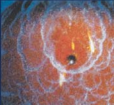
LEES' LOSS PREVENTION IN THE PROCESS INDUSTRIES

VOLUME 1

Hazard Identification, Assessment and Control

THIRD EDITION



Edited by
SAM MANNAN

Lee's Loss Prevention in the Process Industries

Volume 1

This book is dedicated to

Herbert Douglas Lees (1860–1944), gas engineer;
Frank Priestman Lees (1890–1916), gas engineer;
Herbert Douglas Lees (1897–1955), gas engineer;
David John Lees (1936–), agricultural engineer;
Frank Lyman MacCallum (1893–1955), mining engineer and missionary;
Vivien Clare Lees (1960–), plastic and hand surgeon;
Harry Douglas Lees (1962–), restaurateur
and their families

‘They do not preach that their God will rouse them a little before
the nuts work loose.
They do not teach that His Pity allows them to drop their job when
they dam’-well choose.
As in the thronged and the lighted ways, so in the dark and the
desert they stand,
Wary and watchful all their days that their brethren’s days may be
long in the land.’

Rudyard Kipling (The Sons of Martha, 1907)

Wo einer kommt and saget an,
Er hat es allen recht getan,
So bitten wir diesen lieben Herrn,
Er wöll uns solche Kunste auch lehrn

(Whoever is able to say to us
‘I have done everything right’,
We beg that honest gentleman
To show us how it is done)

Inscription over the ‘Zwischenbau’ adjoining the Rathaus in Brandenburg-on-the-Haven
(quoted by Prince B.H.M. von Bulow in *Memoirs*, 1932)

If the honeye that the bees gather out of so manye floure of herbes . . . that are growing in other mennis medowes . . . may justly be called the bees’ honeye . . . so maye I call it that I have . . . gathered of manye good autores . . . my booke.

William Turner (quoted by A. Scott-James in *The Language of the Garden: A Personal Anthology*)

Preface to Third Edition

The first edition of this book appeared in 1980, at the end of a decade of rapid growth and development in loss prevention. In the preface to the second edition, Frank P. Lees wrote, "After another decade and a half the subject is more mature, although development continues apace. In preparing this second edition it has been even more difficult than before to decide what to put in and what to leave out." Frank Lees' statement in 1996 rings even truer today, another eight years later in 2004. Industrial advances and technology changes coupled with recent events have made it essential to focus on new topics while keeping a complete grasp of all of older technologies and learnings as well. Safety programs today must also consider issues such as chemical reactivity hazards, safety instrumented systems, and layer of protection analysis. In the post 9-11 world, process safety and loss prevention must also include consideration of issues related to chemical security and resilient engineering systems.

The history of safety regulations in the United States can be traced back to the year before the beginning of the twentieth century. The River and Harbor Act, the first known federal legislation relevant to safety was promulgated in 1899. Since then, the total number of legislations has steadily increased. In addition to the federal government, local entities such as the state, county, and cities have also promulgated regulations and ordnances, which impose safety requirements on process facilities. Varying degrees of similar legislative action has also occurred in the rest of the world. These legislation were all promulgated in response to some event, demographic changes, as well as changes in the industry. Also, as our understanding of the hazards associated with industrial processes developed, procedures and practices were put in place to limit or eliminate the damage. Government programs and industry initiatives spurred improvements in the science and technology needed for the recognition of hazards and associated risks.

Management systems have been put in place to implement regulations and industry practices. Government regulations will continue to be a significant driver for safety programs. As such, one of the main objectives of these management systems is to ensure compliance. However, it is also quite clear that profitability is directly related to safety and loss prevention. Thus the management systems for safety are intricately tied into the operational management.

The industrial revolution brought prosperity and along with it the use of hazardous processes and complex technologies. Growing economies and global competition has led to more complex processes involving the use of hazardous chemicals, exotic chemistry, and extreme operating conditions. As a result, a fundamental understanding of the hazards and associated risks is essential. Process safety and risk management requires the application of the basic sciences and a systematic approach. Recent advances, such as overpressure protection alternatives and reactive chemistry allow safer design and operation of processes.

In the multiple barriers concept, plants are designed with several layers so that an incident would require the failure of several systems. Another novel approach to process safety and risk management is to consider various actions in a descending hierarchical order. Inherently safer design consideration should be first in the hierarchy followed by prevention systems, mitigation, and response. The success of these systems is dependent on the fundamental understanding of the process and the associated hazards. Chronic as well as catastrophic consequences resulting from toxic and flammable substances can be reduced and/or eliminated through appropriate design and operating practices.

Managing safety is no easy task, but it makes bottom-line sense. There is a direct payoff in savings on a company workers' compensation insurance, whose premiums are partly based on the number of claims paid for job injuries. The indirect benefits are far larger, for safe plants tend to be well run in general and more productive. The recipe for safety is remarkably consistent from industry to industry. It starts with sustained support of top management followed by implementation of appropriate programs and practices that institutionalize safety as a culture as compared to add-on procedures. The ingraining of safety as second nature in day-to-day activities requires a paradigm shift and can only be accomplished when safety is viewed as an integral and comprehensive part of any activity as compared to being a stand-alone or add-on activity.

This third edition of ***Loss Prevention in the Process Industries*** represents a combination of appropriate revisions of the essential compilations put together by Frank P. Lees, along with several new chapters and additions on new areas that deserve attention and discussion. The third edition includes five new chapters and three new appendices. The five new chapters address incident investigation, inherently safer design, reactive chemicals, safety instrumented systems, and chemical security. The three new appendices address process safety management regulation in the United States, risk management program regulation in the United States, and incident databases.

The chapter on incident investigation provides a summary of incident investigation procedures that can be used not only to determine causes of incidents but also provides a primer on capturing and integrating lessons learned from incident investigations into design, operations, maintenance, and response programs. Chemical process incidents can be accompanied by significant consequences, both in terms of human life and in financial impact. Many major chemical process incidents are the result of a complex scenario involving simultaneous failures of multiple safeguards. A robust system for incident investigation is usually necessary to determine and understand the causes, as well as implement measures to prevent a repeat event. This chapter is intended to provide an overview of incident investigation by addressing major concepts, principles, and characteristics of effective incident investigations of chemical process events. The focus is on incidents pertaining to chemical processes and their associated hazards, and the associated investigation techniques appropriate for complex systems and scenarios. This chapter is based on

best practices for incident investigation, and those common concepts (i.e., tools, techniques, definitions) included in root cause investigation methodologies currently in the public domain in use in the process industry. It is not the intention to provide a stand-alone investigation methodology/guideline, nor address internal or proprietary investigation methodologies.

The chapter on inherently safer design addresses options and issues that can be considered with regard to the design and operation of plants. Inherently safer design is a philosophy that focuses on elimination of hazards or reduction of the magnitude of hazards rather than the control of hazards. Many of the concepts of inherently safer design have been applied by engineers in a wide variety of technologies for many years, without recognizing the common approach. In the late 1970s, in the wake of many large incidents in the chemical industry, Trevor Kletz recognized the common philosophies of hazard elimination and hazard reduction, gave the philosophy the name "inherently safer design," and developed a specific set of approaches to help engineers in the chemical process industries to design inherently safer processes and plants. Trevor realized that increased expectations for safety, from companies, regulatory bodies, and society in general, combined with the increased potential damage from incidents in the larger plants being built to meet increased demand and global markets, resulted in increased complexity and cost for the safety systems required to satisfy these demands. Furthermore, while hazard control systems can be made highly reliable, they can never be perfect and will always have some failure probability. While this probability can be made very small, there is always some chance that all safety systems will fail simultaneously and the result would be a large incident. Also, the hazard management systems require ongoing maintenance, as well as management and operator training, for the life of the plant. This results in ongoing costs, and the potential for future deterioration of the safety systems. Deteriorated systems will have reduced reliability, increasing the potential for a catastrophic accident. Trevor Kletz suggested that in many cases, a simpler, cheaper, and safer plant could be designed by focusing on the basic technology, eliminating or significantly reducing hazards, and therefore the need to manage them.

The chapter on reactive chemicals provides an overview of this critical issue and provides guidance on management systems as well as experimental and theoretical methods for analyses of chemical reactivity hazards. Serious incidents arising from uncontrolled reactivity have taken place since the inception of the chemical industry. The human toll of such incidents has been staggering. In recent decades, greater recognition and resources have been directed toward preventing and mitigating such occurrences. A number of incidents have been so severe as to prompt regulatory initiatives to force better management of reactivity. It is prudent for any company, organization, or other group to scrutinize the chemicals being handled and implement measures to limit the risk of a major reactive hazards event. A sampling of incidents that have substantially heightened concerns regarding reactive hazards in the general public, in governmental agencies, and in industry includes:

- The 1976 ICMESA incident in Seveso, Italy in which an uncontrolled chemical reaction generated pressure resulting in relief venting of a highly toxic dioxane into the neighboring villages and countryside.
- The 1984 Union Carbide incident in Bhopal, India in which methyl isocyanate was contacted with water, generating highly toxic cyanide gas and leading to thousands of fatalities.
- The 1994 Napp Technology incident in Lodi, New Jersey in which an uncontrolled reaction involving gold ore processing led to the deaths of five firefighters.
- The 1999 Concept Sciences incident in Allentown, Pennsylvania in which an explosion arising from a process concentrating hydroxylamine resulted in five fatalities. Another event involving purified hydroxylamine took place in a Nissin Chemical plant in Gunma Prefecture, Japan in 2000 and led to four fatalities.
- The 2001 TotalFinaElf incident in Toulouse, France in which ammonium nitrate being processed for nitrogen fertilizers exploded leading to 30 fatalities.

These events, as well as numerous others, have influenced the perception and approach to reactive hazards.

The chapter on safety instrumented systems addresses systems and procedures that need to be in place with regard to this area of safety and instrumentation. In many processes, technical or manufacturing issues limit the engineer's capability to design an inherently safer process. Further, there is generally a point where the required capital investment is disproportional to the additional risk reduction provided by the process modification. In other words, the derived safety benefit is too low relative to the economic investment. When this occurs, protection layers or safeguards must be provided to prevent or mitigate the process risk. A Safety Instrumented System (SIS) is a protection layer, which shuts down the plant, or part of it, if a hazardous condition is detected. Throughout the years, SIS have also been known as Emergency Shutdown Systems (ESD, ESS), Safety Shutdown Systems (SSD), Safety Interlock Systems (SIS), Safety Critical Systems (SCS), Safety Protection Systems (SPS), Protective Instrumented Systems (PIS), interlocks, and trip systems. Regardless of what the SIS may be called, the essential characteristic of the SIS is that it is composed of instruments, which detect that process variables are exceeding preset limits, a logic solver, which processes this information and makes decisions, and final control elements, which take necessary action on the process to achieve a safe state.

The chapter on chemical security deals with this new and critical element of the management of a process facility following the events of September 11, 2001. Security management is required for protecting the assets (including employees) of the facility, maintaining the ongoing integrity of the operation, and preserving value of the investment. Process security and process safety have many parallels and make use of many common programs and systems for achieving their ends. Process security requires a management systems approach to develop a comprehensive security program, which shares many common elements to process safety management.

The new appendix on process safety management regulation in the United States provides a summary of this regulatory requirement. The fourteen elements of the OSHA Process Safety Management (PSM) regulation (*29 CFR 1910.119*) were published in the U.S. Federal Register on February 24, 1992. The objective of the regulation is to

prevent or minimize the consequences of catastrophic releases of toxic, reactive, flammable, or explosive chemicals. The regulation requires a comprehensive management program: a holistic approach that integrates technologies, procedures, and management practices. The process safety management regulation applies to processes that involve certain specified chemicals at or above threshold quantities, processes that involve flammable liquids or gases on-site in one location, in quantities of 10,000 pounds or more (subject to few exceptions), and processes that involve the manufacture of explosives and pyrotechnics. Hydrocarbon fuels, which may be excluded if used solely as a fuel, are included if the fuel is part of a process covered by this regulation. In addition, the regulation does not apply to retail facilities, oil or gas well drilling or servicing operations, or normally unoccupied remote facilities.

The new appendix on risk management program regulation in the United States provides a summary of this regulatory requirement administered by the U.S. Environmental Protection Agency. In 1996, EPA promulgated the regulation for ***Risk Management Programs for Chemical Accident Release Prevention*** (40 CFR 68). This federal regulation was mandated by section 112(r) of the Clean Air Act Amendments of 1990. The regulation requires regulated facilities to develop and implement appropriate risk management programs to minimize the frequency and severity of chemical plant accidents. In keeping with regulatory trends, EPA required a performance-based approach towards compliance with the risk management program regulation. The EPA regulation also requires regulated facilities to develop a Risk Management Plan (RMP). The RMP includes a description of the hazard assessment, prevention program, and the emergency response program. Facilities submit the RMP to the EPA and subsequently is made available to governmental agencies, the state emergency response commission, the local emergency planning committees, and communicated to the public.

The new appendix on incident databases addresses compilations of incident databases that can used for improving safety programs, developing trends, performance measures, and metrics. Incident prevention and mitigation of consequences is the focus of a number of industry programs regulatory initiatives. As part of these programs and regulations, accident history data are often collected. There are two basic types of information. One is a database consisting of standardized fields of data usually for a large number of incidents. The second are more detailed reports of individual incidents. Analysis of these incident history databases can provide insight into incident prevention needs. While the analysis and conclusions obtained from the incident database are often limited by the shortcomings of the databases themselves, the fact remains that incident history databases are very useful and can be a powerful tool in focusing risk reduction efforts. The conclusions can be used to identify systematically the greatest risks to allow prioritization of efforts to improve process safety. At the plant level this might entail identifying certain processes, types of equipment, chemicals, operations and other factors most commonly associated with incidents. Databases that cover a very large number of facilities are likely to reveal trends and patterns that no one company or facility could determine from their own experience. Statistical knowledge of the likelihood of the release of certain types of chemicals could help emergency responders, state emergency response commissions, and local emergency planning committees determine the most likely and most serious chemical releases in their areas and plan appropriate chemical accident responses. Incident databases may also help identify technologies and practices to prevent chemical accidents, or the need to develop them. For example, the data could indicate that inspection and preventive maintenance of equipment and instruments should become more thorough or more frequent.

Preface to Second Edition

The first edition of this book appeared in 1980, at the end of a decade of rapid growth and development in loss prevention. After another decade and a half the subject is more mature, although development continues apace. In preparing this second edition it has been even more difficult than before to decide what to put in and what to leave out.

The importance of loss prevention has been underlined by a number of disasters. Those at San Carlos, Mexico City, Bhopal and Pasadena are perhaps the best known, but there have been several others with death tolls exceeding 100. There have also been major incidents in related areas, such as those on the Piper Alpha oil platform and at the nuclear power stations at Three Mile Island and Chernobyl.

Apart from the human tragedy, it has become clear that a major accident can seriously damage even a large international company and may even threaten its existence, rendering it liable to severe damages and vulnerable to takeover.

Accidents in the process industries have given impetus to the creation of regulatory controls. In the UK the Advisory Committee on Major Hazards made its third and final report in 1983. At the same time the European Community was developing its own controls which appeared as the EC Directive on Major Accident Hazards. The resulting UK legislation is the NIHHS Regulations 1982 and the CIMAH Regulations 1984. Other members of the EC have brought in their own legislation to implement the Directive. There have been corresponding developments in planning controls.

An important tool for decision-making on hazards is hazard assessment. The application of quantitative methods has played a crucial role in the development of loss prevention, but there has been lively debate on the proper application of such assessment, and particularly on the estimation and evaluation of the risk to the public.

Hazard assessment involves the assessment both of the frequency and of the consequences of hazardous events. In frequency estimation progress has been made in the collection of data and creation of data banks and in fault tree synthesis and analysis, including computer aids. In consequence assessment there has been a high level of activity in developing physical models for emission, vaporization and gas dispersion, particularly dense gas dispersion; for pool fires, fireballs, jet flames and engulfing fires; for vapour cloud explosions; and for boiling liquid expanding vapour explosions (BLEVEs). Work has also been done on injury models for thermal radiation, explosion overpressure and toxic concentration, on models of the density and other characteristics of the exposed population, and on shelter and escape.

Some of these topics require experimental work on a large scale and involving international cooperation. Large scale tests have been carried out at several sites on dense gas dispersion and on vapour cloud fires and explosions. Another major cooperative research programme has been that of DIERS on venting of chemical reactors.

The basic approach developed for fixed installations on shore has also been increasingly applied in other fields. For transport in the UK the *Transport Hazards Report* of the Advisory Committee on Dangerous Substances represents an important landmark. Another application is in the offshore oil and gas industry, for which the report on the Piper Alpha disaster, the *Cullen Report*, constitutes a watershed.

As elsewhere in engineering, computers are in widespread use in the design of process plants, where computer aided design (CAD) covers physical properties, flowsheeting, piping and instrument diagrams, unit operations and plant layout. There is increasing use of computers for failure data retrieval and analysis, reliability and availability studies, fault tree synthesis and analysis and consequence modelling, while more elusive safety expertise is being captured by computer-based expert systems.

The subject of this book is the process industries, but the process aspects of related industries, notably nuclear power and oil and gas platforms are briefly touched on. The process industries themselves are continually changing. In the last decade one of the main changes has been increased emphasis on products such as pharmaceuticals and agrochemicals made by batch processes, which have their own particular hazards.

All this knowledge is of little use unless it reaches the right people. The institutions which educate the engineers who will be responsible for the design and operation of plants handling hazardous materials have a duty to make their students aware of the hazards and at least to make a start in gaining competence in handling them.

I would like again to thank for their encouragement the heads of the Department of Chemical Engineering at Loughborough, Professors D.C. Freshwater, B.W. Brooks and M. Streat; our Industrial Professors T.A. Kletz and H.A. Duxbury and Visiting Professor S.M. Richardson; my colleagues, past and present, in the Plant Engineering Group, Mr R.J. Aird, Dr P.K. Andow, Dr M.L. Ang, Dr P.W.H. Chung, Dr D.W. Edwards, Dr P. Rice and Dr A.G. Rushton – I owe a particular debt to the latter; the members of the ACMH, chaired by Professor B.H. Harvey; the sometime directors of Technica Ltd, Dr D.H. Slater, Mr P. Charsley, Dr P.J. Comer, Dr R.A. Cox, Mr T. Gjerstad, Dr M.A.F. Pyman, Mr C.G. Ramsay, Mr M.A. Seaman and Dr R. Whitehouse; the members of the IChemE Loss Prevention Panel; the IChemE's former Loss Prevention Officer, Mr B.M. Hancock; the members of the IChemE Loss Prevention Study Group and of the Register of Safety Professionals; the editorial staff of the IChemE, in particular Mr B. Brammer; numerous members of the Health and Safety Executive, especially Dr A.C. Barrell, Mr J. Barton, Dr D.A. Carter, Mr K. Cassidy, Mr P.J. Crossthwaite, Dr N.W. Hurst, Dr S.F. Jagger, Dr J. McQuaid, Dr K. Moodie, Dr C. Nussey, Dr R.P. Pape, Dr A.F. Roberts and Dr N.F. Scilly; workers at the Safety and Reliability Directorate, particularly Dr A.T.D. Butland, Mr I. Hymes, Dr D.W. Phillips and Dr D.M. Webber; staff at Shell Thornton Research Centre, including Dr D.C. Bull and Dr A.C. Chamberlain; staff at British Gas, including Dr J.D. Andrews, Dr M.J. Harris, Mr H. Hopkins, Dr J.M. Morgan and Dr D.J. Smith; staff at the Ministry of

Defence, Explosives Storage and Transport Committee, including Mr M.A. Gould, Mr J. Henderson and Mr P. Stone; and colleagues who have taught on post-experience courses at Loughborough, in particular Dr C.D. Jones, Dr D.J. Lewis and Mr J. Madden; BP International and Mr R. Malpas for allowing me to spend a period of study leave with the company in 1985–86 and Mr F.D.H. Moysen, Mr G. Hately, Mr M. Hough, Mr R. Fearon and others in the Central Safety Group and in Engineering Department; the Honourable Lord Cullen, my fellow Technical Assessors on the Piper Alpha Inquiry, Mr B. Appleton and Mr G.M. Ford and the Cremer and Warner team at the inquiry, in particular Mr G. Kenney and Mr R. Sylvester-Evans; other professional colleagues Dr L.J. Bellamy, Professor B.A. Buffham, Dr D.A. Crowl, Mr T.J. Gilbert, Mr D.O. Hagon, Dr D.J. Hall, Mr K.M. Hill, Professor T.M. Husband, Mr M. Kneale, Dr V.C. Marshall, Dr M.L. Preston, Dr J. Rasmussen, Dr J.R. Roach, Dr J.R. Taylor, Dr V.M. Trbojevic, Mr H.M. Tweeddale, Dr G.L. Wells and Dr A.J. Wilday; my research colleagues Dr C.P. Murphy, Mrs J.I. Petts, Dr D.J. Sherwin, Mr R.M.J. Withers and Dr H. Zerkani; my research students Mr M. Aldersey, Mr D.C. Arulanantham, Dr A. Bunn, Dr M.A. Cox, Dr P.A. Davies, Dr S.M. Gilbert, Mr P. Heino, Dr A. Hunt, Dr B.E. Kelly, Dr G.P.S. Marrs, Dr J.S. Mullhi, Dr J.C. Parmar, Mr B. Poblete, Dr A. Shafaghi and Dr A.J. Trenchard as well as colleagues' research students Mr E.J. Broomfield, Mr R. Goodwin, Mr M.J. Jefferson, Dr F.D. Larkin, Mr S.A. McCoy, Dr K. Plamping, Mr J. Soutter, Dr P. Thorpe and Mr S.J. Wakeman; the office staff of the Department, Mrs E.M. Barradell, Mr D.M. Blake, Miss H.J. Bryers and Miss Y. Kosar; the staff of the University Library, in particular Miss S.F. Pilkington; and my wife Elizabeth, whose contribution has been many-faceted and in scale with this book.

FRANK P. LEES
Loughborough,
1994

Preface to First Edition

Within the past ten or fifteen years the chemical and petroleum industries have undergone considerable changes. Process conditions such as pressure and temperature have become more severe. The concentration of stored energy has increased. Plants have grown in size and are often single-stream. Storage has been reduced and interlinking with other plants has increased. The response of the process is often faster. The plant contains very large items of equipment. The scale of possible fire, explosion or toxic release has grown and so has the area which might be affected by such events, especially outside the works boundary.

These factors have greatly increased the potential for loss both in human and in economic terms. This is clear both from the increasing concern of the industry and its insurers and from the historical loss statistics.

The industry has always paid much attention to safety and has a relatively good record. But with the growing scale and complexity involved in modern plants the danger of serious large-scale incidents has been a source of increasing concern and the adequacy of existing procedures has been subjected to an increasingly critical examination.

Developments in other related areas have also had an influence. During the period considered there has been growing public concern about the various forms of pollution, including gaseous and liquid effluents and solid wastes and noise.

It is against this background that the loss prevention approach has developed. It is characteristic of this approach that it is primarily concerned with the problems caused by the depth of technology involved in modern processes and that it adopts essentially an engineering approach to them. As far as possible both the hazards and the protection are evaluated quantitatively.

The clear recognition by senior management of the importance of the loss prevention problem has been crucial to these developments. Progress has been made because management has been prepared to assign to this work many senior and capable personnel and to allocate the other resources necessary.

The management system is fundamental to loss prevention. This involves a clear management structure with well defined line and advisory responsibilities staffed by competent people. It requires the use of appropriate procedures, codes of practice and standards in the design and operation of plant. It provides for the identification, evaluation and reduction of hazards through all stages of a project from research to operation. It includes planning for emergencies.

The development of loss prevention can be clearly traced through the literature. In 1960 the Institution of Chemical Engineers held the first of a periodic series of symposia on *Chemical Process Hazards with Special Reference to Plant Design*. The Dow Chemical Company published its *Process Safety Manual* in 1964. The American Institute of Chemical Engineers started in 1967 an annual series of symposia on Loss Prevention. The European Federation of Chemical Engineers' symposium on *Major Loss Prevention in the Process Industries* at Newcastle in 1971 and the Federation's symposium on *Loss Prevention and Safety Promotion in the Process Industries* (Buschmann, 1974) at Delft are further milestones.

Another indicator is the creation in 1973 by the Institution of Chemical Engineers Engineering Practice Committee of a Loss Prevention Panel under the chairmanship of Mr T.A. Kantyka.

In the United Kingdom the Health and Safety at Work etc. Act 1974 has given further impetus to loss prevention. The philosophy of the *Robens Report* (1972), which is embodied in the Act, is that of self-regulation by industry. It is the responsibility of industry to take all reasonable measures to assure safety. This philosophy is particularly appropriate to complex technological systems and the Act provides a flexible framework for the development of the loss prevention approach.

The disaster at Flixborough in 1974 has proved a turning point. This event has led to a much more widespread and intense concern with the loss prevention problem. It has also caused the government to set up in 1975 an Advisory Committee on Major Hazards. This committee has made far-reaching recommendations for the identification and control of major hazard installations.

It will be apparent that loss prevention differs somewhat from safety as traditionally conceived in the process industries. The essential difference is the much greater engineering content in loss prevention.

This is illustrated by the relative effectiveness of inspection in different processes. In fairly simple plants much can be done to improve safety by visual inspection. This approach is not adequate, however, for the more technological aspects of complex processes.

For the reasons given above loss prevention is currently a somewhat fashionable subject. It is as well to emphasize, therefore, that much of it is not new, but has been developed over many years by engineers whose patient work in an often apparently unrewarding but vital field is the mark of true professionalism.

It is appropriate to emphasize, moreover, that accidents arising from relatively mundane situations and activities are still responsible for many more deaths and injuries than those due to advanced technology.

Nevertheless, loss prevention has developed in response to the growth of a new problem, the hazard of high technology processes, and it does have a distinctive approach and some novel techniques. Particularly characteristic are the emphasis on matching the management system to the depth of technology in the installation, the techniques developed for identifying hazards, the principle and methods of quantifying hazards, the application of reliability assessment, the practice of planning for emergencies and the critique of traditional practices or existing codes, standards or regulations where these are outdated by technological change.

There is an enormous, indeed intimidating, literature on safety and loss prevention. In addition to the symposia already referred to, mention may be made of the *Handbook of Safety and Accident Prevention in Chemical Operations* by Fawcett and Wood (1965); the *Handbook of Industrial Loss*

Prevention by the Factory Mutual Engineering Corporation (1967); and the Industrial Safety Handbook by Handley (1969, 1977). These publications, which are by multiple authors, are invaluable source material.

There is a need, however, in the author's view for a balanced and integrated textbook on loss prevention in the process industries which presents the basic elements of the subject, which covers the recent period of intense development and which gives a reasonably comprehensive bibliography. The present book is an attempt to meet this need.

The book is based on lectures given to undergraduate and postgraduate students at Loughborough over a period of years and the author gladly acknowledges their contribution.

Loss prevention is a wide and rapidly developing field and is therefore not an easy subject for a book. Nevertheless, it is precisely for these reasons that the engineer needs the assistance of a textbook and that the attempt has been considered justified.

The structure of the book is as follows. Chapter 1 deals with the background to the historical development of loss prevention, the problem of large, single-stream plants, and the differences between loss prevention and conventional safety, and between loss prevention and total loss control; Chapter 2 with hazard, accident and loss, including historical statistics; Chapter 3 with the legislation and legal background; Chapter 4 with the control of major hazards; Chapter 5 with economic and insurance aspects; Chapter 6 with management systems, including management structure, competent persons, systems and procedures, standards and codes of practice, documentation and auditing arrangements; Chapter 7 with reliability engineering, including its application in the process industries; Chapter 8 with the spectrum of techniques for identifying hazards from research through to operation; Chapter 9 with the assessment of hazards, including the question of acceptable risk; Chapter 10 with the siting and layout of plant; Chapter 11 with process design, including application of principles such as limitation of inventory, consideration of known hazards associated with chemical reactors, unit processes, unit operations and equipments, operating conditions, utilities, particular chemicals and particular processes and plants, and checking of operational deviations; Chapter 12 with pressure system design, including properties of materials, design of pressure vessels and pipework, pressure vessel standards and codes, equipment such as heat exchangers, fired heaters and rotating machinery, pressure relief and blowdown arrangements, and failure in pressure systems; Chapter 13 with design of instrumentation and control systems, including regular instrumentation, process computers and protective systems; Chapter 14 with human factors in process control, process operators, computer aids and human error; Chapter 15 with loss of containment and dispersion of material; Chapter 16 with fire, flammability characteristics, ignition sources, flames and particular types of process fire, effects of fire and fire prevention, protection and control; Chapter 17 with explosion, explosives, explosion energy, particular types of process explosion such as confined explosions, unconfined vapour cloud explosions and dust explosions, effects of explosion and explosion prevention, protection and relief; Chapter 18 with toxicity of chemicals, toxic release and effects of toxic release; Chapter 19 with commissioning and inspection of plant; Chapter 20 with plant operation; Chapter 21 with plant maintenance and modification; Chapter 22 with storage; Chapter 23 with transport, particularly by road, rail and pipeline; Chapter 24 with emergency planning both for works and transport emergencies; Chapter 25 with various aspects of personal safety such as occupational health and industrial hygiene, dust and radiation hazards, machinery and electrical hazards, protective clothing and equipment, and rescue and first aid; Chapter 26 with accident research; Chapter 27 with feedback of information and learning from accidents; Chapter 28 with safety systems, including the roles of safety managers and safety committees and representatives. There are appendices on Flixborough, Seveso, case histories, standards and codes, institutional publications, information sources, laboratories and pilot plants, pollution and noise, failure and event data, Canvey, model licence conditions for certain hazardous plants, and units and unit coversions.

Many of the matters dealt with, such as pressure vessels or process control, are major subject areas in their own right. It is stressed, therefore, that the treatment given is strictly limited to loss prevention aspects. The emphasis is on deviations and faults which may give rise to loss.

In engineering in general and in loss prevention in particular there is a conflict between the demand for a statement of basic principles and that for detailed instructions. In general, the first of these approaches has been adopted, but the latter is extremely important in safety, and a considerable amount of detailed material is given and references are provided to further material.

The book is intended as a contribution to the academic education of professional chemical and other engineers. Both educational and professional institutions have long recognized the importance of education in safety. But until recently the rather qualitative, and indeed often exhortatory, nature of the subject frequently seemed to present difficulties in teaching at degree level. The recent quantitative development of the subject goes far towards removing these objections and to integrating it more closely with other topics such as engineering design.

In other words, loss prevention is capable of development as a subject presenting intellectual challenge. This is all to the good, but a note of caution is appropriate. It remains true that safety and loss prevention depend primarily on the hard and usually unglamorous work of engineers with a strong sense of responsibility, and it is important that this central fact should not be obscured.

For this reason the book does not attempt to select particular topics merely because a quantitative treatment is possible or to give such a treatment as an academic exercise. The subject is too important for such an approach. Rather the aim has been to give a balanced treatment of the different aspects and a lead in to further reading.

It is also hoped that the book will be useful to practising engineers in providing an orientation and entry to unfamiliar areas. It is emphasized, however, that in this subject above all others, the specialized texts should be consulted for detailed design work.

Certain topics which are often associated with loss prevention, for example included in loss prevention symposia, have not been treated in detail. These include, for example, pollution and noise. The book does not attempt to deal in detail with total loss control, but a brief account of this is given.

The treatment of loss prevention given is based mainly on the chemical, petrochemical and petroleum industries,

but much of it is relevant to other process industries, such as electrical power generation (conventional and nuclear), iron and steel, gas, cement, glass, paper and food.

The book is written from the viewpoint of the United Kingdom and, where differences exist within the UK, of England. This point is relevant mainly to legislation.

Reference is made to a large number of procedures and techniques. These do not all have the same status. Some are well established and perhaps incorporated in standards or codes of practice. Others are more tentative. As far as possible the attempt has been made to give some indication of the extent to which particular items are generally accepted.

There are probably also some instances where there is a degree of contradiction between two approaches given. In particular, this may occur where one is based on engineering principles and the other on relatively arbitrary rules-of-thumb.

The book does not attempt to follow standards and codes of practice in drawing a distinction between the words *should, shall* and *must* in recommending particular practices and generally uses only the former. The distinction is important, however, in standards and codes of practice and it is described in Appendix 4[a].

An explanation of some of the terms used is in order at this point. Unfortunately there is at present no accepted terminology in this field. In general, the problems considered are those of loss, either of life or property. The term *hazard* is used to describe the object or situation which constitutes the threat of such loss. The consequences which might occur if the threat is realized are the *hazard potential*. Associated with the hazard there is a risk, which is the probability of the loss occurring. Such a risk is expressed as a *probability* or as a *frequency*. Probability is expressed as a number in the range 0 to 1 and is dimensionless; frequency is expressed in terms of events per unit time, or sometimes in other units such as events per cycle or per occasion. Rate is also used as an alternative to frequency and has the same units.

The analysis of hazards involves qualitative *hazard identification* and quantitative hazard assessment. The latter term is used to describe both the assessment of hazard potential and of risk. The assessment of risk only is described as *risk assessment*.

In accident statistics the term *Fatal Accident Frequency Rate* (FAFR) has some currency. The last two terms are tautologous and the quantity is here referred to as *Fatal Accident Rate* (FAR).

Further treatments of terminology in this field are given by BS 4200: 1967, by Green and Bourne (1962), by the Council for Science and Society (1977) and by Harvey (1979b).

Notation is defined for the particular chapter at the point where the symbols first occur. In general, a consistent notation is used, but well established equations from standards, codes and elsewhere are usually given in the original notation. A consolidated list of the notation is given at the end of chapters in which a large number of symbols is used.

The units used are in principle SI, but the exceptions are fairly numerous. These exceptions are dimensional equations, equations in standards and codes, and other equations and data given by other workers where conversion has seemed undesirable for some reason. In cases of conversion from a round number it is often not clear what degree of rounding off is appropriate. In cases of description of particular situations it appears pedantic to make the conversion where a writer has referred, for example, to a 1 inch pipe.

Notes on some of the units used are given in Appendix 12[a]. For convenience a unit conversion table is included in this appendix. Numerical values given by other authors are generally quoted without change and numerical values arising from conversion of the units of data given by other authors are sometimes quoted with an additional significant figure in order to avoid excessive rounding of values.

Some cost data are quoted in the book. These are given in pounds or US dollars for the year quoted.

A particular feature of the book is a fairly extensive bibliography of some 5000 references. These references are consolidated at the end of the book rather than at the end of chapters, because many items are referred to in a number of chapters. Lists of selected references on particular topics are given in table form in the relevant chapters.

Certain institutions, however, have a rather large number of publications which it is more convenient to treat in a different manner. These are tabulated in Appendices 4[a] and 5[a], which contain some 2000 references. There is a cross-reference to the institution in the main reference list.

In many cases institutions and other organizations are referred to by their initials. In all cases the first reference in the book gives the full title of the organization. The initials may also be looked up in the Author Index, which gives the full title.

A reference is normally given by quoting the author and, in brackets, the date, e.g. Kletz (1971). Publications by the same author in the same year are denoted by letters of the alphabet a, b, c, etc., e.g. Allen (1977a), while publications by authors of the same surname and in the same year are indicated for convenience by an asterisk against the year in the list of references. In addition, the author's initials are given in the main text in cases where there may still be ambiguity. Where a date has not been determined this is indicated as n.d.

In the case of institutional publications listed in Appendices 4[a] and 5[a] the reference is given by quoting the institution and, in brackets, the date, the publication series, e.g. HSE (1965 HSW Bklt 34) or the item number, e.g. IChemE (1971 Item 7). For institutional publications with a named author the reference is generally given by quoting the author and, in brackets, the initials of the institution, the date and the publication series or item number, e.g. Eames (UKAEA 1965 Item 4).

The field of loss prevention is currently subject to very rapid change. In particular, there is a continuous evolution of standards and codes of practice and legislation. It is important, therefore, that the reader should make any necessary checks on changes which may have occurred.

I would like to thank for their encouragement in this project Professor D.C. Freshwater and the publishers, and to acknowledge the work of many authors which I have used directly or indirectly, particularly that of Dr J.H. Burgoyne and of Professor T.A. Kletz. I have learned much from my colleagues on the Loss Prevention Panel of the Institution of Chemical Engineers, in particular Mr T.A. Kantyka and Mr F. Hearfield, and on the Advisory Committee on Major Hazards, especially the chairman Professor B.H. Harvey, the secretary Mr H.E. Lewis, my fellow group chairmen

---

[a] Appendices 4, 5 and 12 in the first edition correspond to Appendices 27, 28 and 30, respectively, in this second edition.

Professor F.R. Farmer and Professor J.L.M. Morrison and the members of Group 2, Mr K. Briscoe, Dr J.H. Burgoyne, Mr E.J. Challis, Mr S. Hope, Mr M.A. McTaggart, Professor J.F. Richardson, Mr J.R.H. Schenkel, Mr R. Sheath and Mr M.J. Turner, and also from my university colleagues Dr P.K. Andow, Mr R.J. Aird and Dr D.J. Sherwin and students Dr S.N. Anyakora, Dr B. Bellingham, Mr C.A. Marpegan and Dr G.A. Martin-Solis. I am much indebted to Professor T.A. Kletz for his criticisms and suggestions on the text. My thanks are due also to the Institution of Plant Engineers, which has supported plant engineering activities at Loughborough, to the Leverhulme Trust which awarded a Research Fellowship to study *Loss Prevention in the Process Industries* and to the Science Research Council, which has supported some of my own work in this area. I have received invaluable help with the references from Mrs C.M. Lincoln, Mrs W. Davison, Mrs P. Graham, Mr R. Rhodes and Mrs M.A. Rowlatt, with the typing from Mrs E.M. Barradell, Mrs P. Jackson and, in particular, Mrs J. Astley, and with the production from Mr R.L. Pearson and Mr T. Mould. As always in these matters the responsibility for the final text is mine alone.

FRANK P. LEES
Loughborough,
1979

Acknowledgements

Many have helped with the long and tedious production process for this 3rd edition of ***Frank P. Lees Loss Prevention in the Process Industries***. However, I would be seriously remiss if I did not start with Frank P. Lees himself. I have always had great respect and admiration for Frank Lees, the engineer and the educator. After Frank passed away, and late in 2002, our mutual friend, Roy Sanders contacted me with a request from Frank's publisher to take up the job of editing the next version. I had no idea of the enormity of the task and Frank's accomplishment. I must say that this experience has truly humbled me and has given me a new respect and new appreciation for Frank Lees' knowledge, grasp, and mastery of the subject of safety and loss prevention. I am honored and privileged to be the editor of the 3rd edition of ***Frank P. Lees Loss Prevention in the Process Industries***. I have tried to maintain Frank's high standards and appreciate the help that many others have given me, but ultimately any *faux pas* or mistakes in the 3rd edition are all mine.

I want to thank all the people who have helped revise and update the chapters that were carried over from the 2nd edition. In this respect, I would like to mention A.A. Aldeeb, J.A. Alderman, P.C. Berwanger, C.A. Brown, S. Chervin, J. Cowling, W.F. Early, M. Gentile, J.P. Gupta, J.A. Havens, D.C. Hendershot, N. Keren, K. Krishna, S.H. Landis, M.E. Levin, P.N. Lodal, M.E. Livingston, S. Mohindra, D.A. Moore, T.M. O'Connor, S.W. Ostrowski, M. Paradise, J.A. Philley, W.J. Rogers, R.E. Sanders, S.R. Saraf, M.E Sawyer, R.L. Smith, T.O. Spicer, A.E. Summers, Y. Wang, H.H. West, J.L. Woodward, and J. Zanoni. Special thanks go to individuals who helped with the new chapters and appendices: J.A. Philley for the incident investigation chapter; J.P. Gupta and D.C. Hendershot for the inherently safer design chapter; S. Chervin, M.E. Levin, and W.J. Rogers for the reactive chemicals chapter; A.E. Summers for the safety instrumented systems chapter, D.A. Moore for the chemical security chapter and T.M. O'Connor for the new appendix on incident databases.

I also want to thank those who helped with research, literature review, galley proofing, and many other jobs without which such a project is never complete. I would like to specifically mention S. Anand, L.O. Cisneros-Trevino, W. Kowhakul, Y.-S. Liu, Y. Qiao, V. Raghunathan, S. Rajaraman, J. Suardin, M. Vidal, C. Wei, C. Zhang, and Y. Zhou. I would like to make specific mention of K.L. Potucek and L.J. Littlefield who undertook the painful task of converting the pdf files of the 2nd edition to Word format. I would like to thank M.A. Cass and D.K. Startz for administrative support and keeping things going through the long haul.

I would also like to take this opportunity to thank two individuals who have provided more than moral support and encouragement. They are Trevor Kletz and Mike O'Connor. First, I have appreciated Trevor's support for our work at the Mary Kay O'Connor Process Safety Center. I also want to thank him for his pioneering leadership in many areas of process safety. Trevor is really a giant in this field, and as Roy Sanders likes to say, "Trevor does cast a long shadow in the field of process safety." I am proud to have Trevor's friendship and his support. I also want to take this opportunity to thank Mike O'Connor. He has converted his personal tragedy into an opportunity to integrate process safety into education, research, and service activities at universities. He has been a true friend and supporter of the mission and goals of the Center.

I also want to thank Mrs. Elizabeth Lees for being kind, gracious, and helpful throughout this process. I am especially grateful for her hospitality and help during my visit to Loughborough to look through Frank's notes and books.

I am grateful to my mother for her love and everything she has done for me and continues to do. I am indebted to my father for having taught me the desire for learning. He was a humble man who truly believed that, "If you stop learning, you must already be dead." I would also like to thank my wife, Afroza, and our daughters, Joya and Rumki, for their love and support. Quite often a project of this magnitude causes the personal and family life to suffer and my wife and daughters have borne the brunt of it. I appreciate their understanding.

I am sure I have failed to mention everybody who has helped me with the many facets of this project. To them I apologize and want to assure them the oversight is not intended. To everyone who has helped put this 3rd edition together, I extend my heartfelt thanks and warmest gratitude again. I must say that you have helped in a noble cause, spread the word and disseminate information that will, we hope and pray, lead to a safer industry and society.

College Station,
Texas, USA
2004

Terminology

Attention is drawn to the availability in the literature of a number of glossaries and other aids to terminology. Some British Standard glossaries are given in Appendix 27 and other glossaries are listed in Table 1.1.

Notation

In each chapter a given symbol is defined at the point where it is first introduced. The definition may be repeated if there has been a significant gap since it was last used. The definitions are summarized in the notation given at the end of the chapter. The notation is global to the chapter unless redefined for a section. Similarly, it is global to a section unless redefined for a subsection and global to a subsection unless redefined for a set of equations or a single equation. Where appropriate, the units are given, otherwise a consistent system of units should be used, SI being the preferred system. Generally the units of constants are not given; where this is the case it should not be assumed that a constant is dimensionless.

Use of References

The main list of references is given in the section entitled References, towards the end of the book. There are three other locations where references are to be found. These are Appendix 27 on standards and codes; Appendix 28 on institutional publications; and in the section entitled Loss Prevention Bulletin which follows the References.

The basic method of referencing an author is by surname and date, e.g. Beranek (1960). Where there would otherwise be ambiguity, or where there are numerous references to the same surname, e.g. Jones, the first author's initials are included, e.g. A. Jones (1984). Further guidance on names is given at the head of the section References.

References in Appendices 27 and 28 are by institution or author. Some items in these appendices have a code number assigned by the institution itself, e.g. API (1990 Publ. 421), but where such a code number is lacking, use is generally made of an item number separated from the date by a slash, e.g. IChemE (1971/13). Thus typical entries are

API Std 2000: 1992	a standard, found in Appendix 27 under American Petroleum Institute
API (1990 Publ. 421)	an institutional publication, found in Appendix 28 under American Petroleum Institute
HSE (1990 HS(G) 51)	an institutional publication, found in Appendix 28 under Health and Safety Executive, Guidance Booklets, HS(G) series
Coward and Jones (1952 BM Bull. 503)	an institutional publication, found in Appendix 28 under Bureau of Mines, Bulletins

Institutional acronyms are given in the section Acronyms which precedes the Author Index.

There are several points of detail which require mention concerning Appendix 28. (1) The first part of the appendix contains publications of a number of institutions and the second part those of the Nuclear Regulatory Commission. (2) The Fire Protection Association publications include a number of series which are collected in the *Compendium of Fire Safety Data* (CFSD). A typical reference to this is FPA (1989 CFSD FS 6011). (3) The entries for the Health and Safety Executive are quite extensive and care may be needed in locating the relevant series. (4) The publications of the Safety and Reliability Directorate appear under the UK Atomic Energy Authority, Safety and Reliability Directorate. A typical reference is Ramskill and Hunt (1987 SRD R354). These publications are immediately preceded by the publications of other bodies related to the UKAEA, such as the Health and Safety Branch, the Systems Reliability Service and the National Centre for Systems Reliability.

References to authors in the IChemE *Loss Prevention Bulletin* are in the style Eddershaw (1989 LPB 88), which refers to issue 88 of the bulletin.

Introduction

Contents

Over the last three decades there has developed in the process industries a distinctive approach to hazards and failures that cause loss of life and property. This approach is commonly called loss prevention. It involves putting much greater emphasis on technological measures to control hazards and on trying to get things right the first time. An understanding of loss prevention requires some appreciation of its historical development against a background of heightened public awareness of safety, and environmental problems, of its relation to traditional safety and also to a number of other developments. Selected references on safety and loss prevention (SLP) are given in Table 1.1.

1.1 Management Leadership

By the mid-1960s, it was becoming increasingly clear that there were considerable differences in the performance of companies in terms of occupational safety. These disparities could be attributed only to differences in management. There appeared at this time a number of reports on safety in chemical plants arising from studies by the British chemical industry of the safety performance in the US industry, where certain US companies appeared to have achieved an impressive record. These reports included *Safety and Management* by the Association of British Chemical Manufacturers (ABCM) (1964, 3), *Safe and Sound* and *Safety Audits* by the British Chemical Industry Safety Council (BCISC) (1969, 9; 1973, 12). The companies concerned attributed their success entirely to good management and this theme was reflected in the reports.

1.2 Industrial Safety and Loss Trends

About 1970, it became increasingly recognized that there was a worldwide trend for losses, due to incidents, to rise more rapidly than gross national product (GNP).

This may be illustrated by the situation in the United Kingdom. The first half of this century saw a falling trend in personal incidents in British factories, but about 1960, this fall bottomed out. Over the next decade, very little progress was made; in fact there was some regression. Figure 1.1 shows the number of fatal incidents and the total number of incidents in factories over the period 1961–74. The Robens Committee on Health and Safety at Work, commenting on these trends in 1972, suggested that part of the reason was perhaps the increasingly complex technology employed by industry (Robens, 1972).

Another important index is that of fire loss. The estimated fire damage loss in factories and elsewhere in the United Kingdom for the period 1964–74 is shown in Figure 1.2.

1.3 Safety and Environment Concerns

There was also at this time growing public awareness and concern regarding the threat to people and to the environment from industrial activities, particularly those in which the process industries are engaged. Taking the United Kingdom as an illustration, the massive vapour cloud explosion at Flixborough in 1974 highlighted the problem of major hazards. This led to the setting up of the Advisory Committee on Major Hazards (ACMH) that sat from 1975 to 1983, and to the introduction of legislation to control major hazard installations. Likewise, there was a continuous flow of legislation to tighten up both on emissions

from industrial installations and on exposure of workers to noxious substances at those installations.

Similarly, in the United States, the Bhopal incident as well as other highly publicized tragedies (Flixborough, 1974; Seveso, 1976; Three Mile Island, 1979; Cubato, February 1984; Mexico City, November 1984; Houston, 1989) caused widespread public concerns about major incidents in US chemical plants that might disastrously affect the public. Not only was the public's confidence in the chemical industry shaken, but also the chemical industry itself questioned whether its provisions for protection against major accidental releases were adequate. The recognition of the chemical industry's need for technical advances led to a number of initiatives. For example, in 1985, the Chemical Manufacturers Association (CMA – now known as the ACC, the American Chemistry Council) published its guidelines on Process Safety Management and the American Institute of Chemical Engineers (AIChE) created the Center for Chemical Process Safety (CCPS) with significant financial support by industry. Over the next several years, many other

Figure 1.2 *Total fire losses in the UK, 1967–74 (Courtesy of the British Insurance Association)*

centers such as the National Institute for Chemical Safety, the National Environmental Law Center and the Mary Kay O'Connor Process Safety Center also came into existence. During this same period, the United States Environmental Protection Agency (USEPA) and the Occupational Safety and Health Administration (OSHA) of the United States Department of Labor started several technical initiatives aimed at gathering information about major accident risks.

It is against this background, therefore, that the particular problems of the process industries should be viewed. The chemical, oil and petrochemical industries handle hazardous substances and have always had to devote considerable effort to safety. This effort is directed both to the safe design and operation of the installations and to the personal safety of the people who work on them. However, there was a growing appreciation in these industries that the technological dimension of safety was becoming more important.

1.4 Loss Prevention-1

The 1960s saw the start of developments that have resulted in great changes in the chemical, oil and petrochemical industries. A number of factors were involved in these changes. Process operating conditions such as pressure and temperature became more severe. The energy stored in the process increased and represented a greater hazard. Problems in areas such as materials of construction and process control became more taxing. At the same time, plants grew in size, typically by a factor of about 10, and were often single stream. As a result they contained huge items of equipment, such as compressors and distillation columns. Storage, both of raw materials and products and of intermediates, was drastically reduced. There was a high degree of interlinking with other plants through the exchange of by-products.

The operation of such plants is relatively difficult. Whereas previously chemical plants were small and could be started up and shut-down with comparative ease, the start-up and shut-down of a large, single-stream plant on an integrated site is a much more complex and expensive matter. These factors resulted in an increased potential for loss – both human and economic. Such loss may occur in various ways. The most obvious is the major incident, usually arising from loss of containment and taking the form of a serious fire, explosion or toxic release. But loss due to such situations as delays in commissioning and downtime in operating is also important.

The chemical and oil industries have always paid much attention to safety and have a relatively good record in this respect. In the United Kingdom, for example, the fatal accident rate for the chemical industry has been about equal to that for industry generally, which in view of the nature of the industry may be regarded as reasonable. These are high technology industries and there has always been a strong technological element in their approach to safety. However, the increasing scale and technology of modern plants caused the chemical industry to re-examine its approach to the problem of safety and loss. If the historical development of this concern in the United Kingdom is considered, there are several problem areas that can be seen, in retrospect, to have given particular impetus to the development of loss prevention.

One of these is the problem of operating a process under extreme conditions and close to the limits of safety. This is usually possible only through the provision of relatively sophisticated instrumentation. About the mid-1960s, several such systems were developed. One of the most sophisticated, influential and well documented was the high integrity protective system developed by R.M. Stewart (1971) for the ethylene oxide process. About the same time many difficulties were being experienced in the commissioning and operation of large, single-stream plants, such as ethylene and ammonia plants, involving quite severe financial loss. On the design side, too, there was a major problem in getting value for money in expenditure aimed at improving safety and reducing loss. It was increasingly apparent that a more cost-effective approach was needed.

These developments did not take place in isolation. The social context was changing also and other themes, notably pollution, including effluent and waste disposal and noise, were becoming of increasing concern to the public and the government. In consequence, the industry was obliged to examine the effects of its operations on the public outside the factory fence and, in particular, to analyse more carefully the possible hazards and to reduce emissions and noise. Another matter of concern was the increasing quantities of chemicals transported around the country by road, rail and pipeline. The industry had to take steps to show that these operations were conducted with due regard to safety. In sum, by the 1970s, these problems became a major preoccupation of senior management. Management's recognition of the problems and its willingness to assign to their solution many senior and capable people as well as other resources has been fundamental in the development of loss prevention.

1995	USA – Risk Management Program regulation promulgated by USEPA; Texas A&M University established the Mary Kay O'Connor Process Safety Center

The existence of expertise in related areas has been of great value. In the United Kingdom, the UK Atomic Energy Authority (UKAEA), initially through its Health and Safety Branch and then through its Safety and Reliability Directorate (SRD) was able to advise on reliability assessment. Industry adopted UKAEA techniques in the assessment of major hazards and of protective instrumentation and data on failure rates. Many firms in the industry now have their own reliability engineers.

The historical development of loss prevention is illustrated by some of the milestones listed in Table 1.2. The impact of events has been different in different countries. Within the industry, loss prevention emerged as a theme of technical meetings which indicated an increasingly sophisticated technological approach. The Institution of Chemical Engineers (IChemE) established a Loss Prevention Panel which operates an information exchange scheme and publishes the *Loss Prevention Bulletin*. This growing industrial activity was matched in the regulatory sphere. The Robens Committee (1972) emphasized the need for an approach to industrial safety that is more adapted to modern technology, and recommended self-regulation by industry as opposed to regulation from outside. This philosophy is embodied in the Health and Safety at Work etc. Act 1974 (HSWA), which provides the framework for such an approach. However, the Act does more than this. It lays a definite statutory requirement on industry to assess its hazards and demonstrate the effectiveness of its safety systems. It is enforced by the Health and Safety Executive (HSE). The General Duty Clause requirements under US regulations enforced by OSHA and USEPA have been interpreted similarly.

The disastrous explosion at Flixborough in 1974 has proved a watershed. Taken in conjunction with the Act, it has greatly raised the level of concern for SLP in the industries affected. It also led, as mentioned, to the setting up of the ACMH. The incident at Seveso in 1976 has been equally influential. It had a profound impact in Continental Europe and was the stimulus for the development of the EC Directive on Control of Industrial Major Accident Hazards in 1982. Further disasters such as those at San Carlos, Bhopal and Mexico City have reinforced these developments.

1.5 Large Single-stream Plants

For some decades up to about 1980, there was a strong trend for the size of plants to increase. The problems associated with large, single-stream plants are a major reason for the development of loss prevention. These problems are now considered in more detail in order to illustrate some of the factors underlying its growth. Selected references on large, single-stream plants are given in Table 1.3.

The increase in the size of plant in the period in question for two principal chemicals is shown in Figure 1.3, which gives the size of the largest ethylene and ammonia plants built by a major contractor and the year in which they came on stream. Thus, whereas in 1962 an ethylene plant with a capacity in excess of 100,000 ton/year was exceptional, by 1969 this had become the minimum size ordered, whilst the newest UK plant, the No. 5 Unit of Imperial Chemical Industries (ICI), had a capacity of 450,000 ton/year. Although briefly the largest single-stream naphtha cracker in the world, it was soon overtaken by other plants of 500,000 ton/year capacity or more. Similar trends occurred in ammonia plants.

This increase in plant size took place in a rapidly expanding market. Thus, the growth in world demand for

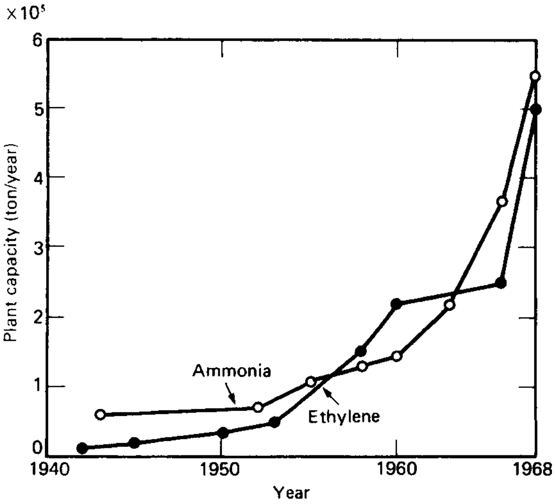

Figure 1.3 *Capacity of ethylene and ammonia plants, 1940–68 (after Axelrod, Daze and Wickham, 1968) (Courtesy of the American Institute of Chemical Engineers)*

ethylene was given as follows (Walley and Robinson, 1972):

1965	8.5 megatonnes/year
1970	20 megatonnes/year
1975 (estimated)	39 megatonnes/year

The basic cause of the increase in size was concern for capital cost. Up to the early 1950s, the chemical industry did not give minimization of capital cost particular priority. But with the move to naphtha feedstocks and the growth of petrochemicals, capital came to represent a much more significant cost than before compared with other costs such as raw materials and labour.

The relationship between size and capital cost is given by the well-known equation:

$$C = kP^n \tag{1.5.1}$$

where C is the capital cost of the plant, P its design output, k is a constant, and n is the scale-up index. The value of n is often about 0.6–0.7 so that if design output is doubled, the capital cost increases by only 50–60%. There are also some savings on operating costs, particularly in terms of the thermal economy and labour.

Most calculations of the savings obtainable by building big showed the savings to be large; therefore, it was difficult in a competitive industry to avoid doing so, despite the recognized risks. The world price tended to be set by the larger plants, so that smaller plants became obsolete. Although calculations showed savings from large plants, there was considerable variation in the size of these savings, depending on the assumptions made. One figure given was a reduction in the cost of ethylene to about 50% in going from a 150,000 to a 450,000 ton/year plant (Holroyd, 1967); another calculation gave a reduction to about 80% in going from a 200,000 to a 400,000 ton/year plant (Lofthouse, 1969).

The calculation depends on many factors and is complex. This is particularly so for ethylene, which is only one of a number of products from an ethylene plant. The values of the propylene and butadiene produced were each about as great as that of the ethylene. Much therefore depended on whether these and other by-products could be sold at full or only at fuel value. A typical calculation of the effect of plant size and co-product credit on the economics of an ethylene plant at that time is shown in Table 1.4.

Another important factor for an ethylene plant is the acquisition of load. The best situation is where the ethylene is taken away by gas pipeline. The alternative of sea transport, which involves liquefaction, is more expensive and may well cancel the cost advantage of a large plant. However, ethylene pipelines are difficult to justify except where there is a long-term contract, and it is not easy to create an ethylene grid into which other users can tap.

The economics of a large plant are also badly affected if it fails to reach full output immediately, either on account of commissioning difficulties or of lack of demand. A typical calculation of the effect of plant size, lateness and underloading on ammonia plant economics is shown in Table 1.5.

Despite these problems, the general assessment around, say, 1966 was that the building of large plants was justified. However, there continued to be a lively debate as to whether the expected economies of scale were realizable. Several difficulties became apparent. The economies of scale depend very largely on the retention of the single-stream philosophy. This gives economies not only in the cost of the equipment itself but of the associated pipework, heat exchangers, instrumentation, civil engineering etc. These are largely lost if there is resort to duplication. However, in some cases, the equipment appeared to be nearing the limits of size. This had long been so for the furnaces on an ethylene plant, which typically had multiple furnaces with outputs of about 30,000 ton/year. The main compressor was very large – that on ICI's No. 5 plant being 35,000 h.p. The main distillation column was also very big and had to be fabricated on site.

At large sizes, the value of the scale-up index n is subject to some modification. A common value of n for ethylene plants was 0.65 (Lofthouse, 1969). However, as already mentioned, the cracking section of the plant, which accounts for about 30% of the capital cost, offers little scope for scale-up economies. Other items, such as compressors, distillation columns and heat exchangers, may be near their limits and may have a higher index. Some facilities such as storage and effluent control may even have an index greater than 1.0. Thus, it was suggested (Walley and Robinson, 1972) that a more realistic actual value of n is 0.9.

Storage is a serious problem with large plants. For the size of plant described, storage, whether of raw materials or products, is extremely expensive and has to be kept to a minimum.

The reliability of large plants was often unsatisfactory, there being a number of reasons for this. Compact layout made maintenance more difficult and increased the vulnerability to fire. Arrangements aimed at thermal economy increased the degree of interdependence in the plant. Economies were made in capital cost in areas such as materials of construction and duplication of equipment. As Holroyd (1967) comments:

> Faulty welding has resulted in leaky high pressure piping systems and there has been little improvement as regards jackets, dinners, and footballs left in equipment despite the much more serious effect this sort of thing has in high cost, high capacity single plant units. There have been many examples of faulty equipment – faulty fabrication of interchangers, improper assembly of compressors and high-pressure reactors which have failed under test. Complete shut-down of the plant due to failure of a simple piece of equipment, such as a pump of established design, and of negligible cost in itself, has been a frequent experience. Faulty supervision and human error in operation has shown up in not following the proper sequence of actions in emergencies, inadvertent tripping out of machines, failure to isolate equipment under maintenance and carelessness in checking instruments and with regard to such matters as water treatment.

Table 1.4 *Effects of plant size and co-product credit on ethylene plant economics (after Walley and Robinson, 1972)*

Plant size (ton/year)	200,000	300,000	400,000	500,000
Plant capital (£m.)	25.0	33.0	40.0	47.0
Working capital (£m.)	2.0	2.9	3.8	4.6
Capital charge (£/ton ethylene)	33.5	29.8	27.5	25.9
Fixed costs	9.3	7.7	6.8	6.2
Feedstock	30.5	30.5	30.5	30.5
Fuel, utilities, catalysts	*8.6*	*8.6*	*8.6*	*8.6*
	81.9	76.6	73.4	71.2
Co-product credit (£/ton ethylene)	34.2	34.2	34.2	34.2
Ethylene cost (£/ton)	47.7	42.4	39.2	37.0
Co-product credit (£/ton ethylene)	34.2	29.1	26.6	25.1
Ethylene cost (£/ton)	47.7	47.5	46.8	46.1

As a result of such factors, there were many cases of difficulties and delays in commissioning and operation of such plants throughout the world. A breakdown of the causes of such problems in ammonia plants is given in Table 1.6.

