. Propositions are also referred to as statements, sentences or formulas. Statements are represented by prepositional symbols, which are capital letters, commonly P, Q, R, etc.

30.3.2 Syntax

The main feature of the syntax of prepositional logic is the connectives, the symbols for which are shown in Table 30.2, Section A. Use is also made of parentheses ( ) as delimiters, but where there is no chance of ambiguity, parentheses may be omitted, in which case the order of precedence of the connectives is, from highest to lowest: $\neg$, $\wedge$, $\vee$, $\Rightarrow$, $\Leftrightarrow$.

The set of statements commonly used to illustrate the connectives is as follows:

$\neg \mathrm{P}$

$\mathrm{P} \wedge \mathrm{Q}$

$\mathrm{P} \vee \mathrm{Q}$

$\mathrm{P} \Rightarrow \mathrm{Q}$

$\mathrm{P} \Leftrightarrow \mathrm{Q}$

Table 30.2 *Some features of propositional logic*

A Connectives

Type	*Meaning symbol*	*Symbol*	*Alternative*
Negation	not	$\neg$	$\sim$
Conjunction	and	$\wedge$	&
Disjunction	or	$\vee$	$\vee$
Implication	if . . . then	$\Rightarrow$	$\rightarrow$
Double implication	if and only if	$\Leftrightarrow$	$\leftrightarrow$

B Some equivalence laws

Idempotency	$\mathrm{P} \wedge \mathrm{P} \equiv \mathrm{P}$ $\mathrm{P} \vee \mathrm{P} \equiv \mathrm{P}$
Commutativity	$\mathrm{P} \wedge \mathrm{Q} \equiv \mathrm{Q} \wedge \mathrm{P}$ $\mathrm{P} \vee \mathrm{Q} \equiv \mathrm{Q} \vee \mathrm{P}$ $\mathrm{P} \Leftrightarrow \mathrm{Q} \equiv \mathrm{Q} \Leftrightarrow \mathrm{P}$
Associativity	$(\mathrm{P} \wedge \mathrm{Q}) \wedge \mathrm{R} \equiv \mathrm{P} \wedge (\mathrm{Q} \wedge \mathrm{R})$ $(\mathrm{P} \vee \mathrm{Q}) \vee \mathrm{R} \equiv \mathrm{P} \vee (\mathrm{Q} \vee \mathrm{R})$
Absorption	$\mathrm{P} \wedge (\mathrm{P} \vee \mathrm{Q}) \equiv \mathrm{P}$ $\mathrm{P} \vee (\mathrm{P} \wedge \mathrm{Q}) \equiv \mathrm{P}$
Distributivity	$\mathrm{P} \wedge (\mathrm{Q} \vee \mathrm{R}) \equiv (\mathrm{P} \wedge \mathrm{Q}) \vee (\mathrm{P} \wedge \mathrm{R})$ $\mathrm{P} \vee (\mathrm{Q} \wedge \mathrm{R}) \equiv (\mathrm{P} \vee \mathrm{Q}) \wedge (\mathrm{P} \vee \mathrm{R})$
De Morgan	$\neg(\mathrm{P} \wedge \mathrm{Q}) \equiv \neg \mathrm{P} \vee \neg \mathrm{Q}$ $\neg(\mathrm{P} \vee \mathrm{Q}) \equiv \neg \mathrm{P} \wedge \neg \mathrm{Q}$
Conditional elimination	$\mathrm{P} \Rightarrow \mathrm{Q} \equiv \neg \mathrm{P} \vee \mathrm{Q}$
Bi-conditional elimination	$\mathrm{P} \Leftrightarrow \mathrm{Q} \equiv (\mathrm{P} \Rightarrow \mathrm{Q}) \wedge (\mathrm{Q} \Rightarrow \mathrm{P})$

C Truth table for equivalent statements

P	Q	$\neg P$	$P \wedge Q$	$P \vee Q$	$P \Rightarrow Q$
T	T	F	T	T	T
T	F	F	F	T	F
F	T	T	F	T	T
F	F	T	F	F	T

30.3.3 Semantics

Some principal features of the semantics of propositional logic are the properties of statements and the rules of inference. The semantics of a statement is the truth value assigned to it, the process of assignment being known as interpretation. The truth values assigned are true or false. These values are commonly denoted by T for true and F for false, particularly in truth tables. It should be noted that the symbols T and F themselves represent statements and are used in compound statements.

Some properties of statements are:

Satisfiability – a statement is satisfiable if there is an interpretation for which it is true.
Contradiction – a statement is contradictory, or unsatisfiable, if there is no interpretation for which it is true.
Validity – a statement is valid, or autologous, if it is true for every interpretation.
Equivalence – two statements are equivalent if they have the same truth value for every interpretation.
Logical consequence – a statement is a logical consequence of another if it is satisfied by all interpretations that satisfy the first.

In the interpretation of compound statements use is often made of substitution of equivalent statements. Table 30.2, Section B shows some equivalence laws that may be used in making such substitutions. Another way of determining equivalence is the use of truth tables. A truth table for equivalent statements is shown in Table 30.2, Section C.

30.3.4 Inference rules

The means to perform deductions is provided by the rules of inference. Some principal rules are as follows.

Modus ponens

Assertion:	P
Assertion:	$\underline{P \Rightarrow Q}$
Conclusion:	Q

Chain rule

$P \Rightarrow Q$
$\underline{Q \Rightarrow R}$
$P \Rightarrow R$

Disjunctive syllogism P

$\underline{P}$
$P \vee Q$

Resolution

$P \vee \neg Q$
$\underline{Q \vee R}$
$P \vee R$

Other rules of inference are:

Substitution – if s is a valid statement, a statement s′ derived from it by consistent substitution is also valid.
Simplification – from $P \vee Q$ inference is P.
Conjunction – from P and Q inference is $P \vee Q$.
Transposition – from $P \Rightarrow Q$ inference is $\neg Q \Rightarrow \neg P$.

30.4 Predicate Logic

30.4.1 Basic entities

The basic entities handled in first order predicate logic (FOPL) are constants, variables, functions and predicates. The first three are referred to as terms, and predicates are referred to as atomic formulas, or atoms. An atom or its negation is referred to as a literal.

A constant is a term that has a fixed value and a variable is a term that can take different values. A function maps elements of the domain to further elements of the domain. A predicate maps elements of the domain to truth values. Commonly used constant symbols are *a, b, c, . . .*; function symbols *f, g, h, . . .*; variable symbols *x, y, z*; and predicate symbols P, Q, R, ... Use is also made of quantifiers. These are for existential quantification and ∀ for universal quantification. The meanings are:

$\exists x$ For some x; there is an x
$\forall x$ For all x

The expression $\exists x P(x)$ means that there exists at least one element of the domain which makes $P(x)$ true.

30.4.2 Syntax

In respect of syntax, the logical connectives used in FOPL are the same as those for prepositional logic.

30.4.3 Well-formed formulas

There are rules for the construction of syntactically correct formulas. Formulas derived by correct application of these rules are termed well-formed formulas, or wffs (pronounced woofs). An atomic formula is a wff. Wffs are obtained from predicates, or atomic formulas, by application of quantifiers and connectives.

Some wffs contain variables. If a variable follows or is within the scope of a quantifier, it is said to be bound; otherwise it is free. The variable x in the expression $\forall x(P(x) \Rightarrow Q(x,y))$ is bound, whereas the variable y is free. For a formula to be evaluated, it is necessary that all the variables in it be bound. This leads to the requirement that a wff should contain only bound variables.

A wff, or a predicate, which has no variable is referred to as a ground atom.

30.4.4 Semantics

The semantics of FOPL are somewhat more complex than those for prepositional logic. They largely revolve around the conversion of wffs to clausal form and the application of the rules of inference and the principle of resolution.

Accounts of the semantics for FOPL, including equivalence and truth tables are given by Frost (1986) and Patterson (1990).

30.4.5 Clausal form

One of the most powerful methods of interpretation in FOPL is the resolution principle. But, in order to apply it, it is necessary first to convert the wffs to clausal form. A formal six-step procedure exists to effect this conversion.

30.4.6 Inference rules

Interpretation of the wffs is effected by application of the rules of inference for FOPL. One of these is modus ponens

An illustration of modus ponens in FOPL is the following:

Assertion	$P(a)$
Implication	$\underline{\forall x\, P(x) \Rightarrow Q(x)}$
Conclusion	$Q(a)$

In this interpretation since the implication $P(x) \Rightarrow Q(x)$ is true for all x, it is true in particular for $x = a$.

30.4.7 Resolution principle

Resolution is an inference procedue that is applied to a set of clauses to determine if the set is unsatisfiable.

The principle of resolution is as follows. If there are two clauses Cl and C2, the parent claues, which have no variables in common and if there is a iteral in Cl that is the complement of a literal in C2, bot literals are deleted and a new clause C, the resolvent, is formed from the remaining reduced clauses.

An illustration of the principle is the following resolution:

$\neg P \vee Q$
$\underline{\neg Q \vee R}$
$\neg P \vee R$

There is a family of types of resolution applicable to particular combinations of numbers and of types of parent clauses.

30.5 Non-deductive Inference

The form of inference just described is deductive inference, but this is not the only form of inference in use. Other forms are abductive inference, inductive inference and analogical inference, and these are now described. These forms of inference are not strictly valid, but they are nevertheless in common use.

30.5.1 Abductive inference

Abductive inference may be represented as

$$\begin{array}{l} \mathrm{Q} \\ \mathrm{P}^{c} \Rightarrow \mathrm{Q} \\ \hline \mathrm{P} \end{array}$$

where the superscript c denotes a possible causal relationship. A proposition Q and a causal relation $\mathrm{P} \Rightarrow \mathrm{Q}$ are used to infer a proposition P.

30.5.2 Inductive inference

Induction involves generalization based on a limited sample of entities from the universe of entities. Inductive inference may be represented as:

$$\frac{\mathrm{P}(\mathrm{a}_1)\ldots\mathrm{P}(\mathrm{a}_n)}{\forall x\,\mathrm{P}(x)}$$

30.5.3 Analogical inference

Analogical inference is based on the assumption that two situations that are similar in some respects are also similar in other respects. It, in fact, appears to utilize a combination of deductive, abductive and inductive inference. Analogical inference may be represented as:

$$\frac{\mathrm{P}^{r} \Rightarrow \mathrm{Q}}{\mathrm{P}'^{r} \Rightarrow \mathrm{Q}'}$$

where the superscript r means related to and superscript $'$ denotes similar to.

30.6 Production Rules

As already mentioned, one form in which knowledge may be represented is as a set of rules, also called productions. Such rules may be regarded as a special case of prepositional logic.

The rules are of the type IF . . . THEN . . . . They have a left-hand side (LHS), which is variously known as the antecedent, premise, condition or situation and a right-hand side (RHS), which is known as the consequent, conclusion, action or response. The proposition on the LHS may be a compound one with a number of propositions ANDed together.

A suitable set of rules, or productions, can be used to form the basis of a production system. Production systems are one of the main methods of implementing expert systems and are discussed further below.

30.6.1 Production systems

A production system has three main features: the rule base, a working memory and the inference engine. The rule base holds the set of rules that embody the expertise of the system. The working memory is supplied with the input data, or facts, on the problem to which the rules are to be applied. The inference engine controls the operation of the rules to deduce conclusions from these data.

The rules in the rule base are laid out as a set of logic statements. The rule base may be inspected by an expert to check for correctness. Rules may be added, removed or modified with relative ease.

The operation of a production system is quite different from the execution of a program in a procedural language. Execution is not controlled by a procedure as such, but involves making a pass through the rule base and determining which rules are satisfied.

The inference engine applies the input facts to the rules and determines which rules are satisfied, or 'trigger'. Provided there is no conflict between the output from a rule and that for another rule, the rule then 'fires'.

30.6.2 Conflict resolution

If such conflict does occur, it becomes necessary to apply a suitable conflict resolution strategy. The application of this strategy determines which rules should fire. The conflict resolution strategy used may be a generalized one or it may be one specific to the particular problem. There are a number of generalized strategies for conflict resolution. Winston (1984) lists the following six strategies: (1) specificity ordering, (2) rule ordering, (3) data ordering, (4) size ordering, (5) recency ordering and (6) context limiting. Specificity ordering applies to a group of rules where the conditions of one rule are a superset of which the conditions in the other rules are subsets; priority is given to the rule with the superset of conditions. In rule ordering, the rules are arranged in a priority list and rule first triggered has priority. In data ordering, all possible aspects of the situation are arranged in a priority list and the rule having the highest priority condition has priority. In size ordering, the rule has priority that has the largest number of conditions. In recency ordering, priority is given either to the rule that fired most recently or, alternatively to that which fired least recently. Context limiting involves dividing the rules into groups and creating a procedure that activates and deactivates groups; those rules that are in the active groups, having priority.

30.7 Non-classical Logics

The point has already been made that a classical prepositional logic is not sufficiently expressive. The creation of another, now classical, logic, the predicate calculus, was a response to this deficiency. The same need has given rise to the development of further, non-classical logics.

These newer logics extend the range of the knowledge that can be represented and are thus more expressive. They make it possible to handle knowledge that is incomplete, uncertain, vague and/or inconsistent, or associated with time. They are often more efficient in handling the knowledge.

The properties of a logic are that it has a well-defined method for representing knowledge, for obtaining proofs by syntactical manipulation and for extracting meaning using a semantic model.

30.7.1 Many-sorted logics

In a many-sorted logic the entities in the universe of discourse are divided into sorts. There are different sort structures. One is a structure where all the sorts are different, or disjoint. Another is a structure where the sorts are related as in a tree, with the sorts at a lower layer being subsets of those in the layer above. Another is a structure in which the sorts are related as in a lattice, with non-hierarchical links between them.

Such many-sorted logics are used to place appropriate limitations on searches, and thus to improve search efficiency, and on logical operations, and thus avoid nonsensical interpretations.

30.7.2 Situational logics

A situational logic is a method of representing relationships that pertain in a particular situation. The usual device for effecting this is to augment the predicate with an extra argument which denotes the situation.

30.7.3 Non-monotonic logic

The point was made earlier that the classical logics are monotonic logics. They do not accommodate the revisions that are necessary to cope with real-life situations. There are several reasons why it may become necessary to revise knowledge. One is that the original knowledge may have been incomplete so that a default value had to be used. Another is that in problem-solving it is often necessary to make a temporary assumption. Another is that the situation may have changed.

30.7.4 Many-valued logics

The classical logics utilize in their semantics just two values, true and false. Other logics have been developed which permit the use of a wider range of values. One such many-valued logic is that of Lukasiewicz (1951), which utilizes three values. In addition to true and false, there is an intermediate value, which is applicable where the statement may be true, or 'sort of true'.

30.7.5 Fuzzy logic

Fuzzy logic, which is based on fuzzy sets, permits reasoning where there is uncertainty and vagueness. It is considered further in Section 30.10.

30.7.6 Modal logics

The classical logics deal with statements in the indicative mood concerning what is. There has been developed a family of modal logics which have been characterized as being in the subjunctive mood and which deal with what must be, should be, might be, is believed to be, etc.

Some principal modalities and the descriptor pairs associated with them are:

Alethic modality: necessary, possible. Temporal modality: always, sometimes. Deontic modality: obligatory, permissible. Epistemic modality: known, believed. Each modality has its associated modal operators. Thus for alethic modality operators are necessary (L) and possible (M).

30.7.7 Temporal logic

The classical logics do not accommodate time. The temporal logics that have been developed to overcome this limitation follow two broad approaches. One is the use of a temporal modality. In this form of temporal logic, use is made of the modalities:

Always, sometimes.

Other modalities used are:

Past, present, future

and

Precedes, succeeds.

There are corresponding temporal operators, of which the most common are probably always (A) and sometimes (S).

The other approach is to adapt FOPL to handle time. One method makes use of time points. The predicate is augmented with an extra argument that denotes the time point. The approach is somewhat similar to that used in situational logic.

30.7.8 Epistemic logic

Epistemic logic is a form of logic used to reason about knowledge possessed by other agents.

30.8 Uncertainty and Inconsistency

The foregoing discussion has brought out the need to be able to handle uncertainty and inconsistency. Some approaches to this problem are now described.

30.8.1 Sources of uncertainty

There are a number of sources of uncertainty. Uncertainty arises due to the randomness of events and to incompleteness, vagueness, unreliability, and unbelievability of and contradictions in knowledge.

30.8.2 Probability theory

The traditional approach to handling uncertainty is the use of probabilistic reasoning. This has been considered in some detail in Chapter 7. The treatment there was in the context of reliability engineering, but the basic probability theory is of wide applicability.

Probabilistic reasoning is utilized in AI and an account is given in Section 30.9. However, it also has a number of limitations, which have led to the development of alternative approaches. These limitations are perhaps best understood by considering these other techniques.

30.8.3 Certainty theory

Expert systems are typically based on a set of rules. In some cases it is not certain that a rule is correct. It is not easy to characterize this uncertainty using conventional probability theory and certainty theory has been developed to handle this problem.

For a statement S a certainty measure, or certainty, C(S) is defined such that

$C(S)$	If S is true
$C(S) = -1.0$	If S is false
$C(S) = 0$	If nothing is known about S

C(S) may also have values intermediate between $+1.0$ and -1.0, reflecting the degree of certainty that it is true or false.

For a rule a certainty factor CF is defined

If A then X with certainty factor CF

CF has the value 1.0 if it is certain that the rule is true, it has the value -1.0 if it is certain that the rule is false, and may take intermediate values, reflecting the degree of certainty that it is true or false.

In the approach, a rule is taken to be either true (CF = 1.0) or false (CF = –1.0), and its application results in a conclusion X that has a value true or false. A truth value of X is obtained by application of a single rule. Application of a second rule which gives a truth value for X either confirms the original value or contradicts it. Using certainty theory, however, the truth value of X is associated with a certainty value which is subject to adjustment each time a rule is applied and yields a truth value for X.

The relations used to determine the certainty C(X) of the statement X given A are:

$$C(\mathrm{X}\,|\,\mathrm{A}) = C(\mathrm{X}) + [\mathrm{CF}\,(1.0 - C(\mathrm{X}))] \quad C(\mathrm{X}) > 0;\ \ \mathrm{CF} > 0 \qquad [30.8.1a]$$

$$C(\mathrm{X}\,|\,\mathrm{A}) = C(\mathrm{X}) + [\mathrm{CF}\,(1.0 - C(\mathrm{X}))] \quad C(\mathrm{X}) < 0;\ \ \mathrm{CF} < 0 \qquad [30.8.1b]$$

$$C(\mathrm{X}\,|\,\mathrm{A}) = \frac{C(\mathrm{X}) + \mathrm{CF}}{1.0 - \min[|C(\mathrm{X})|; |\mathrm{CF}|]} \quad \begin{array}{l} C(\mathrm{X}) > 0;\ \ \mathrm{CF} < 0 \\ \text{or}\ \ C(\mathrm{X}) < 0;\ \ \mathrm{CF} > 0 \end{array} \qquad [30.8.1c]$$

In the original work the certainty factor for a rule was formally related to the probability that it is true, as follows:

$$\mathrm{CF} = \frac{\max[P(\mathrm{X}\,|\,\mathrm{A}); P(\mathrm{X})] - P(\mathrm{X})}{1 - P(\mathrm{X})} \quad \mathrm{CF} > 0 \qquad [30.8.2a]$$

$$\mathrm{CF} = \frac{\min[P(\mathrm{X}\,|\,\mathrm{A}); P(\mathrm{X})] - P(\mathrm{X})}{P(\mathrm{X})} \quad \mathrm{CF} < 0 \qquad [30.8.2b]$$

The certainty factor CF in Equation 30.8.2a is also referred to as the measure of belief (MB) that the rule is true, and CF in Equation 30.8.2b as the measure of disbelief (MD).

In subsequent work certainty factors have often been used in a heuristic way to attach subjective estimates of certainty to rules. As an illustration of the application of certainty factors, consider the following illustrative example.

If A then X CF = 0.8
If B then X CF = 0.7

with an initial certainty $C(\mathrm{X}) = 0$. For both rules the relation applicable is Equation 30.8.1a. Successive applications give for $C(\mathrm{X})$ values of 0.8 and 0.94.

30.8.4 Dempster/Shafer theory

The Dempster/Shafer theory is a theory of evidence that makes a distinction between uncertainty and ignorance. It utilizes a belief function that is essentially a probability function to which confidence limits have been assigned. In other words, the belief function gives the probability that the probability estimate lies within certain bounds.

As the bounds narrow, the belief function tends to the conventional probability function. In other words, probability theory may be regarded as a special case of Dempster/Shafer theory.

30.8.5 Possibility theory and fuzzy logic

Another type of uncertainty is that which arises from the vagueness of natural language. This can be handled using fuzzy logic. This approach is also known as possibility theory. Fuzzy logic is considered in Section 30.10.

30.8.6 Incidence calculus

In probability theory the relationships between events are based on the assumption that the events considered are independent. Formulations of the basic probability relations exist that incorporate correlation terms which allow for dependency between events. The problem is the difficulty of furnishing numerical values for these correlation terms.

An alternative approach is the use of the incidence calculus of Bundy (1984). A set *W* is defined which is the set of all possible worlds or incidents. The incidence *i*(*A*) of a formula *A* with respect to *W* is that subset containing all those incidents for which *A* is true. The independence of two formulas is obtained from the intersection of the two incidences, or subsets.

30.8.7 Plausibility theory

Another problem that needs to be addressed is reasoning with knowledge obtained from sources that are not totally reliable. This is the province of plausibility theory. Plausibility theory makes it possible to reason with inconsistent sets of knowledge obtained from imperfect sources. It utilizes p-sets, a p-set being a set of assertions vouched for by sources with some degree of reliability. Each member of a p-set is assigned a plausibility value that is determined by reference to the source with the highest status.

30.8.8 Truth maintenance systems

As already described, non-monotonic reasoning involves revision, and therefore the possibility of introducing inconsistency into the knowledge base. It is the function of a truth maintenance system (TMS) to maintain the consistency of the knowledge base during the process of reasoning by the inference engine, which is thereby freed to get on with its main task. A TMS is also known as a belief revision system or revision maintenance system.

A TMS maintains a record of the current beliefs and of the justifications for these beliefs. It identifies contradictions and the statements responsible for them and implements retractions. The record of the knowledge base takes the form of a dependency network, the nodes of which represent premises, conclusions, rules, etc. Each node has attached to it a justification enumerating the inference steps by which it was derived. The exception is premise nodes, since premises require no justification.

Two types of justification record are used, support lists (SLs) and conceptual dependencies (CDs), the first being the more widely used. A support list takes the form

(SL < in-list > < out-list>)

An active node must have at least one valid node in the in-list and hence IN the current belief set, and all nodes in the out-list must be OUT of the belief set. The state of a TMS may be represented in tabular form. A typical example might be:

Node	*Status*	*Support list*	
n1	IN	(SL ( ) ( ))	Premise
n2	OUT	(SL (nl) (n3))	Unjustified belief
n3	IN	(SL (n5) (n4))	Justified belief
n4	OUT	(SL ( ) ( ))	Retracted premise
n5	IN	(SL ( ) ( ))	Premise

The TMS can also be represented in graphical form using a special set of symbols.

When a contradiction is discovered, the TMS examines the dependency structure that supports the contradictory node and identifies the offending nodes directly. This process is termed dependency-directed backtracking (DDB) and is for this purpose a more efficient search strategy than chronological backtracking. The other type of record, the CD, may be regarded as a form of conditional proof. It takes the form:

(CD < consequent > < hypothesis in-list > < hypothesis out-list >)

The CD is valid if the consequent node is IN when each node in the hypothesis in-list is IN and each node in the hypothesis out-list is OUT. CDs can be, and usually are, converted to SLs.

There are a number of different types of TMS. These include the non-monotonic TMS (NMTMS) or justification-based TMS (JTMS); the logic-based TMS (LTMS); and the assumption-based TMS (ATMS).

30.8.9 Default reasoning

Another form of non-monotonic logic is default reasoning. This permits default assumptions to be handled. The method is non-monotonic because it may be necessary at some later stage to retract an assumption. Default reasoning may be represented as

$$\frac{\mathrm{P}(x)\colon \mathrm{MQ}(x)}{\mathrm{R}(x)}$$

where M is a consistency operator, which has the meaning 'and if it is consistent to assume. . .'.

30.8.10 Default reasoning: closed world assumption

The method of default reasoning just described is suitable for making specific individual default assumptions, but it is sometimes desirable to be able to make some more global set of assumptions. This is the function of the closed world assumption (CWA).

The CWA is that if a proposition cannot be proven it is false. It is often a reasonable assumption in a situation which is well understood and in which most of the facts are known.

Formally, the CWA involves the use of a metarule that if P(a) cannot be disproved, the assumption ¬P(a) is to be made.

30.8.11 Default reasoning: predicate completion and circumspection

Whilst default assumptions are valuable, they need to be carefully handled. Proliferation of default assumptions can cause problems. Two methods of doing this are predicate completion and circumspection.

Predicate completion involves the use of completion formulas to restrict the application of predicates to those entities to which they are applicable. Circumspection formulas fulfil a somewhat similar function by restricting the entities to which a predicate is applied to those with defined characteristics.

30.8.12 Heuristics

In many AI applications, particularly in expert systems, use has been made of heuristics and of *ad hoc* methods to take account of uncertainty. There are no doubt various reasons for this. One is probably unfamiliarity with the more formal methods available. Another is the difficulty of providing the probability estimates required in many formal methods.

A feature for which heuristics have been developed is the treatment of the degree of confidence in particular rules. For example, the expert system SOLOMON of P.R. Cohen (1985) utilizes a system of 'endorsements', effectively weightings, to be applied to rules.

30.9 Probabilistic Reasoning

30.9.1 Probability

Probability theory is considered at some length in Chapter 7 and it is sufficient here to restate the following basic relations for independent events A and B:

$$P(\mathrm{A\ AND\ B}) = P(\mathrm{A}) * P(\mathrm{B}) \qquad [30.9.1]$$

$$P(\mathrm{A\ OR\ B}) = P(\mathrm{A}) + P(\mathrm{B}) - P(\mathrm{A}) * P(\mathrm{B}) \qquad [30.9.2]$$

$$\neg P(\mathrm{A}) = 1 - P(\mathrm{A}) \qquad [30.9.3]$$

30.9.2 Bayes' rule

Much use is made in AI of Bayesian inference. Restating Bayes' rule for an event E and a hypothesis H

$$P(\mathrm{H} \mid \mathrm{E}) = \frac{P(\mathrm{E} \mid \mathrm{H}) * P(\mathrm{H})}{P(\mathrm{E})} \qquad [30.9.4]$$

Generalizing for a set of hypotheses $\mathrm{H}_1, \ldots, \mathrm{H}_n$:

$$P(\mathrm{H}_i \mid \mathrm{E}) = \frac{P(\mathrm{E} \mid \mathrm{H}_i) * P(\mathrm{H}_i)}{\sum_1^n P(\mathrm{E} \mid \mathrm{H}_j) P(\mathrm{H}_j)} \qquad [30.9.5]$$

30.9.3 Odds

Another formulation of probability that is often used in AI is odds. The odds $O(\mathrm{E})$ in favour of an event E are related to its probability $P(\mathrm{E})$ as follows:

$$O(E) = \frac{P(\mathrm{E})}{1 - P(\mathrm{E})} \qquad [30.9.6]$$

or, altnernatively

$$P(\mathrm{E}) = \frac{O(\mathrm{E})}{1 + O(\mathrm{E})} \qquad [30.9.7]$$

For Bayes' rule, where there is a hypothesis H, the two associated ratios of likelihood are

$$\mathrm{LS} = \frac{P(\mathrm{E} \mid \mathrm{H})}{P(\mathrm{E} \mid \neg\mathrm{H})} \qquad [30.9.8]$$

$$\mathrm{LN} = \frac{P(\neg\mathrm{E} \mid \mathrm{H})}{P(\neg\mathrm{E} \mid \neg\mathrm{H})} \qquad [30.9.9]$$

These relationships are used, for example, in the expert system PROSPECTOR. In the terminology there used the two likelihood ratios are termed logical sufficiency (LS) and logical necessity (LN).

Another useful concept associated with odds is that of the weight of evidence. In the use of Equation 30.9.4, the process of updating for a series of events $E_1, \ldots, E_n$ is somewhat clumsy. An elegant device introduced by Turing is to reformulate using odds and then to take logarithms. This gives

$$\log_e O(H\,|\,E) = \log_e O(H) + \sum_{i=1}^{n} w_i \qquad [30.9.10]$$

with

$$w_i = \log_e\left(\frac{P(E_i\,|\,H)}{P(E_i\,|\,\neg H)}\right) \qquad [30.9.11]$$

$$= \log_e f_i \qquad [30.9.12]$$

where f_t was termed by Turing the Bayesian factor in favour of H yielded by E_i, and w_i is the weight of evidence.

30.10 Fuzzy Logic

Fuzzy logic, and fuzzy set theory generally, addresses the problem of vagueness as opposed to randomness. The term fuzzy logic is used in two senses. In the broader sense it is virtually co-terminous with fuzzy set theory, whilst in the narrower sense it refers to that part of fuzzy set theory that deals with inference. Fuzzy set theory was introduced by Zadeh (1965). Accounts are given in *Fuzzy Sets and Systems* (Dubois and Prade, 1980), *Multistage Decision-Making under Fuzziness* (Kacprzyk, 1983), *Fuzzy Sets Theory and Its Applications* (Zimmerman, 1986), *Fuzzy Sets, Decision-Making and Expert Systems* (Zimmerman, 1987), *Fuzzy Relation Equations and Their Application to Knowledge Engineering* (di Nola *et al*., 1989) and *Fuzzy Logic for the Management of Uncertainty* (Zadeh and Kacprzyk, 1992) and by Zadeh (1968, 1975a,b, 1978, 1983a,b, 1985) and Kacprzyk (1992).

Fuzzy logic provides a means of handling the vagueness inherent in natural language. Some of the quantities with which it deals are:

Fuzzy predicates: *small, large; young, old*
Predicate modifiers: *very, quite, extremely*
Fuzzy quantifiers: *most, many, few, often, usually*
Fuzzy numbers: *about* n, *a little more than* n
Fuzzy probabilities: *likely, unlikely*
Fuzzy possibilities: *quite possible, virtually impossible*
Fuzzy truth values: *true, quite true, mostly untrue*

Fuzzy quantifiers are also termed linguistic quantifiers, and predicate modifiers are also termed linguistic hedges.

Fuzzy logic effectively involves a numerical encoding of natural language terms, or linguistic variables. It is sometimes known as linguistic variable theory.

If $X = \{x\}$ is a universe of discourse, consider a fuzzy set A which is a subset of X, denoted $A \subseteq X$. The set A is a set of ordered pairs. $\{(x_{A,}\ \mu_A(x))\}$. The $\mu_A(x)$ is the grade of membership of x in A.

For example if $X = \{1, 2, \ldots, 10\}$, a fuzzy set for large numbers might be given as $A = 0.3/6 + 0.5/7 + 0.85/8 + 1/9 + 1/10$, where the grade of membership of the numbers 1–5 is zero, where that of the number 6 is 0.3, meaning that there is a probability of 0.3 that 6 is a member of the set, and so on.

The grade of membership in a set may be defined in terms of a membership function. Figure 30.1 shows two functions commonly used. Figure 30.1(a) is a form used for a linguistic variable such as a fuzzy quantifier and Figure 30.1(b) is a form used for a fuzzy number.

For the determination of the number of members in a fuzzy set with a given attribute, if A is the set of n items and $x_1, \ldots, x_n$ the members of that set and these members have to some degree the attribute F and therefore have a membership function $\mu_F(x_i)$, the number n_F of items which have this attribute F, or cardinality of the set, is determined as

$$n_F = \sum_{i=1}^{n} \mu_F(x_i) \qquad [30.10.1]$$

As an illustration, consider the problem of a set of items some of which are said to need replacement. If this set is $A = 0.3/x_1 + 0.3/x_2 + 0.8/x_3 + 0.8/x_4 + 0.8/x_5$, then from Equation 30.10.1 $n_F = 3.0$.

For the determination of the truth of a statement involving a fuzzy quantifier, such as 'most xs are F', the problem may be posed as the evaluation of the truth value τ of the statement, which may be expressed in a form such as τ(Qxs are F), where $A = \{x_1, \ldots, x_n\}$ is the set of interest, F is an attribute and Q is a fuzzy quantifier. The grade of membership of an item x_i in the set A with respect to the attribute F is $\mu_F(x_i)$. The membership function is $\mu_Q(r)$. Then the relations for the determination of the truth value are

$$r = \frac{1}{n}\sum_{i=1}^{n} \mu_F(x_i) \qquad [30.10.2]$$

$$\tau(\text{Q}x\text{s are F}) = \mu_Q(r) \qquad [30.10.3]$$

As an illustration, consider the problem of determining the truth of the statement 'Most compressors are reliable'. The problem is then to evaluate the truth value τ of this statement which may be expressed as τ(Qxs are F), where A is the set of n compressors, F is the attribute *reliable* and Q is the fuzzy quantifier *most*. Suppose that the grades of membership $\mu_F(x_i)$ for the attribute *reliable* in the set of compressors are taken as $A = 0.1/x_1 + 0.6/x_2 + 0.8/x_3$ and that the fuzzy quantifier may be represented by a suitable membership function $\mu_Q(r)$ taken as

$$\begin{aligned} \mu_Q(r) &= 1 & r &\geq 0.8 \\ \mu_Q(r) &= 2r - 0.6 & 0.3 < r &< 0.8 \\ \mu_Q(r) &= 0 & r &\leq 0.3 \end{aligned}$$

Then from Equations 30.10.2 and 30.10.3 $r = 0.5$ and $\mu_Q(r) = 0.4$, giving a truth value τ of 0.4.

For fuzzy logic there is no unique set of inference rules, but the following are those most generally quoted. In terms of the truth value τ

$\tau(\neg A) = 1 - \tau(A)$	Negation
$\tau(A \wedge B) = \min(\tau(A), \tau(A))$	Conjuction
$\tau(A \vee B) = \max(\tau(A), \tau(A))$	Disjuction

The application of inference rules in fuzzy logic tends to be considerably more complex than the corresponding exercise in classical logics.

30.11 Programming Languages

Many accounts of knowledge representation and of inferential reasoning give examples cast either in the form of the

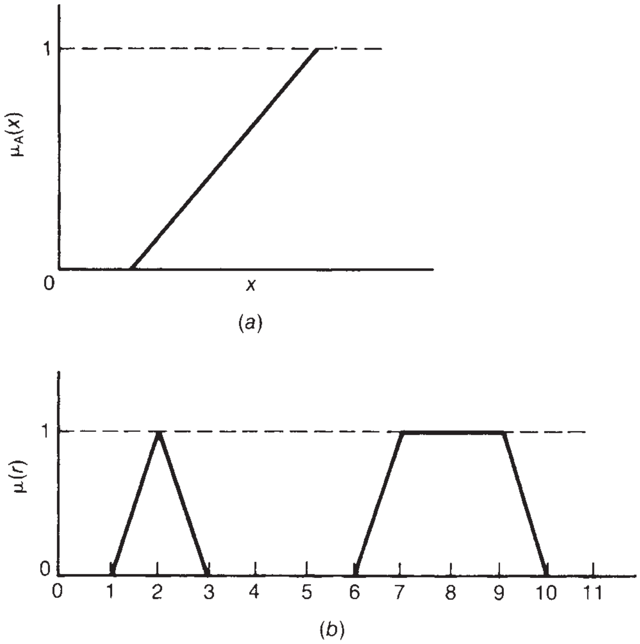

Figure 30.1 *Some Functions in fuzzy logic: (a) membership function of a fuzzy set; (b) two examples of a fuzzy number*

predicate calculus or of a specific programming language such as LISP or PROLOG. This section is a short introduction to these three languages, which is given for the purpose of making more concrete some of the concepts in the preceding sections and indicating how they are implemented in practice.

30.11.1 Predicate calculus

Knowledge representation and inferential reasoning are often exemplified using not a specific programming language but the predicate calculus. This is the approach adopted, for example, by Charniak and McDermott (1985).

The following are examples of some of the forms of knowledge representation and of inferential reasoning described in earlier sections cast in predicate calculus form.

Assertions

(inst vessel-1 vessel)	Vessel-1 is an instance of a vessel.
(structure vessel-1 thick-walled)	A structural feature of vessel-1 is that it is thick-walled.
(opens fitter flange)	A fitter opens a flange.

Isa hierarchy

(isa pump pressure-raiser)	A pump is a pressure raiser.

Connectives

(if (and (inst thermocouple instrument) (robustness instrument delicate) (robustness thermocouple delicate)	If a thermocouple is an instrument and an instrument is delicate then a thermocouple is delicate.

Quantifiers

(forall x (if (inst x instrument) (robustness x delicate)	All instruments are delicate.
(forall x (if (control-valve x) (exists y) (power-source-of x y)	All control valves have a power source.

1.	(inst thermocouple instrument)	A thermocouple is an instrument.
2.	(forall x (if (inst x instrument) (robustness x thermocouple)	All instruments are delicate.
3.	(if (inst thermocouple instrument) (robustness thermocouple delicate)	If a thermocouple is an instrument, then a thermocouple is delicate.
4.	(robustness thermocouple delicate)	A thermocouple is delicate.

The third entry is obtained from universal instantiation and assertion 2 and the fourth by modus ponens from assertions 3 and 1.

Abductive inference

(has-inspections vessel-1)	Vessel-1 has inspections.
(for all x (if (contains-chlorine x) (has-inspection x))	All vessels which contain chlorine have inspections.
(contains-chlorine vessel-1)	Vessel-1 contains chlorine.

This example illustrates the fact that abductive inference is not a strictly valid form of reasoning and may given a incorrect conclusion.

Inductive inference

(if (inst instrument-1 instrument) (robustness instrument-1 delicate)	Instrument-1 is delicate.
(if (inst instrument-2 instrument) (robustness instrument-2 delicate)	Instrument-2 is delicate.
(forall *x* (if (inst *x* instrument) (robustness *x* delicate)	All instruments are delicate.

Frame

An assertion

(opens fitter flange)	A fitter opens a flange.

may be cast in the frame form as

(opens opens-1)	Opens-1 is an instance of opening.
(agent-opening opens-1 fitter)	The agent opening is a fitter.
(object-opened opens-1 flange)	The object opened is a flange.

Forward chaining

(if (inst ?*x* pump) (inst ?*x* pressure-raiser)	If an object is a pump, then it is a pressure-raiser.

30.11.2 LISP

LISP (List Processing language) is a high level, symbolic processing language devised by McCarthy (1960, 1978) and embodies his calculus for symbolic processing.

Accounts of LISP are given in *LISP 1.5 Primer* (Weissman, 1967), *The Little LISPer* (D.P. Friedman, 1974), *Let's Talk LISP* (Siklossy, 1976), *Anatomy of LISP* (J. Allen, 1978), *A Beginner's Guide to LISP* (Hasemer, 1984a), *Common LISP* (Steel, 1984), *LISP* (Winston and Horn, 1981) and by D. Shaw, Swartout and Green (1975), J. Allen (1979), Pratt (1979), Hasemer (1984b), Laubsch (1984), Patterson (1990), Tanimoto (1990) and Gabriel (1992).

LISP can be run in the interpreted or compiled modes, the former being more commonly used.

There are a number of dialects of LISP. A widely used form is Common LISP, which was created in an attempt to obtain a standard form. There are, however, several other widely used forms, including MACLSP and INTERLISP. The syntax of LISP is very simple. All data and program statements are represented in LISP as s-expressions. The valid s-expressions are the following: atoms, strings, lists and dotted pairs. An atom is a number or string of contiguous characters, including letters, numbers and special characters. A string is a sequence of characters enclosed in double quotation marks. A dotted pair, or cons, is an ordered pair of s-expressions enclosed in parentheses. A list is a sequence of s-expressions enclosed in parentheses.

Atom	a–b
String	"a b"
Dotted pair	(a · b)
List	(a b)

The basic operation of LISP is evaluation.

Instruction in LISP are described as forms. There are three basic types: functions, macros and special forms.

LISP contains a number of forms, which include the following: input and output forms; control forms; list manipulation forms; arithmetic functions; logical functions; evaluation forms; predicates; and function and property forms.

A principal feature of LISP is list processing and it possesses a number of functions for the manipulation of lists. These include cons, car, cdr and append.

30.11.3 Prolog

Prolog (Programming in Logic) is a programming language based on the predicate calculus. A number of researchers contributed to its origins; it was implemented by Colmerauer and co-workers (Colmerauer, Kanoul and van Caneghem, 1983).

Accounts of Prolog are given in *Programming in Prolog* (Clocksin and Mellish, 1981), *The Art of Prolog* (Sterling and Shapiro, 1986) and *Prolog Programming for Artificial Intelligence* (Bratko, 1986) and by K.L. Clark and McCabe (1982), Clocksin (1984), J. Cohen (1985), Colmerauer (1985) and Patterson (1990).

Programming in a language such as Prolog is referred to as logic programming. Prolog programming may be viewed as the creation of a database of facts and rules about objects, their attributes and relationships. This database can then be interrogated.

Prolog has a simple syntax. A program consists of *terms*. A term is a *constant*, a *variable* or a *structure*. It consists of a sequence of *characters*. A character may be of four kinds: an upper case letter, a lower case letter, a digit or an operator. A constant may be of two kinds: an *atom* or an *integer*. Examples of atoms are:

vessel
pressure_raiser

A variable is similar to an atom except that it starts with an upper case letter of underline sign '_'. A structure consists of a *functor* and of *components,* with the functor written first followed by the components in parentheses. An example of a structure is:

pressure_raiser (pump)
meaning 'a pump is a pressure raiser'.

Facts

A fact or assertion is exemplified by:

corrodes (wet_chlorine, mild_steel)
meaning 'wet chlorine corrodes mild steel'

Rules

A rule is cast in the form:

conclusion if condition 1 and condition 2 . . .

where the first term is the head and the rest is the body. Such a form is termed a Horn clause. An example of a rule is

corrodes(X, Y): wet_chlorine(X), mild_steel(Y)

where: denotes *if* and the commas between the structures *and.* The meaning is X corrodes Y if X is wet chlorine and Y is mild steel.

Lists
A list is written as a sequence of terms with commas between and enclosed in square brackets. An example of a list is:

[steel, aluminium, copper]

An empty list is denoted by [ ].

The head and tail of a list may be distinguished by the use of a vertical bar. An example of this is:

[a|b, c, d]

List manipulation
There are a number of list manipulation functions: append, member, cone, add, delete; cone denotes concatenate.

Queries
A query is exemplified by:

?-corrodes (X, mild_steel)
meaning 'what X corrodes mild steel?'.

Prolog program
A Prolog program proceeds by taking the rule condition, or headless Horn clause, and 'instantiating' the variables (X and Y in the above examples) to identify those instances which satisfy the rule. Thus for the rule given above the clause

?- wet_chlorine (X), mild_steel(Y)

satisfies

corrodes (X,Y)

The program continues by this process of resolution. A Prolog program may be regarded as a resolution theorem prover for Horn clauses.

The search strategy used in Prolog is depth-first. This strategy is in many ways simpler, but it does involve backtracking and the search can get into a 'loop'.

30.11.4 Object oriented programming

Another type of language that is now widely used in AI is object oriented programming (OOP).

Object oriented programming is described in *SMALLTALK-80, The Language and its Implementation* (Goldberg and Robsen, 1983) and in *Object Oriented Programming* (B.J. Cox, 1986) and by Stephanopoulos (1987) and Hodgson (1991).

In OOP, the program consists entirely of objects. An object is a frame-like entity with slots that hold not only data but also procedures. Procedures may perform a wide range of functions such as symbolic manipulation, numerical calculation and inferencing. Objects are arranged in hierarchies. Computation involves the sending of messages between objects.

One feature of object oriented programming is data encapsulation. Data structures incorporate within themselves the procedures that are used to manipulate them. An object can be regarded as a frame with slots that are the operations allowable on the object.

Another feature is the class hierarchy. At the top of the hierarchy is a single-object class, consisting of the principal object. Other objects lower down in the hierarchy belong to classes that are in effect subclasses. Inheritance occurs through the hierarchy.

OOP is an extremely powerful tool. A whole manufacturing process may be represented as an object, covering not only the physical plant but also its operation, documentation, hazards and so on.

30.11.5 C++ programming language

Of the more conventional programming languages, mention should be made in particular of C++. This language supports object oriented programming and interfaces with both LISP and Prolog.

30.11.6 Language characteristics and facilities

Work in AI makes use of a number of languages, and there are major differences between them. An account is given by Frost (1986). A distinction is often made between procedural languages and declarative languages, with conventional languages such as FORTRAN being described as procedural and those such as LISP and Prolog as declarative. However, the term procedural is not well defined.

The essential distinction is whether or not the 'flow of control' is specified. The flow of control is specified in conventional languages, using such commands as GO TO statements and DO loops, but not in languages such as LISP and Prolog. In these latter declarative languages there are no explicit commands that determine the flow of control. This does not mean, however, that the programmer has no influence on control. In a language such as Prolog the flow of control is affected by the order in which the statements are written.

Languages used in AI work include: the functional language LISP; the logic programming language Prolog; the frame languages AM and KRL; and the script language SAM.

The flexibility of a language may be increased by the use of an add-on facility. Thus, for example, the program FLEX provides Prolog with an object oriented enhancement.

A language such as Prolog is used particularly as a research tool. A commercial implementation may well be rewritten in a conventional language such as C++.

30.12 Structured Knowledge

The foregoing sections have described some ways of representing knowledge. It is now necessary to consider in more detail the representation of knowledge in structured form.

30.12.1 Indexing

A basic form of structure is that provided by the use of indexing, addresses, pointers and lists. These structures are not, however, generally sufficient for the purposes of AI.

30.12.2 Associative networks

A widely used form of representation in AI is the associative network. This is a form of directed graph with labelled nodes and arcs. An example is shown in Figure 30.2(a). An associative network may be expressed in terms of the predicate calculus, with nodes and arcs represented by terms and relations. An example illustrating this equivalence for a blocks world scene is given by Charniak and McDermott (1985).

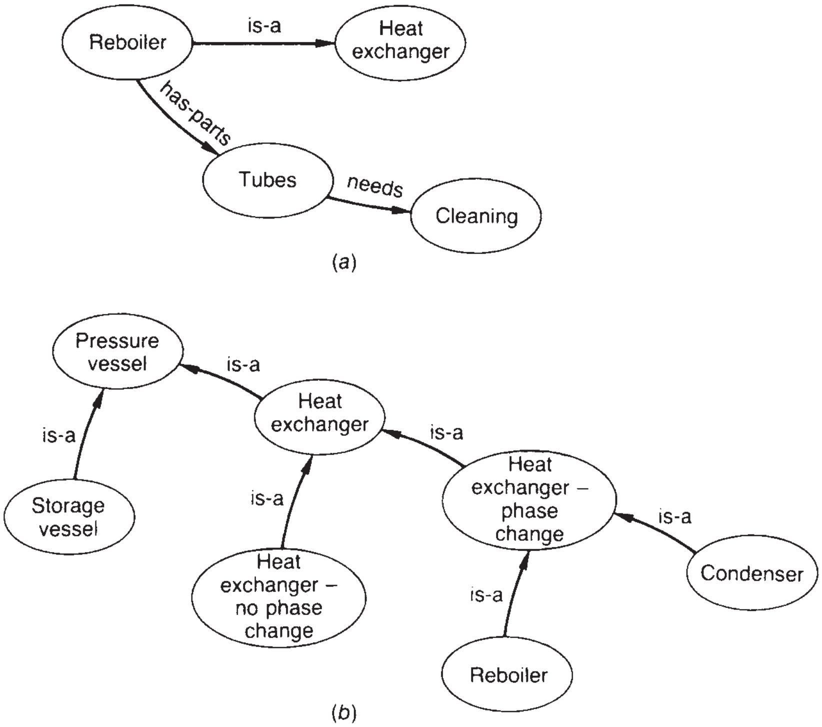

Figure 30.2 *(a) An associative network and (b) an is-a network*

The arcs of an associative network may represent a number of different relations. Some principal relations are:

Label	*Meaning*	*Used with*
is-a	Is an instance of	Generic noun
has	Has as parts	Specific noun
ako	Is a kind of	Generic noun
is	Is	Attribute
member-of	Is a member of	Larger set or entity
subset-of	Is a subset of	Larger set or entity

The ISA and HAS links are of particular importance for structured form inheritance.