Large plants also have some undesirable features from the safety point of view. Particularly significant is the scale of the inventory. The amount of material in the main distillation column of a large ethylene plant exceeds that formerly contained in the storage vessels of smaller plants.

Problems of pollution and noise, including flares and pressure relief, also appear to increase in severity rather rapidly for large plant sizes. Some more specific faults on ammonia plants have been quoted (Holroyd, 1967). One of these, migration of silica under the more severe operating conditions, is a matter of advanced technology. Most of the others are more mundane.

It is not surprising, therefore, that the trend to large-scale plants was criticized and the economies of scale questioned. The debate was particularly lively over the period 1967–72. Even at the start of the debate, the large, single-stream plant

Table 1.5 *Effects of plant size, lateness and underloading on ammonia plant economics (after Holroyd, 1967)*

Equipment	40	61
Operating	30	13

had its defenders (Holroyd, 1967; Lofthouse, 1969). The cost sensitivity and other problems of large plants were admitted. It was also conceded that the economies of scale were not as great as initial estimates suggested. But these factors were not considered sufficient to negate the economies of large plants or to make the return to small ones appear attractive.

It was agreed that part of the problem was that the increase in size of plants had been accompanied by a drive to reduce capital costs which may have been taken too far:

> This drive took many other forms besides increase of scale. It tended to lead to elimination of duplicates of even minor items of plant, to economies which sometimes proved to be false economies in the provision of services such as steam and power, to extreme sophistication in energy recovery which sometimes added so much to the complexity of the plants as to make them difficult to run, and to the concentration of the plant within very much smaller areas which increased their vulnerability to fire and also complicated maintenance. (Lofthouse, 1969)

Moreover, it was reasonable to claim that the industry had already learnt much from the troubles of the first generation of large plants and that it would be able to avoid many of these in the future.

In effect, the argument was that failures in large plants were not primarily due to the size of items of equipment, the single-stream arrangement or the use of high technology. It was conceded, however, and indeed emphasized, that the penalties of failures on large, single-stream plants are very great and that it is essential for their success to put maximum effort into ensuring high reliability and good operation. Particular emphasis was laid on the effectiveness of the operation and maintenance in large plants. Here the main factor is the quality of personnel at all levels: management, process operators and maintenance crews. Close supervision and rigorous inspection have an important part to play, but are no substitute for well-educated and well-trained people.

The large, single-stream plant offers substantial rewards for success, but this does not come easily. It can be achieved only by first class management and engineering in design and operation. The large plant places a premium on these factors and is thus a means by which a firm that possesses them gains a competitive advantage.

The growth in the size of plants has now slowed appreciably. The typical size of a new ethylene plant in 1978 was about 500,000 ton/year. This is still typical for a new plant worldwide. A plant for 700,000 ton/year still ranks among the largest plants (Mahoney, 1990). There is no marked trend to yet larger plants, but equally there is little sign of reversion to smaller ones. However, consequent to widespread interest in inherent safety and security concerns, process intensification and miniaturization are starting to receive some renewed interest. The results of this renewed interest are yet to be seen.

1.6 Loss Prevention-2

The area of concern and the type of approach which goes by the name of loss prevention is a development of safety work. But it is a response to a changing situation and need, and it has certain particular characteristics and emphases. The essential problem which loss prevention addresses is the scale, depth and pace of technology. In fact, control of such hazards is possible only through effective management. The primary emphasis in loss prevention is, therefore, on the management system. This has always been true, of course, with regard to safety. But high technology systems are particularly demanding in terms of formal management organization, competent persons, systems and procedures, and standards and codes of practice. On top of all of this, there is a growing realization that safety performance is quite often influenced by the safety culture of the company. The 2003 Columbia shuttle disaster and the following investigation report brings to light some of NASA's safety culture issues that may have doomed Columbia as well as Challenger.

According to Mannan (2003a), perhaps we should pay more attention to safety culture. One school of thought is that safety culture even though a very important issue is not a specific problem of process safety or loss prevention. However, it seems there is a special set of problems that go along with extreme events and the associated risks. Before the event there is great confidence that such a thing could never happen. Afterward there is denial and no cultural change occurs. This may be true of NASA as well as some process companies as well. What are the attributes of a good safety culture? How do organizations accomplish a good safety culture and maintain it over the life of the organization? How can the safety culture survive through changing leaderships, turnovers, budget pressures, early retirements and other changes? How can we get organizations that do not have a good safety culture make the necessary changes to move towards a good safety culture? These are questions that should be answered.

Mannan (2003a) goes on to describe the investigation of one incident where everyone involved felt that they had done everything they were supposed to do and the incident was just something that was beyond anyone's control. In fact, a few people in the organization even claimed that if the same set of circumstances were to happen again, the same incident would occur again, possibly with the same consequences. Now, that is a safety culture that needs major overhaul.

Mannan (2003b) states that there are a number of attributes of a good safety culture. It is quite difficult to identify objective characteristics of a good safety culture. However, some known characteristics include:

(1) Commitment AND involvement of the highest level personnel.
(2) Open communication at all levels of the organization.
(3) Everyone's responsibilities and accountabilities regarding safety is clearly defined and understood.
(4) Safety is second nature.

(5) Zero tolerance for disregard of management systems, procedures and technology.
(6) Information systems allow all parties access to design, operational and maintenance data.

As part of a multi-layered approach for a good safety culture, organizations use analysis of trends to spot problems. Trend analysis should be focused on leading as well as trailing indicators. A trailing indicator is a downstream measurement of the outcomes of safety and health efforts. These indicators reflect successes or failures of the system to manage hazards. Examples of trailing indicators include fatalities, injuries and incidents. A leading indicator is an upstream measure that characterizes the level of success in managing safety systems; measurement of activities towards risk reduction prior to occurrence of incidents. While every effort should be made to measure and track trailing indicators, relying on the trailing indicators to assess safety performance is self-defeating. Thus, it is very important to measure and track leading indicators, particularly for high-risk activities such as space flight. Leading indicators, however, are more difficult to define and measure and vary according to the activity and the mission of the organization. Examples of leading indicators might include:

(1) the level of near-miss reporting;
(2) effectiveness of incident investigation and corrective action;
(3) management of change;
(4) emphasis on inherently safer design;
(5) effective application of risk assessments;
(6) level of deferred maintenance;
(7) Level of repetitive maintenance;
(8) Number and severity of faults detected by inspection, testing and audits;
(9) Number and nature of unresolved safety issues;
(10) Participation in continuing education and symposia;
(11) Employee morale, level of expertise.

The method of approach is also somewhat different. When systems are small scale and relatively non-hazardous and change slowly over the years, they are able to evolve by trial and error. This is often simply not possible with modern systems, where the pace of change is too fast and the penalties of failure are too great. It becomes necessary to apply forethought to try to ensure that the system is right the first time. In a related area, the widespread application of human factors to large man–machine systems has been motivated by very similar considerations. A major hazard in a modern process plant usually materializes due to loss of containment. The three big major hazards are fire, explosion and toxic release.

Thus, loss prevention is characterized by

(1) an emphasis on management and management systems, particularly for technology;
(2) a concern with hazards arising from technology;
(3) a concern with major hazards;
(4) a concern for integrity of containment;
(5) a systems rather than a trial-and-error approach.

Some other features that are characteristic of loss prevention are the use of

(6) techniques for identification of hazards;
(7) a quantitative approach to hazards;
(8) quantitative assessment of hazards and their evaluation against risk criteria;
(9) techniques of reliability engineering;
(10) the principle of independence in critical assessments and inspections;
(11) planning for emergencies;
(12) incident investigation;

together with

(13) a critique of traditional practices or existing regulations, standards or codes where these appear outdated by technological change.

The identification of hazards is obviously important, since the battle is often half won if the hazard is recognized. A number of new and effective techniques have been developed for identifying hazards at different stages of a project. These include hazard indices, chemicals screening, hazard and operability studies, and plant safety audits.

Basic to loss prevention is a quantitative approach, which seeks to make a quantitative assessment, however elementary. This has many parallels with the early development of operational research. This quantitative approach is embodied in the use of quantitative risk assessment (QRA). The assessment produces numerical values of the risk involved. These risks are then evaluated against risk criteria. However, the production of numerical risk values is not the only, or even the most important, aspect. A QRA necessarily involves a thorough examination of the design and operation of the system. It lays bare the underlying assumptions and the conditions that must be met for success, and usually reveals possible alternative approaches. It is therefore an aid to decision-making on risk, the value of which goes far beyond the risk numbers obtained.

Reliability engineering is now a well-developed discipline. Loss prevention makes extensive use of the techniques of reliability engineering. It also uses other types of probabilistic calculation that are not usually included in conventional treatments of reliability, such as probabilities of weather conditions or effectiveness of evacuation. Certain aspects of a system may be particularly critical and may require an independent check. Examples are independent assessment of the reliability of protective systems, independent audit of plant safety and independent inspection of pressure vessels.

Planning for emergencies is a prominent feature of loss prevention work. This includes both works and transport emergencies.

Investigation of incidents plays an important part in loss prevention. Frequently there is some aspect of technology involved. But the recurring theme is the responsibility of management. While a good safety culture varies according to the mission and activities of the organization, one of the attributes of a good safety culture that is a 'must' is 'learning from incidents'. There is no excuse when 'lessons learned' from incidents are ignored or not implemented, particularly 'lessons learned' from incidents that have occurred in one's own organization or incidents that are widely publicized.

The loss prevention approach takes a critical view of existing regulations, standards, rules or traditional practices where these appear to be outdated by changing technology. Illustrations are criticisms of incident reporting requirements and of requirements for protection of pressure vessels. These developments taken as a whole do constitute a new approach and it is this which characterizes loss prevention.

It might perhaps be inferred from the foregoing that the problems which have received special emphasis in loss prevention are regarded somehow as more important than the aspects, particularly personal incidents, with which traditionally safety work in the process industries has been largely concerned. Nothing could be further from the truth. It cannot be too strongly emphasized that mundane incidents are responsible for many more injuries than and as many deaths as those arising from high technology.

1.7 Total Loss Control

It is now necessary to consider some other developments that have contributed to the modern approach to SLP. The first of these is total loss control. The basic concept underlying total loss control is that loss due to personal incident and injury is only the tip of the iceberg of the full loss arising from incidents. It follows that attention should be paid, and controls applied, to all losses. Early work in this area is described in *Industrial Accident Prevention* (Heinrich, 1959) and by Bird (1966). Accounts are given in *Total Loss Control* (G.A. Fletcher and Douglas, 1971) and *Practical Loss Control Leadership* (Bird and Germain, 1985).

Total loss control, like loss prevention, is concerned with losses associated with hazards and incidents or other incidents. It is not concerned with losses that do not have a hazard element. It may be seen, therefore, as an extension of the activity of the safety manager. The attraction of such a change of emphasis is that the safety manager becomes involved in a major cost area that is of concern to other managers and thus increases his influence, with consequent benefit to safety.

The ratio between different types of incidents is a key concept in loss control. Early work on this was done by Heinrich (1959), who gave the following ratio for the different types of incidents:

Major or lost time injury/Minor injury/No injury = 1 : 29 : 300

These ratios are frequently shown in the form of the incident pyramid illustrated in Figure 1.4.

The numbers of incidents on which the above ratios were based were evidently fairly limited. Later studies have been done involving much larger numbers. Bird and Germain (1985) report a study of some 1.75 million incidents from 297 cooperating organizations in which the ratio was:

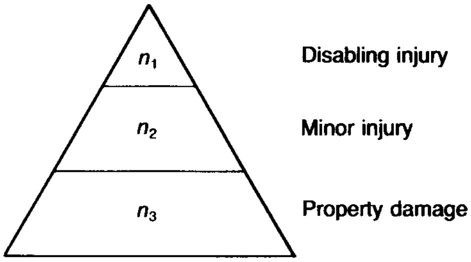

Figure 1.4 *The accident pyramid (after Bird and Germain, 1966)*

Disabling injury/Minor injury/Property damage/No injury or damage = 1 : 10 : 30 : 600

Tye and Pearson (HSE, 1991b) give the results of an investigation of almost 1 million incidents:

Disabling injury/Minor injury/First-aid injury/Property damage/No injury or damage = 1 : 3 : 50 : 80 : 400

The incident definitions and ratios tend to vary between different studies, but the relationship between the different kinds of event is usually consistent in a given study.

In another study, *The Costs of Accidents at Work* (HSE, 1993a), an investigation was made of incidents at a creamery, a construction site, a transport company, a hospital and an oil platform. For the oil platform, the most relevant here, the ratios obtained were as follows (the values given in parentheses being those for all the studies except the construction site):

Over 3-day injury/Minor injury/Non-injury incident = 1 : 4(7) : 126(189).

Another ratio quoted by Heinrich is the ratio of uninsured to insured costs of incidents, which he gives as about 4 : 1. However, J.A. Fletcher and Douglas (1971) report studies in which this ratio ranges from 2.3 to 101 and suggest that it is necessary to investigate this in any particular work places.

In another recent study in the United States, Mannan *et al.* (2001) reported the statistics on 34,527 incidents for 1998 in all of United States. According to this study, the incidents were distributed in the following ratio:

Fatalities/Serious injury/Minor injury/No injuries = 1 : 7 : 44 : 300.

In the same study mentioned above, Mannan *et al.* (2001) concluded that the underlying causes for incidents are usually the same regardless of which part of the pyramid the incident falls in. In other words, an incident that causes no injury and is classified in the lower part of the pyramid could easily have been classified in the top part of the pyramid. Consider, for example, a gas release that occurs when the wind speed and wind direction are such that the gas disperses before it can encounter an ignition source. The incident would then be classified as a near-miss falling in the lower part of the incident pyramid. But, now consider the same gas release that occurs when the wind speed and wind direction are such that the gas encounters a nearby ignition source. The situation could be more aggravated if nearby workers are knocked down or thrown against concrete walls or equipment. The event could likely lead to injuries or fatalities. Thus, it seems that the same learning could be developed and captured into the procedures and training by analysing and investigating the near-miss. Thus, the broader the incident definition, the more statistically sound the lessons from the incident analysis. In fact, it would seem that as safety programmes mature, the incident definition should be expanded to include not only near-misses but also other leading indicators as well.

An illustration, given by Fletcher and Douglas, of a typical situation in a medium sized factory is shown in Table 1.7 The actual numbers of disabling and minor injury incidents were as indicated, while the number of property damage

Table 1.7 *Losses in a medium sized factory (after J.A. Fletcher and Douglas, 1971) (Courtesy of Associated Business Programmes Ltd)*

Type of incident	*No. of uninsured per year*	*Cost per accident* (US$)	*Total incidents cost* (US$)
Disabling injury	71	52	3,692
Minor injury	10,122	3.86	39,032
Property damage (est.)	35,500	34.67	1,230,794
Total			1,273,518

incidents was computed from the number of disabling incidents using Bird's ratio of 500. In this case, the insured costs were the workmen's compensation costs of US$208,300, while, as shown, the uninsured costs were US$1,273,518, of which the major part was property damage costs. The ratio of uninsured to insured costs was about 6.1.

The relative importance of the damage costs is enough to justify paying attention to damage incidents. But there is the further point that assessment of such costs is straightforward compared with the assessment of injury costs, which frequently involves some rather dubious assumptions. The policy suggested, therefore, is one of monitoring not only injury incidents but also damage incidents. For this it is necessary to have damage control centres that give general information on damage incidents in much the same way as first-aid points and medical centres generate information on injury incidents. The existing maintenance system can normally be adapted for this purpose. As an illustration of the application of such a policy, J.A. Fletcher and Douglas (1971) describe a study on the reporting of damage incidents by crane drivers. In the 3 years prior to the institution of the policy, the number of damage incidents reported was rather less than 25 per year. During the 10 years after its institution, some 1643 incidents per year were reported. Reporting was enforced with an average of nine warnings and three work suspensions per year. Although many incidents were of a minor nature, many others revealed the need for prompt action to avert a more serious incident.

Total loss control areas are listed as: (1) business interruption, (2) injury, (3) property damage, (4) fire, (5) security, (6) health hygiene, (7) pollution and (8) product liability. Each of these areas is treated as follows:

(1) identification – of possible loss producing situations;
(2) measurement – of such losses;
(3) selection – of methods to minimize loss;
(4) implementation – of methods within the capability of the organization.

The application of total loss control in the chemical industry has been described by Webster (1974), Hearfield (1975) and Ling (1976, 1979).

In the company described by Hearfield, incidents reported in 1 year on a particular plant cost about £25,000, including consequential losses. It was estimated that if all the unreported incidents had been included, this figure might have been double. A total loss control programme was instituted, which revealed that the estimated loss in the works was about £350,000. One source of loss on the plant was associated with steam condensate systems. Following an incident involving condensate, a full plant investigation of the use of condensate and demineralized water was undertaken. A 20% deficiency in the demineralized water balance was reported. It was found that the orifice plate was completely missing from one of the water flowmeters. The investigation was extended to the works. Expenditure of £40,000 was incurred on pipework and instrumentation modification. In the first year of operation, savings of £130,000 were made due to reduced consumption of demineralized water, and capital expenditure of £200,000 on new demineralization plant was deferred.

1.8 Quality Assurance

Another development that shapes the modern approach to SLP is quality assurance and total quality management (TQM). Methods of ensuring that a product meets the required quality standards are the province of quality control and quality assurance. The first of these terms in particular tends to be used with different meanings.

Quality control of products has long been standard practice in a range of industries, from those manufacturing cars to those making ice cream. In many cases, the emphasis in such quality control has traditionally been on inspection of the product.

The creation of systems to ensure that the product meets the required standards is the role of *quality assurance*. These systems are applied not only to the intermediate and final products made within the company but also to the inputs, raw materials and products purchased from outside, since unless these meet their specifications, it may be impossible for the company to meet its own quality standards.

The 1980s have seen a strong movement in industry worldwide to adopt quality assurance systems and to seek accreditation to a recognized standard. The international standard is ISO 9000 and the corresponding British Standard is BS 5750:1987:Quality Systems. As just indicated, a move by one firm to seek accreditation creates a chain reaction that obliges its suppliers to do likewise. Adoption of quality assurance involves the creation, and documentation, of a set of systems designed to ensure quality outputs from all the activities of the company.

1.9 Total Quality Management

A related, but not identical, development is TQM. The concept underlying TQM is that the problem of failures and their effects has an influence on company performance that is far greater than is generally appreciated, defining failure in a broad way. TQM has its origins in quality control on production lines. It has spread to industry generally, including the process industries.

Most accounts of TQM highlight the role played by a number of individuals who have been influential in its development. Some principal texts are *Quality is Free* (Crosby, 1979), *Quality Control Handbook* (Juran, 1979), *Quality Planning and Analysis* (Juran and Gryna, 1980), *Quality, Productivity and Competitive Position* (Deming, 1982) and *Out of the Crisis* (Deming, 1986). An overview, including an account of the different schools, is given in *Total Quality Management* (Oakland, 1989).

The TQM approach has been pioneered in Japan, particularly in the motor industry. Accounts of the Japanese approach are given by Ishikawa Kaoru (1976, 1985), Taguchi (1979, 1981) and Singo Shigeo (1986).

In many countries, industry is well advanced with the adoption of TQM concepts. Worldwide this typically involves implementation of the requirements of ISO 9000. Guidance on this process is given in ISO 9000 (P.L. Johnson, 1993). In the United Kingdom, the relevant standard to which organizations are accredited is BS 5750 : 1987. Guidance is given in *Implementing BS 5750* (Holmes, 1991). A guide to the associated audit is *Quality Management System Audit* (C.A. Moore, 1992).

As stated earlier, the basic concept of TQM is that failures of various kinds have effects which are much more widespread, damaging and costly than has been generally appreciated. Failures have effects both internal and external to the company. The internal effects experienced by the company include loss of production, waste of materials, damage to equipment and inefficient use of manpower. The external effects experienced by the customer include the same features. Failures undermine the competitiveness of both parties.

The starting point in tackling this problem is to review the product that is required and the system that is to produce it. The requirement for the product is 'fitness for purpose'. In determining fitness for purpose, it is necessary to consider both the effectiveness of the product while it is operating and its reliability of operation. In order to achieve fitness for purpose, it is necessary to ensure that the design of the product is suitable and that the product made conforms to that design. These are two separate aspects and success depends on getting them both right. It is of little use to make a product that conforms well with the design if the design is defective, or to make a product that has a good design but which is produced in such a way that it does not conform to that design.

Given a product that is well designed, it is necessary to consider the system that will deliver conformability to the design. Traditionally, industry has placed much emphasis on an approach to quality control based on inspection. The approach taken in TQM is radically different. The attempt to inspect quality into an inherently defective production process is regarded as ineffective. Instead, the emphasis is on prevention. The basic question asked therefore, is whether the production process is actually capable of producing to the quality required. In many cases it has been concluded that it was not. Attempts were being made to deal with the situation by intensifying the inspection effort, attempts that were largely futile.

The spirit of the TQM approach has been summarized in *Right First Time* (F. Price, 1985) as:

(1) Can we make it OK?
(2) Are we making it OK?
(3) Have we made it OK?
(4) Could we make it better?

The TQM approach seeks to root out failures in all aspects of the company's operation, not just failures of equipment but also in all aspects of the company's operation, including systems, documentation, communications, purchasing and maintenance. TQM is therefore concerned with both products and activities. In assessing the quality of a product or activity, it seeks to identify the 'customers' and to make sure that their requirements are properly defined and met. An important technique for reducing failures is the involvement of the workforce, who are encouraged to not allow failures to persist but to report them and make proposals for their elimination.

The prime responsibility for TQM lies with management, and management leadership is essential to its success. It is management that is responsible for the necessary features such as organization, personnel, systems, design, planning and training. All employees are involved, however, in dealing with failure. An important part of TQM, therefore, is the involvement and motivation of the workforce. The quality circles (QCs) developed in Japan are an example of this. Another aspect of TQM is the 'just-in-time' (JIT) approach developed in Japan, notably in the motor industry. Each section of the production line operates with little or no inventory of input components, but takes them as required from the upstream supplier. This system requires an intolerance of failure, with rapid detection and rectification.

One way of expressing this intolerance is to adopt 'zero defects' as the performance standard, as advocated by Crosby (1979). In the variant of TQM given by Crosby, the overall approach adopted is summarized as:

Definition	Conformance to requirements
System	Prevention
Performance standard	Zero defects
Measurement	Price of non-conformance

It will be apparent that, insofar as the process industries are concerned, this emphasis on, and intolerance of, failures constitutes an approach very close to that of loss prevention.

Accounts of the relationship between quality management and management of safety, health and environment have been given by Berkey, Dowd and Jones (1993), Rooney, Smith and Arendt (1993) and Olsen (1994).

1.10 Risk Management

Another related development is that of risk management. Any industrial project involves risk. But some of the developments described above, such as the increase in the technological dimension and the growth of public concern over safety and pollution, have tended to introduce further dimensions of unpredictability. Risk management addresses these latter risks and provides a means of assessing and managing them along with the normal commercial risks.

Accounts of risk management are given in *Managing Risks* (Grose, 1987), *Risk Management* (Jardine Insurance Brokers Ltd, 1988), *Managing Risk* (Bannister, 1989), *Risk Assessment and Risk Management for the Chemical Process Industry* (Greenberg and Cramer, 1991) and *Reliability, Safety and Risk Management* (S.J. Cox and Tait, 1991), and by Turney (1990a,b) and Frohlich and Rosen (1992b).

The variety of risks and the vulnerability of a business to these risks is now such that they need to be managed explicitly. Individual risks are recognized by line managers, but are frequently not fully addressed by them. There is a tendency to defer consideration and to take too optimistic a view. In any case, the individual line manager sees only part of the picture. It is for such reasons that risk management has emerged as a discipline in its own right. A systematic review of hazards is now normal practice in the management of projects in the process industries. A complementary system for the review of the totality of risks (commercial, legal and technological) is increasingly common.

1.11 Safety-critical Systems

Another concept that is gaining increasing prominence is that of safety-critical systems. These are the systems critical to the safe operation of some larger system, whether this be a nuclear power station or a vehicle. In a modern aircraft, particularly of the fly-by-wire type, the computer system is safety critical. An account of safety critical systems is given by P.A. Bennett (1991a,b).

1.12 Environment

Another major concern of the process industries is the protection of the environment. Developments in environmental protection (EP) have run in parallel with those in SLP. These two aspects of process plant design and operation have much in common. In recent years, there has been a trend to assign to the same person responsibilities for both. There are also some situations where there is a potential conflict between the two. The environment, and pollution of the environment, are considered in Appendix 11.

1.13 Professional Institutions and Bodies

The professional engineering institutions have responded to the problems described above with a number of initiatives.

1.14 Responsible Care

In a number of countries, the chemical industry has responded to safety, health and environmental concerns with the Responsible Care initiative, which was developed in the early 1980s by the Canadian Chemical Producers Association and was then taken up in 1988 in the United States by the ACC, in 1989 in the United Kingdom by the Chemical Industries Association (CIA), and elsewhere.

Companies participating in Responsible Care commit themselves to achieving certain standards in terms of safety, health and environment. Guidance is given in *Responsible Care* (CIA, 1992 RC53) and *Responsible Care Management Systems* (CIA, 1992 RC51). An account of the development of Responsible Care is given by Jacob (1992). The Canadian perspective is described by Buzzelli (1990) and Creedy (1990).

As stated earlier, in 1973, the IChemE created a Loss Prevention Panel. The Institution itself publishes a range of monographs and books on SLP and the panel publishes the Loss Prevention Bulletin and a range of aids for teaching and training.

In 1985, the AIChE formed the CCPS. The Centre publishes a series of guidelines on SLP issues.

At the European level, the European Process Safety Centre (EPSC) was set up in 1992 to disseminate information on safety matters, including legislation, research and development, and education and training (EPSC, 1993).

The work of these and other bodies is described in Chapter 27. Much of the material referred to in this book derives from these sources.

1.15 Academic and Research Activities

Over the years, academic and research activities aimed at process SLP have ebbed and flowed. However, lately these activities are becoming more formalized. Engineering departments in various universities throughout the world have begun to realize the importance of the subject and the significant role they can play in educating the students and the solution of industry problems through fundamental research. Many universities in the United States, United Kingdom, elsewhere in Europe, Japan, Korea, and other countries now offer specialized courses, certificate programmes, and degree programmes on process SLP. In some universities, for example Texas A&M University and University of South Carolina, process safety courses instead of being optional electives are now part of the required core curriculum. University professors and researchers are also dedicating extensive efforts towards research topics on process SLP. With regard to academic and research activities, the Mary Kay O'Connor Process Safety Center at Texas A&M University is a classic example of a comprehensive academic and research programme dedicated to education, research and service activities on process SLP.

1.16 Overview

The modern approach to the avoidance of injury and loss in the process industries is the outcome of the various developments just described. Central to this approach is leadership by management, starting with senior management, and creation of a safety culture that provides the appropriate environment for reduction of incidents and improvement of safety performance. Such leadership and safety culture are indispensable conditions for success. They are not, however, sufficient conditions. Management must also identify the right objectives. The contribution of total loss control, quality assurance and TQM is to identify as key management objectives the elimination of failures of all kinds and the conduct of activities so that they are satisfactory to those affected by them. These disciplines provide in QCs a tool for meeting these objectives.

As far as the process industries are concerned, it is the contribution of loss prevention to handle the technological dimension and to provide methods by which failure is eliminated. In the modern approach to SLP, these themes come together. The ends are the safety of personnel and the avoidance of loss. The means to achieve both these aims is leadership by management, informed by an understanding of the technology and directed to elimination of failures of all kinds.

2

Hazard, Incident and Loss

Contents

A rational approach to loss prevention must be based on an understanding of the nature of incidents and of the types of loss that actually occur. Therefore, in this chapter, first the nature of the incident process is considered and then the incident and loss statistics are reviewed to give an indication of the problem. Selected references on incident and loss experience are given in Table 2.1. In addition, many other tables of data are given in other chapters. Cross-references to some of these tables are given in Table 2.2.

2.1 The Incident Process

There are certain themes that recur in the investigation of incidents and which reveal much about the incident process. First, although in some reporting schemes the investigator is required to determine the cause of the incident, it frequently appears meaningless to assign a single cause as the incident has arisen from a particular combination of circumstances. Second, it is often found that the incident has been preceded by other incidents that have been 'near-misses'. These are cases where most but not all of the conditions for the incident were met. A third characteristic of incidents is that when the critical event has occurred, there are wide variations in the consequences. In one case there may be no injury or damage, while in another case that is similar in most respects, there is some key circumstance that results in severe loss of life or property. These and other features of incidents are discussed in *Man-Made Disasters* (B.A. Turner, 1978). It is in the nature of disasters that they tend to occur only as the result of the combination of a number of events and to have a long incubation period before such a conjunction occurs.

It is helpful to model the incident process in order to understand more clearly the factors that contribute to incidents and the steps that can be taken to avoid them. One type of model, discussed by Houston (1971), is the classical one developed by lawyers and insurers that focuses attention on the 'proximate cause'. It is recognized that many factors contribute to an incident, but for

practical, and particularly for legal, purposes, a principal cause is identified. This approach has a number of defects: there is no objective criterion for distinguishing the principal cause; the relationships between causes are not explained; and there is no way of knowing if the cause list is complete.

There is need for incident models that bring out with greater clarity the common pattern in incidents. Some models of the incident process that may be helpful in incident investigation and prevention are given below, with emphasis on the management and engineering aspects. Further incident models are discussed in Chapters 26–28 and incident investigation procedures are given in Chapter 31. However, irrespective of the incident model used for incident investigation, it is essential that investigations result in the identification of root causes, and recommendations are identified and implemented that target root causes. For example, take the case of a guillotine rupture of a gas pipeline caused by a construction crew. The subsequent gas release accumulates for an extended period of time and ultimately is ignited resulting in an explosion and fire causing multiple fatalities, injuries and extensive loss of property. For the investigation to focus on just how the rupture was caused defeats the purpose of incident investigation completely. In other words, dramatically different answers are obtained when the incident investigation tries to answer any one the following questions:

(1) Why did the rupture occur? OR
(2) Why did the explosion and fire occur? OR
(3) Why did the people die or get hurt?

An investigation trying to answer the first question will quite clearly identify flaws with the construction and digging procedures and may well come up with recommendations aimed at correcting those deficiencies. However, that does not answer the question of why did the explosion and fire occur. An investigation that tries to answer this second question assumes that irrespective of pipeline operating procedures, how should pipeline systems be designed and operated so that the probability of explosions and fires are minimized to the lowest extent possible. Thus, recommendations resulting from such an investigation would identify flaws in the design and operation of the pipeline system. Issues such as engineered systems capable of shutting the flow of gas in a reasonably short period of time would be addressed in answering this second question.

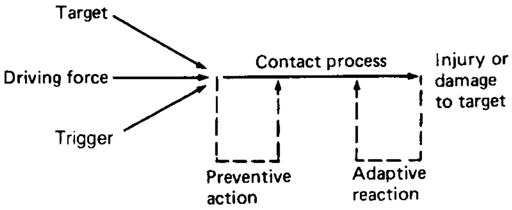

Figure 2.1 *Houston model of the accident process (after Houston, 1977)*

An investigation that tries to answer the third question opens up a lot of additional issues that are also very important. Not only is the design and operation of the pipeline system analysed, but also issues such as emergency response and evacuation of the affected area would be addressed. After all it is a very relevant question to ask that irrespective of the causes of the rupture and accumulation of the gas, was not there any way to evacuate the personnel or respond to their plight in order to reduce or eliminate the casualties.

2.1.1 The Houston model

The model given by Houston (1971, 1977) is shown schematically in Figure 2.1. Three input factors are necessary for the incident to occur: (1) target, (2) driving force and (3) trigger. Principal driving forces are energy and toxins. The target has a threshold intensity θ below which the driving force has no effect. The trigger also has a threshold level θ' below which it does not operate.

The development of the incident is determined by a number of parameters. The contact probability p is the probability that all the necessary input factors are present. The contact efficiency ε defines the fraction of the driving force that actually reaches the target, and the contact effectiveness η is the ratio of damage done to the target under the actual conditions to that done under standard conditions. The contact time t is the duration of the process.

The model indicates a number of ways in which the probability or severity of the incident may be reduced. One of the input factors (target, driving force or trigger) may be removed. The contact probability may be minimized by preventive action. The contact efficiency and contact effectiveness may be reduced by adaptive reaction.

Work by Haddon (1973a,b) emphasizes prevention of incidents by control of the energy. His list of energy control strategies is given in Table 2.3. Failure of one or more of these modes of control is a normal feature of an incident and hence of incident models.

2.1.2 The fault tree model

A simple fault tree model of an incident is given in Figure 2.2. An initiating event occurs which constitutes a potential incident, but often only if some enabling event occurs, or has already occurred. This part of the tree is the 'demand' tree, since it puts a demand on the protective features. The potential incident is realized only if prevention by protec-tive equipment and human action fails. An incident occurs that develops into a more severe incident only if mitigation fails.

A somewhat similar model has been proposed by Wells *et al.* (1992).

Table 2.3 Some energy control strategies (after Haddon, 1973a)

(1) To prevent the initial marshalling of the form of energy
(2) To reduce the amount of energy marshalled
(3) To prevent the release of energy
(4) To modify the rate or spatial distribution of release of energy from its source
(5) To separate in space or time the energy being released from the susceptible structure
(6) To separate the energy being released from the susceptible structure by interposition of a material barrier
(7) To modify the contact surface, subsurface, or basic structure which can be impacted
(8) To strengthen the living or non-living structure which might be damaged by energy transfer
(9) To move rapidly in detection and evaluation of damage and to counter its continuation and extension
(10) All those measures which fall between the emergency period following the damaging energy exchange and the final stabilization of the process (including intermediate and long-term reparative rehabilitative measures)

2.1.3 The MORT model

A more complex fault tree model is that used in the management oversight and risk tree (MORT) developed by W.G. Johnson (1980) and shown in Figure 2.3. This tree is the basis of a complete safety system, which is described further in Chapter 28.

2.1.4 The Rasmussen model

Incident models that show the role of human error have been developed by Rasmussen (1982a,b). Figure 2.4 shows such a model. The role of human error in causing incidents is considered in more detail in Chapter 14.

2.1.5 The ACSNI model

Figure 2.5 shows a model proposed by the Advisory Committee on the Safety of Nuclear Installations (ACSNI, 1991). The model provides a general framework that can be used to identify latent failures that are likely to lead to critical errors.

2.1.6 The Bellamy and Geyer model

A model that emphasizes the broader, socio-technical background to incidents has been developed by Geyer and Bellamy (1991) as shown in Figure 2.6. Figure 2.6(a) gives the generic model and Figure 2.6(b) shows the application of the model to a refinery incident.

2.1.7 The Kletz model

Another approach is that taken by Kletz (1988h), who has developed a model oriented to incident investigation. The model is based essentially on the sequence of decisions and actions that lead up to an incident, and shows against each step the recommendations arising from the investigation. An example is shown in Figure 2.7, which refers to an incident involving a small fire on a pump.

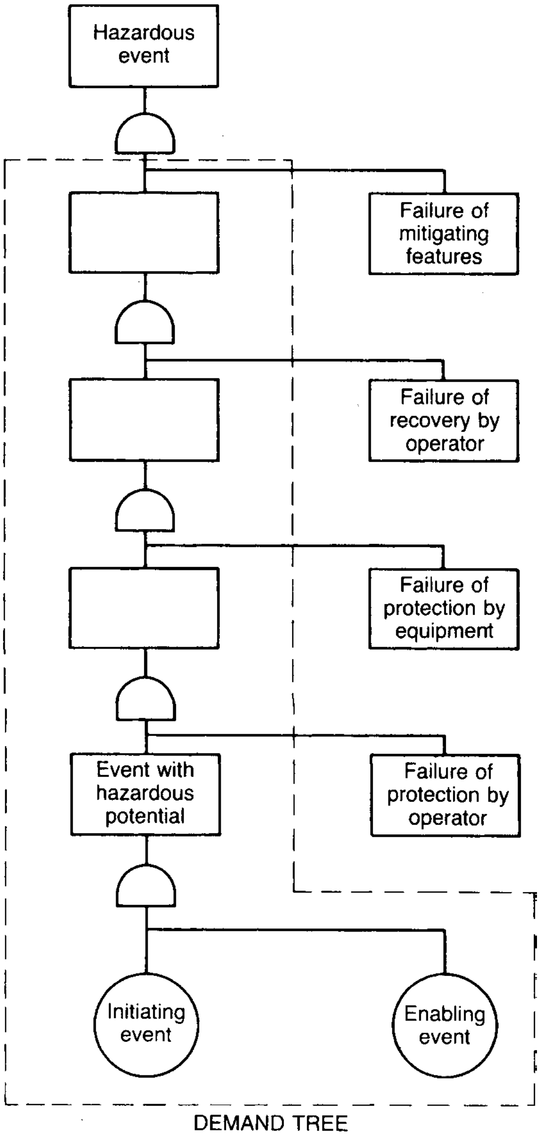

Figure 2.2 *Fault tree model of the accident process*

2.2 Standard Industrial Classification

Statistics of injuries and damage in the United Kingdom are generally classified according to the Standard Industrial Classification 1980 (SIC 80). In this classification, the classes relevant here are: Class 1 Energy and water industries; Class 2 Extraction of minerals and ores other than fuels, manufacture of metals, mineral products and chemicals; Class 3 Metal goods, engineering and vehicles industries; and Class 4 Other manufacturing industries. The mineral oil processing industry falls into Class 1, Subclass 14, and the chemical industry in Class 2, Subclass 25.

In the United States as well, incident and damage statistics are compiled by SIC codes. However, the difference with

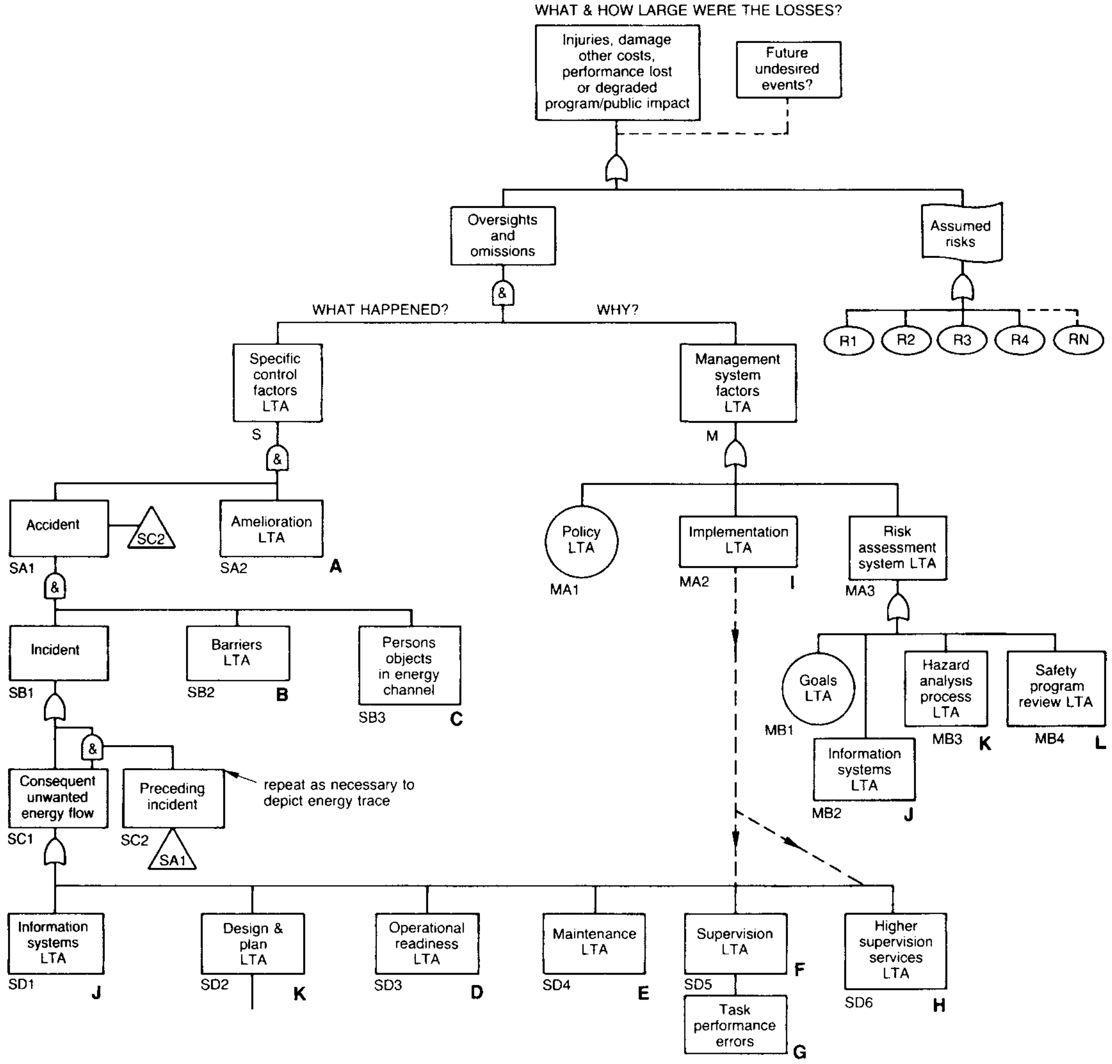

Figure 2.3 *MORT model of the accident process (W.G. Johnson, 1980). The letter A–H refer to further subtrees. LTA, less than adequate (Courtesy of Marcel Dekker)*

United Kingdom is that in the United States, the statistics are compiled by different agencies each of which has different incident definitions and incident taxonomy. A vast amount of data is available in these incident databases and statistics; however, the user must be careful and experienced in dealing with the respective anomalies and inaccuracies of each one of these databases. More details of the advantages and problems associated with these databases are discussed in the next section.

2.3 Injury Statistics

2.3.1 United States of America

In the United States, many federal agencies gather information about the chemical industry. Under statutory mandate, the agencies gather data on releases of chemicals, and on injuries, illnesses and fatalities caused by chemicals. These federal databases, some of which have received information for over three decades, may provide the information needed to develop trends of chemical-related incidents. However, despite the magnitude of data available, chemical industry stakeholders cannot answer the question, ‘How do we assess the status of chemical safety in the United States?’ In 1995, the US Environmental Protection Agency (EPA) stated in its *Users Guide to Federal Accidental Release Databases*, ‘The existence of many different (and often incompatible) federal databases makes it difficult to develop a national picture of the problem of accidental releases’. EPA also determined that federal databases do not provide comparable data sets. This has inhibited data interpretation, comparative analysis and cross agency use of accident data.

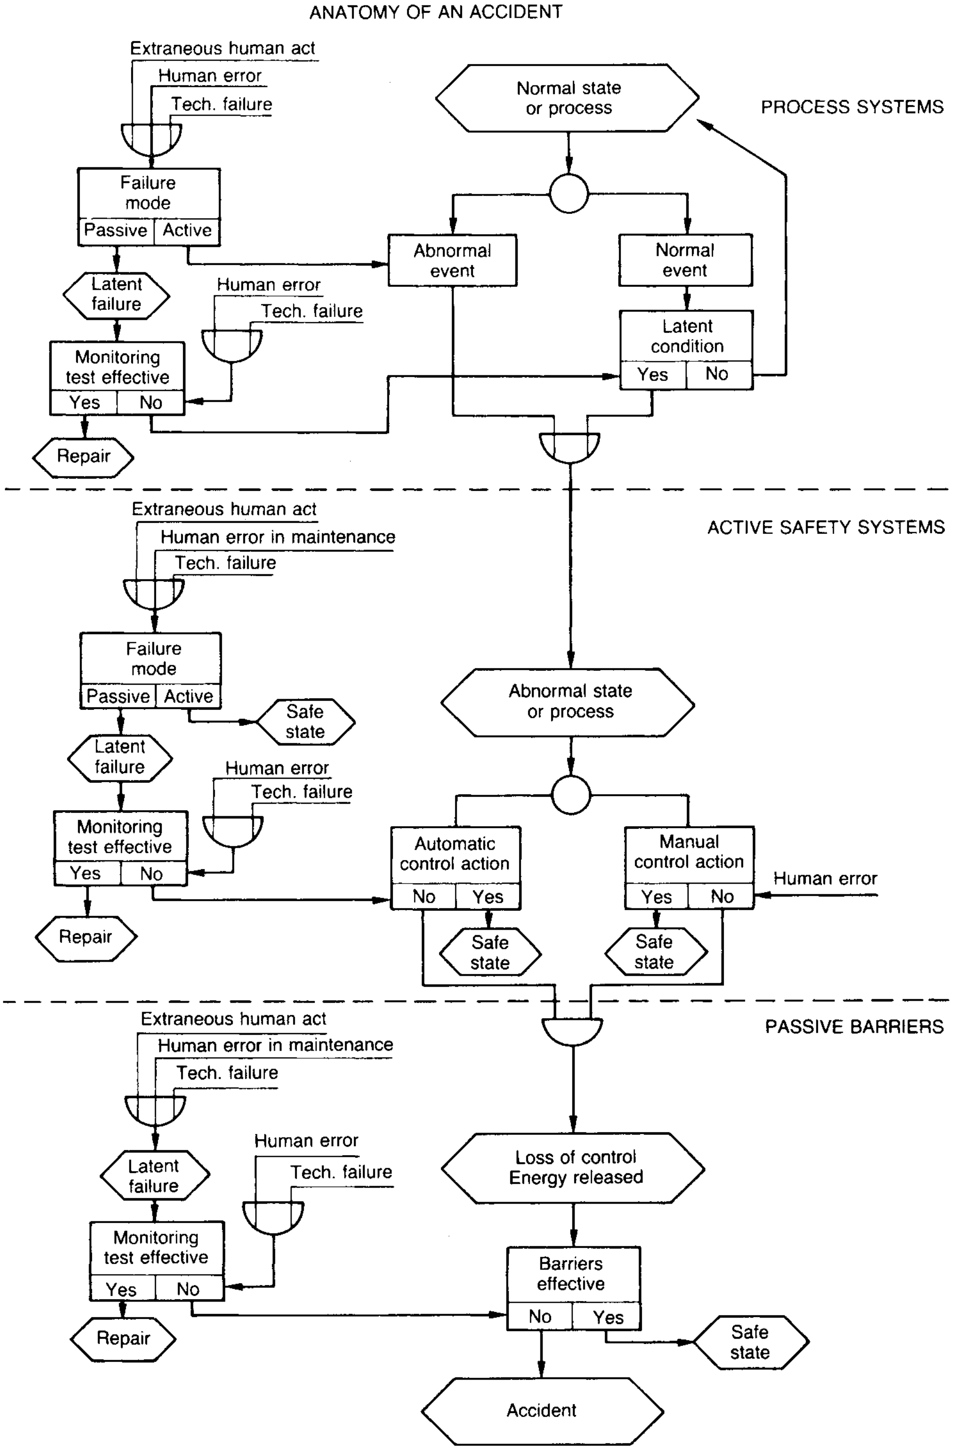

Figure 2.4 *Rasmussen model of the accident process (Rasmussen, 1982b) (Reproduced by permission from High Risk Safety Technology by A.E. Green, copyright John Wiley)*

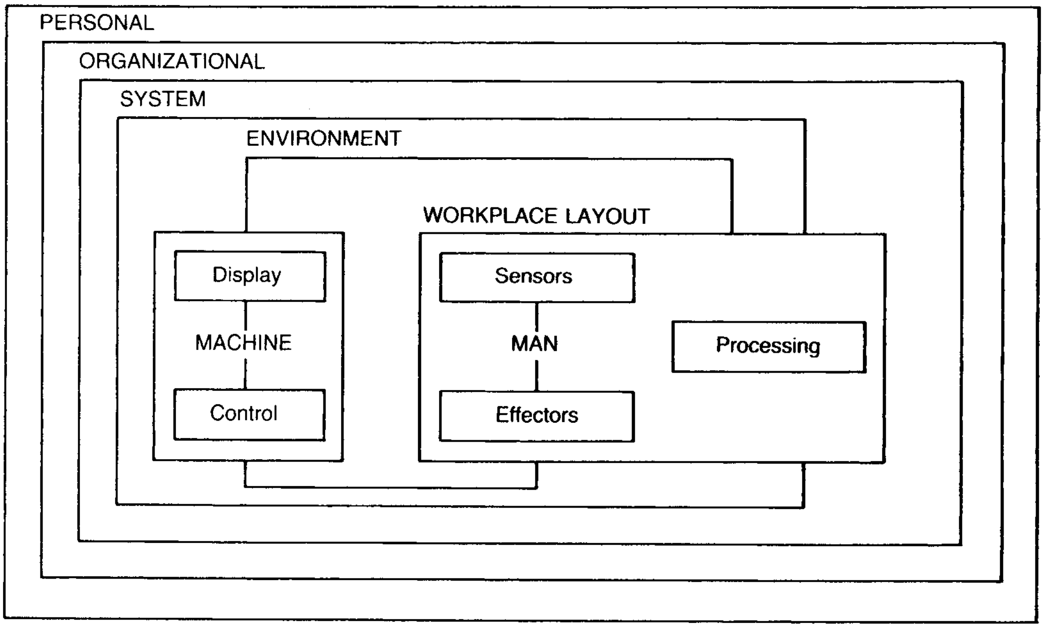

Figure 2.5 *ACSNI model of the accident process (ACSNI, 1991) (Courtesy of HM Stationery Office)*

Six US federal databases provide information about incidents and incident statistics related to chemical safety at fixed facilities. They are:

National Response Center's (NRC) Incident Reporting Information System (IRIS)

Covered Universe IRIS contains data on reported releases from fixed facilities, marine/offshore facilities, pipelines and transportation vehicles. Many federal statutes require reporting of releases to the NRC. Oil spills are reported under:

(1) Section 311(b) of the Federal Water Pollution Control Act of 1973;
(2) Section 306(a) of the Outer Shelf Lands Act Amendments of 1978; and
(3) Section 18(b) of the Deepwater Ports Act of 1974.

Chemical spills are reported under:

(1) Section 302 of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) of 1980;
(2) Section 304 of the Emergency Planning and Community Right-to-Know Act of 1986; and
(3) Federal Hazardous Materials Transportations Laws.

Pipeline spills are reported under the Hazardous Liquid Pipeline Safety Act.
Air releases are reported under:

(1) Clean Air Act;
(2) Toxic Substances Control Act;
(3) Federal Hazardous Materials Transportations Law and
(4) Resource Conservation and Recovery Act.

Collection Method This database is primarily used for emergency response notification and is operated 24 h a day, 7 days a week. The initial notification of a release is usually by telephone. These reports are comprised of primarily short answer questions.
Principal Data Elements The database contains data on oil, chemical, biological and etiological discharges into the environment anywhere in the United States or its territories. The NRC collects information nationally on reports of hazardous material releases, as well as releases of hazardous substances and oil from fixed facility and transportation incidents. Two files, INCRPT and MATRPT, compose the IRIS database. The INCRPT file contains information about the location of the release, the company owner of the facility (when it applies), a short description of the incident, and the information related to the consequences (affected medium, fatalities, injuries, evacuations, cost of damages) of the incident. No information regarding the released substance is reported in this file. The MATRPT file contains the information related to the chemical substance(s) involved in the incident (name of the substance, CHRIS code, and quantity and phase of the released chemical).
Strengths NRC handles approximately 300,000 telephone calls each year, of which approximately 25,000 are unique incidents. Coverage of such a large number of incidents provides the potential for statistical analysis to capture meaningful trends.
Weaknesses While reporting to the NRC is required by a number of statutes, it also receives numerous 'complaints' from the public. In addition, practice drills for emergency

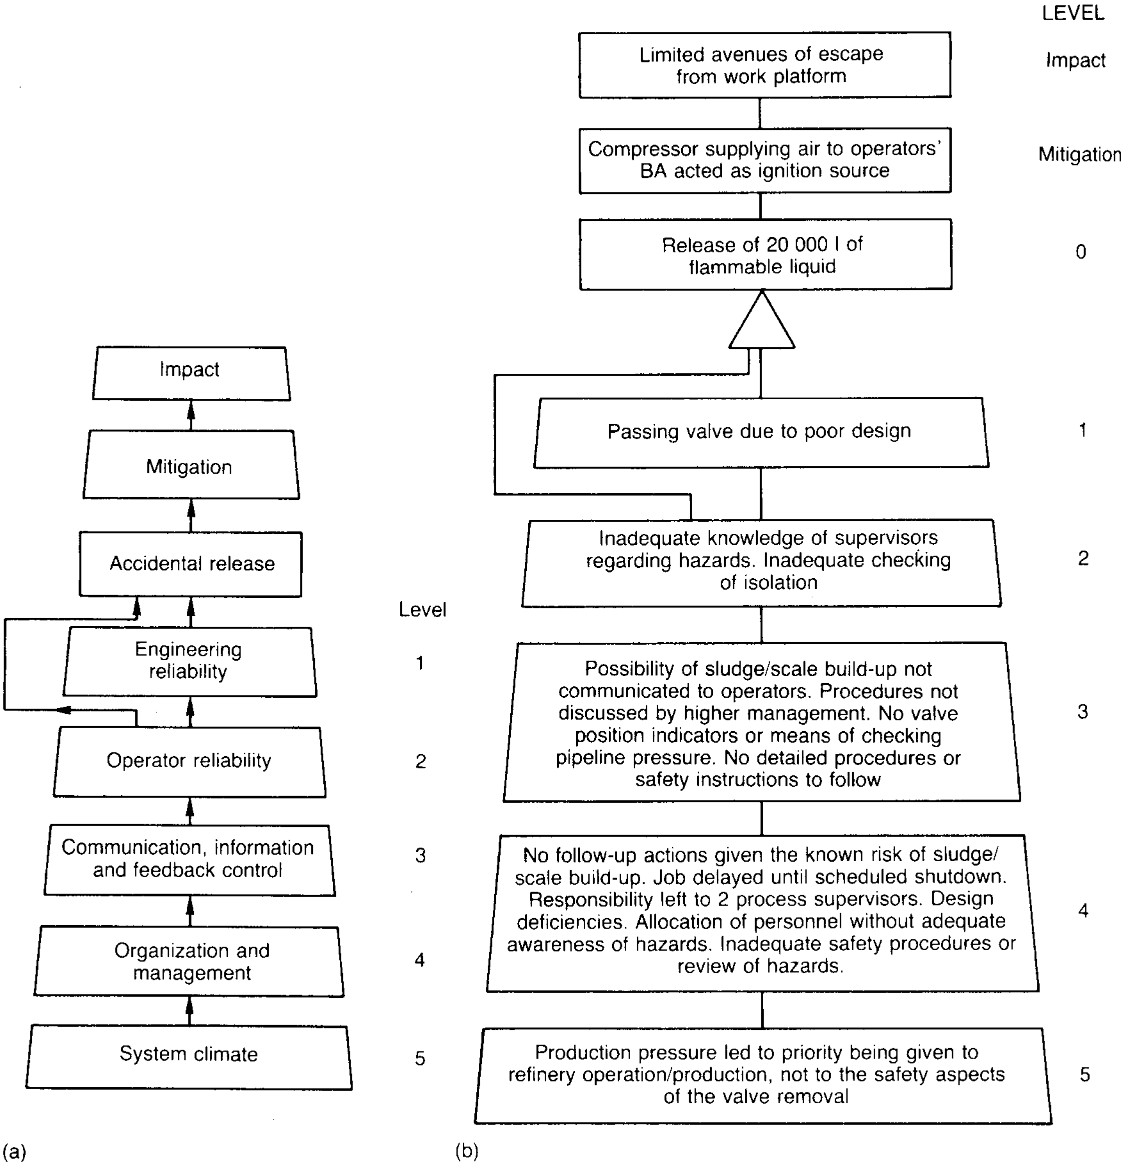

***Figure 2.6** Bellamy and Geyer model of the accident process: (a) generic model; (b) model applied to a refinery incident (Geyer and Bellamy, 1991) (Courtesy of the Health and Safety Executive)*

releases are captured in the database. The NRC also collects in the same database non-chemical-related events such as railroad crossing accidents. Also, both actual and potential releases may be reported to IRIS. Many of the reported incidents are spills of fuel from motor vehicles, small spills of low hazard materials such as lubricating oil and oil sheens on water with unknown sources, quantities and effects. Because this system contains initial reports, the information is preliminary and many times inaccurate or incomplete. There is also duplicate reporting of incidents. The completeness and accuracy of chemical names depend on the knowledge level of the person reporting the incident.

EPA's Risk Management Program (RMP) Rule's 5-year Accident History Database

Covered Universe RMP-covered facilities that have released a listed substance, which is stored above a threshold

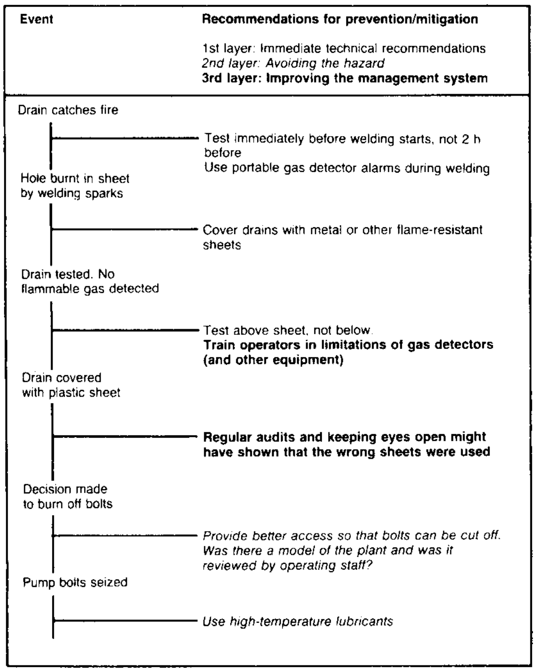

Figure 2.7 *Kletz model of the accident process (Kletz, 1988h) (Courtesy of Butterworths)*

quantity and results in fatalities, injuries, or significant environmental or property damage are required to report 5-year accident histories.

Collection Method 5-year Accident History Report.

Principal Data Elements It contains information on RMP-covered facilities that meet the reporting criteria listed in the 'Covered Universe'. The facility must provide EPA with the following information:

(1) date, time and approximate duration of the release;
(2) chemical(s) released;
(3) estimated quantity released in pounds;
(4) type of release event and its source;
(5) weather conditions, if known;
(6) on-site impacts;
(7) known off-site impacts;
(8) initiating event and contributing factors if known;
(9) whether off-site responders were notified if known; and
(10) operational or process changes that resulted from investigation of the release.

Strengths The reporting is from a well-defined universe of facilities and it allows statistical treatment of the frequency of releases per facility or process unit that is not available from other systems. The reports do address such items as the causes and consequences of the release and steps taken to prevent or mitigate future incidents. Future data from EPA's 5-year Accident History Database may provide more information to be able to determine statistically significant trends and the effects of implementing EPA's RMP Rule and Occupational Safety and Health Administration (OSHA)'s Process Safety Management (PSM) Standard of Highly Hazardous Chemicals, which were promulgated to improve safety in the chemical industry.

Weaknesses The database is limited to RMP-covered facilities that have experienced an incident with a consequence involving a listed chemical stored above its threshold quantity. The reporting criteria excludes a large number of incidents. As a result, only 1900 releases are reported from about 14,500 facilities for the 5-year period. Of the 1900 releases, only 1500 were required to be reported, because 400 of the incidents were without consequences. The RMP data is currently only available in 5-year cycles beginning in 1994. By limiting reporting to cases with consequences, a great deal of information is lost about releases without consequences. Releases without consequences or near misses provide valuable information on how to prevent incidents and the ability to predict possible consequences. There may be corrections and revisions to RMP* Info at any time through submission by a facility of a corrected RMP. It is critical in performing analysis to report the date of last revision and any notable modifications to the data.

EPA's Accidental Release Information Program (ARIP) Database

Covered Universe Facilities were asked by EPA to provide information to the ARIP database if the facility reported an incident to EPA's Emergency Response Notification System and the release event met one or more of the following criteria:

(1) the release resulted in a death or injury;
(2) the release involved 1000 pounds or more of a hazardous substance with a reportable quantity of 1, 10 or 100 pounds, or the release involved 10,000 pounds or more of a hazardous substance with a reportable quantity of 1000 to 5000 pounds;
(3) the release was the fourteenth release in a 12-month period; or
(4) The release involved an extremely hazardous substance from Section 302 of Emergency Planning and Community Right-to-Know Act.

EPA was authorized to gather this information under:

(5) section 3007(a) of the Resource Conservation and Recovery Act;
(6) section104(b)(1) and (e) of CERCLA;
(7) section 308(a) of the Clean Water Act; and
(8) section 114 of the amended Clean Air Act.

Collection Method Facilities were requested to complete a questionnaire with 23 questions.

Principal Data Elements The ARIP database was developed by EPA in 1986 to determine the causes of accidental chemical releases, to identify the steps that could be taken by industrial facilities to prevent releases, and to outline industry prevention practices. The facilities were asked to provide information about the facility, the listed chemical, the circumstances and causes of the incident, the accidental release prevention practices and technologies in place prior to the event, and any additions or changes made to these technologies and practices as a result of the event. The questionnaire focuses on several areas of accident prevention including hazard assessments, training, emergency response, public notification procedures, mitigation techniques, and prevention equipment and controls.

Strengths ARIP is one of the larger collections of incidents with details concerning causes, consequences, operating mode and corrective actions. ARIP has collected over 4800 release records since its inception. The data are considered accurate because the data are provided directly by facilities several months after the release when most information should be known. This system provides detailed information about causes and prevention practices not available in most other systems.

Weaknesses This programme is discontinued. No trends with time can be gathered. The chemicals reported are the ones reported to EPA under existing statutes and regulations, which tends to exclude gasoline, methane, ethane, propane and other chemicals some of which are included in the EPA 5-year Accident History database. In September 1993, EPA took steps to streamline the database by including only releases with significant off-site consequences, such as casualties, evacuations, sheltering-in-place or any other necessary precautions taken by individuals off-site as a result of a release. In addition, the questionnaire for the database has been revised over time so that some information was added and other information was deleted. Thus, analysis on some data fields cannot be performed on the entire database. In addition, the short description of the accident is not contained in the database and must be analysed in the hard copy of the questionnaire. The collection of ARIP data was dependent on the sometimes uneven collection efforts of the EPA regions; therefore, the data does not truly represent the geographical distribution of releases, nor does it reflect release trends over time.

Bureau of Labor Statistics' (BLS) Databases for the US Occupational Safety and Health Administration (OSHA)

Covered Universe All OSHA-covered facilities.

Collection Method Surveys.

Principal Data Elements The BLS database is a comprehensive statistical system covering work-related deaths, injuries and illnesses in private industry. Work-related fatalities are counted and profiled more accurately in a separate BLS table, Census of Fatal Occupational Injuries. Survey information on non-fatal incidents involving days away from work profiles:

(1) occupation and other demographics (e.g. age and gender) of workers sustaining such injuries and illnesses;
(2) the nature of these disabling conditions and how they occurred; and
(3) the resulting time away from work.

Strengths These statistics are based on an annual sampling of about 250,000 companies in the United States. There is very good detail for chemicals and industries involved in accidents, from a statistical sample, not individual incidents. The data have been collected and reported on in a consistent manner since 1992. Thus, trends from 1992 can be determined and compared with injury rates.

Weaknesses Chemical incidents are only identified for cases with days away from work. Also, the survey was redesigned between 1987 and 1992; thus, statistical analysis is limited for the years prior to 1992.

U.S. Centers for Disease Control and Prevention's (CDC) Wide-ranging On-line Data for Epidemiological Reporting (WONDER)

Covered Universe All fatalities in the United States.

Collection Method Death certificates as recorded by physicians.

Principal Data Elements This database provides the numbers of fatalities and their associated causes.

Strengths The WONDER database is useful for the purpose of determining overall trends in fatalities due to chemicals. The database allows sorting by codes that describe a class of chemicals or a type of event. It also allows sorting by the age of the deceased. This feature was used to eliminate victims under 20 years of age as it is unlikely these were industrial accidents. Unlike most other databases, a physician, who is presumably not biased when determining the cause of death, codes the data. The data is available since 1979 that provides a long and statistically significant trend.

Weaknesses The scope of incidents in WONDER is very broad and contains incidents such as a teenager huffing butane which resulted in a fatal incident, and incidents involving consumer products in residences. The data is not related to specific incidents. Public access to WONDER is limited. Thus, it is not possible to eliminate selected types of incidents. Data can only be gathered by presenting queries by the numbe of fatalities due to a certain cause in a given year by age group.

U.S. Department of Health and Human Services' Agency for Toxic Substances and Disease Registry's (ATSDR) Hazardous Substances Emergency Events Surveillance (HSEES) Database

Covered Universe Sixteen state health departments currently have cooperative agreements with ATSDR to participate in HSEES. The state health departments report an 'event' if it meets the HSEES definition, which is 'any release(s) or threatened release(s) of at least one hazardous substance'. A substance is considered hazardous if it might reasonably be expected to cause adverse human health effects. Releases of petroleum products are excluded from this system.

Collection Method Data are entered by participating state health departments into a web-based application that enables ATSDR to instantly access data for analysis.

Principal Data Elements Data collected on incidents for this database include the following:

(1) time, date and day of the week;
(2) geographical location within the facility where the event occurred;
(3) event type (fixed-facility or transportation-related event);
(4) factors contributing to the release;
(5) environmental sampling and follow-up health activities;
(6) specific information on injured persons: age, sex, type and extent of injuries, distance from spill, population group (employee, general public, responder, student) and type of protective equipment used;
(7) information about decontaminations, evacuation or shelter-in-place;
(8) land use and population information to estimate the number of persons at home or work who were potentially exposed; and
(9) whether a contingency plan was followed and which plan was used.

Strengths ATSDR has a proactive approach to incident collection that facilitates more complete and accurate reporting.

Weaknesses ATSDR's HSEES programme only covers 16 states, which vary, and excludes petroleum products. The public does not have access to the data; ATSDR provides summary reports of the data.

In the United Kingdom, incident statistics are available in the *Annual Report* of HMCIF, or its current equivalent, and the annual *Health and Safety Statistics*. The former also gives occasional detailed studies for particular industrial sectors.

2.3.2 United Kingdom

In the United Kingdom, the definition of a major injury changed with the introduction of the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1985 (RIDDOR). The *Health and Safety Statistics 1990–91* (HSE, 1992b) show that in 1990–91 there were 572 fatalities reported under RIDDOR, of which 346 were to employees, 87 to the self-employed and 139 to members of the public. The fatal injury incidence rate for employees was 1.6 per 100,000 workers.

Major injuries to employees in 1990–91 reported under RIDDOR were 19,896 and the incidence rate was 89.9 per 100,000 workers.

For the manufacturing industry (SIC 2–4), fatalities were 88 in 1990–91 and averaged 100 in the 5-year period between 1986–87 and 1990–91 and the fatal injury incidence rate was 1.8 per 100,000 workers.

Fatal and major injuries in the oil and chemical industries in the period 1981–85, inclusive, are shown in Table 2.4. For 1990–91, the Health and Safety Statistics 1990–91 show that in the oil and chemical industries, the incidents to employees were as shown in Table 2.5.

The comparative incidence of fatalities in some principal industries and jobs in the United Kingdom is given in Table 2.6. The table shows that there is a wide variation between industries. It also shows a downward trend. The fatal accident rate of the chemical industry is approximately the same as that for all manufacturing industry. The injury statistics can be dramatically changed, however, by a single major disaster. In the process industries, the worst disaster since 1945 was the VCE at Flixborough in 1974, which killed 28 people. Offshore in the British sector of the North Sea, the Piper Alpha disaster resulted in 167 deaths. The comparative incidence of fatalities in some leading industrial countries, mainly in 1983, is given in Table 2.7.

2.4 Major Disasters

It is appropriate at this point briefly to consider major disasters. A list of the worst disasters in certain principal categories, both for the world as a whole and for the United Kingdom, is given in Table 2.8.

Those that are of primary concern in the present context are fire, explosion and toxic release. Both of the worst fires listed occurred in theatres. The explosion at Halifax which killed 1963 people was that of a ship carrying explosives. The Chilwell explosion, in which 134 people died, was in an explosives factory. The toxic gas release at Bhopal, where the death toll was some 2500, was an escape of methylisocyanate from a storage tank.

There are available a number of accounts of disasters, both natural and man-made, and these are summarized in Table 2.9. *Disasters* (Walker, 1973), *Darkest Hours* (Q.R. Nash, 1976), *Man-Made Disasters* (B.A. Turner, 1978), *The Disaster File: The 1970s* (Ferrara, 1979), *Disasters* (Whittow, 1980) and *Catastrophes and Disasters* (R. Smith, 1992) all contain large numbers of disaster case histories, including those

Table 2.4 *Fatal and major incidents in chemical and petroleum factories in the UK 1981–85 (Cox, Lees and Ang, 1990) (Courtesy of Institution of Chemical Engineers)*

A Period 1981–85: number of fatal (F) and major (M) injuries

Mineral oil processing	18,200	1	14	82.4

Sources: Health and Safety Executive (1986c); HM Chief Inspector of Factories (1986a).

from the process industries. Rail incidents in the British Isles are described in *Red for Danger* (Rolt, 1982) and incidents in the process industries are described in *Chemical Industry Hazards* (V.C. Marshall, 1987).

2.5 Major Process Hazards

The major hazards with which the chemical industry is concerned are fire, explosion and toxic release. Of these three, fire is the most common but, as shown later, explosion is particularly significant in terms of fatalities and loss. As already mentioned, in the United Kingdom, the explosion at Flixborough killed 28 people, while offshore 167 men died in the explosion and fire on the Piper Alpha oil platform. Toxic release has perhaps the greatest potential to kill a large number of people. Large toxic releases are very rare but, as Bhopal indicates, the death toll can be very high. There have been no major toxic release disasters in the United Kingdom.

The problem of avoiding major hazards is essentially that of avoiding loss of containment. This includes not only preventing an escape of materials from leaks, etc., but also avoidance of an explosion inside the plant vessels and pipework. Some factors that determine the scale of the hazard are:

(1) the inventory;
(2) the energy factor;
(3) the time factor;
(4) the intensity–distance relations;
(5) the exposure factor and
(6) the intensity–damage and intensity–injury relationships.

These factors are described below.

2.5.1 The inventory

The most fundamental factor that determines the scale of the hazard is the inventory of the hazardous material. The larger the inventory of material, the greater the potential loss. As plants have grown in size and output, so inventory in process and in storage has grown. In the early days of this growth, there was perhaps insufficient appreciation of the increase in the magnitude of the hazard. There is now, however, much wider recognition of the importance of inventory. At the same time, it is important to emphasize that inventory is not the only factor which determines the scale of the hazard.

2.5.2 The energy factor

For an inventory of hazardous material to explode inside the plant or to disperse in the form of a flammable or toxic vapour cloud, there must be energy. In most cases this energy is stored in the material itself as the energy either of chemical reaction or of material state.

In particular, a material which is held as a liquid above its normal boiling point at high pressure and temperature, in other words superheated, contains large quantities of physical energy, which cause a large proportion of it to vaporize by instantaneous flash-off and to disperse if there is loss of containment. On the other hand, a material that is held as a refrigerated liquid at atmospheric pressure contains much less physical energy and does not vaporize to anything like the same extent if containment is lost. In this case, the energy necessary for vaporization has to be supplied by the ground and the air, which is a relatively slow process. Similarly, the hazard presented by an ultratoxic material depends very largely on whether there is energy available for its dispersion. There is a

[b] International Labour Office (1985b).
[c] For 1983 unless otherwise stated.
[d] HSE (1977d). Described in *Chemical Industry Hazards* (V.C. Marshall, 1987).

hazard, for example, if an ultratoxic substance is produced as a by-product in a chemical reactor in which a runaway exothermic reaction may occur. But if there is no such source of energy, the hazard is much less.

The energy requirement is thus another fundamental feature. Unless it is taken into account in the calculation, the scenarios considered may be not merely unlikely, but literally physically impossible.

2.5.3 The time factor

Another fundamental factor is the development of the hazard in time. The time factor affects both the rate of release and the warning time.

The nature and scale of the hazard is often determined by the rate of release rather than by the inventory. Thus, it is the rate of release which determines the size of a flammable gas cloud formed from a jet of flashing hydrocarbon liquid, such as occurred at Flixborough. Similarly, the hazard presented by an escape of toxic gas depends on the rate of release. There is a considerable difference in the concentrations attained between an instantaneous and a continuous release of toxic gas.

The warning time available to take emergency countermeasures and reduce the number of people exposed is also very important. An explosion gives a warning time that is usually measured only in seconds and may be zero, whereas a toxic release gives a warning that is often measured in minutes.

2.5.4 The intensity–distance relationship

An important characteristic of the hazard is the distance over which it may cause injury and/or damage. In general, fire has the shortest potential range, then explosion and then toxic release, but this statement needs considerable qualification. The range of a fireball is appreciable and the range of a fire or explosion from a vapour cloud is much extended if the cloud drifts away from its source.

It is possible to derive from the simpler physical models for different hazards analytical expressions that give the variation of the intensity of the physical effect (thermal radiation, overpressure, toxic concentration) with distance. For some models the variation follows approximately the inverse square law. This aspect is discussed in Chapter 9.

With regard to the exposure of the public to process hazards, it is of interest to know the distance at which there might be a significant number of fatalities or injuries and the maximum distance at which any fatality or injury might occur. Estimates of the distance necessary to reduce the risk of fire and explosion to members of the public to a level that is assumed to be not unacceptable, based on criteria such as thermal radiation from fire and overpressure from explosion, are generally of the order of 250–500 m for a major plant handling hydrocarbons, but may be less or more. Estimates of the distance necessary to reduce the risk from toxic release tend to be somewhat greater.

The maximum distance at which there might conceivably be fatalities or injuries cannot be determined with any great accuracy. The explosion effect that can occur at the greatest distance is the shattering of glass – this has happened at distances of up to 20 miles from a very large explosion. But in such cases the energy of the glass fragments is low and very rarely causes injury. Similarly, cases of injury from toxic gas at large distances, say over 10 miles, are rare but are reported to have occurred.

The effects of fire, explosion and toxic release are discussed further in Chapters 16–18. Although a potential effect of a hazard is often expressed as a function of distance, it is the area covered by the effect that determines the number of people at risk.

2.5.5 The exposure factor

A factor that can greatly mitigate the potential effects of an incident is the reduction of exposure of the people who are in the affected area. This reduction of exposure may be due to features that apply before the hazard develops, or to emergency measures that are taken after the hazard is recognized.

The principal mitigating features are shelter and escape. Escape may be by personal initiative or by preplanned evacuation. It should not be assumed that emergency measures are synonymous with evacuation. A combination of evacuation, shelter-in-place as well as other measures may be taken based on the event as well as preplanning evaluations. For releases of flammable substances, evacuation of non-emergency personnel is always beneficial and leads to reduction of casualties. On the other hand, for toxic releases, the emergency instructions may be to evacuate the area but are more likely to be to stay indoors and seal the house. Emergency measures may be of great value in reducing the toll of casualties from a major incident.

For an explosion that gives no advance warning, there is no time for emergency measures such as evacuation. This does not mean, however, that evacuation has no role to play as far as fire and explosion are concerned. On the contrary, although the initial event may be sudden, there are frequently further fire and explosion hazards. Evacuation may then be applicable.

Table 2.8 *Some of the worst non-industrial and industrial disasters worldwide and in the UK (Material from Guinness Book of Records, copyright © reproduced by permission of the publishers)*

Event		*Date*	
A Worst world disasters			
Earthquake	Near East and East Mediterranean	1201	1,100,000
Volcanic eruption	Tambora Sumbawa, Indonesia	1815	92,000
Landslide	Kansu Province, China	1920	180,000
Avalanche	Yungay, Juascaran, Peru	1970	≈18,000
Circular storm	Ganges Delta Islands, Bangladesh	1970	1,000,000
Tornado	Shaturia, Bangladesh	1989	≈1,300
Flood	Hwang-Ho river, China	1887	900,000
Lightning	Hut in Chinamasa Krael nr Umtali, Zimbabwe (single bolt)	1975	21
Smog	London fog, UK (excess deaths)	1951	2,850
Panic	Chungking (Zhong qing), air raid shelter, China	1941	≈4,000
Dam burst	Manchu River Dam, Morvi, Gujarat, India	1979	≈5,000
Fire (single building)	The Theatre, Canton, China	1845	1,670
Explosion	Halifax, Nova Scotia, Canada	1917	1,963
Mining	Hankeiko Colliery, China (coal dust explosion)	1942	1,572
Industrial	Union Carbide methylisocyanate plant, Bhopal, India	1984	≈2,500
Offshore platform	Piper Alpha, North Sea	1988	167
Nuclear reactor	Chernobyl Reactor No. 4	1986	31[a]
Aircraft	KLM-Pan Am, Boeing 747 crash, Tenerife	1977	583
Marine (single ship)	Wilhelm Gustloff, German liner torpedoed off Danzig by Soviet submarine S-13	1945	≈7,700
Rail	Bagmati River, Bihar, India	1981	>800
Road	Petrol tanker explosion inside Salang Tunnel, Afghanistan	1982	≈1,100
Atomic bomb	Hiroshima, Japan	1945	141,000
Conventional bombing	Tokyo, Japan	1945	≈140,000
B UK			
Earthquake	London earthquake, Christ's Hospital, Newgate	1580	2
Landslide	Pantglas coal tip No. 7, Aberfan, Mid-Glamorgan	1966	144
Avalanche	Lewes, East Sussex	1836	8
Circular storm	'The Channel Storm'	1703	≪8,000
Tornado	Tay Bridge collapsed under impact of two tornadic vortices	1879	75
Flood	Severn Estuary	1606	≪2,000
Smog	London fog (excess deaths)	1951	2,850
Panic	Victoria Hall, Sunderland	1883	183
Dam burst	Bradfield Reservoir, Dale Dyke, near Sheffield (embankment burst)	1864	250
Fire (single building)	Theatre Royal, Exeter	1887	188
Explosion	Chilwell, Nottinghamshire (explosives factory)	1918	134
Mining	Universal Colliery, Senghenydd, Mid-Glamorgan	1913	439
Offshore platform	Piper Alpha, North Sea	1988	167
Nuclear reactor	Windscale (now Sellafield), Cumbria (cancer deaths)	1957	[b]
Marine (single ship)	HMS Royal George, off Spithead	1782	≈800
Rail	Triple collision, Quintinshill, Dumfries	1915	227
Road	Coach crash, River Dibb, near Grassington, North Yorkshire	1975	33
Conventional bombing	London, 10–1 May	1941	1,436

[a] The *Guinness Book of Records* states: 'Thirty one was the official Soviet total of immediate deaths. On 25 April 1991 Vladimir Shovkoshitny stated in the Ukrainian Parliament that 7000 "clean-up" workers had already died from radiation. The estimate for the eventual death toll has been put as high as 75,000 by Dr Robert Gale, a US bone transplant specialist'.

[b] The *Guinness Book of Records* states: 'There were no deaths as a direct result of the fire, but the number of cancer deaths which might be attributed to it was estimated by the National Radiological Protection Board in 1989 to be 100'.

Measures that can be taken to mitigate exposure are discussed in Chapter 24.

2.5.6 The intensity–damage and intensity–injury relationships

The range of the hazard depends also on the relationships between the intensity of the physical effect and the proportion of people who suffer injury at that level of the effect. The annular zone within which injury occurs is determined by the spread of the injury distribution. If the spread is small, the injury zone will be relatively narrow, while if it is large, the zone may extend much further out. Similar considerations apply to damage. This aspect is discussed further in Chapter 9.

2.6 Fire Loss Statistics

The loss statistics of interest are primarily those for fire loss. In the United Kingdom, principal sources of statistics on such losses are the Home Office, the FPA, the Loss Prevention Council and the insurance companies. These organizations produce annual statistics for fire losses. Loss due to explosions is generally included in that for fire loss. There are no regular loss statistics on toxic release, since this is a rare event and usually causes minimal damage to property.

Fire loss data are given in *Fire Statistics United Kingdom 1990* (Home Office, 1992), in *FPA Large Fire Analysis for 1989* (FPA, 1991) and in *Insurance Statistics 1987–91* (Association of British Insurers (ABI), 1992).

The Home Office data show that in 1990 fire brigades were called to some 467,000 fires, of which 108,000 were in buildings. The FPA defines a large loss fire as one involving a loss of £50,000 or more. In 1990 there were 739 such fires, with a total cost of £282 million and an average cost of £0.382 million. In the chemical and allied industries, in 1990, there were eight large loss fires, with a total cost of £5.24 million and an average cost of £0.656 million. There were no large loss fires in the coal and petroleum industries class.

A more detailed analysis of fires in the chemical and petroleum industries given by the FPA in 1974 is shown in Tables 2.10 and 2.11, the former giving analysis by number and cost and the latter by number and occupancy, by place of origin, by ignition source, by material first ignited and by time of day. There are a number of significant points in the tables. The chemical industry had the largest number of fires, but the oil industry the most expensive. The origin of the fires is predominantly in storage and in leakages. The sources of ignition are fairly evenly spread. There is only one fire attributed to static electricity and two to arson. But in 35 cases, that is, 44%, the ignition source was unknown. The material phase first ignited also shows a balanced spread, with the solid phase actually being predominant. There is no marked trend in the time of day of the fires, although the number is somewhat higher during the day shift.

Further analyses of fire statistics have been given by H.D. Taylor and Redpath (1971), the FPA (1976) and Redpath (1976). In particular, these sources present additional data of the type given in Tables 2.10 and 2.11. These data are a useful general pointer. They constitute, however, a rather small sample. Moreover, they are not necessarily representative of the type of fire or explosion that constitutes a major disaster.

Work on the occurrence of fires in industrial buildings has been described by Rutstein and Clarke (1979) and Rutstein (1979b). The probability of fire was found to increase with the size of building according to the equation:

$$P = aB^c \qquad [2.6.1]$$

where B is the floorspace (m^2) and P is the probability of fire per year, and a and c are constants. For production buildings in manufacturing industry generally (SIC Classes 3–19), the values of the constants *a* and *c* were 0.0017 and 0.53, and in the chemical and allied industries (SIC 4), they were 0.0069 and 0.60, respectively. (These SIC numbers refer to the Standard Industrial Classification at the time.) The probability of fire in a 1500 m^2 production building was thus 0.083 for manufacturing industry and 0.21 for the chemical industry.

Table 2.10 *Large fires in the chemical and petroleum industries*[a] *in Great Britain, 1963–75: number and cost (FPA, 1974; Redpath, 1976)*

Year	*No. of fires*	*Cost* (£m.)
1963	44	2.3
1964	43	2.9
1965	40	3.0
1966	43	2.5
1967	51	4.4
1968	53	3.1
1969	44	3.2
1970	67	6.2
1971	65	6.2
1972	66	3.5
1973	80	12
1974	45	43
1975	46	6.6

[a] The chemical and petroleum industries are taken as Standard Industrial Classification Order 4 (Coal and petroleum products) and 5 (Chemical and allied industries).

An analysis of some 2000 large loss claims at Cigna Insurance has been given by Instone (1989) and is summarized in Table 2.12.

A study of the contribution of human factors to failures of pipework and in-line equipment by Bellamy, Geyer and Astley (1989) contains a large amount of information characterizing releases, as shown in Table 2.13. As with fatal injuries so with fire losses, a single incident may dominate the process industries' loss for a particular year. In the United, the Flixborough disaster constituted a significant proportion of the fire loss in 1974, whilst the Piper Alpha disaster dominated that for 1988. Fire losses are considered further in Chapter 5.

2.7 Fire and Explosion

So far no distinction has been made between fire and explosion losses. The latter are normally included in the overall fire statistics. In fact it is explosions that cause the most serious losses. This is illustrated by Table 2.14, which shows losses in the chemical industry insured by the Factory Insurance Association (FIA) of the United States (W.H. Doyle, 1969). Some two-thirds of the loss is attributable to explosions. The nature of these explosions is shown in Table 2.15. Over three-quarters of the explosions involve combustion or explosive materials.

Note: BLEVE, boiling liquid expanding vapour explosion.

Further analyses of fires and explosions, treated separately, have been made by Norstrom (1982a), as shown in Tables 2.16 and 2.17.

The problem of large fires or explosions in vapour clouds is considered in Chapter 17. The data given in Table 17.33 by V.C. Marshall (1976a), in which the incidents are ranked in terms of the amount of vapour released, suggest that the large releases often result in explosions rather than fires.

2.8 Causes of Loss

There are almost as many analyses of the causes of loss as there are investigators. Unfortunately, there is no accepted taxonomy, so that it is often difficult to reconcile different analyses. Two typical breakdowns of the causes of loss are given in Table 2.18 (W.H. Doyle, 1969) and in Table 2.19 (American Insurance Association (AIA), 1979), the latter being an up-date of an earlier table (Spiegelman, 1969). Doyle emphasizes the importance of poor maintenance, followed by poor design and layout of equipment and inadequate knowledge of the properties of chemicals. Spiegelman (1969) gives, in addition to the table referred to, a fairly detailed breakdown of the factors considered under each heading. His category of equipment failures evidently has a large element of poor maintenance.

Further information on causes of loss is provided by the data of Norstrom (1982a) given in Tables 2.16 and 2.17.

2.9 Down-time Losses

The losses considered so far are insured losses arising from fire and explosion. Another important, but often uninsured,

loss arises from plant shut-down and down-time. Once again there are many different analyses of shut-down and down-time, and its causes on different types of plant. Three sets of statistics on shut-down and down-time are given in Tables 2.20–2.22 for a refinery (McFatter, 1972), in Tables 2.23 and 2.24 for another refinery (Anon., 1970b), and in Tables 2.25–2.28 (G.P. Williams, Hoehing and Byington 1987). In addition, data on down-time causes in ammonia plants were given earlier in Table 1.5.

Plant site problems	27	3.5
Inadequate plant layout	18	2.4
Structures not in conformity with use requirements	17	2.2
Total	764	100.0

McFatter's data in Tables 2.20–2.22 are for a single refinery consisting of seven units over a 10-year period. During this time, the overall availability of all the units was 96.4%. In other words, the units were down for scheduled or unscheduled shut-down 3.6% of the time. But in addition there were some 122 failures that were significant in that they resulted in 1313 equivalent days of lost production, although they did not cause shut-down. The large number of unscheduled shut-downs in 1967 was due to a major hydrocarbon line leak and fire, which resulted in complete shutdown of the refinery.

The importance of compressors, furnaces and heat exchangers is clear from Table 2.22. Other data given by McFatter show a rising trend of equivalent days lost due to failures. He comments that this is due to large increases in throughput, reduction in sparage of critical items, for example, compressors and pumps, and lack of opportunity to take items, for example, furnaces, off for maintenance. The data for another refinery given in Tables 2.23 and 2.24 show an essentially similar picture; as do the data given by McIntire (1977a,b). Surveys of ammonia plant shut-downs have been published by Sawyer, Williams and Clegg (1972), G.P. Williams and Sawyer (1974), G.P. Williams (1978),

G.P. Williams and Hoehing (1983) and G.P. Williams, Hoehing and Byington (1987). The 1987 survey covers 136 plants, divided into three groups: (1) large-tonnage, single-stream, centrifugal compressor type plants, worldwide in North America, Europe and the rest of the world; (2) small plants, usually with multiple parallel streams of reciprocating compressors and (3) partial oxidation plants. The general nature of the shut-downs and down-time is shown in Table 2.25. Part of the down-time is due to non-plant problems (gas curtailment and market problems) and part is due to plant problems.

The service factor is the availability net of non-plant problems. The contributions to shut-downs and down-time are given in Table 2.26 in terms of plant area and type of equipment and in Table 2.27 in terms of individual items of equipment. Table 2.28 gives data on fires in the plants.

2.10 Trend of Injuries

The long-term trend of injury rates in the process industry is downwards. The trend in United Kingdom may be seen in Table 2.6, which shows that between 1970–74 and 1987–90, the fatal accident rate for the chemical and allied industries fell from 4.3 to 1.2. However, as Table 2.4 shows, the actual number of fatalities in this industry is small. Consequently, one large incident would have a significant effect on the figures, even if its effect was absorbed over quite a long period such as 10 years.

Evidence is available that the efforts devoted to safety and loss prevention by some companies have borne fruit. Figure 2.8 (Hawksley, 1984) shows the trend of the fatal accident rate in ICI over the period 1960–82. The data represent the 5-year moving average. They show that particular success was achieved in reducing the fatal incidents associated with the process risks, the reduction factor being about 15. The success achieved by certain US companies in reducing the lost time injury rate (LTIR) is illustrated in Figure 2.9 (Brian, 1988). The LTIR is the percentage of workers in the organization who, in a given year, suffer an injury so severe that it causes the worker to lose some work days. In one case the reduction factor is 280.

The trend in multiple fatality incidents has been studied by Keller and Wilson (1991), who obtained the results given in Table 2.29. The table shows a broadly stable situation.

2.11 Trend of Losses

There have been a number of studies addressing the question of whether the number of major incidents in the chemical and oil industries is increasing. Early work on these

lines was done by V.C. Marshall (1975c) and Kletz and Turner (1979). The insurers Marsh and McLennan (M&M) publish periodically a list of the 100 largest losses in the chemical and oil industries worldwide over a running 30-year period (e.g. Garrison, 1988b; Mahoney, 1990; Marsh and McLennan, 1992). The 1987 edition contains the analysis shown in Table 2.30. This indicates a trend that is rising up to 1986.

1975–79	22
1980–84	8
1985–89	15
1990–July 1991	7

A further review of loss trends is that given by Crook (1994, LPB 115). He comments that the M&M data suggests that until 1989 losses were doubling each decade. He gives further data from a study drawing on the Lloyds Weekly Casualty Reports (LWCRs). The frequency for the incidents that he considers, has risen from some 28/year in 1971 to some 103/year in 1991.

A particular type of incident that has received individual attention is the VCE, formerly generally referred to as unconfined vapour cloud explosion (UVCE). In the United Kingdom, the VCE at Flixborough resulted in a heightened awareness. A study at that time by V.C. Marshall (1975c) showed that the number of VCEs worldwide was indeed on an apparently increasing trend. Similarly, in his book on VCEs, Gugan (1979) stated: 'The trends in frequency, proportion of incidents producing blast and fatalities in UVCEs are all upwards'. This trend appears now to have been arrested. Industrial Risk Insurers (IRI) publish a periodic survey of VCE incidents. The number of VCEs obtained from this survey is given in Table 2.31.

2.12 Case Histories

The generalized statistics may be supplemented by individual case histories. These are treated in Appendix 1, which describes the various sources and gives specific case histories. The sources include: the incident reports of the HSE and the National Transportation Safety Board (NTSB); the collections of the Manufacturing Chemists Association (MCA) and the American Petroleum Institute (API); the periodic reviews of insurers, such as the *100 Large Losses* (Marsh and McLennan); the *NFPA Quarterly* of the National Fire Protection Association (NFPA), the *Chemical Safety Summary* of the Chemical Industry Safety and Health Council (CISHC) and its successor, the Chemical Industries Association (CIA), and the *Loss Prevention Bulletin* of the Institution of Chemical Engineers (IChemE), all of which publish case histories.

Accounts of major incidents are given in: Appendices 2–6 on Flixborough, Seveso, Mexico City, Bhopal and Pasadena, respectively; Appendix 16 on San Carlos; Appendix 19 on Piper Alpha; and Appendices 21 and 22 on Three Mile Island and Chernobyl.

3

Legislation and Law

Contents

It is the object of this chapter to give a brief account of the principal legislation and of the legal background relevant to safety and loss prevention. The account is largely restricted to the situation in the United States. Previous editions of this handbook detailed UK law. The development of legislation on health and safety in the United States may also be followed through the references given in Table A1.4 in Appendix 1. In particular, attention is drawn to the problems of toxic chemicals in the workplace, of pollution and of transport; of litigation; and to the resulting legislation.

In general, it is probably fair to say that legislation has been tougher in the United Kingdom in some areas and in the United States in others, and also that the rate at which controls have been tightened has often been different in the two countries. It is worth emphasizing also that in these areas it is not sufficient merely to pass legislation – it is necessary to enforce it. There has been, in both countries, a considerable tightening of methods of enforcement.

3.1 US Legislation

In the 1970s, there occurred in the United States, a very rapid development of public awareness of problems of health and safety, and of environmental problems, and a corresponding growth in the creation of controls in this area. In the United States, both State and Federal Governments are sources of legislation. In recent years the involvement of the Federal Government in health and safety legislation has greatly increased.

Major categories of safety legislation impacting the process industry can be categorized as follows:

(1) occupational health and safety,
(2) environment,
(3) toxic substances,
(4) accidental releases and
(5) transport

References on major safety issues are detailed below:

Occupational Safety and Health Act 1970

Occupational Safety History
Occupational safety did not begin with the passage of the Occupational Safety and Health Act of 1970. The ill effects of the environment on the worker have been known for thousands of years. Unfortunately, just because the hazards are known does not mean that they have been corrected. Some significant events in occupational safety in the United States include:

(a) 1812, the Embargo of the War of 1812 spurred the development of the New England textile industry and the founding of factory mutual companies. These early insurance companies inspected properties for hazards and suggested loss control and prevention methods in order to secure low rates for their policyholders.
(b) 1864, The Pennsylvania Mine Safety Act (PMSA) was passed into law.
(c) 1864, North America's first accident insurance policy was issued.
(d) 1867, the state of Massachusetts instituted the first government-sponsored factory inspection programme.
(e) 1877, the state of Massachusetts passed a law requiring guarding for dangerous machinery, and took authority for enforcement of factory inspection programmes.
(f) 1878, the first recorded call by a labour organization for a federal occupational safety and health law is heard.
(g) 1896, an association to prevent fires and write codes and standards, the National Fire Protection Association (NFPA), was founded.
(h) 1902, the state of Maryland passed the first workers' compensation law.
(i) 1904, the first attempt by a state government to force employers to compensate their employees for on-the-job injuries was overturned when the Supreme Court declared Maryland's workers' compensation law to be unconstitutional.

(j) 1911, the American Society of Mechanical Engineers (ASME) was founded. A professional, technical organization responsible for developing safety codes for boilers and elevators.
(k) 1911, the American Society of Safety Engineers (ASSE) was founded. The ASSE was dedicated to the development of accident prevention techniques, and to the advancement of safety engineering as a profession.
(l) 1912, a group of engineers representing insurance companies, industry and government met in Milwaukee to exchange data on accident prevention. The organization formed at this meeting was to become the National Safety Council (NSC). (Today, the NSC carries on major safety campaigns for the general public, as well as assists industry in the development of safety promotion programmes.)
(m) 1915, by this time, 30 states passed workers' compensation laws.
(n) 1916, the Supreme Court upheld the constitutionality of state workers' compensation laws.
(o) 1918, the American Standards Association was founded. Responsible for the development of many voluntary safety standards, some of which are referenced into laws, today, it is now called the American National Standards Institute (ANSI).
(p) 1936, Frances Perkins, Secretary of Labor, called for a federal occupational safety and health law. This action came 58 years after organized labor's first recorded request for a law of this nature.
(q) 1936, the Walsh–Healey (Public Contracts) Act passed. This law required that all federal contracts be fulfilled in a healthful and safe working environment.
(r) 1948, all states (48 at the time) now had workers' compensation laws.
(s) 1952, Coal Mine Safety Act (CMSA) was passed into law.
(t) 1960, specific safety standards were promulgated for the Walsh–Healey Act.
(u) 1966, the Metal and Nonmetallic Mines Safety Act (MNMSA) was passed.
(v) 1966, the US Department of Transportation (DOT) and its sections, the National Highway Traffic Safety Administration (NHTSA) and the National Transportation Safety Board (NTSB), were established.
(w) 1968, President Lyndon Johnson called for a federal occupational safety and health law.
(x) 1969, the Construction Safety Act (CSA) was passed.
(y) 1970, President Richard Nixon signed into law the Occupational Safety and Health Act, thus creating the OSHA administration and the National Institute for Occupational Safety and Health (NIOSH).
(z) 1992, The Process Safety Management rule was adopted by OSHA.

3.2 US Regulatory Agencies

The OSHA was created by the Occupational Safety and Health Act of 1970 and has responsibility for enforcing that Act. OSHA comes under the Secretary of Labor and is headed by an Assistant Secretary of Labor. Its activities include the adoption of standards and making of rules, the inspection of workplaces and the investigation of accidents.

The EPA, created by the National Environmental Policy Act (NEPA) 1969, is responsible for environmental legislation, including that on air pollution, water pollution and hazardous wastes. The areas of responsibility between the OSHA and the EPA are not clearcut. Although the OSHA is concerned with the workplace and the EPA with the environment, there are some areas where both agencies are involved. One of these is accidental releases and another is toxic substances, as described below. The relation between the two agencies is discussed by Spiegelman (1987) and Burk (1990).

Mining and mineral processing (such as Alumina refineries and lime processing) are the responsibility of the Mine Safety and Health Administration (MSHA).

Offshore production safety is the responsibility of the Mineral Management Service (MMS), which took over from the original US Coast Guard duties in the mid-1980s. However, the Coast Guard now has responsibility for deep water facilities, in addition to its traditional role of marine safety.

Pharmaceutical safety comes under the watchful eye of the Food and Drug Administration (FDA).

Pipeline safety, rail transport safety, and motor carrier safety issues are the responsibility of the Department of Transportation.

3.3 Codes and Standards

Standards are documented agreements containing technical specifications or other precise criteria to be used as rules, guidelines or definitions of characteristics, to ensure that materials, products, processes and services are fit for their purpose (ISO). Standards may be met on a voluntary basis unless and until they are incorporated into government regulations.

Codes, on the other hand, are legal requirements, which are incorporated in the US Code of Federal Regulations or the equivalent State or local code document. Hence, Code and regulation are synonymous, but standards may or may not be regulations. Laws are passed by government bodies, such as Congress. Then Government agencies (such as OSHA and EPA) are authorized to create regulations, which are eventually codified in the US Code of Federal Regulations. Announcement of new regulations or changes to existing regulations must be published in the US Federal Register.

Many industrial standards are incorporated directly by reference. For example, the OSHA flammable liquid code, 29CFR(106), directly references the ASME standard on pressure vessels. Unfortunately, this direct reference can cause some confusion, specifically on which edition of the ASME standard the government code is actually referencing. Since OSHA originally adopted the NFPA 30 standard flammable liquids in 1972, the ASME section VIII pressure vessel code existing at that specific instance in time was incorporated into law. Even though many updates to the ASME code were made over time, the older edition of the ASME code was a requirement whereas the updates in later editions are voluntary recommendations. OSHA eventually updated their regulations by publishing an announcement in the Federal Register.

There are many examples where older standards are still the referenced edition in regulatory codes. For example, the OSHA regulation on gas turbine facilities 29CFR 1910.110(b)(20) directly references the 1970 version of NFPA 37 (standard for the installation and use of stationary combustion engines and gas turbines), even though the latest update of this particular NFPA standard is 1998.

Both State and Federal legislation make use of national standards and recommended practices. In particular, standards such as those of the ANSI and the National Fire Codes of the NFPA are widely quoted in legislation. MMS frequently updates its references to American Petroleum Institute standards through announcements in the US Federal Register.

3.4 Occupational Safety and Health Act 1970

The Occupational Safety and Health Act 1970 (OSHA) is the framework Act. It provides that the Secretary of Labor should promulgate safety standards, inspect workplaces and assess penalties. There is a separate commission called the Occupational Safety and Health Commission, which deals with violations of the OSHA. The OSHA has some similarity with the HSWA 1974 in the United Kingdom, in that it is essentially an enabling measure which is superimposed on existing health and safety legislation, lays duties on employers and employees to comply with standards and regulations, and has provisions for inspection and enforcement.

However, there is one most important difference between UK and US regulatory concepts. OSHA regulations do not override any other equivalent federal safety regulation.

Regulations are issued under the Act by OSHA. The initial standards promulgated under the Act were published in the Federal Register 29 May 1971. The OSHA also established the NIOSH to develop and establish recommended occupational safety and health standards.

The Act places the onus for compliance with the law primarily on the employer. This applies even in cases where employees are not working according to instructions that have been issued to them to provide for their safety. An employer has the right to seek a variance from a standard, and may file a petition challenging the validity of a standard.

Accounts of the Act are given by Anon. (1971c), Hodgson (1971), Nilsen (1972a), L.J. White (1973b) and Corn (1976).

3.5 US Environmental Legislation

Of the issues, which have assumed an increasingly high profile in the last two decades, pollution attained an early prominence and has given rise to a large volume of legislation. Legislation of particular importance in this field includes: the Water Quality Act 1965, the NEPA 1969, the CAA 1970, the Federal Environmental Pollution Control Act 1970, the Federal Water Pollution Control Act (FWPCA) 1972, the Safe Drinking Water Act, 1974 and the Noise Control Act 1972.

The NEPA 1969 created the EPA.

The CAA 1970 gives the EPA power to adopt and enforce air pollution standards. The EPA has promulgated air quality standards that set the maximum concentrations for various gaseous pollutants. There have been amendments to the CAA in 1977, 1981 and 1990. Accounts of air pollution legislation are given by Vervalin (1972d), Zarytkiewicz (1975), Halley (1977), Lipton and Lynch (1987), G.A. Brown, Cramer and Samela (1988), Veselind, Peirce and Weiner (1990) and Asante-Duah (1993).

The FWPCA 1972 gives the EPA power to adopt and enforce water pollution standards. The EPA has promulgated effluent quality standards and guidelines that set the maximum concentrations for all liquid pollutants. Accounts of water pollution legislation are given by Weisberg (1973), L.J. White (1974), Veselind, Peirce and Weiner (1990) and Asante-Duah (1993).

Hazardous wastes are regulated by the RCRA 1976. There are rules governing the storage of such wastes in storage tanks, including underground storage tanks. The Act is administered by the EPA.

The Comprehensive Environmental Response, Compensation and Liability Act 1980 (CERCLA, or Superfund) strengthens the regulation of hazardous wastes by the EPA. It creates controls on hazardous waste sites and enforces clean-up of existing and abandoned sites. It seeks to identify potentially responsible persons (PRPs) and, where such parties are not found, it supervises a clean-up paid for from the Superfund. The Act has to be renewed periodically. The Superfund Amendments and Reauthorization Act 1986 (SARA) renews the Superfund. The part of the Act known as SARA Title III extends its application to accidental releases, as described below. Accounts of hazardous waste legislation and of Superfund are given by Caruana (1986), Edelman (1987), Melamed (1989), Veselind, Peirce and Weiner (1990) and Asante-Duah (1993).

The development of legislation on pollution may be followed through the references given in Table A1.4. These references show the evolution of the air and water quality standards and of their application. The NEPA 1969 imposes a duty on Federal agencies to obtain from a developer an environmental impact statement (EIS) before they take any action that affects the environment, such as granting a permit. A number of other Acts also include a requirement for an EIS. A regulation of the President's Commission on Environmental Quality (CEQ) made in 1978 defines requirements for an EIS. Permits may be required from a number of agencies at federal, state and local level. Environmental legislation in the United States is described further in Appendix 11.

3.6 US Toxic Substances Legislation

The Toxic Substances Control Act 1976 (TSCA) is a framework Act, which creates a comprehensive system of controls over toxic substances. It empowers the EPA to regulate the manufacture, processing, distribution, use and disposal of existing and new chemicals in order to avoid unreasonable risk to health or the environment and to delay or ban manufacture or marketing. It provides for the creation of an inventory of existing chemicals and for notification by a manufacturer of a new chemical or of new uses for a chemical. There are requirements for the toxicity testing of chemicals and for Premanufacture Notices (PMNs). The EPA has an Office of Toxic Substances (OTS) dealing with the Act. Accounts of the Act are given by Ricci (1976c), C.W. Smith (1977) and A.S. West (1979, 1982, 1986, 1993b).

Section 313 of SARA Title III also deals with toxic substances, but essentially in relation to high level emissions. It requires the EPA to compile a toxic chemical inventory database, the Toxic Release Inventory (TRI). Section 313 is discussed by Bowman (1989). The control of toxic substances in the workplace and in the atmosphere is also covered by the OSHA 1970 and by pollution legislation.

The development of legislation on toxic substances in the workplace and in the atmosphere may be followed through the references given in Table A1.4. The case of vinyl chloride is of particular interest.

3.7 US Accidental Chemical Release Legislation

The accidents at Flixborough, at Seveso and, above all, at Bhopal, and the development of major hazard controls in Europe led in the second half of the 1980s to US legislation on accidental releases. Accidental releases are covered by the EPCRA 1986. This is Title III of the SARA 1986. It is commonly known as SARA Title III and was signed into law in 1988. It contains four main parts;

(1) emergency planning,
(2) emergency notification,
(3) community right-to-know and
(4) toxic chemicals inventory.

The Act is enforced by the EPA. An account of the EPA's chemical accident release prevention programme is given by Matthiesen (1994).

Controls on accidental releases have also been introduced by the OSHA in the form of a rule for the Process Safety Management of Highly Hazardous Chemicals. This introduces a requirement for a process safety management system to identify, evaluate and control such hazards. An account of OSHA's process safety management rule is given by Donnelly (1994).

Individual states have also brought in their own legislation. The New Jersey TCPA 1985 creates a requirement for a risk management programme for facilities handling certain toxic chemicals above a given inventory. The California Hazardous Materials Planning Program is based on a codification of four laws within the California Health and Safety Program.

Accounts of legislation on hazardous chemicals with potential impact off site are given by Brooks *et al.* (1988) and Horner (1989).

3.8 US Transport Legislation

Another major concern in the United States in recent years has been the problem of the transport of hazardous materials, and this has given rise to a large volume of legislation. Some principal items of legislation (considered further in Chapter 23) in the field include

(1) Rivers and Harbors Act 1899
(2) Explosives Transportation Acts 1908, 1909 and 1921
(3) Tank Vessels Act 1936
(4) Natural Gas Act 1938
(5) Federal Aviation Act 1958
(6) Natural Gas Pipeline Safety Act 1968
(7) Dangerous Cargo Act 1970
(8) Hazardous Materials Transportation Act 1970
(9) Coastal Zone Management Act 1972
(10) Ports and Waterways Safety Act 1972

3.9 Regulatory Support

Legislation that is based on good industrial practice and is developed by consultation with industry is likely to gain greater respect and consent than that which is imposed. Actions by individuals who have little respect for some particular piece of legislation are a common source of ethical dilemmas for others.

The professionalism of the regulators is another important aspect. A prompt, authoritative and constructive response may often avert the adoption of poor practice or a short cut. The regulatory body can contribute further by responding positively when a company is open with it about a violation or other misdemeanor that has occurred.

Major Hazard Control

Contents

Foreword by Jerry Havens

I am honored to have the opportunity to update Professor Lees' discussion of Major Hazards. Had the events of 9/11 not occurred, there would be little that I could add, but there is today a new dimension to the problem of major hazards. For fifty years now, we have been wrestling, sometimes not effectively enough, with problems of human error – since 9/11 we are forced to consider malicious acts as well.

I cannot improve on Lees' definition of a major hazard – as being of low probability of realization combined with the likelihood of very great harm if realized. Although this definition may be virtually useless in the eyes of the law, hence most regulatory uses, I think Lees had in mind the public, and the public will ultimately decide the acceptability of activities it considers major hazards. Although benefits accrue to all effective loss prevention activities, major or not, prevention of the realization of major hazards will, I believe, become increasingly important in maintaining industry's reputation as a good, and safe, neighbour.

Lees is primarily interested here in major technological hazards, but he skillfully compares them with natural hazards with which the public is more familiar. He points out that technological hazards can rival natural hazards in severity, as some incidents that have occurred in the twentieth century suggest. Despite significant efforts made to improve public safety, the general public is sadly uninformed about the extent of misery that can accompany major accidental releases of hazardous materials – perhaps best exemplified by the Bhopal and Chernobyl disasters. I have been surprised to find in my teaching experience that few chemical engineering students today know anything about Bhopal – excepting Indian students.

As Lees suggests, the problem of major hazards requires an essential understanding of, and respect for, the most basic desires of our society. If the methods adopted for dealing with these problems do not address the larger desires of society, failure is likely. He hits the nail on the head when he says, 'Policy decisions would be so much easier if a purely quantitative analysis were enough or nearly so.'

The suggestion that 'people select certain risks for attention to defend their preferred lifestyles and as a forensic resource to place blame on other groups' is provocative and sobering. And, his comment that 'While one school of thought argues that the prevention of incidents requires strict discipline and the attribution of blame for error, the other holds that incidents arising from human error are conditioned by the work situation and that the rectification of defects in that situation requires the free flow of information which is inhibited by a blame culture' is all the more sobering in view of the current controversies surrounding the withholding post-9/11 in the United States of Risk Management Plans and other 'sensitive' information from the parties for which it was designed – for fear that it will be used with malice.

Lees' book summarizes the technical/scientific tools that are available for application to the management of major hazards – to define the consequences of scenarios which must be considered, and to define and minimize the likelihood of those scenarios being realized. There remain some areas that are worthy of continued research, to 'sharpen the pencil', and a continued commitment to research and development of loss-prevention management methods is essential. However, it is my belief that the major hazards problems society faces are less a problem of insufficient information about those hazards and more a problem of insufficient application of the tools that we have in hand.

With this foreword, I have decided that Lees' discussion is best left unaltered and unexpanded. To my mind, excepting the growing emergence of a global terrorist threat, there has been little that has occurred since he wrote these words that change the dimensions of the problem of major hazards or the methods that are available for their management.

Some of the installations operated by the chemical industry constitute major hazards. In the early days of the industry, there were some major disasters, particularly ammonium nitrate explosions, involving hundreds of fatalities. The period 1950–80, however, was relatively free of such disasters, but since then there have been several accidents with death tolls of over 100, of which Bhopal was by far the worst.

Process operations are one of a number of activities that are of concern to communities and governments. In particular, high technology, which sometimes brings unforeseen hazards, causes some unease. Inevitably, therefore, the evolution of hazard control policy for the chemical industry must be influenced by developments in public policy for the control of hazards generally.

One area of activity that attracts hazard controls is transport. The evolution of hazard controls on the railways is very instructive and has many lessons for the chemical industry, while air transport illustrates the controls developed for an industry in which high technology is particularly important. Another area of activity closer to the process industries where there has long been a well-developed hazard control policy is the nuclear industry. This has often been suggested, therefore, as a model for the control of hazards in the process industries. Other models include the hazard control systems used in mines, in the explosives industry and in the pharmaceuticals industry.

Selected references on hazard control are given in Table 4.1.

4.1 Superstar Technologies

Within the last two decades, there has been a growing awareness of the problems associated with industrial growth and technological development. This has manifested itself in debate and conflict on such topics as

(1) environment (amenities, countryside, pollution, waste disposal, noise);
(2) resources (oil, metals);
(3) transport (road building, road accidents, aircraft crashes, tanker shipwrecks);
(4) buildings and structures (high rise flats, bridges);
(5) oil and chemical industry (pollution, noxious release, noise);
(6) nuclear power (major accidents, low-level release, waste disposal);
(7) toxic substances (drug and food additive side effects, materials at work).

It is also increasingly recognized that these problems have certain common features and that there is a generic problem in the assessment and control of technological developments. The question is considered in Superstar Technologies (Council for Science and Society, 1976) and the following discussion draws on this work.

The existence of a problem is due to the combination of a number of factors. Human artefacts are now often large and complex. Society also is complex, interdependent and vulnerable. Technological developments are often rapid and of large scale, and economic pressures militate against extensive testing. Devices are scaled up by extrapolation into untested areas and there is no opportunity for gradual evolution and learning by trial and error.

At the same time, some of the former moderating influences have grown weaker. The complexity of projects involving numerous teams dilutes individual responsibility. There are many new specialisms which tend not to have the same ethos as the older professions. In some of the more important areas the project is so specialized that the organization concerned has a virtual monopoly of the experts available. The combination of the variety and depth of technology increases the difficulty of monitoring by government inspectors.

The degree of acquiescence by the public in technological development has changed considerably in recent years. The increased militancy of interest groups from trade unions to neighbourhood associations shows that people are not prepared to put up with the hazards and nuisances which were tolerated in the past.

Part of the problem is that high technology projects tend to be vulnerable to failures of all kinds. There is only one way in which they can go right, but many in which they can go wrong. In reliability terms, they are series systems in which all the elements must work if the system is to be a success. There is a particular problem in identifying all the ways in which the system may fail. Another aspect of the problem is the question of unforeseen dangerous side effects, of which there have been numerous examples. These include the side effects of drugs and of industrial materials such as asbestos and vinyl chloride.

Occasionally a disaster occurs which is sufficiently dramatic to result in action. Some major technological disasters in the United Kingdom in recent years have been the crashes of the Comet aircraft, the release of radioactive material from Windscale, the side effects of the drug Thalidomide, the defects in the Ronan Point high rise flats, the oil pollution from the Torrey Canyon tanker, the failures of box girder bridges, the collapse of structures built in high alumina cement, the vapour cloud explosion at Flixborough, the sinking of the Herald of Free Enterprise, the fire at the Kings Cross Underground station, the rail crash at Clapham Junction and the explosion and fire on the Piper Alpha oil platform. Some of these have led to improvements of safety procedures (e.g. Windscale), and some to the abandonment of the technology (e.g. Ronan Point). All parties, including the public, the professions and the government tend to react more strongly to such disasters than they do to smaller scale failures, even where these are very frequent.

It is possible to identify a number of factors that allow high technology projects to develop to the point where a disaster can result. At the intellectual level there is the difficulty of trying to foresee the potential problems and of judging where knowledge is inadequate or experiment is required. It is necessary, but not easy, to keep abreast of the technical literature and to maintain contact with experts in other fields. In the moral sphere there are the difficulties of maintaining a conscientious approach to the frequently tedious requirements of safety and of speaking out when doubts arise on safety features. The problem has an organizational aspect in that it tends to require a strong personality to run a major project, but such a person is frequently intolerant of criticism. As a consequence, colleagues are discouraged from dissenting.

Studies of major failures in man-made systems have been described in *Catastrophic Failures* by Bignell, Peters and Pym (1977) and *Man-Made Disasters* by B.A. Turner (1978), and by Wearne (1979).

4.2 Hazard Monitoring

The Council for Science and Society argues for the creation of mechanisms by which the community can monitor and control hazards. Monitoring is likely to be effective only if it is generally accepted as a necessary and constructive activity that not only protects society but also contributes to the project. There is an analogy here with the role of 'Her Majesty's Loyal Opposition' in Parliament.

The project needs to be monitored at all stages: conception, decision and operation. At the conceptual stage, the need is to discover the problems, the hazards and the disbenefits. There should be testing of the basic assumptions, speculative reviews of hazards and study of various scenarios. The debate should involve the public as well as the experts. Argument continues in the decision stage, but now centres on detailed proposals and designs of the project. Here the discussion is mainly between the project team and the other agencies involved. At the operational stage, the emphasis changes to enforcement of operational requirements and monitoring of operating hazards.

Monitoring should be carried out both within the organization itself and through external agencies and fora. Internal monitoring may be conducted by internal but independent functions, such as a pressure vessel inspection section, and by consultants. External monitoring takes place through the activity of interest groups and government agencies. An interest group requires a forum in which to operate; typical fora are courts of law, public inquiries and the news media.

Monitoring by government agencies has a crucial role, but again there are certain difficulties. Despite the resources of government, it is not easy for a government agency to deploy the full range of up-to-date expertise which ideally it should possess. Like any other activity, monitoring may become routine, and complacency may set in. The agency must expect to be subject to the internal politics of the civil service machine. Government itself is not infrequently involved in some way in the projects that require to be monitored.

There are certain relatively detached institutions, such as universities and the professional bodies, which contain expertise and which have a role to play in the monitoring process. It does not follow, however, that they should necessarily themselves be monitors. Their function is rather to provide a source of independent expertise.

An explicit attempt needs to be made to enhance the effectiveness of the individual as a monitor. One important measure is to increase the backing that professional standards can give to the individual. Another is to afford protection to the individual who 'blows the whistle' on a hazard or an abuse.

The process of communal decision-making also places an obligation on those who claim to speak on behalf of the community to be well informed and responsible in their arguments.

4.3 Risk Issues

High technology projects involve risks. These risks raise a number of issues including:

(1) risk perception;
(2) risk criteria;
(3) risk management;
(4) risk estimation.

There is a growing literature on risk issues, which includes *How Safe is Safe?* (Koshland, 1974), *Of Acceptable Risk* (Lowrance, 1976), *The Acceptability of Risks* (Council for Science and Society, 1977), *An Anatomy of Risk* (Rowe, 1977), *Society, Technology and Risk Assessment* (Conrad, 1980), *Societal Risk Assessment* (Schwing and Albers, 1980), *Science, Technology and the Human Prospect* (Starr and Ritterbush, 1980), *Technological Risk* (Dierkes, Edwards and Coppock, 1980), *Acceptable Risk* (Fischhof *et al.*, 1981), *The Assessment and Perception of Risk* (F. Warner and Slater, 1981), *Dealing with Risk* (R.F. Griffiths, 1981), *Risk in the Technological Society* (Hohenemser and Kasperson, 1982), *Major Technological Risk* (Lagadec, 1982), *Technological Risk* (Lind, 1982) and *Risk in Society* (Jouhar, 1984).

The Health and Safety Executive (HSE) has published *The Tolerability of Risks from Nuclear Power Stations* (HSE, 1988c), *Risk Criteria for Land Use Planning in the Vicinity of Major Hazard Installations* (HSE, 1989e) and *Quantified Risk Assessment: Its Input to Decision Making* (HSE, 1989c).

A review of risk issues is given in *Risk: Analysis, Perception and Management* (Royal Society, 1992; the RSSG Report) which provides the framework for the following discussion.

The treatment of this topic here is necessarily brief and is limited to an account of some of the principal themes. A further discussion of risk and in particular of risk criteria for hazard control is given in Chapter 9.

4.4 Risk Perception

Work on risk perception shows that people tend not to think in terms of an abstract concept of risk, but rather to evaluate the characteristics of a hazard and to perceive risk in a multi-dimensional way. The idea that risk is an inherent property of the hazard has been criticized by Watson (1981) as the 'phlogiston theory of risk'. Various authors have attempted to define risk. One such attempt is that of Vlek and Keren (1991), who have given 10 different definitions.

4.4.1 Acceptable risk

This question of risk is often treated in the same way as that of 'acceptable risk', although the latter term is itself contentious, raising as it does the question: Acceptable to whom? Nevertheless, the term 'acceptable risk' has been widely used to describe this generic problem. A discussion of the problem has been given in The *Acceptability of Risks* by the Council for Science and Society (1977). Some of the considerations affecting judgements about risks given by Lowrance (1976) are shown in Table 4.2.

The Council for Science and Society takes up the argument advanced by earlier workers that the distinction between risks that are assumed voluntarily and those that are borne involuntarily is a crucial one. In general, people are prepared to tolerate higher levels of risk for hazards to which they expose themselves voluntarily. The risk to which a member of the public is exposed from an industrial activity is an involuntary one. It is a common view that the risk to which an employee is exposed from this activity is in some degree voluntarily assumed. Thus, the Council's report states:

> Some hazards are accepted voluntarily, even when the risk is high. At one extreme we may say that the risk is 'embraced' when it is an integral part of the challenge in a hazardous sport, such as pot-holing or motor-racing . . . .

The personal attitude is different in emergencies, where the risk may be said to be 'defied' in the course of a response to a call for help. Rescue operations are the prime example of such hazards. In them, the balance of costs and benefits may be very different from that which prevails in ordinary life, as we can see from the lengths to which kind-hearted people will go in retrieving lost or trapped animals . . . .

When a serious hazard is encountered involuntarily, acceptance may extend only to a much lower level of risk than otherwise. When, in addition, the sufferer feels impotent in the face of danger, tolerance is further reduced. Accidents in trains seem peculiarly unacceptable, perhaps more so than accidents in aeroplanes, where rightly or wrongly the passengers are generally considered to have taken the risk on themselves for the sake of the extra benefit of the time saved. In underground tube-trains, only absolute safety seems to be good enough; perhaps the enclosed environment exerts a strong psychological influence. The stark terror of impotence in the face of impending destruction is an important part of the evaluation of such risks. For a strong contrast, we notice how the illusion of control by a driver in a private motor car who is under the influence of alcohol makes very high risk levels acceptable to him.

Table 4.2 *Some considerations affecting judgements on safety (after Lowrance, 1976)*

Risk assumed voluntarily/Risk borne involuntarily
Effect immediate/Effect delayed
No alternative available/Many alternatives available
Risk known with certainty/Risk not known
Exposure is an essential/Exposure is a luxury
Encountered occupationally/Encountered non-occupationally
Common hazard/'Dread' hazard
Affects average people/Affects especially sensitive people
Will be used as intended/Likely to be misused
Consequences reversible/Consequences irreversible

Perhaps the most difficult class of hazards for judgements of acceptability are those called 'major hazards'. These are defined by a low probability of realization, combined with the likelihood of very great harm if the hazard is realized. In this case, the intuitions derived from ordinary experience provide little help in conceiving the hazard; and the experts themselves may well disagree even over the probabilities. When harm is liable to be inflicted on people who have neither any conceivable power to avert it, nor any responsibility for its occurrence, the judgement of the 'acceptability' of the risk is at its most difficult.

This variety of perceptions may well be a cause of irritation to the expert on risk assessment. Policy decisions would be so much easier if a purely quantitative analysis were enough or nearly so. The subjective perceptions of risk can have enormous political importance, possibly to the extent of distorting priorities in programmes for coping with the real risks that society encounters. (This problem is most noticeable in medicine.) There is occasionally a temptation on the part of the expert in technological risks to throw in a couple of extra orders of magnitude of restriction of unacceptable hazards and then perhaps be annoyed when even this does not render them acceptable to critics.