30.12.3 ISA hierarchy

A particular aspect of associative nets is the ISA hierarchy. This is effectively a way of expressing a taxonomy using a network with is-a arcs and working down from the generic to the specific. The associative network is shown in Figure 30.2(b) is an example of an ISA hierarchy.

30.12.4 Inheritance

Children can inherit a characteristic from their parents. Similarly, entities in an ISA hierarchy may inherit from entities directly above them. Another way of putting this is that a set can inherit a characteristic from a superset of which it is part, and a subset can inherit from a set. Multiple inheritance occurs when a set is part of more than one superset and may thus inherit from both supersets. This obviously creates the potential for conflict between the inherited values.

As stated earlier, the use of inheritance may be regarded as a form of default reasoning. The point has also been made, however, that the proliferation of defaults through inheritance can cause problems and it is necessary to proceed cautiously. In some cases it may be appropriate to allow most members of a set to inherit a certain characteristic but to arrange to override this for some members of the set.

30.12.5 Semantic networks

Associative networks are widely used in natural language comprehension and are then often termed semantic networks.

30.12.6 Slot and filler systems

Another type of representation goes by the general name of a slot and filler system. Particular forms are frames and scripts. In terms of the predicate calculus, a slot and filler system may be represented by a single statement with a number of arguments corresponding to the number of slots.

Slot and filler systems are useful for: representing archetypes, or stereotypes; handling default values; matching and pattern recognition; and error detection.

30.12.7 Conceptual dependency

Before considering particular slot and filler systems, it is appropriate to mention conceptual dependency (CD) theory. The basic concept here is that a set of sentences that have different structures but identical meaning should have a CD representation that is both unique and unambiguous. CD methodology provides a set of tools such as primitives, syntax, rules, etc., for the formulation of such sentences.

30.12.8 Frames

A frame is a structure that contains a number of pieces of information on some entity such as an object, event or situation. It is applicable where the entity has a stereotype that is sufficiently strong to define the features on which information should be stored. Typical situations treated in the AI literature are attending a meeting or eating in a restaurant.

A frame consists of a frame name and a list of attribute-value, or slot-filler, pairs. In other words, the attributes are also called slots and the values fillers. A slot is simply the name of an attribute and the filler its value. Many accounts use the mixed terminology of slots and values, and this is adopted here. An empty frame, or schema, contains only the frame and slot names, whilst an instantiated frame contains also the values. In some cases default values may be supplied for slots.

Alternatively, or in addition, a slot may be furnished with associated information in the form of a procedural attachment, or demon. Two commonly used types of attached information are a procedure to determine the value for the slot if one is needed (the if-needed attachment) and one to be executed when the value has been filled in (the if-added attachment). Another type is a constraint on the value which can be added to the slot. A slot may also be filled with the name of another frame. In this way hierarchies of frames may be created.

Frames are a natural form of representation for default reasoning and for inheritance.

30.12.9 Scripts

Like a frame, a script is a structure that contains a number of pieces of information on some entity such as an event, situation or activity. It differs in that the slots contain not values but sentences written in terms of CD primitives. Typical situations treated in the AI literature are eating in a restaurant or shopping in a supermarket. Thus, a script will typically have a script name and slots for the situation, actors, initial conditions and props.

There will then be slots for several scenes and one for the outcomes. A script may be used to reason about a current situation by filling in those parts which characterize the situation, retrieving from memory another script which matches this situation. Slots in the current script are filled by inference using inherited and default values.

Like frames, scripts are a natural form to use for default reasoning and inheritance.

30.12.10 Constraints

A simple constraint may be represented as a predicate of the predicate calculus. Alternatively, it may be required to represent a more generalized constraint in the form of an algebraic equation relating several variables. In this case a constraint schema may be created which lists the variables in the equation and, for each of these variables, the algebraic expression by which it is evaluated.

30.12.11 Relational databases

Another form of structured knowledge representation is the relational database. This has been described in Section 30.2.

30.12.12 Production systems

Another form of structured knowledge is a production system. Production systems have already been described in Section 30.6 and are therefore not considered further here, except to note that the knowledge held in a production system is not necessarily confined to that embodied in the rules, but may include, in the conflict resolution section, knowledge about the control strategy which governs the application of the rules. It is often in this latter that much of the expertise resides.

30.12.13 Objects

Objects constitute another form for the representation of structured knowledge. They have been described in the previous section in the context of OOP.

30.13 Search

The application of the tools described to problem-solving typically involves some form of search. Search is one of the fundamental activities in AI.

30.13.1 Search procedures

There are a large number of search procedures that are used in AI. They may be classified in several ways. Some procedures are used to search for optimal paths; others for any path, not necessarily an optimal one; and others again for game playing. Another distinction is between uninformed, unguided, or blind search and informed or guided search. Some principal procedures category are:

General	*Informed*	*Optimal*
Breadth-first	No	No[a]
Depth-first	No	No[a]
Hill-climbing	Yes	No
Beam	Yes	No
Best-first	Yes	No
British Museum	No	Yes
Branch and bound	Yes	Yes
A* algorithm	Yes	Yes
Games		
Minimax		
Alpha beta		

[a] Search does not necessarily find the optimal, or shortest, path unless it is exhaustive.

30.13.2 Uninformed search

Uninformed search is inefficient, but it may be necessary to resort to it if there is difficulty in formulating heuristics or an evaluation function to guide the search.

30.13.3 Breadth-first search

Breadth-first search involves visiting all the nodes at a given level before moving to the next level. A breadth-first search is illustrated in Figure 30.3(a).

30.13.4 Depth-first search

Depth-first search involves moving down the tree as rapidly as possible, visiting nodes at successively lower levels until the lowest node in the branch is reached, then returning back up the tree to the point at which a downward

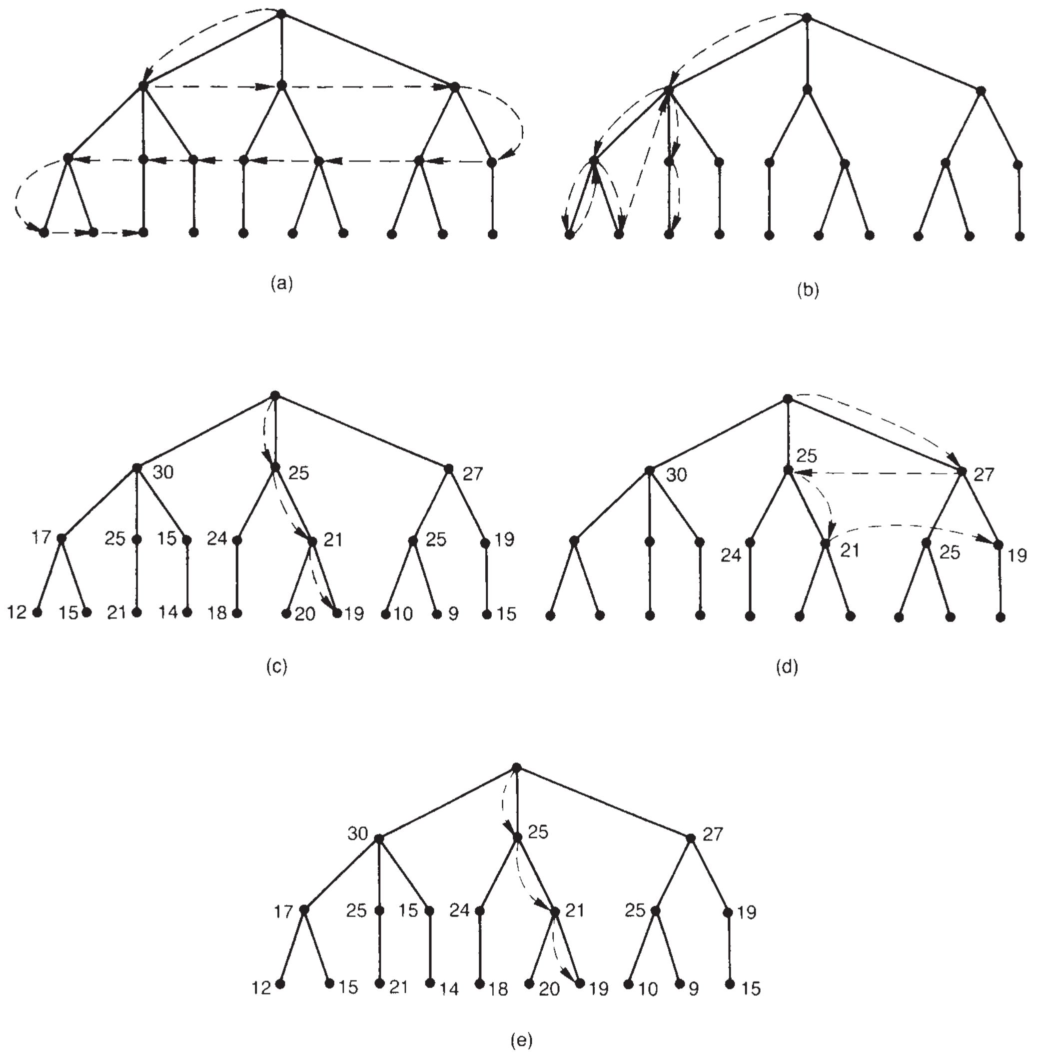

Figure 30.3 *Search through a goal tree: (a) breath-first search; (b) depth-first search; (c) hill-climbing; (d) beam search; (e) best-first search*

move again becomes possible, and so on. A depth-first search is illustrated in Figure 30.3(b). A depth-first search, therefore, necessarily involves backtracking.

30.13.5 Informed search

It will be clear from the account just given that uninformed search methods are subject to combinatorial explosion and become impractical for larger problems. The remedy is to inform the search in some way.

30.13.6 Heuristic search

One approach to informed search is the use of heuristics. These may take various forms, but generally have to do with the characteristics of the goals, states and paths between states.

30.13.7 Evaluation function

It may be possible to guide the search by using a formal evaluation function, which may also go by other names such as an objective function or a figure of merit. The formulation of such a function is an aspect of matching, which is discussed in Section 30.14. Given an evaluation function it becomes possible to utilize search methods which are much more efficient. The sum of the values of an evaluation function between the nodes on a path is known as the path length.

30.13.8 Hill-climbing

A hill-climbing search utilizes an evaluation function that it seeks to minimize and is essentially a form of depth-first search. It differs from a regular depth-first search in that at a given node the next move made is to the child node for which the evaluation function is minimized. A hill-climbing search is illustrated in Figure 30.3(c).

Like other forms of hill-climbing, there are certain classic topological problems which a hill-climbing search may encounter. They include the foothill, plateau and ridge problems.

Although, in general, hill-climbing is a common form of optimization, a hill-climbing search as just described does not guarantee a global optimum solution.

30.13.9 Beam search

A beam search resembles a breadth-first search in that it proceeds level by level, but differs from it in that the search utilizes an evaluation function and moves downwards only through the best *w* nodes at each level. A beam search is illustrated in Figure 30.3(d). By comparison with breadth-first search, beam search is much more economical.

30.13.10 Best-first search

A best-first search resembles hill-climbing in that it utilizes an evaluation function, but differs from it in that it uses this function in a different way. Whereas in hill-climbing the function is used to select between the child nodes of the current node, in a best-first search the function values for all nodes visited are stored and the search moves from the node for which the function is a minimum, wherever it may be in the tree. A best-first search is illustrated in Figure 30.3(e). Like hill-climbing, a best-first search does not guarantee a global optimum.

30.13.11 British Museum method

Of the methods that provide an optimum solution, the British Museum method involves an exhaustive search through the whole tree to identify the optimum path. The search may be breadth-first or depth-first, but in either case it is modified so that it does not stop when a path is found but continues until all paths are found and the optimum can be identified. The method is even more subject to combinatorial explosion than the regular uninformed search methods.

30.13.12 Branch-and-bound search

A branch-and-bound search proceeds by storing the path lengths and expanding that node which at any given stage has the shortest path length. This means that the search may move down a path in one branch of the tree and then jump to one in a second, quite different, part of the tree when movement down the current path has raised the path length above that in the second part. A branch-and-bound search is somewhat complex; an account is given by Winston (1984).

In this search method termination when a path is found does not actually guarantee an optimal solution, since in principle there may be a path that is incomplete but very close to the solution point. For an optimal solution, it is necessary to use the condition that termination occurs when the shortest complete path is shorter than the shortest incomplete one.

30.13.13 A* algorithm

The A* algorithm is a special form of branch-and-bound search which utilizes instead of the path length from the start to the current node the total path length from the start to the goal node. This means that it must possess a heuristic for estimating the distance between the current and the goal node. If this estimate is a lower bound on the actual distance, the solution obtained is optimal. This condition is known as the admissibility of the algorithm.

30.13.14 Games search

Games differ from other problems handled in AI in that there is an active opponent. This has led to the development of specialized forms of search for game playing. The tree through which the search is conducted is known as a game tree. The head of the tree is the start position and the successive layers represent the 'turns' of the two players. Game trees are considered further in Section 30.15.

30.13.15 Move generation and evaluation

A particular form of heuristic search that has been developed for games such as checkers and chess is move generation and position evaluation. Some of the heuristics for these are described in Section 30.15.

30.13.16 Minimax method

The Minimax method utilizes the concepts of move generation and position evaluation and searches for the moves most likely to win the game.

The two players seek to achieve conflicting goals. One player is taken as seeking to maximize the evaluation function and the other as seeking to minimize it. The maximizing player (Max) has to assume that, when it is his or her turn, the minimizing player (Min) will select that move which minimizes the function.

It is assumed in the Minimax method that it is practical to perform only a limited evaluation of a position; in other words, that it is practical to look only a limited number of moves ahead. The maximum number of levels to which the search can be extended before evaluation takes place is the lookahead depth.

For a start which is Max's move, the even numbered levels contain nodes where the evaluation function is applied to obtain a maximum score and the odd numbered levels nodes where it is applied to obtain a minimum score. A move is evaluated by backing up from the current node to the start, summing the scores at each level. The best move for Max is then that with the maximum backed-up value.

30.13.17 Alpha beta method

Another search method used for game playing is the alpha beta method. It is essentially a form of the Minimax method which prunes those branches of the tree that give a bad result and are therefore irrelevant. The essential principle is that if the opponent has even one good response to a move that would cause it to give a bad result, the move is bad and that branch is pruned.

30.13.18 Control

In general, search needs to be subject to some control strategy. The methods just described in effect constitute particular strategies. However, problems differ, and a strategy suitable for one may not be appropriate for another. The development of search control strategies is an important area of work in AI.

30.13.19 Dependency-directed backtracking

One of the most widely used search methods is depth-first search. This involves backtracking, which unless guided can be an inefficient process. One common method of providing such guidance is dependency-directed backtracking (DDB).

In conventional backtracking, on failing to find a solution the search tracks back to the last node visited at which an alternative path exists. In DDB, the search returns instead to the node which is implicated in the failure. In this case the backtracking is guided by the data dependencies of the rules involved, which it uses to seek out the node causing the contradiction. This function may be performed by the truth maintenance system.

30.13.20 Forward and backward chaining

Search may proceed by forward chaining or by backward chaining. These two modes of search may be explained either in terms of the rules or of the search tree.

In forward chaining the left-hand side of the rule is instantiated first, so that this mode is termed data-driven inference. In backward chaining, by contrast, the right-hand side of the rule is instantiated first, and this mode is termed goal-driven inference. In terms of the search tree, forward chaining involves a search from the bottom to the top of the tree, or from leaf to root, whilst backward chaining involves a search from the top down, or from root to leaf. Thus, forward chaining is referred to as data-driven or bottom-up, or as antecedent reasoning, and backward chaining as goal-driven, top down, or as consequent reasoning.

The mode of chaining which is most appropriate depends on the shape of the tree. Figure 30.4 shows two search trees. Forward chaining is best suited to the fan-in case shown in Figure 30.4(a) and backward chaining to the fan-out case shown in Figure 30.4(b).

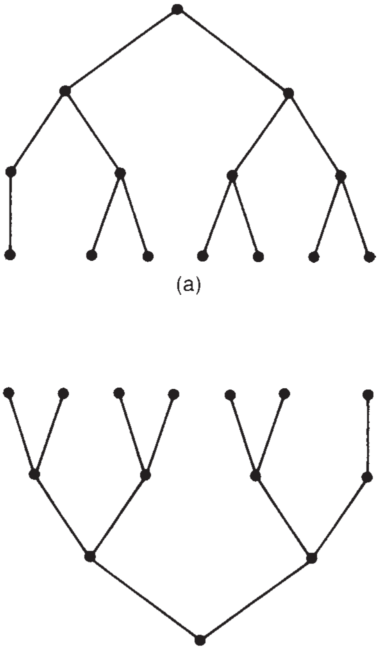

Figure 30.4 Direction of chaining as a function of the shape of the goal tree: (a) forward chaining; (b) backward chaining. In each diagram the search is from the bottom

30.14 Matching and Pattern Recognition

30.14.1 Matching

Another major activity in AI, and one closely related to search, is matching. Some form of matching is involved in virtually all AI work but the nature of the matching process depends on the particular field of application. Areas of AI in which matching is required include logical reasoning, learning, planning, expert systems, vision and natural language comprehension.

Matching is required for a number of purposes. It may serve to identify and classify objects, retrieve objects from a knowledge base, establish the eligibility of objects for inheritance, select alternatives, control a sequence of operations, and so on.

The overall process of matching may be described as one of representation, transformation and comparison. The object to be matched must first be represented in a form that captures the relevant characteristics. This representation may then need to be transformed to make it conformable for comparison with another object, the referrent. This comparison is based on a matching measure, or metric, which forms the basis of comparison, and a matching criterion, which is used to decide whether a match is established.

There is a variety of representational structures to which matching may be applied. They include: clauses in prepositional or predicate logic and logic rules; sets and bags; frames and scripts; and graphs, trees and networks.

There are a number of types of matching metric. There are various distance metrics based on quantitative variables. They may be deterministic or probabilistic. Probability metrics include product moment correlation and measures of clustering. There are also distance metrics based on qualitative variables. These variables may be: binary variables, denoting one of two states; nominal variables, denoting equality or inequality; and ordinal variables, denoting rank order.

There are a number of similarity measures. One type of similarity measure is based on the sets of attributes common to the object and its referrent. Another type which is used for labelled graphs is based on the 'cost' of transforming the graph into its referrent graph. Another metric is the distance that can be defined between the fuzzy sets associated with an object and those associated its referrent. The matching criteria used, and the types of matching obtained, may be exact, partial or fuzzy.

30.14.2 Pattern recognition

Pattern recognition comprehends, but is somewhat broader than, matching. The term is applied particularly to vision. The process of pattern recognition involves feature selection, matching and classification. Pattern recognition is often closely associated with learning by the development of classification rules. Pattern recognition is one of the strengths of neural networks, described in Section 30.21.

30.15 Problem-solving and Games

An important part in the development of AI has been played by problem-solving of various kinds, particularly puzzles and games. An influential early program was General Problem Solver (GPS).

30.15.1 Puzzles

Puzzles frequently quoted in the AI literature include missionaries and cannibals, painted squares, the travelling salesman and the Towers of Hanoi (or Hanoi Towers) problems. The solution of these puzzles is treated essentially as a search. A particular form of search applied to puzzles is means–ends analysis.

In the Towers of Hanoi the goal is to transfer three graded discs from one peg to another, starting from an initial state in which the three discs are on one peg, with the smallest disc on top and the largest at the bottom, and there are two empty pegs. The rules are that a disc can be moved only when there is no disc on top of it and that it may not be placed on a smaller disc at the destination peg. The puzzle is therefore a planning problem in a world akin to the blocks world described below.

30.15.2 Games

Games likewise feature strongly in AI. These are generally two-person, zero-sum games, and include tic-tac-toe (noughts and crosses), checkers (draughts) and chess. These may all be treated as board games and have well-defined rules. Such games are generally represented by a game tree, with the first state at the root of the tree and with the successive move options represented by the successive plies below.

For any but the simplest game, a blind search is impractical for combinatorial reasons and some more sophisticated search method is needed. As already described, characteristic search methods used for game tree searches include the Minimax and alpha beta methods.

Practical problems may be handled by a games approach insofar as they can be treated as games against nature; in particular, against a nature which seeks to defeat the human player by invoking Murphy's law that whatever can go wrong, will go wrong.

30.15.3 Samuel's checkers program

An early and influential games program was the checkers program of Samuel (1959, 1963a,b). This program used Minimax search and heuristic methods for state evaluation and move generation. State evaluation utilized a function with some 16 features such as the number of pieces, piece location and piece advantage. Move generation was guided by tree pruning heuristics. The program also possessed a learning capability, with storage and retrieval of board states that had occurred in previous games.

30.15.4 Chess playing programs

Another game that received attention early in the work on AI and has been influential in its development is chess. Work on computer chess is described in *Computer Chess* (Newborn, 1975). A short account of its historical development is given by Charniak and McDermott (1985).

Early workers in computer chess were C.E. Shannon (1950a,b) and Turing (1953). An early program was written by Bernstein. A major advance occurred in 1967 with the program by Greenblatt. Another influential treatment was that of Newell and Simon (1972).

The general approach to chess playing is broadly similar to that applied to checkers, as just described. A search is conducted through the game tree using methods such as Minimax and alpha beta, and exploiting heuristics for state evaluation and move generation.

The conduct of a game such as a chess may be regarded as a form of planning, albeit under conditions where there is an opponent who seeks to frustrate the plan.

30.15.5 General Problem Solver

General Problem Solver (GPS) by Newell and Simon (1963) was another early and influential program. It is described in GPS: *A Case Study in Generality and Problem-Solving* (Ernst and Newell, 1969).

GPS may be regarded as the first AI system to make a clear separation between problem-solving and task knowledge. It was designed to tackle the class of problems that can be formulated in terms of a set of objects, which include states, and of operators that are applied to these objects to transform them into goal objects, or states.

The basic method used in GPS is means–ends analysis. The search is depth-first, with backtracking, and utilizes forward chaining.

In GPS an operator has three features: the preconditions, the transformation function and the differences reduced. The first is a state description which it is a necessary condition that the current state should match for the operator to be applicable. The second is the function that the operator performs. The third links the operator to the differences that it is effective in reducing.

30.15.6 Blocks world

An environment widely studied in AI work is the so-called blocks world. This world consists of a set of blocks on a flat surface. It is a world that is relatively simple and predictable.

Blocks world has been used as an object of study in several areas of AI. It has obvious application to manipulation by robots, but it has also been used in work on computer vision.

30.16 Vision

A quite different area of work is that of vision. This topic is a major one in AI but is not of prime concern here, and will be treated briefly.

Accounts of visual image processing and computer vision are given in *Computer Techniques in Image Processing* (Andrews, 1970), *Computer Vision Systems* (Hanson and Riseman, 1978), *Computer Vision* (Ballard and Brown, 1982), *Vision* (Marr, 1982), *Robot Vision* (Horn, 1986) and by Winston (1984), Patterson (1990) and Tanimoto (1990).

Most applications of visual image processing lie outside the process field, but its use in robotics may have some bearing. There are also applications in accident investigation, as described below.

Visual image processing is generally described as involving an image acquisition stage followed by low level, intermediate and high level processing stages. The image acquisition stage yields a digitization of the image. Low level processing deals with noise reduction, outline and edge definition, thresholding, and texture and colour. Thresholding converts a grey image into one with regions of black and white only. Intermediate level processing handles shape formation and interpretation and involves operations such as connecting, filling in, combining boundaries, determining regions and assigning labels. High level processing deals with semantic analysis and interpretation and involves the identification and characterization of objects and relationships. The various processes utilize a number of specialized techniques such as the determination of the edge distance and surface direction, region growing, shape analysis, and so on. More advanced topics include three-dimensional images and motion. Work on aspects of visual image processing, notably on blocks world problems, has had influence on AI generally.