In the last analysis, the Council continues, there is only one sort of risk 'that is truly "acceptable" in the ethical sense: the risk that is judged worthwhile (in some estimation of costs and benefits), and is incurred by a deliberate choice made by its potential victims in preference to feasible alternatives'. The important question, therefore, is 'under what conditions, if any, is someone in society entitled to impose a risk on someone else on behalf of a supposed benefit to yet others?'

The Council concludes that it is not practical to give the individual an absolute veto over any development which may be a hazard to him or her. The public interest must also be considered. This does not necessarily mean, however, that it is sufficient to leave the judgement on the acceptability of risk to the organization concerned or to government. The Council cites a number of cases in which it considers that control by government inspection agencies has not achieved the proper balance of risk. It suggests:

> Rather than continuing to demand an answer to the question whether a risk is fair in itself, we should redirect our attention to the ways that risks come about and are controlled. That is, we should focus on the procedures by which the decisions are taken on the creation or persistence of risks, and ask whether these procedures are fair.

The Council advocates that decisions on projects involving hazards should be openly arrived at and that those affected should be able to participate in the decision through the medium of public inquiries and other similar fora.

The report contains a number of appendices that deal with risk in aircraft (D.V. Warren, 1977), in nuclear radiation (Burhop, 1977), with explosives (R.L. Allen, 1977a), at Flixborough (R.L. Allen, 1977b), with asbestos (Woolf, 1977) and with the use of mathematics in risk assessment (Ravetz, 1977b). Many of these are discussed further in later chapters.

4.4.2 Acceptable vs tolerable risk

The account of the acceptability of risk in the RSSG Report describes some of the approaches taken to the problem of acceptable risk and the distinction between acceptable and tolerable risk.

Fischhoff *et al.* (1981) suggest that there are three main methods used to resolve risk questions. These are professional judgements by experts, formal cost–benefit analyses and methods based on comparisons with the risks accepted from existing hazards. The authors suggest that the relevant factors are whether a method is: comprehensive, logically consistent; practical, open to evaluation, politically acceptable, compatible with existing institutions, conducive to society's learning about risk and whether it improves decision-making in the long run. Fischhoff *et al.* use these seven criteria to evaluate the approaches described.

The concept of acceptable risk came in for criticism from Sir Frank Layfield, chairman of the Sizewell B Inquiry. He argued that the concept understates the seriousness of the problem and that the term 'tolerable risk' is preferable. He expressed the view that the opinions of the public should underlie the evaluation of risk, although he saw no practical way in which they could reliably be so used. The Tolerability of Risk from Nuclear Power Stations, produced following this inquiry (HSE, 1988b) gives the following definition:

> Tolerability does not mean 'acceptability'. It refers to the willingness to live with a risk to secure certain benefits and in the confidence that it is being properly controlled. To tolerate a risk means that we do not regard it as negligible or something we might ignore, but rather as something we need to keep under review and reduce still further if and as we can.

4.4.3 Actual vs perceived risk

One aspect of the risk debate concerns the relationship between objective, or statistical, risk and subjective, or perceived, risk. One line of inquiry draws a distinction between actual and perceived risks, and seeks to investigate the extent to which perceived risks differ from actual ones. The opposing school of thought holds that such a distinction is misconceived.

The attempt to assess the risks arising from a hazard involves a number of areas of considerable difficulty. The RSSG Report highlights two of these: (1) consequences and (2) uncertainty.

Scenarios for the realization of a hazard generally involve a whole range of consequences. There may be injuries, which may be fatal or non-fatal, prompt or delayed. There may be environmental damage where the effects may appear promptly or only after a delay. In other words, the consequences are multi-dimensional.

The assessment of the risk is subject to uncertainty. Traditionally, uncertainty has been discussed in terms of probability, but this does not exhaust the matter. In the taxonomy of ignorance given by Smithson (1989), probability is one aspect along with others such as incompleteness and distortion. Even the concept of probability has different meanings, four conventional interpretations being the classical, frequency, logical and Bayesian.

One type of uncertainty that arises in risk assessments concerns the values to be assigned to the parameters. A more fundamental uncertainty arises over the completeness and correctness of the structure of the analysis. There are both parametric and systemic uncertainties – or as C.H. Green, Tunstall and Fordham (1991) put it 'What you know you don't know' and 'What you don't know you don't know'.

Expert risk assessments do not provide an unambiguous and reproducible measure of risk. The validity of the assessment depends very largely on its pedigree, but this can be mixed, with highly expert and less expert elements, such that the latter may well be the weak link. A study by Lathrop and Linnerooth (1983) found widely differing assumptions underlying three separate studies of the same proposed facility in the United States. Considerations of this kind undermine the assumption that it is possible to determine an objective measure of 'risk' that can then be used as a basis for judging perceptions of risk.

4.4.4 Psychological issues

One of the main fields of study in psychology is sense perception and the methodology for this is one starting point for investigating risk perception. In such a work, an investigation is made of the extent to which the subject's perception of objective stimuli corresponds with reality. The difficulty in applying these methods to risk perception is that risk is not an objective property.

There are, however, several specific topics bearing on risk where progress has been made using the psychological approach. The RSSG Report describes three such areas: (1) estimation of fatality, (2) characterization of hazards and (3) differences between individual and group perceptions.

Lichtenstein *et al.* (1978) investigated the estimation by laymen of the annual number of fatalities in the United States from 40 different hazards. The estimates made by the laymen showed two biases. One was that they overestimated the number of deaths due to infrequent causes such as tornadoes, but underestimated those due to frequent causes such as diabetes. The other was that the infrequent events for which overestimates were highest tended to be those of which laymen have a vivid picture and which are salient in their memory. The authors term this the 'availability heuristic'. The correspondence between the lay estimates and the statistical data were better in respect of rank ordering than in respect of the absolute number of deaths. The conclusion drawn in the Report from this and other work is that individuals are quite capable of making well-founded judgements of the relative magnitude of expected fatalities.

A study of the perception of the qualitative characteristics of hazards was made by Slovic, Fischhoff and Lichtenstein (1980). In this study, respondents were asked to rate 90 hazards in respect of 18 qualitative characteristics. The latter were then reduced to three dominant factors of which the first two were 'dread risk' and 'unknown risk'. Dread has to do with features such as whether the hazard is uncontrollable and exposure to it involuntary, unknowability has to do with features such as whether the hazard is a familiar one and whether its effects are immediate or delayed. The results obtained are shown in Figure 4.1. The third factor was the number of people exposed to the hazard. The findings of this and subsequent studies have also shown that respondents tend not to be satisfied with existing trade-offs between risks and benefits and to desire stricter regulation of hazards.

An individual's perception of risk is likely to be affected by his personality but also by his membership of a group. A number of studies have been done of the effect of membership of groups differentiated by culture, gender or age. Work on groups also includes investigation of the attitudes of individuals within groups with different stances on a

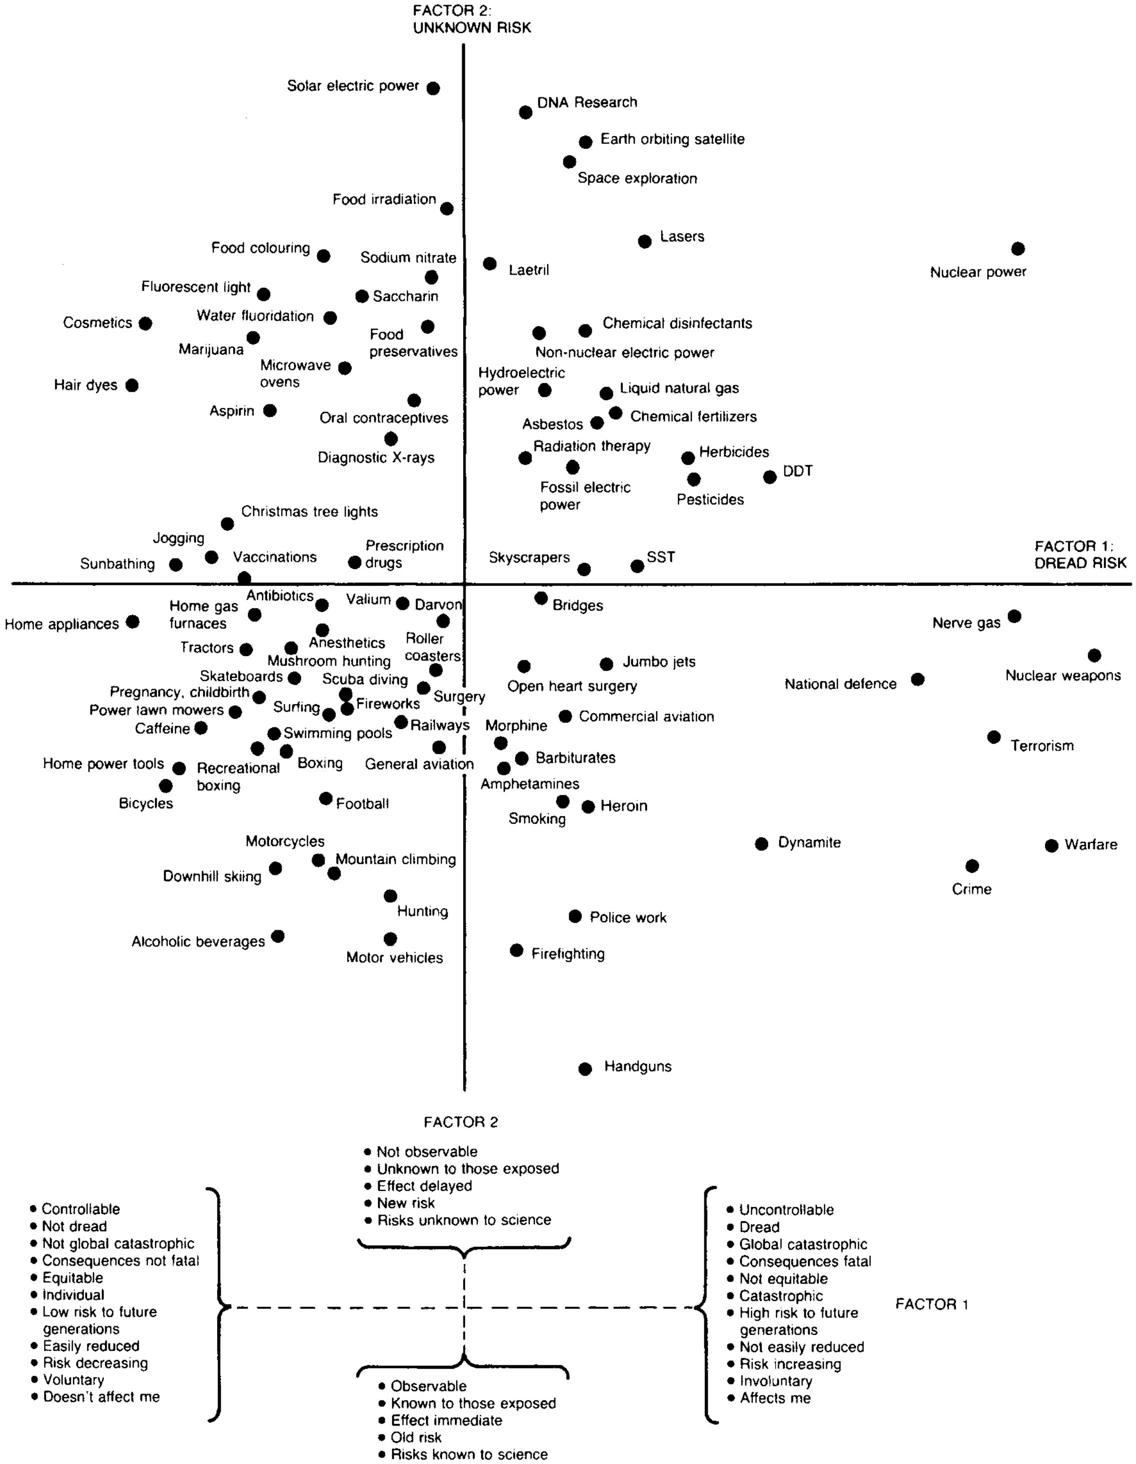

Figure 4.1 *Perception of different hazards: 'dread risk' vs 'unknown risk (Stovic, Fischhoff and Lichtenstein, 1980): locations of 90 hazards on factor 1 (dread risk) and factor 2 (unknown risk) of the three-dimensional space derived from the interrelationships among 18 risk characteristics. Factor 3 (not shown) reflects the number of people exposed to the hazard and the degree of one's personal exposure (Courtesy of Plenum Press)*

particular issue such as pro- and anti-nuclear groups. One finding of this work is that individuals in the two groups had rather similar attitudes to particular undesirable characteristics such as increased centralization of power or imposition of involuntary risk, but differed rather in the extent to which they perceived these characteristics as applying to nuclear power.

Another finding of work in this area is that an attitude which favours a technology is often accompanied by a desire that it be more closely regulated and, therefore, that a call for stricter regulation is not necessarily evidence of hostility.

4.4.5 Social science issues

A starting point for the social sciences is that there is every reason to expect that a person's attitude to hazards is related to his overall system of values and beliefs and that it is affected by broad social factors. Three insights of social science which bear on risk issues described in the RSSG Report are (1) cultural theory, (2) social amplification and (3) social framing.

Cultural theory, developed by Douglas (1966, 1982, 1985, 1990, 1992), holds that attitudes such as that to risks vary systematically with cultural bias. The cultural bias of an individual depends partly on the extent to which he is part of a bounded group ('group') and partly on social interactions which are conducted according to rules rather than negotiated ('grid'). Four principal biases are recognized: hierarchists (high grid/high group), egalitarians (low grid/high group), fatalists (high grid/low group) and individualists (low grid/low group). The Report describes these different types as follows:

> The argument goes that individualists see risk and opportunity as going hand-in-hand; fatalists do not knowingly take risks but accept what is in store for them; hierarchists are willing to set acceptable risks at high levels so long as decisions are made by experts or in other socially approved ways; but egalitarians accentuate the risks of technological development and economic growth so as to defend their own way of life and attribute blame to those who hold to other cosmologies.

It continues:

> The implications of this approach for risk assessment and perception are revolutionary. It implies that people select certain risks for attention to defend their preferred lifestyles and as a forensic resource to place blame on other groups. That is, what societies choose to call risky is largely determined by social and cultural factors. If the cultural theory is accepted, no 'single metric' for risk analysis can be developed on which the different cultural biases can find common ground. Studies point to a divide between egalitarians, who are anti-risk, and others.

The concept of social amplification is that risk perceptions are amplified or attenuated by social processes. This occurs because the knowledge of risk that the individual possesses is largely second-hand. It was suggested by Kasperson *et al.* (1988) that the transformations that occur as the risk signal passes through social 'amplification stations' such as expert groups, mass media, government agencies and politicians may be predictable.

'Social framing' or 'expert framing' is the term used to describe the fact that the risk assessments made by expert groups tend to involve a set of implicit assumptions. These assumptions have been the subject of a series of studies by Wynne (1982, 1989, 1992). One area where the expert group typically makes implicit assumptions is the social and institutional framework within which the risks are to be managed. Another area where implicit assumptions are common relates to operations. Discussing the problem of pesticide safety, Wynne (1992) comments that expert framing involved the assumptions that

> . . . pesticides manufacture process conditions never varied so as to produce dioxin or other toxic contaminants of the main product stream; drums of herbicide always arrived at the point of use with full instructions intact and intelligible; in spite of the inconvenience farmers and other users would comply with the stated conditions, such as correct solvents, proper spray nozzles, pressure valves and other equipment, correct weather conditions, and full protective gear. As a model of the 'real' social world and thus of the typical risk system, this was utterly naive and incredible however good the laboratory science.

4.4.6 Risk communication

Another area of study is that of risk communication. Here the RSSG Report addresses four principal topics: (1) risk communication as a discipline, (2) conceptual approaches, (3) applications and (4) trust.

Risk communication occurs at national and company levels. At the latter level a company needs to communicate about risks both with its employees and with the public. In particular, risk communication is an essential part of emergency planning. More recently, legislative requirements for the provision of information to the public have been introduced. Risk communication at the national level is seen most clearly when opposition arises to developments such as hazardous installations or waste disposal sites.

Risk communication in such a context is now recognized as a discipline, but its study is not well advanced. However, the need for a professional approach is clear. The Report comments that 'One should no more release an untested communication than an untested product.' It distinguishes four conceptual approaches to risk communication. One treats it within a technological framework in which there is one-way communication from the expert to the non-expert. The second emphasizes the need for a two-way dialogue. The third deals with the social and institutional context within which communication occurs and the actions, or inaction, as well as the words of the organizations involved. The fourth views risk communication as an aspect of the general political process.

At the level of applications, some of the attempts made to provide reassurance by comparison of the risks of the activity in question with other, more familiar risks come in for criticism. It is suggested by Covello, Sandman and Slovic (1988) that if such attempts are made, they need to take into account the work described above on the principal qualitative dimensions by which people characterize hazards.

Another aspect of applications is the layman's mental model and the effect which this has on his response to risk communication. Using as a baseline an expert model, the layman's model can be studied, and concepts which are erroneous or entirely absent identified. The attempt can then be made to clear away factual misunderstandings at least.

The credence placed in a communication about risk depends crucially on the trust reposed in the communicator. Wynne (1980, 1982) has argued that differences over technological risk reduce in part to different views of the relationships between the effective risks and the trustworthiness of the risk management institutions. People tend to trust an individual who they feel is open with, and courteous to, them, is willing to admit problems, does not talk above their heads and whom they see as one of their own kind.

Trust in a company depends on many factors and may be put at risk in a number of ways. Its general reputation may be undermined by persistent practice or by particular incidents. Distrust of the political process may rub off on the regulatory body. Risk assessment involves the treatment of uncertainties and mishandling can result in loss of trust.

4.5 Risk Management

'Risk management' is the term generally used to cover the whole process of identifying and assessing risks and setting goals and creating and operating systems for their control. An important input to risk management is risk assessment. Indeed the two terms are sometimes treated as synonymous. Generally, however, risk management is accorded a broader meaning to cover both a wider range of risks and a more complete set of activities.

The hazards with which risk management is concerned include, in general, those from natural events and man-made systems that give rise to a range of physical, financial, legal and social risks. The main concern here is with the risks from technological systems.

Risk management is practised at government as well as company level and, indeed, many of the important issues in risk management have to do with the design of the institutions required for public risk management and with the associated risk evaluation.

4.5.1 Public risk management

Ultimately it is up to the government to decide which activities can be allowed and which must be banned and how any disbenefits from the former are handled. Thus, the government is involved in risk management, but the extent to, and manner in, which it should be is a matter of debate.

Many activities involve external 'costs' that are imposed on other parties. These externalities include danger and environmental pollution. A market solution is to require the party responsible to pay these costs. In the case of pollution, this is the principle of 'polluter pays'. Another market approach is the use of insurance to pool risks. However, there are a number of difficulties in these approaches. The party responsible may not be readily identifiable and may have limited resources. This is illustrated by the difficulties in enforcing clean-up of hazardous waste sites.

Insurance also has it problems. Insurers may be reluctant to provide cover for perils that are poorly defined such as pollution. Even where insurance is available, there are recognized problems. Adverse selection occurs where parties know their own risks better than the insurers and insure only the high risks. Moral hazard occurs where the possession of insurance lessens the incentive to reduce the risk.

Public risk management is subject to two types of error. One is the prohibition of an activity or product that may be harmless; the other is failure to prohibit an activity or product which is harmful. By analogy with the terms applied to hypotheses, these two errors are termed Type I and Type II errors, respectively. A Type II error can lead to public outcry, whereas a Type I error, which may involve foregoing great economic benefit, is unlikely to do so.

Risk management is practised not only at national level but at the supranational and local government levels also.

The RSSG Report identifies nine types of institutional 'player', as shown in Table 4.3. It describes the implications as follows:

> As soon as more than one organization enters the risk management scene, different priorities and preoccupations must be resolved through bargaining. Problems of deadlock, jurisdictional tensions, ordering of preferences and varying levels of preference intensity become more acute. The policy 'packaging' processes involved in trading preferences, particularly in multilevel bargaining situations such as those involved in EC decision-making,

Table 4.3 *Some types of player in institutional risk management (The Royal Society, 1992) (Courtesy of The Royal Society)*

Territorial level	*Institutional type*		
	Core executive bodies	*Independent public bodies*	*Private or independent bodies*
Supranational	Example: EC commission	Example: EC Court of Justice	Example: Greenpeace
National	Example: national Parliaments and ministerial departments	Example: national courts and independent regulatory bodies, like the NRA[a]	Example: National Associations of Insurers
Subnational	Example: state or local governments	Example: independent regional/local statutory bodies	Example: local firms and activists

[a] National Rivers Authority.

may result in outcomes that do not match the preferences of any of the negotiating parties.

Many of the public bodies such as advisory committees concerned with risk management have an advisory rather than an executive role. In this they are analogous to a staff function in a company.

The RSSG Report identifies the following four modes of operation available in public risk management: (1) information, (2) resources, (3) legislation and (4) direct action. Information is of particular importance in relation to emergency warnings of impending natural hazards, although the problem of liability for false alarms is a severe one. Where resources are required and unavailable elsewhere, the state may provide them, as in the clean-up of hazardous waste sites. Direct action, by police or other agencies, is largely limited to emergencies.

The approach taken may rely on prevention or on mitigation. For a major hazard at a fixed installation, this typically means either preventing an incident or providing an adequate distance between the plant and the public offsite. However, the applications of the two approaches are much wider. Mitigation, for example, may include financial compensation.

4.5.2 Risk management rules

Some of the dimensions of risk management systems have been studied by Ostrom (1986), as described in the RSSG Report. Table 4.4 shows six such dimensions and their characteristic trends.

The boundary rules determine the parties allowed to participate in the risk management process. The decision process within the regulatory body typically involves the internal experts, consulting with approved expert groups; it is not readily accessible to other parties and becomes less so at supranational level. The boundaries are a matter of debate. They are challenged, for example, by interest groups seeking to participate.

The scope rules determine the type of decision that the risk management body can take. Typical choices are fact-finding vs blame attribution, national vs international measures in sea and air transport, integrated pollution control vs control of particular vectors.

The position rules determine the hierarchy and relationships of the decision points in the risk management structure, including the power of appointment and dismissal. Thus, in the United Kingdom, many regulatory bodies are independent with direct accountability to Parliament, and Ministers are readily able to dismiss them.

The information rules determine access to information. This has many aspects. The risk management system needs to be able to obtain information, such as the location of major hazard installations or sources of pollution, which it can obtain only by specific legislation. The public needs information on the hazards to which it is exposed and on what to do in an emergency. In this case, the information may be made available on a ‘right-to-know’ or a ‘need-to-know’ basis. Again, legislation is required to ensure this information is made available.

The authority and procedural rules determine the mode of decision-making, its timing and the evidence admissible. Typical choices, or emphases, are adversarial vs inquisitorial procedures, anticipatory action vs incident investigation, and qualitative vs quantitative assessments.

The preference-merging rules determine the process by which the individual inputs contribute to the collective decision. Two principal rules are unanimity and majority voting. Both are exemplified in the decision-making processes of the European Community (EC).

Table 4.4 *Some dimensions of, and putative trends in, risk management (Royal Society, 1992; after Ostrom, 1986) (Courtesy of de Gruyter Verlag and The Royal Society)*

Rule type	*Explication*	*Range of key types*	*Characteristic trends*
Boundary	Who is counted as a player?	Technocratic/ participative	More participation
Scope	What is managed and what can be decided?	Broad/narrow	Extension of scope
Position	What is the hierarchy of players?	Single organization/ multi-organization	More multi-organizations
Information	Who is entitled to know what from whom?	Open/closed	More open
Authority and procedure	Under what conditions must decisions be made?	Formal/informal	More formal
Preference merging	How are individual preferences aggregated into collective decisions?	Consensus (integration)/ conflict (aggregation)	More conflict

4.5.3 Risk management issues

The RSSG Report identifies, but does not attempt to resolve, seven areas of debate in risk management. These issues are: (1) anticipation, (2) liability and blame, (3) quantitative risk assessment (QRA), (4) institutional design, (5) risk reduction costs, (6) participation and (7) regulatory goals. They are summarized in Table 4.5. For each issue, the Report presents both sides of the argument, but with caveats that the issues are not usually so starkly posed, that opposing views are not necessarily irreconcilable and that one of the two viewpoints may be much more accepted than the other. The anticipation issue concerns the relative priorities to be given to prevention and to mitigation. The term 'anticipation' has a rather wide meaning and covers different aspects, depending on the context. For accidents, anticipation has to do with the management systems which assure effective hazard control. For pollution, it has to do with caution in not permitting activities or products the effects of which are not fully known. Two complementary arguments are advanced against anticipation. One is that it is not totally effective, so that the alternative (resilience) is necessary anyway; the other is that emphasis on anticipation reduces the motivation and resources needed to promote resilience.

The liability and blame issue concerns the desirability or otherwise of attributing blame where investigation of an incident indicates that someone has made an error. One school of thought argues that the prevention of incidents requires strict discipline and the attribution of blame for error, whilst the other holds that incidents arising from human error are conditioned by the work situation and that the rectification of defects in that situation requires the free flow of information which is inhibited by a blame culture.

Studies are quoted to the effect that such information flow is essential to the efficient functioning of complex

Table 4.5 *Some issues in risk management (Royal Society, 1992) (Courtesy of The Royal Society)*

Doctrine	*Justificatory argument*	*Counter-docirine*	*Justificatory argument*
Anticipationism	Apply causal knowledge of system failure to *ex ante* actions for better risk management	Resilienism	Complex system failures not predictable in advance and anticipation makes things worse
Absolutionism	A 'no-fault' approach to blame avoids distortion of information and helps learning	Blamism	Trageted blame gives strong incentives for taking care on the part of key decision-makers
Quantificationism	Quantification promotes understanding and rationality, exposes special pleading	Qualitativism	Proper weight needs to be given to the inherently unquantifiable factors in risk management
Designism	Apply the accumulated knowledge available for institutional design	Design agnosticism	There is no secure knowledge base or real market for institutional design
Complementarism	Safety and other goals go hand in hand under good management	Trade-offism	Safety must be explicitly traded off against other goals
Narrow participationism	Discussion is most effective when confined to expert participants	Board participationism	Broader discussion, better tests assumptions and avoids errors
Outcome specificationism	The regulatory process should concentrate on specifying structures or products	Process specificationism	The regulatory process should concentrate on specifying institutional processes

organizations (Laporte, 1982; K.H. Roberts, 1989; K.H. Roberts and Gargano, 1989). Mention is made of the explicit adoption of a no-blame policy by Shell International (1988).

The argument concerning blame also extends to the corporate level. In 1990, a suit was brought against P&O Ferries for corporate manslaughter in respect of the sinking of the Herald of Free Enterprise. This case collapsed, but it may well indicate a trend.

The QRA issue concerns the contribution of QRA to decision-making about risks. Supporters of QRA advance it as an aid to, though not the sole determinant of, rational decision-making and argue that it is an effective means of understanding complex technological systems, and also natural hazards, and that there is no real alternative method of ordering priorities. The opponents' critique develops two main themes. One is that QRA contains value judgements that are not made explicit. The other is that QRA is beset by uncertainty, which extends not just to values of the parameters but to the whole structure and completeness of the assessment. The more radical argue that QRA is liable to mislead and is positively harmful.

The institutional design issue concerns the feasibility of designing institutions for risk management and the extent to which good practice in this area can be defined. Changes in risk management systems are typically among the principal recommendations of accident inquiries. Those who believe good practice can be articulated refer to the safety management systems and safety culture in major companies such as those in the oil and chemical industries. Sceptics point to wide differences of practice, or even contradictory practices, which they perceive to yield similar outcomes, such as the blame and no-blame cultures mentioned earlier.

The risk reduction cost issue concerns the cost of risk reduction and trade-offs of risk against other goals. One view is that reduction of risks incurs additional costs and that there has to be a trade-off between risk reduction and other goals. The types of risk cover a wide spectrum, including both safety and environmental risks. The opposing viewpoint is essentially that good practice in respect of risks is generally profitable also, but the arguments that support this appear to differ, depending on the type of risk considered. In safety, the argument is that the good management that ensures high safety also delivers high profits. In terms of the environment, the argument relies rather on examples where the move to more environmentally friendly products appears not to have disadvantaged the company.

The participation issue concerns the extent of participation appropriate in risk management. The general proposal for wider participation embraces a number of different types of participant and does so for different reasons. Thus, it is suggested that human factors experts should participate more in engineering projects to avert the problems which otherwise are liable to arise. Participation by lay groups is held to force consideration of wider issues and to improve the quality of the decision-making in large technological projects. Another argument for the involvement of the latter is to improve public accountability and to broaden the base of those committed to the project. Others are more sceptical and fear that the process is liable to result in less rational decisions and to dispersion of responsibility.

The regulatory goals issue concerns the emphasis to be placed on outputs and on process in respect of risks. The engineering, and regulatory, culture tends to concentrate on outputs in the form of physical products or systems. These are typically designed with safety margins which are implicitly based on doing what is 'practical' and 'reasonable'. Critics argue that the risks of these outputs are subject to such uncertainty that this approach is inadequate, and call for more emphasis on process by the application of quality management concepts.

As stated earlier, whilst it is convenient for purposes of exposition to present these viewpoints as thesis and antithesis, there is on all these issues a spectrum of views, and in many cases a synthesis can be envisioned.

4.5.4 Cost–benefit analysis

The RSSG Report contains an appendix on cost–benefit analysis in relation to risks by Marin (1992), with particular emphasis on risks to people. The application of cost–benefit analysis to such risks is based on the principle of reducing the risks until the marginal cost equals the marginal benefit. In order to do this, costs and benefits have to be expressed in the same units, which means in money terms.

The first requirement is therefore to devise methods of estimating the 'value of a statistical life' or for short, the 'value of a life'. Marin describes both the wide variety of approaches that have been used and the perceived ethical problems. The process of putting a price on life is apt to appear cold-blooded or even unethical. In practice, the allocation of scarce resources demands ordering of priorities. Administrative decisions are constantly being made in which a value is placed on life, if not explicitly then implicitly. Thus, at present, society mainly leaves this problem in the hands of special groups.

There are certain approaches to the determination of the value of a life that have not proved fruitful. One is to base the assessment on the individual's earning power, the 'human capital' approach. This implies that those who cannot work, for whatever reason, are without value and are unethical. It is also incompatible with the normal approach in cost – benefit analysis, which is to ascertain what the course of action proposed is worth to the person(s) affected. On the other hand, it is also not helpful to ask an individual what sum he would be prepared to pay in exchange for his life. This sum may be regarded as infinity.

A more fruitful approach is to consider small increments of risk and then determine what people will pay to eliminate these. Two main methods are available to make this determination. One is to ask people, the other is to observe their behaviour. Typical studies make comparisons of choices such as those between modes of transport or between jobs of different degrees of safety.

Marin quotes two UK studies which both put the value of a life at £3 million at 1990 values, one based on fatal accident rates in different occupations (Marin and Psacharopoulos, 1982) and the other on willingness to pay for improved safety (Qones-Lee, Hammerton and Philips, 1985). For comparison, the estimate given based on the human capital approach is about £235,000.

It is also possible to consider large increments of risk, in particular those that are at the threshold where they are not acceptable to the individual, whatever the financial compensation. This aspect is not well developed, but it is relevant to situations such as those which occur in nuclear accidents where people may be asked to do work in conditions where the levels of radiation are high.

Modes of fatality, non-fatal injury and age pose further problems in determining the value of a life.

4.6 Hazard Control Policy

It is appropriate at this point to consider some of the elements that go to make up a hazard control policy. An account of this has been given in Hazard Control Policy in Britain (Chicken, 1975). The legislation referred to is that current at the time. Chicken considers five fields that illustrate hazard control policy. These are (1) road transport, (2) air transport, (3) factories, (4) nuclear power and (5) air pollution. These fields represent very different hazard control situations.

His argument runs as follows. In road transport, hazard control is mainly by legislation aimed at general improvement. Research is conducted by the Road Research Laboratory (RRL), manufacturers are encouraged to improve design standards, road construction takes account of safety knowledge and compulsory testing of vehicles is required.

Air transport, by contrast, is controlled not only by legislation (Civil Aviation Act 1971) but by a strict system of licensing operated by the Civil Aviation Authority (CAA). Aircraft are technologically much more complex and give rise to hazards that provoke much greater public outcry. The hazards are subjected to quantitative assessment and are reduced to a minimal level by sophisticated technology.

Control of factories is carried out through legislation (Factories Act 1961) which is enforced by a rather thinly spread inspectorate. The level of technology, the degree of hazard and the sophistication in control vary widely.

Nuclear power is again controlled not only by legislation (Nuclear Installations Act 1965) but by a strict licensing system operated by a well-staffed Nuclear Installations Inspectorate. Again, nuclear reactors are technologically complex and constitute major hazards, and full hazard assessment and control is carried out.

Control of air pollution by legislation (Alkali etc. Works Regulation Act 1906, Clean Air Acts 1956 and 1968) is enforced again by a somewhat thinly spread Alkali Inspectorate.

Thus, arrangements for hazard control for factories and for air pollution are rather similar, but they are very different from those for air transport and nuclear power, which are also similar. The situation in road transport does not constitute a hazard control arrangement in the same sense.

It is apparent that there are wide differences in the voluntary component in these policies. In general, this is greatest where a large number of units are involved, where the controls were first applied to an established activity, where other regulatory bodies such as local authorities are involved and where there are strong interest groups.

Thus, the controls are most stringent in air transport and nuclear power, where the number of units or operators is small, the activity is a relatively new technology, there is strong central government involvement and interest groups opposing regulation are absent. It is relevant to note also that these are the two high technology activities considered.

The elements of hazard control policy are (1) identification, (2) legislation and control arrangements, (3) research, (4) consultative arrangements and (5) priorities in resource allocation.

Hazard control policy appears to develop in response to (1) demands for improved control, (2) developments in hazard reduction; (3) defects in existing policies and (4) developments abroad. Study of the way in which hazard control policy evolves indicates that the initiating role of political parties and Parliament is relatively small and that it is most directly influenced by the Civil Service in the departments primarily involved, with the various inspectorates playing a leading role. When major developments are being considered, extensive use is made of independent specialist committees, such as the Edwards Committee on Air Transport or the Robens Committee on Health and Safety at Work. It is largely through these committees that the interest groups are able to influence policy.

Interest groups have an important role to play in the development of hazard control policy. The study of interest groups is a well-established aspect of social science (e.g. Moodie and Studdert-Kennedy, 1970; G.K. Roberts, 1970; Wootton, 1970). Wootton classifies interest groups as economic (e.g. Confederation of British Industry (CBI)), integrative (e.g. Institution of Chemical Engineers) or cultural (e.g. National Trust), and as first, second or third order, depending on whether they operate at local, regional or national level. This role is well illustrated by the proceedings of the Robens Committee, whose report contains much material from such organizations.

It is suggested by Chicken (1975) that the most influential interest groups are the economic (e.g. industrial) and integrative (e.g. professional) groups that operate at national level. While this is no doubt true in terms of detailed positive recommendations, the effect of agitation by local groups and of news media campaigns by groups at all levels on the general spirit in which policy-makers approach their task should not be underestimated.

The broad conclusions of this study remain valid.

4.7 Nuclear Hazard Control

Hazard control is well established in nuclear energy, which is an obvious model for control of chemical industry hazards. It is helpful, therefore, to consider briefly the arrangements in the nuclear industry. A short account of nuclear energy is given in Appendix 20 and the treatment here is confined to hazard control policy for the industry.

One of the principal features of the control of nuclear hazards is the role played by hazard assessment. Many of the hazard assessment techniques used in the process industries were developed in the nuclear industry. Nuclear hazard assessment is one of the topics discussed in Appendix 20.

Selected references on nuclear hazard control are given in Table 4.6.

4.7.1 Nuclear plant licensing

The early work on nuclear energy in the United Kingdom was for military purposes and was controlled by the Ministry of Supply, but in 1954, the UK Atomic Energy Authority (UKAEA) was established and began to operate nuclear power reactors at Calder Hall. Although these were again primarily for defence, they confirmed the feasibility of nuclear power. In 1958, the Central Electricity Generating Board (CEGB) was created and became the main operator of nuclear power reactors. These two operators were later joined by two others, the South of Scotland Electricity Board (SSEB) and British Nuclear Fuels Ltd (BNFL).

The responsibility for the control of nuclear power reactors was shared between the UKAEA and the Nuclear Installations Inspectorate (Nil). The Atomic Energy Act 1954, which established the UKAEA, gave the latter responsibility for the safety of its own reactors. Reasons for this rather unusual arrangement include the facts that the

initial purpose of the UKAEA was to produce nuclear weapons and that the UKAEA had virtually all the experts. The coincidence of the occurrence in 1957 of the Windscale incident and of the creation in 1958 of the CEGB, which was to operate nuclear power reactors for civil use, led the Fleck Committee, which investigated the former, to recommend a separate nuclear inspectorate. The Nuclear Installations (Licensing and Insurance) Act 1959 created the NII and also laid down that reactors other than those of the UKAEA must be insured to cover all claims which might arise from the release of radioactivity. The situation that developed was one in which the UKAEA was responsible for the safety of its own reactors, with the NII controlling other nuclear reactors through a licensing system.

The nuclear licence that the operator of a nuclear power reactor is required to obtain represents a very stringent system of control. The licensee must furnish design and operating documents that effectively cover all aspects of the design and operation of the reactor. A Nuclear Safety Committee must be created to advise the licensee and the names and qualifications of the persons nominated submitted to the Minister for approval. Individuals must also be nominated as Competent Persons to execute particular tasks.

Licensing is not a once-for-all affair but an on-going procedure. The first stage in the granting of a licence is simply the permission, in principle, to use a particular piece of land for a nuclear power reactor. Subsequent stages result in the granting of permission to build and to operate. Inevitably the licensee will wish to make changes in design features, operating procedures and nominated personnel, and these must then be agreed with the licensing authority.

This licensing system has some characteristic features that are important in relation to hazard control. It is flexible and adaptable to change and avoids the disadvantages of general and often irrelevant regulations, but it is highly detailed and involves considerable effort in making changes. And it makes heavy demands on manpower both for the licensee and the controlling authority. It also inevitably tends to shift some of the responsibility from the operator to the inspectorate. It is a highly effective but resource intensive system.

The particular approach taken to the control of nuclear hazards reflects the uncertainties in the early days of nuclear energy, say the mid-1950s, about the hazards of this very high technology industry. It is debatable how applicable this approach is to other hazards.

4.7.2 Nuclear plant siting

In the United Kingdom, the sites that might be used in a power network vary by a factor of 10 at most in population density. Hazard assessments for nuclear plants are accurate only within a similar factor. Thus, reactors cannot be matched to sites with any precision. In effect, the design must be to a standard which, it may be argued, then permits complete freedom of siting.

Hazard assessments have been presented by F.R. Farmer (1967a,b, 1971) to support the relaxation of the historical restrictions requiring remote siting and to permit siting nearer urban areas. However, it is not government policy to allow this degree of freedom in siting nuclear plants. The siting of nuclear reactors in or near large centres of population is not permitted. A major determinant of this policy is the difficulty of devising effective emergency countermeasures to the hazards of a radioactive release.

An account of UK siting policy is given by Gronow and Gausden (1973).

4.7.3 Nuclear safety case

An important feature of the nuclear licensing system is the safety case. The nuclear safety case is broadly similar, *mutatis mutandis*, to the process safety case described below.

The safety issues to be addressed are outlined in *Nuclear Safety. Safety Assessment Principles for Nuclear Reactors* (HSE, 1979d) and, for pressurized water reactors, in PWR (HSE, 1979e).

Quantification of the risks has long been a feature of the nuclear safety case. The evaluation of these risks is addressed in *The Tolerability of Risks from Nuclear Power Stations* (HSE, 1988c).

4.8 Process Hazard Control: Background

The growth of major industrial hazards, especially those associated with the process industries, and the means of controlling them, was one of the main concerns of the Robens Committee. The subsequent Health and Safety at Work etc. Act 1974 (HSWA) provides a much improved framework for control. Even before this, a Department of the Environment (DoE) circular DoE 72/1 had drawn attention to the need to take account of major hazards in planning.

The disaster at Flixborough in 1974 caused a great surge of public concern over such hazards and represents a watershed as far as process industry hazards are concerned. Following Flixborough, the Health and Safety Commission took certain steps to improve control of major hazard installations. A Major Hazards Unit was set up within the HSE and an Advisory Committee on Major Hazards (ACMH) was appointed. Within the Major Hazards Unit, a Risk Appraisal Group (RAG) was formed to give advice to local planning authorities (LPAs) on planning applications for major hazard installations. The supervision of these installations by the Factory Inspectorate was intensified. These arrangements were interim measures taken pending the recommendations of the committee.

Selected references on major hazard control in the process industries are given in Table 4.7.

4.9 Process Hazard Control: Advisory Committee on Major Hazards

The ACMH under the chairmanship of Professor B.H. Harvey, a former Deputy Director-General of the HSE, was set up soon after Flixborough in 1974. The terms of reference of the committee were:

> To identify types of installations (excluding nuclear installations) which have the potential to present major hazards to employees or to the public or the environment, and to advise on measures of control, appropriate to the nature and degree of hazard, over the establishment, siting, layout, design, operation, maintenance and development of such installations, as well as over all development, both industrial and non-industrial, in the vicinity of such installations.

The work of the Committee, which ended in 1983, is described in the three Reports of the ACMH (Harvey, 1976, 1979b, 1984). Some of the main themes of these reports are given in Table 4.8. The first task of the Committee was to define, or rather identify, major hazards. It concluded that, with few exceptions, a major hazard arises only if there is a release from containment. The hazard that then arises is a release that is flammable, toxic or both. A flammable release may give rise to a jet or pool fire or a fireball, or the vapour cloud may burn as a flash fire, or it may give a vapour cloud explosion.

Although there is little in the three reports on numerical risk criteria, the discussion on identification of major hazards in the First Report does contain the following statement:

> Since we cannot achieve or expect to achieve no risk of failure in any of the areas discussed, we feel bound to put

Table 4.8 Some principal themes in the reports of the Advisory Committee on Major Hazards

First Report 1976
Identification of major hazards
Notification of major hazard installations
Review of types of regulatory control
Control of major hazards by self-regulation
Monitoring of control by the HSE
Management of major hazards
Prevention of loss of containment
Design and operation of pressure systems
Limitation of hazardous inventory
Limitation of exposure
Planning controls for major hazards

Second Report 1979
Notification of major hazard installations
Comparison of theoretical potential and historical experience
Bounds on consequences of major releases
Unconfined vapour cloud explosions
Limitation of exposure of workforce
Design and location of control rooms
Planning controls for major hazards
Research on major hazards
Model licence conditions

Third Report 1984
Discussion of risk
Role of quantitative assessment
Inherently safer design
High reliability plant
Monitoring of warning events
Separation of major hazards and public
Information to the public
Emergency planning
Planning controls for major hazards
Education of engineers and scientists
Research on major hazards

> forward some quantitative objective. If, for instance, such tentative conclusions indicated with reasonable confidence that in a particular plant a serious accident was unlikely to occur more often than once in 10000 years (or – to put it another way – a 1 in 10000 chance in any one year), this might perhaps be regarded as just on the borderline of acceptability, bearing in mind the known background of risks faced every day by the general public.

The first step in the control of major hazards was clearly that they should be notified, and an outline notification scheme was presented in the First Report. The principle adopted was notification of hazardous substances above a certain level of inventory. It was recognized that inventory is by no means the only factor that determines the hazard, but it was nevertheless adopted as the basis because it is simple to administer. Other characteristics of the materials were to some extent taken into account by the pragmatic approach of specifying different inventories for the principal hazardous materials.

At this basic level of inventory, only notification was proposed, but it was envisaged that for a level of inventory 10 times the notification level, a hazard survey would be required and that the HSE would also have the further power to call for a detailed assessment if it judged this necessary. The Committee held strongly to the view that it should set priorities and should confine its proposals to major hazards. It was appreciated that the various cut-offs were to some degree arbitrary.

The Committee strongly endorsed the principle of self-regulation by industry that it considered particularly appropriate to major hazard plants with their high level of technology. Self-regulation is a constant theme in the reports. The arrangements proposed for the control of major hazards are therefore intended to be part of a continuum of controls for all types of hazard under the HSWA and to avoid introducing a discontinuity specifically for major hazards. On the other hand, it was clear that the community expects not only that such hazards should be under control but also that they should be seen to be so. Consequently, the view was taken that some form of monitoring by the HSE was necessary.

The First Report also began consideration of the measures necessary to prevent major accidents, against the background of Flixborough. Here the factor on which the Committee placed most emphasis was the management. Unless the management is competent to operate a major hazard plant, other measures are likely to be rendered ineffective.

The Flixborough explosion occurred because the plant held a very large inventory of flammable material that on release would undergo partial flashing to form a vapour cloud. The report takes up the theme of the need to limit such hazardous inventories. Given that the plant does contain an inventory of such material, it must be the aim of management to avoid loss of containment.

The design and operation of pressure systems is therefore of particular importance. Here the report places emphasis on pressure systems, including pipes, valves, pumps, etc., as well as pressure vessels and on operation as well as design.

The Committee held strongly to the view that planning powers even for developments involving major hazards should continue to reside with the LPA. There are many factors besides safety which affect the planning decision and which need to be taken into account in arriving at a balanced decision and only the LPA is able to do this.

The Committee also identified the problems in planning control over major hazards. These largely centre around the definition of 'development' in the Town and Country Planning Act 1971 (TCPA). The preferred solution was to amend the Act, but the implications of a change in definition were very far-reaching, and alternative though less satisfactory proposals were also made. A major difficulty in planning identified in the report is that of the compensation due if planning permission already granted is revoked. The sums involved can be very large.

The Second Report gave revised proposals for notification. This revision took into account the problem of ultratoxic materials, which had been highlighted by the Seveso disaster. Various models of regulatory control were considered, including those for the nuclear industry, mines and pharmaceuticals. The possibility of a licensing scheme similar to that applied to nuclear installations was given particular consideration but, in the event, the Committee decided against licensing.

Much of the work described in the report is concerned with comparison of theoretical estimates of major hazard scenarios with historical experience and with putting some bounds to the effects to be expected from major releases. The problem is that, for some hazards, taking the most pessimistic scenarios and models yields theoretical estimates of casualties that are very high and barely credible in the light of the historical record. Work on this aspect included collection of incident data and development of a mortality index relating the number of fatalities to the quantity released historically. Work was also done to set some bounds on the range of certain specific hazards which it seemed might have lethal effects at rather far distances, such as vapour cloud explosions and glass breakage. The Flixborough disaster was a vapour cloud explosion, and the report goes into some detail on the technical aspects of such explosions and on methods of estimating their effects.

The influence of Flixborough is also seen in the proposals in the report on the design and location of control rooms for major hazard plants. It became apparent in considering control rooms that this problem is part of the wider question of the limitation of exposure of the workforce. The report gives detailed recommendations for limitation of exposure both by location of the work base and by control of access to the high hazard zone.

The vapour cloud explosion problem highlighted the fact that many major hazard phenomena were imperfectly understood. Another important problem area was that of heavy gas dispersion. The Committee therefore gave encouragement to research on these topics.

Background studies to the reports are described by V.C. Marshall (1976a,c, 1977b, 1978, 1980d, 1982d, 1987).

The Second Report gives as an appendix a set of model licence conditions for a possible licensing scheme for major hazard plants. Although the Committee did not in fact opt for licensing, it retained the model licence conditions and proposed that these be used as a kind of code of practice for such plants. These model licence conditions are given in Appendix 24.

The Third Report opens with a discussion of risk. It does not give any specific numerical criteria, but states certain principles which may assist in deriving such criteria. The report brings together the overall system of hazard control proposed by the Committee. The essential elements are identification, avoidance and mitigation of the hazard and planning for it. In the context of hazard identification, it gives a discussion of the historical development of quantitative hazard assessment in the process industries and of its role in major hazard control.

The report gives support to the avoidance of hazard by inherently safer design, a generalization of the earlier theme of limitation of inventory.

It also discusses the measures necessary to ensure high plant reliability. Another aspect of avoidance is the monitoring of and learning from warnings, specifically the application of hazard warning concepts.

Measures to mitigate consequences which are discussed in the report are separation distances between the hazard and the public and emergency planning. The committee broadly endorsed methods then being devised by the HSE for the control over development at major hazard sites aimed at stabilizing and, where practical, reducing the population at risk.

The Committee took the view that, although a major hazard plant should be designed to high standards, it is nevertheless prudent to seek to have some separation between the plant and the public as a further line of defence. This may be regarded as the extension to the public of the principle of limitation of exposure applied earlier to the workforce.

Both the Second and Third Reports re-echo the basic proposals on planning outlined in the First Report. The Third Report calls again for research on major hazards and also for education on major hazards for the engineers and scientists who are likely to have responsibility for major hazard plants.

4.10 Process Hazard Control: Major Hazards Arrangements

The first legislative initiative in response to the ACMH's recommendations was proposals for the Hazardous Installations (Notification and Survey) Regulations 1978. These draft regulations contained requirements for the notification of installations holding a specified inventory of listed hazardous materials and for a hazard survey for installations containing 10 times the notifiable level.

These legislative proposals were overtaken by the EC Directive on the Major-Accident Hazards of Certain Industrial Activities 1982 (82/501/EEC) (the Major Accident Hazards Directive) and were never implemented. They were replaced by two sets of regulations, the Notification of Installations Handling Hazardous Substances Regulations 1982 (NIHHS) and the Control of Industrial Major Accident Hazards Regulations 1984 (CIMAH).

4.10.1 NIHHS Regulations 1982

The NIHHS Regulations implement a notification scheme based on the ACMH proposals and similar to that of the original Hazardous Installations Regulations proposals. They are confined essentially to notification and do not contain requirements for a hazard survey, which is now covered by the CIMAH Regulations. The NIHHS Regulations provide for the notification of the installations which the authorities in Britain wish to see notified and provide the basis for planning controls over these installations. The schedule of hazardous installations is given in Table 4.9. A critique of inventory levels for substances covered by the NIHHS Regulations is given by D.C. Wilson (1980).

4.10.2 CIMAH Regulations 1984

The CIMAH Regulations are confined to those requirements necessary to implement the EC Directive. The industrial activities covered by the regulations are defined in terms of processes and of storage involving specified hazardous materials.

The EC Major Accident Hazards Directive 1982 has been amended twice, in 1987 (87/216/EEC) and in 1988 (88/610/EEC). The first amendment, prompted by the disastrous toxic release at Bhopal, made a revision of some of the threshold inventories. The second, following the pollution of the Rhine by chemicals from the Sandoz warehouse fire, modified the controls on storage. These amendments of the Directive were implemented by amendments to the CIMAH Regulations in 1988 and 1990.

The regulations apply to defined industrial activities (Regulation 2). There are certain activities to which the regulations do not apply, notably defence, explosives and nuclear installations (Regulation 3). Two levels of activity are defined. For the first level, the requirements are to take the precautions necessary to prevent a major accident and to

Table 4.9 *Notification of Installations Handling Hazardous Substances Regulations 1982: Schedule 1: notifiable inventories*

PART I Named substances

substance	*Notifiable quantity (tonne)*
Liquefied petroleum gas, such as commercial propane and commercial butane, and any mixtures thereof held at a pressure greater than 1.4 bar absolute	25
Liquefied petroleum gas, such as commercial propane and commercial butane, and any mixture thereof held under refrigeration at a pressure of 1.4 bar absolute or less	50
Phosgene	2
Chlorine	10
Hydrogen fluoride	10
Sulfur trioxide	15
Acrylonitrile	20
Hydrogen cyanide	20
Carbon disulfide	20
Sulfur dioxide	20
Bromine	40
Ammonia (anhydrous or as solution containing more than 50% by weight of ammonia)	100
Hydrogen	2
Ethylene oxide	5
Propylene oxide	5
tert-Butyl peroxyacetate	5
tert-Butyl peroxyisobutyrate	5
tert-peroxymaleate	5
tert-Butyl peroxisopropyl carbonate	5
Dibenzylperoxydicarbonate	5
2,2-bis(*tert*-Butylperoxy)butane	5
1,1-bis(*tert*-Butylperoxy)cyclohexane	5
Di-*sec*-butylperoxydicarbonate	5
2,2-Dihydroperoxypropane	5
Di-*n*-propylperoxydicarbonate	5
Methylethyl ketone peroxide	5
Sodium chlorate	25
Cellulose nitrate other than: (a) cellulose nitrate to which the Explosives Act 1875 applies or (b) solutions of cellulose nitrate where the nitrogen content of the cellulose nitrate does not exceed 12.3% by weight and the solution contains not more than 55 parts of cellulose nitrate per 100 parts by weight of solution	50
Ammonium nitrate and mixtures of ammonium nitrate where the nitrogen content derived from the ammonium nitrate exceeds 28% of the mixture by weight other than: (a) mixtures to which the Explosives Act 1875 applies, or (b) ammonium nitrate based products manufactured chemically for use as fertilizer which comply with Council Directive 80/876/EEC	500
Aqueous solutions containing more than 90 parts by weight of ammonium nitrate per 100 parts by weight of solution	500
Liquid oxygen	500

PART II Classes of substance not specifically named in Part I

Class of substance	*Notifiable quantity* (tonnes)
1. Gas or any mixture of gases which is flammable in air and is held in the installation as a gas	15
2. A substance or any mixture of substances which is flammable in air and is normally held in the installation above its boiling point (measured at 1 bar absolute) as a liquid or as a mixture of liquid and gas at a pressure of more than 1.4 bar absolute	25 being the total quantity of substances above the boilding points whether held singly or in mixtures
3. A liquefied gas or any mixture of liquefied gases, which is flammable in air, has a boiling point of less than 0°C (measured at 1 bar absolute) and is normally held in the installation under refrigeration or cooling at a pressure of 1.4 bar absolute or less	50 being the total quantity of substances having boiling points below 0°C whether held singly or in mixtures
4. A liquid or any mixture of liquids not included in items 1 to 3 above, which has a flashpoint of less than 21°C	10,000

limit the consequences and generally to demonstrate safe operation (Regulation 4) and to report any major accident which does occur (Regulation 5). For the higher level of activity (defined in Regulation 6), more extensive requirements apply (Regulations 7–12). These include the requirements to submit a safety report (Regulation 7), to update the safety report (Regulation 8), to provide on request additional information (Regulation 9), to prepare an on-site emergency plan (Regulation 10) and to provide information to the public (Regulation 12). The local authority is required to prepare an off-site emergency plan (Regulation 11).

The initial directive made a distinction between storage associated with a process and isolated storage. In accordance with the directive, the CIMAH Regulations 1984 gave separate lists of inventories for the application of the regulations for isolated storage (Schedule 2) and other storage (Schedule 3). The 1990 revision again gives lists of inventories as Schedules 2 and 3, but the type of storage to which Schedule 2 applies has been broadened to include certain process-associated storage. Schedule 2 gives two sets of inventories. Inventories at either level attract Regulation 4, but only an inventory in the higher level attracts Regulations 7–12.

An outline of the regulations is given in Table 4.10 and details of Regulations 4, 6, 7 and 8 are shown in Table 4.11. Tables 4.12–4.17 give details of Schedules 1–4, 6 and 8, respectively. Schedule 1 gives the indicative criteria for the application of Regulations 2 and 4. Schedule 3 gives the list of substances, with associated inventories, for the application of Regulations 7–12. As just described, Schedule 2 gives two lists of inventories, both attracting Regulation 4, but only the higher level attracting Regulations 7–12. Schedule 4 lists the types of industrial installation other than isolated storage which come within Regulation 2. Schedule 6 gives the information to be included in the safety report (Regulation 7) and Schedule 8 that to be given to the public (Regulation 12).

Guidance on the CIMAH Regulations is given in *A Guide to the Control of Industrial Major Accident Hazards Regulations 1984* (HSE, 1990 HS(R) 21 rev.). A decision tree for the application of the regulations is shown in Figure 4.2.

The requirements for the safety report are discussed below, those for emergency planning, both on-site and off-site, in Chapter 24 and those for provision of information to the public in Section 4.11.

An account of the CIMAH arrangements has been given by Cassidy and Pantony (1988). The sites covered are classified as large inventory top tier sites (LITTSs), holding large inventories of flammable and/or toxic materials, and small inventory top tier sites (SITTSs), holding smaller quantities of more toxic substances.

They state that in the United Kingdom there are over 1700 NIHHS sites and 'several hundred' CIMAH sites.

Table 4.10 *Control of Industrial Major Accident Hazards Regulations 1984: outline of regulations*[a]

Regulation 2	Interpretation
Regulation 3	Application of these Regulations
Regulation 4	Demonstration of safe operation
Regulation 5	Notification of major accidents
Regulation 6	Industrial activities to which Regulations 7–12 apply
Regulation 7	Reports on industrial activities
Regulation 8	Updating of reports under Regulation 7
Regulation 9	Requirement of further information to be sent to the Executive
Regulation 10	Preparation of on-site emergency plan by the manufacturer
Regulation 11	Preparation of off-site emergency plan by the local authority
Regulation 12	Information to the public
Regulation 13	Disclosure of information notified under these Regulations
Regulation 14	Enforcement
Regulation 15	Charge by the local authority for off-site emergency plan
Schedule 1	Indicative criteria
Schedule 2	Storage other than of substances listed in Schedule 3 associated with an installation referred to in Schedule 4
Schedule 3	List of substances for the application of Regulations 7–12
Schedule 4	Industrial installations within the meaning of Regulation 2(1)
Schedule 5	Information to be supplied to the Commission of the European Communities by the Member States pursuant to Regulation 5(2)
Schedule 6	Information to be included in a report under Regulation 7(1)
Schedule 7	Preliminary information to be sent to the Executive under Regulation 7(3)
Schedule 8	Items of information to be communicated to the public in the application of Regulation 12

[a] This table and the following seven tables incorporate the 1990 amendments to the regulations.

4.10.3 CIMAH safety case

A central feature of the regulations is the safety report, commonly called the 'safety case'. Two aspects of particular interest are the requirements concerning the management system and the quantification of the hazards. With regard to the former, Schedule 6 of the original CIMAH Regulations 1984 requires that the report provide information on the management system and specifically on the staffing arrangements, including: for certain responsibilities, the names of the persons assigned; the arrangements for safe operation; and the arrangements for training. The wording of the 1990 Regulations is identical. However, the Guide to the latter (HSE, 1990 HS(R) 21 rev.) is much more explicit on the matters to be covered and is in effect a description of good practice in respect of a safety management system. When the regulations were brought in, it was a matter of some concern to know the extent to which the HSE would require QRA. The guidance to the original regulations (HSE, 1985 HS(R) 21) stated:

> Whilst it may be possible for manufacturers to write a safety case in qualitative terms, HSE may well find it easier to accept conclusions that are supported by quantitative arguments. A quantitative assessment is also a convenient way of limiting the scope of the safety case by demonstrating either that an adverse event has a very

Table 4.11 Control of Industrial Major Accident Hazards Regulations 1984: Regulations 4, 6, 7 and 8

Regulation 4 Demonstration of safe operation

(1) This Regulation shall apply to:

(a) An industrial activity to which subparagraph Regulation 2(1) applies and in which a substance which satisfies any of the criteria laid down in Schedule 1 is involved or is liable to be involved; and

(b) An industrial activity to which subparagraph (b) of that definition applies and in which there is involved, or liable to be involved –

(i) For a substance specified in column 1 of Part I of Schedule 2, a quantity of that substance which is equal to or more than the quantity specified in the entry for that substance in column 2 of that Part.

(ii) For substances and preparations falling within a category or categories specified in an entry in column 1 of part II of Schedule 2, a total quantity of such substances and preparations in the category or categories in that entry which is equal to or more than the quantity for that entry specified in column 2 of the Part.

(2) A manufacturer who has control of an industrial activity to which this Regulation applies shall at any time provide evidence including documents to show that he has:

(a) Identified the major accident hazards; and

(b) Taken adequate steps to:

(i) Prevent such major accidents and to limit their consequences to persons and the environment, and

(ii) Provide persons working on the site with the information, training and equipment necessary to ensure their safety.

Regulation 6 Industrial activities to which Regulations 7 to 12 apply

(1) Regulations 7 to 12 shall apply to:

(a) An industrial activity to which subparagraph (a) of the definition of industrial activity in Regulation 2(1) applies and in which there is involved, or liable to be involved, a substance listed in column 1 of Schedule 3 in a quantity which is equal to or more than the quantity specified in the entry for that substance in column 2 of that Schedule; and

(b) An industrial activity to which subparagraph (b) of that definition applies and in which there is involved, or liable to be involved –

(i) For a substance specified in column 1 of Part I of Schedule 2, a quantity of that substance which is equal to or more than the quantity specified in the entry for that substance in column 3 of that Part;

(ii) For substances and preparations falling within a caegory or cateories specified in an entry in column 1 of Part II of Schedule 2, a total quantity of such substances and preparations in the category or categories in that entry which is equal to or more than the quantity for that entry specified in column 3 of that Part.

(2) For the purposes of Regulations 7 to 11:

(a) A 'new industrial activity' means an industrial activity which –

(i) Was commended after the date of the coming into operation of this Regulation, or

(ii) If commenced before that date, is an industrial activity in which there has been since that date a modification which would be likely to have important implications for major accident hazards, and that activity shall be deemed to have been commenced on the date on which the change was made;

(b) an 'existing industrial activity' means an indusrial activity which is not a new industrial activity.