Image enhancement may sometimes be used in accident investigation. The Piper Alpha Inquiry heard evidence on image enhancement of photographs taken of the west side of the platform in the early stages of the fire, with particular reference to the issues of the nature and source of the fireball and of any damage which may have occurred to the firewall between the modules, though in the event it was not possible in this case to take much from this evidence.

30.17 Natural Language

Another area of work is that of natural language. This too is a major topic in AI, but again one that can be treated briefly here.

Accounts of natural language processing and machine translation are given in *Syntactic Structures* (Chomsky, 1957), *Semantic Information Processing* (Minsky, 1968), *Understanding Natural Language* (Winograd, 1972), *Semantics* (Lyons, 1977), *Syntax* (Culicover, 1982), *Practical Experience of Machine Translation* (Lawson, 1982), *Language as a Cognitive Process* (Winograd, 1983), *Language Learnability and Language Development* (Pinker, 1984), *Conceptual Structure* (Sowa, 1984), *Natural Language Processing* (Cullingford, 1986), *Understanding Natural Language* (J. Allen, 1987) and by Winston (1984), Charniak and McDermott (1985), Patterson (1990) and Tanimoto (1990).

Natural language processing as such is of little interest here, but work in this area has an important bearing on topics that are relevant such as knowledge and knowledge representation. Work on natural language covers areas such grammars, parsing, syntax, semantics and language generation.

Some kinds of knowledge used in understanding language include: syntax, or the structure of language; semantics, or the meaning of language; pragmatic knowledge, which relates sentences and their meaning to context; and world knowledge, which is required to use a language effectively.

In the areas of semantics, work relevant to the topics discussed earlier includes that on the semantics of quantity, time, space, and knowing and belief.

Transition networks, a technique for parsing sentences, and their development, augmented transition networks (ATNs), are based on directed graphs. ATNs have been used in Stone World, a program that simulates some of the activities of a stonemason, moving objects around an environment.

Some understanding of natural language is likely to be helpful in applying AI techniques in areas such as operating procedures.

30.18 Planning

Another major area of work in AI is that of planning.

Accounts of AI planning include those in GPS (Ernst and Newell, 1969), *A Structure for Plans and Behavior* (Sacerdoti, 1975), *Planning and Understanding* (Wilensky, 1983) and *Readings in Planning* (J. Allen, Hendler and Tate, 1990) and by Fikes and Nilsson (1971), Tate (1976, 1977), Sacerdoti (1977, 1985), Waldinger (1977), Steflk (1981), Vere (1983, 1992), Winston (1984, 1992), Chapman (1985), Charniak and McDermott (1985), Currie and Tate (1991) and Lyons and Hendricks (1992).

Planning programs which have been influential in the development of planning in AI are GPS by Ernst and Newell (1969), STRIPS by Fikes and Nilsson (1971) and Fikes, Hart and Nilsson (1972), NOAH by Sacerdoti (1975, 1977), NONLIN by Tate (1977), MOLGEN by Steflk (1981), DEVISER by Vere (1983) and TWEAK by Chapman (1985).

30.18.1 Planning and plans

Requirements for planning are that there be an initial world state, a set of actions that change that state and a set of goals for the final state, and that the environment be sufficiently predictable, though not necessarily completely determined.

The need for planning arises where the situation is novel or critical. Often, however, the situation is familiar. In such cases it may well be sufficient to retrieve from store an existing plan.

It is instructive to compare a plan and a program. A plan is typically executed once, whilst a program may be run many times, albeit with different input data. A plan may have to cope with an environment that is subject to changes, whereas the environment in which a program operates is stable. A plan defers commitment in order to be able respond to the environment.

Planning may be regarded as a special case of reasoning about time, or temporal reasoning. The temporal relationships may be shown in a time map, which is a specialized form of associative network. In one form of time map the nodes represent times, in another they represent situations.

Planning involves decomposing a task into a set of subtasks. These subtasks are then further decomposed until a level is reached at which a subtask decomposes into a set of primitive actions. The task may be represented in the form of a task network, which is a special kind of time map. The structure of the task is in effect a plan for performing it.

Accounts of the overall activity of planning tend to break it down in different ways. One broad type of activity is plan generation. This involves creating a plan to perform a task. The generation of plans is one of the more difficult areas of planning. Plan generation tends currently to be domain-specific, with domain-independent plan generation often a rather distant goal.

It may not always be necessary to generate a fresh plan. In some cases it is sufficient to recognize that the task is, or is sufficiently close to, one for which a plan has already been devised and is already in store.

Another broad area of planning is plan selection and coordination decisions, which are rather more amenable to domain-independent treatment. Plan selection involves choosing from candidate plans and plan coordination the sequencing of a set of plans. Criteria for making these decision include avoidance of interference between plans and minimization of resources, including time.

Planning, therefore, involves the manipulation of a number of plans. These plans are not necessarily treated as a global plan. The emphasis may be rather on the planner and on the way in which it manipulates these plans during execution. In general, plans may be relatively simple, but the planning algorithms that manipulate them can be rather complex.

Plan execution involves executing the primitive actions of the plan, monitoring for failures and, if necessary, replanning.

30.18.2 Blocks world and mundane planning

Much AI work on planning has centred around the blocks world situation in which a robot performs actions such as stacking or unstacking the blocks. In the simple case, it is assumed that the only changes to the environment are those caused by the robot's action and that these actions are predictable, instantaneous and performed one at a time.

Features of this situation are the relative simplicity of the goals, the world state and the resultant plans. In real-life, or mundane, situations the case is quite different. There are likely to be a number of goals some of which may conflict and there may be a large amount of common sense information that needs to be taken into account.

30.18.3 Goal ordering and meta-goals

Planning is sensitive to the order in which the goals are attempted. An inappropriate ordering can result in extensive backtracking. Methods of goal ordering are therefore needed.

One method is to permute the order of the goals if there is difficulty in obtaining a solution. A more systematic approach is to order the goals in a hierarchy. High level goals have features such as: they are the most difficult to achieve, they determine the structure of the space, and they are not themselves affected by actions.

In many cases, particularly in mundane situations, the problem of the ordering of goals becomes quite severe. There are multiple goals that may interfere or are conflicting so that there is a need to be able to reconcile goals and to abandon goals. This problem has often been tackled by the use of *ad hoc* rules that set meta-goals such as achieving as many goals as possible, maximizing the value of the goals achieved, avoiding impossible goals and economizing resources such as time.

Wilensky (1983) has attempted a more fundamental approach which eschews this *ad hoc* approach and in which planning of meta-goals, or meta-planning, is conducted in exactly the same way as regular planning of goals. This approach is implemented in the program PANDORA.

30.18.4 Protection of goals

Planning requires that certain goals and states be protected from alteration. It is normal that a goal, once achieved, is protected. However, if subsequently a solution cannot be found, it may be necessary to violate this protection in order to seek a solution by goal permutation or some other method.

Protection is also applied to states. A state is protected during an interval if it is required to be true throughout that interval. An important class of plan failure is that of protection violations.

One strategy for preventing protection violations is to detect them as they occur. Another is to anticipate them. The basic method of dealing with a protection violation is reordering.

30.18.5 Events, actions and macroactions

The interaction of an agent with an environment may be described in terms of the actions of the agent and of the events in the environment.

The general form of a primitive action routine specifies (1) objects (to be used), (2) steps (to be executed), (3) order (of steps) and (4) protection (of goals). A primitive action is modelled by specifying the action routine and the pre-conditions and post-conditions of the action, or in other words the conditions for it to be taken and its effects.

A set of primitive actions may be grouped together in a structure with associated goal protections to form a macroaction. The plan implemented by a macroaction is thus one created by a human rather than an AI planner. Macroactions are a useful device, but also have drawbacks. In some cases a macroaction may be inflexible or inappropriate.

30.18.6 Operators

Closely related to the above is the concept of an operator. In AI planning an operator acts on a state to effect transition to some other state. An operator is an action with attached lists of pre-conditions and post-conditions. The pre-conditions are the conditions that must be met for the operator to be applied and the post-conditions those that will then pertain. One of the most widely used operators is the STRIPS operator, described below.

30.18.7 The frame problem

In most cases, when an action in a plan is implemented, only a limited proportion of the system states alters, so that the effect is localized. There may, however, be a large number of states that might change. The need to infer that a state will not change across an event is known as the 'frame problem', the term frame here having no connection with frame as a form for knowledge representation.

30.18.8 Planning by search

In AI, planning is effectively a specialized form of search. There are two approaches that may be taken to this search. One is to search through the space of world situations, or possible states of the world. In this type of search the initial state and final states are given by initial and final world models and the operators are the primitive acts.

The alternative, and generally preferred method, is to search the space of plans. In this case operators are applied to reduce the task to subtasks and primitive tasks and to order unordered tasks. The search is conducted to discover a sequence of operations to transform the initial state into the goal state.

30.18.9 Measures of complexity

A measure of complexity in planning may refer either to the planning algorithm or to the planning task. The computational time for the implementation of a planning algorithm may be expressed in terms of a function $O(n)$, where n is the number of items or some other suitable metric of problem size. If in the algorithm $O(n)$ is a polynomial in n, the problem is said to have polynomial time complexity. If, on the other hand, $O(n)$ is such that n appears as an exponent, the problem is said to have exponential time complexity. The increase in computational time with n for exponential time complexity is such that the task of solution is regarded as intractable, whereas with polynomial time complexity the task may be tractable.

The difficulty of a planning task is commonly expressed in terms of NP-completeness. Known algorithms for the solution of NP-complete problems have an exponential time complexity and the task is generally assumed to be intractable. A task which is difficult in this sense is said to be NP-hard.

30.18.10 Means–ends analysis

One of the basic techniques of planning is means–ends analysis. The essential features are an initial state, a goal state, a set of operators with pre-conditions, and a difference function. The latter is a measure of the difference between the goal state and the current state.

Means–ends analysis starts with a small number of general steps that are then expanded into more detailed steps. If in the current state an operator cannot be applied because a pre-condition is not satisfied, the algorithm creates a subgoal. It moves to an adjacent state in which the pre-condition is satisfied.

One problem in means–ends analysis is that of real and apparent difference, or distance from the goal. If the difference function is crude and inappropriate, the search can enter a dead end where the apparent distance to the goal is short but the real distance is large. An analogy is reaching a point that is close to the goal as the crow flies but where the path is blocked by an insurmountable cliff face.

30.18.11 General Problem Solver

Mention has already been made of the General Problem Solver (GPS) program of Ernst and Newell (1969). The basic method used in GPS is means–ends analysis. GPS works from the current state to the goal in a forward-chaining process. It proceeds by selecting and applying operators to reduce the difference function. If necessary, it resorts to the creation of subgoals. If the search reaches a dead end, it backtracks. Thus GPS in effect uses a depth-first search.

30.18.12 STRIPS

A development from GPS is the planner STRIPS (Standford Research Institute Problem Solver) created by Fikes and Nilsson (1971) and Fikes, Hart and Nilsson (1972). STRIPS has had a major influence on AI planning, being widely used, copied and modified. STRIPS is a linear planner, as described below.

A characteristic feature of STRIPS is the operator used. The STRIPS operator consists of an action with a specified list of pre-conditions and post-conditions. The pre-conditions are the conditions that must be met for the operator to be applied and the post-conditions those that will then pertain.

Another feature of STRIPS is that it tackles the frame problem by making the default assumption that an action has the effects specified, no less and no more.

30.18.13 Linear and non-linear planning

A distinction is made in planning between linear and non-linear planning. Early planning programs used linear plans. The planner starts at one end, either the initial or the goal state, and moves step by step closer to the other end. The order of the operations performed is completely specified. Non-linear planning, by contrast, utilizes partial plans. A partial plan is a set of steps that is not fully determined. Features of a partial plan that may not be fully specified are the order of the steps or the choice of operator to be used. A single partial plan may comprehend a number of total plans, or completions.

The use of non-linear instead of linear planning is much more efficient, being characterized by polynomial time, as opposed to exponential time.

30.18.14 NOAH

The first non-linear planner was NOAH by Sacerdoti (1975, 1977).

30.18.15 Planning theorems

A feature of AI planning is the formulation of governing theorems. This aspect is associated particularly with the work of Chapman. This work moves planning away from *ad hoc* approaches and emphasizes the proving of planning theorems, on correctness or attainability.

30.18.16 TWEAK

The planning theorem approach is embodied in the TWEAK program developed by Chapman (1985). This is a non-linear planner that retains the STRIPS-type operator. A plan produced by the program is guaranteed to be correct.

30.18.17 Hierarchical planning

In the foregoing account, frequent reference has been made to goals and some to subgoals. It might perhaps be inferred from this that AI planning always involves a hierarchy of goals, but this is not so. Hierarchical planning is only one approach.

In hierarchical planning, the higher level goals are expressed in relatively general terms and are then expanded into the more detailed lower level goals. Translation from higher to lower levels goals is a matter of inference. To this extent hierarchical planning may be distinguished from planning proper, which involves the selection and ordering of goals.

30.18.18 Non-subgoaling planning

An alternative to hierarchical planning is to use a single level of goals. Such non-hierarchical planning is sometimes known as non-subgoaling planning. The characteristic non-subgoaling planner proceeds by forward chaining using means–ends analysis and adds actions to the plan in the order in which they will be used. Using this approach it is relatively easy to check that the current plan does not enter into an undesirable state, and hence that the final plan does not do so either.

30.18.19 State graph planning

In state graph planning the problem is represented as a graph of the possible states of the system, the states being represented by the nodes and the actions by the arcs connecting the nodes. State graph planning can provide solutions to a wide range of planning problems, including most operating procedure synthesis problems. However, it has a number of limitations. Problems of modelling and of undesirable states have to solved by the user in the process of creating the state graph. The state graph can be very large and it may not be easy to modify it. There are issues of the correctness and completeness of the stage graph.

30.18.20 Goals of protection

A planner should ensure that entry is not made into an undesirable state. However, AI planning methods for the avoidance of such states are not well developed. Hence in applying such planning to process problems such as operating procedure synthesis, where it is essential to avoid unsafe states, some adaptation is necessary.

A variety of terms have been used to describe the negative goal of avoiding entry into an undesirable state. They include domain constraints, avoidance goals, preservation goals and goals of prevention. The latter term is the one used here.

30.18.21 Functional operators

As already described, a central concept in planning is that of an operator. Reference has been made particularly to the STRIPS operator, which has been widely used. However, in systems such as process networks the conditions after an event can depend on those that pertain before it. In other words there is a functional dependency between the input and output states. This cannot be handled by a STRIPS-type operator.

This problem has led to the development of the conditional, or functional, operator. This type of operator has a number of sets of pre-conditions and a number of sets of post-conditions. For each set of pre-conditions, there is a corresponding set of post-conditions which apply.

30.18.22 Action synergy

It commonly occurs in planning that a group of actions has an effect which is not exhibited by the individual actions taken in isolation. This is known as action synergy.

A simple example is a pair of valves in a pipe. If the initial state is that both are closed, the action of opening one of them does not have the effect of allowing flow through the pipe. This effect is obtained only by the actions of opening both valves.

There are there thus some goals that can be achieved only by action synergy. Action synergy may also be the cause of an undesirable effect. In some cases it can have the effect of entering an unsafe state.

30.18.23 Subplan merging

Another situation common in planning is the need to merge two subplans. This can often be a non-trivial operation.

A simple example of the need for subplan merging is the problem of taking a tool from a toolbox. The initial states are that the toolbox is shut and that the tool is inside. The desired end state is that the toolbox is shut and that the tool is outside. The last two states therefore constitute goals for the end state. The plan must ensure that the two subplans for removing the tool and shutting the toolbox are so merged that the tool is removed before the toolbox is shut.

30.18.24 Planner operation

At this point an account is given, following Vere (1992), of the operation of a typical AI planner. The planner operates by keeping a stack of goals and conducting an ordered depth-first search to achieve them.

It proceeds by a process of node expansion, involving backward chaining. Each node represents a subgoal. The planner achieves the subgoal by selecting an action with a post-condition which matches the subgoal. The preconditions of that action then become the new subgoals.

It is not always necessary or appropriate to expand a pre-condition. In many cases a pre-condition can be achieved by linking. Linking is used where the precondition of a subgoal is already satisfied, in that there already exists elsewhere in the plan above the current subgoal a node with an assertion which achieves that pre-condition. In some instances, there may be several linkings which satisfy a pre-condition. Associated with this are syntactic conventions in action descriptors which inhibit backward chaining of a pre-condition and thus reduce the extent of backtracking.

Where node expansion throws up more than one candidate action, in other words where an OR branch occurs, it is necessary to select one of them. Rules are therefore required for action selection. These rules may be domain-independent or domain-specific. Some criteria for domain-independent selection are to choose an action on the basis of: the number of non-linkable pre-conditions; the number of additional, or bonus, goals which it achieves; and the resources which it consumes.

Conflict can arise where there are two unordered nodes with contradictory assertions. Resolution of the conflict needs to be made immediately. It is effected by placing the two nodes in order and maintaining the protection of the upper node.

Node expansion, linking and conflict resolution by ordering are the three fundamental operations of this type of planner. Vere gives an example of a blocks world plan utilizing only these three operations. If neither node expansion nor linking is possible, the subgoal cannot be achieved and it then becomes necessary to backtrack.

30.18.25 NONLIN

The program NONLIN by Tate (1976) is a hierarchical planner that operates broadly on the above lines and has been applied to turbine overhaul and naval missions.

30.18.26 Execution monitoring

A plan may fail in execution due to a number of causes. One such cause is simply random events. Hence execution monitoring is an essential part of planning. Planning of a task and its execution need to be interleaved. There is no point in formulating a comprehensive plan if it is likely to be negated by events occurring at an early stage. On the other hand, some degree of forward planning is desirable. One issue in planning is how far ahead to plan.

There is no agreed approach to execution monitoring, but it is possible to identify certain issues. At any given time the planner has an expectation that a number of states are true. It may conduct tests to verify them. In this case it requires criteria for selecting the tests.

A related problem is the explanation of unexpected results. These may arise for a number of reasons such as a defective model of the world situation or a random event.

30.18.27 Reactive planning

The conventional approach to planning is the creation of a plan which in the absence of changes in the environment will achieve the goals but which has some capability to respond to such changes and to replan. There exists, however, a quite different approach, which is to achieve goals by a process of responding to the environment. This is reactive planning, which is described by Lyons and Hendricks (1992).

Conventional planning has typically been applied to situations of the blocks world type. Other worlds exist, however, and need to be dealt with. One envisioned by Schoppers (1987) is ‘baby world’, in which the environment is disturbed by activities characteristic of babies, such as throwing bricks around, and so on. It is with this type of world that reactive planning is concerned.

Like conventional planning, reactive planning seeks to achieve goals, but when a change in the environment occurs, it reacts not by making a modest change to the original plan, or replanning, so much as by creating a new plan.

Thus, the techniques used in reactive planning are based on some form of reaction between the agent and the environment. For example, Brooks (1986, 1989) has used a hierarchy of routines that react with the environment to achieve goals, the hierarchy being termed the ‘subsumption architecture’ and the routines the ‘behaviours’.

Another aspect of reactive planning is the work of Nilsson (1988), who has addressed the problem that in conventional planning the higher levels surrender control and have to suspend action until they receive it back, so that the situation is liable to occur that the lower levels of control continue with activities which have been rendered inappropriate by a change in the environment.

Reactive planning is a relatively new but now influential approach.

30.18.28 Temporal planning

Planning necessarily deals with the ordering of subtasks, but it does not necessarily deal with time constraints. Temporal planning addresses problems where such time constraints exist.

These time constraints have been handled in work by Vere (1983), in which each action is assigned a start time and a duration. Temporal relationships are defined using words such as before, equal, meets (adjoins), overlaps, during, etc. He has implemented this method in the program DEVISER.

30.18.29 Domain dependency

Initial work on planning utilized domain-independent approaches. Later work has moved to domain-dependent methods. This change of approach was prompted by experience. In addition, however, it has been shown by Chapman (1985) that there are theoretical reasons for thinking that it is not practical to build a domain-independent planner that is able to tackle real-life problems and is also provably correct.

30.18.30 Decision theory

One method of analysing a plan is the use of decision theory. Since AI work on planning has largely been concerned with synthesis and since decision theory is a tool for analysis, the extent of application of decision theory in planning has been limited. Human planners are well able to create plans in mundane situations. Decision theory was developed to assist in the analysis of plans for the more complex cases.

More extensive application of decision theory for the analysis of plans synthesized by AI planning methods is likely to highlight the problem of obtaining estimates for the values of probability and utility used in the theory.

30.19 Learning

From the earliest day of AI, the creation of a machine which can learn has been one of the principal goals. Accounts of learning in AI are given in *Learning Machines* (Nilsson, 1965), *Machine Learning* (Michalski, Carbonell and Mitchell, 1983–) and by Lenat (1982, 1983) and Simon (1983).

Two principal categories of task in machine learning are (1) classification and (2) problem-solving.

The representation of the objects that the machine experiences may take various forms. Objects may be described in various ways, including in terms of binary features, multi-valued attributes, classes or structural relationships.

Learning may be classified in a number of ways. The learning modes considered here may be described as (1) learning by instruction, (2) learning by classification, (3) learning by exploration and conceptualization, (4) learning by experience and analogy, (5) learning from failure and (6) learning by problem-solving.

In addition to these learning modes, there are also particular devices that have a learning capability. Two that figure prominently in AI are (1) neural networks and (2) genetic algorithms.

Of particular importance in learning is the use of inference by induction and this is discussed in Section 30.20.

In the following, an account is given of the learning modes and learning devices just described. It needs to be said, however, that for some of the learning modes the work described constitutes only a very partial exploration of the mode both in breadth and depth.

30.19.1 Supervised and unsupervised learning

Most work on classification tasks involves supervised learning. Typically, the program is given a learning set in which both the class and attributes of each object are specified and it is then required to create a discrimination hierarchy.

There is some work, however, on learning in unsupervised classification tasks where the program has to perform the assignment to classes itself.

In problem-solving unsupervised learning is the norm, but some work has been done on supervised learning in which an expert prompts the program at crucial junctures.

30.19.2 Learning from data and stored knowledge

Another distinction is between learning from data and from stored knowledge. It is often assumed that learning requires new data about the interaction of the agent and its environment. In fact, there is generally much to be learned from knowledge already in store which can be retrieved and processed in various ways so as to learn new concepts, rules and so on. In particular, learning may take place in the course of problem-solving.

30.19.3 Learning by instruction

One method by which a program may learn is to receive instruction from a tutor. Such learning by instruction may proceed in various ways.

One type of instruction that the tutor may give is modifications or additions to rules such as those in the knowledge base of an expert system. The tutor may provide additional rules, perhaps rules-of-thumb. Or he may monitor the responses of the system, detect deficiencies in these responses, examine the explanations given for them, and identify and modify the rules causing these defective responses.

Instruction of an expert system on these lines is performed by the expert system TEIRESIUS of R. Davis (1980), created as an intelligent editor for MYCIN. An account of its operation is given by Charniak and McDermott (1985).

There is an element of instruction in some of the other methods of learning also, insofar as the learning set or environment presented to the program has been chosen by the tutor. This choice is often of considerable importance.

30.19.4 Learning by classification

Learning by classification involves inductive reasoning in which generalizations are made from a learning set of specific objects, each of which is labelled with attributes and assigned to a class. This form of learning is considered in more detail in Section 30.20.

30.19.5 Learning by exploration

Learning by exploration is essentially concerned with concepts. The program is given a learning set in which the objects are unclassified and required to develop concepts.

One area of work here is conceptual clustering in which the program determines how to cluster and to describe objects. It typically involves the creation of a hierarchy of concepts.