Regulation 7 Report on industrial activities

Regulation 7(1) gives the requirement for the submission of a written safety report, 7(2) and 7(3) deal with new activities and existing activities, respectively, and 7(4) wih exemptions granted by the HSE.

Regulation 8 Updating of reports under Regulation 7

(1) Where a manufacturer has made a report in accordance with Regulation 7(1), he shall not make any modification to the industrial activity to which that report relates which could materially affect the particulars in that report, unless he has made a further report to take account of those changes and has sent a copy of that report to the Executive at least 3 months before making those changes or before such shorter time as the Executive may agree in writing.

(2) Where a manufacturer has made a report in accordance with Regulation 7(1), paragraph (1) of this Regulation or this paragraph, and that industrial activity is continuing, the manufacturer shall within three years of the date of the last such report, make a further report which shall have regard in particular to new technical knowledge which materially affects the particulars in the previous report relating to safety and development in this knowledge of hazard assessment, and shall within one month, or in such longer time as the Executive may agree, send a copy of the report to the Executive.

(3) A certificate of exemption issued under Regulation 7(4), shall apply to reports or declarations made under this Regulation as it applies to reports made under Regulation 7(1).

> remote probability of occurring or that a particular consequence is relatively minor (p. 34)

The 1990 Guide states that

> The nature and extent of the consequence assessment needed depends upon the magnitude of the hazard, its likelihood of occurrence and, most importantly, the need to describe the adequacy of the prevention, control and mitigatory measures.

It later continues

> In many cases explicit quantification of the consequences of a major accident combined with relatively broad, but justifiable, qualitative predictions about the likelihood of occurrence will be sufficient to enable both

the manufacturer and HSE to judge whether the precautionary measures are adequate. However, there will be some activities involving highly hazardous and difficult to control processes, e.g. the oxidation of ethylene to produce ethylene oxide, where it may be necessary for the manufacturer to be more precise about the frequency of the various events which could lead to a major accident. . . (p. 65)

Table 4.12 *Control of Industrial Major Accident Hazards Regulations 1984: Schedule 1: indicative criteria*

Regulations 2(1) and 4(1)

(a) *Very toxic substances:*

— Substances which correspond to the first line of the table below,

— Substances which correspond to the second line of the table below and which, owing to their physical and chemical properties, are capable of producing major accident hazards similar to those caused by the substance mentioned in the first line.

	LD_{50} (oral)$^{(1)}$ (mg/kg body weight)	LD_{50} (cutaneous)$^{(2)}$ (mg/kg body weight)	$LC_{50}$$^{(3)}$ (mg/l inhalation)
1	$LD_{50} \leq 5$	$LD_{50} \leq 10$	$LC_{50} \leq 0.1$
2	$5 < LD_{50} \leq 25$	$10 < LD_{50} \leq 50$	$0.1 < LC_{50} \leq 0.5$

(1) LD_{50} oral in rats.
(2) LD_{50} cutaneous in rats or rabbits.
(3) LC_{50} by inhalation (4 h) in rats.

(b) *Other toxic substances:*
The substances showing the following values of actue toxicity and having physical and chemical properties capable of producing major accident hazards.

LD_{50} (oral)$^{(1)}$ (mg/kg body weight)	LD_{50} (cutaneous)$^{(2)}$ (mg/kg body weight)	$LC_{50}$$^{(3)}$ (mg/l inhalation)
$25 < LD_{50} \leq 200$	$50 < LD_{50} \leq 400$	$0.5 < LC_{50} \leq 2$

(1) LD_{50} oral in rats.
(2) LD_{50} cutaneous in rats or rabbits.
(3) LC_{50} by inhalation (4 h) in rats.

(c) *Flammable substances:*

(i) *Flammable gases;*
Substances which in the gaseous state at normal pressure and mixed with air become flammable and the boiling point of which at normal pressure is 20°C or below;

(ii) *Highly flammable liquids;*
Substances which have a flash point lower than 21°C and the boiling point of which at normal pressure is above 20°C;

(iii) *Flammable liquids;*
Substances which have a flash point lower than 55°C and which remain liquid under pressure, where particular processing conditions, such as high pressure and high temperature, may create major accident hazards.

(d) *Explosive substances:*
Substances which may explode under the effect of flame or which are more sensitive to shocks or friction than dinitrobenzene.

(e) *Oxidizing substances:*
Substances which give rise to highly exothermic reaction when in contact with other substances, particularly flammable substances.

4.11 Process Hazard Control: Planning

Some appreciation of the planning system is necessary for the understanding of overall arrangements for the control of major hazards. The treatment given here is limited to providing this essential background. Fuller accounts are given by Petts (1984b,c, 1985a,b, 1988a,b, 1989, 1992). Legislation relevant to planning and major hazards is discussed in Chapter 3.

4.11.1 Planning system

The essential function of planning is the control of land use. This control may be used to prevent incompatible uses of adjacent pieces of land, but such control is much easier to exercise before development has taken place than after it. The control of land use is effected through the structure plans of the counties, which set the overall framework, and through the local plans of the LPAs, which deal in specific developments. New developments are required to relate to these plans. Structure and local plans are essentially instruments for forward planning. Difficulties can arise when the problem is one not of a greenfield development but of an existing installation.

An example of positive forward planning to accommodate hazardous activities is the National Planning Guidelines issued in 1977 by the Scottish Development Department. The guidelines give detailed advice on the incorporation of such activities in local plans.

The main responsibility for planning lies with the LPA. In arriving at a planning decision on an industrial activity, the LPA has to take into account a large number of factors, including employment, safety and amenity. The LPA is publicly accountable both through the elected members on the local planning committee and through the procedures allowing for individual representations which it is required to follow.

Planning control has been exercised through the powers embodied in the TCPA. In general, this allows new development to be controlled by withholding planning permission or by attaching planning conditions. There is provision for a voluntary agreement between the developer and the LPA. There are limited powers to revoke or discontinue planning permission which has been granted.

The TCPA 1971 gives an LPA certain powers to control 'development' but these are circumscribed by the definition of 'development' in the Act and on the subsequent interpretation of this in the courts. The term development is defined as 'the carrying out of building, engineering, mining or other operations, in, on, over or under land or the making of any material change in the use of land'. However, while planning powers exist for the control of the general type of use, they do not extend to the control of particular uses within the general type.

Since the definition of 'development' is so wide, it has been necessary in order not to overload the planning system

Table 4.13 *Control of Industrial Major Accident Hazards Regulations 1984: Schedule 2: storage other than of substances listed in Schedule 3 associated with an installation referred to in Schedule 4*

Regulations 2(1), 4(1) and 6(1)

This Schedule applies to storage of dangerous substances and/or preparations at any place, installation, premises, building, or area of land, isolated or within an establishment, being a site used for the purpose of storage, except where that storage is associated with an installation covered by Schedule 4 and where the substances in question appear in Schedule 3.

The quantities set out below in Parts I and II relate to each store or group of stores belonging to the same manufacturer where the distance between the stores is not sufficient to avoid, in foreseeable circumstances, any aggravation of major accident hazards. These quantities apply in any case to each group of stores belonging to the same manufacturer where the distance between the stores is less than 500 m.

The quantities to be considered are the maximum quantities which are, or are liable to be, in storage at any one time.

Part I Named substances

Where a substance (or a group of substances) listed in Part I also falls within a category of Part II, the quantities set out in Part I shall be used.

Substances or groups of substances (Column 1)	*Quantities* (tonnes)	
	For application of Regulation 4 (Column 2)	*For application of Regulations 7 – 12 (Column 3)*
Acetylene	5	50
Acrolein (2-propenal)	20	200
Acrylonitrile	20	200
Ammonia	50	500
Ammonium nitrate[a]	350	2,500
Ammonium nitrate in the form of fertilizers[b]	1,250	10,000
Bromine	50	500
Carbon disulfide	20	200
Chlorine	10	75
Diphenylmethane di-isocyanate (MDi)	20	200
Ethylene dibromide (1,2-dibromoethane)	5	50
Ethylene oxide	5	50
Formaldehyde (concentration $\geq 90\%$)	5	50
Hydrogen	5	50
Hydrogen chloride (liquefied gas)	25	250
Hydrogen cyanide	5	20
Hydrogen fluoride	5	50
Hydrogen sulfide	5	50
Methyl bromide (Bromomethane)	20	200
Methylisocyanate	0.15 (150 kg)	0.15 (150 kg)
Oxygen	200	2,000
Phosgene (carbonyl chloride)	0.75 (750 kg)	0.75 (750 kg)
Propylene oxide	5	50
Sodium chlorate	25	250
Sulfur dioxide	25	250
Sulfur trioxide	15	100
Tetraethyl lead or tetramethyl lead	5	50
Toluene di-isocyanate (TDI)	10	100

[a] This applies to ammonium nitrate and mixtures of ammonium nitrate where the nitrogen content derived from the ammonium nitrate is $>28\%$ by weight and to aqueous solutions of ammonium nitrate where the concentration of ammonium nitrate is $>90\%$ by weight.

[b] This applies to straight ammonium nitrate fertilizers which comply with Council Directive 8/876/EEC (OJ No. L250, 23.9.80, p. 7) 'on the approximation of laws of the Member States relating to straight ammonium nitrate fertilizers of high nitrogen content' and to compound fertilizers where the nitrogen content derived from the ammonium nitrate is $>28\%$ by weight (a compound fertilizer contains ammonium nitrate together with phosphate and/or potash).

Part II Categories of substances and preparations not specifically named in Part I

The quantities of different substances and preparations of the same category are cumulative. Where there is more than one category specified in the same entry, the quantities of all substances and preparations of the specified categories in that entry shall be summed up.

Categories of substances and preparations (Column 1)	*Quantities* (tonnes)	
	For application of Regulation 4 (Column 2)	*For application of Regulations 7 – 12 (Column 3)*
(1) Substances and preparations that are classified as 'very toxic'	5	20
(2) Substances and preparations that are classified as 'very toxic', 'toxic',[a] 'oxidizing' or 'explosive'	10	200
(3) Gaseous substances and preparations including those in liquefied form, which are gaseous at normal pressure and which are classified as 'highly flammable'[b]	50	20

(4)	Substances and preparations (excluding gaseous substances and preparations covered under item 3 above) which are classified as 'highly flammable' or 'extremely flammable'[c]	5,000	50,000

---

[a] Where the substances and preparations are in a state which gives them properties capable of producing a major accident hazard.

[b] This includes flammable gases as defiend in paragraph c(i) of Schedule 1.

[c] This includes highly flammable liquids as defined in paragraph (c)(ii) of Schedule 1.

Substances and preparations shall be assigned categories in accordance with the classification provided for by Regulation 5 of the Classification, Packaging and Labelling of Dangerous Substances Regulations 1984 (SI 1984/1244, amended by SI 1986/1922, SI 1988/766, SI 1989/2208 and SI 1990/1255) whether or not the substance or preparation is required to be classified for the purposes of those Regulations, or, in the case of a pesticide approved under the Food and Environment Protection Act 1985 (c.48), in accordance with the classification assigned to it by that approval.

***Table 4.14** Control of Industrial Major Accident Hazards Regulations 1984: Schedule 3: list of substances for the application of Regulations 7–12*

The quantities set out below relate to each installation or group of installations belonging to the same manufacturer where the distance between the installations is not sufficient to avoid, in foreseeable circumstances, any aggravation of major accident hazards. These quantities apply in any case to each group of installations belonging to the same manufacturer where the distance between the installations is less than 500 m.

Substance (Column 1)	*Quantity (for applications of Regulations 7 – 12) (Column 2)*
Group 1 Toxic substances (quantity ≤ 1 tonne)[a]	
	(kg)
Arsine	10
Methyl isocyanate	150[b]
Parathion	100
Phosgene	750[c]
2, 3, 7, 8-Tetrachlorodibenzo-p-dioxin (TCDD)	1
Group 2 Toxic substances (quantity >1 tonne)[d]	
	(tonne)
Acetone cyanohydrin	200
Acrolein	200
Acrylonitrile	200
Allyl alcohol	200
Allylamine	200
Ammonia	500
Bromine	500
Carbon disulfide	200
Chlorine	25[e]
Ethylene dibromide	50
Ethyleneimine	50
Formaldehyde (concentration $\geq 90\%$)	50
Hydrogen chloride (liquefied gas)	250
Hydrogn cyanide	20
Hydrogen fluoride	50
Hydrogen sulphide	50
Methyl bromide	200
Nitrogen oxides	50
Propyleneimine	50
Sulfur dioxide	250[f]
Tetraethyl lead	50
Tetramethyl lead	50
Group 3 Highly reactive substances[a]	
	(tonne)
Acetylene	50
Ammonium nitrate[g]	2,500
Ammonium nitrate in the form of fertilizers[h]	5,000
Ethylene oxide	50
Hydrogen	50
Oxygen (liquid)	2,000
Propylene oxide	50
Sodium chlorate	250
Group 4 Explosive substances[a]	
	(tonne)
Cellulose nitrate (containing $>12.6\%$ nitrogen)	100
Lead azide	50
Mercury fulminate	10
Nitroglycerine	10
Pentaerythritol tetranitrate	50
Picric acid	50
2, 4, 6-Trinitrotoluene	50
Group 5 Flammable substances[b]	
	(tonne)
Flammable substances as defined in Schedule 1, paragraph c(i)	200
Flammable substances as defined in Schedule 1, paragraph c(ii)	50,000
Flammable substances as defined in Schedule 1, paragraph c(iii)	200

---

[a] Selection from complete list for this group.

[b] Reduced from inventory of 1 tonne in original CIMAH Regulations 1984.

[c] Reduced from inventory of 20 tonne in original CIMAH Regulations 1984.

[d] Complete list for this group.

[e] Reduced from inventory of 50 tonne in original CIMAH Regulations 1984.

[f] Reduced from inventory of 1000 tonne in original CIMAH Regulations 1984.

[g] This applies to ammonium nitrate and mixtures of ammonium nitrate where the nitrogen content derived from the ammonium nitrate is $>28\%$ by weight and aqueous solutions of ammonium nitrate where the concentration of ammonium nitrate is $>90\%$.

[h] This applies to ammonium nitrate fertilizers which comply with Council Directive 80/876/EEC and to compound fertilizers where the nitrogen content derived from the ammonium nitrate is $>28\%$ by weight (a compound fertilizer contains ammonium nitrate together with phosphate and/or potash).

***Table 4.15** Control of Industrial Major Accident Hazards Regulations 1984: Schedule 4: industrial installations within the meaning of Regulation 2(1)*

(1) Installations for the production, processing or treatment of organic or inorganic chemicals using for this purpose, amongst others:
  - Alkylation
  - Amination by ammonolysis
  - Carbonylation
  - Condensation
  - Dehydrogenation
  - Esterification
  - Halogenation and manufacture of halogens
  - Hydrogenation
  - Hydrolysis
  - Oxidation
  - Polymerization
  - Sulfonation
  - Desulfurization, manufacture and transformation of sulfur-containing compounds
  - Nitration and manufacture of nitrogen-containing compounds
  - Manufacture of phosphorus-containing compounds
  - Formulation of pesticides and of pharmaceutical products
  - Distillation
  - Extraction
  - Solvation
  - Mixing.

(2) Installations for distillation, refining or other processing of petroleum or petroleum products.
(3) Installations for the total or partial disposal of solid or liquid substances by incineration or chemical decomposition.
(4) Installations for the production, processing or treatment of energy gases, for example, LPG, LNG, SNG.
(5) Installations for the dry distillation of coal or lignite.
(6) Installations for the production of metals or non-metals by a wet process or by means of electrical energy.

***Table 4.16** Control of Industrial Major Accident Hazards Regulations 1984: Schedule 6: information to be included in a report under Regulation 7(1)*

(1) The report required under Regulation 7(1) shall contain the following information.
(2) Information relating to every dangerous substance involved in the activity in a relevant quantity as listed in Schedule 2 column 3 or Schedule 3, namely:
  (a) the name of the dangerous substance as given in Schedule 2 or 3 or, for a dangerous substance included in either of those Schedules under a general designation, the name corresponding to the chemical formula of the dangerous substance;
  (b) a general description of the analytical methods available to the manufacturer for determining the presence of the dangerous substance, or references to such methods in the scientific literature;
  (c) a brief description of the hazards which may be created by the dangerous substance;
  (d) the degree of purity of the dangerous substance, and the names of the main impurities and their percentages.
(3) Information relating to the installation, namely:
  (a) a map of the site and its surrounding area to a scale large enough to show any features that may be significant in the assessment of the hazard or risk associated with the site;
  (b) a scale plan of the size showing the locations and quantities of all significant inventories of the dangerous substance;
  (c) a description of the processes or storage involving the dangerous substance and an indication of the conditions under which it is normally held;
  (d) the maximum number of persons likely to be present on site;
  (e) information about the nature of the land use and the size and distribution of the population in the vicinity of the industrial activity to which the report relates.
(4) Information relating to the management system for controlling the industrial activity, namely:
  (a) the staffing arrangements for controlling the industrial activity with the name of the person responsible for safety on the site and the names of those who are authorized to set emergency procedures in motion and to inform outside authorities;
  (b) the arrangements made to ensure that the means provided for the safe operation of the industrial activity are properly designed, constructed, tested, operated, inspected and maintained;
  (c) the arrangements for training of persons working on the site.
(5) Information relating to the potential major accidents, namely:
  (a) a description of the potential sources of a major accident and the conditions or events which could be significant in bringing one about;
  (b) a diagram of any plant in which the industrial activity is carried on, sufficient to show the features which are significant as regards the potential for a major accident or its prevention or control;
  (c) a description of the measures taken to prevent, control or minimize the consequences of any major accident;
  (d) information about the emergency procedures laid down for dealing with a major accident occurring at the site;
  (e) information about prevailing meteorological conditions in the vicinity of the site;
  (f) an estimate of the number of people on site who may be exposed to the hazards considered in the report.
(6) In the case of the storage of substances and preparations to which Part II of Schedule 2 applies, paragraphs 2(a), (b) and (d) and 5(b) of this Schedule shall apply so far as is appropriate.

to grant certain general permissions. Under the Town and Country Planning General Development Order (GDO) 1977, a number of changes of land use are classed as 'permitted' developments, which do not require planning permission.

***Table 4.17** Control of Industrial Major Accident Hazards Regulations 1984: Schedule 8: items of information to be communicated to the public in the application of Regulations 2 and 12*

Regulations 2(1) and 12(1)

(1) Name of manufacturer and address of site.
(2) Identification, by position held, of person giving the information.
(3) Confirmation that the site is subject to these Regulations and that the report referred to in Regulation 7(1) or at least the information required by Regulation 7(3) has been submitted to the Executive.
(4) An explanation in simple terms of the activity undertaken on the site.
(5) The common names, or in the case of storage covered by Part II of Schedule 2 the generic names or the general danger classification, of the substances and preparations involved on site which could give rise to a major accident, with an indication of their principal dangerous characteristics.
(6) General information relating to the nature of the major accident hazards, including their potential effects on the population and the environment.
(7) Adequate information on how the population concerned will be warned and kept informed in the event of an accident.
(8) Adequate information on the actions the population concerned should take and on the behaviour they should adopt in the event of an accident.
(9) Confirmation that the manufacturer is required to make adequate arrangements on site, including liaison with the emergency services, to deal with accidents and to minimize their effects.
(10) A reference to the off-site emergency plan drawn up to cope with any off-site effects from an accident. This shall include advice to cooperate with any instructions or requests from the emergency services at the time of an accident.
(11) Details of where further relevant information can be obtained, subject to the requirements of confidentiality laid down in national legislation.

Further, under the Town and Country Planning (Use Classes) Order (UCO) 1972, changes within a particular Use Class are permitted development. The definition of a Use Class, however, is very broad, for example, light industry. A change of use of a piece of land or a building is not classed as development unless it constitutes both a 'material change' and a change from one Use Class to another.

For large developments it is usual to seek planning permission in two stages: 'outline' permission and then 'detail' permission. This allows the developer to ascertain that it has permission before incurring costs of development. Outline planning permission is full planning permission. Permission is granted subject to 'reserved matters', which cover such aspects as building design, plant design, landscaping and access. These are the only matters which the LPA is subsequently entitled to consider.

In granting outline planning permission, the LPA may stipulate planning conditions. This is an important power, but the conditions must be reasonable and the use of such conditions to deal with matters which are properly the concern of the HSE is discouraged.

A developer which has been refused planning permission or had permission granted subject to planning conditions may appeal to the Secretary of State for the Environment. Alternatively, where the land has become incapable of reasonably beneficial use, it may serve on the LPA a purchase notice.

Planning permission may be revoked before it has been implemented or discontinued for an existing installation or it may be modified, but in such cases the LPA may be liable to pay compensation. The sums involved in such compensation can be very large and are a strong deterrent to revocation.

The Secretary of State has powers to approve all structure and certain local plans, to consider appeals against planning decisions, to call in a planning application for his own consideration and to confirm or reject revocations, modifications and discontinuances of planning permission.

This remains the general framework under the TCPA (1990).

4.11.2 Planning and major hazards

The problem of developments involving major hazards was recognized well before the Flixborough disaster. In 1972, the DoE issued the first of a number of circulars to LPAs on hazardous installations. This circular, DoE 72/1, gave a list of hazardous inventories for which it was recommended that the LPA should seek advice. Some of the DoE circulars are listed in Table 4.18.

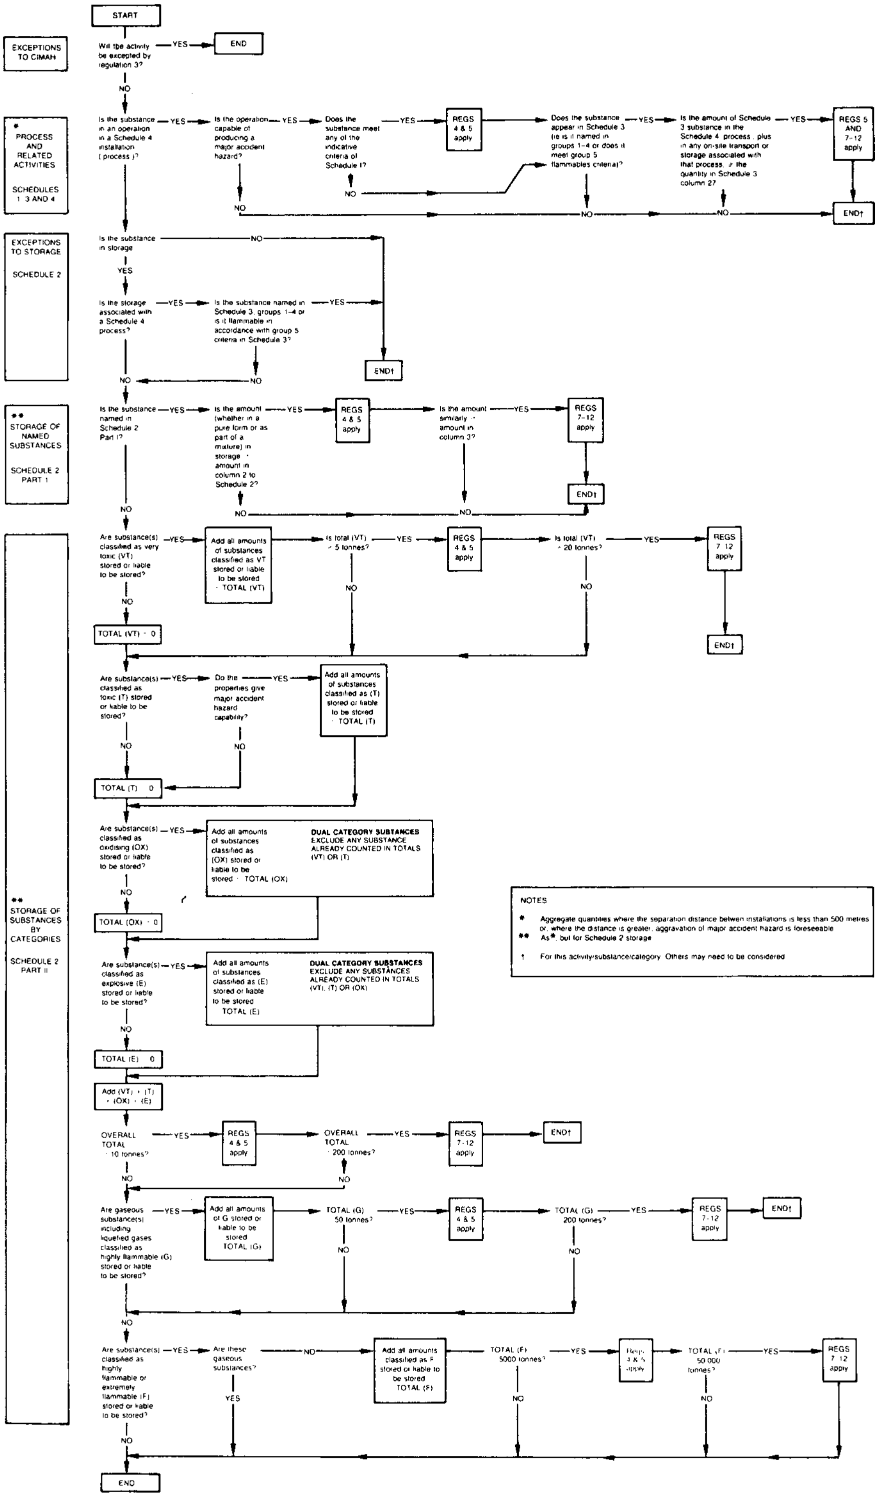
Following Flixborough, the HSE experienced an increased number of inquiries from LPAs concerning developments involving hazardous installations and set up a RAG to give advice in response to these queries. In 1974, the ACMH was set up with a membership which included planners. Planning was one of the principal topics considered by the Committee which made a number of recommendations in this area.

Decisions on planning for major hazard installations as for other developments are taken by the LPA. The alternative that the decision might be made by the HSE was considered at some length by the ACMH but rejected. The case for leaving the decision with the LPA was made in the committee's First Report in the following terms:

> It might be argued that the siting of potentially hazardous installations should be controlled by the Health and Safety Executive as part of their application of comprehensive safety controls in general, but we hold very firmly to the view that siting of all industrial developments should remain a matter for planning authorities to determine since the safety implications, however important, cannot be divorced from other planning considerations (paragraph 72)

In its Second and Third Reports, the Committee recognized that this opinion was not universally shared, but reaffirmed its view:

> When a planning application is being considered a balanced view should be taken of all aspects including social and economic factors and not just health and safety. Our view is that the HSE ought to provide a clear assessment of the risks associated with the development and to ensure that plant standards are appropriate for those risks. The decision on whether or not to grant planning permission for an installation which meets



NOTES

* Aggregate quantities where the separation distance betwen installations is less than 500 metres or, where the distance is greater, aggravation of major accident hazard is foreseeable

** As*, but for Schedule 2 storage

† For this activity/substance/category. Others may need to be considered

Figure 4.2 *Control of Industrial Major Accident Hazards Regulations 1990: decision tree for application of the regulations (Courtesy of HM Stationery Office)*

***Table 4.18** Department of the Environment Circulars relevant to planning and major hazards*

Circular	
DoE 1/72 (WO 3/72)	Development involving the use or storage in bulk of hazardous materials
DoE 71/73	Publicity for planning applications, appeals and other proposals for development
DoE 4/79	Memorandum on structure and local plans
DoE 22/80 (WO 40/80)	Development control – policy and practice
DoE 26/82	Hazardous substances
DoE 9/84 (WO 17/84)	Planning controls over hazardous development
DoE 22/84	Memorandum on structure and local plans
DoE 1/85	The use of conditions in planning permissions
DoE 2/85	Planning control over oil and gas operations
DoE 15/88	Environmental assessment

> health and safety criteria should however rest with the local authority who, on behalf of the local community, attempts to come to a balanced decision, having taken all the factors into consideration. In some cases where an installation is of wider regional or national significance, the final decision may be taken by central government (Third Report, paragraph 111)

On siting policy, the committee stated:

> The overall objective should always be to reduce the number of people at risk, and in the case of people who unavoidably remain at risk, to reduce the likelihood and the extent of harm if loss of control or containment occurs (Third Report, paragraph 109)

The Committee distinguished between several different development situations involving major hazards:

(1) initial introduction of hazards to 'greenfield' sites;
(2) initial introduction of hazards to existing installations;
(3) intensification of hazards at existing installations;
(4) proposed development in the vicinity of hazardous installations;
(5) existing development in the vicinity of hazardous installations.

In the Committee's view, the existing planning system was well able to handle the initial introduction of hazards to a greenfield site. They recommended that the LPA should impose a standard planning condition prohibiting without specific consent the introduction onto a site of notifiable hazards.

The problems of the initial introduction of a hazard or of intensification of an existing hazard were recognized as more difficult. The ideal solution would have been to amend the definition of 'development' in the TCPA, but this was a fundamental change which in the short term at least the DoE was unable to accept. An alternative approach to the initial introduction of hazard which the Committee recommended in default of amendment of the TCPA was to amend the GDO and UCO, the former to exclude from permitted development modifications which have the effect of creating a notifiable installation, and the latter to omit notifiable activities altogether from the Use Classes. These proposals did not, however, solve the problem of the intensification of an existing hazard.

With regard to development in the vicinity of a hazardous installation, the Committee endorsed the aim of first stabilizing and then reducing the number of people exposed to the hazard. It recommended that, for proposed development, the LPA should consult the HSE. It also drew attention to the power of the LPA to enter into a voluntary agreement with the owners of land to restrict the use to which the land is put.

The Committee recognized that, in a limited number of cases, the LPA might consider it necessary to revoke or discontinue planning permission and recommended that the government review its discretionary powers to make payments to local authorities to meet compensation liabilities.

With regard to existing development, the Committee stated:

> The HSE is also frequently asked to comment on proposals to develop or redevelop land in the neighbourhood of an existing hazardous undertaking where there may be other land users who are closer and possibly incompatible. In these cases the HSE tell us that it takes the view, which we fully endorse, that the existence of intervening development should not in any way affect the advice that it gives about the possible effects of that activity on proposed developments which may appear to be less at risk than the existing ones. In other words the existing situation should never be regarded as providing grounds for failing to draw attention to the implications for development at a greater distance (Second Report, paragraph 108)

The ACMH emphasized the importance of LPAs having available adequate information on which to reach its decision and on the need for the authority to consult the HSE on developments involving hazardous installations and on the necessity for the HSE's advice to be in a form appropriate to a planning authority which is not expert in major hazards.

Following the work of the ACMH, legislative changes have been made to the planning arrangements, as described below. In parallel with these legislative developments have gone administrative changes. The HSE has upgraded its capabilities to provide advice to LPAs. The ability of the HSE to provide advice has been much enhanced by the creation of the Major Hazards Assessment Unit (MHAU), while the local Factory Inspectorate, who have always had the prime responsibility for the control of hazardous installations, has been reorganized so that offices dealing with the process industries have inspectors who specialize in those industries. The problem of major hazards has proved a troublesome one for LPAs. Major hazards involve both high technology and difficult issues of risk. Most local planners have had little training on major hazards matters.

4.11.3 Planning reforms

A number of changes have been made to the planning system to deal with the problem of major hazards. The first step is to ensure that the LPA knows of the existence of hazardous installations in its area. This is effected by the NIHHS

Regulations 1982 and the CIMAH Regulations, originally 1984 and now 1990. Consultation by the LPA with the HSE is now mandatory for any new hazardous development and recommended for other development.

Under the Town and Country Planning General Development (Amendment) Order 1983, development of new hazardous installations and development at an existing notifiable site involving a three-fold increase in inventory is excluded from the general permissions of the GDO, while under the Town and Country Planning Use Classes (Amendment) Order 1983, uses involving notifiable inventories are excluded from the provisions of the UCO. The notification referred to here is that applicable under the NIHHS Regulations 1982.

The Housing and Planning Act 1986 creates a requirement for a written consent from the LPA for a new notifiable inventory. This consent is separate from planning permission. The effect of this written consent procedure is to obviate for such inventories the difficulties of redefining development under planning legislation, to freeze existing hazards at their notified level and to remove liability for compensation.

The Town and Country Planning (Assessment of Environmental Effects) Regulations 1988 require that an environmental impact assessment be submitted to the LPA along with the planning application.

The loophole associated with the concept of development is closed by the provisions of the Planning (Hazardous Substances) Act 1990 and the Planning (Hazardous Substances) Regulations 1992. The Act requires that the presence of a hazardous substance needs the consent of the Hazardous Substance Authority, or LPA.

The Planning and Compensation Act 1991 strengthens the function of the local plan as a means of planning for major hazard installations.

4.11.4 HSE consultation and advice

As stated above, the policy of the HSE is to stabilize and then reduce the number of people at risk from a hazardous installation. The HSE implements this policy primarily through its advice to LPAs. An early account of the HSE's approach was given as an appendix in the Third Report of the ACMH. It is reproduced here in Appendix 25. A later description has been given by Pape (1984).

The vast majority of planning decisions are concerned not with development on industrial sites, but with development in the vicinity of such sites. The HSE issues to LPAs guidelines on the size of 'consultation zones' around these sites and asks to be consulted on developments within these zones. Consultation with the HSE is not appropriate for minor planning applications. Guidance on the type of application for which consultation is required is given in DoE Circular 9/84.

Initially, the HSE set a general consultation distance of 2 km around a hazardous site. This proved to be excessive and the HSE has since refined its assessment methods and now specifies consultation distances which are related to the particular hazard. In particular, it has developed model approaches for two base cases, liquefied petroleum gas and chlorine which have been described by Crossthwaite (1984) and Pape and Nussey (1985), respectively. These model cases are considered in more detail in Chapter 9. Here consideration is limited to the consultation distances and advice which result from them.

The HSE distinguishes three types of development: A, B and S (special). Type A developments are those where control may well be appropriate. They are situations where people would be present most of the time or where large numbers might be present quite often and the people are not highly protected. Examples are housing, markets, large shops, transport termini and sports stadia. Type B developments are those where the risk would not normally be great enough to warrant control. This includes situations where individuals may be present regularly but not full time even though the total number of people is not necessarily small, and situations where people might be readily incorporated into an emergency plan and where they are not particularly vulnerable to the hazard. Examples are relatively low density factories or warehouses, small office buildings, small shops, sport fields and roads. Type S is intended to cover developments which are significantly more vulnerable than type A. Examples are hospitals, old people's homes and schools.

The replies from the HSE following consultation by the LPA are generally in terms of the risk categories given in DoE 9/84: 'negligible', 'marginal' and 'substantial'. Negligible risk means that the HSE assessment of the consequences of realization of the hazard is that it is unlikely, if not inconceivable, that people in the development would be killed, and that if someone was killed, this would be a 'freak' effect. Marginal risk means that the probability of people being affected by a major release is remote, that in such a case they might be seriously affected but that death is unlikely. Safety reasons would not in themselves justify a refusal of planning permission, but might justifiably be among those contributing to it. Substantial risk means that people might be seriously injured by a major release. The risk could in itself justify refusal of planning permission and safety should be a major factor in the decision. If there were other factors strongly favouring granting permission, the HSE would suggest that the LPA should hear a more detailed explanation of its assessment. In quantitative terms, negligible risk means an individual risk of less than the 'trivial' level of 10^{-6}/year, marginal risk an individual risk of about the trivial level and low societal risk, and substantial risk is an individual risk above the trivial level and more substantial societal risk.

Table 4.19 shows the HSE guidelines on consultation zones for LPG storage installations. The table gives guidance not only on the consultation zone but also on zones within this. Section A of Table 4.19 gives the distances to the zone boundaries for different tank sizes and Section B the risk categories for these zones.

The effectiveness of advice from the HSE to the LPAs has been studied by Petts (1987). An account of the use of hazard assessment by the HSE in relation to its advice to planning authorities is described by Pantony and Smith (1982).

4.11.5 Emergency planning

There is a statutory requirement for counties and equivalent authorities to undertake emergency planning for civil defence, and the tendency has been to extend these arrangements to cover process site and transport emergencies. The extent of emergency planning undertaken has been variable. Some authorities whose areas contain major chemical complexes have long had comprehensive emergency plans, while others have not. The CIMAH Regulations 1984 require such authorities to have emergency

Table 4.19 HSE guidelines on consultation and related zones and risk categories for LPG storage (after Crossthwaite, 1984)

A Distances to zone boundaries

Zone	*Tank size* (tonnes)

[a] Individual assessment necessary.

plans for installations notifiable under CIMAH (though not under NIHHS). Off-site emergency plans are considered in Chapter 24.

4.11.6 Information to public

The CIMAH Regulations 1984 contain a requirement that the public be given information about the hazards to which they are exposed and the action which they should take in an emergency. The choice of body to be responsible for informing the public proved a difficult one. The arrangements decided on are as follows. It is intended that the body which informs the public is the local authority. The manufacturer is required to try to reach with the local council an agreement on the information to be provided and then to furnish this to the council, which then issues it to the public. If, however, an agreement cannot be reached, the manufacturer is responsible for informing the public directly.

The information provided must include a statement that the activity is notifiable under the CIMAH Regulations and has been notified to the HSE and information on the nature of the hazard (e.g. fire, explosion or toxic release) and on the safety measures and actions to take in the event of an accident.

4.11.7 Public inquiries

A planning application may become the subject of a public inquiry. This may occur if the developer is refused planning permission and appeals or if the application is called in by the Secretary of State. In some cases, this call-in may be at the behest of the HSE.

It is only relatively rarely that a planning application for a process plant becomes the subject of a formal planning or public inquiry. Nevertheless, there have been a number of public inquiries on such developments. They include

(1) the Mossmorran Inquiry (1977), dealing with proposals by Shell and Esso to build a natural gas liquids plant and ethylene cracker (McGill, 1982);
(2) the Canvey Inquiries (1980 and 1982) into United Refineries' permission for a new refinery and British Gas operation of a methane terminal (Petts, 1985a);
(3) the Pheasant Wood Inquiry (1980) into housing development near an ICI chlorine and phosgene plant (Petts, 1985b).

These inquiries have shown a trend towards the increasing use of hazard assessment. They have also brought out some of the problems in the use of an adversarial forum for the discussion of technical matters.

A discussion of the problems posed by public inquiries with special reference to the use of hazard assessment and to the presentation of expert evidence has been given by Petts, Withers and Lees (1986).

Experience at inquiries indicates that the use of hazard assessments has been fraught with difficulties, but that many of these relate to obscurity, incompleteness and inconsistency in the assessments. Another difficult area is the public perception of risk.

The adversarial approach used in inquiries poses another problem. Many engineers feel it to be a poor way of arriving at the truth in scientific and engineering matters as well as being unfamiliar and intimidating. The Flixborough Inquiry gave rise to some debate on this question (e.g. Mecklenburgh, 1977a; R. King, 1990). It is considered further in relation to accident inquiries in Chapter 27.

The study by Petts, Withers and Lees (1986) suggests that many of the problems of inquiries into hazardous installations can be greatly mitigated if certain practical steps are taken. The adversarial approach is supported as the least imperfect means of arriving at the truth on technical matters and of allowing public participation, but the use is encouraged of informal meetings between parties before and during the inquiry.

The problems experienced over hazard assessment are regarded as capable of mitigation, provided that the deficiencies of hazard assessments in past inquiries are remedied, and provided that the necessary information is available to all the parties and on a suitable schedule. The means proposed is that for any installation to which the NIHHS or CIMAH Regulations apply and which goes to a planning inquiry, a form of open safety case should be made available by industry.

Although public perception of risk at inquiries remains a continuing problem, there is evidence that much of it is related to deficiencies in the hazard assessments and also to the existence of risks which assessment shows to be rather high. A fuller account of public inquiries is given in Appendix 26.

4.11.8 Planner's viewpoint

The viewpoint of the LPA is given in *Major Hazard Installations: Planning and Assessment* (Petts, 1984b) and *Major Hazard Installations: Planning Implications and Problems* (Petts, 1984c).

Certain LPAs have been conscious from an early date of the need to provide for major hazard installations in their area. Accounts of the measures taken following Flixborough by Halton Borough Council have been given by Brough (1981) and Payne (1981).

4.12 Process Hazard Control: European Community

The arrangements for the control of major hazards in the EC and in certain other European countries are now briefly reviewed. Comparative accounts are given in Risk Assessment for Hazardous Installations Q.C. Consultancy Ltd, 1986), and by Beveridge and Waite (1985) and Milburn and Cameron (1992).

4.12.1 European Community

Controls over major hazards in the EC are established by Directive 82/501/EEC, the Major Accident Hazards Directive, amended by 87/216/EEC and 88/610/EEC, as described in Section 4.10. The Directive contains requirements for notification of installations, for a safety report and for emergency planning.

A critique of the inventory levels set for particular hazardous substances is given by V.C. Marshall (1982b).

A fundamental revision of the major hazard arrangements is in prospect, as outlined in Proposal for a Council Directive on the Control of Major-Accident Hazards Involving Dangerous Substances (COMAH) (Commission of the European Communities, 1994). Features emphasized in the document are land use planning, management and human factors, and the safety report. It proposes requirements on: land use planning, the safety management system, a major accident prevention plan (MAPP) and inspection. It is proposed that the safety report should include management systems, should be harmonized in style and should be available to the public, subject to certain safeguards.

4.12.2 Germany

In Germany, basic safety requirements are embodied in a number of measures which include the Industrial Code 1869–1978, the Imperial Insurance Code 1911, the rules for Prevention of Accidents to Man and the Technical Means of Work Act 1968. Selected legislation relevant to major hazards in Germany is given in Table 4.20.

The Federal Emission Control Act 1974 (FECA) (*Bundesimmissionsschutzgesetz*) is the basic legislation on environmental protection and on major hazards. It creates a system of licensing for installations liable to cause 'harmful effects' to the environment or 'considerable disadvantages' to the public.

These terms are vague and give rise to difficulties of interpretation. More specific requirements are given in the Ordinance on Installations Subject to Licensing 1975 (ISLO), which lists 58 types of installation with a hazard potential sufficient to attract licensing.

Control of major hazards is effected, still under the FECA, through the Hazardous Incident Ordinance 1980 (HIO) (*Stb'rfallverordnung*). The ordinance gives lists of processes and chemicals. The licensing requirements apply to installations which carry out these processes and use these chemicals.

Exemption from the HIO is allowed if the inventory of the hazardous substance is very small. The levels of inventory below which exemption is given are specified in the First General Administrative Regulation 1981 to the ordinance.

The HIO requires the preparation of a safety analysis. The requirements for this are specified in greater detail in the Second General Administrative Regulation 1982. The information supplied must be such as to allow the regulatory authority to assess adequately the compliance by the operator with its safety obligations. Where this involves calculations, the documentation must show that these have been done. There is no stated requirement for QRA.

An account of the legislation is given by Stahl (1988) and an industrial viewpoint is given by Pilz (1982, 1987, 1989).

4.12.3 France

In France, safety legislation is based on the Imperial Decree of 1810, which has been subject to amending Laws in 1917, 1932 and 1961. This legislation was extensively modified in the Law of 19 July 1976 on Registered Works for Environment Protection (Installations Classes) and the associated Decree of 10 September 1977. Under this legislation, a distinction is made between authorized and declared installations. Installations subject to authorization, which is effectively licensing, are defined by inventory of hazardous chemicals.

A safety study is required for an authorized installation. The study must include a justification of the measures taken to reduce the probability of realization of the hazard and its effects. No requirement is stated for a probabilistic risk assessment. The coverage of these arrangements is wide. There are some 50,000 authorized

Table 4.20 *Selected legislation relevant to major hazards in Germany*

Substances at Work Act 1939

Second General Administrative Regulation on the Hazardous Incident Ordinance 1982

installations and the number of declared installations is presumably greater still.

4.12.4 The Netherlands

In the Netherlands there are separate systems for the assurance of safety of employees at the workplace and of the public. The first is the responsibility of the Ministry of Social Affairs, and specifically the Labour Inspectorate, and the second that of the Ministry of the Environment. This division is reflected in the requirements for two safety reports, an occupational safety report and an external safety report.

Safety legislation in the workplace is based on the employee safety law of 1934. The Statute of 23 November 1977 creates a requirement for hazardous installations to submit a safety report. This occupational safety report statute is the basic legislation on major hazards at the workplace. Accounts of the safety report have been given by Meppelder (1977), van de Putte and Meppelder (1980), van de Putte (1981, 1983), Husmann and Ens (1989), Oh and Albers (1989) and Bothelsburgh (1995).

The installations for which a safety report is required are defined not by inventory but on a 'threshold value', which is defined as the quantity of material which would present a serious danger to human life at a distance of over 100 m from the point of release. There is a specified method of calculating this value.

The report must contain an assessment of the hazards in the form of a specified fire and explosion index and a toxicity index, derived from the Dow Index method. With regard to QRA, the account given by van de Putte (1981) indicates a view that quantification of probabilities and consequences is desirable, but so is a recognition of the difficulties in the current state of the art. Husmann and Ens (1989) state that a quantitative study involving risk assessment should be performed where novel technology is used.

The external safety report is the concern of the Ministry of the Environment. It deals with the effects of major hazards outside the factory. Accounts are given by Versteeg (1988) and Ale (1991, 1992).

The Ministry of the Environment is deeply involved in QRA. It was one of the sponsors of the Rijnmond Report on hazardous installations in the Rijnmond. It has sponsored the development of the computer-based SAFETI package by Technica (see Ale and Whitehouse, 1986).

4.13 Process Hazard Control: USA

The arrangements for the control of major hazards in the United States are now briefly described. Overviews are given by Brooks *et al.* (1988) and Horner (1989). US legislation on safety has been outlined in Chapter 3. The account given here is confined to accidental releases, which include major hazards.

4.13.1 Plant siting

The development of these controls needs to be seen against the background of the growing problems experienced in the siting of new hazardous installations since the late 1970s.

A case in point at this time was the siting of LNG facilities, as described in the Transportation of Liquefied Natural Gas by the Office of Technology Assessment (OTA) of the US Congress (1977). The Federal Power Commission (FPC) was the lead agency in determining whether an individual LNG project should be allowed. It was the practice of the FPC to make decisions on siting on a case-by-case basis. The OTA identified several problems in this approach. The FPC was a regulatory rather than a policy-making body and there was no national siting policy to which it could refer. The criteria on which the FPC made its decisions on siting were not known to the industry, since no guidelines were issued. There had been pressure from the state legal authorities and from industry for the issue of uniform siting criteria. In some cases the FPA had made its approval contingent on the receipt of state and local approval, so that the criteria that the industry had to satisfy had become even more obscure.

There were several areas of overlapping jurisdiction. The Office of Pipeline Safety Operations (OPSO) was involved through the Natural Gas Pipeline Safety Act 1968, although there appeared to be a statutory provision against OPSO standards prescribing the location of LNG facilities. In the past, the two agencies had clashed directly on the standards required. The FPC required a temporary shut-down on an LNG facility which OPSO had inspected and approved. The US Coast Guard (USCG) was also involved through the Coastal Zone Management Act 1972. This Act required an applicant for a Federal licence or permit for an activity in a coastal zone of a state to certify the project to be consistent with the state's programme.

Siting was also affected by other legislation. The National Environmental Policy Act 1969 required an environmental impact statement.

4.13.2 Accidental releases

The US legislation that covers major hazards is framed in terms of accidental releases. It has been decisively influenced by releases at home and abroad, and particularly by the toxic gas disaster at Bhopal.

The principal Federal legislation is the Emergency Planning and Community Right-to-Know Act 1986 (EPCRA), which is Title III of the Superfund Amendments and Reauthorization Act 1986 (SARA), generally known as SARA Title III, and is enforced by the Environmental Protection Agency (EPA). Other relevant federal legislation is the Occupational Health and Safety Administration (OSHA) rule for Process Safety Management of Highly Hazardous Chemicals 1990. There are also the state laws in New Jersey and California. One focus of concern is the control of high toxic hazard materials (HTHMs).

4.13.3 SARA Title III

SARA Title III is the Federal legislation that creates controls on accidental releases of hazardous substances. The legislation followed soon after Bhopal. Accounts are given by Brooks *et al.* (1988), Bowman (1989), Horner (1989), Burk (1990) and Fillo and Keyworth (1992). SARA Title III has four main parts dealing with emergency planning, emergency notification, community right-to-know and toxic chemicals inventory.

For each state the governor appoints an Emergency Response Commission (ERC) that in turn designates local emergency planning committees charged with the preparation of an emergency plan. The facilities that attract such an emergency plan are those containing certain chemicals above specified inventory levels. These chemicals and inventories are given in the List of Extremely Hazardous Substances and Their Threshold Planning Quantities

(TPQ) developed by the EPA. Management is required to provide any information needed by the local emergency planning committee to implement the emergency plan. The wording has deliberately been left broad enough for the local emergency planning committee to request a QRA (Florio, 1987).

The emergency notification arrangements require the management of the facility to report immediately to the local planning committee any accidental release and the area likely to be affected.

With regard to the right-to-know requirements, for any hazardous chemical that attracts the requirement for a Material Safety Data Sheet (MSDS) under the OSHA 1970, the facility has to submit either the data sheets or a list of the chemicals to the local emergency planning committee, the state ERC and the responsible fire department. The facility must also submit to the same three bodies information on the hazardous inventory.

Section 313 contains the requirement to submit information on the 'toxic chemical release emission inventory', or Toxic Release Inventory (TRI), on the Toxic Chemical Release Form. The data required in this form are concerned primarily with passage of toxic chemicals into the environment. For each chemical, a mass balance and the quantity emitted annually is required.

The subjects of the principal sections of SARA Title III may be summarized as follows: Section 301, state ERC; Section 302, notification requirements; Section 304, accidental release reporting; Section 305, study of safety capabilities; Sections 311 and 312, information for the public; and Section 313, toxic emissions.

4.13.4 Special Emphasis Program

In 1986, OSHA initiated a Special Emphasis Program for installations with large inventories of hazardous chemicals. The purpose of the programme was to ensure that such facilities were subject to a systems safety inspection (Hanson, 1986). The systems safety inspection emphasizes four main areas: risk management, hazard identification and assessment, process design and control, and emergency planning.

4.13.5 Process Safety Management Rule

The OSHA has further extended its controls to prevent accidental releases with the rule for Process Safety Management of Highly Hazardous Chemicals (the Process Safety Management Rule). The governing document (Federal Register 1990 July 17, 29 CFR Part 1901) refers to major accidents such as Flixborough, Seveso and Bhopal, and to EC controls on major hazard installations in the 'Seveso' Directive and to the need to strengthen such controls in the United States, which otherwise largely rely on the OSHA 1970 and on standards. As its name implies, the Process Safety Management rule places particular emphasis on management. The rule covers hazard identification, evaluation and control.

4.13.6 New Jersey Toxic Catastrophe Prevention Act

The New Jersey Toxic Catastrophe Prevention Act 1985 (TCPA) is also addressed to the identification, evaluation and control of hazards for facilities handling extraordinarily hazardous substances (EHSs), there being 11 such chemicals on the initial list. It creates a requirement for a risk management plan (RMP). The RMP covers risk management, safety review, risk assessment and emergency planning.

4.13.7 California Hazardous Materials Planning Program

The California Hazardous Materials Planning Program draws together four complementary laws that are codified in chapter 6.95 of the state Health and Safety Code. It requires a facility handling more than a specified minimum inventory of a hazardous material to establish a 'business plan for emergency response', giving details of the inventory and the emergency plan. The programme requires a business that handles a defined 'acutely hazardous material' to register with the administrative authority. If a business is notified by the authority that a Risk Management and Prevention Program (RMPP) is required, it must then prepare one.

4.13.8 Regulatory agencies

As just described, both the EPA and the OSHA are involved in the regulation of accidental releases, primarily in the case of the former through SARA Title III and of the latter through the OSHA 1970 and, more recently, the Process Safety Management Rule. The division of responsibility between the two agencies is not clear-cut. The Jeffreys Amendment of 1990 defined roles for OSHA and EPA in preventing accidental releases. OSHA was directed to bring in the regulation on Process Safety Management of Highly Hazardous Chemicals and EPA to bring in a regulation on accidental releases that would complement the OSHA requirements and would focus on community issues.

4.13.9 Voluntary initiatives

Mention should also be made of some of the voluntary initiatives that have been taken in the United States in this area. Since 1985, the Chemical Manufacturers Association (CMA) has recommended to its members the Community Awareness and Emergency Response (CAER) programme. This voluntary programme deals particularly with emergency planning. The creation in 1985 of the Center for Chemical Process Safety (CCPS) of the AlChE, described in Chapter 1, is another such initiative.

5

Economics and Insurance

Contents

5.1 Economics of Loss Prevention

Loss prevention is concerned with the avoidance both of personal injury and of economic loss. In both spheres there is an economic balance to be struck. But there are also quite difficult problems in making the economic assessments. There is no doubt, however, about the economic importance of loss prevention. Some costs arise through failure to take proper loss prevention measures; others are incurred through uninformed and unnecessarily expensive measures. Both types of cost are numerous and can involve major items. The financial viability of a project is often determined by loss prevention factors.

In today's environment, many loss prevention measures that were optional in the past are now mandated by government regulation. Others are voluntarily provided in some countries as they have become 'industry practice'. Still others are provided due to court rulings in liability cases. In the above situations, traditional cost benefit analysis studies may not be relevant.

Selected references on process economics and on economics of loss prevention are given in Table 5.1.

5.2 Cost of Losses

The result of not taking adequate loss prevention measures is to give rise to losses and costs such as those of: (1) accidents, (2) damage, (3) plant design delays, (4) plant commissioning delays, (5) plant downtime, restricted output, (6) equipment repairs, (7) loss of markets, (8) public reaction and (9) insurance. A rational approach to loss prevention requires some understanding of the economic importance of these factors and of the means of estimating them.

Unless otherwise stated, the cost figures given below are those for the year referred to. The cost in real terms may be obtained by correcting the values given using the appropriate inflation index. There may be no single index which is totally applicable, but in some cases the retail price index (RPI) and in others a plant cost index may be the most suitable. There is also the further complication of exchange rate conversion.

5.2.1 National level

It is convenient to consider first the cost of these losses at national level in the United States. Estimates may be based on information on the following: (1) accident statistics, (2) fire loss statistics, (3) insurance statistics, (4) maintenance and downtime statistics and (5) major accidents.

Accident statistics are fairly readily available from the US Department of Labor, Bureau of Labor Statistics and from the National Safety Council in the United States for injuries and from the National Fire Protection Association (NFPA) for fires in the USA (Table 5.2). Accident statistics in the United Kingdom can be obtained from the *Annual Report* of HM Chief Inspector of Factories and the annual *Health and Safety Statistics*. By making certain assumptions, the national resource cost, or cost to the nation, of these accidents may be estimated.

The total number of fatal accidents as listed above for 2001 in the United States is 5270. Of this total, there were 599 fatalities in manufacturing facilities, and, of these, 7.2% or 43 were due to fire or explosion incidents.

In the United Kingdom, statistics for fires are published by the Home Office in the annual *Fire Statistics United*

Industrial accidents[a]	978
Under-reporting	5,200
Non-reportable accidents	1,500
Total	139,778

[a] Property damage only, from NFPA.

Kingdom and by the Fire Protection Association (FPA). The FPA defines a large fire as one costing £50,000 or more and the Home Office uses this definition. The *Fire Statistics United Kingdom 1990* (Home Office, 1992) gives the annual loss due to large fires over the 4-year period 1986–89 as some £290 million.

The *FPA Large Fire Analysis 1989* (FPA, 1991) gives the number of large loss fires as 739, with an average loss of £0.382 million, making a total loss of £282 million. In the chemical and allied industries there were eight such fires, with an average loss of £0.656 million, making a total loss of £5.2 million, which was 1.9% of the total.

The NFPA report of *Large-Loss Fires* (NFPA, 2002), reports the total number of fires as 1,734,500 with an estimated loss of $44,023 billion. NFPA considers a large loss as one resulting in more than $5 million damage. There were 36 large loss fires in excess of $5 million (measured in 1992 dollars) for 2001 and 20 in excess of $10 million. Total estimated property damage from the 20 largest losses excluding the World Trade Center (WTC) incident was $762 million. Three of the largest 20 losses involved oil refineries.

In previous editions of this guide, the expenditure on insurance was used as a measure of the cost of incidents. With the continued growth of multinational corporations, the globalization of the world economy and the emergence of supermajors in the energy business, insurance costs can no longer be used to effectively estimate the cost of incidents. A large number of events no longer are reported to insurers and the costs of these are absorbed fully by the corporation.

Table 5.3 *Property damage and business interruption losses worldwide, 1985–89 (after Munich Re, 1991)*

No. of losses		*Loss* (US$ million)	
		Unindexed	*Indexed*

1989	115	1,336	1,350
Business interruption losses			
1985	53	146	178
1986	22	71	85
1987	31	304	349
1988	31	284	309
1989	56	1,862	1,937

Within the refining industry, Solomon Associates conduct annual surveys of member company facilities that analyse numerous costs and other factors as a means of comparing refineries in geographic market areas. The Solomon ratings provide an indirect measure of the cost of incidents as they impact maintenance costs and on-stream factors.

Data on worldwide fire and explosion losses have been given in *Losses in the Oil, Petrochemical and Chemical Industries* by Munich Re (1991). The property damage and business interruption losses worldwide in the Munich Re data base for the years 1985–89 are given in Table 5.3.

A more recent study, '*The 100 Largest Losses 1972–2001/ Large Property Damage Losses in the Hydrocarbon–Chemical Industries*', 20th Edition, James C. Coco, editor, was published by Marsh Inc., a leading insurance broker. According to this study, the 100 largest losses in the hydrocarbon and chemical process industries during the 30-year period covered cost $10.8 billion in property damage for an average of $108 million per incident. In a separate section covering large losses to offshore facilities, the Marsh study listed 15 incidents that occurred between 1987 and 2001. The total property damage loss for these incidents was $3.81 billion or an average $254 million per incident. All loss amounts in this study were adjusted for inflation to reflect US dollars as of 2002 and include only the cost of direct property damage and debris removal. The greater concentration of assets and the greater likelihood of total loss at offshore installations accounts for the substantially higher average loss compared with the land-based facility losses.

Even at the international level, large losses such as those of the Piper Alpha oil platform in 1988 and of Pasadena in 1989 have a major impact on the cost of losses in a given year. This is even more true at the national level. This needs to be taken into account if annual average figures for periods when no such loss occurs are not to be misleading.

Public reaction to incidents involves the industry in additional costs. A major disaster such as Flixborough may result in legislation or other measures which affect costs throughout the industry. This may occur even if the disaster is in another country. Seveso had a marked influence in Europe and Bhopal worldwide, not least in the United

States, the base of the parent company. In other cases the reaction is at local level. Intermediate cases occur when public reaction causes changes in the practice of a particular branch of the industry. The costs due to public reaction have been discussed in general terms by S.B. Gibson (1976d), but the estimation of such costs is very much a matter of judgement.

Further information relevant to the cost of losses is given in Appendix 1. This appendix lists, in Table A1.4, numerous cases of fires and explosions which resulted in property damage and or business interruption. Also listed in Table A1.4 are numerous instances where, for reasons of hazard and/or pollution, a company has either ceased production at an existing plant or has not proceeded, or has not been allowed to proceed, with a planned development of production. Such cases often involve, of course, heavy financial losses.

5.2.2 Company and works level

If now the methods of determining these costs are considered at the level of the individual company or works, estimates may again be based on the same types of information as before: (1) accident statistics, (2) fire loss statistics, (3) insurance statistics, (4) maintenance and downtime statistics and (5) major accidents. There are some important differences, however, between company and national level. The two principal points are that the company generally has access to higher quality information than is available at national level. The other is that the company is much more vulnerable to a single major incident.

An illustration of the cost of accidents at company level has been given in a Dupont study referred to by McKee of Conoco at the Piper Alpha Inquiry as evidence that safety is good business (1990). Worldwide, in 1985 Conoco had 39 lost work-day cases. On the basis of the industry average, the expected value was 372, so that 333 cases, and their associated costs, were avoided. This was equivalent to a saving of some $6.2 million at the time.

Accident costs for injuries at work was reported by the National Safety Council as costing US economy $132.1 billion in 2001 from 10,700 injuries per day and 15 fatalities. Off the job injuries cost the economy an additional $184 billion. *The Costs of Accidents at Work* by the HSE (1993a) describes a set of five case studies of accident ratios, on the lines described in Chapter 1, and gives corresponding cost estimates.

Company level fire loss statistics may be used, but the effect of a possible single large loss fire needs to be borne in mind.

For companies that purchase insurance with relatively low deductible or self-retention layers, insurance costs may be viewed. The insurance costs incurred by the company are as another measure of the cost of losses. Where relevant, insurance costs need to be considered both in terms of the rates which are currently quoted and of those which might be obtained by the adoption of further loss prevention measures, if any. Actual insurance rates are no longer available, and will need to be obtained from company data and from insurer's quotations. The extent to which reduced rates may be obtained which give credit for loss prevention measures is considered below.

Costs which the company is especially well placed to assess are those of commissioning delays, downtime and maintenance in its own plants. Delays in design or commissioning related to plant safety tend to arise mainly from failure to recognize serious hazards sufficiently early. The influence of plant lateness on profitability is a well-developed topic in process economics and methods are available to estimate it. Estimates of the effect of plant lateness on ammonia plant economics are given in Table 1.5.

Plant unavailability, or downtime, may or may not incur serious cost penalties, depending on whether there is a ready market for the products. Similar considerations apply to partial unavailability or limited output. Moreover, the penalties of unavailability are not necessarily linear. It is quite possible to live permanently with a degree of undesirable downtime, but a single protracted stoppage may be catastrophic in terms of loss of profits and markets. Methods of estimating both the mean and spread of plant availabilities are described in Chapter 7.

The effect of downtime on plant profitability is another standard topic in process economics (e.g. D.H. Allen, 1973). A theoretical study, which considers the effect of downtime, and in particular the point in the plant life when this occurs, has been made by J.A. Richardson and Templeton (1973). A case study of the effect of downtime on the profitability of an actual petrochemical plant has been described by Jenkins, Ottley and Packer (1971).

Data on equipment failures are available as generic failure data given in the literature or as data obtained from the works; similarly for equipment repair times and costs. Often the works accounting system can yield much valuable information in this area (R.P. Reynolds, 1976). It is then a relatively straightforward matter to estimate the direct costs of repairing failures.

If an incident occurs at a works, public reaction must be expected and is likely to give rise to expenditure. The costs outlined are not all mutually exclusive categories. For example, property damage costs as determined by a total loss control programme also appear as equipment repair costs, but the costs have been listed in this way to illustrate the different approaches which may be made to their assessment.

5.3 Cost of Prevention

Some of the areas in which costs tend to be incurred to prevent loss are: (1) management effort, (2) research effort, (3) design effort, (4) process route, (5) operational constraints, (6) plant siting, (7) plant layout and construction, (8) plant equipment (safety margins, materials, duplication), (9) process instrumentation (trip systems), (10) fire protection, (11) inspection effort and (12) emergency planning. Since all aspects of a project have safety implications, any such list is somewhat arbitrary. Others are given in the literature (e.g. Pratt, 1974). The areas listed are those in which additional costs attributable to loss prevention are particularly likely to occur.

Loss prevention requires considerable additional effort in management generally (see Chapters 1, 6, 20 and 21), hazard identification (Chapter 8), process and pressure system design (Chapters 11 and 12), plant inspection (Chapter 19), emergency planning (Chapter 24) and research (Chapter 27).

Considerations of safety may well determine the process route, that is, the basic chemical reactions, and define the operating limits for the process parameters, for example, pressure, temperature, concentration (see Chapter 11). Obviously these factors are of fundamental importance to the economics of the process. Process economics are also greatly affected by plant siting and layout (see Chapter 10). The site which is otherwise most attractive may be ruled out on safety grounds. A layout which requires large separation distances may be expensive in land and pipework.

The various safety factors which are incorporated in the plant design greatly increase costs. These include design with thicker vessel walls, use of more costly materials of construction, selection of more expensive equipments and duplication of items (see Chapter 12). Additional instrumentation such as trip systems (see Chapter 13) and additional fire protection and fire fighting equipment (Chapters 10 and 16) constitute further costs. While expenditure in all these areas is unavoidable, it is the aim of loss prevention to get value for money in this expenditure.

There are available some global estimates for expenditure attributable to safety and loss prevention, and also to environmental protection. Kletz (1988g) quotes three sets of estimates. One estimate for safety and environmental costs for plant in the United Kingdom given by a Chemical Industries Association (CIA) source is 12–15% of total investment. A second estimate derives from his own survey of 10 ICI plants, which showed that on average 10–15% of the capital cost was spent on safety measures over and above the irreducible minimum necessary for a workable plant; items such as relief valves are regarded as basic equipment and are not included in this figure. Another 5% was spent on pollution control. The proportions spent varied widely between plants; in one case the expenditure on safety was 50% of capital cost. The third estimate is that of a US source to the effect that during the 1990s in the hydrocarbon processing industry (HPI) some 60–75% of capital was spent on safety and environmental compliance issues due to the EPA Clean Air Act, the OSHA 1910.119 PSM Regulation, and other federal and state-related initiatives. A sum equal to 9% of capital is spent on health and safety, though a large part of this is on revenue items.

5.4 Level of Loss Prevention Expenditure

5.4.1 General considerations

The effect of different levels of expenditure on safety is shown in general terms in Figure 5.1 (Kletz, 1986d). The expenditure shown refers to that required over and above that necessary for a workable plant. At the left-hand end of the graph, expenditure on safety is also good business, but as the expenditure is increased the returns diminish and lead eventually to the company going out of business.

The loss prevention approach has altered considerably the terms of the long-standing debate on the optimum level of safety expenditure. An essential element in this approach is the quantitative assessment of hazard. This in turn makes it necessary to take a view of the levels of risk which are unacceptable and which must be removed by expenditure. Moreover, quantification also provides the information on which can be based rational decisions on the cost-effectiveness of additional expenditure in reducing the risk to human life.

The question of safety expenditure then largely revolves around the decisions on these primary and secondary criteria, the levels of unacceptable risk and the expenditure to save a life. Both criteria can be compared with those used explicitly or implicitly in other industries and activities. The question of acceptable risk and risk criteria is considered in more detail in Chapters 4 and 9.

In fact, the area of choice in safety expenditure in the chemical industry is not as wide as sometimes appears from general discussions of optimum levels of expenditure. The standards of safety which are already obligatory are high and have tended to rise. Since in the chemical industry safety is both relatively good and relatively expensive to improve, the high minimum standard may well tend to become the norm. This is not unreasonable provided, but only provided, that additional expenditure is incurred where it is cost-effective in terms of human life.

It can be misleading to assume that increased safety necessarily involves increased expenditure. It is undoubtedly true that safety expenditure which is based on reaction to incidents can be very expensive. But it is general experience that good practice usually costs no more than bad and gives both improvements in safety and reductions in costs. The reason is that high levels of safety require high quality management and management systems, and that

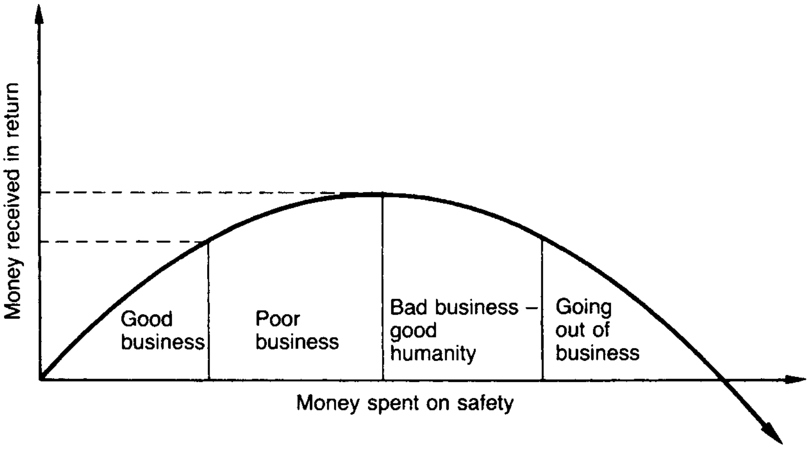

Figure 5.1 *Effects of increasing expenditure on safety and loss prevention (Kletz, 1986d) (Courtesy of the Institution of Chemical Engineers)*

if the company has these, it also has the capability to achieve its other goals.

Thus, given good loss prevention practice, large improvements in safety can be achieved relative to poor practice at no additional cost. That said, there are within the context of good practice some additional costs which are attributable only to safety and which must be borne.

Another aspect of safety expenditure is the estimation of the effect which additional expenditure already incurred has had in improving safety. This is considered in Chapter 27.

5.4.2 Decision aids

The various techniques of economic analysis such as net present value (NPV) and discounted Cash Flow (DCF) may also be used in support of assessment of the economic level of loss prevention expenditure (D.H. Allen, 1973; C.S. Park, 2002). Engineering economic analysis tools are also available on the internet at http://www.eng.auburn.edu/~park/cee2.html; http://www.eng-tips.com; http://www.isr.umd.edu/~austin/ence202.d/economics.html and other sites. The difficulties lie principally in assessing the savings.

Some decisions on the level of loss prevention expenditure are amenable to treatment by other formal decision-making techniques, in particular decision analysis. Current techniques and models for economic decision analysis can be found in Contemporary Engineering Economics by C.S. Park (2002) and Capital Investment Analysis for Engineering and Management by J.R. Canada *et al.* (1995).

Accounts of decision analysis are given by G.H. Mitchell (1972) and Hastings and Mellow (1978). In a typical decision analysis there is a set of possible outcomes, or states of nature, and a set of possible options for action, or decisions. The aim is to choose the decision(s) which maximize the gain, or utility, or minimize the loss, or regret. A common form of the problem is that there is a possibility of obtaining better information, which will improve the decision but will itself involve a cost.

The application of this technique to loss prevention has been illustrated by R.C. Hanna (1979). The problem considered is the appropriate level of fire protection for a process unit handling liquefied petroleum gas (LPG). Three states of nature are considered – S_1 no fire; S_2, a small fire and S_3, a major fire incident – in a given year. There are also three decisions: d_1, no fire protection; d_2, fireproofing and sprinklers; and d_3, fireproofing, sprinklers and surveillance and control instrumentation. There is the option to do a hazard survey which should provide improved information on which to make the decision. The three outcomes of the survey, or indicators, I_1–I_3 correspond to recommendations to implement decisions d_1–d_3, respectively.

The data required for the analysis are shown in Table 5.4. Sections A and B give, respectively, the estimates made of the costs of preventive measures and of probabilities $P(S_j)$ of no fire, a small fire and a major fire, the latter being based on historical data. Section C gives the estimated loss costs, prevention costs and total costs. The loss costs are calculated using the relationship:

$$D(d_i) = \sum_j P(S_j)C(d_i, S_j) \qquad [5.4.1]$$

where C is the loss cost for a particular state of nature and level of protection (US$k/year) and D is the loss cost for a

Table 5.4 *Decision analysis for level of fire prevention expenditure (after R.C. Hanna, 1979)*

A Prevention

	Cost M^* (US$)

	d_3	2.72	17.02	100	117.02
I_3	d_1	266.2	1666.15	0	1666.15
	d_2	55.4	346.75	25	371.75
	d_3	13.67	85.56	100	185.56

particular level of protection for all states of nature (US$k/year).

The annual loss cost is converted to a capital sum, the present value, in order to put it on the same basis as the prevention cost. Assuming a 20-year project life and 15% cost of capital the conversion is

$$D^* = 6.259D \qquad [5.4.2]$$

where D^* is the present value of the loss cost (US$k). The total cost is then

$$T^* = M^* + D^* \qquad [5.4.3]$$

where M^* is the prevention cost (US$k) and T^* is the total cost (US$k).

It is possible to make a decision on the basis of the information in Section C. The minimum value in the total cost, or expected cost of the decision, is that which corresponds to decision d_2 and is US$65.7k.

Alternatively, the decision may be deferred until more information has been obtained by conducting the hazard survey. In this case it is necessary to estimate also the probability that the survey will correspond with reality. Section D of Table 5.4 gives the estimates made for the conditional probabilities $P(I_k/S_j)$ of the survey recommendations given the states of nature. The probabilities $P(4)$ of the survey recommendations and the conditional probabilities $P(5,|4)$ of the states of nature given the survey recommendations must also be calculated as shown in Section E. The relationships used are:

$$P(I_k) = \sum_j P(I_k|S_j)P(S_j) \qquad [5.4.4]$$

$$P(S_j|I_k) = \sum_k P(I_k|S_j)P(S_j)/P(I_k) \qquad [5.4.5]$$

Equation 5.5^3 is a form of Bayes' theorem, which is described in Chapter 7.

Then, using the probabilities given in Section E of Table 5.4, the loss cost may be recalculated using the relationship:

$$D(I_k, d_i) = C(d_i, S_j)P(S_j \mid I_k) \qquad [5.4.6]$$

The present values of the loss cost and the total cost may then be recalculated using Equations 5.4.2 and 5.4.3. The results are shown in Section F of Table 5.4. The analysis is also illustrated in the decision tree diagram shown in Figure 5.2.

The expected cost of the decision is then given by the relationship:

$$E^* = \sum_k P(I_k)(T_k^*)_{\min} \qquad [5.4.7]$$

where E^* is the loss cost (with survey) (US$k). The value of E^* is US$38.76. This contrasts with the earlier value of US$65.7k. The difference of US$26.94k is a measure of the value of the survey.

5.4.3 Major hazards

While it is generally true in the process industries that good practice costs no more than bad, in the case of major hazards it is often necessary to incur expenditure on safety which is not self-financing. This is illustrated by the following simple calculation given by Lowe (1980). Consider an installation on which an incident causing US$10 million damage is estimated to occur once in 10^4 years so that the average annual loss is US$1000. Expenditure to reduce the frequency of the event to once in 10^5 years would yield a saving of US$900/year. This would justify only about US$2000 capital plus US$200/year operating costs. It is highly unlikely that a 10-fold reduction in incident frequency could be obtained for this expenditure. For major hazards, therefore, some decisions on the level of expenditure are influenced rather by risk criteria for such hazards.

5.5 Insurance of Process Plant

Insurance has always been based on the principle of solidarity, and the more balanced, or homogeneous, the risk structure is within a community of insureds, the better this principle works. When the insurer wants to fit a risk into his portfolio, he checks it against 'his' other risks with regard to quality and homogeneity. An on-site inspection often provides important information for this purpose. Claims analyses and research into the cause of losses show quite clearly that with today's complex production and monitoring processes, risk and safety depend less on technology than on management systems and the risk and safety awareness of the individual employees. In other words, they depend on the way a company deals with risks: on its safety culture.

The insurer cannot be expected to pass judgement on the safety culture of individual companies as such. His only responsibility is to set up communities of insureds. However, this involves evening out recognizable inhomogeneity either through selection, or the pricing and design of cover, or by supporting the insureds' risk management efforts.

Assessing individual industrial risks requires more than experience and technical know-how; it also requires special tools for the systematic appraisal of the factors relevant to safety and risk.

There are a number of ways in which questions of insurance impinge on safety and loss prevention. It is the business of the insurer to carry out assessments of risk in order to set premium rates. The insurer is also increasingly

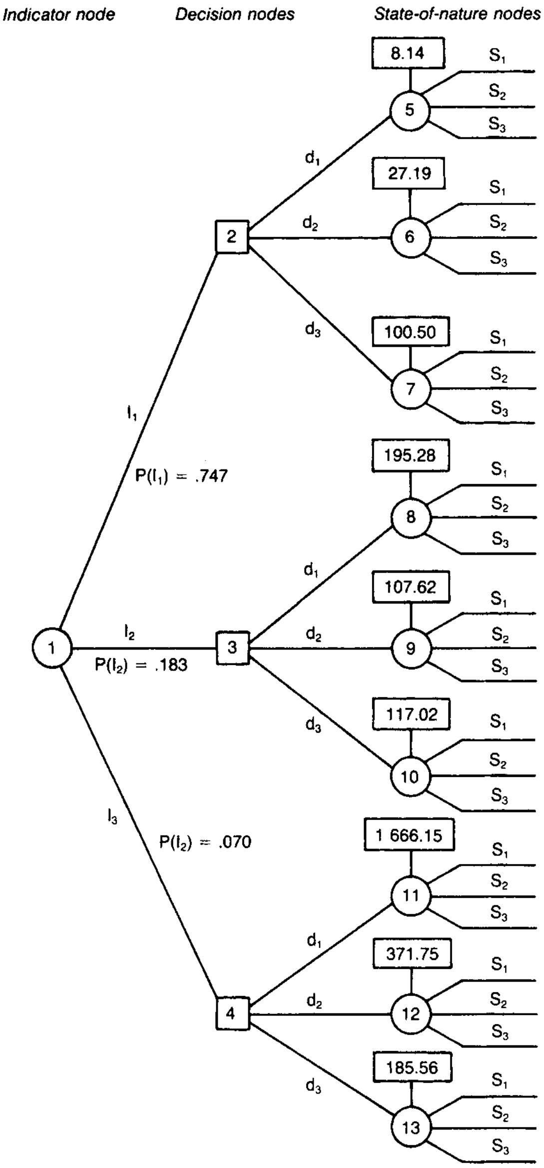

Figure 5.2 *Decision tree for level of fire prevention expenditure (after R.C. Hanna, 1979) (Courtesy of Hydrocarbon Processing)*

concerned with the management of risk and with the effectiveness of loss prevention measures. The economics and the design of the process operated by the insured are affected by insurance factors.

The company operating a hazardous plant must either itself bear the whole financial risk or seek outside insurance for this risk. The decision is an important but difficult one and it needs to be related to the overall approach taken by the company to loss prevention. Insurance practices vary, of course, from country to country and it is essentially the practice in the United Kingdom which is described here.

The insurance scene is constantly changing. There may be some restriction on insurance capabilities where there are novel risks or bad loss experience, but the market is usually able to adapt. The insurance which is of principal interest here is essentially fire insurance, which effectively covers fire and explosion risks.

5.5.1 The insurance process

The basic principle of insurance is to spread the risk so that losses incurred by the few are borne by the many. For industrial fire insurance this is done by a combination of risk sharing called 'quota share' co-insurance and re-insurance. In a quota-share arrangement, co-insurance, the insurers take direct responsibility for providing a specified proportion of the cover. The prime responsibility for assessing the risk is taken by a leading company. In re-insurance the primary insurers and co-insurers lay off their risk with other insurers. For a large risk the re-insurers may themselves re-insure further. The re-insurance business is an international one.

The extent of an individual insurer's participation is usually determined not by the full sum insured but by a loss measure such as the probable maximum loss (PML) or estimated maximum loss (EML), as described below. The underwriter determines his share of the insurance as a proportion of the PML; he usually does this using his company's table of PML limits. He may exercise his discretion to reduce this share, if he has doubts about either the magnitude or the probability of the PML. On this basis the underwriter writes his 'net line.' This net line may then be augmented if re-insurance facilities are brought into play, so that the gross acceptance notified to the buyer may be several times the net line.

The procedure adopted by the insurer in response to an insurance inquiry is to do a breakdown of insurance values by site and by installation, and to obtain a report from the insurance surveyor. Inspection is a normal preliminary to insurance. In general, the industry operates on the principle of 'no insurance without inspection.' Frequently, however, insurers will accept reports or an inspection or survey conducted by an insurance broker or an engineering consultant retained by the insurer or the broker.

5.5.2 Insurance policies

In the past an insurance policy covered a named peril for a specified period. The perils may be standard or special perils. Some of the types of insurance available in a multiline policy in the United States are given by Spiegelman (1987): (1) public liability, (2) product liability, (3) workers' compensation, (4) motor vehicle, (5) business interruption, (6) professional liability, (7) boiler and machinery and (8) property damage.

More recently, insurers have provided policies covering 'all risks of direct physical loss' except for perils or events specifically excluded by the policy language.

The principal peril relevant here is fire. Industrial fire insurance almost invariably includes fire, explosion and lightning, and may include, depending on the geographical location, windstorm, flood and earthquake. The effects of fire include both property damage and business interruption. Insurance may be limited to the first or may cover both.

For property insurance, the sum assured may cover either the current value or the replacement cost.

5.5.3 Loss measures

The insurance policy may provide cover for the full sum at risk, but, as just described, insurers generally find it convenient to work in terms of a more limited sum. There are various measures which are used, notably normal maximum loss (NML), PML and EML, but the definitions of the terms tend to vary. These terms are discussed further below.

5.5.4 Insurance surveyors

It is the function of the insurance surveyor to provide the insurer with a report on the risk to be insured. Insurance surveyors are employees of the insurance companies or insurance brokers, and, in the United Kingdom, are typically experienced people, but are not necessarily qualified engineers. Insurance surveyors have wide experience in risk assessment and there is considerable consensus on the critical features and on good and bad practice in loss prevention.

5.5.5 Insurance surveyor's report

The insurance surveyor's report includes an assessment of the loss measure used such as the PML and serves as a guide to the underwriter in setting the premium. The report involves assessing the fire load and fire risk on a plant and then making allowance for protective features.

5.5.6 Tariff and non-tariff systems

The traditional approach to setting premium rates for industrial fire damage risks has been classification by trade or occupation. Classifications run to as many as 300 trades. For many trades there is a detailed tariff which consists of a basic rate together with increments or decrements for factors which increase or decrease the risk, respectively. However, for some trades there is no tariff.

Investment income potential is a major driver of insurance capacity and pricing. The business of insurance entails a significant time delay between premium collection and payment of losses. Insurance companies invest these funds, which they hold in a fiduciary capacity. When certain economic conditions such as high interest rates or a steadily rising stock market increase investment income, insurers attempt to obtain more money to invest by increasing their business by means of rate reductions or more liberal policy terms. Trade professionals refer to this condition as a 'soft market' for insurance.

The opposite happens when investment-market conditions provide less income on fiduciary funds. The result is a 'hard market' as underwriters raise premiums to offset falling investment income.

In the United States, strict regulation of insurance by individual states prevailed from 1945 through the early 1960s as a consequence of a decision by the US Supreme Court. During the regulated era, insurance associations developed various rating schedules. Among these schedules were the 'Schedule for Petroleum Properties' and the 'Schedule for Rating Petrochemical Plants,' which applied to the process industries. These two schedules were last revised in the early 1960s and gradually fell out of use over the following 10–20 years.

Inherent deficiencies in these schedules lead to their demise. First and most important, the schedules took no account of the potential for investment income. Second, adjustment of rates to reflect recent loss experience was cumbersome and not done often enough to keep schedule-derived rates commensurate with loss payments. Third, as technology changed much about the way process plants were designed, built, operated and protected, many rating criteria used in the schedules no longer reflected the degree of risk. In particular, there has never been a tariff for the chemical industry. Instead, in this industry the premium rates are set according to a scale of relative risk as assessed by the insurance surveyor's report.

5.5.7 Fire insurance in the United Kingdom

Throughout the 1960s there was a history of growing fire loss in many trades in the United Kingdom. Many of these fires were in industries where fire losses have always been high. Insurers dealt with this by applying to each trade appropriate premium weighting factors. This approach was presumably adopted in the belief that the problem was a temporary one. In the event this proved not to be the case so that by the end of the decade the weighing factors in use ranged as high as 7.5. This suggested that the rating structure was no longer an appropriate one.

5.5.8 Business interruption insurance

Business interruption (BI) insurance covers the consequential loss from an insured peril that interrupts or diminishes production. Following a waiting period stated in the policy, BI insurance covers lost profit and continuing or non-avoidable expenses during the time required to restore production. The BI insurance policy may provide for a monetary deductible in lieu of or in addition to the waiting period. Because the coverage related to the time production is impaired, BI insurance is sometimes referred to as 'time-element' insurance.

The advent of large, single-train process plants increased exposure to BI loss and demand for BI insurance. For example, if production depends on the availability of one very large gas compressor that requires an 18-month lead time to replace, a relatively moderate property loss can result in a large BI loss. Today, BI losses frequently exceed the associated property damage (PD) loss. Until about the 1960s much fire insurance was virtually synonymous with PD insurance. There then came into prominence another type of insurance – consequential loss or BI insurance. The need for this is due mainly to the very heavy losses which can occur if a large, single-stream plant is out of action for more than a short period. The costs of losses due to, and of insurance for, BI now tend to exceed several times those of damage.

5.5.9 Large, single-train plants

As described in Chapter 1, the 1960s saw the growth of the large, single-train plant. This has presented many problems to insurers. In considering the problems posed by such plants, it is necessary to distinguish between average and maximum losses and between property and business interruption losses. There does not appear to be much evidence that for property the average losses are any worse than for other plants, but for BI the situation is probably different, although it is difficult to assess, because BI insurance is largely limited to such plants. The PML is much greater, of course, on such plants for both property and BI insurance.

Large plants pose several problems to insurers. One is the magnitude of the PML for both property and BI. Another is the high premium rates required to provide cover for BI. Another is the difficulty of assessing the adequacy of the management and of the technology.

Insurers have been virtually unanimous in expressing their dislike of large plant risks and in suggesting to the industry that it may have gone too far in putting its eggs in one basket. On the other hand, whilst the early generations of large plants gave rise to many problems, it is arguable that the management and technology of such plants are now better understood, not least due to the development of loss prevention.

Some perspective on this is also provided by the fact that many of the worst losses in the 1960s were on medium-sized, medium-technology plants. Neil (1971) suggests that this may have been due partly to the diversion of management resources to the large plants.

5.5.10 Insurance market

The insurance market is an international one and the insurance of a large plant will normally be spread with insurance companies around the world. Just as business is subject to the business cycle, so the insurance industry is subject to the insurance cycle. This is described by Norstrom (1982b). Expansion of capacity in the insurance industry creates competitive forces which drive premium rates down and reduce profitability, thus causing a contraction of capacity. At some times the business and insurance cycles come together. This was the case, for example, during the period 1977–81 in the United States.

When investment income is high, rates are high and loss experience is good, the insurance industry is more profitable and capacity expands, whilst when investment income falls, rates fall and losses are heavy, profitability and capacity fall. The insurance market is in a continuous state of change and adaptation to new risks. The development of seepage and pollution insurance is an example of the growth of insurance capacity in a new area. The industry has also been able to create capacity to cover very large loss potentials, as described below.

5.5.11 Loss experience

As just indicated, the loss experience of the insurance industry is variable and this has an impact both on capacity and on premium rates.

In the United Kingdom, the late 1960s and the 1970s saw loss on an increasingly serious scale in the chemical industry, which up to this time had had a good record. The experience of the insurance companies was therefore not a happy one. In general, in fire insurance, premium income did not cover losses sustained and administrative costs, so that underwriting was in deficit, although insurance companies benefited from investment income. The insurance market is very competitive and in too many cases business was taken at rates which later experience showed to have been unrealistic.

Likewise in the United States the insurance industry experienced large losses around 1967 with the vapour cloud explosion at Lake Charles in 1967 and other major incidents. The period 1974–76 also saw heavy losses. This trend culminated in the late 1980s with vapour cloud explosion losses at Pampa, Texas (1987), Norco, Louisiana (1988) and Pasadena, Texas (1989).

5.5.12 Insurance capacity

The capacity of the insurance market is usually given in terms of the extent of cover which can be obtained for a single potential loss. As just described, this capacity fluctuates. Although generally the market is able to provide insurance even for very large loss potentials, there is some degree of restriction.

In 1971, the capacity of the worldwide insurance market was described by Neil (1971) as quite limited. He estimated that the theoretical capacity was about £30 million per loss, but also stated that it was difficult to obtain insurance for a PML exceeding £6 million for property damage or £10 million for PD and BI combined. This was certainly not sufficient for complete insurance cover on a large ethylene plant. This limitation of the market was evidently a consequence of the adverse experience in industrial fire insurance in the 1960s and the 1970s.

The vapour cloud explosion at Flixborough had an influence on the insurance market. Some insurers recognized the possibility of such an explosion, either by allowing for it in their assessment of PML or by buying specific re-insurance. A loss of US$100 million from damage and BI due to a major vapour cloud explosion was considered within the realm of possibility.

A later estimate of insurance market capacity by Neil (1978) put the capacity for PML at about £40 million for companies with a good loss record and good reputation for management and design. After 1975 the bulk of oil and petrochemical risks owned by oil companies and to be insured on the London market was directed to International Oil Insurers (IOI), a body set up by the leading British insurers, including Lloyds, to underwrite such business. The capacity of IOI was estimated by Neil (1978) as about US$15 million on a PML basis.

Redmond (1990) describes the capacity available through the Oil Insurance Limited (OIL) mutual together with the London Master Energy Line Slip, which is a facility whereby many insurers commit their capacity automatically. However, disasters such as Piper Alpha, Pasadena and the Exxon Valdez have caused reduction of capacity for periods of time called ‘hard markets.’ A similar hard market condition developed after the terrorist attacks of 11 September 2001. Market capacity decreased dramatically and has only recently started to improve. Worldwide capacity is now in excess of one billion US dollars for certain risks.

5.5.13 Insurance restrictions

In periods when the capacity of the insurance market is restricted, there may be pressure on the insured to bear part of the risk. There are various ways in which this may be effected. The restrictions may take the form of exclusions, limited coverage for particular activities, or the application of deductibles. If deductibles, or excesses, are applied, the insured company itself is required to meet a fixed degree of loss. Typically, for property damage this is a cash sum, whilst for BI it is typically a waiting period stated in hours or days before insurance coverage applies a number of days of downtime. Alternatively, the operating company may insure itself. Either the company with the risk carries that risk itself, or it is insured by a subsidiary insurance company.

5.5.14 Self-insurance

A company may often choose not to seek full insurance cover but to bear some or all of the losses itself. Indeed, the demands placed on the world insurance market by the chemical industry have tended to leave companies with little choice but to carry some of the risk themselves. Policy on the purchase of insurance is a complex matter and depends very much on the circumstances of the individual firm, so that only a few general points are made here. Perhaps the most obvious and important is that the scale of potential loss is such that it would be severely damaging to even the largest firm, so that some degree of outside insurance is advisable.

Insurers usually emphasize that it is not reasonable that industry should seek to place only selected risks while withholding from the insurers the 'bread-and-butter' business. A healthy insurance industry cannot tolerate such adverse selection; the former alone cannot sustain a healthy insurance industry. On the other hand, the industry does expect to receive credit for high standards of management and technology and for loss prevention measures, and its decision to purchase insurance may be influenced by its confidence in the assessment made of these by the insurers.

5.5.15 Vapour cloud explosions

A significant proportion of the loss potential on process plants is attributable to vapour cloud explosions. Alexander (1990a) quotes his own estimate made in about 1980 that this proportion was in the range 5–10%. A method for the assessment of the EML due to a vapour cloud explosion has been developed by the IOI (1985 based upon a TNT equivalency calculation). A discussion of insurance with special reference to vapour cloud explosions is given by Davenport (1987). These original vapour cloud loss estimate methodologies have been modified over the years to allow the calculated overpressure diameters to encompass sufficient plant value to match historical loss events. The results have been less than desirable since a point source explosion overpredicts blast loads close to the epicentre and underpredicts blast loads in the far field. Extensive research has been conducted during the past 15 years to analyse vapour cloud explosions of various purity and mixture materials to determine what factors influence the energy released in an explosion. Congestion and confinement and ignition energy and location, are among the more critical variables. The impulse or time element factor of the produced pressure wave is also a critical element that influences damage levels. Insurers are just beginning to incorporate this science into their loss estimating models.

The Marsh study (February, 2003) showed that of the 10 largest on-shore losses in the hydrocarbon–chemical process industries from 1972 to 2001, vapour cloud explosions were the primary damage-causing mechanism in five of the incidents. Each of these losses exceeded $262 million in property damage alone, measured in constant 2002 US dollars.

5.5.16 Major disasters

Disasters such as Piper Alpha in 1988 and Pasadena in 1989 have a significant impact on the insurance world.

The losses incurred in these two accidents have been discussed by Redmond (1990). Piper Alpha was not simply a single oil platform, but the centre of an oilfield, with pipelines coming onto it from other platforms and from satellite fields. The interim estimates of loss given are: for physical damage, US$680 million; BI, US$275 million; fatalities and injuries, US$160 million; removal of wreckage, US$100 million and other items, US$155 million. These items total US$1370 million. The interim estimates for the loss at Pasadena quoted by Redmond are very similar, about US$1400 million, divided almost equally between property damage and BI. The HSE (1993a) has estimated the loss due to Piper Alpha as amounting to some £2 billion, including about £750 million in direct insured losses.

5.6 Property Insurance

There are a variety of factors which are taken into account by insurance surveyors to assess property damage risk for the purpose of premium rating. Some of the features which are frequently mentioned by insurers are: (1) size of plant, (2) novelty of technology, (3) process materials (flammable liquids at high pressures and temperatures), (4) process features and controls, (5) plant layout, (6) building design, (7) fire protection of structures, (8) fire fighting arrangements, (9) management of hazards and (10) natural perils such as earthquakes, floods and hurricanes.

5.6.1 Loss measures

As already mentioned, a number of measures of loss are utilized, but different meanings are attached to the terms used. Alexander (1990a) utilizes the following terms: average loss; NML, or PML; EML, or possible maximum loss and maximum credible loss (MCL), or maximum foreseeable loss. The average loss is self-explanatory. NML is the maximum loss which would be expected if all protective functions work, EML is the maximum loss if one critical item of protection does not work, and MCL is the maximum loss in circumstances where a number of critical items of protection do not work or where a catastrophic event occurs which is just credible. He gives the following approximate frequencies:

NML $\geq 10^{-3}$/year
EML $10^{-4} - 10^{-3}$/year
MCL $10^{-5} - 10^{-4}$/year

5.6.2 Risk profiles

The estimates just given for the frequency of the various levels of loss are general ones. It is also possible, and instructive, to construct the loss profile for a particular plant. The construction and use of such profiles is discussed by Alexander (1990a). The method which he describes is the use of what may be termed a frequency–loss (FL) plot. This plot has similarities with the frequency–number (FN) plot for major accidents described in Chapter 9 but, since the loss levels plotted on it are simply the single values of NML, EML and MCL, the frequency is an absolute rather than a cumulative one.

Figure 5.3 illustrates profiles for two hypothetical plants. For plant (A), a well-protected plant, the frequency of the EML is much less than that of the NML and the frequency for the MCL much less again, but for plant (B),

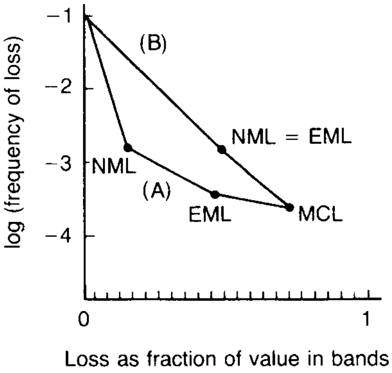

Figure 5.3 *Frequency – loss profiles of two hypothetical process plants (Alexander, 1990a) (Courtesy of the Institution of Chemical Engineers)*

an unprotected plant, the EML has the same frequency as the NML.

It is also possible to construct FL curves for the industry as a whole. In this case the use of a cumulative frequency is more appropriate. Such curves might be constructed from the data published periodically by insurers (e.g. Norstrom, 1982b; Munich Re, 1991; Marsh and McLennan, 1992).

5.6.3 Risk assessment methods

Insurance assessors use a variety of methods to assess the risk and to arrive at a premium rating. These methods include the use of checklists, of various types of hazard index, and of formal premium rating plans. The last two are closely related. Increasingly, such hazard indices and premium rating plans emphasize management aspects. A number of specific management audit methods have been developed.

5.6.4 Checklists

The insurance surveyor tends particularly to use checklists of features to be assessed. A series of such checklists is given by Spiegelman (1969). Later versions of such checklists are given by Norstrom (1982b) and Spiegelman (1987), the latter in the context of gas plants; the two checklists are similar and may be summarized as shown in Table 5.5. The original checklists are much more detailed. Further checklists are given by Ashe (1971) and Ackroyd (1974).

5.6.5 Hazard indices

From such checklists there have evolved a number of hazard indices and premium rating plans. The best known hazard index is probably the Dow Index, given in the so-called Dow Guide, which has gone through a number of versions. The most recent is the *Dow Fire and Explosion Index Hazard Classification Guide* (AIChE, 1994). Another hazard index is the Mond Index, which is an adaptation of the Dow Index (D.J. Lewis, 1979). A third index is the instantaneous fractional annual loss (IFAL). This index was specifically developed for the insurance industry at the Insurance Technical Bureau (Munday *et al.*, 1980). These three indices are described further in Chapter 8.

Table 5.5 *Headings of a checklist for insurance assessment of a chemical plant (after Norstrom, 1982b; Spiegelman, 1987)*

Plant siting
Plant layout
Buildings and structures
Process materials
Chemical process
Materials movement and storage
Operations
Equipment (design, testing and maintenance)
Loss prevention programme

5.6.6 Premium rating plans

Premium rating plans have evolved over the years to incorporate many other risk management factors than previously considered (Tables 5.6 and 5.7). The plans are no longer used to develop a premium rate for insurance, but rather are used to judge the quality of a risk. With this information, the underwriter can determine if he wishes to participate in an insurance programme, at what level he will participate and how much of the risk he is willing to take.

An example of a current risk assessment scheme is provided in Table 5.6.

Another scheme which is relevant to premium rating for damage insurance is the Dow Index (AIChE, 1994). The scheme involves the determination of the Fire and Explosion Index (F&EI) and then of the Maximum Probable Property Damage (MPPD). The Dow F&EI, including determination of the MPPD, is considered in detail in Chapter 8.

5.6.7 Technical services

In the early 1970s, the British insurance industry recognized the need for technological back-up and supported the formation of the Insurance Technical Bureau (ITB) (Chilver, 1973). The IFAL method, mentioned above and described in Chapter 8, was developed by the ITB. The ITB was subsequently dissolved and technical support is now provided by in-house engineers or outside consultancies.

5.6.8 Management audits

The increasing emphasis on management is reflected in the use of audit methods which concentrate particularly on management. Redmond (1984) gives a checklist by which the management may be assessed. A more detailed discussion of the assessment of management for insurance purposes is given by Instone (1990) and in the Swiss Re publication entitled *'Safety Culture – a reflection of risk awareness'* (2003). In this publication, Swiss Re describes additional tools they have developed for assessing management systems as they relate to loss prevention. Their initial effort was a development of an assessment process called Safety Management Audit in the Process Industries (SMAPI). This has since been supplemented by their Safety Awareness Program (SAP) and Change Management Audit Program (ChangeMAP) which are aimed at assessing 'Liveware' systems.

5.6.9 Estimation of EML

Some of the problems of assessing the EML are discussed by Redmond (1984). In general, this assessment is relatively easy for indoor plant with subdivisions each of

Table 5.6 *Outline of a risk assessment scheme for property damage insurance on large capital value plants (Drewitt, 1975)*

Rating factor

L factor	Normal maximum loss
C factor	Inherent hazard classification
HSF factor	Hardware (H), software (S), Fire fighting facilities (F)

L factor

Normal maximum loss (%)	(£m.)	*L factor*
≯20	≯2	1
$33\frac{1}{3}$	4	2
50	6	3
$66\frac{2}{3}$	8	4
$>66\frac{2}{3}$	>8	5

If the % and final NMLs give different L values an average may be taken. m. denotes million.

C factor

	C factor
Low risk plants	1–3
Medium risk plants	4–6
Relatively high risk plants	7–9
High risk plants	10–12

C factor parameters:

1. Nature of raw materials	0 Non-flammables 1 Flammable solids, heavy flammable liquids or vapours, dusts at ambient conditions 2 Light flammable liquids, hydrogen, combustible gases, naphtha, petrol 3 LPG-type materials or other flashing liquids (any substance which is flashing above 5%) materials in use above their ignition point
2. Nature of products	As (1) above
3. Process type	Rather difficult to define but must range from the innocuous mixing of solids and liquids under ambient conditions to oxidation reactions, reactions carried out at high temperatures and pressures, reactions involving the use of acetylene above 20 psi, reactions involving the use of explosive materials, special hazards ancillary to the main process, for example, catalyst preparation, catalyst changing or equipment cleaning
4. Heat content	In considering any plant, cognizance must be taken of the inherent heat content. This involves consideration of heats of combustion of the raw materials and products (hydrocarbons have heats of combustion about 10,000 tcal/t, while most other organic materials are below this value), heat of reaction or heat of polymerization. Associated with these considerations should also be the quantity effect. If we are dealing with large stocks and inventories, then the total heat content potential in the event of an incident must affect the plant hazard rating. The highest of these should be used as the assessment factor. The extent to which inventories of flammable materials within process areas are in excess of actual practical requirements must be taken into account in assessing the hazard in relationship to the minimum unavoidable risk
5. Reaction temperature	0 Atmospheric temperature 1 Up to 100°C or above flash point of materials involved 2 In range 100–250°C or above boiling point of materials involved 3 Above 250°C or above autoignition point of materials involved
6. Reaction pressure	0 Atmospheric pressure 1 Vacuum or up to 5 at pressure 2 Up to 100 at pressure 3 Above 100 at pressure
7. Corrosion and erosion hazards	On a well-designed plant due consideration will have been given to the corrosive and erosive nature of the materials being handled. However, it is accepted that corrosive fluids are difficult to contain and that leakages due to corrosion, particularly at moving parts, do occur. Similarly, the erosive nature of moving fluids and particles is well known

Table 5.6 *(continued)*

8. Domino effect	This factor is included to take account of the hazard that can occur if leakage of a hazardous material can lead to the escalation of the incident, for example, a small leak which fires and damages by flame impingement at larger pipe or vessel with subsequent spillage of a large inventory or hazardous material
HSF factor	
H factor parameters:	
1. Location	Is the plant well sited in relation to dwelling houses, other industries, office blocks, warehouses, other plants, etc.? Is the site well drained? Are soil characteristics suitable for plant requirements?
2. Construction	Is the plant well designed and constructed with adequate safety and contingency factors? Are the materials of construction suitable for the duties involved? Are girders protected with fire resisting cement? Are vessels, particularly up to 20 ft from ground level, protected with fire resisting cement?
3. Separation	Is adequate spacing available between sections of the plant (minimum 20 m) and between items of equipment within the sections of the plant? Are control rooms well sited so that adequate protection is afforded in the event of an incident? Are storage tanks sited away from operating plant? Are storage tanks adequately bunded? Are plants suitably provided with dykes to retain any inadvertent spillage of hazardous material?
4. Ventilation	Is the plant well ventilated? Are machines operating inside buildings or out in the open? Are compressors housed in 'Dutch barn' type structures? Can an inadvertent leak of gas or liquid disperse easily? Are buildings equipped with adequate fire break walls and these fitted with adequate fire doors? Are buildings fitted, where necessary, with explosion relief panels to deal with explosions that may arise from leakage of combustible gases, liquids or dusts?
5. Instrumentation	Is the plant adequately instrumented? Are the instruments kept in Al condition? Are there sufficient trips and alarms to deal with all the eventualities on the plant (see also S factor parameters, item (4), and F factor parameters, item (10))
6. Process valves and lines	Are there sufficient valves and lines to eliminate the possibility of contamination through common-pipe usage? Are there adequate facilities for washing out pipes and valves? Is it possible to divert inventories of hazardous materials to other vessels or to portable containers in the event of an incident? (see also F factor parameters, item (9).) Are there dumping and blowdown facilities available so that inventories of hazardous materials can be safely dispersed in the event of an incident?
7. Cooling	Is there sufficient reserve in the cooling system to deal with happenings outside the normal run of events? Are there adequate facilities to deal with a total cooling water failure?
8. Electrics	Are the electrics well designed and installed to conform with present-day thoughts of area classification? Are there adequate facilities to deal with a complete failure of electricity supply? Are the electric cables adequately protected against fire damage? Are alternative cable runs installed?
9. Emergency supplies	Are there sufficient supplies of nitrogen and inert gases to deal with all blanketing and purging problems? Is there an adequate supply of compressed air and instrument air? Is there an emergency power supply?
10. Flammable waste disposal	Are full facilities available for dealing with the safe disposal of all flammable wastes?
S factor parameters:	
1. Management attitude	What is the management attitude to safety? Are expenditure proposals sympathetically received and treated? Does management take an active interest in the organization and running of safety committees? Does management make a regular inspection of plants to ensure that safety standards are being maintained?
2. Housekeeping	Is the plant clean and truly free from debris, pieces of pipe, paper, plastic bags, wood, etc.?
3. Maintenance	Is the plant well maintained? Is it free from leakage of steam, water and hazardous fluids? Is maintenance conducted in a clean and orderly manner?
4. Plant operating instructions	Are plant operating instructions written in a clear and concise manner? Are they available to all operators? Are they kept up to date and revised at regular intervals? Are they obeyed? Are automatic safety devices tested on a regular schedule and with programmed monitoring on display? Have emergency instructions been written to deal with plant abnormalities?

Table 5.6 *(continued)*

5. Use of permit-to-work system	Is the permit-to-work system clearly defined and rigidly followed? (Consider competence of issuing authority)
6. Reporting of accidents	Are all accidents (and near misses) reported accurately and in detail? Are these reports circulated to those in authority? Are they effective in reducing accidents in the future? Are the lessons learned from accidents brought to the attention of new starters on the plants? (Accidents should be considered as abnormal occurrences and it should not be assumed that injury always results)
7. Labour	What is the quality of plant labour? What is the attitude of plant labour to work, discipline and safety? Is there a high turnover of labour?
8. Personnel training in plant operation	Are operators well trained in plant operation and tested before given a position of responsibility? Do they have frequent refresher courses?
9. Personnel training in safety	Is there adequate training in plant safety? Are regular Works Safety Meetings called?
10. Frequency of technical audits	Are technical audits of plant safety conducted at frequent intervals by an outside body?
F factor parameters:	
1. Works facilities	Is there a works fire brigade? Is there a full-time Chief Fire Officer? Are adequate fire fighting machines available on site? Are adequate stocks of foam-forming compounds retained on site?
2. Municipal fire brigade	Is there good liaison with the local municipal fire brigade? How long does it take the municipal brigade to reach the site? Do the works and municipal brigades carry out combined exercises on site?
3. Water supplies	Is there adequate water supply on site for fire fighting purposes? Is it a separate system or can supplies be tapped off for process use?
4. First aid extinguishers	Is the plant well provided with first aid extinguishers? Are plant personnel familiar with the use of the extinguishers?
5. Fixed protection	Is the plant provided with fixed fire protection equipment appropriate to the work, for example, a sprinkler system, a steam fire curtain, a water curtain, fixed monitors?
6. Automatic fire alarms	Are adequate fire alarms installed throughout the plant? Are adequate gas leak detectors installed throughout the plant?
7. Communications	Are communications good between the plant and the shift manager and between the plant and the fire services so that incidents can be reported with the minimum of delay?
8. Training of first aid fire fighters	Are there adequate first aid fire fighters on site? Are they well trained in dealing with the type of incident that might be expected on their plant? Are they familiar with the protective devices installed? Do they have frequent refresher courses?
9. Remote isolation valves	Is the plant well provided with remote isolation valves so that large inventories of hazardous materials can be isolated in the event of inadvertent leakage, say due to a fractured pipe?
10. Testing of protective devices	Are the protective devices installed on the plant tested at regular intervals according to an agreed schedule?

If the % and final NMLs give different L values, an average may be taken. m. denotes million.

which is provided with fire protection. It is more difficult to determine for outdoor plant, where there are no such physical barriers. Modes of escalation which must be taken into account include, in particular, running liquid fires and vapour cloud explosions.

Improvements in vapour cloud explosion EML loss estimating techniques have been made during the 1990s, but these have not been adopted by all insurers. This has led to inconsistencies between the various insurers vapour cloud EML assessments for the same plant location. Work is ongoing to develop a consensus methodology which utilizes state of the art vapour cloud analysis techniques.

5.6.10 Risk assessment approaches

There are variations of practice in the methods used to determine the premium rating. As indicated, some insurers have developed formal quantitative methods. Others consider that such quantitative methods offer little advantage over qualitative approaches. This is the view argued by Hallam (1990).

By the 1980s the setting of insurance premiums had become much more market-driven and rating-schedule or similar analytical approaches fell by the wayside. The potential for an insurer to earn investment income on fiduciary funds became the key factor in determining the

Table 5.7 *Illustrative examples for premium rating plans for damage insurance for large capital value plants (Drewitt, 1975)*

	Example 1	*Example 2*
Total insured value	£15 m.	£30 m.

[a] ‰ = rate per £1000 insured.
m. = million.

state of the insurance market. Brokers gradually gained control over large insurance placements, parcelling out small shares of the total sum insured to individual insurers. Insurers continued to consider a prospective insured's loss record and the industry's loss record over the previous 5- or 10-year period as well as the state of the prospective insured's hazard-control efforts and results as documented in survey reports. However, supply and demand forces were paramount. By the mid-1990s no single insurer had so large a share of worldwide insurance capacity that it could enforce pricing by analytical means such as a rating schedule.

5.7 Business Interruption Insurance

The need for BI insurance did not really arise until the mid-1960s, when the first large, single-train plants began to make their appearance. At about the same time, large onshore and offshore oil and gas production fields (North Sea and Alaska North Slope) came on-stream and presented very large cash flow loss potentials for the operators. It then became apparent that consequential losses could be as costly as, or more costly than, property damage losses. The problem of BI insurance is a difficult one. The viability of such insurance depends on the charging of realistic premiums, on the evolution of effective assessment methods and on the progress made in the reduction of loss. Accounts of BI insurance are given by Neil (1971), Cloughton (1981) and di Gesso (1989).

5.7.1 Large, single-train plants

As just indicated, the advent of the large, single-train plant changed the relationship between property damage and BI insurance. The consequential losses which may occur with such plants apply not only to the plant itself, but also to the suppliers of the plant's inputs and the customers for its outputs. The nature and vulnerabilities of such plants have been discussed in Chapter 1.

5.7.2 Minor incidents

Serious BI can be caused by incidents in which the property damage is relatively minor. Typical incidents which may involve only minor damage but which can cause BI for a number of weeks include damage to control rooms, instrument cables, or individual items of equipment, especially large compressors, reactors and fractionation towers. Examples cited are a flash fire resulting from an escape of flashing hydrocarbon liquid and causing damage to instrument cables, and damage to a large gas compressor causing a large section of plant to be shut-down. In oil and gas production operations, the temporary loss of critical pipeline transportation systems, as well as support utility systems, can have significant BI consequences.

5.7.3 BI insurance

The initial approach to BI loss was to assess it as a proportion of damage loss. There is in fact only a weak connection between the two, the BI loss depending rather on the extent to which the loss interrupts a complex business chain. Moreover, the relative magnitude of the two losses has changed dramatically. Whereas BI loss was at first evaluated as a fraction of damage loss, it is now commonly estimated at several times damage loss.

Thus BI insurance merits separate treatment. Basically, the insurance provides cover for a fixed period and against an insured peril, and relates to the margin between expected sales income and variable costs on loss of sales suffered due to the interruption at the insured's plant and, if extended, interruption at suppliers' and customers' plants. It also covers increased working costs incurred in attempts to minimize loss of margin.

BI insurance is for a specified maximum indemnity period. Typical periods are 12 or 18 months. There is a tendency for insurers to require the insured to bear, as an excess, the losses sustained over some initial period such as 5, 10 or 20 days. Insurance may be extended to cover also the contingent liability for losses due to incidents at supplier and customer plants. The cover generally applies provided the losses are due to damage from a peril for which the insured's plant is covered.

5.7.4 BI survey

When BI insurance is to be underwritten, the nature and scope of the insurance survey or inspection is modified accordingly. It is normal to carry out a damage survey as a basis for damage insurance. It is appropriate to conduct an interruption survey for the purposes of BI insurance. This type of survey is, however, rather less well developed.

An interruption survey may extend the assessment of a plant to include features additional to those covered in the damage survey. The factors listed by Neil (1971) are given in Table 5.8 The main object of the interruption survey is normally the assessment of EML/PML on the BI. Survey for BI should not be a one-time exercise, but should be repeated at intervals to ensure that the information is up to date.

Further aspects of BI surveys have been described by Cloughton (1981). Essentially, the problem is that of recovery from the event causing the interruption. People are one of the most significant resources in enabling the recovery to take place. A resourceful purchasing manager is particularly important. Another vital factor is preservation of information on all aspects of the business, from design drawings to customer lists.

In assessing the vulnerability of a single-train operation, Cloughton somewhat discounts in the UK context problems of availability of services and of fuels, but emphasizes weak points in single-train operation. In particular, he highlights vulnerability to loss of particular pieces of

Table 5.8 *Some aspects of an interruption survey (after Neil, 1971) (Courtesy of the Institution of Chemical Engineers)*

1. Whether the process is single- or multi-train, batch or continuous, innovatory or proven
2. Process dependency on a major, unspared equipment item requiring a long lead time to replace
3. The protection of essential services, routing of cables, etc.
4. Dependency on a key unit and the extent to which spares or standby facilities are available, and the time-scale involved in achieving replacement or repair
5. The size of buffer stocks, over and above the minimum necessary to cover shut-down for planned maintenance, and the possibility of alternative sources of supply to keep downstream plants in operation
6. If the plant is a replacement, whether existing plants and production will remain available as insurance against teething troubles and whether there will be an excess of capacity over demand in the short and long term
7. Whether the use of a computer is to control or maximize efficiency of the plant

equipment. Here he draws a distinction between a sole supplier and a unique source. A company may choose to buy from a single supplier, but there may nevertheless be other potential suppliers in the marketplace. In some cases, however, there is a unique source which for some reason may be unable to supply promptly.

Vulnerability to interruption depends not only on features of the production process but also potential loss of stocks in the same incident. Another relevant aspect is the expected profile of the recovery over time. This may be a short total interruption followed by a gradual recovery. Or it may be a partial interruption with production and sales partially maintained but at increased cost.

Generally speaking, the existence or lack of inventory of intermediate or finished products will not significantly affect BI analysis. Inventory costs money to finance and management is not likely to maintain more inventory than that which is necessary to sustain normal operations. If a particular weakness is revealed, such as high exposure to loss of a particular piece of equipment, the solution is not necessarily more insurance. It may make more sense to remedy the exposure.

5.7.5 Estimation of EML

It will be apparent that the assessment of the EML for BI is not straightforward. It involves first determining the downtime of the plant, or sections of it, and then converting this loss of production to loss of financial contribution to fixed costs and profit. This last step may be particularly problematic. The assessment of EML for BI is discussed by di Gesso (1989), who gives an illustrative example.

5.7.6 Property damage and BI

The worldwide data from Munich Re (1991) quoted above show that over the five-year period 1985–89 for property material damage the annual average number of incidents was 144 and the average annual loss US$754 million. The corresponding figures for BI are annual number of incidents 39 and annual loss US$572 million.

At the level of the individual plant, some examples of claims for property damage and BI have been given by di Gesso (1989) (Table 5.9). He quotes the following three cases. Case 1, in 1981, involved a tower which failed during a hydrostatic test with water at a temperature of 10°C rather than at 20°C as recommended. In Case 2, also in 1981, a compressor trip led to a furnace tube burst and damage to a common stack. In Case 3, in 1984, a fire in a cable trench damaged a control room. The losses sustained are given in Table 5.9.

5.7.7 BI Insurance Capacity

During the 1960s, it rapidly became apparent, however, that the premiums asked for this class of business had been set at an unrealistically low level. There were some very large claims and some insurers sustained heavy losses. The nature of the problem can be seen from the fact that Neil (1971) estimated the total BI insurance premium income at £35 million. Such a sum could easily be swallowed up by one or two disasters. And in fact, as already mentioned, his estimate of the combined damage and BI insurance obtainable in practice was £10 million per loss.

As already described, since then the market has adapted and has been able, for example, to cover the large BI risks of offshore oil platforms. For Piper Alpha, one estimate of the BI loss, given above, is US$275 million.

Because of the greater uncertainty in assessing BI loss exposure as opposed to PD loss exposure, many insurers will not underwrite BI unless the insured also purchases insurance for PD. Such insurers view an insured's attempt to purchase insurance for BI along as a form of adverse selection.

5.8 Other Insurance Aspects

5.8.1 Insurance credit

The extent to which insurers should encourage and give credit for good practice in general and for loss prevention measures is a long-standing question. Insurers have always been very much involved in measures against fire. The first organized fire brigades in the United Kingdom were run by the insurance companies. In the nineteenth century, the Fire Offices Committee was formed and set standards for fire construction, alarms, sprinklers, etc., which have been widely applied. In 1946, the Joint Fire Research Organization (JFRO) was set up jointly by the Fire Offices Committee and the government and this was followed in 1947 by the formation of the FPA.

Insurers usually emphasize that they prefer to keep both risks and premiums down. Buyers of insurance are equally keen to hold premiums down and seek credit for loss prevention measures. This is well illustrated by the growth of the Factory Mutual Insurance Corporation, which is one of the largest fire insurance groups in the United States and which originated from a group of manufacturers who were dissatisfied with the credit which existing insurers were prepared to allow for such measures and who therefore formed their own insurance co-operative. The loss prevention measures which constitute the Factory Mutual System are described in the *Handbook of Industrial Loss Prevention* (Factory Mutual Engineering Corporation (FMEC), 1967). There is one particular protective measure on which insurers have placed considerable emphasis and for which they have given generous credit in premium ratings. This is the use of sprinklers. The effectiveness of sprinklers is well proven across a wide range of fire risks, including hotels, schools, offices, factories and warehouses. The premium recognition given to this particular protective measure appears, however, somewhat exaggerated relative to other measures as far as concerns the process industries. These industries have developed a whole range of loss prevention measures and an expectation that they should receive credit for them appears reasonable.

Clearly a precondition for a system of premium rating which allows such credits is the possession by the insurer of a method of risk assessment which it is confident gives a reliable discrimination between risks. In fact, for a period in the 1970s, the trend was rather towards a reduction of differentials. The range of risks in chemical plants is wide. The insurance industry was reluctant, however, to reduce the minimum premium for low risk plants. In consequence, the chemical industry, whose loss experience up to the 1960s had been relatively good, put pressure on insurers to reduce premium rates on the more hazardous plants. The result was an excessive narrowing of the rating scale between the lowest and highest risks. The extent to which the chemical industry does now receive credit for loss prevention measures in the form of reductions in premium rating appears variable. The success of ICI in obtaining reduced insurance premiums for damage cover is illustrated in Figure 5.4 (Hawksley, 1984).

5.8.2 Insurance in design

The degree to which reduction of insurance costs is a design objective is discussed by Alexander (1990a), who suggests that it is not a major aim. The factors governing the safety and loss prevention features of the design, he argues, are, in order: (1) the attitude of the planning and licensing authorities, (2) the policy of the company, (3) the BI assessment, (4) the acceptability as an insurance risk and (5) the cost of insurance.

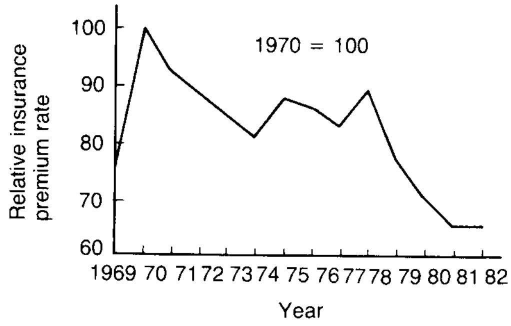

Figure 5.4 Relative insurance premium rate (1970 = 100) for material damage cover for ICI United Kingdom (Hawksley, 1984)

He considers the example of the layout of a large petrochemical plant. One design option might be a more generous layout. For this an increase in capital cost of 10% would be a reasonable estimate. Assuming the need for a real return of 15% on this additional capital, the annual cost would be 1.5% of the total replacement cost. Yet the premium rate for the insurance might well be no more than 0.5% of this latter cost. This example suggests that it is not economic to seek to reduce the insurance costs by additional capital expenditure.

5.8.3 Insurers' advice

The experience of the insurer is available to the operating company. There are several forms which advice from the insurer may take. Spiegelman (1987) emphasizes that the primary and only real function of the insurance surveyor is to make a report to the underwriter. Although it is often assumed that he is also there to offer a free consulting service, this is a misconception. However, as described by Redmond (1984), an insurance survey report generally contains recommendations for improvements. Hallam (1990) enumerates some of the recommendations typically made in such reports. In addition an insurer may also offer a separate consulting service. Thus, a large proportion of the major insurers offer inspections in respect of OSHA compliance.

It is constantly emphasized by insurance surveyors that the surveyor should be called in at the design stage, when modifications can be done relatively easily.

5.8.4 Loss adjusters

When an incident involving loss has occurred, it is the job of the loss adjuster to assess the financial value of that loss. The loss adjuster is usually employed by a firm specializing in this business and is independent of the insurer and insured. The report of the loss adjuster is primarily a financial rather than a technical document.

5.8.5 Loss data and analysis

The insurance industry is uniquely placed to provide information on loss and is in fact a prime source of loss data. This is illustrated by the large proportion of the loss data given in Chapter 2 which derives from insurance sources. Data sources include the annual report of bodies such as the Association of British Insurers and the Loss Prevention Council in the United Kingdom, the corresponding bodies in other countries, the periodic reports *Large Property Damage Losses in the Hydrocarbon–Chemical Industries: A Thirty Year Review* (Marsh and McClennan, 1992), earlier versions being those by Garrison (1988b) and Mahoney (1990), as well as occasional publications such as *Losses in the Oil, Petrochemical and Chemical Industries* (Munich Re, 1991). Insurers are also well placed to assess the significant sources of loss in the process industries. This has already been discussed in general terms in Chapter 2, but brief reference may be made here to the features particularly mentioned by insurers. Explosions are identified by W.H. Doyle (1969) as the main type of loss in the chemical industry. Many of his data have already been given in Chapter 2. Weldon (1971) singles out as the predominant initiating factors deviation from standard operating procedures and failure to perform proper maintenance. Almost invariably, insurers emphasize that most losses are caused by common hazards rather than by high technology.