Two programs which perform learning by exploration are AM and EURISKO, both by Lenat (Lenat, 1982, 1983; Lenat and Brown, 1984). Their operation is described by Charniak and McDermott (1985). Exploration differs from search in that the purpose is to develop and enhance concepts rather than to achieve goals. Essentially such exploration involves activities such as determining similarities and differences between objects and classifying them into sets, frames and hierarchies.

30.19.6 Learning by experience

Learning by experience may take various forms, but the aspect that is considered here is essentially learning by analogy. This type of learning is also known as case-based learning. In such learning, numbers of specific cases are stored in memory. An issue is the extent to abstraction of the salient features is performed at the time of storage or is deferred until the case is to be used. Clearly this affects the storage of cases in, and retrieval from, the memory.

A program that learns by experience is MACBETH by Winston (1980, 1982). An account is given by that author (Winston, 1984). This program deals with the process of learning from situations by analogy with other situations and the discovery of general rules. A situation, or precedent, is presented in the form of a natural language description. This description is transformed using techniques of natural language understanding. This transformation facilitates the creation of a cause structure for the precedent. The precedent has constraints that are to be matched before the precedent can be applied. The precedent is then applied by analogy to other situations where such a match exists and rules are derived. Such reasoning by analogy is liable to deduce rules that are too sweeping, and 'censors' are used to modify the rules by introducing additional conditions.

30.19.7 Learning from failure

A particular form of learning by experience is learning by failure. A type of failure that features strongly in AI is the failure of a plan.

A program that learns by the failure of plans is HACKER by Sussman and Stallman (1975), another influential system. An account is given by Charniak and McDermott (1985). The program has been used in the blocks world environment. It contains a simulated effector system that reports the reason for failure of a particular step in a plan. The program revises the plan on the basis of the report.

The program also has a collection of 'critics' that have the function of criticizing plans. These critics too have an ability to learn, which they do by analysing the experience of failures.

30.19.8 Learning by problem-solving

As stated earlier, learning does not necessarily have to be based on new data; it is also possible to learn by processing stored data. This type of learning is sometimes called analytical learning, as opposed to inductive learning from data.

Accounts of such analytical learning tend to deal particularly with learning by problem-solving. One problem-solving tool that may be learned is a set of rules. The task of problem-solving is performed. Learning from this solution proceeds by identifying the features of the problem and the problem-solution pairs that were used. From this explanation, general rules are derived. This form of analytical learning is also called explanation-based learning.

Besides rules, other features of problem-solving which may be learned include macro-operators and heuristics.

30.19.9 Neural networks

Turning to devices with learning capability, one of the principal developments is neural networks. A neural network is a network of 'neurons' that in a simplified way models the operation of the human brain. It learns from a learning set of input-output patterns. It is in effect a device for learning by experience. A fuller account of neural networks is given in Section 30.21.

30.19.10 Genetic algorithms

Another device described in biological terms is the genetic algorithm, so called from a loose analogy with genetic change in a population. A genetic algorithm utilizes a set of patterns the weighting of which is changed as learning proceeds. In effect the patterns compete and only the fit survive. Genetic algorithms are used both for classification and for problem-solving.

The genetic algorithm method may be applied to the development of rules in a rule-based production system. The weighting of the rules is adjusted to reflect their contribution to desirable behaviour.

In some applications, use is made of operators that propose new rules and the exploration conducted is primarily on the effect of different combinations of rule rather than of weightings of individual rules.

30.20 Inductive Learning

A large proportion of learning in AI proceeds by inference through induction. One of the principal uses of induction is the classification of objects, events and situations, but applications of inductive reasoning are much wider than this and extend to concepts, rules and so on. An account of induction in AI is given by Patterson (1990).

The concept underlying inductive learning is the basic logic of inductive inference:

$$\begin{array}{ll} \text{Assertions} & \mathrm{P}(\mathrm{a}_1) \rightarrow \mathrm{Q}(\mathrm{b}_1) \\ & \underline{\mathrm{P}(\mathrm{a}_1) \rightarrow \mathrm{Q}(\mathrm{b}_1)} \\ \text{Conclusion} & \forall xy\ \ \mathrm{P}(x) \rightarrow \mathrm{Q}(y) \end{array}$$

Induction may be regarded as a process of class formation. The task is to partition the universe U of objects into classes. The minimum partition is into a single class C and the rest U − C. To this end use if made of concepts, a concept being a description or rule which subdivides a set. The target concept is the concept that classifies all the objects in the universe. The positive instances are those objects that fit the target concept and the negative instances are those that do not. A consistent classification rule is one that is true for all positive instances and false for all negative instances.

30.20.1 Generalization and specialization

There are a number of recognized techniques of induction involving generalization and its converse, specialization. The basic process in induction is generalization. However, generalization may become too sweeping, so that the class created includes negative as well as positive instances. Such overgeneralization may be corrected by specialization.

Methods of generalization are exemplified by the techniques of changing constants to variables, dropping conditions and closing an interval. Replacement of constants by variables simply means that, given that a relation holds in a number of instances, it is inferred that it is generally true. Dropping a condition involves removing a condition in a description and thus widening the class. In closing an interval it is inferred that what is true of objects at the two bounds of the interval is true of objects in between.

30.20.2 Inductive bias

Generalization may be treated as a search problem. As such, it involves the familiar need to attend to the efficiency of the search. The term bias is applied in this context to those factors, other than those of the learning set, which influence the selection of hypotheses. One type of bias involves restricting the hypothesis space to be searched. Another involves ranking the hypotheses.

30.20.3 Classification

A principal application of inductive learning is classification, in which the program is presented with a learning set of objects each of which is assigned to a class and described by a number of attributes. The task is then to induce a discrimination hierarchy, or a set of rules, for the assignment of the objects to the classes.

In the more straightforward cases the learning set is consistent in that it does not contain counter-examples. More advanced work addresses the problem of such noisy learning sets.

In using a classification algorithm, the selection of the learning set requires some care to ensure that the set provides comprehensive coverage of the domain of interest and, where necessary, to exclude counter-examples.

30.20.4 ID3

One of the principal classification methods is the ID3 algorithm of Quinlan (1983a,b). ID3 is based on an information theory approach.

If in a sample of n objects there is a proportion p which belong to class C and hence a proportion $(1-p)$ which do not, a quantity H_c may be defined as

$$H_c = -p\log_2 p - (1-p)\log_2(1-p) \qquad [30.20.1a]$$

$$= -\sum p_i \log_2 p_i \qquad [30.20.1b]$$

H_c may be regarded as the expected information content of a message from a discrimination, or decision, tree for a set C of objects.

The attribute on which to branch first is selected on the criterion that the information gain is to be maximized. The information gain G_j for attribute j is

$$G_j = H_c - H_j \qquad [30.20.2]$$

with

$$H_j = \sum p_i H_{jk} \qquad [30.20.3]$$

$$H_{jk} = -p_{jk}\log_2 p_{jk} - (1-p_{jk})\log_2(1-p_{jk}) \qquad [30.20.4]$$

where H_j is the information content at the node for attribute j, H_{jk} is the information content associated with the individual branches at the node, and p_{jk} is the proportion of objects having attribute j in branch k at the node.

The algorithm is illustrated by Quinlan using the following single-class classification problem. Objects either belong to the class or they do not and are then denoted by + or –, respectively. There are three attributes: height, hair and eyes. The learning set of objects is:

short, blond, blue: +
tall, blond, brown: –
tall, red, blue: +
short, dark, blue: –
tall, dark, blue: –
tall, blond, blue: +
tall, dark, brown: –
short, blond, brown: –

There are therefore three branch points in the decision tree.

Then, since there are three objects out of eight that are in class C, and five that are not, Equation 30.20.1 gives

$$H_c = -(3/8)\log_2(5/8) - \log_2(5/8) = 0.954 \text{ bits}$$

Taking the first attribute, height, the information still needed for a rule for the 'tall' branch is, from Equation 30.20.4,

$$H_{j1} = -(2/5)\log_2(2/5) - (3/5)\log_2(3/5) = 0.971 \text{ bits}$$

and that needed for the 'short' branch is

$$H_{j2} = -(1/3)\log_2(1/3) - (2/3)\log_2(2/3) = 0.918 \text{ bits}$$

and hence from Equation 30.20.3 the expected information content is

$$H_j = (5/8) \times 0.971 + (3/8) \times 0.918 = 0.951 \text{ bits}$$

Then from Equation 30.20.2 the information gain is

$$G_j = 0.954 - 0.951 = 0.003$$

This value is negligible. Computing the information gains for the second attribute, hair, and the third attribute, eyes, in the same way yields information gains of 0.454 and 0.347, respectively. Thus the second attribute, hair, is selected for the first branch. Then the first branch of the decision tree is:

Node	*Link*
hair:	red: tall, red, blue: + dark: short, dark, blue: – tall, dark, blue: – tall, dark, brown: – blond: short, blond, blue: + tall, blond, brown: – tall, blond, blue: + short, blond, brown: –

Proceeding in a similar manner, the third attribute, eyes, is selected for the second branch. This then gives:

Node	*Link*	*Node*	*Link*
hair:	red: tall, red, blue: +		
	dark: short, dark, blue: − tall, dark, blue: − tall, dark, brown: −		
	blond:	eyes:	blue: short, blond, blue: + tall, blond, blue: + brown: tall, blond, brown: − short, blond, brown: −

A further, more complex example is given by Patterson (1990).

Further work on this algorithm has addressed aspects such as handling the noise in the data, the detection of thresholds for numeric attributes and updating of the tree with new data.

In one application to the classification of diseases, the algorithm outperformed an expert system constructed by conventional methods over a period of years (Quinlan *et al.* 1986).

The classification tool EXTRAN is an implementation of IDS.

30.20.5 INDUCE

Another program for inductive learning is INDUCE developed by Michalski and co-workers (Larson and Michalski, 1977; Dietterich and Michalski, 1981). This program discovers class patterns and formulates generalized descriptions of these patterns. A characteristic feature is its utilization for its descriptive language of an extension of first-order predicate logic.

30.21 Neural Networks

A quite different kind of learning device is exemplified by neural networks. These utilize a form of learning which in certain respects mimics that of the human brain. Neural networks are described in *Neural Computing* (Beale and Jackson, 1990) and *Neural Networks in Artificial Intelligence* (Zeidenberg, 1990) and by Patterson (1990) and Tanimoto (1990).

Work on neural networks was originally inspired by research on modelling of the human brain. Another input comes from studies of associationist psychology, particularly behaviourism. A neural network is a large network of nodes connected by links. These nodes are information processing elements based on a simple model of the neuron in the human brain. A node sums the stimuli entering it through the links and has a threshold above which it will execute, or fire, and pass a stimulus to the connected nodes. A link has a weighting that is applied to the stimulus passing along it. The link weights enhance or inhibit the stimuli. The knowledge held in the network is distributed throughout it in the form of features such as these thresholds and weights. The network has an input layer of nodes, an output layer and a number of intermediate layers in between.

Learning in, or ‘programming’ of, a neural network proceeds broadly as follows. The network is set to its initial condition, typically with thresholds and weights set at random. It is presented with a learning set of pairs of inputs and outputs that it is then taken through. For each input the output is observed and adjustments are made to the thresholds and weights according to some strategy. The process is repeated until the learning set is exhausted.

A common strategy for adjusting the adjustable features during learning is error back-propagation. In this method, the error between the desired and actual outputs is used to adjust first the hidden layer next to the output. This error in then propagated back, ultimately to the input layer. The features most commonly adjusted are the thresholds and weights, but other strategies may be used which involve adjustments to the network topology or even to the learning strategy.

A neural network is a form of statistical associative model. The statistic inference that it utilizes is better able to handle randomness and exceptions than is rule-based inference. Rule-based systems can handle exceptions, but generally at the price of much increased complexity.

Neural networks have been used for knowledge representation, production systems and expert systems, pattern recognition, visual image processing, speech recognition and natural language understanding.

Production systems and expert systems created using the neural network technique are known as connectionist systems. One application, by Touretszky and Hinton (1985), simulates the firing of rules and thus the operation of a production system. Another application is the creation of expert systems, as in the work of Gallant (1988) and Saito and Nakano (1988).

Gallant has described a neural network expert system for the diagnosis and treatment of the medical condition of acute sarcophagal disease. The system handles two forms of disease, six symptoms and three treatments. It is able to make deductions from an incomplete set of data on the symptoms and to give an explanation of the route by which it arrived at its conclusions.

30.22 Graphs, Trees and Networks

AI makes use of a large number of graphs, trees and networks, some of which are now briefly described. Some of these graphical forms constitute forms of knowledge representation, whilst others relate to the reasoning process. The graphical forms can be represented by suitable program structures in the programming languages used. Some graphs, trees and networks used in AI are listed in Table 30.3 and some are shown in Figures 30.2 and 30.5.

Taxonomic hierarchies for classification of entities go by various names. One form of particular importance is the ISA hierarchy, which has been described in Section 30.12 and which is shown in Figure 30.2(b). Another form is the object oriented system (OOS) hierarchy.

An inheritance hierarchy is a particular type of taxonomic hierarchy, which in addition to showing the classification shows also inheritance of attributes.

A discrimination net represents the process of discrimination between entities and attributes in order to identify an object. An object identification net is similar.

Also the term ‘decision tree’ is sometimes applied to this type of diagram.

Table 30.3 *Some graphs, trees and networks used in artificial intelligence*

Type	*Application*	*Nodes*[a]	*Reference*[b]
Taxonomic hierarchies	Classification	Entities	
All things hierarchy		Entities	Winston, p. 322
ISA hierarchy		Entities	C&M, p. 26
OOS hierarchy	Classification	OOS entities	Patterson, p. 155
Inheritance hierarchy	Inheritance	Entities	C&M, p. 406
Discrimination net, object identification net	Identification	Entities; entities, attributes; entities	C&M, p. 154 Patterson, p. 317
Parse tree	Grammar	Syntactic categories	Frost, p. 531
Syntax tree	Grammar	Syntactic categories	Frost, p. 527
Transition network	Grammar	Syntactic categories	C&M, p. 202
Augmented transition network	Grammar	Syntactic categories	
Associative network	Relationships	Entities, attributes	Patterson, p. 129
Semantic net	Relationships	Nouns, verbs, adjectives	Frost, p. 457
Semantic tree	Logical reasoning	Logical expression; truth values	Tanimoto, p. 234
Bayesian network	Bayesian inference	Evidence; inferences; conclusions	C&M, p. 478
Truth maintenance network, belief network	Truth maintenance systems	Premises, assumptions, facts; beliefs	Patterson, p. 85 Winston, p. 244
Constraint propagation network	Constraint propagation	Facts; beliefs	Winston, p. 243
Goal tree	Planning	Goals; subgoals; primitive actions	C&M, p. 277
AND/OR tree	Planning	Goals; subgoals; primitive actions	Winston, p. 39
Search tree	Search	Start; intermediate nodes; end	C&M, p. 265
Games tree	Games	Start; positions; end	C&M, p. 281
Time map	Action sequences	Actions	C&M, p. 432
Task network	Planning	Task; subtasks; primitive actions	C&M, p. 492
Frame network	Frames	Frames	Patterson, p. 138
Decision tree[c]	Decisions	Utility values	C&M, p. 521
Neural network	Neural networks	Model neurons	Patterson, p. 344

[a] where there is a single entry, all nodes are of this type; where there are two entries (separated by a semi-colon), the first refers to the top node and the second to the intermediate and bottom nodes; and where there are three entries, the first refers to the top node, the second to the intermediate nodes and the third to the bottom nodes.

[b] References are to: Charniak and McDermott (1985) (C&M); Frost (1986); Patterson (1990); Tanimoto (1990); Winston (1984).

[c] The term decision tree is commonly used in AI for a tree which represents decision-making in terms of decision theory, and this is the meaning here.

Diagrams used in the syntactical analysis of natural language include parse trees, syntax trees, transition networks and augmented transition networks (ATNs). A semantic net is used to represent the meaning of sentences.

The associative network is a widely used tool for representing relationships of various kinds, as shown in Figure 30.2(a).

A semantic tree shows the development of a logical expression in terms of its truth values. A Bayesian network gives the structure of the relationships between evidence, inferences and conclusions in Bayesian inference.

A truth maintenance system (TMS), or belief network, shows the structure of the TMS in terms of the current beliefs and the premises, assumptions and facts that support them. A constraint propagation network is somewhat similar.

A goal tree shows the expansion of a goal into its subgoals and ultimately to the primitive actions that are necessary to achieve it. Where AND/OR logic is involved, the diagram may also be referred to as an AND/OR tree. A goal tree is shown in Figure 30.5(a).

A game tree shows the development of a game from the start position, through the moves to the end position. A game tree is shown in Figure 30.5(b).

A search tree shows the process of search from the start through the nodes to a solution, if one is found. Search trees are considered in Section 30.13.

A time map shows a series of actions in time, as shown in Figure 30.5(c).

A task network shows the expansion of a task into its subtasks and ultimately to the primitive actions that are necessary to perform it. A task network is illustrated in Figure 30.5(d).

A frame tree shows a hierarchy of frames.

The term 'decision tree' is used to describe more than one type of diagram. In terms of decision theory it shows the structure of a decision in relation to the utility values. In other cases the term is applied to discrimination trees. Another, and common, form of decision tree is that used in human decision-making, as described in Chapter 14.

30.23 Directed Graphs

A graphical representation of some importance in engineering is the directed graph, or digraph. Digraphs have been widely used in process modelling. Accounts of directed graphs are given in *Graph Theory in Modern Engineering* (Henley and Williams, 1973), *Structural Models: An Introduction to the Theory of Directed Graphs* (Harary, Norman and Cartwright, 1975) and *Graph Theory* (Gould, 1988).

Directed graphs are also known as directed linear graphs, directed networks or signal flow graphs. A digraph consists of a set of vertices, or nodes, joined by branches, which are also termed links, arcs or edges.

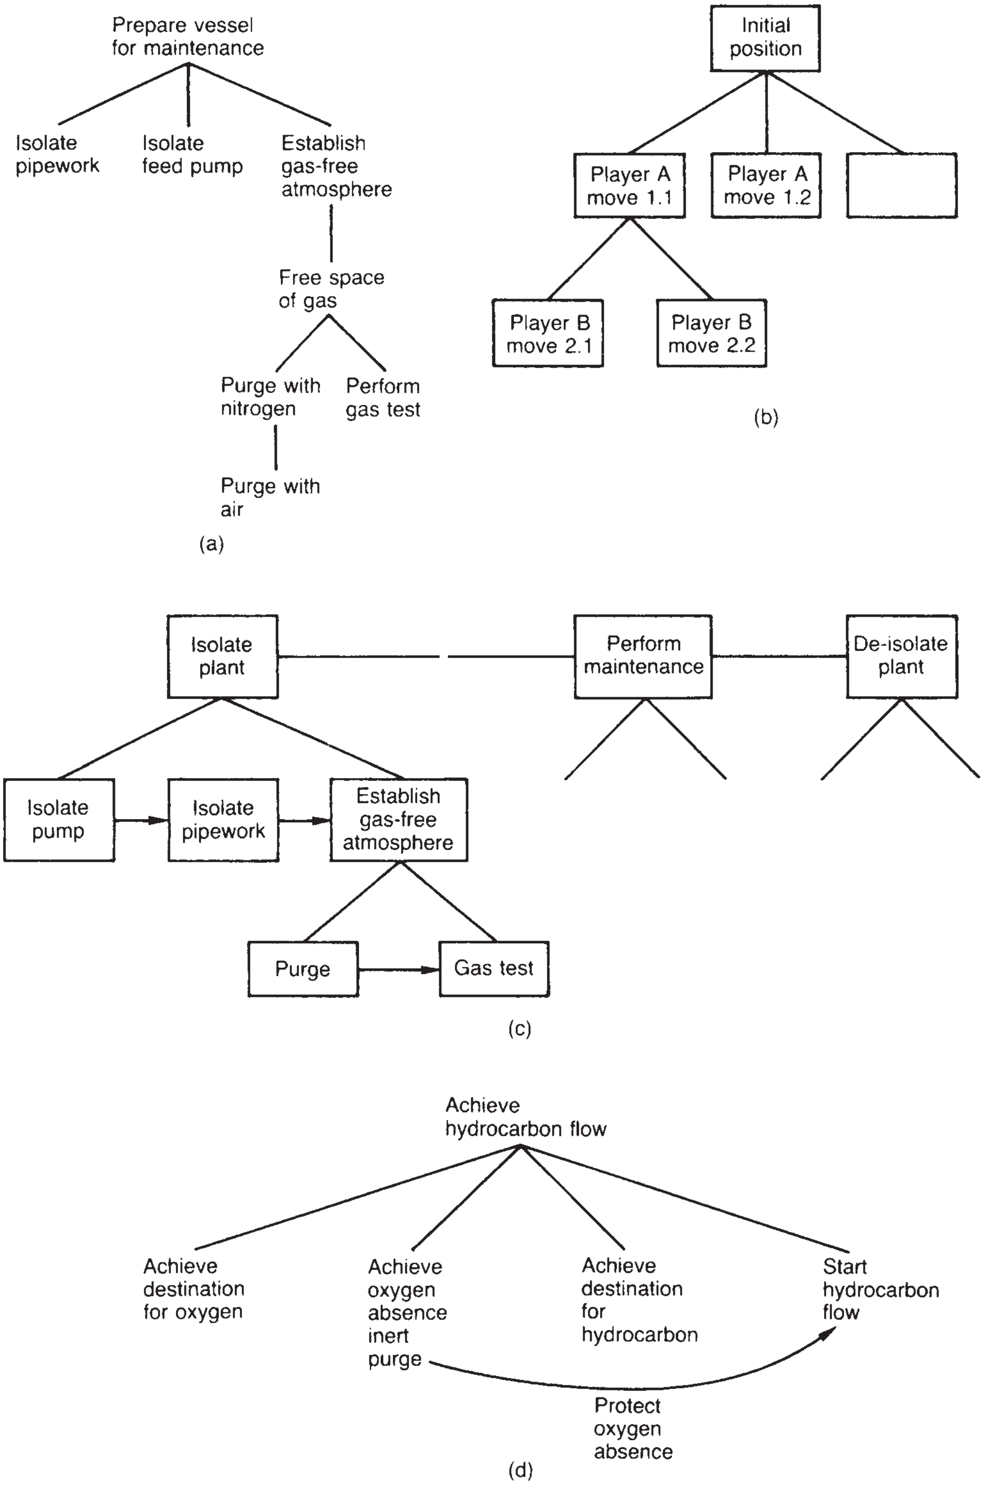

Figure 30.5 *Some graphs trees and networks used in artificial intelligence: (a) goal tree; (b) game tree; (c) time map; (d) task network. See Figure 30.2 for associative network and ISA forms*

A digraph is said to be connected if it has no pair of vertices that are not connected by branches. It is strongly connected, or strong, if for each vertex there exists a directed path from that vertex to another vertex. Otherwise it is said to be weakly connected, or weak.

A path is a set of at least two connected branches. A closed path is called a cycle, or loop. A digraph that contains no cycles, or loops, is referred to as an acyclic graph. A tree is an acyclic graph.

30.23.1 Flow graph algebra

Three principal rules of flow graph algebra are (1) the addition rule, (2) the transmission rule and (3) the product rule.

The addition rule states that the value of a variable represented by a vertex is the sum of all the transmittances entering the vertex. The transmission rule states that the value of a variable represented by a vertex is transmitted on every branch leaving the vertex. The product rule states that if a series connected graph has n vertices the $n-1$ branches can be replaced by a single branch whose transmittance function equals the product of the original branches.

The transmittance function, or operator modifying the value leaving one vertex and entering another, is generally a gain constant. Where differential equations are handled, however, it may also be an integration. For an independent variable such as time t this integration may be expressed as $\int dt$, or in the Laplace domain as $1/s$.

A signal flow graph (SFG) is used to represent a set of simultaneous linear algebraic equations or linear differential equations. A typical signal flow graph is shown in Figure 30.6.

These equations may also be cast in matrix form and manipulated in the usual way. Thus, SFG theory is a way of modelling system that is not only convenient but has a sound theoretical basis.