5.9 Notation

C	loss cost for a particular state of nature and level of protection (US$k/year)
d	decision
D	loss cost for a particular level of production for all states of nature (US$k/year)
D^*	loss cost (present value) (without survey) (US$k)
E^*	loss cost (with survey) (US$k)
i	counter for decisions
/	outcome or indicator
j	counter for of states of nature
k	counter for outcomes
M^*	prevention cost (US$k)
P	probability
S	state of nature
T^*	total cost (US$k)

Management and Management Systems

Contents

The preceding chapters have indicated the nature of and the background to the problem of safety and loss prevention (SLP). The starting point for its solution is the management and the management system.

The importance of effective management systems has been stressed in a number of reports on safety in the chemical industry, including *Safety and Management* by the Association of British Chemical Manufacturers (ABCMs) (1964/3), in *Safe and Sound and Safety Audits* by the British Chemical Industry Safety Council (BCISC) (1969/9, 1973/12). It was the main lesson drawn from the Flixborough disaster and is the principal theme of the three reports of the Advisory Committee on Major Hazards (ACMH) (Harvey, 1976, 1976b, 1984). The *Cullen Report* on the Piper Alpha disaster (Cullen, 1990) has a similar emphasis. Accounts of process safety management (PSM) include *Safety Management* (D. Petersen, 1988b) and *Techniques of Safety Management* (D. Petersen, 1989).

Management systems help ensure long-term sustainability of effective safety health and environmental performance. Competent people drive performance. And effective management systems drive sustainability. The importance of having both strong people and well-documented effective management systems cannot be overemphasized.

The importance of management has long been recognized by the Health and Safety Executive (HSE), which has produced a series of publications on safety management and on its regulation, including *Success and Failure in Accident Prevention* (HSE, 1976d), *Managing Safety* (HSE, 1981d), *Monitoring Safety* (HSE, 1985c), *Effective Policies for Health and Safety* (HSE, 1986a), *Successful Health and Safety Management* (HSE, 1991b) and *The Costs of Accidents at Work* (HSE, 1993a).

Other relevant publications include *The Management of Health and Safety* (Industrial Society, 1988), *Developing a Safety Culture* by the Confederation of British Industry (CBI, 1990), *Guidelines for Implementing Process Safety Management Systems* (Center for Chemical Process Safety (CCPS) 1994).

Management is also well represented in the publications of the CCPS, which are described in Section 6.28 of this chapter and Responsible Care Program sponsored by the American Chemistry Council.

The management system is in part specific to the particular process and should be matched to it. This is a point emphasized in the *Code of Practice for Particular Chemicals with Major Hazards: Chlorine* issued by the BCISC (1975/1).

Many treatments of safety and management touch on virtually the whole range of subjects dealt within this book. It is convenient here, however, to limit consideration of the management system to the specific management topics outlined below. The present chapter is structured in the following way. Sections 6.1–6.3 start by laying emphasis on:

(1) management attitude;
(2) management leadership;
(3) management organization.

Sections 6.4–6.11 describe elements of the management system for major hazard installations and in large part reflect the work of the ACMH. These are:

(4) competent people;
(5) systems and procedures;
(6) project safety reviews;
(7) management of change;
(8) standards and codes of practice;
(9) pressure systems;
(10) documentation;
(11) audit systems;
(12) independent checks;
(13) major hazards.

The next part of the chapter describes the management system in more detail and reflects the impact of developments in management generally on the management of SLP. It is introduced by Sections 6.14 and 6.15 on:

(14) quality management;
(15) safety management.

Sections 6.16–6.20 draw on the accounts of management systems in works on safety management such as *Safety Management* (D. Petersen, 1988b) and *Successful Health and Safety Management* (HSE, 1991b). The elements of the management system described are:

(16) policy;
(17) organization;
(18) planning;
(19) measurement;
(20) control;
(21) audit.

Sections 6.22–6.25 deal with four additional topics:

(22) process knowledge;
(23) safety strategies;
(24) human factors;
(25) contractors.

Sections 6.26–6.28 treat:

(26) safety management systems;
(27) process safety management;
(28) CCPS management guidelines.

Section 6.29 covers:

(29) regulatory control;

and Section 6.30 covers the HSE management audit system:

(30) STATAS.

Treatments of the management system typically cover a number of topics, which in this book are dealt with elsewhere. These include hazard identification and assessment (HAZ) (Chapters 8 and 9), process design (Chapter 11), human factors and training (Chapter 14) and the safety system (Chapter 28).

Selected references on management and organization of SLP are given in Table 6.1.

6.1 Management Attitude

Safety and loss prevention in an organization stand or fall by the attitude of senior management. This fact is simply

stated, but it is difficult to overemphasize and it has far-reaching implications.

6.1.1 Safety culture

It is the duty of senior management to ensure that this attitude to SLP is realized throughout the company by the creation of a safety culture in which the company's way of doing things is also the safe way of doing things. It is not easy to create a proper attitude to safety. The most effective approach appears to be to treat safety as a matter of professionalism. This fits particularly well with the development of loss prevention with its more technical and quantitative approach. The discipline required to create and maintain a safety culture brings benefits not only to safety but also to the other aspects of the operation of the company. At this point the culture becomes self-reinforcing.

6.1.2 Will to safety

There is a danger that the emphasis in loss prevention on technological aspects of hazards and their control may obscure a very simple truth that in many cases an accident occurs because the will to avoid it was lacking. This theme has been developed by W.B. Howard (1983, 1984), who has given a number of telling examples of accidents where the essential cause was a conscious decision to take a particular course of action. Among the accidents cited are instances where an operator: was put in charge of equipment for which he had no training; omitted to check trip systems thus allowing them to degrade; chose to bypass trips and alarms to obtain increased production; and failed to provide a necessary trip on a temporary filling system. He also instances the installation of the temporary bypass pipe at Flixborough. Direction of attention to the role of conscious decisions in accidents is a necessary corrective. The specific techniques associated with loss prevention are necessary, but they are not sufficiently alone. It is crucial that there also exists the will to safe design, operation and maintenance.

6.2 Management Commitment and Leadership

The creation and maintenance of a safety culture requires strong commitment and leadership by senior management. This means that the attitude of senior management must be demonstrated in practical ways so that all concerned are convinced of its commitment. Without management commitment and leadership of management, SLP programs are doomed to fail. An account of some of the ways in which management commitment and leadership is demonstrated was given by McKee (1990) of Conoco, part of Dupont, in evidence to the Piper Alpha Inquiry. They include giving safety a high profile, giving managers safety objectives, backing managers who give priority to safety in their decisions, operating an active audit system and responding to deficiencies and incidents.

Safety is given a high profile in a number of ways. This is achieved by the measures just mentioned and also by putting it as the first item on the agenda of the appropriate meetings and making sure that personnel are aware of management's actions both in initiation of, and in response to, safety matters. McKee states:

> I keep the safety priority in front of the organization on a daily basis, mainly through my close interest in safety reporting and my continuous 'drumbeat' about the safety priority.

Managers are given specific safety objectives and are assessed on their performance in achieving them. These objectives cover both personal safety and major hazards. But whereas the former may be monitored in terms of personal accident statistics, the latter are realized so rarely that event statistics are not the appropriate measure and adherence to systems and procedures is a better one. In McKee's words:[6] 'He is accountable not only for what is achieved but also for how it is attempted'.

One of the situations most revealing of senior management's real attitude to safety is its response to a manager's decision in a specific case not to act in a way which he considers unsafe even though there is an immediate financial penalty. As McKee puts it:

> I have to do my part in helping people instinctively feel comfortable about the boundaries within which they make everyday decisions. In Conoco, we all try to let safety be the number one influence on every decision or action.

With regard to audits, McKee states:

> I receive safety audit reports and react to them if required by raising the issues involved directly with the departmental director involved. I conduct my own informal audits on my frequent visits to our installations. I participate in the London safety action committee and I specifically discuss the audit system in general with managers and employees alike.

Another principle is the prompt correction of deficiencies. A deficiency should not be allowed to persist, it should be corrected. But in addition the correction should be prompt and any delay explicitly justified.

Closely related to this is the investigation of, and response to, incidents. An incident should be investigated and the lessons drawn. But, in addition, the involvement of senior management should be explicitly demonstrated. McKee states that he receives a daily report on safety from his safety manager, who is the only manager to report daily to him. If an incident occurs, the manager informs him immediately: 'He interrupts whatever I am doing to do so, and that would apply whether or not I happened to be with the Minister for Energy or the Dupont chairman at the time.' In sum, in McKee's words: The fastest way to fail in our company is to do something unsafe, illegal or environmentally unsound.

The attitude and leadership of senior management, then, are vital, but they are not in themselves sufficient. Appropriate organization, competent people and effective systems are equally necessary.

6.3 Management Organization

The discharge of senior management's duty to exercise due care for the safety of its employees, of other people on the site and of the public requires that it create a rather comprehensive and formal system and that it be active in creating, operating, maintaining, auditing and adapting the system. It is necessary to define clearly the management structure. The distinction between the line, or executive, functions and the staff, or advisory, functions is a crucial one and is a well-established aspect of good management practice, but it is particularly important in SLP. Responsibility needs to be assigned unambiguously. There should be a job description for each of the jobs shown in the management structure. Once a job is defined, it is possible to select a competent person to fill it.

These are essential steps, but they are not sufficient alone. There are other aspects to which it is necessary to pay attention if the organization is to be fully supportive of the efforts of individuals.

One important matter is arrangements to ensure that there is cover available for key jobs. The importance of this point was underlined by the Flixborough disaster. Such cover involves both short-term standby measures and long-term career planning.

A more subtle point concerns discrepancies between function and seniority. This has frequently arisen, for example, in relation to the safety officer, who in many cases has lacked the authority to carry out his functions with full effectiveness. It is necessary to consider the possibility of such problems and to take appropriate steps.

6.4 Competent People

In addition to strong management systems, the design, operation and maintenance of hazardous processes requires competent people. Here it is necessary to try to define carefully what is required. The question is particularly important in respect of the technical executive management which has prime responsibility for the process. The statement of the management structure and the job description is a necessary first step, but does not in itself take the matter very far.

It is generally common ground that academic qualifications, practical training, recent relevant experience and personal qualities are all important. The educational requirement raises questions both of level and content. As far as the former is concerned, the greatest need is for breadth of technological understanding. The person concerned should have his own area of expertise, but should also be able to appreciate what he does not know and where he needs help from others. In the United Kingdom, a first degree or equivalent in engineering or science is commonly held to be some assurance of such a broad technological education, although it may not be the only route.

With regard to the most suitable content, this may depend on the process. Much emphasis was placed following the Flixborough disaster on maintaining the integrity of the plant, which favours chemical or mechanical engineering. In some cases, on the other hand, it may be as important to maintain the integrity of the process, which points to chemistry. Each case should be treated on its merits.

As far as training and experience are concerned, distinctions may be made between design and operation and between different processes. Experience in design does not necessarily fit someone for operation nor does experience in operation of a chlorine cellroom necessarily make him suitable to operate an ethylene cracker. It is necessary that the experience be not only relevant but also recent. This is particularly important in processes with a large content of complex and rapidly changing technology. On the other hand, these requirements should not be interpreted so restrictively that career development is hindered.

Personal qualities are equally important, particularly in relation to operation of major hazard plants. Effectiveness in this job is in large part a question of such qualities as temperament. Particular emphasis is placed on the operation of plants, especially major hazard plants. Here recent relevant experience and personal qualities are particularly important.

6.5 Systems and Procedures

It is fundamental that responsibility for SLP should be shared by all concerned in the project. It cannot be delegated to a separate safety function. This does not mean, however, that reliance should be placed simply on individual competence and conscientiousness. It is essential to support the competent people with appropriate systems of work. Experience indicates that effective systems require quite a high degree of formality.

The purpose of these systems of work is to ensure a personal and collective discipline, to exploit the experience gained by the organization, and to provide checks to minimize problems and errors. The framework of such systems is typically a set of standing orders or instructions which lay down requirements for the conduct of particular activities at the different stages of the project from research and development through to operation.

Some key systems are those which are concerned with (1) Management leadership, commitment and accountability, (2) Risk analysis, assessment and management, (3) Facilities design and construction, (4) Process and facilities information and documentation, (5) Operation of plant (normal, emergency), (6) Control of access to plant, (7) Control of plant maintenance (permits-to-work), (8) Management of change, (9) Inspection and maintenance of plant equipment, (10) Emergency preparedness (9) Third party services and (11) Incident reporting. All these systems are considered in detail in other chapters.

It is important that the various activities be properly phased and matched to the project stages. Thus, for example, hazard identification should be undertaken at a stage early enough to identify any serious hazards which might threaten the viability of the whole project, but such an investigation can be on a relatively coarse scale. As design progresses, other more detailed hazard identification procedures are required.

There is, in principle, no limit to the number of systems which may be devised, but the aim is to have the optimum number which leaves no serious gaps and yet avoids confusion due to overlapping. Inevitably, formal systems sometimes appear tedious or unnecessary. They need to be well thought out so as to minimize this reaction. But experience shows that large proportions of incidents occur due to lack of proper procedures or to non-observance of them.

6.6 Project Safety Reviews

The management system should include a formal system of project safety reviews for the identification of hazards, evaluation of risk and an assessment of the adequacy of controls. The system of reviews should be comprehensive in that it covers all aspects of the project and does so over the whole life cycle.

A typical set of project safety reviews is (1) Inherent safety/health/environment review (2) HAZard and OPerability (HAZOP) Review, (3) Detailed design review, (4) Construction review, (5) Pre-commissioning review and (6) Post-commissioning review. Project safety reviews are considered in Chapter 8.

6.7 Management of Change

A large project is subject throughout its life cycle to numerous changes, or modifications. It is necessary to have systems which will manage these changes satisfactorily. In particular, it is necessary to keep control of modifications, which may occur in design or operation.

These modifications may be to the process or the plant. Either way, modification control systems are required to detect intent to modify, to refer the modification to the appropriate function for checking, to record a modification authorized, to inform others of the modification and to follow up any implications such as a need for training. Modifications may be proposed during the design of a new plant or for existing plant. The latter also embraces major plant extensions. Different modification control systems are required for the design and operation stages. Management of change and control of modifications is discussed in Chapters 11 and 21.

6.8 Standards and Codes of Practice

An important aspect of the procedures is the use of standards and codes of practice, both external and internal. These are referred to extensively throughout this book and it is difficult to overemphasize their importance. They represent a distillation of industry's experience and are not to be disregarded lightly.

Although the majority of standards and codes relate to design, there are also many which are concerned with operation.

6.9 Pressure Systems

Central to SLP is the problem of loss of containment. The management system for the design and operation of pressure systems is therefore of crucial importance. Major failure of a properly designed, fabricated, constructed, tested, inspected and operated pressure vessel is very rare. But failures do occur in pressure systems. They tend to be failures of other pressure system components such as pipework and fittings, pumps and heat exchangers or failures due to maloperation of the system. The management systems for the control and monitoring of a pressure system should be in two parts, covering the two broad areas of design and operation and administered by two separate authorities.

The design authority should be responsible for systems for control of design, fabrication, testing and inspection, and the operating authority for those for control of commissioning, operation, maintenance and modification. The design authority should define the parameters within which the system is to operate, should specify the design codes, should execute the actual design, should identify and assess hazards, should specify standards for fabrication, construction and testing of the systems and should prescribe the documentation required on all these aspects. It should also ensure the inspection of the plant during fabrication and construction. This inspection may be done by the design authority itself or by an external body such as an insurance company or an engineering inspection agency. The inspection should be done to the specified standards and should be recorded in the prescribed way.

The operating authority should prepare written operating instructions based on the method of operation envisaged in the design, the design parameters and the hazard studies, and covering both normal and abnormal conditions. It should also create a system for the control of modifications in order to ensure the integrity both of the plant and of the process. The system should distinguish between proposed modifications that might affect the integrity of the plant and routine maintenance, and should require that the former be referred back to the design authority for checking. Similarly, the system should identify proposed modifications of operating procedures that go beyond established practice and might affect the integrity of the process, and should require that these also be referred back for checking by the design authority.

The operating authority should also provide a code for the regular inspection of the pressure system. There should be documentation on each component giving its unique identification, location, engineering description, operating conditions, inspection interval and maintenance record. Inspection intervals for each class of equipment should be specified and rules stated for the alteration of inspection intervals. The code should ensure that the inspection authority is independent of the operating authority.

6.10 Documentation

A project in the chemical industry involves a large amount of documentation. A list of some principal items is given in Table 6.2.

Some of the material is general documentation on company systems and on standards and codes, but most is specific to the particular process and plant. As the list given indicates, a large project requires a considerable amount of documentation. The table shows essentially the basic elements of the documentation. Selected items may be put together to form manuals for various purposes. Typical manuals are the Design Manual, the Plant Manual and the Operating Manual.

6.11 Audit System

It is essential that there is a mechanism to monitor the system as a whole and to make sure that it is working correctly and is not falling into decay; in other words, an audit system. Audit differs from control. In control, the outputs of a system are measured and corrections made as necessary. Audit examines the control system itself to check that it is still fit for purpose. It takes place over a much longer timescale.

The need for audit may vary. It may be fairly clear without the need for an audit whether certain systems or procedures are working properly. But for others audit is required. Thus, for example, an audit of a permit-to-work system is generally necessary to prevent it from degenerating. The audit system may include a specific instruction that the plant manager should each week examine a sample of the permits issued. The essential point is that the approach adopted is not simply to exhort the plant manager to monitor the permit system but to build the instructions to do an audit into the system.

The audit function is considered further in Section 6.21. The essential point to make at this stage is the need for an audit system.

6.12 Independent Checks

The principle of independent checks is extremely important in ensuring reliability. It is already widely practiced in relation to pressure vessel inspection. Other areas where use is already made of independent checks are audits of management systems, hazard assessment of the plant as a whole and reliability assessment of protective instrumentation.

It is not essential, in order to ensure independence, to go to an outside organization. An independent function can

Table 6.2 *Some principal items of documentation in a large chemical plant project*

Subject area	*Documentation*
Systems	Documents on company systems (e.g., see Section 6.5)
Standards and codes, legal requirements	National standards and codes applicable to the design. In-house standards and codes applicable to the design, including guidance on situations where national standards and codes do not apply Legal requirements, statutory approvals
Organization	Organization chart of personnel Job descriptions and duties of personnel, including: (a) Process operators (b) Maintenance personnel (c) Supervisory staff
Process design	Description and history of process Design basis for plant including economics, output, yield, availability, storage, siting, pollution, loss prevention aspects Design data for process, including: (a) Process reactions and reaction kinetics, including possible reactions under abnormal conditions (b) Physical and chemical properties of materials including flammable, explosive and toxic features (c) Specifications for raw materials, products, by-products and effluents (d) Data relevant to selection of materials of construction (e) Data from pilot plant Process flowsheet giving main items of equipment, quantities of materials and services, inventories and operating conditions Process flow diagram giving all items of equipment, flow rates and other operating conditions Process design data sheets for items of equipment giving design basis, operating conditions, characterizing parameters, safety factors, equipment dimensions Inventories of hazardous materials in process and in storage Safety relief device contingency basis Sources of information (people, literature) Some of this documentation is usually collected together in a Design Manual
Plant layout	Site and plant layout diagrams Site and plant pipework drawings Equipment and pipework identification schemes Documents on hazardous area classification, means of escape, site vehicle routing
Mechanical design	Mechanical job specifications, design data sheets and general arrangement, detail and layout drawings, parts lists for items of equipment Piping job specifications, piping and instrument diagrams, piping plan, elevation and isometric drawings, piping stress and piping support documents, piping parts lists Documentation on pressure relief, blowdown and flare systems
Services design	Job specifications, including arrangements for loss of services covering electricity, steam, cooling water, process water, instrument air, process air, nitrogen and any other service required
Electrical, civil, structural design	Job specifications, general arrangement, detail and layout drawings, and materials or parts lists as appropriate
Plant buildings	Design basis for control room and other buildings Documents on siting, layout, construction and explosion resistance, ventilation, fire limitation, explosion relief as appropriate
Control and instrumentation	Design basis for process control Cause and effect diagrams for all protective systems Instrument job specifications, piping and instrument diagrams, instrument design data sheets Documents on alarm, trip and interlock systems

Table 6.2 *(continued)*

Effluents, waste disposal, noise	Environmental Permits including their basis Effluent, waste disposal and noise specifications and requirements of regulatory agencies Pollution, waste disposal and noise surveys of plant
Fire protection	Design basis for fire protection system Documents on fire protection system, including fire water supply
Plant operation	Works and plant safety rules Chemical data sheets Operating instructions, including instructions on: (a) Normal operation, including all sequential operations (b) Normal start-up and shut-down, including variations dependent on length of shut-down (c) Start-up on new plant (d) Shut-down under abnormal or emergency conditions (e) Trip systems Sampling instructions, including location and identification of sample points, sampling frequency, sampling method, safety precautions Instructions on dealing with leaks and spillages Instructions for reporting incidents Operating documents, including process operator's log, plant manager's log, storage logs, standard calculations of efficiency, costs, etc. Some of this documentation and some documentation from other sections, for example, process design, are usually collected together in a Plant Manual and/or Operating Manual
Training	Documents for process operator training (e.g., see Table 14.10) Documents for safety training (e.g., see Table 28.5)
Safety equipment	Documents on safety equipment covering for installed equipment: (a) Equipment location guide (b) Equipment inspection schedules (c) Equipment use manual (d) Equipment maintenance manual and for equipment in stock (e) Equipment stock control (f) Instructions on equipment issue
Hazard identification and assessment	Records from pilot operation, of work on screening of chemicals or reactions, of hazard and operability studies, of hazard assessments, of safety audits Checklists of all kinds (e.g., see Table 8.4)
Security	Lists of permanent personnel and of temporary personnel, e.g., construction personnel Security passes
Plant maintenance	Documents on plant maintenance, including: (a) Code for maintenance and modifications with supporting documents (permits to work, clearance certificates, modifications forms, etc.) (b) Equipment identification and location guide (c) Equipment inspection and lubrication schedules (d) Equipment maintenance manuals and instructions (e) Instructions on lubricants, gaskets, valve packings, pump seals (f) Maintenance stock requirements (g) Maintenance stock control (h) Standard repair times (i) Equipment turnaround schedules
Plant inspection	Code for inspection of pressure systems Records of equipment, including identification, location, engineering description, operating conditions, inspection intervals and maintenance history Records of non-destructive or condition monitoring tests
Emergency planning	Documents on emergency planning (e.g., see Chapter 24)
Environmental control	Environmental standards (e.g., OESs) Sampling schedules

exist within the organization – but it must be genuinely independent. In fact, many organizations do rely on outside bodies, such as insurers for the inspection of pressure vessels or consultants for hazard assessments of plants.

Another independent check is furnished by the Factory Inspectorate. The most important function which the Inspectorate performs is to provide a further independent audit of the management and management system. It is emphasized, however, in accordance with the principle of self-regulation, that it is the responsibility of management to audit itself and that it should not rely on the Inspectorate to do this.

6.13 Major Hazards

The principles just outlined apply with special force to the management of major hazard installations. But there are also some particular considerations which need to be borne in mind in dealing with major hazards. These have been discussed by Challis (1979). What Challis particularly emphasizes is the combination on major hazard plants of high technology and people. If such plant is to be operated safely, it is necessary that there be strong leadership by management. The level of management which is particularly crucial is the first level of executive technical management.

The people who operate and maintain the plant cannot always be expected to have a full appreciation of all aspects of the complex technology involved. It is the responsibility of the manager on such a plant to address this problem. The workforce needs to have an understanding of the process and the plant, of the hazards involved and of the actions required. It should be well trained. It should be provided with clear instructions, both for normal operation and for emergencies. The manager on such an installation needs to be 'out and about' rather than in the office. There should be a strong executive atmosphere and discipline on the plant.

6.14 Quality Management

Increasingly, SLP is subject to the influence of quality assurance (QA) and total quality management (TQM). An account of these was given in Chapter 1.

6.14.1 Quality assurance

As described in Chapter 1, there is a strong trend for companies to adopt QA throughout their operations and to seek accreditation. In the United Kingdom, this means accreditation to BS 5750: 1987. Since QA covers inputs to the company's activities, this requires that subcontractors and suppliers also address QA.

QA affects all aspects of a company's activities and it will not generally be introduced solely as a means of improving SLP. But given that it is introduced, it will have an impact on the latter. Some SLP activities to which QA has been applied include, in particular, HAZOP (hazard and operability) studies and quantitative risk assessment and the work of consultants.

6.14.2 Total quality management

Essentially similar considerations apply to TQM. This also is unlikely to be introduced for the sole purpose of SLP, but if adopted it will have an impact. It is of interest that the Piper Alpha Inquiry was invited to recommend that TQM be adopted by offshore operators as a means of improving safety, but that the *Cullen Report* (Cullen, 1990) did not do so, considering that although this might be so, the implications of a requirement for TQM went far beyond safety.

The concept underlying loss prevention is that the problem of failures and their effects has an influence on company performance which goes far beyond safety of personnel. Essentially the same concept underlies the TQM approach. Thus TQM and SLP have much in common.

There is some tendency for those involved with TQM to treat SLP as a subset of TQM. Insofar as TQM covers the whole range of a company's activities whereas SLP deals with one aspect, this view might be held to have some force. Against this, SLP has developed within its own field the basic principle of TQM and has evolved a highly successful approach of some depth and sophistication. This evolution may be expected to continue within the context of TQM.

The degree of sophistication of SLP in the process industries is well illustrated by developments in the nuclear power industry. A glance through the publications of the Nuclear Regulatory Commission (NRC) given in Appendix 28 shows clearly the efforts made to foresee and forestall failures. Accounts of the application of TQM in the chemical industry have been given Whiston and Eddershaw (1989) and by Whiston (1991). A description of the application of TQM to HAZOP studies has been given by Turney (1991).

6.15 Safety Management

An account is now given of some principles of a PSM system. Figure 6.1 illustrates the key elements and structure of a safety management system (SMS) as given in *Successful Health and Safety Management* (HSE, 1991b).

The elements described here are similar, except that measurement and control are considered as separate elements, whilst review is treated as an aspect of control. The structure considered here is therefore:

(1) policy;
(2) organization;
(3) planning;
(4) measurement;
(5) control;
(6) audit.

Some of the insets and appendices given in the HSE publication in support of the above topics are listed in Table 6.3.

6.16 Policy

Policy on safety should aim to set appropriate goals and objectives, to organize and plan to achieve these objectives in a cost-effective way, and to ensure by systems of measurement and control and of audit that the plan is implemented. The safety policy should be integrated with the other policies of the business, with the aim of achieving high standards of performance across the whole range of the activities undertaken. It should be the goal of safety policy to ensure that activities take place in a controlled manner and to eliminate deficiencies and failures which result in undesired events, some of which escalate to cause damage and/or injury. Safety policy should take full recognition of the importance of human resources and human factors, in other words of the people, the job they do and the organization within which they work, as shown in Figure 6.2.

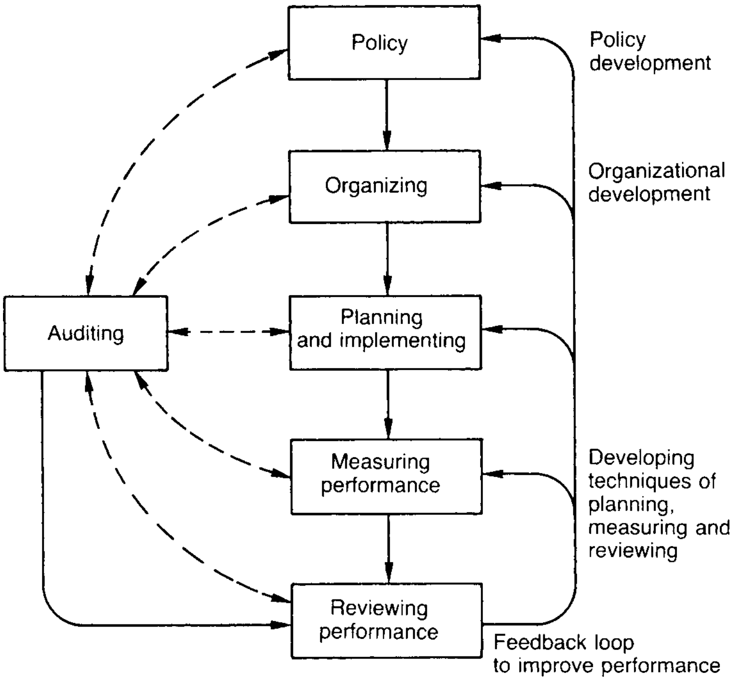

Figure 6.1 *Key elements of health and safety management (HSE, 1991b) (Courtesy of HM Stationery Office)*

Table 6.3 *Insets and appendices given in Successful Health and Safety Management (HSE, 1991b)*

16. Effective health and safety audits

Appendix
1. Terminology
2. Organizing for health and safety
3. Minimum objectives for performance standards
4. Accident incidence and frequency rates

6.17 Organization

Organization for safety is considered by the HSE under the following headings:

(1) control;
(2) cooperation;
(3) communication;
(4) competence.

6.17.1 Control

The safety goal is to ensure that activities take place in a controlled, and therefore safe, manner. This means putting in place systems of control. Such a control system is analogous to the typical feedback control system used in process control. The variable to be controlled is identified, the variable is measured, the measured value is compared with a desired value, and if necessary control action is taken to effect correction. Furthermore, there may be a system of nested control loops, with the higher loops controlling higher level functions and operating on longer timescales.

Measurement is an essential function in any control system. It is necessary to decide first what specific variables need to be regulated in order to bring the system as a whole under a satisfactory degree of control and then to decide whether for a given variable it is practical to measure it directly or whether it is necessary to infer it from some other measurement. Given that the variable can be measured, it is

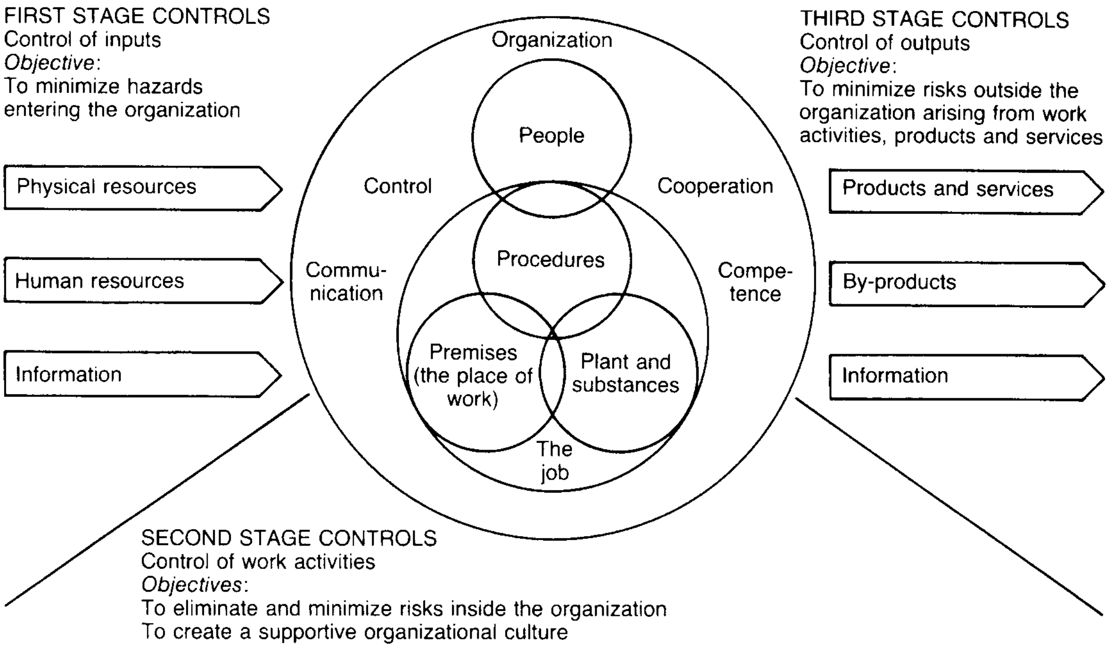

Figure 6.2 *Human factors in industrial safety (HSE, 1991b) (Courtesy of HM Stationery Office)*

necessary to decide what value is acceptable, by establishing a desired value or performance standard.

In the control systems considered here, the control function is exercised by people. It is therefore essential to define responsibilities. There is normally a hierarchy of responsibilities down through the successive levels of line management. It is then necessary to establish accountability for the discharge of responsibility at each level. Accountability may be reinforced by making it part of the job description, using it as an indicator of individual performance, and identifying lapses.

Motivation is crucial to good performance. The most effective motivation is the existence of a safety culture that provides strong reinforcement. Training which enhances understanding and motivation also has an important contribution.

Supervision provides guidance, example and discipline, and furnishes the external element that complements the internal motivation.

6.17.2 Cooperation

A safety culture necessarily involves the cooperation of the whole workforce. Specific measures have to be taken to obtain this. A system of safety committees and safety representatives, such as is required by UK legislation, is one means whereby such involvement can take place. This system alone, however, does not generally yield the degree of cooperation obtained by a TQM culture in which the people at all levels are encouraged to identify and correct deficiencies and failures, by participation in safety circles (analogous to quality circles) and like methods.

6.17.3 Communication

Effective operation of the control systems described involves large flows of information. The forms of communication distinguished by the HSE are: (1) information inputs, (2) internal information flows, (3) visible behaviour, (4) written communications, (5) face-to-face discussion and (6) information outputs. The operation of a SMS actually requires a considerable input of information into the organization.

Good communication within the organization is critical. Effective communication uses three complementary modes: visible behaviour, written communications and face-to-face discussion. Management needs to demonstrate leadership that is visible to all. Written communications are the principal means of transmitting information. The information needs of the recipients differ, however, and such communication is most effective if tailored to those needs. Face-to-face contact provides feedback and allows personal contribution.

6.17.4 Competence

The competence of personnel, particularly those in key positions, is crucial. Some of the relevant factors were discussed in Section 6.4. It is necessary, therefore, to identify those jobs where competence is particularly important and to define what is required for each job. In some cases, the competence needed is a broad managerial one; in others it is a specialism. Competence depends partly on education and training, and partly on experience. Once the competence required is defined, it is possible to try to match the person to the job.

In some cases, the appointment of a 'competent person' is a legislative requirement. A supply of competent people is generally assured by a combination of career progression within the company and external recruitment. For both sources, definition of the relevant competence is required.

Individual competence is not the sole issue, however; there is also an organizational aspect. It is necessary to ensure that for any critical post there is cover if the individual currently filling it is out of action.

6.18 Planning

Planning of the SMS involves:

(1) setting goals and objectives;
(2) defining control systems;
(3) setting performance standards.

6.18.1 Goals and objectives

Broad safety goals need to be translated into specific objectives. The objectives which it is practical to set are essentially determined by the variables which can be measured.

6.18.2 Control systems

In management theory, a distinction is commonly made between the following three stages of an activity to which controls may be applied: (1) input, (2) process and (3) output. Again, on the analogy of process control, the first two may be likened to open loop control in that the required output is obtained if the process gain remains constant and the input is maintained at an appropriate value. Alternatively, the output can be measured, and closed loop (or feedback) control applied. The application of controls to all three stages therefore involves a degree of redundancy. As redundancy enhances reliability, this is a desirable feature.

The systems required for hazards include systems for (1) hazard identification, (2) evaluation of risk and (3) an assessment of the adequacy of hazard controls.

6.18.3 Performance standards

Once objectives have been defined, suitable measurements, or metrics, have been selected and control systems based on those devised, the performance standards which these control systems should meet can be set. The performance standards should cover inputs, process and outputs. Some of the performance standards required are identified by the HSE as follows: (1) For inputs: (a) physical resources, (b) human resources and (c) information. (2) For process, or work activities: (a) control, cooperation, communication and competence; (b) premises, (c) plant and substances, (d) procedures and (e) people. (3) For outputs: (a) products and services, (b) by-products and (c) information.

Performance standards should be set for the systems for hazard identification, hazard assessment and hazard control just mentioned.

6.19 Measurement

The account just given brings out the crucial role played by measurement. Effective systems of control can be devised only if suitable measures, or metrics, can be found. The problem is addressed in the HSE publications mentioned at the start of this chapter.

6.19.1 Accident pyramid

It is helpful to begin by revisiting the accident pyramid described in Chapter 1. What this shows is that for every serious or disabling injury incident there are a number of minor injury incidents; that for every minor injury incident there are a number of damage only incidents; and that for every damage only incident there are a number of incidents with no visible injury or damage. It follows that if incidents at this latter, and lowest, level can be kept under control, the incidence of the former will be much reduced. This is true, although there can be some practical problems. Since such incidents have no visible effect, it is not easy either to define them or to persuade people that they should be reported. The accident pyramid is the centrepiece of the study in *The Costs of Accidents at Work* (HSE, 1993a), which gives five case studies, including one of an offshore oil platform.

6.19.2 Frequent and rare events

There are various definitions of accidents. One of the best known is the lost time accident (LTA). Statistics of such accidents can be compiled and monitored. If the accidents are occurring with a sufficiently high frequency, the accident statistics provide a suitable measure of performance. Some definitions of accidents and the monitoring of accident statistics are discussed in Chapters 26 and 27.

The goal of the SMS, however, is to eliminate accidents. The greater the success achieved, the less useful become the statistics of the more serious types of accident. This is seen most clearly in respect of major hazards, since the realization of a major hazard is a rare event in any company. The fact that there has been no such accident is a poor indicator of the company's performance in the control of major hazards. In dealing with major hazards, the aim is to reduce the already low probability of a realization. Thus, the performance of the system in this regard has to be judged rather in terms of its effectiveness in operating and maintaining safety systems. This points to the need to measure inputs.

It is pertinent to ask, however, whether performance in respect of accidents for which meaningful statistics are available correlates with performance in respect of major hazards. The answer appears to be that it does. Although realizations of major hazards occur too infrequently for their statistics to be a practical measure of the performance of an individual manager, except perhaps at the highest level, over a period statistics of major accidents and near-misses may be compiled for a company and are then a measure of its performance. This point has been discussed by Brian (1988). A correlation does exist between the level of minor accidents and that of major accidents. The common factor is people, their attitude and discipline.

The upshot of this is that for control systems for frequent events there is a need to measure both inputs and outputs, whereas for rare events the only option is to measure inputs.

6.19.3 Proactive monitoring

Turning then to specific measures, some items which may be made the subject of proactive monitoring include (1) achievement of objectives, (2) adherence to systems and procedures, (3) conduct of auditing, (4) state of plant and equipment and (5) state of documentation.

A manager, for example, will be concerned with personal safety and may have responsibility for one or more major hazards. He will have objectives which have been set. There will be various systems and procedures to which he is required to adhere. He needs to audit the performance of his subordinates in achieving their objectives and adhering to systems and procedures.

The state of plant and equipment is monitored by inspection. This is a feature on which monitoring has traditionally concentrated. The state of the associated documentation can also be very revealing.

If there are noxious substances in the plant environment, reduction of the levels of these should be an objective. In this case, there is something physical to measure and monitor.

6.19.4 Reactive measures

Some items which may be made the subject of reactive monitoring include (1) injuries, (2) damage, (3) other losses, (4) incidents and (5) workplace deteriorations.

6.20 Control

The purpose of the measurement activities just described is to provide the basis for control actions to correct deviations and for review of the performance of the system.

6.20.1 Control and action

If a deviation is detected, control action is required to correct it. In some cases, the corrective action needed is obvious and it can then be taken. In other cases, it is necessary to carry out an investigation. The purpose of the investigation is to discover not a single 'cause' but the total situation which has given rise to the deviation and the corrective action, or actions, required to prevent it.

6.20.2 Review

The other aspect of the control system is the review of performance to ensure that the performance standards are being met. Review is continuous and is performed by line management. These features make it a control rather than an auditing activity.

6.21 Audit

The whole management system just described needs to be examined periodically to ensure that its goals and objectives remain appropriate and that the control systems to achieve these objectives are working. This is the function of the audit system. Continuing the analogy of process control, the audit system constitutes a set of outer, higher level loops around the control systems.

The purpose of an audit is to detect degradations and defects in a management system. This may be the management system of the company as a whole, a subsidiary company, a works or a plant. An audit is performed by competent people who are independent of the organization being audited. It may be carried out by an individual or a team. It is a task requiring its own particular skills.

A full audit of the management system will address the complete set of activities just described: policy, organization, planning, measurement and control. It is more usual to conduct audits with a more limited scope. Two approaches may be taken. One is to examine a specific function such as maintenance or fire protection; this is sometimes termed the vertical approach. The other is to examine a specific level of activity such as planning; this is the horizontal approach.

At plant level, there will typically be a post-commissioning audit followed by audits at a fixed interval. Where the installation is owned by a partnership but operated by a single company, as is typical of many offshore oil platforms, the other partners will usually require audits.

It is not easy to perform an effective audit. That this is so was brought out at the Piper Alpha Inquiry. One of the crucial systems of work on the platform was the permit-to-work system. The installation had been subject to a number of audits, but critical defects in the permit system had not been picked up. Yet, in less than 2 h of evidence from the witness who was describing the system, these defects were laid bare.

Audits are discussed further in Chapters 8 and 28.

6.21.1 Proprietary systems

There exist proprietary audit systems which may be used within a company to promote SLP. One of the best known is the International Safety Rating System (ISRS) (Bird and Germain, 1985). This system is described in Chapter 28.

A critique of packaged audit systems is given by D. Petersen (1989). Essentially the criticism is that in such systems the items on which the rating is based tend to be arbitrary and do not accord well with items identified in other studies as being crucial to safety performance.

6.22 Process Knowledge

Knowledge of its processes and plants is one of the prime assets of a company, but the management of this asset often appears to be relatively neglected.

6.22.1 Organizational memory

In safety, the problem of knowledge management manifests itself most obviously in the repetition of similar incidents, which suggests defects in the collective memory. It is a matter of experience that incidents continue to occur despite the fact that similar, even virtually identical, incidents have occurred before, were fully investigated and reported, and should in principle be known to the profession. The collective memory of the profession is deficient. Likewise, at company level, incidents are repeated even though in the past there has been full knowledge of the problem in the company.

This phenomenon has been discussed and illustrated by Kletz (1980g). One particularly telling case which he quotes is where two similar accidents occurred within a couple of hundred metres, one in 1948 and one in 1968, though in this case in areas which were under separate management.

6.22.2 Awareness

The first requirement in process safety knowledge is simply awareness of hazards. Familiarity with a large number of case histories is one of the most effective ways of acquiring this awareness. Consideration should be given to any additional measures required to promote awareness in personnel entering into new responsibilities or undertaking new tasks.

6.22.3 Understanding

Knowledge is held within the organization in a variety of forms, including systems and procedures, in-house standards and codes, design manuals and other forms of codifications of practice. In sum, these generally represent an enormous store of knowledge. Such traditional forms are now supplemented by computer programs and databases, and in some cases by expert systems.

In almost all cases, these forms constitute abstractions from the original raw data. As necessarily happens when this is performed, some important features of these data disappear. The immediacy of the individual accident case history is lost. The reason why a code contains a particular recommendation is no longer clear. Information is lost in the process of abstraction. The promotion of understanding of the reasons for particular features in codes enhances their effectiveness.

6.22.4 Issues

In the course of a design, there arise a large number of issues, some of which are of considerable importance. Issues may also arise at other stages of the life cycle of the plant. These issues need to be managed. There are two problems. One is to ensure that when the issue first arises it is satisfactorily handled. An important aspect of this is ensuring that the right people participate in its resolution. The other problem is to be able to retrieve information about the issue at a later date, so that the reasons underlying the decisions taken can be understood. It is not uncommon for a plant to have design features, the purposes or limitations of which are not fully understood.

6.22.5 Operating procedures

Design of a plant proceeds on assumptions about the way in which it is to be operated, which may or may not be made fully explicit. Most incidents that occur are related in some way to plant operation or maintenance. Any mismatch between the design and operation of the plant is to be avoided.

6.22.6 Knowledge base

The safe design and operation of process plants requires an effective knowledge base within the company. This knowledge base has some similarities to a living organism. Much attention is devoted to databases. The knowledge base is at least as important. Among other things, it determines the effectiveness of the utilization of the databases.

The knowledge base takes various forms. These include in-house standards, codes and manuals, as already described. But above all it consists of the expertise of individuals.

The maintenance of the knowledge base depends on a certain critical level of activity within the company, and within its individual functions. If this is not sustained, the knowledge base can decay quite rapidly. This is a particular danger if the company goes through a bad patch.

Certain forms of knowledge can be documented, as described. Expertise derived from experience is more difficult to capture, although there is increasing interest in methods of doing so.

6.22.7 Knowledge utilization

There are factors which favour the maintenance, and enhancement, of the knowledge base. The most effective way to maintain it is to utilize it. In effect, it is a case of 'use it or lose it'.

A crucial factor, therefore, is a safety culture in which people are motivated and have occasion to draw on the knowledge base.

A safety culture as such is not enough, however. Specific steps need to be taken to make the necessary knowledge available by an inflow of information into the organization from publications and personal interchange, by converting information to transparent and utilizable forms, by facilitating access and by dissemination. Such arrangements will permit a company of moderate size to maintain a knowledge base which would otherwise be available only to a much larger organization.

6.22.8 Incident investigation

An important aspect of this activity is learning. It is usual in accounts of safety management to assign a prominent place to incident investigation. The point has already been made that incidents tend to repeat themselves. In many cases, investigation of the incident reveals little that is genuinely new. Nevertheless, the emphasis on incident investigation is not misplaced. It has a significant role in educating and motivating people and in keeping alive the knowledge base.

6.23 Safety Strategies

For a given hazard, it is necessary to devise a suitable safety strategy. The strategy should fit the particular hazard, but there are certain principles which can be stated. At the most general level, the basic elements of a hazard control strategy are:

(1) elimination;
(2) control
  (a) reduction of frequency,
  (b) reduction of consequence;
(3) mitigation.

If practical, the hazard should be completely eliminated. Otherwise, it should be controlled by reducing both the frequency and consequence of realization of the immediate event. Other measures to mitigate the effect of this event should be taken as practical. In process plants, the event of particular concern tends to be loss of containment. The strategy will then be built in large part around measures to reduce the frequency of such emission and to reduce the quantity released.

There is frequently a choice of measures which may be taken to ensure safe operation. It is good practice, therefore, to define a 'basis of safety' and then to ensure that the necessary measures are taken. The basis of safety approach has found particular application in relation to the safety of chemical reactors. Another concept is that of the 'design basis accident'. In some cases, it is not practical to have a design which will withstand all eventualities. Instead, a level of accident is defined which the plant is designed to withstand. The safety strategy is particularly important for major hazards.

6.24 Human Factors

The increasing emphasis on management is accompanied by a growing recognition of the importance of human factors. The human element in incidents is illustrated in the numerous case histories described by Kletz in *Learning from Accidents in Industry* (Kletz, 1988h), *What Went Wrong?* (Kletz, 1988n), *Improving Chemical Engineering Practices* (Kletz, 1990d), *An Engineer's View of Human Error* (Kletz, 1991e), and numerous other publications. The essential message is that attribution of such incidents to human error is not an appropriate response and that it is more constructive to treat them as arising from the work situation, which is the responsibility of management. Human factors is the subject of a number of HSE publications, including *Deadly Maintenance* (HSE, 1985b), *Dangerous Maintenance* (HSE, 1987a) and *Human Factors in Industrial Safety* (HSE, 1989b). Human factors are treated in Chapter 14.

6.25 Contractors

A particular problem is posed by contractors. In some sections of the process industries, contractors constitute a large proportion of the workforce. They carry out not only construction work, but also specialist engineering and, in some cases, serve as process operators or maintenance personnel. These contractors have to conform to the systems and procedures of the company. They must therefore be trained in these and then subject to a discipline that ensures that they comply with them.

Contractors constitute a high proportion, typically some 70%, of the workforce in the UK sector of the North Sea. The problems associated with this surfaced at the inquiry into the Piper Alpha disaster, where the gas release which led to the explosion occurred from the site of a pressure safety valve. The valve had been removed and it was held that the flange assembly had not been made leak-tight. The man leading the two-man specialist team overhauling the valve was on his first tour as a supervisor and was not fully familiar with the permit-to-work system operated on that particular platform.

Good practice requires that a company apply to contractors the same philosophy as it applies to its own personnel. This should cover all aspects, including safety culture, training, discipline and audits. There are certain steps which a company can take to ensure that the work of contractors is satisfactory. One is to specify the standards to be met and to enforce adherence to them as part of a QA system. Another is to be prepared to pay a price which is realistic and not to drive it down below the point at which the contractor is able to deliver the quality required; in some cases this means not accepting the lowest bid.

6.26 Safety Management Systems

The system that delivers the approach to process SLP described above is in effect an SMS. A requirement for a formal SMS has been introduced in UK legislation following the Piper Alpha disaster. The inquiry into the disaster was urged to strengthen the management of safety by requiring offshore operators to adopt TQM, but such a recommendation would have had implications which go far beyond safety. The *Cullen Report* (Cullen, 1990) recommended instead that for offshore installations the safety case should include a formal SMS and this requirement is embodied in the Offshore Installations (Safety Case) Regulations 1992. The corresponding regulations for onshore major hazard plants, the Control of Industrial Major Accident Hazards (CIMAH) Regulations 1984, contained no such requirement. The *Cullen Report* states that *inter alia* the SMS should cover the elements listed in Table 6.4.

Table 6.4 *Elements of the safety management system listed in the Cullen Report (Cullen, 1990)*

Organizational structure
Management personnel
Training for operations and emergencies
Safety assessment
Design procedures
Procedures for operations, maintenance, modifications and emergencies
Management of safety by contractors in respect of their work
The involvement of the workforce (operators and contractors) in safety
Accident and incident reporting, investigation and follow-up
Monitoring and auditing of the operation of the system
Systematic reappraisal of the system in the light of experience of the operator and industry

An account of industrial practice in safety management is given in *Safety Management Systems* by the European Process Safety Centre (EPSC) (1994). The ten components of a typical management system are:

(1) A charter defining the system's purpose, responsible resources and time expectations, (2) The rationale of why the system's purpose is important, its expected outcome, and how the output will be used, (3) The scope, clearly defining boundaries, constraints, specifications of input/output, resources required and excluded areas, (4) An administrator, defined as a single function or individual responsible for ensuring that the system is effective and provides continuity over time, (5) Tools/procedures/resources/schedules, the documentation of what when, how and by whom tasks must be done, including scheduling and measuring or results and periodic assessment of competency of resources, (6) Communications of results and plans to whom, by whom, how often, by what method, (7) Management sponsor to facilitate, monitor, recognize, provide commitment and sustainability, (8) Verification, which includes a measurement process to determine if desired results are being achieved and communicated to customers, sponsor, and members of the system, (9) A continuous improvement mechanism to facilitate improvements over time and (10) A document defining how the system works.

6.27 Process Safety Management

6.27.1 OSHA PSM Rule

In the United States, certain hazardous chemicals attract the statutory requirement for a PSM system, introduced by the Occupational Safety and Health Administration (OSHA) Rule Process Safety Management of Highly Hazardous Chemicals (Federal Register 29 CFR 1910.119). An account is given by Ozog and Stickles (1992).

The PSM system rule specifies national performance standards in 14 elements: (1) employee participation, (2) process safety information, (3) process hazard analysis, (4) operating procedures, (5) training, (6) contractors, (7) pre-start-up safety review, (8) mechanical integrity, (9) hot work permit, (10) management of change, (11) incident investigation, (12) emergency planning and response, (13) compliance audits and (14) trade secrets.

6.27.2 EPA Risk Management Program

In addition to the PSM system given in the OSHA Rule, there are several other American systems. One is the EPA Risk Management Program, the components of which are as follows: (1) hazard assessment, (2) prevention programme, (3) emergency response programme and (4) risk management plan. The prevention programme covers: (1) management system, (2) process hazard analysis, (3) process safety information, (4) standard operating procedures, (5) training,

(6) maintenance of mechanical integrity, (7) pre-start-up review, (8) management of change, (9) safety audits and (10) accident investigation.

6.27.3 API RP 750

Another process safety system is that given in API RP 750: 1990 *Management of Process Hazards*. The elements of the American Petroleum Institute (API) system are (1) process safety information, (2) process hazards analysis, (3) management of change, (4) operating procedures, (5) safe work practices, (6) training, (7) assurance of the quality and mechanical integrity of critical equipment, (8) pre-start-up safety review, (9) emergency response and control, (10) investigation of process-related incidents and (11) audit of process hazards management system.

6.27.4 The ACC system

The process safety system developed by the American Chemistry Council (ACC) has four main parts: (1) management leadership in process safety, (2) process safety management of technology, (3) process safety management of facilities and (4) managing personnel for safety. Detailed elements are given under each of these headings.

6.27.5 CCPS system

Finally, there is the management system of the CCPS, which is described in Section 6.28.

6.28 CCPS Management Guidelines

The CCPS has published several sets of guidance on management. The first of these was *A Challenge to Commitment* (CCPS, 1985) addressed to senior management in the industry. There have since followed a number of guidelines on management systems, as described below.

6.28.1 Guidelines for Technical Management of Chemical Process Safety

The *Guidelines for Technical Management of Chemical Process Safety* (the *Technical Management Guidelines*) by the CCPS (1989/7) give a comprehensive treatment of the management of SLP. An account of these *Guidelines* is given by Schreiber (1991). The main headings of the *Guidelines* may be summarized as follows:

(1) overview;
(2) management and management systems;
(3) goals and objectives;
(4) process knowledge and documentation;
(5) process safety reviews;
(6) process risk management;
(7) management of change;
(8) process and equipment integrity;
(9) human factors;
(10) training and performance;
(11) incident investigation;
(12) company standards, codes and regulations;
(13) audits and corrective action;
(14) enhancement of process safety knowledge.

The *Guidelines* are concerned with PSM. Process safety is defined as 'the operation of facilities that handle, use, process, or store hazardous materials in a manner free from episodic or catastrophic incidents' and PSM as 'the application of management systems to the identification, understanding, and control of process hazards to prevent process-related injuries and accidents'. A distinction is drawn between process and personal safety, the scope of the work being confined to the former. The starting point is the recognition that 'major accidents could not be prevented by technology-oriented solutions alone'.

The *Guidelines* identify 12 key elements of process safety, each of which is broken down into a number of components. These are shown in Table 6.5, together with the location in this book where they are treated. Management leadership is emphasized. Management systems and management of process safety are treated in terms of the functions of (1) planning, (2) organization, (3) implementation and (4) control. Each of these functions operates are three levels: (1) strategic, (2) managerial and (3) task. The format of planning, organization, implementation and control (POIC) is applied to the other elements of the system.

Accountability needs to be: planned so that the general goals are converted into specific objectives owned, or sponsored, by individuals; organized so that roles are defined, lines of authority are established and formal systems specified; implemented by demonstration of compliance to senior management and controlled by performance measurement and audit.

Process knowledge and documentation provides the basis for much of the safety programme. Examples are given of topics on which documentation is required such as chemical data and Material Safety Data Sheets (MSDSs), process definition, process and equipment design, and protective systems.

Process safety review procedures are required for capital projects, whether for new or existing plants, extensions or acquisitions. The review procedure described is a five-stage one: (1) conceptual engineering, (2) basic engineering, (3) detail design, (4) equipment procurement and construction and (5) commissioning. A comparison is given of hazard identification, or review, procedures such as hazard and operability studies, failure modes and effects analysis and fault trees, and of their role in the review process. Examples are given of topics covered in different types of process safety review such as the design stage, review or commissioning review.

Process risk management involves a process of hazard identification, risk analysis, risk reduction, residual risk management and emergency planning. An account is given of the ranking of risks and of risk acceptability. The point is made that the analysis may reveal that the risks of the project may be simply too great to be acceptable.

Management of change requires that mechanisms be in place to recognize and handle changes in the process, the plant or the organization. The features which prompt changes to the process or the plant and the effect of personnel changes on the organization are described.

Process and equipment integrity is assured by measures which include: reliability engineering; materials selection; fabrication and inspection procedures; installation procedures; preventive maintenance; inspection and testing, of process, hardware and software; maintenance procedures; alarm and instrument management; and demolition procedures.

Human factors need to be taken into account in: the operator–process and operator–equipment interfaces; the choice between administrative control (procedures) and hardware controls (interlocks); and the assessment of human error.

Table 6.5 *Elements and components of CCPS Technical Management Guidelines (CCPS, 1989/7)*

		Chapter[a]
1.	*Accountability: Objectives and Goals*	6
	Continuity of operations	
	Continuity of systems (resources and funding)	
	Continuity of organizations	
	Company expectations (vision or master plan)	
	Quality process	
	Control of exceptions	
	Alternative methods (performance vs specification)

[a] Chapter in this book in which this topic is principally addressed.

[b] For new or existing plants, expansions, and acquisitions.

Training is necessary to provide both knowledge and motivation. Some principal topics requiring training are listed, including operating and maintenance procedures. The approach to training is described, including definition of the knowledge and skills required, assessment before and after training and keeping of training records.

Incident investigation should be approached in terms of failure of the management system rather than of human error. An account is given of the incident investigation process, including: preparation; team selection; recording, reporting and analysis; follow-up and resolution and dissemination of results.

Company standards, codes and regulations provide a framework of requirements and guidance. Use is made of both external and in-house codes. The principal US codes relevant to the process industries are outlined. A plan is given for the repositories of external codes and regulations within a company.

Audits are required to show the company whether its systems and procedures and its practices are adequate and are being adhered to, so that corrective action can be taken if they are not. The reasons for establishing an audit programme are described. They include the raising of safety awareness, acceleration of the development of safety control systems, improvement of safety performance and optimization of safety resources. A particular type of audit is the compliance review, which is carried out to ensure that the company is meeting the legal requirements.

Enhancement of process safety knowledge is an ongoing activity and involves the utilization of a range of resources, some of which are enumerated. The direction in which this work may progress is outlined by Sweeney (1992). The emphasis is on the development of measures of performance.

6.28.2 Plant Guidelines for Technical Management of Chemical Process Safety

The Plant Guidelines for Technical Management of Chemical Process Safety (*the Plant Technical Management Guidelines*) by the CCPS (1992/11) have the same basic structure as the *Technical Guidelines*, but emphasize concrete examples.

These are principally given in the appendices, the titles of which are listed in Table 6.6.

6.28.3 Guidelines for Implementing Process Safety Management Systems

The implementation of a PSM system is covered in *Guidelines for Implementing Process Safety Management Systems* (CCPS 1994/13). The elements of the system are those given in the Technical Management Guidelines and shown in Table 6.5. The treatment of implementation is under the headings: (1) management commitment, (2) definition of goals, (3) evaluation of the present status, (4) development of a plan, (5) development of specific PSM systems, (6) implementation of the system, (7) measurement and monitoring of system installation and (8) expansion beyond the original scope. The guidelines describe a case study.

6.28.4 Guidelines for Auditing Process Safety Management Systems

The auditing of a PSM system is dealt with in *Guidelines for Auditing Process Safety Management Systems* (CCPS 1993/12). These guidelines cover topics closely aligned to, but not identical with, the 12 elements of the CCPS PSM system, the headings being: (1) management of PSM systems audits, (2) audit techniques, (3) accountability and responsibility, (4) process safety knowledge, (5) project safety reviews, (6) management of change, (7) process equipment integrity,

Table 6.6 *Appendices of CCPS Plant Management Guidelines (CCPS, 1992/11)*

14C	Examples of subjects covered in process safety libraries

(8) process risk management, (9) incident investigation, (10) human factors, (11) training and performance and (12) emergency response planning.

6.29 Regulatory Control

The crucial role of the management and management system in SLP means that it is, or should be, of prime concern to the regulatory body. The organization and activities of that body should reflect this.

6.29.1 Evolution of policy

The HSE has for a long time placed emphasis on the crucial role of management, but its approach has naturally undergone a process of evolution. The process has been described by Bleeze (1992). This evolution is documented in the series of publications on management already referred to: *Managing Safety* (HSE, 1981d), *Monitoring Safety* (HSE, 1985c), *Effective Policies for Health and Safety* (HSE, 1986a) and *Successful Health and Safety Management* (HSE, 1991b).

6.29.2 Inspection *vs.* audit

In the United Kingdom, as elsewhere, the traditional approach to enforcement has been by inspection. This is reflected in the title of the arm of the HSE which operates at works level, the Factory Inspectorate.

This approach is increasingly being supplanted by the auditing of the management and management systems. The features which are of interest to the regulator are now those such as the arrangements for the identification and assessment of hazards, for the proof testing of protective systems or for the investigation of incidents.

The deficiencies of an approach to regulation based on inspection were highlighted by the *Cullen Report* on the Piper Alpha disaster and the report recommended a change in the regulatory regime away from one based on inspection and towards one based on audit of the SMS (Cullen, 1990).

6.29.3 Accident Prevention Advisory Unit

In order to provide assistance to inspectors in the assessment of management and management systems, the HSE has created the Accident Prevention Advisory Unit (APAU). Much of the HSE work described above derives from this unit.

6.29.4 Management assessment

As described above, the HSE has given guidance on good practice in the management of process safety. It may be assumed to apply much the same criteria in the assessments which it undertakes. It is also active in the evaluation of research models of management effectiveness, including as proprietary systems. An account of one such study has been given by J.C. Williams and Hurst (1992). Against this background, the HSE has been developing a method for auditing a SMS. This is now described.