30.23.2 Flow graph reduction

There are a number of techniques for the reduction of SFGs. In addition to the product rule already mentioned, they include elimination of 'self-loops', various elementary transformations and Mason's rule. An account of these techniques is given by Henley and Williams (1973).

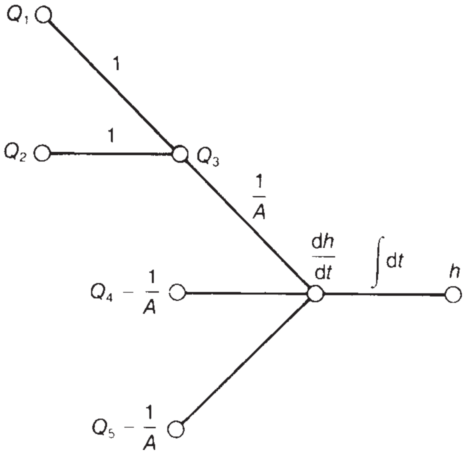

Figure 30.6 *A signal flow graph. Graph for* $Q_3 = Q_1 + Q_2$; $dh/dt = (1/A)(Q_3 - Q_4 - Q_5)$; $h = \int (dh/dt)dt$

30.23.3 Digraphs in process modelling

Extensive use has been made of digraphs in the modelling of process plants, particularly in the modelling of fault propagation. In such work the nodes represent process variables such as flow, pressure, and temperature, and the edges represent the effects of one variable on the other.

In qualitative modelling, using digraphs a convention commonly employed is to use a transmittance function of +1, 0 and −1 for a positive influence, zero influence and a negative influence, respectively. Some workers also use +10 and −10 to denote, respectively, strong positive and negative influences.

Generally, it is only certain variables which are of interest. In such cases use may be made of the techniques for the reduction of graphs mentioned earlier.

The use of digraphs in process modelling is discussed further in Section 30.36.

30.24 Expert Systems

One of the AI tools which has been most widely taken up with a view to industrial application is expert systems. Accounts of expert systems are given in *Building Expert Systems* (Hayes-Roth, Waterman and Lenat, 1983), *Build Your Own Expert System* (Naylor, 1983), *Expert Systems* (Alty and Coombs, 1984), *Expert Systems* (Forsyth, 1984b), *Expert Systems* (Harmon and King, 1985), Expert Systems (Sell, 1985), *Competent Expert Systems* (Keravnou and Johnson, 1986), *Expert Systems: Strategic Implications and Applications,* (Beerel, 1987), *Programmer's Reference Guide to Expert Systems* (Hu, 1987), *Knowledge Acquisition for Expert Systems* (Kidd, 1987), *Building Expert Systems: A Tutorial* (J. Martin and Oxman, 1988), *Artificial Intelligence and Expert Systems* (Savory, 1988), *Expert Knowledge and Explanation: The Knowledge-Language Interface* (Ellis, 1989), and *Expert Systems and Artificial Intelligence: An Information Manager's Guide* (Ford, 1991) and by Winston (1984), Charniak and McDermott (1985), Frost (1986), Patterson (1990) and Tanimoto (1990).

The vast majority of expert systems are rule-based production systems, though other methods can be used such as neural networks.

The description of actual expert systems is deferred to Section 30.25, but occasional reference is made in this section to certain major systems, notably MYCIN.

30.24.1 Project management and organization

The strategic aspects of expert systems are considered in *Expert Systems: Strategic Implications and Applications* (Beerel, 1987).

The management and organization of an expert system project depend very much on the nature and scale of the project. Most industrial applications are relatively modest. For a more substantial project, however, the management and organization may well determine the success.

The selection of an appropriate application is crucial. Some characteristics bearing on suitability are discussed in the next section. There are two essential conditions for undertaking the development of an expert system: that it be feasible and that, once created, it will be used.

The first condition requires that there be available at least one domain expert who can provide the necessary expertize. A decision has to be made whether sole reliance is to be placed on this expert or whether other experts are to be brought in. The function of the experts is not only to furnish expertise, but also to evaluate the system produced.

The second condition, that at the end of the day the system actually be used, implies the involvement of the potential users right from the start. One view is that it is a user who should be responsible for the project. Whether or not this is adopted, the principle of user involvement is not in doubt.

Knowledge acquisition in a project of any size is the responsibility of a knowledge engineer. The knowledge engineer is not a domain expert, but should be skilled both in knowledge acquisition and knowledge representation and in the building of expert systems.

The basic team for the creation of an expert system is thus the project manager, the expert, the knowledge engineer and the user.

30.24.2 Selection of applications

Experience with expert systems indicates that there are some types of problem for which an expert system is suitable and others for which it is not. For the latter, this does not necessarily mean that there is no suitable AI tool, only that an expert system is not that tool.

The most basic requirement is that there be an established domain expertise and an expert from whom the domain knowledge can be elicited.

Another equally basic requirement is that there should be a need for the system so that adequate resources can be made available for its development and so that once it has been developed it is used and maintained.

A distinction is sometimes made between common sense and mundane knowledge, to the effect that common sense involves various forms of reasoning and mundane knowledge various kinds of knowledge about the world. Common sense and mundane knowledge are strong points for humans but weak features of machine intelligence.

The characteristics of a problem which favour an expert system application are: that there is a defined domain of expertise; that the task to be performed is well focused and of moderate complexity; and that the knowledge can be represented in standard forms, particularly by facts and rules.

The task should be one performed by an expert and be of a level of complexity that it is neither trivial nor so involved that creation of an expert system becomes impractical. The time taken to perform such a task is typically between a few minutes and a few days.

In a given organization, the question of the selection of the first application of an expert system is of some importance. As with any other innovation, a bad first experience is likely to set the technology back for some years.

30.24.3 System development

The development of an expert system proceeds through the following typical stages: (1) system concept, (2) feasibility study, (3) outline specification, (4) preliminary knowledge acquisition, (5) knowledge representation, (6) tool selection, (7) prototype development, (8) main knowledge acquisition, (9) revised specification, (10) system development, (11) testing and evaluation and (12) handover. The process is an iterative one, with looping back between some of these stages.

Prototyping covers the creation of the prototype, the writing of the documentation, the induction of the user, and use and evaluation by the user.

The point has already been made that the user should be involved from the start. This involvement should cover not only the specification and evaluation of the final system, but also evaluation at intermediate stages.

An account of the development of a large expert system is given by J. Martin and Oxman (1988).

30.24.4 System architecture and facilities

A minimal architecture for an expert system is a knowledge base, an inference engine and a user interface.

The knowledge base contains the set of facts and rules that constitutes the expertise. A distinction is sometimes made between a database of facts and a knowledge base containing rules. The knowledge base itself is frequently spoken of in terms of a set of knowledge bases. The inference engine performs the process of inference from the facts and rules in the knowledge base. It is a basic principle of the architecture that the knowledge base and inference engine are separate.

The user interface has several functions. It is the means whereby the user supplies additional information to the system, either in response to demand or by volunteering it, and the means whereby he receives the output.

To these three basic features may be added a number of others. They include a blackboard, a knowledge acquisition facility, a learning facility and an explanation facility. A blackboard is a device for communicating with the knowledge bases and holding intermediate hypotheses and decisions. Only a proportion of systems incorporate a blackboard. A knowledge acquisition facility provides the means for the knowledge engineer to input knowledge elicited from the domain expert, allowing him to input and edit facts and rules, and so on. An inductive learning facility may also be provided. The user interface may contain an explanation facility.

30.24.5 Inference engine

The inference engine may incorporate any of a number of different inferencing, search and problem-solving methods. It may have forward or backward chaining, corresponding respectively to data- or goal-driven inference, or a mixture of both. It may use depth-first or breadth-first search, hill-climbing, means–ends analysis, generate-and-test, pattern-matching, and so on. Or it may use some hybrid scheme.

30.24.6 Blackboard

A blackboard is a device for holding a set of intermediate hypotheses and decisions, in other words partial solutions. It communicates with and draws knowledge from the set of knowledge bases in an opportunistic way. In some cases it can be regarded as being split into three parts: plan, agenda and solution. The plan part contains the goals, plans, states and contexts; the agenda the potential actions awaiting execution; and the solution the hypotheses and decisions. The blackboard can be altered only by the knowledge bases. Such forms of control as the blackboard has act to focus attention on a problem and the knowledge bases then indicate what contribution they can make.

30.24.7 Knowledge acquisition facility

It is helpful to the creation of an expert system if there is a knowledge acquisition facility (KAF) that provides for the editing of facts and rules and for their entry into the knowledge base.

There may also be provided a facility for inductive learning. This may be regarded as part of the knowledge acquisition facility or as a separate feature. In any event, the purpose of this facility is to allow knowledge to be entered in the form of a learning set of examples provided by the expert and rules to be induced from these examples. This is an alternative to the provision of explicit rules by the expert.

30.24.8 Explanation facility

Most expert systems are provided with an explanation facility which can provide some form of justification for the conclusion reached, but the sophistication of such facilities varies. Accounts of explanation facilities are given in *Expert Knowledge and Explanation* (Ellis, 1989) and by Sell (1985) and J. Martin and Oxman (1988).

There are two main types of user for an explanation facility, the knowledge engineer and the client user. There are several types of explanation that a user requires. One is elaboration of the questions that he is asked in order to assist him to answer them correctly. Another is justification for these questions in order to motivate him to provide answers to them. The third is an explanation of the reasoning process.

One of the simplest forms of explanation facility is rule-tracing. The system keeps track of the path by which it has reached the current point and can display this to the user on demand. A rule trace is relatively easy for the system to provide. A detailed example is given by Ellis (1989).

However, an explanation facility that utilizes a simple rule trace is somewhat crude. It is preferable that the line of reasoning be explained rather in terms of the principles that govern the domain, using domain knowledge in a structured way.

Considering the explanation facilities in actual expert systems that used in MYCIN is effectively a rule trace. NEOMYCIN by W.J. Clancey and Letsinger (1981) utilizes a number of domain-specific meta-rules which control the problem-solving and is thus able to provide a more domain-related explanation.

The program XPLAIN by Swartout (1983) utilizes both a domain model, which is descriptive, and domain principles, which are prescriptive, and is able to provide an explanation that justifies rather than simply records the program behaviour.

In most cases the output of an explanation facility is confined to text. STEAMER by Hollan, Hutchings and Weitzman (1984), on the other hand, which deals with operations on a steam plant, provides both graphical and textual output.

Generally, an expert system is used by a quite small number of people. There tend to be considerable differences in individual preferences for output from an explanation facility. One way of accommodating this is to provide options which individual users can select.

In more advanced work on this topic, user models are utilized to improve the design of the explanation facility.

30.24.9 Building tools

There are available a number of tools for building expert systems. They include programming languages, expert system shells and expert system building environments. Accounts of building tools for expert systems are given in Hayes-Roth, Waterman and Lenat (1983) and J. Martin and Oxman (1988). Lists of some principal tools are given by Frost (1986) and Hu (1987).

The languages traditionally used for building expert systems are LISP and Prolog. Insofar as the early and classic systems were built in the United States where LISP was the favoured language, LISP has been predominant. Prolog implements logic programming. For object-oriented programming use may be made of SMALLTALK. Of the general purpose languages, C++ is particularly compatible.

An expert system shell is strictly a tool created from an existing expert system by removing the features which are specific to the original problem, whilst retaining the general structure and in particular the inference method. A tool of the same general type may be created from scratch, and is sometimes also referred to as a shell.

Shells are widely used and can be especially useful for prototyping. The weakness of shells is that problems vary in nature and a shell capable of dealing with a wide range of problems needs to be rather sophisticated. Thus, some applications require data-driven search, others require goal-driven search and others again require a mix. Some applications involve uncertainty, whilst others do not. Some applications may have large quantities of data but few rules, and others the converse. Lists of the principal shells are given by Frost (1986) and Hu (1987).

There are in addition a number of so-called ‘environments’ for the building of expert systems. These differ from shells in that they are more flexible. The concept of an expert system building environment is that it offers a wide range of features, particularly for the knowledge representation and the inference engine. Environments include KAS, OPS5 and AGE, described in the next section.

There are also numerous tools for particular individual features of expert systems. They include tools for building knowledge bases, knowledge acquisition facilities, learning facilities, the user interface, explanation facilities, and so on. There are knowledge base management systems, which fulfil functions somewhat similar to those of database management systems.

30.24.10 Knowledge elicitation and acquisition

Crucial activities in building an expert system are knowledge elicitation and knowledge acquisition. The two terms are often used almost interchangeably, but whereas in knowledge elicitation the emphasis is on eliciting the domain knowledge from the expert, in knowledge acquisition it is on providing the program with this knowledge. Accounts are given in *Knowledge Acquisition for Expert Systems* (Kidd, 1987) and *Knowledge Elicitation* (Diaper, 1989) and by Beerel (1987) and J. Martin and Oxman (1988).

The expertise of the domain expert has a number of facets. Typically, he or she has a wide experience and knowledge of case histories, problems and solutions, both successful and failed. This background provides him with an understanding of the structure of the domain, of the crucial distinctions which have to be made, of the constraints which apply, of the problems to be solved, of the decompositions which can be made, of problem-solving and search strategies, of heuristics and rules-of-thumb, of facts and rules, and of exceptions and refinements.

The task of knowledge elicitation is generally undertaken by the knowledge engineer. His or her task is to acquire and represent the domain knowledge and to engineer the system so that it is easy for the user to utilize. The most common method of knowledge elicitation is interviewing of the expert by the knowledge engineer. The aim is to make explicit the expertise. There is a large literature on interviewing, especially in the social sciences. Another approach is close observation of the expert as he performs the task. Typically this utilizes some form of verbal protocol in which the expert explains what he is doing and why he is doing it. A third approach is for the expert to provide sets of problems and solutions and for the knowledge engineer to induce from these the internal rules which the expert is evidently using to obtain the solutions. A fourth method is prototyping, in which the expert and knowledge engineer cooperate to build a system. The expert furnishes knowledge for, and provides tests of, the system, while the knowledge engineer tries to create a suitable system structure.

The interaction between the knowledge engineer and the expert is not limited to debriefing the expert. They need also to work together to design the user interface. Decisions are required on the questions that he or she is to be asked and on the explanations that are to be provided for him or her.

The process of knowledge elicitation is generally incremental and iterative. The expert is unlikely to be able to make explicit his or her expertise in a particular area in a single pass, and the process of elicitation is likely to prompt him or her to make additions and refinements, or even to undertake a more fundamental restructuring.

The main domain expert is not the sole source of knowledge available to the knowledge engineer. He or she may also utilize the literature and databases, historical records, case histories and case studies, and interviews with other engineers. It should be borne in mind, however, that whereas the expertise of the single expert can reasonably be presumed to be coherent, an eclectic approach that draws on a wide range of sources is more likely to involve both inconsistencies and contradictions and out-of-date methods.

In some cases, an expert system is created by the domain expert himself or herself. In particular, it has become quite common for systems to be created utilizing an induction tool that is provided by the expert with a learning set of examples and solutions.

30.24.11 System evaluation

It is clearly necessary that at some stage an expert system should be evaluated, but such evaluation raises a number of issues that need to be addressed if it is to be done satisfactorily. The evaluation and validation of expert systems are discussed by Hayes-Roth, Waterman and Lenat (1983), Sell (1985), Beerel (1987) and Ellis (1989).

It is not self-evident that there is need for an evaluation of the system other than the ultimate test of successful use. In fact, however, there are benefits to be gained from evaluation prior to entry into service, both in terms of the quality of the system finally produced and of the learning process of the organization that is building the system.

Some issues that arise in the evaluation of an expert system are the criteria, the assessors, the timing, the methods and the overall evaluation process. An expert system generally captures the expertise of a single expert. A question therefore arises as to whether the system is to be judged by its success in reproducing that expertise or in solving problems. The distinction is a fundamental one. Another basic question to be decided is who is to perform the evaluation. The assessment may, in principle, be performed by the expert, the knowledge engineer and/or the client users. The timing of the evaluation is another issue, the options being to carry out interim assessments throughout the building of the system or to defer evaluation until it is complete. The methods used for the evaluation may be informal or formal ones.

Evaluation criteria that are based on the requirement that the system reproduce the expertise of the domain expert centre essentially on the ability of the system to provide high quality advice based on correct and acceptable reasoning. More specifically, criteria for the quality of the advice may relate to the following features: (1) consistency, (2) completeness, (3) soundness, (4) precision and (5) usability. Consistency means that the system should give similar answers to similar questions. A small change should not induce totally different behaviour. Completeness implies that the coverage of the domain is comprehensive. The requirement for soundness is that the statements made are true. The precision requirement applies only where there are quantitative outputs, and has the usual meaning. Usability means here that the user interface should operate as intended, a requirement distinct from user-friendliness. The evaluation should address not only the quality of the conclusions but also the quality of the reasoning by which they are arrived at. This is not just a matter of correct inference, but has to do also with the extent to which particular conclusions are supported by an overall structure.

Criteria are also required to evaluate the discourse with the user. In large part these will centre round the questioning of the user and the provision of explanation to the user, which were discussed above.

An expert system is built with particular categories of user in mind, and ultimately it is they who must be satisfied. This does not necessarily mean that evaluation should be carried out solely by these users. Generally it will be appropriate for the knowledge engineer, the expert and the users all to be involved. The knowledge engineer is able to evaluate the program technically as an expert system, including here the user interface, whilst the expert can assess it in terms of the expert advice which is provided and the user in terms of the ease of use and value of the advice.

With regard to timing, it is preferable to conduct the evaluation as the building of the system progresses rather than to defer it to the end. User evaluation and feedback as the system is being created is a recurring theme in discussions of system evaluation.

The evaluation may be informal and qualitative or it may use formal and possibly quantitative methods. Some formal methods are described in Hayes-Roth, Waterman and Lenat (1983). Whatever other methods are used, two that are unavoidable are testing by the expert and use by the users. These tests may be informal but they should address the task that the system has been designed to perform and the criteria which have been agreed for its evaluation.

Evaluation of an expert system is not a straightforward matter. Sources of difficulty are: the potential confusion between defects in the system and in the expertise which it embodies; a lack of understanding by users of the scope and limitations of the system and unrealistic expectations for its performance; importation by users of extraneous criteria; disagreement about the relative importance of criteria; and deficiencies of the system whilst it is still only partially developed.

Accounts of case studies of the evaluation of expert systems are given in Hayes-Roth, Waterman and Lenat (1983). They describe assessment of the Rl system for computer system configuration and of the ORNL spill crisis management system, and the lessons learned about evaluation. Foremost among these lessons are the need to involve users early and fully. At the end of the day the ultimate test is whether the system is used, and, if so, whether it has proved cost-effective.

30.25 Expert Systems: Some Systems and Tools

30.25.1 DENDRAL

DENDRAL is an expert system that discovers molecular structures. Work on DENDRAL dates from 1965 and its creation was a landmark in AI. It is described by E.G. Buchanan, Sutherland and Feigenbaum (1969, 1970), B.C. Buchanan *et al.* (1976), B.C. Buchanan and Feigenbaum (1978) and Lindsay *et al.* (1980) and also by Hayes-Roth, Waterman and Lenat (1983), Winston (1984) and Patterson (1990).

The program determines the molecular structure of a substance from information on the constituent elements, or chemical formula, and the mass spectrograph. It has a structure enumerator, which synthesizes candidate chemical structures subject to constraints, derived largely from the mass spectrograph data, that certain structures must be present (the necessary list) and that certain structures must not (the forbidden list). For each candidate structure it synthesizes a mass spectrograph. It matches the synthesized spectrographs of the candidate structures to the experimental ones and selects the structure that gives the best fit.

The system is thus a problem-solving program which uses a generate-and-test strategy. The generation part involves a search that is partly guided by heuristic rules. It also contains other rule-based systems, one of which is a set of rules for structures in the forbidden list that supplement the mass spectrograph information. The test part is the spectrograph matching process.

The use of DENDRAL showed up some of the problems of knowledge elicitation. This led to the development of META-DENDRAL, which induces rules from examples (E.G. Buchanan and Feigenbaum, 1978).

30.25.2 MYCIN

MYCIN is an expert system for the diagnosis of infectious blood diseases. It is described in *Computer-Based Medical Consultation: MYCIN* (Shortliffe, 1976) and Rule-Based Expert Systems (E.G. Buchanan and Shortliffe, 1984) and also by Hayes-Roth, Waterman and Lenat (1983), Winston (1984), Charniak and McDermott (1985) and Patterson (1990).

The program is a rule-based production system. Initially it had some 200 rules that by the early 1980s had risen to about 600. A feature of the rules is the use of certainty theory. Each rule is assigned a certainty factor that is propagated through to yield a certainty for the result for each hypothesis. Search in MYCIN is a slightly modified form of depth-first search with backward chaining. The current hypothesis constitutes the goal of an AND/OR tree. MYCIN has an interactive facility. Backward chaining has the advantage over forward chaining that it is more compatible with user interaction. A search that proceeds by a process of elimination tends to generate a large number of questions, which is liable to irritate the user, and the interaction is modified so that the user is asked a smaller number of direct questions, the answers to which then guide the search.

Associated with MYCIN is TEIRESIAS, which was developed as a front end to aid knowledge acquisition. MYCIN has also given rise to EMYCIN, an expert system shell based on MYCIN.

30.25.3 CASNET

CASNET is an expert system for the diagnosis and treatment of glaucoma, and is a research program. It is described by Weiss, Kulikowski and co-workers (Weiss, Kulikowski and Safir, 1977, 1978; Weiss *et al.,* 1978; Weiss and Kulikowski, 1981, 1983; Kulikowski and Weiss, 1982) and also by Hayes-Roth, Waterman and Lenat (1983) and Patterson (1990).

The program carries out diagnosis using three levels of knowledge: patient observations, pathological state and disease. Its general structure is shown in Figure 30.7.

The use of the intermediate level of pathological state is a key feature of the approach taken in CASNET. CASNET utilizes an associative network or semantic net. Inference is effected by traversing the network in a search for the most plausible paths of cause and effect. The program also utilizes production rules.

30.25.4 PROSPECTOR

PROSPECTOR is an expert system that gives advice on mineral deposits. It is described by Duda *et al.* (1978), Hart, Duda and Einaudy (1978), Duda, Gaschnig and Hart (1979) and A. Campbell *et al.* (1982) and also by Hayes-Roth, Waterman and Lenat (1983), Charniak and McDermott (1985) and Tanimoto (1990).

The program utilizes geological field data to advise on the likely locations of deposits of a particular mineral. Like CASNET, it makes use of an intermediate level of knowledge, and is one of the best examples of an expert system based on this feature. It contains ‘models’ of situations in which deposits of particular ores tend to occur.

PROSPECTOR is a rule-based production system. Explicit use is made of Bayesian inference, as shown in Figure 30.8. Where use is made of such Bayesian probabilities, it is necessary that the prior probabilities be consistent. Methods of approach to this problem are discussed by Tanimoto (1990).

The user has a facility to interact with PROSPECTOR. This includes the option to volunteer information.

30.25.5 CADUCEUS

CADUCEUS, originally called INTERNIST, is an expert system for the diagnosis of diseases of the internal organs, and is a research program. It is described by R.A. Miller, Pople and Myers (1982), Pople (1982) and also by Hayes-Roth, Waterman and Lenat (1983) and Charniak and McDermott (1985).

The authors of the program claim that it covers some two-thirds of the diseases of the internal organs. It deals with about 500 diseases in terms of some 3500 conditions. In addition to its wide coverage, another of its strengths is its ability to handle multiple diseases. The information used in the program includes not only symptoms but also medical history and laboratory test results. A feature of the search strategy used in CADUCEUS is that it involves a large bottom-up element.

Work on the development of CADUCEUS aims to make the program act more like a physician by making an initial global assessment, decomposing the problem and partitioning the symptoms among the separate subproblems.

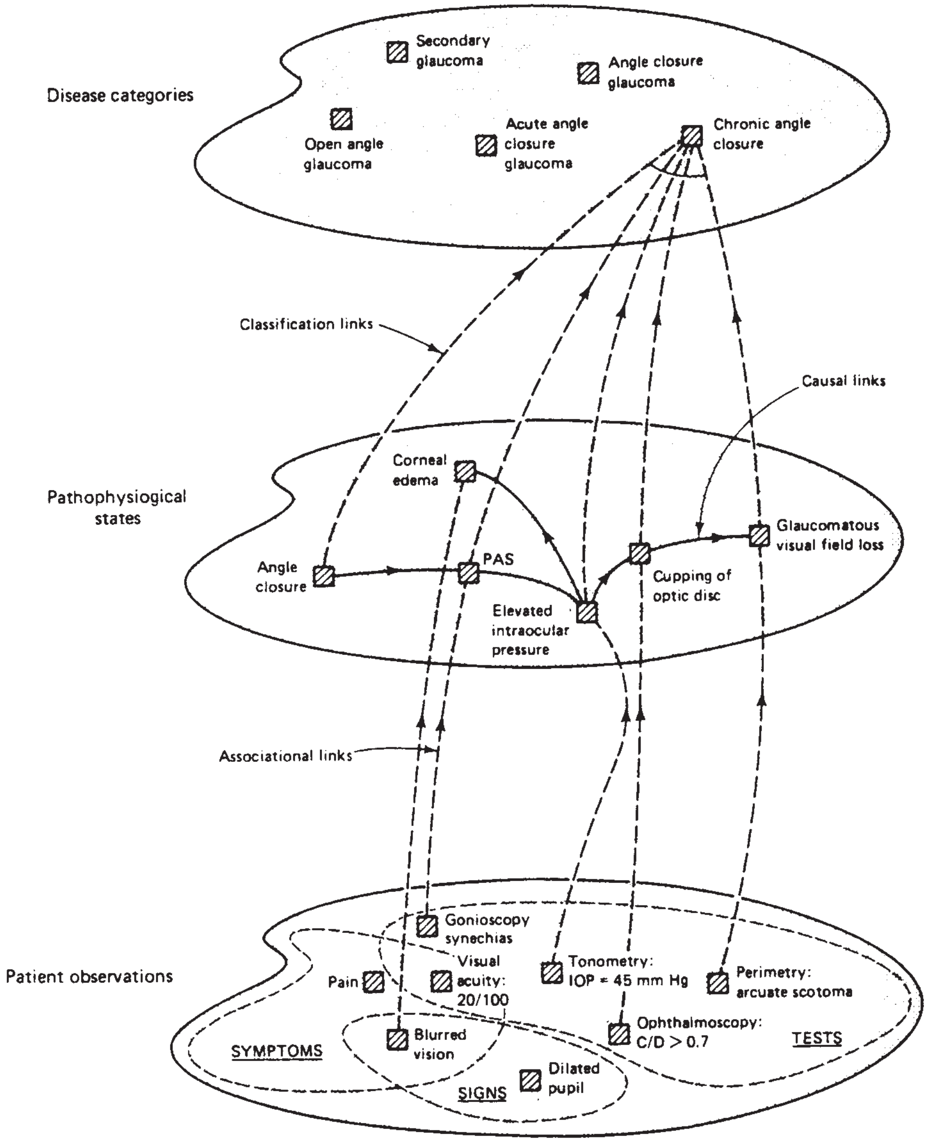

***Figure 30.7** Levels of knowledge in CASNET (Weiss et al., 1978) (Courtesy of North Holland Publishing Company)*

30.25.6 R1/XCON

XCON, originally called Rl, is an expert system for the configuration of VAX computer systems, and is in industrial use. It is described by McDermott (1980, 1981, 1982a), and also by Hayes-Roth, Waterman and Lenat (1983), Winston (1984), Charniak and McDermott (1985) and Tanimoto (1990).

The program accepts an order for a computer system and performs the following aspects of system configuration: (1) check the order for missing and mismatched items, (2) create the layout of the processor in cabinets, (3) put boxes in the input/output cabinets and place components in these boxes, (4) put panels in the input/output cabinets, (5) create the floor plan layout and (6) do the cabling. XCON is thus a problem-solving program. It is based on production rules.

The number of rules in XCON is large. In 1979 the program had about 800 rules, by 1983 about 3000 and by 1990 some 12,000. The large number of rules requires an efficient search strategy. Search in XCON is by forward chaining. This search involves minimal backup. The rules apparently incorporate sufficient constraint that the search rarely goes up a blind alley. The method of inference in XCON is deductive. This distinguishes it from the diagnostic programs, where inference is by abduction. The program illustrates the fact that an expert system can be useful even

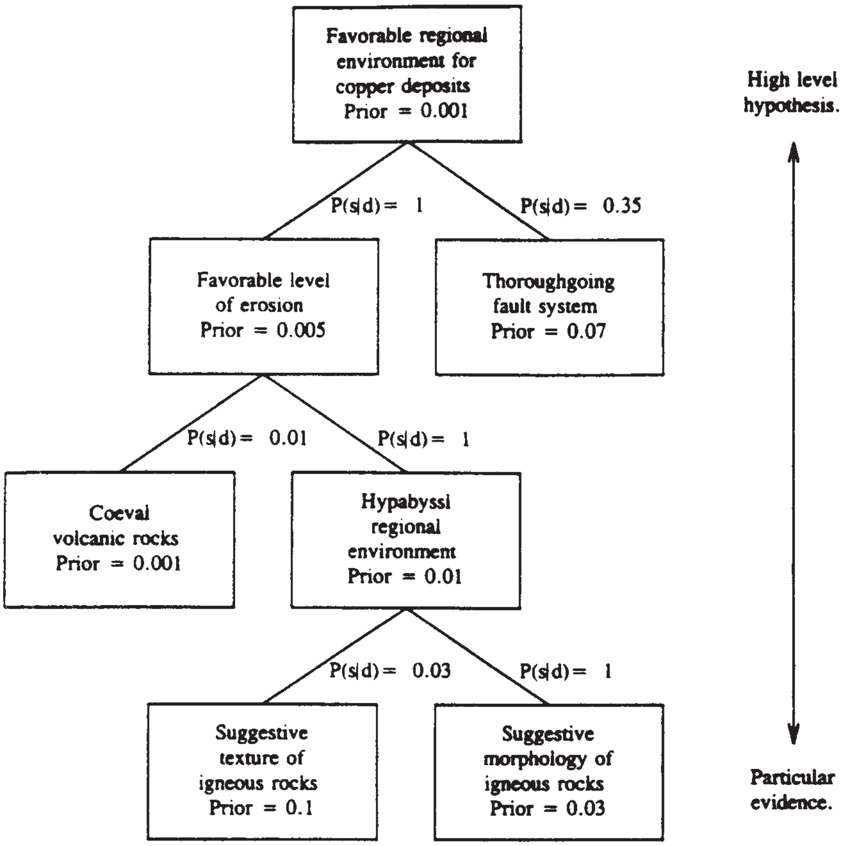

Figure 30.8 *Bayesian inference in PROSPECTOR (Charniak and McDermott, 1985) (Courtesy of Addision-Wesley Publishers)*

if it is at a relatively early stage in its overall development. It was already in use in 1979.

XCON is of particular interest here for two reasons. It is the only one of the classic systems described that deals with design, and it is a system that has been in industrial use for well over a decade.

30.25.7 BAGGER

In addition to the classic expert systems just described, there are certain others that are also instructive. One of these is BAGGER, an expert system for bagging groceries in a supermarket, which is described by Winston (1984). Although essentially a toy system, BAGGER constitutes a useful introduction to an expert system based on production rules, including features such as conflict resolution.

30.25.8 EMYCIN

An early shell was EMYCIN (Empty MYCIN) (van Melle, 1979, 1980, 1981; van Melle, Shortliffe and Buchanan, 1981). It is a domain-independent system for the creation of expert systems for diagnosis or consultation. It retains the basic rule structure, inference engine and explanation facility of MYCIN. A further account is given in Hayes-Roth, Waterman and Lenat (1983).

30.25.9 Other shells

Other shells frequently mentioned are ESP ADVISER and SAVOIR. Some systems are variously referred to as shells or building tools.

30.25.10 ART

ART (Automated Reasoning Tool) was one of the first building tools. It is intended for use in building large systems and integrates a number of problem-solving techniques. ART is written in CommonLISP. An account is given by J. Martin and Oxman (1988).

30.25.11 AGE

Another early building tool was AGE (Nil and Aiello, 1979). AGE contains two types of entity: components and frameworks. A component is a routine that supports a basic AI mechanism and a framework a fixed configuration of components. A back-chaining framework and a blackboard framework are the two original frameworks. AGE is described by Hayes-Roth, Waterman and Lenat (1983).

30.25.12 KAS

KAS (Knowledge Acquisition System) (Duda, Gaschnig and Hart, 1979) is a knowledge acquisition system derived from PROSPECTOR. It places more emphasis than EMYCIN on information volunteered by the user, trying to avoid a large number of low pay-off questions and utilizing a mix of forward and backward chaining. Hayes-Roth, Waterman and Lenat (1983) give a further account.

30.25.13 OPS5

OPS5 (Official Production System 5) (Forgy, 1981) is one of the OPS family of building tools. It was developed as an aid in the building of Rl/XCON. It may be described as a rule-based programming language and is used to build rule-based production systems that use, primarily, forward chaining. It incorporates the RETE algorithm. Accounts are given in Hayes-Roth, Waterman and Lenat (1983) and by Patterson (1990).

30.25.14 KEE

KEE (Knowledge Engineering Environment) is variously described as an expert system shell or building tool. It has production rule, frame and object oriented system facilities. Inference is by inheritance and by forward and backward chaining. Accounts are given by Frost (1986) and Patterson (1990).

30.25.15 KES

Another system building tool is KES, which has production rule and frame facilities. An account is given by Frost (1986).

30.25.16 EXPERT

EXPERT (Weiss and Kulikowski, 1979, 1981) is a building tool for diagnosis- or classification-type consultation systems. An account is given in Hayes-Roth, Waterman and Lenat (1983).

30.25.17 EXPERTEASE and EXTRAN

EXTRAN, and the earlier EXPERTEASE, are classification tools based on the IDS algorithm for inductive learning.

30.26 Qualitative Modelling

In engineering, the conventional method of modelling a physical situation to create a mathematical model consisting of algebraic and differential equations based on classical physics. In recent years, there has been growing interest in an alternative approach that goes by the names of naive physics, and of qualitative modelling, qualitative physics or qualitative simulation.

Accounts of naive physics and qualitative modelling are given in *Mental Models* (Centner and Stevens, 1983), *Qualitative Reasoning about Physical Systems* (Bobrow, 1985), *Formal Theories of the Commonsense World* (Hobbs and Moore, 1985), *Readings in Qualitative Reasoning about Physical Systems* (Weld and de Kleer, 1990) and *Recent Advances in Qualitative Physics* (Faltings and Struss, 1991) and by Forbus (1984), de Kleer and Brown (1984), Kuipers (1984), Hardt (1992) and de Kleer (1992).

30.26.1 Naive physics

Classical physics is based on qualitative concepts that are then translated into quantitative mathematical models. Naive physics utilizes the same concepts but derives from them qualitative models. Work on naive physics has been described by Hayes (1979, 1985) and Hardt (1992). The work on qualitative modelling by de Kleer and Brown (1984), Forbus (1984) and Kuipers (1984) also comes under this head.

In naive physics the physical situation is modelled formally but qualitatively. The modelling remains symbolic and the variables take a limited number of discrete states. Naive physics retains all the basic concepts of classical physics such as state, equilibrium, conservation of mass, momentum and energy, and so on, but treats them in a qualitative way. It follows the same sequence of model formulation, solution and interpretation of the results.

One way of looking at naive physics is that it is a formal encoding of common sense reasoning about physical situations. In many cases, particularly in mundane situations, it can be quite difficult to formulate a quantitative mathematical model, but it is feasible to derive a qualitative model. In its own terms the qualitative model can be made as rigorous as the quantitative one.

A naive physics model can also be viewed from the opposite perspective as a reduction of a quantitative model to its essential qualitative form. In some work on naive physics models have been derived both by encoding of natural language statements and by reduction of the equations of a conventional mathematical model to qualitative model format.

The formalization of common sense reasoning about physical situations in a naive physics model is not easy. Common sense draws on large quantities of knowledge about the physical world and the forms of knowledge representation involved are often specialized. The approach advocated by Hayes (1979) in his 'naive physics manifesto' is the use of predicate calculus. In fact, the three main developments in qualitative modelling have not adopted this approach. These developments are component-based modelling, constraint-based modelling and process-based modelling.

30.26.2 Fault propagation

As it happens, some of the early work on qualitative modelling was in the process field. Qualitative models were used by Andow and Lees (Andow, 1973; Andow and Lees, 1975) to model fault propagation in process plants. The purpose of the work was to determine the interaction between process variables with a view to creating alarm trees for alarm diagnosis by process computer.

The basic principle may be illustrated by considering the differential equation for the change in level in an open tank with water flowing in and out:

$$\frac{\mathrm{d}L}{\mathrm{d}t} = Q_1 - Q_2 \qquad [30.26.1]$$

where L is the level, Q is the flow and t is time, and subscripts 1 and 2 denote the inlet and outlet, respectively.

In the work of Andow and Lees the equations of the corresponding qualitative model were obtained from those of a conventional mathematical model. Thus, the qualitative model equation equivalent to Equation 30.26.1 is

$$L = (+Q_1, -Q_2) \qquad [30.26.2]$$

that signifies that L increases if Q_1 increases or Q_2 decreases, or vice versa. It may be noted that Equation 30.26.2 may also be obtained by encoding an engineer's natural language statement that 'The level increases if the flow in increases or the flow out decreases, and vice versa'. It constitutes, in effect, a half-way house between a description in natural language and that of a quantitative model.

Work on fault propagation is described in Section 30.36.

30.26.3 Qualitative modelling

As stated above, qualitative modelling has developed in three main directions. These are: component-based, or device-based, modelling, as in the work of de Kleer and Brown (de Kleer, 1975, 1985; J.S. Brown and de Kleer, 1981; de Kleer and Brown, 1983, 1984, 1986); process-based modelling, as in the work of Forbus (1983, 1984, 1990); and constraint-based modelling, as in the work of Kuipers (1984, 1986). Of these three methods, component-based modelling appears the most suitable for the qualitative modelling of process plant and it is therefore this which is primarily considered here, but a brief account of the other two methods is appropriate.

30.26.4 Process-based modelling

In the process-based modelling of Forbus (1984), the physical situation is described in terms of the physical process which over time cause changes to occur. The physical processes are those such as flowing, heating, cooling, boiling and so on.

30.26.5 Constraint-based modelling

In the constraint-based modelling of Kuipers (1984, 1986), the physical situation is described in terms of the variables and the constraints relating these variables. Three principal types of constraint are used. These are:

Arithmetic: $X = Y + Z$
Functional: $Y = M^{+}(X)$
Derivative: $Y = \mathrm{d}X/\mathrm{d}t$

The arithmetic constraint requires that the values of the variables have the indicated relationship at all times; the functional constraint requires that Y is a strictly increasing function of X (or, for M^{-}, a decreasing function); and the derivative constraint requires that Y is the rate of change of X. Thus, the constraints consist of a qualitative adder, a qualitative proportionality and a qualitative differential.

30.26.6 Component-based modelling

The component-based modelling approach of de Kleer and Brown (Q.S. Brown and de Kleer, 1981; de Kleer, 1984, 1992; de Kleer and Brown, 1984) involves decomposing the system into separate, context-independent entities which are then modelled. These entities are materials, components and conduits. Examples of materials are fluids or current; examples of conduits are pipes or wires.

A component-based approach is well suited to the modelling of systems with a fixed topology such as items in a process plant. The approach is essentially reductionist. An overview of component-based modelling has been given by de Kleer (1992) and the account here draws on this.

30.26.7 Composability

It is a basic principle of qualitative modelling that the model of a component should be independent of the context. This is the 'no-function-in-structure' principle. De Kleer illustrates this principle with the example of an electric light switch. A model of the switch that makes the unqualified statement 'If the switch is off, no current flows; and if the switch is on, current flows' violates the principle. Situations can be envisaged, such as that where there is another switch in series, where it might not be true. The correct formulation is that current flows if the switch is on and there is potential for current flow.

30.26.8 Quantity spaces and landmarks

In the notation for qualitative modelling used by de Kleer a qualitative value of x is denoted by $[x]$. The qualitative value of x is defined in relation to some reference, or landmark, value. A basic quantity space is the $+$, $-$, 0 value space. This means that $[x] = +$ if $x > 0$; $[x] = -$ if $x < 0$ and $[x] = 0$ if $x = 0$.

The landmark value may be taken not as zero but as some other value, say a. In this case the origin is shifted by defining some new variable, say y, as $y = x - a$.

Basic issues in qualitative modelling are the choice of the quantity space and of the landmarks.

30.26.9 Qualitative equations and arithmetic

Basic arithmetic operations in qualitative modelling are addition

$$[z] = [x] + [y] \qquad [30.26.3]$$

and multiplication

$$[z] = [xy] = [x][y] \qquad [30.26.4]$$

In these relations, the qualitative value of $[z]$ is fully defined for multiplication, but for addition it is indeterminate. The relationships for addition and multiplication in qualitative arithmetic are shown in Table 30.4.

For derivatives, the notation

$$\left[\frac{\mathrm{d}x}{\mathrm{d}t}\right] = +$$

signifies that x is increasing. An alternative notation for $[\mathrm{d}x/\mathrm{d}t]$ is Mx.

It is not permissible to manipulate qualitative equations according to the same rules as conventional ones. In particular, an operation such as the subtraction of $[y] + [z]$ from $[x] + [y] + [z] = 0$ does not necessarily yield $[x] = 0$.

Table 30.4 *Some relationships of qualitative arithmetic*

A Addition $[x] + [y]$

$[y]$		$[x]$	
	$-$	0	$+$
$-$	$-$	$-$	?
0	$-$	0	$+$
$+$	?	$+$	$+$

B Multiplication $[x]$ $[y]$

$[y]$		$[x]$	
	$-$	0	$+$
—			
$-$	$+$	0	$-$
0	0	0	0
$+$	$-$	0	$+$

In the qualitative modelling method of de Kleer, an expression in terms of qualitative values, operators and variables is referred to as a confluence. A typical confluence used by this author is

$$\partial P + [P]\partial A - \partial Q = 0 \qquad [30.26.5]$$

where A is the area of an open control valve, P is the pressure drop across the valve and Q is the flow through it.

A set of qualitative values satisfies a confluence either if the qualitative equality strictly holds in accordance with the relations given in Table 30.4 or if one side of the confluence remains indeterminate because the addition operation is not closed. A set of values contradicts a confluence if both sides evaluate to a distinct qualitative value and the confluence is not satisfied. These statements imply that a confluence may be neither satisfied nor contradicted if some of the variables do not have assigned values.

Confluences are not used in the qualitative modelling work of Forbus or Kuipers.

30.26.10 Qualitative models

A component may have a number of states, each associated with a particular regime. A model of a component for the full set of regimes is termed a state specification.

Such a model may be illustrated by the valve model given by de Kleer (1992). This is

$$[A = A_{\max}]; \quad [P] = 0; \quad \partial P = 0 \quad \text{Valve open}$$
$$[0 < A < A_{\max}]; \quad [P] = [Q] \quad \text{Valve working}$$
$$\partial P = [P]\partial A - \partial Q = 0$$
$$[A = 0]; \quad [Q] = 0; \quad \partial Q = 0 \quad \text{Valve closed}$$

where the subscript max denotes the maximum.

An account has been given by de Kleer of the treatment of flow-like and pressure-like variables in component modelling. For flow it is assumed that the fluid is incompressible and the conduit runs full, and the principle of conservation of mass is applied. This rule is termed the continuity condition. For pressure it is assumed that the sum of the pressure drops in the conduit is constant. This rule is the compatibility condition.

30.26.11 Time effects

Qualitative modelling is concerned with changes, and changes take place over time. The modelling must therefore take time into account in some way. It is not unusual in qualitative modelling work for the time aspect to be somewhat fuzzy. This is commonly so in fault tree studies, as already described.

There are three main methods which have been used for modelling change over time: the use of a sequence of intervals (Forbus, 1984); the use of intervals separated by a number of instants (de Kleer and Brown, 1984); and the use of intervals separated by single instants (Kuipers, 1984).

Rules necessary for reasoning about change over time have been derived by B.C. Williams (1984a,b) and are described by de Kleer (1992).

30.26.12 Dependence and causality

De Kleer draws a distinction between dependence and causality. It does not follow that because one variable is dependent on another, it is necessarily caused by it. For causality to apply, stricter criteria must be met. Two such criteria are locality and temporal order. Locality requires that for one variable to be a cause of another, the two variables must describe the behaviours of components which are physically adjacent, and temporal ordering requires that for one variable to be the cause of another it must precede it, even if only by an infinitesimally short interval of time, or mythical time.

30.26.13 Ambiguities and multiple interpretations

As already indicated, qualitative modelling is inherently ambiguous, and thus gives rise to multiple behaviour predictions, or interpretations. How serious this is for modelling in a particular application depends largely on the extent to which it is possible to devise rules for the elimination of some of the interpretations.

30.26.14 Envisioning

The reasoning process that uses qualitative modelling to produce a description of the behaviours of the system over time is termed envisioning. An illustration of envisioning is given by de Kleer (1992). He presents a stage-by-stage account of the behaviour of a mass–spring–friction system and shows that qualitative modelling can be used to envision the oscillatory behaviour of the system.

30.27 Engineering Design

Applications of AI have been mainly in the fields already described, but there is an increasing amount of work in engineering. The material of prime interest here is that on process plant design, which is described below, but first some consideration is given to design expertise and to AI applications in engineering design generally.

30.27.1 Design expertise

Accounts of the design process in general include *Introduction to Design* (Asimow, 1962), *The Nature of Design* (Pye, 1964), *Design Engineering* (Dixon, 1966), *An Introduction to Engineering and Engineering Design* (Krick, 1969), *Engineering Design* (Middendorf, 1969), *Management of Engineering Design* (Leech, 1972), *Supplementary Readings in Engineering Design* (Geiger, 1975), *A Students Introduction to Engineering Design* (Simon, 1975) and *The Sciences of the Artificial* (Simon, 1969).

The design process and expertise in design are somewhat elusive. Designers have found it difficult to explain their skill and others who have studied it have also found it hard to pin down. Broadly, however, the design process involves problem recognition and definition, problem decomposition, the generation of alternative options and selection from these options.

The expert possesses a knowledge base in which knowledge may be represented in a number of forms, many being analogous to those described earlier. He has available a mental library of design archetypes. He has knowledge relevant to the evaluation of situations such as: the frequency, or probability of events; the consequences of events; and the costs, in money and other factors. He is aware of constraining factors such as project objectives; costs; time; hazards; regulatory requirements; standards and codes requirements; and so on. He is able to make distinctions of all sorts that would probably not occur to the layman. He possesses the ability to decompose a problem into subproblems which have only weak interactions and which are more manageable. He has methods of working which include logical argument, rules-of-thumb, mental models and analogues.

Part of the skill in engineering design consists of a knowledge of design methods for specific situations and equipment, based usually on appropriate mathematical models. This is the type of expertise with which the young engineer fresh from college may be expected to be familiar. Another part of the expertise comprises a personal collection of rules, many of them not explicit. These include both rules-of-thumb and heuristics, which guide the search for solutions. In this type of expertise the experienced engineer may be expected to have the advantage.

With design, in general, it is the initial conceptual stage that is the most critical. Closely related to this is the concept of design based not on trial and error but in getting it right first time.

30.27.2 Expert systems

The application of AI to engineering design is still in its infancy. A principal trend, however, has been the use of expert systems. An influential application of expert systems to engineering design was Rl, or XCON, which has already been described in Section 30.25. Another application of AI quite common in engineering design is the use of classification systems.

30.27.3 Design architectures

There are, however, developments that start from a critique of these current approaches. One such is described in *Design Problem Solving* by D.C. Brown and Chandrasekaran (1989). The stance taken by these authors is broadly as follows. Most applications of AI in engineering design take the form of expert systems. These tend to be general expert systems, often shells, which use domain-independent control and inference, and are simply loaded with the rules and data for the particular problem. They argue that typical practice with programming languages, system building tools and shells tends to involve the use of particular control structures even though this may not be apparent. They state:

> The fact that the low level language is used to implement a higher level control structure results in the knowledge base actually containing quite a few rules that are really programming devices for expressing this higher level of control. That is, the much talked about separation of knowledge from inference is not really true in practice for complex problems.

It is argued by Brown and Chandrasekaran that for efficient design it is necessary to take account of the specific domain and that there are generic tasks characteristic of each domain. Whilst there may be a range of features that are common to tasks in any domain of engineering, the relative importance of these features varies so greatly that it is not effective to adopt a uniform approach. Excessive emphasis on domain-independence suppresses the distinctions in control and inference which are characteristic of human conduct of generic tasks in different engineering design domains.

The framework for design that they propose is one that accommodates the domain-specific features. Design is viewed as the use of a number of different, and cooperating, types of problem-solver. The basic design process is that of generate and test. Four strategies are described for generating, or proposing, designs; (1) design decomposition, (2) design plans, (3) design by critique and modification of nearly correct designs and (4) design by constraint processes.

The first approach involves decomposing the design problem into suitable subproblems and creating a design hierarchy. Features of this process are the conversion of the goals and constraints of the overall problem into goals and constraints on the subproblems.

The design plans are pre-compiled partial design solutions. A design plan contains a sequence of design actions. Strategies for the retrieval of such plans include attachment of plans to goals or to components. NOAH may be viewed as a program which instantiates and expands design plans, since for each goal of the item under design, there is a stored procedure, effectively a plan.

Another way to proceed is by critique and modification of almost correct designs. This is applicable where such almost correct designs can be retrieved and converted to correct designs by processes of matching, critique and modification. Modification may involve the use of a number of problem-solving methods which may include means–ends analysis, hill-climbing and dependency-directed backtracking.

The fourth approach is design by constraint processes. This is applicable where there is a structure but the parameters are still to be determined. It proceeds by propagation of the constraints and incremental convergence on a solution which satisfies them all.

The authors distinguish three classes of design. Class 1 is creative design, essentially innovation and invention. Class 2 typically involves powerful decomposition and complex failure recovery features. Class 3 is routine design in which the problem is readily decomposable with only weak interactions between the subproblems and which is characterized by routine plans and failure recovery mechanisms.

30.27.4 DSPL

Brown and Chandrasekaran describe an expert system architecture for a Class 3 design and the programming language DSPL (Design Specialists and Plans Language) created to perform such design. DSPL contains design agents in the form of specialists, plans, tasks and steps. There is a hierarchy of specialists each of which possesses a set of plans and has the function of plan selection. A plan is a sequence of calls to specialists or tasks. Each plan has a sponsor that matches the characteristics of the plan with those of the task for which it is a candidate. A task is a sequence of steps that it executes. The primitive design agent is the step. It provides a value for an attribute of the design.

A feature of DSPL is failure handling. The basic approach taken is that the design agent concerned detects, diagnoses and fixes its own local failures and passes on only those failures that it cannot correct.

The authors give a detailed account of DSPL covering, in addition to the architecture features just mentioned, the handling of the database, constraints, dependencies and problem-solving. They describe DSPL itself and given an example of the design of an air cylinder system.

30.28 Process Applications

Turning now to the use of AI, expert system and other advanced techniques in the process industries, a number of overviews have been published. They include those of Stephanopoulos and Townsend (1986), Westerberg (1989), Mutton, Ponton and Waters (1990) and Stephanopoulos (1990). The following areas of application can be identified:

(1) project aids
  (a) aids for handling issues,
  (b) aids for handling requirements;
(2) process synthesis
  (a) reaction route,
  (b) energy;
(3) plant design: synthesis
  (a) inherently safer design,
  (b) classification activities,
  (c) designs with shallow structure,
  (d) designs with deep structure;
(4) plant design: analysis
  (a) hazop,
  (b) fault tree analysis;
(5) operating procedures;
(6) process monitoring;
(7) fault administration;
(8) malfunction detection.

These various computer aids fall into four broad categories, as aids for (1) the design project, (2) the design synthesis, (3) the design analysis and (4) the plant operation. Thus item (1) in the above list covers aids for the design project as a whole, items (2) and (3) cover the process and plant design synthesis aids, item (4) covers plant analysis aids and items (5)–(8) plant operations aids.

Computer aids for process and plant synthesis may be termed front-end aids, whilst aids for plant analysis are back-end aids. Another way of looking at the matter is in terms of the generate-and-test concept: the synthesis aids represent the generate phase and the analysis aids the test phase. These various aids are considered in the sections that now follow.

30.29 Project Aids

It is appropriate to begin the account of AI aids for process plant design by considering those which address design problems at the highest level.

30.29.1 Aids for representing design issues and history

Design involves the identification of a succession of issues, discussion of these issues and decisions to select particular options. There are a number of benefits to be had by adopting a more formal approach to the handling of design issues. Such an approach imparts greater structure to the decision-making process, assists communication and cooperation between the different design disciplines and provides a record of design information. This information is of various kinds and includes the design intent, the chronological development of the design, the issues raised, the constraints recognized, the rules applied and the decisions made.

This record is of particular value when a design is undertaken which draws on that for an existing plant. Unless such information can be retrieved, the designers of the new plant may be unaware of significant issues and constraints and may not appreciate the reasons for certain design features. In the more serious cases, some assumption or feature critical to safety is not appreciated.

Parties concerned with the design can see the issues under discussion and can make their contribution by raising further issues, proposing alternative solutions, advancing further arguments for or against a solution and drawing attention to facts relevant to, or making comments on, an argument. Needless to say, if a decision aid is used in this way there needs to be a policy governing the parties authorized to access it and to modify it.

Work on this topic, and on the creation of associated computer aids, has been described by a number of workers including Kunz and Rittle (1970), Conklin and Begeman (1988), Potts and Bruns (1988), Ganeshan, Finger and Garrett (1991), Lubers (1991), Chung, Abbas and Robertson (1993), Ramirez-Dominguez and Banares-Alcantara (1993) and Chung and Goodwin (1994).

An intelligent information system for safe plant design is described by Chung and Goodwin (1994). An overview of the system is shown in Figure 30.9. The system is issue-based, allowing the issues arising in the design and the arguments related to the issues to be represented and captured. It provides a historical record of the development of the design and of the issues affecting this development. Elements of the system are (1) the viewpoint mechanism, (2) the issue base and (3) the rule base.

The viewpoint mechanism is used to represent the design hierarchy. Each viewpoint is a single point in the design space. The viewpoint hierarchy provides a chronological record of the states of the design. The viewpoint mechanism allows the designer to move around the design from node to node whilst maintaining consistency. A record is kept of the design changes and of the constraints and rules together with a list of previous viewpoints. When the designer changes the viewpoint the mechanism traces back from the root to that point, reasserting all the constraints, rules and decisions stored along the way. The viewpoint mechanism also ensures that all changes made to one node are propagated through the design from the parent node to the child nodes.

The core of the system is the issue base. This provides a record of the issues considered. An issue is identified, positions are taken and arguments adduced for or against each position. In due course a decision is made to select one of the positions, or options.

Figure 30.10 shows an issue base for the following case:

> A chemical company wants to build a new plant in the United States. There is an existing plant for the same tonnage and product in the United Kingdom which uses both recycled cooling water (RCW) at 21°C and chilled water at 5°C. There are heavy demands on the cooling. The atmospheric ambient and wet bulb temperatures are higher at the proposed US site by 5°C and 8°C, respectively, on average. Are any modifications needed to the plant items and/or cooling supply systems?

The structure consists of nodes and semantic links. As shown, an argument is linked to a position by a *support* or an *against* link and a position is linked to an issue by a response-to link.

The authors also describe other types of node and link found necessary in developing this basic structure. Additional types of node used are *fact, comment* and *decision* nodes and additional types of link are *follow-up, combined-with* and *replaced-by* links. The first of these links allows re-examination of an issue on which a decision has already been made, the second allows the combination of several positions to form a single response and the third

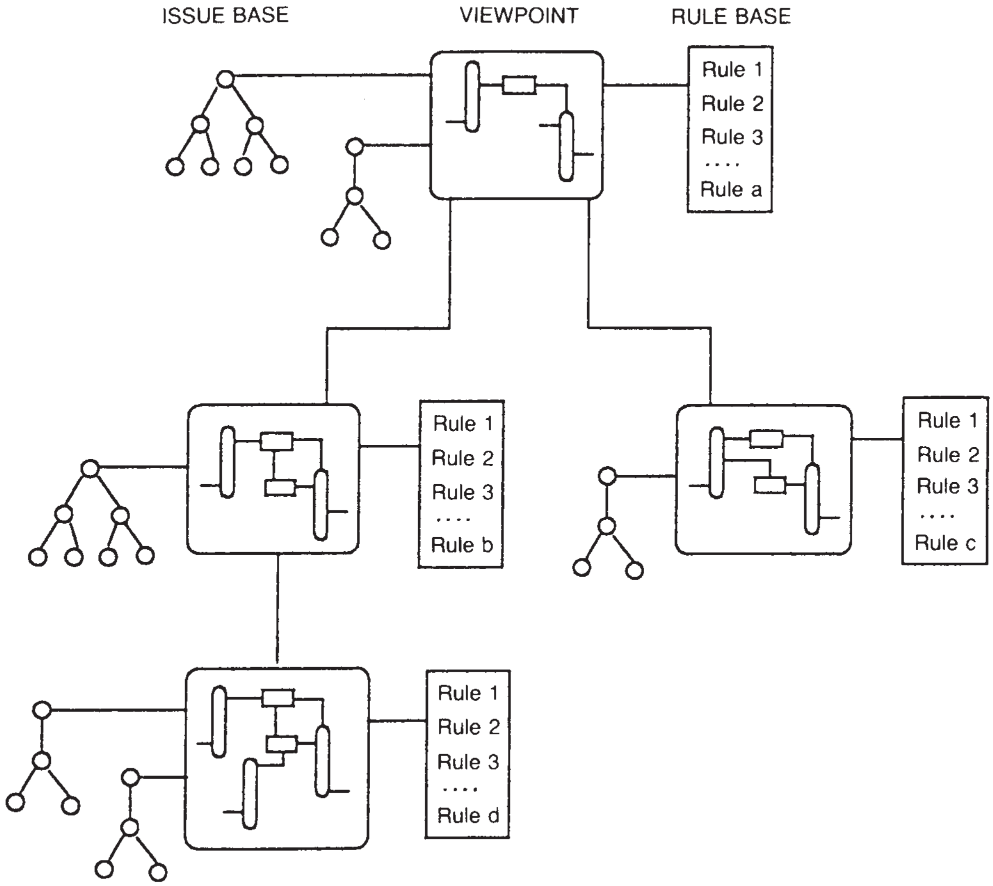

Figure 30.9 *Aid for the representation of design issues and history: system overview (Chung and Goodwin, 1994) (Courtesy of Kluwer Academic Publishers)*

decomposition of the problem into a set of smaller ones. These extensions thus cater for features such as iteration and decomposition, which are characteristic of design.

The rule base constitutes the third main element of the system. This contains both general rules and rules specific to the particular design.

30.29.2 Aids for representing regulatory and code requirements

Another generic problem in design is the handling of the requirements of legislation, standards and codes, and company policies. The number of documents containing requirements and the number of individual requirements is generally very large, and this poses a major information handling problem. An account of the development of the aids to assist with such information handling has been given by Chung and Stone (1994). The problem has several different aspects, including the retrieval of the requirements relevant to a particular issue and the comprehension of these requirements.

Considering first an individual document such as a standard, three distinct approaches to the problem may be identified. The first is to accept the document as it is and provide aids to the user in finding his way around it. The second is to perform some kind of processing on the document. The third, and most radical, is to intervene at the stage when the document is being written and provide aids to assist the author in writing it.

The retrieval problem has two aspects: retrieval of whole documents and retrieval of requirements from within a document. For both types of retrieval widespread use is made of keywords. For retrieval of whole documents these may be words in the title, keywords provided by the author or keywords searched in the text. The use of combinations of keywords narrows the search space.

Bourdeau (1991) has described the creation of a major keyword-based system REEF which is a 15,000 page encyclopaedia consisting of about 1000 documents commonly used by French building professionals. The database contains about 75% text with the rest made up of some 3500 tables, 9000 drawings and numerous formulae. Information is indexed at two levels, that of the document and that of the information unit.

Another approach is to analyse the hierarchy of concepts in a document and to provide an aid based on search down through the hierarchy.

Summary of the major nodes

Issue 1	—	Is the cooling adequate?
Issue 2	—	What other cooling changes need to be made?
POS 1/1a	—	Replace some RCW duties by chilled water
POS 2/2a	—	Redesign plant items where practicable
POS 3	—	Redesign the cooling tower to obtain a lower RCW temp
POS 4	—	Redesign the cooling supply system and add parallel plant items
POS 5	—	Reschedule the plant operations
POS 6	—	Mix RCW with chilled water to produce RCW at 21 C
POS 7	—	Chill all the RCW (from 29 C to 21 C

Another aid to retrieval is hypertext. This allows the user to browse through a document looking at related items. This too is based on some form of hierarchy or network of relationships.

Further progress is likely to depend on a more fundamental approach. Work in this area has developed in the direction of the modelling of the knowledge domain. This work bears both on retrieval and on comprehension. There are a number of methods that deal with relationships. Relationships between objects in a hierarchy and attributes of objects may be represented in a type hierarchy and the constituent parts of an object in a part hierarchy. Dependencies may be represented in network form. For the conclusion of a conditional statement, the pre-conditions may be shown in order of precedence in an ingredience network. A complementary representation is a dependence network that shows all the conclusions to which a given condition contributes. Requirements can be converted to various logical forms. These include logic programming, production rules, decision tables and so on.

One outcome of this sort of approach is the conversion of the document into an expert system. As can be imagined, this is a major task. Nevertheless, several expert systems of this type have been created, mainly in the building field.

The use of methods such as logic programming or production rules raises a number of issues such as the mixing of domain and control information and the updating of the program when requirements are changed, which are discussed by Chung and Stone. One approach being taken to overcome such problems is the development of generic standards processors, which allow the user to input the domain information in a purely declarative way. Another development is automated text formalization, which is essentially the application of natural language comprehension methods such as parsing to convert the text into formal language. A more radical departure is the development of author support systems to ensure that the original document is written in a more structured and formal manner. This addresses at source the defects that later lead to problems of retrieval and comprehension.

In the account given so far, consideration has been limited to a single document. There is also the problem of retrieving, comprehending and reconciling requirements from a variety of bodies. A limited amount of work has been done by researchers on author support systems, such as the work by Stone and Tweed (1991) on the capture of information from the common sources on which regulations, standards and codes draw.

Aids for handling the requirements that a design must meet are potentially invaluable, but it will be apparent from the foregoing that their development is in its early stages.

30.30 Process Modelling

Before considering process and plant design as such, it is necessary at this point to say something about modelling. It has become clear from attempts to apply AI to a number of problems in this area that a common lesson is the need for modelling of the process and the plant. Such models are often referred to as deep level knowledge in contrast to compiled knowledge such as rules. Some areas in which modelling is required are process and plant design, planning of plant operations and the diagnosis of faults on operating plant.

Such modelling draws particularly on the fundamental work on qualitative modelling described in Section 30.26, and especially on that of Kuipers and of Forbus on componented qualitative modelling and qualitative process theory, respectively. Some principal developments in qualitative modelling are now described.

30.30.1 Modelling languages and environments

Methods based on qualitative modelling tend to require the availability of a considerable number of models. The manual configuration of models requires considerable effort and can be a limiting factor in the use of the methods.

There have been a number of approaches aimed at mitigating this problem. One is the development of modelling languages such as OMOLA (Andersson, 1989; Nilsson, 1989), MODEL.LA (Stephanopoulos, Manning and Leone, 1990a,b) and ASCEND (Piela *et al.*, 1991). Another development is automatic model generation.

The characteristic approach is the identification of common features of models and of a hierarchy of models with inheritance of features.

30.30.2 MODEL.LA

MODEL.LA is a modelling language for the interaction or automatic construction of models of process systems. It is designed to be able to generate models at various levels of abstraction, to capture qualitative, semi-quantitative and quantitative knowledge, and to produce complete documentation of the modelling context such as the process task and the assumptions and simplifications.

It has an object oriented structure. The syntax is described as an extended Backus–Naur form. It utilizes six modelling elements: generic unit, port, stream, modelling scope, constraint and generic variable. There are 11 semantic relationships obeying basic axioms of transitivity, monotonicity, commutativity and merging. The structure of the models is depicted by digraphs that are constructed by algorithms driven by the modelling context.

30.30.3 Model generation

Closely related to the use of modelling languages is the systematic, and hence automatic, generation of models. Work on this topic has been described by Catino, Grantham and Ungar (1991). These authors' work utilizes Forbus' qualitative process theory (QPT). The approach taken is based not so much on process units such as reactors and heat exchangers as on process phenomena such as reactions and heat exchange. The authors describe the use of an adaptation of QPT to configure such models, and the creation of a prototype model library.

30.30.4 Order-of-magnitude modelling

A methodology for formal order-of-magnitude, or O(M), reasoning in process engineering has been outlined by Mavrovouniotis and Stephanopoulos (1988). In qualitative modelling use is made of qualitative values (−, 0, +). For some purposes, this treatment of the quantity space is not sufficiently expressive. It is desirable to be able to have a more adequate treatment of absolute and relative values and to be able to take into account concepts such as 'much smaller than' or 'slightly larger than'. The O(M) method provides a means of doing this.

30.30.5 Dynamic qualitative modelling

Most work in qualitative modelling is confined to the steady state, but there is some work emerging on unsteady-state, or dynamic, qualitative modelling. Thus, a method for the dynamic qualitative modelling and simulation of process systems is described by Dalle Molle, Kuipers and Edgar (1988).

30.30.6 Mathematical programming

Another area of modelling is mathematical programming, specifically mixed integer linear programming (MILP) and mixed integer non-linear programming (MINLP). An account of the relationship between MILP and logical inference for process synthesis is given by Raman and Grossman (1991), who show that qualitative knowledge on process synthesis that can be expressed in prepositional logic form can also be represented in the form of equivalent linear equations and inequalities.

30.31 DESIGN-KIT

A number of computer aids for design such as building tools and environments have been created. One of these is DESIGN-KIT described by Stephanopoulos *et al.* (1987). DESIGN-KIT is a process design environment built on CommonLISP and KEE. It is intended in the first instance to support the synthesis of process flowsheets, the configuration of control loops for complete plants, the planning and scheduling of plant-wide operations and the operational analysis of plants.

The underlying philosophy is that the designer should have available an environment which allows him to move consistently between the tasks of: (1) the conceptual design of processing schemes and the evaluation of alternative chemistries, and mass and energy balances; (2) the simulation and evaluation of designs in respect of operability and economics; (3) the sizing and costing of major equipment; (4) the creation of control loop configurations; (5) the design for start-up, shut-down and alternative operating modes and (6) the generation of piping and instrument diagrams, fabrication isometrics, etc. Further, the environment should allow high-level communication between the user and the computer, full and transparent integration of its various facilities, and easy maintenance and modification.

Some specific features of DESIGN-KIT are shown in Table 30.5.

Table 30.5 *Some features of DESIGN-KIT (after Stephanopoulos et al., 1987)*

1. Generation of graphic descriptions, for example, flowsheets, control structures, material and energy balances, operational paths, etc., with windowing facilities and menu-driven operations
2. Automatic generation of data structures describing the graphic objects
3. Modular construction of new graphic objects, process units models, design methodologies, operational objectives, etc.
4. High-level descriptions of various tasks, for example, graphic operations, design procedures, specification-directed simulation, definition of design or operational goals, automatic modelling of process units, etc.
5. Equation-oriented simulation and design facilities with dynamic generation of the relevant equations (specified by the problem to be solved), pre-processing of the equations, selection of the design variables, symbolic differentiation, etc.
6. Reasoning capabilities for the utilization of heuristic knowledge, qualitative information, O(M) analysis, goal-directed design or planning, as well as query and explanation facilities
7. Unified database management system with contextual description of the information and capability, through a common data model, to handle all types of knowledge (data, graphs, equations, inequalities, procedures, qualitative statements, heuristics, etc.)

30.32 Process Synthesis

Turning now to the actual design process, the most creative part of the design is the synthesis of the process and of the plant.

Accounts of process and plant synthesis have been given in *Strategy of Process Engineering* (Rudd and Watson, 1968) and in *Conceptual Design of Chemical Processes* (Douglas, 1988). Reviews include those of Westerberg (1980, 1985), Nishida, Stephanopoulos and Westerberg (1981), Umeda (1982), Stephanopoulos and Townsend (1986), Grossman and Floudas (1987), Gundersen and Naess (1988), Floquet, Piboleau and Domenech (1988), R. Smith and Linnhoff (1988), Grossman (1989) and Mutton, Waters and Ponton (1990).

The work of Rudd and Watson deals with in the first part, the creation and assessment of alternatives under the headings of (1) the synthesis of plausible alternatives, (2) the structure of systems, (3) economic design criteria, and (4) cost estimation; in the second part, optimization under the headings (5) the search for optimum conditions, (6) linear programming, (7) the suboptimization of systems with acyclic structure, (8) macrosystem optimization strategies and (9) multi-level attack on very large problems; and in the third part, engineering in the presence of uncertainty under the headings (10) accommodation to future developments, (11) accounting for uncertainty in data, (12) failure tolerance, (13) engineering around variations and (14) simulation.

A series of studies on process synthesis have been described by Rudd and co-workers (Masso and Rudd, 1968, 1969; Rudd, 1968; Siirola, Powers and Rudd, 1971a,b; Powers and Jones, 1973; Rudd, Powers and Siirola, 1973; and May and Rudd, 1976).

Douglas (1988) describes a hierarchical approach to conceptual design with the following hierarchy of decisions:

(1) batch vs continuous;
(2) input–output structure of the flowsheet;
(3) recycle structure of the flowsheet;
(4) general structure of the separation system
    (a) vapour recovery system,
    (b) liquid recovery system;
(5) heat exchanger network.

Douglas' work deals with: in the first part, a strategy for process synthesis and analysis under the headings (1) the nature of process synthesis and analysis, (2) engineering economics, and (3) economic decision-making; in the second part, developing a conceptual design and finding the best flowsheet under the headings (4) input information and batch vs continuous, (5) input–output structure of the flowsheet, (6) recycle structure of the flowsheet, (7) separation system, (8) heat-exchanger networks, and (9) cost diagrams and the quick screening of process alternatives; and in the third part, other design tools and applications under the headings (10) preliminary process optimization, (11) process retrofits, (12) computer aided design programs and (13) summary of, and extensions to, the conceptual design procedure.

Process synthesis is of great importance. In particular, it is relevant to (1) inherently safer design, (2) inherently cleaner design and (3) inherently low energy design, or process integration.

30.32.1 Process route

If the process involves a chemical reaction, this reaction is generally the most fundamental feature of the process. A number of studies have been carried out with a view to developing computer aids to selecting the chemical route, or process synthesis. Such work has been described, for example, by May and Rudd (1976). This is an area with great potential that has barely been broached.

30.32.2 Process flowsheet

The synthesis of the overall flowsheet is the least developed area of process synthesis. Most work addresses the more tractable subproblems such as energy economy.

A prototype system for the synthesis of the process flowsheet, PIP, has been described by Kirkwood, Locke and Douglas (1988). PIP has a hierarchical structure. It utilizes heuristics to select unit operations, to establish interconnections between them, to identify the dominant design variables and to generate process alternatives. It attempts to devise a flowsheet using a depth-first search.

Beltamini and Motard (1988) have described the development of an expert system, KNOD, which acts as a front end to a process simulator. It is used to test strategies and heuristics for the design and simulation of process structures.

A method of synthesizing a flowsheet which combines hierarchical and algorithmic approaches is described by Mizsey and Fonyo (1990). A prime purpose of this system is to give the designer confidence that the initial universe of potential process paths generated contains all the relevant paths.

30.32.3 Process simulators and databases