6.30 STATAS

The HSE is well advanced with the development of a methodology for the audit of SMSs. The method goes by the name of Structured Audit Technique for the Assessment of Safety Management Systems (STATAS) and is described by Ratcliffe (1993, LPB 112, 113, 114) and Hurst and Ratcliffe (1994). The starting point is a field study of failures in vessels and pipework (Bellamy, Geyer and Astley, 1989; Geyer *et al.*, 1990; Geyer and Bellamy, 1991; Hurst *et al.*, 1991). An account of the study and of the pipework failure data is given in Chapter 12, whilst the human error aspects are considered in Chapter 14.

From this study a loss of containment model has been derived. The pipework failures are classified on three dimensions:

(1) origin of failure (basic or underlying cause);
(2) direct (immediate) cause;
(3) recovery (preventive) mechanism.

The origins of failure are divided into nine categories:

(1) design;
(2) manufacture/assembly;
(3) construction/installation;
(4) normal operation;
(5) maintenance;
(6) natural causes;
(7) domino;
(8) sabotage;
(9) unknown.

There are 12 categories of direct cause:

(1) corrosion;
(2) erosion;
(3) external load;
(4) impact;
(5) overpressure;
(6) vibration;
(7) temperature (high, low);
(8) wrong equipment;
(9) defective equipment;
(10) human error;
(11) other;
(12) unknown.

There are four preventive mechanism categories. Two relate to equipment:

(1) hazard identification and assessment (HAZ);
(2) routine checking and testing (ROUT).

and two to people:

(1) human factors review (HF);
(2) task checking (TCHECK).

The influencing factors which bear on the failures are represented by a socio-technical model. The structure of this model is shown in the socio-technical pyramid given in Figure 2.6(a). The model has six levels as follows:

Level	
5	System climate
4	Organization and management
3	Communication and feedback
2	Operator reliability
1	Engineering reliability
0	Loss of containment and mitigation

Some influencing factors at Level 5 are background, legislation, regulation and resources; at Level 4, policies, management structure, formal systems, assigned responsibilities, performance criteria and emergency response organization; at Level 3, job descriptions, written procedures, performance evaluation, safety audits, incident reporting and follow-up, and meetings; at Level 2, design, procedures, competence, manning and shifts; at Level 1 plant layout and equipment design.

In STATAS, these models are combined with an audit scheme. The five phases of the plant life cycle are:

(1) design (DBS);
(2) manufacture (MANF);
(3) construction (CON);
(4) operation (OP);
(5) maintenance (MAINT).

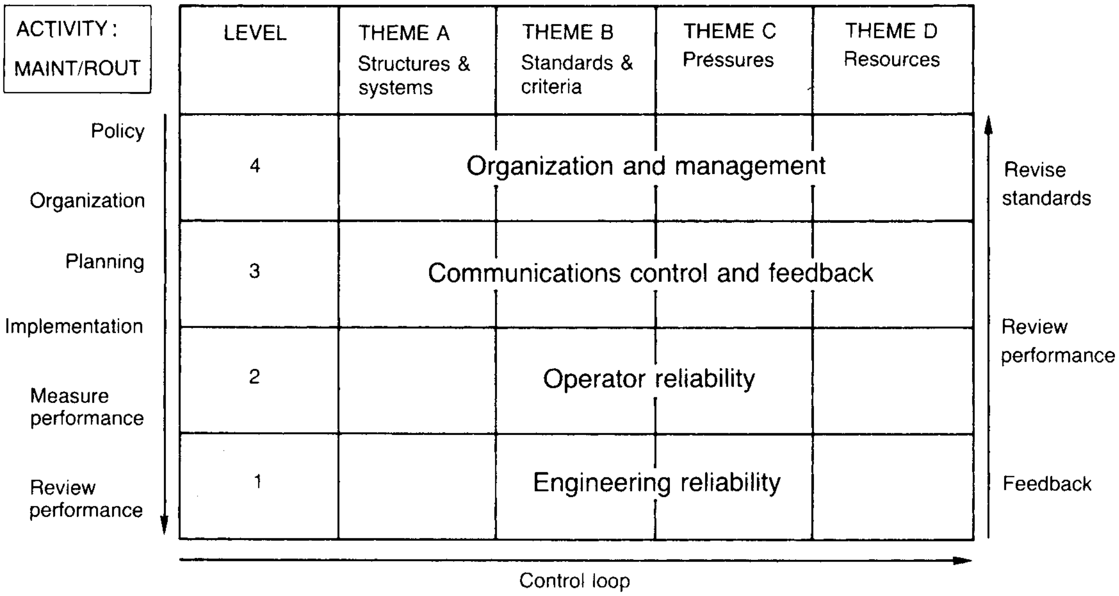

Figure 6.3 *Arrangement of question cell sets for audit of topic MAINT/ROU is STATAS (Ratcliffe, 1993 LPB 114)*

Since there are four recovery, or preventive, categories, there are in principle 20 combinations of plant phase and preventive category. The field study showed, however, that the great majority of failures are associated with just eight combinations. These eight cover 83% of vessel failures, the proportion recoverable being assessed as 87%; the corresponding figures for pipework are 84% and 92%. The eight combinations are

(1) DES/HAZ;
(2) CON/TCHECK;
(3) MAINT/ROUT;
(4) MAINT/HF;
(5) MAINT/TCHECK;
(6) OP/HAZ;
(7) OP/HF;
(8) OP/TCHECK.

Then, for each combination, an audit question set is devised. The themes of the questions are

(1) structures, systems and procedures,
(2) standards and criteria,
(3) mitigation of pressures,
(4) availability and use of resources.

Each question set contains some 40–80 questions. The questions are grouped in cells containing between 2 and 10 questions which explore a particular topic.

The conduct of the audit aims to take samples 'horizontally' and 'vertically' through the system, concentrating mainly on Levels 1–4. The method is illustrated in Figure 6.3, which shows the arrangement of question cell sets for the topic MAINT/ROUT. Work on the question sets links with that of Wells, Hurst and co-workers described in Chapter 8.

7

Reliability Engineering

Contents

Loss prevention is in large part the application of probabilistic methods to the problems of failure in the process industries. The discipline which is concerned with the probabilistic treatment of failure in systems in general is reliability engineering. This chapter gives an account of reliability engineering and of some reliability techniques.

Selected references on reliability engineering are given in Table 7.1. There are numerous books on the subject. These include *Reliability Theory and Practice* (Bazovsky, 1961), *Reliability Principles and Practices* (Calabro, 1962), *Reliability: Management, Methods and Mathematics* (Lloyd and Lipow, 1962), *System Reliability Engineering* (Sandler, 1963), *Reliability Engineering* (von Alven, 1964), *Reliability Engineering*

It is intended that the material given in this chapter be supplemented by this literature.

7.1 Development of Reliability Engineering

Some of the earliest developments in reliability engineering occurred during the Second World War. The Germans had problems with the reliability of the V-1 missile (Bazovsky, 1961). The project team leader, Lusser, has described how the first approach taken to the problem was based on the argument that a chain is no stronger than its weakest link. This concentrated attention on the small number of low reliability components. But this approach was not successful. It was then pointed out by a mathematician, Pieruschka, that the probability of success p in a system in which all the components must work if the system is to work is the product of the individual probabilities of success p_i:

$$p = \prod_{i=1}^{n} p_i \qquad [7.1.1]$$

This drew attention to the need to improve the reliability of the many medium reliability components. This approach was much more successful in improving missile reliability. Equation 7.1.1 is known as Lusser's product law of reliabilities.

On the other side of the Channel, Blackett (1962) was drawing attention to the significance of Equation 7.1.1 to military operations in general:

> In the simplest case of air attack on a ship, the four main probabilities are (1) the chance of a sighting, (2) the chance the aircraft gets in an attack, (3) the chance of a hit on a ship, and (4) the chance that the hit causes the ship to sink.

This work was the beginning of operational research.

The US armed forces also had serious reliability problems, particularly with vacuum tubes used in electronic equipment. Studies of electronic equipment reliability at the end of the War showed some startling situations (Shooman, 1968a). In the Navy the number of vacuum tubes in a destroyer had risen from 60 in 1937 to 3200 in 1952. A study conducted during manoeuvres revealed that equipment was operational only 30% of the time. An Army study showed that equipment was broken down between two-thirds and three-quarters of the time. The Air Force found that over a 5-year period, maintenance and repair costs of equipment exceeded the initial cost by a factor of 10. It was also discovered that for every vacuum tube in use there was one held as spare and seven in transit, and that one electronics technician was needed for every 250 vacuum tubes. These studies illustrate well the typical problems in reliability engineering, which is concerned not only with reliability but also with availability, maintenance and so on.

From these early beginnings the study of reliability has become a fully developed discipline. It has received particular impetus from the reliability requirements in the fields of defence and aerospace, and electronics and computers. Perhaps the most spectacular example is the moonshots, which depended crucially on reliability technology.

One of the main fields of application of reliability engineering has been in electronic equipment. Such equipment typically has a large number of components. Initially, the reliability of electronic equipment was much less than that of mechanical equipment. But the application of reliability engineering to electronic equipment has now made it generally as reliable.

Another area in which reliability engineering has been widely used is nuclear energy. Methods have had to be developed to assess the hazards of nuclear reactors and to design instrument trip systems to shut them down safely.

In the United Kingdom, work on reliability of nuclear reactors has been done by the UK Atomic Energy Authority (UKAEA), originally through its Health and Safety Branch and subsequently through the Safety and Reliability Directorate (SRD), which runs the National Centre for Systems Reliability (NCSR) and the Systems Reliability Service (SRS). The latter operates a consultancy service on industrial reliability problems and a failure data bank.

The development of reliability engineering and of loss prevention in the chemical and petroleum industries has been described in Chapter 1.

7.2 Reliability Engineering in the Process Industries

7.2.1 Applicability of reliability techniques

It is entirely right that the process industries should seek to apply the techniques and obtain the benefits of reliability engineering. But it is important to recognize that reliability engineering as a discipline has grown up outside these industries. It is to be expected, therefore, that the techniques will need to be adapted to and developed for the problems of the process industries. A similar adaptation was necessary in order to apply control engineering to process problems. The process industries are particularly concerned with mechanical equipment reliability. This is proving a rather more intractable problem.

7.2.2 Reliability assessment and improvement

Reliability engineering involves an iterative process of reliability assessment and improvement, and the relationship between these two aspects is important. Work on the reliability of a system necessarily involves assessment of that reliability. In some cases the assessment shows that the system is sufficiently reliable. In other cases the reliability is found to be inadequate, but the assessment work reveals ways in which the reliability can be improved. It is generally agreed that the value of reliability assessment lies not in the figure obtained for system reliability, but in the discovery of the ways in which reliability can be improved.

The reliability engineer, however, cannot wait until his fellow engineers have solved all their reliability problems. It is his job to identify the areas where improvements are essential for success. But for the rest, he is obliged to accept, as given, the levels of reliability currently being achieved. This is not the case, however, with other engineers. It is they who are in a position to reduce the number of failures. They too should use reliability techniques. But it would be disastrous if they were to take the existing level of reliability as unalterable.

7.2.3 Reliability and other probabilistic methods

Loss prevention makes use of a wide range of probabilistic methods. A large proportion of these are reliability techniques as conventionally defined, but in addition, use is made of other probabilities. In particular, there is considerable emphasis in loss prevention on the assessment of the consequences of failures, taking into account factors such as numbers of people exposed, weather conditions, etc.

7.2.4 Reliability and quality control

There is a close link between reliability and quality control of equipment. But the two are not identical and the distinction between them is important. An equipment is likely to be unreliable unless there is good quality control over its manufacture. In general, quality control is a necessary condition for reliability. It is not, however, a sufficient condition. Deficiencies in specification, design or application are also causes of unreliability. A badly designed equipment may be manufactured with good quality control, but it will remain unreliable. This aspect is discussed in more detail by F. Nixon (1971).

7.2.5 Reliability standards

The principal British Standards dealing with reliability are BS 4778: 1979 Quality Vocabulary, for terminology, and BS 5760: 1981 Reliability of Systems, Equipment and Components. BS 4200: 1967 Guide on the Reliability of Electronic Equipment and Parts Used Therein, which dealt both with terminology and other matters, is now withdrawn.

The constituent parts of BS 5760 are Part 0: 1986 Introductory Guide to Reliability, Part 1: 1985 Guide to Reliability and Maintainability Programme Management, Part 2: 1981 Guide to the Assessment of Reliability, Part 3: 1982 Guide to Reliability Practices: Examples, Part 4: 1986 Guide to Specification Clauses Relating to the Achievement and Development of Reliability in New and Existing Items, Part 5: 1991 Guide to Failure Modes, Effects and Criticality Analysis (FMEA and FMECA), Part 6: 1991 Guide to Programmes for Reliability Growth, Part 7: 1991 Guide to Fault Tree Analysis, Part 9: 1991 Guide to the Block Diagram Technique, and Part 10: 1993 Guide to Reliability Testing.

Another widely quoted set of standards is the US Armed Services MIL standards, and handbooks. Terminology is given in MIL-STD-721B and MIL-STD-781B. Standards dealing with reliability include MIL-STD-756 Reliability Prediction, MIL-STD-781A Reliability Tests: Exponential Distribution, MIL-STD-7810 Reliability Design Qualification and Production Acceptance Tests, MIL-STD-785 Requirements for Reliability Program, and MIL-STD-1635 Reliability Growth Theory, and handbooks MIL-HDBK-189 Reliability Growth Management and MIL-HDBK-217 Reliability Prediction of Electronic Equipment. Maintainability is covered in MIL-STD-470 Maintainability Program Requirements, MIL-STD-471 Maintainability Demonstration and MIL-HDBK-472 Maintainability Prediction.

7.3 Definition of Reliability

Definitions of reliability are given in various British Standards dealing with terminology on quality and reliability. BS 4778: Part 1: 1987 defines reliability as

> The ability of an item to perform a required function under stated conditions for a stated period of time.

This supersedes the definition given in BS 4200: Part 2: 1974, which has now been withdrawn. Further, essentially similar, definitions are given in BS 4778: Section 3.1: 1991 and BS 4778: Section 3.2: 1991. BS 4778: Section 3.1: 1991 states that in definitions relating to reliability, the word 'time' may be replaced by 'distance', 'cycles', or other quantities or units, as appropriate.

An alternative definition of reliability is: 'The probability that an item will perform a required function under stated conditions for a stated period of time'. This definition brings out several important points about reliability: (1) it is a probability, (2) it is a function of time, (3) it is a function of defined conditions and (4) it is a function of the definition of failure.

Some definitions of failure are: (1) failure in operation, (2) failure to operate on demand, (3) operation before demand and (4) operation after demand to cease. The first of these definitions is applicable to an equipment which operates continuously, while the other definitions are applicable to one which operates on demand.

7.4 Meanings of Probability

It may appear intuitively obvious what is meant by probability, but the word, in fact, has several meanings. Moreover, the distinctions are of some practical importance. They are relevant, for example, to the question of the relative weight that should be attached to field data and to other information available to individuals.

7.4.1 Equal likelihood

One definition of probability derives from the principle of equal likelihood. If a situation has n equally likely and mutually exclusive outcomes, and if nA of these outcomes are event A, then the probability $P(A)$ of event A is:

$$P(A) = \frac{n_A}{n} \qquad [7.4.1]$$

This probability can be calculated *a priori* and without doing experiments.

The example usually given is the throw of an unbiased die, which has six equally likely outcomes: the probability of throwing a one is 1/6. Another example is the withdrawal of a ball from a bag containing four white balls and two red ones: the probability of withdrawing a red one is 1/3. The principle of equal likelihood applies to the second case also, because, although the likelihood of withdrawing a red ball and a white one are unequal, the likelihood of withdrawing any individual ball is equal.

This definition of probability is often of limited usefulness in engineering because of the difficulty of defining situations with equally likely and mutually exclusive outcomes.

7.4.2 Relative frequency

The second definition of probability is based on the concept of relative frequency. If an experiment is performed n times and if the event A occurs on nA of these occasions, then the probability $P(A)$ of event A is:

$$P(A) = \lim_{n \to \infty} \frac{n_A}{n} \qquad [7.4.2]$$

This probability can only be determined by experiment. This definition of reliability is the one that is most widely used in engineering. In particular, it is this definition that is implied in the estimation of probability from field failure data.

7.4.3 Personal probability

A third definition of probability is degree of belief. It is the numerical measure of the belief which a person has that the event will occur. Often this corresponds to the relative frequency of the event. But this is not always so, for several reasons. One is that the relative frequency data available to the individual may be limited or nonexistent. Another is that even if he has such data, he may have other information which causes him to think that the data are not the whole truth. There are many possible reasons for this. The individual may doubt the applicability of the data to the case under consideration, or he may have information which suggests that the situation has changed since these data were collected.

It is entirely legitimate to take into account such personal probabilities:

> Personal probability was cast into disrespect during the nineteenth century when science was believed to be absolute truth, because, with this definition the results will depend upon the person solving the problem. However, this objection to subjectivity has recently been countered quite effectively by Savage, Janes and other physical scientists. (Breipohl, 1970, p. 6)

There are several branches of probability theory which attempt to accommodate personal probability. These include ranking techniques (e.g., Siegel, 1956), which give the numerical encoding of judgements on the probability of ranking of items, and Bayesian methods (e.g., Breipohl, 1970), which allow probabilities to be modified in the light of additional information.

Further discussions of personal probability are given by Savage (1962) and by Tribus (1969).

7.5 Some Probability Relationships

It is appropriate to give, at this point, a brief treatment of some basic probability relationships. These are important in the present context not only because they are the basis of reliability expressions, but also because they are needed for work in areas such as fault trees.

7.5.1 Sets and Boolean algebra

Some set theory definitions, operations and laws are given in Table 7.2 and some of these are illustrated by the Venn diagrams given in Figure 7.1.

The union and intersection of sets may be written, respectively, in the notation

$$C = A \cup B \qquad [7.5.1]$$

and

$$C = A \cap B \qquad [7.5.2]$$

or in the notation

$$C = A + B \qquad [7.5.3]$$

and

$$C = A \cdot B = AB \qquad [7.5.4]$$

It is mainly the latter notation that is used here.

Table 7.2 *Some set theory definitions, operations and laws*

Definitions:	
Null set Ø	Ø is a set with no elements
Sample space set S	S is the set containing all the elements in the sample space
Elements	
$a \in A$	a is an element of A
Subsets	
$A \subset B$	A is a subset of B
$B \supset A$	B contains A
$A \subseteq B$	A is a subset of B or is equal to B
Equality	
$A = B$	A has the same elements as B
$A = Ø$	A has no elements
Operations:	
Union of sets	
$C = A \cup B$ also writen $C = A + B$	C contains all the elements of A and B
Intersection of sets	
$C = A \cap B$ also written $C = AB$ or $A \cdot B$ $C = A$ and B	C contains only the elements common to A and B
Disjoint sets (mutually exclusive sets) $C = A \cap B = Ø$	
Difference of sets $C = A - B$	C contains all the elements of A which are not elements of B
Complement of a set[a] $A' = \mathrm{S} - A$	A' contains all the elements of S which are not elements of A
Laws:	
Commutative laws	
$A + B = B + A$	
$AB = BA$	
Associative laws	
$(A + B) + C = A + (B + C) = A + B + C$	
$(AB)C = A(BC) = ABC$	
Distributive laws	
$A(B + C) = AB + AC$	
$A + BC = (A + B)(A + C)$	
Absorption laws	
$A + A = A$	
$AA = A$	
Dualization (de Morgan's) laws	
$(A + B)' = A'B'$	
$(AB)' = A' + B'$	

[a] Use may also be made of the notation $\bar{A}$ to signify 'not A.'

Attention is drawn in particular to the distributive and absorption laws, which differ somewhat from their apparent analogues in normal algebra. Set theory and Boolean algebra are described in standard texts (e.g., Reza, 1961; Shooman, 1968a; Breipohl, 1970). Probability and set theory are closely related, because the outcomes of a situation constitute, in effect, a set.

7.5.2 Probability of unions

The probability of an event X which occurs if any of the events A_i occur and is thus the union of those events is:

$$P(\mathrm{X}) = P\left(\bigcup_{i=1}^{n} A_i\right) \tag{7.5.5}$$

If there are two events:

$$P(X) = P(A_1) + P(A_2) - P(A_1A_2) \tag{7.5.6}$$

If there are three events:

$$P(X) = P(A_1) + P(A_2) + P(A_3) - P(A_1A_2) - P(A_1A_3) - P(A_2A_3) + P(A_1A_2A_3) \tag{7.5.7}$$

If there are n events:

$$P(X) = P(A_1) + P(A_2) + \cdots + P(A_n) - P(A_1A_2) - P(A_1A_3) - \cdots - P(A_{n-1}A_n) + P(A_1A_2A_3) + P(A_1A_2A_4) + \cdots + P(A_{n-2}A_{n-1}A_n) \cdots (-1)^{n-1} P(A_1A_2 \cdots A_n) \tag{7.5.8}$$

If the events are mutually exclusive, Equation 7.5.5 simplifies to:

$$P(X) = \sum_{i=1}^{n} P(A_i) \tag{7.5.9}$$

In general:

$$P\left(\bigcup_{i=1}^{n} A_i\right) \le P \sum_{i=1}^{n} P(A_i) \tag{7.5.10}$$

For events not mutually exclusive but of low probability the error in using Equation 7.5.9 instead of Equation 7.5.5 is small. Equation 7.5.9 is sometimes called the low probability, or rare event, approximation. The estimate of probability given by Equation 7.5.9 errs on the high side and hence is conservative in calculating failure probabilities, but is not conservative in calculating success probabilities or reliabilities.

7.5.3 Joint and marginal probability

So far the events considered are the outcomes of a single experiment. Consideration is now given to events which are the outcome of several subexperiments.

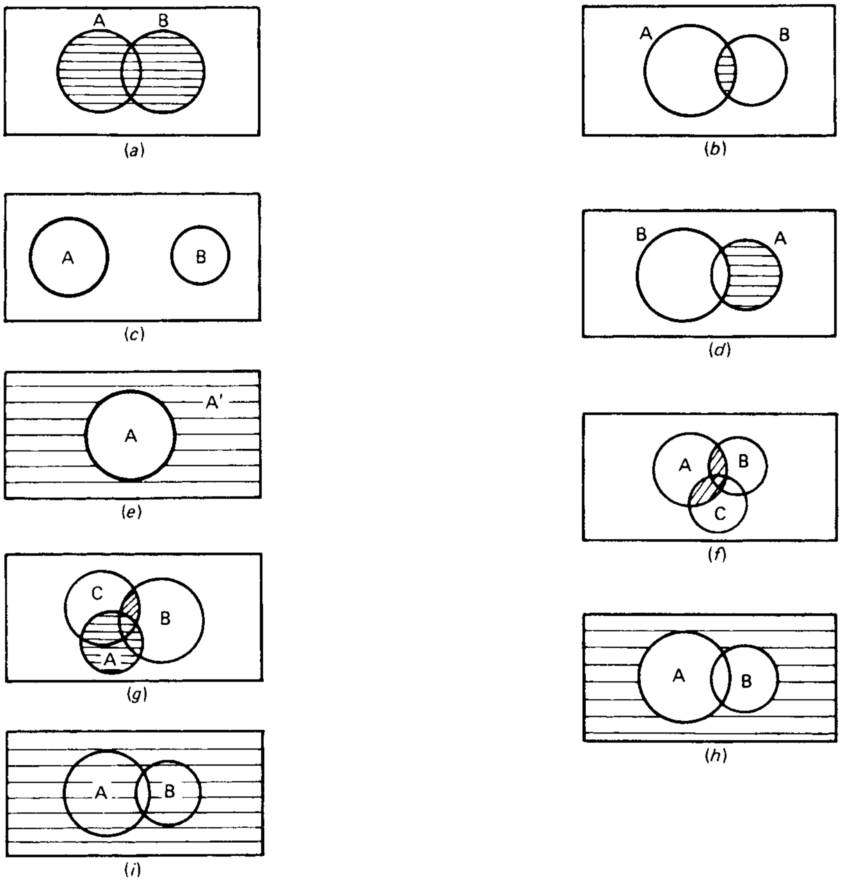

Figure 7.1 *Some set theory definitions, operations and laws: (a) union of sets, A + B: (b) intersection of sets, AB; (c) disjoint sets; (d) difference of sets, A − B; (e) complement of a set; (f) distributive law, A(B + C) = AB + AC; (g) distributive law, (A + B)(A + C) = A + BC; (h) dualization law (A + B) = A′B′; (i) dualization law (AB)′ = A′ + B′*

The probability of an event X which occurs only if all the n events A_i, occur and is thus the intersection of these events is:

$$P(X) = P(A_1 \cdots A_n) = P\left(\bigcap_{i=1}^{n} A_i\right) \qquad [7.5.11]$$

$P(A_1 \cdots A_n)$ is the joint probability of the event.

The probability of an event X which occurs if any of the mutually exclusive and exhaustive n events A_i in one subexperiment occurs and the event B in a second subexperiment occurs is:

$$P(X) = P\left(\bigcup_{i=1}^{n} A_i B\right) \qquad [7.5.12]$$

$$= \sum_{i=1}^{n} P(A_i)P(B) \qquad [7.5.13]$$

$$= P(B) \qquad [7.5.14]$$

$P(B)$ is the marginal probability of the event.

7.5.4 Conditional probability

The probability of an event X which occurs if the event A occurs in one subexperiment and the event B occurs in a second subexperiment where the event A depends on the event B is:

$$P(X) = P(AB) = P(A \mid B)P(B) \qquad [7.5.15]$$

$P(A \mid B)$ is the conditional probability of A, given B.

The probability obtained in Equation 7.5.15 is a joint probability. Marginal probabilities may also be obtained from conditional probabilities:

$$P(X) = P(B) = \sum_{i=1}^{n} P(B \mid A_i)P(A_i) \qquad [7.5.16]$$

7.5.5 Independence and conditional independence

If events A and B are independent:

$$P(AB) = P(A \mid B)P(B) = P(A)P(B) \qquad [7.5.17]$$

which is equivalent to

$$P(A \mid B) = P(A) \qquad [7.5.18]$$

The probability of an event X, which occurs only if all n events A_i occur is given by Equation 7.5.11. If all n events are independent:

$$P(X) = P(A_1 \cdots A_n) = \prod_{i=1}^{n} P(A_i) \qquad [7.5.19]$$

Two events A and B are conditionally dependent if their relationship with a third event C is:

$$P(AB \mid C) = P(A \mid C)P(B \mid C) \qquad [7.5.20]$$

Conditional independence does not imply independence.

7.5.6 Bayes' theorem

The relationship given in Equation 7.5.15 is a form of Bayes' theorem. This theorem is extremely important in probability work. It appears in various forms, some of which are:

$$P(AB) = P(A \mid B)P(B) = P(B \mid A)P(A) \qquad [7.5.21]$$

$$P(A \mid B) = \frac{P(AB)}{P(B)} = \frac{P(B \mid A)P(A)}{P(B)} \qquad [7.5.22]$$

On rewriting the denominator as a marginal probability, and A as A_k

$$P(A_k \mid B) = \frac{P(B \mid A_k)P(A_k)}{\sum_{i=1}^{n} P(B \mid A_i)P(A_i)} \qquad [7.5.23]$$

where $P(A_k \mid B)$ is the posterior probability, $P(B \mid A_k)$ is the likelihood, and $P(A_k)$ is the prior probability.

Further treatment of Bayes' theorem is given in Section 7.14.

7.6 Some Reliability Relationships

7.6.1 Reliability function and hazard rate

If n equipments operate without replacement, then after time t the numbers which have survived and failed are $n_s(t)$ and $n_f(t)$, respectively, and the probability of survival, or reliability, $R(t)$ is:

$$R(t) = 1 - \frac{n_f(t)}{n} \qquad [7.6.1]$$

The instantaneous failure rate, or failure rate expressed as a function of the number of equipments surviving, $z(t)$ is:

$$z(t) = \frac{1}{n - n_f}\frac{\mathrm{d}n_f(t)}{\mathrm{d}t} = -\frac{1}{R(t)} \cdot \frac{\mathrm{d}r(t)}{\mathrm{d}t} = -\frac{\mathrm{d}[\ln R(t)]}{\mathrm{d}t} \qquad [7.6.2]$$

$z(t)$ is also called the 'hazard rate', or just the 'failure rate'.

The cumulative hazard function $H(t)$ is:

$$H(t) = \int_0^t z(t)\,\mathrm{d}t \qquad [7.6.3]$$

Then, by integration of Equation 7.6.2 the reliability $R(t)$ is

$$R(t) = \exp\left(-\int_0^t z(t)\,\mathrm{d}t\right) = \exp[-H(t)] \qquad [7.6.4]$$

$R(t)$ is also called the 'reliability function'.

7.6.2 Failure density and failure distribution functions

The overall failure rate, or failure rate expressed as a function of the original number of equipments, $f(t)$ is:

$$f(t) = \frac{1}{n}\frac{\mathrm{d}n_f(t)}{\mathrm{d}t} = -\frac{\mathrm{d}R(t)}{\mathrm{d}t} \qquad [7.6.5]$$

$f(t)$ is also called the 'failure density function'.

The complement of the reliability, or the unreliability, $Q(t)$ is:

$$Q(t) = 1 - R(t) \qquad [7.6.6]$$

$Q(t)$ is also called the 'failure distribution function' and is then commonly written as $F(t)$.

The failure density function and failure distribution function are often referred to, respectively, as the 'failure density' or the 'density function' and the 'failure distribution', the 'distribution function' or the 'cumulative distribution function'.

7.6.3 Relationships between basic functions

The following relationships can readily be derived from Equations 7.6.1–7.6.6 and are particularly useful:

$$z(t) = \frac{f(t)}{R(t)} \qquad [7.6.7a]$$

$$= \frac{f(t)}{1 - Q(t)} = \frac{f(t)}{1 - F(t)} \qquad [7.6.7b]$$

$$R(t) = \int_t^{\infty} f(t)\,\mathrm{d}t \qquad [7.6.8]$$

$$Q(t) = F(t) = \int_0^t f(t)\,\mathrm{d}t \qquad [7.6.9]$$

7.6.4 Exponential distribution

An important special case is that in which the hazard rate $z(t)$ is constant:

$$z(t) = \lambda \qquad [7.6.10]$$

Then,

$$R(t) = \exp(-\lambda t) \qquad [7.6.11]$$

$$f(t) = \lambda \exp(-\lambda t) \qquad [7.6.12]$$

$$Q(t) = 1 - \exp(-\lambda t) \qquad [7.6.13]$$

These four quantities are shown in Figure 7.2.

In Figure 7.2, the vertical axes for the reliability $R(t)$ and the unreliability $Q(t)$ have the range 0 to 1, but those for the hazard rate $z(t)$ and the failure density function $f(t)$ are proportional to λ. At low values of λt:

$$R(t) = 1 - \lambda t \qquad \lambda t \ll 1 \qquad [7.6.14]$$

$$Q(t) = \lambda t \qquad \lambda t \ll 1 \qquad [7.6.15]$$

Equation 7.6.14 is useful in obtaining accuracy in numerical computation of high values of the reliability $R(t)$. Equation

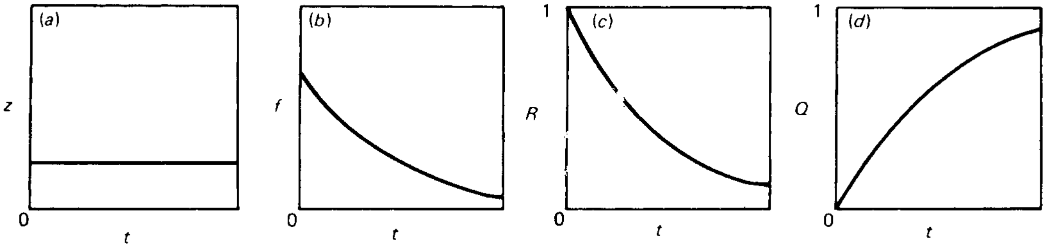

Figure 7.2 The exponential distribution: (a) hazard-rate; (b) failure density; (c) reliability; (d) unreliability

7.6.15 is useful in making simple computations of the unreliability $Q(t)$. This latter point is further discussed below.

The assumption of constant hazard rate is that normally made in the absence of other information. This is therefore a special case of particular importance.

The failure distribution with constant hazard rate is called the 'exponential distribution' or, more accurately but less commonly, the 'negative exponential distribution'. It is also referred to as the 'random failure distribution', although in most cases it is a moot point whether the failures are appropriately called random.

7.6.5 Probability and event rate

The relationship between unreliability and hazard rate represented by Equation 7.6.13, or more generally the relationship between the probability $P(t)$ and the event rate ζ

$$P(t) = 1 - \exp(-\zeta t) \qquad [7.6.16]$$

is an important one. It is frequently necessary in reliability work to calculate a probability from a rate, or vice versa, and it is this equation which then applies.

7.6.6 Unreliability and failure rate

There is sometimes confusion between unreliability $Q(t)$ and failure rate λ. This confusion arises because, given certain assumptions, the two are numerically identical. This occurs if in Equation 7.6.15 time t is equal to unity. Then,

$$Q(t) = \lambda \qquad \lambda \ll 1 \qquad [7.6.17]$$

Thus, for example, if a device has a failure rate A = 0.01 faults/year, then the unreliability over a year is also numerically 0.01. Error occurs, however, if Equation 7.6.15 is used outside its range of applicability.

7.6.7 Bathtub curve

In general, the failure behaviour of an equipment exhibits three stages: initially during commissioning the rate is high, then it declines during normal operation, and finally it rises again as deterioration sets in. For many equipments, particularly electronic equipments, the rate has been found to form a bathtub curve, as shown in Figure 7.3(a) (e.g., Carhart, 1953). This curve has three regimes: (1) early failure, (2) constant failure and (3) wear-out failure.

Early failure, or infant mortality, is usually due to such factors as defective equipment, incorrect installation, etc. It also tends to reflect the learning curve of the equipment user. Constant failure, or so-called 'random failure', is often caused by random fluctuations of load which exceed the design strength of the equipment. A constant failure characteristic is also shown by an equipment which has a number of components that individually exhibit different failure distributions. Wear-out failure is self-explanatory. The corresponding curve for the failure density function is shown in Figure 7.3(b). The bathtub curve is widely quoted in the reliability literature, but it should be emphasized that its applicability to all types of equipment, particularly mechanical equipment, is not established. There are, in fact, good theoretical reasons for treating it with reserve (A.D.S. Carter, 1973). This aspect is considered in more detail below.

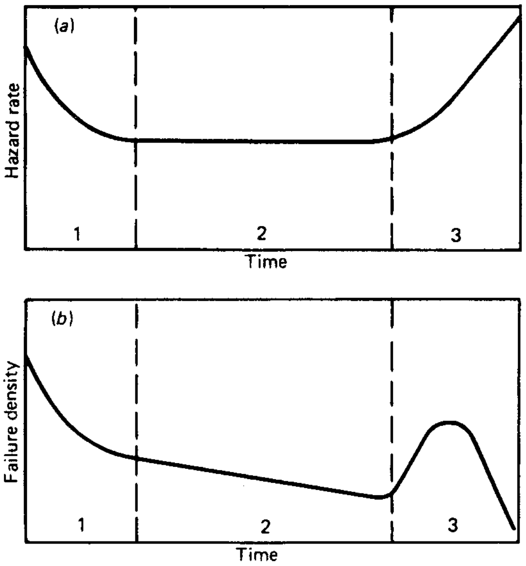

Figure 7.3 The bathtub curve: (a) hazard rate; (b) failure density

It is often said that human mortality follows a bathtub curve. This implies that there are higher death rates in infancy and old age with a lower, nearly constant, death rate in between. However, Aird (1978) has shown that for humans the infant mortality period is followed immediately by the onset of the wear-out period, so that there is effectively no constant failure period.

7.6.8 Mean life

The mean life m is defined as the first moment of the failure density function

$$m = \int_0^\infty tf \, \mathrm{d}t \qquad [7.6.18]$$

Alternatively, from Equations 7.6.5 and 7.6.18

$$m = -\int_0^\infty t\frac{\mathrm{d}R}{\mathrm{d}t}\,\mathrm{d}t \qquad [7.6.19a]$$

$$= -[tR]_0^\infty + \int_0^\infty R\,\mathrm{d}t \qquad [7.6.19b]$$

Since

$$[tR]_0^\infty = 0$$

provided that

$$\lim_{t\to\infty}(tR) = 0$$

then

$$m = \int_0^\infty R\,\mathrm{d}t \qquad [7.6.20]$$

Alternatively, use may be made of the relationships between the moments μ_i and the Laplace transform $\bar{g}(s)$ of a function $g(t)$:

$$\mathcal{L}[g(t)] = \bar{g}(s) = \int_0^\infty g(t)\exp(-st)\,\mathrm{d}t \qquad [7.6.21]$$

Hence:

$$\frac{\mathrm{d}^i\bar{g}(s)}{\mathrm{d}s^i} = (-1)^i\int_0^\infty t^i g(t)\exp(-st)\,\mathrm{d}t \qquad [7.6.22]$$

and

$$\left(\frac{\mathrm{d}^i\bar{g}(s)}{\mathrm{d}s^i}\right)_{s=0} = (-1)^i\int_0^\infty t^i g(t)\,\mathrm{d}t \qquad [7.6.23a]$$

$$= (-1)^i\mu_i \qquad [7.6.23b]$$

Applying these relationships to the present case by substituting $\mathrm{d}R/\mathrm{d}t$ for $g(t)$ in Equation 7.6.23a,

$$m = \left(\frac{\mathrm{d}[sR - R(0)]}{\mathrm{d}s}\right)_{s=0} = (R)_{s=0} \qquad [7.6.24]$$

For the exponential distribution

$$m = \int_0^\infty t\lambda\exp(-\lambda t)\,\mathrm{d}t \qquad [7.6.25a]$$

$$= \frac{1}{\lambda} \qquad [7.6.25b]$$

Other terms used in addition to 'mean life' are the mean time between failures (MTBF), the mean time to failure (MTTF) and the mean time to first failure (MTTFF). These times are sometimes used interchangeably, but they are not identical.

The most widely used is probably MTBF. MTBF has meaning only when applied to a population of components, equipments or systems in which there is repair. It is the total operating time of the items divided by the total number of failures. It is also the mean of the failure distribution, regardless of its form.

MTTF is applied to items without repair and is the mean of the distribution of times to failure. MTTFF is applied to items with repair and is the mean of the distribution of times to first failure.

MTTF and MTTFF are applied particularly to systems. For an n-component parallel system with an exponential failure distribution of the individual components and without repair,

$$\mathrm{MTTF} = \sum_{i=1}^{n}\frac{1}{i\lambda} \qquad [7.6.26]$$

and for an n-component parallel system with repair

$$\mathrm{MTTFF} = \frac{1}{\lambda}\cdot\sum_{i=0}^{n-1}\frac{(1+\mu/\lambda)^i}{i+1} \qquad [7.6.27]$$

where λ is the failure rate of equipment, and μ is the repair rate of equipment Repair rates are discussed in Section 7.10. If the repair rate μ is zero, Equation 7.6.27 reduces to Equation 7.6.26.

Formal definitions of MTBF and MTTF are given in BS 4200: Part 2: 1967. For repairable systems use is also made of mean time to repair (MTTR). A more detailed discussion of these quantities is given by Myers *et al.* (1964).

7.6.9 Expected value

Use is frequently made in reliability engineering of the concept of the expected value. The expected value of a distribution is its mean value. The use of the expected value concept allows convenient manipulation, as the following treatment demonstrates. (A treatment of expected value is given by Breipohl (1970)). For a variable t, the expected value, or mean value, is:

$$m = E[t] \qquad [7.6.28]$$

The variance is:

$$\sigma^2 = E[(t-m)^2] \qquad [7.6.29]$$

The variance may then be expressed in the following alternative forms:

$$\sigma^2 = E[t^2 - 2mt + m^2] \qquad [7.6.30]$$

$$= E[t^2] - 2mE[t] + m^2 \qquad [7.6.31]$$

$$= E[t^2] - 2m^2 + m^2 \qquad [7.6.32]$$

$$= E[t^2] - m^2 \qquad [7.6.33]$$

$$= E[t^2] - E[t]^2 \qquad [7.6.34]$$

7.7 Failure Distributions

There are several statistical distributions which are fundamental in work on reliability. Important discrete distributions are:

(1) binomial distribution;
(2) multinomial distribution;
(3) Poisson distribution.

Important continuous distributions are:

(1) exponential distribution;
(2) normal distribution;

(3) log–normal distribution;
(4) Weibull distribution;
(5) rectangular distribution;
(6) gamma distribution;
(7) Pareto distribution;
(8) extreme value distribution.

Some properties of these distributions are given in Table 7.3 and in Figures 7.4 and 7.5.

The distributions are best regarded as statistical distributions and the independent variable t as a generalized variable, although in the present context the primary interest in many of these distributions is as failure distributions, with time as the independent variable. The distribution function is given as F rather than Q, but the two are identical.

Accounts of the properties of statistical distributions are given in most texts on reliability engineering and in the Center for Chemical Process Safety (CCPS) QRA Guidelines (1989/5). Additional treatments for particular distributions are mentioned below. A rather comprehensive summary of the principal distributions is given by Hastings and Peacock (1974).

7.7.1 Binomial distribution

The binomial distribution is applicable to situations where a series of discrete trials is conducted and each trial can have two outcomes. In reliability work these outcomes are usually success and failure. If the probabilities of success and failure are p and q, respectively, and if there are n trials, then:

$$(p+q)^n = \sum_{k=0}^{n} \binom{n}{k} p^k q^{n-k} = 1 \qquad [7.7.1]$$

with

$$\binom{n}{k} = \frac{n!}{(n-k)!k!} \qquad [7.7.2]$$

The rth term in the expansion in Equation 7.7.1 is the probability $P(r)$ of r events:

$$P(r) = \binom{n}{r} p^r q^{n-r} \qquad [7.7.3]$$

$P(r)$ is the probability density.

A useful expression is the probability $P(0 \leq k \leq r)$ of r or less than r events:

$$P(0 \leq k \leq r) = \sum_{k=0}^{r} \binom{n}{k} p^k q^{n-k} \qquad [7.7.4]$$

$P(0 \leq k \leq r)$ is the probability distribution.

Another useful expression is the probability $P(r \leq k \leq n)$ of r or more than r events:

$$P(r \leq k \leq n) = \sum_{k=r}^{n} \binom{n}{k} p^k q^{n-k} \qquad [7.7.5]$$

The coefficients in the expansion in Equation 7.7.3, or terms of $\binom{n}{r}$, may be obtained from Pascal's triangle

n	r	
0	0	1
1	0, 1	1 1
2	0, 1, 2	1 2 1
3	0, 1, 2, 3	1 3 3 1
4	0, 1, 2, 3, 4	1 4 6 4 1

A number in the triangle is obtained by summing the two numbers directly above it to the left and the right.

The mean of the binomial distribution is np and the variance is npq. The binomial distribution approximates to the normal distribution for large values of n and does so most rapidly for $p = q = 0.5$. The approximation holds for $p \leq 0.5$ and $np \geq 5$ or for $p > 0.5$ and $nq > 5$. In terms of n and p the mean and variance of the normal distribution are np and $np(1-p)$, respectively. The binomial distribution approximates to the Poisson distribution for $p \leq 0.05$ and $n \geq 20$. In terms of n and p, the mean of the Poisson distribution is np.

7.7.2 Multinomial distribution

The multinomial distribution is applicable to situations where a series of trials is conducted and each trial can have more than two outcomes. If the total number of trials is n, the number of outcomes is k, the probabilities of the outcomes are p_i, and the number of times each outcome occurs is n_i, then:

$$f(n_1, n_2, \ldots, n_k) = n! \prod_{i=1}^{k} \frac{p_i^{n_i}}{n_i!} \qquad [7.7.6]$$

$f(n_1, n_2, \ldots, n_k)$ is the probability density.

7.7.3 Poisson distribution

The Poisson distribution is applicable to situations where an event can occur at any point in time. If the mean number of events over a time period is μ so that in terms of the binomial distribution $\mu = np$, then:

$$\exp(-\mu)\exp(\mu) = \exp(-\mu) \sum_{k=0}^{\infty} \frac{\mu^k}{k!} \qquad [7.7.7a]$$

$$= \exp(-\mu)\left(1 + \mu + \frac{\mu^2}{2!} + \frac{\mu^3}{3!} + \cdots\right) \qquad [7.7.7b]$$

$$= 1 \qquad [7.7.7c]$$

The rth term in the expansion in Equation 7.7.7 is the probability $P(r)$ of r events:

$$P(r) = \exp(-\mu)\frac{\mu^r}{r!} \qquad [7.7.8]$$

$P(r)$ is the probability density.

A useful expression is the probability $P(0 \leq k \leq r)$ of r or less than r events:

$$P(0 \leq k \leq r) = \exp(-\mu) \sum_{k=0}^{r} \frac{\mu^k}{k!} \qquad [7.7.9]$$

$P(0 \leq k \leq r)$ is the probability distribution.

Table 7.3 *Some properties of failure distributions*

Distribution	*Failure density function* $f(t)$	*Mean* $m=\int_{-\infty}^{\infty} tf(t)\,\mathrm{d}t$	*Median* $= t$ *where* $\int_{-\infty}^{t} f(r)\,\mathrm{d}r = 0.5$	*Mode* $= t$ *where* $\frac{\mathrm{d}f(t)}{\mathrm{d}t}=0$	*Variance* $\sigma^2=\int_{-\infty}^{\infty}(t-m)^2 f(t)\,\mathrm{d}t$
Exponential	$\lambda\exp(-\lambda t)$	$\frac{1}{\lambda}$	$\frac{1}{\lambda}\ln 2$	0	$\frac{1}{\lambda^2}$
Normal	$\frac{1}{\sigma(2\pi)^{1/2}}\exp\left[-\frac{(t-m)^2}{2\sigma^2}\right]$	m	m	m	σ^2
Log−normal	$\frac{1}{\sigma t(2\pi)^{1/2}}\exp\left[-\frac{[\ln(t)-m^*]^2}{2\sigma^2}\right]$	$\exp\left(m^*+\frac{\sigma^2}{2}\right)$	$\exp(m^*)$	$\exp(m^*-\sigma^2)$	$\exp(2m^*+\sigma^2)[\exp(\sigma^2)-1]$

Rectangular	$\frac{1}{b}$	$a+\frac{b}{2}$	$a+\frac{b}{2}$	–	$\frac{b^2}{12}$
Gamma	$\frac{1}{b\Gamma(a)}\left(\frac{t}{b}\right)^{a-1}\exp\left(-\frac{t}{b}\right)$	ba	–[a]	$b(a-1),\ a\geq 1$	b^2a
Pareto	$at^{-(a+1)}$	$\frac{a}{a-1},\ a>1$	$2^{1/a}$	0	$\frac{a}{a-2}-\left(\frac{a}{a-1}\right)^2,\ a>2$
Extreme value	$\frac{1}{b}\exp\left(\frac{t-a}{b}\right)\exp\left[-\exp\left(\frac{t-a}{b}\right)\right]$	$a+b\Gamma'(1)$[b]	$a+b\ln\ln 2$	a	$\frac{b^2\pi^2}{6}$

[a] No simple expression is available.

[b] $\Gamma'(1)=-0.57721$ is the first derivative of the gamma function.

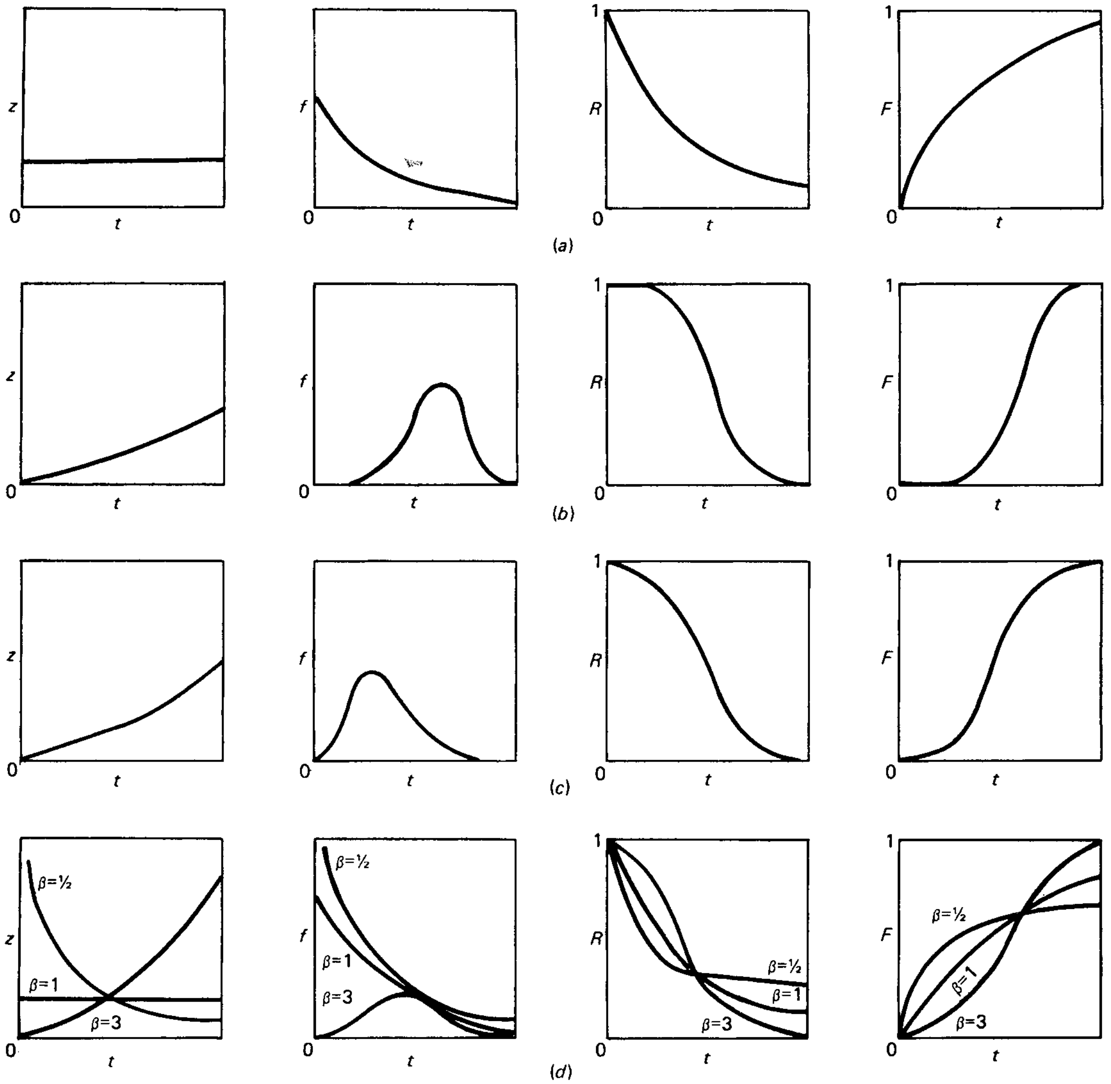

Figure 7.4 Some failure distributions –1: (a) exponential distinction; (b) normal distribution; (c) log–normal distribution; (d) Weibull distribution

The relationship between the binomial and Poisson distributions may be seen by noting that the relation between the mean event rates for the distributions is:

$$\mu = np \qquad [7.7.10]$$

and writing the binomial distribution in the form:

$$\lim_{n\to\infty}\sum_{k=0}^{n}\binom{n}{k}\cdot\left(\frac{\mu}{n}\right)^{k}\cdot\left(1-\frac{\mu}{n}\right)^{n-k}=\sum_{k=0}^{\infty}\frac{\mu^{k}}{k!}\exp(-\mu) \qquad [7.7.11]$$

A derivation of the Poisson distribution from Markov models is given below.

7.7.4 Exponential distribution

For the exponential distribution, the characteristics hazard rate z, failure density f, reliability R and failure distribution F have been derived above, and are:

$$z = \lambda \qquad [7.7.12]$$

$$f = \lambda\exp(-\lambda t) \qquad [7.7.13]$$

$$R = \exp(-\lambda t) \qquad [7.7.14]$$

$$F = 1 - \exp(-\lambda t) \qquad [7.7.15]$$

for the range $0 \le t \le \infty$. These quantities are shown in Figure 7.4(a). The distribution is characterized by a single parameter, the hazard rate λ.

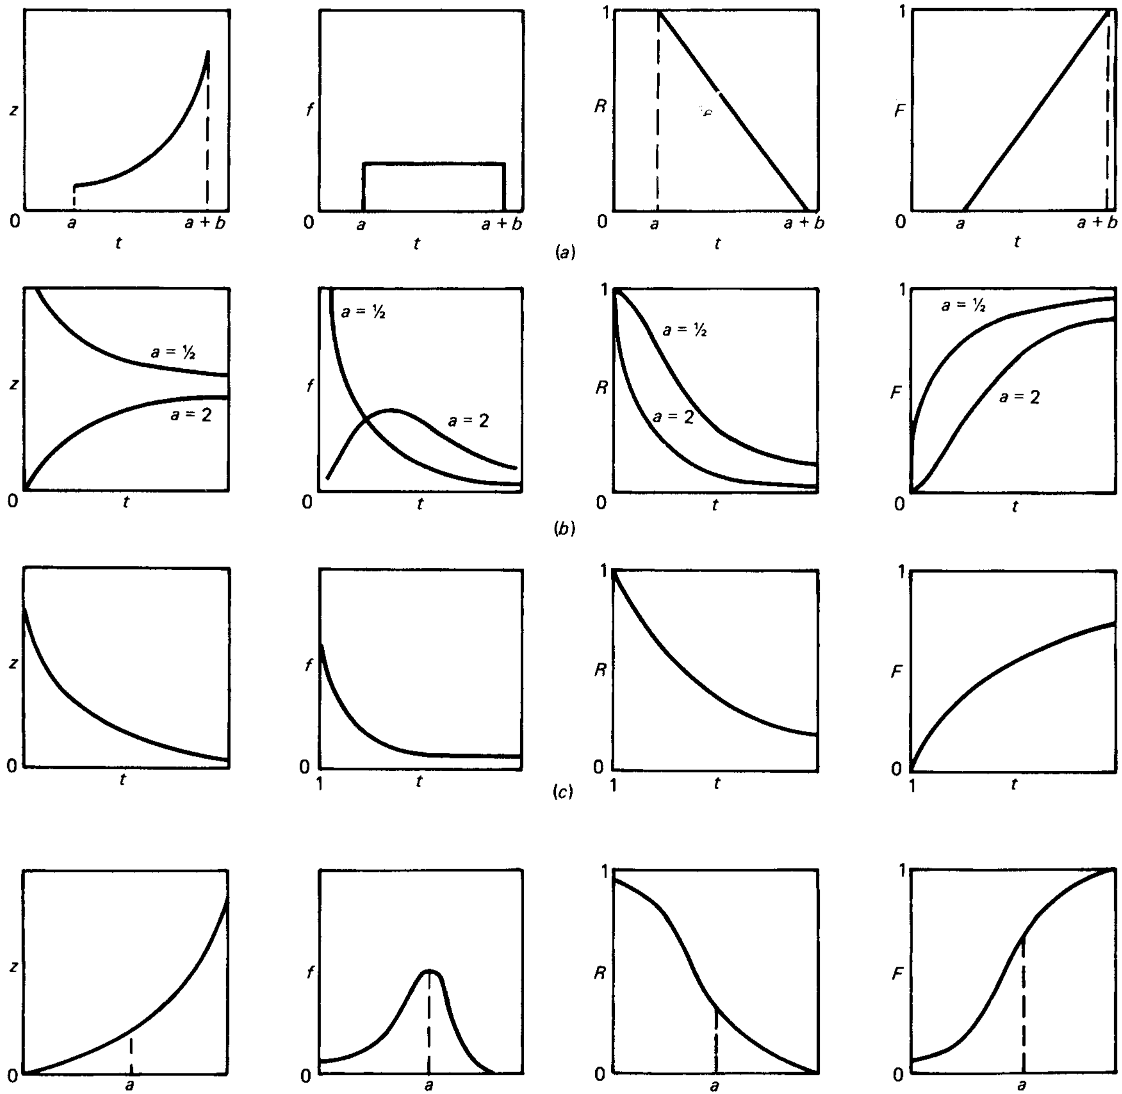

Figure 7.5 *Some failure distributions – 2: (a) rectangular distribution; (b) gamma distribution; (c) Pareto distribution; (d) extreme value distribution*

The exponential distribution, which has a constant hazard rate, is the distribution usually applied to data in the absence of other information and is the most widely used in reliability work.

7.7.5 Normal distribution

For the normal distribution the characteristics are:

$$z = \frac{\exp\left[-(t-m)^2/2\sigma^2\right]}{\int_t^{\infty} \exp\left[-(t-m)^2/2\sigma^2\right] \mathrm{d}t} \qquad [7.7.16]$$

$$f = \frac{1}{\sigma(2\pi)^{1/2}} \cdot \exp\left[-\frac{(t-m)^2}{2\sigma^2}\right] \qquad [7.7.17]$$

$$R = \frac{1}{\sigma(2\pi)^{1/2}} \cdot \int_t^{\infty} \exp\left[-\frac{(t-m)^2}{2\sigma^2}\right] \mathrm{d}t \qquad [7.7.18]$$

for the range $-\infty \le t \le \infty$. These quantities are shown in Figure 7.4(b).

The failure density f is the quantity most commonly used to define the normal distribution. It may be noted that Equations 7.7.16 and 7.7.18 describing the other quantities are readily derived from Equations 7.6.7a and 7.6.8, respectively.

The distribution has two parameters, the mean m and the standard deviation σ. It is the natural distribution which is used to characterize data that lie about a mean value and deviate from it by absolute amounts. The normal distribution is widely used in reliability engineering, particularly to fit certain types of failure such as those due to wear out and to fit repair times.

7.7.6 Log–normal distribution

$$z = \frac{1/t \exp\{-[\ln(t) - m^*]^2/2\sigma^2\}}{\int_t^\infty \exp\{-[\ln(t) - m^*]^2/2\sigma^2\}\,\mathrm{d}t} \qquad [7.7.19]$$

$$f = \frac{1}{\sigma t (2\pi)^{1/2}} \exp\left\{-\frac{[\ln(t) - m^*]^2}{2\sigma^2}\right\} \qquad [7.7.20]$$

$$R = \frac{1}{\sigma (2\pi)^{1/2}} \int_t^\infty \exp\left\{-\frac{[\ln(t) - m^*]^2}{2\sigma^2}\right\} \mathrm{d}t \qquad [7.7.21]$$

for the range $0 \le t \le \infty$. These quantities are shown in Figure 7.4(c).

The distribution has two parameters, m^* and σ. It is the natural distribution to use when deviations from the model value are by factors, proportions or percentages rather than by absolute values as in the normal distribution.

The log–normal distribution has a number of uses in reliability work. It is used to fit certain types of failure such as fatigue failures and to fit repair times. It is also used to describe the range of possible hazard rates of equipment where there is uncertainty about these. In this case the independent variable is the hazard rate z ($=\lambda$ for the exponential distribution) rather than time:

$$f(z) = \frac{1}{\sigma_z z (2\pi)^{1/2}} \exp\left\{-\frac{[\ln(z) - m_z^*]^2}{2\sigma_z^2}\right\} \qquad [7.7.22]$$

The properties of the log–normal distribution are described in more detail by Aitcheson and Brown (1969).

7.7.7 Weibull distribution

For the Weibull distribution the characteristics are:

$$z = \frac{\beta}{\eta}\left(\frac{t-\gamma}{\eta}\right)^{\beta-1} \qquad [7.7.23]$$

$$f = \frac{\beta}{\eta}\left(\frac{t-\gamma}{\eta}\right)^{\beta-1} \exp\left[-\left(\frac{t-\gamma}{\eta}\right)^{\beta}\right] \qquad [7.7.24]$$

$$R = \exp\left[-\left(\frac{t-\gamma}{\eta}\right)^{\beta}\right] \qquad [7.7.25]$$

for the range $\gamma \le t \le \infty$. These quantities are shown in Figure 7.4(d) for values of the parameter $\beta = 0.5$, 1.0 and 3.0.

The distribution given is the three-parameter one with the characteristic life η, the shape factor β and the location parameter γ. If the latter is set to zero, the two-parameter distribution is obtained.

The significance of the shape factor β is:

$\beta < 1$	hazard rate decreasing;
$\beta = 1$	hazard rate constant;
$\beta > 1$	hazard rate increasing.

By suitable choice of the shape factor β the Weibull distribution may be made to equal or approximate other distributions:

$\beta = 1$	exponential distribution;
$\beta = 2$	Rayleigh distribution.

A value of $\beta \approx 3.4$ corresponds approximately to a normal distribution in which the standard deviation is one-third of the mean.

There are several other versions of the two-parameter Weibull distribution. An alternative form (Truscott, 1970) has the characteristics:

$$z = \frac{\beta}{\alpha} t^{\beta-1} \qquad [7.7.26]$$

$$f = \frac{\beta}{\alpha} t^{\beta-1} \exp\left(-\frac{t^\beta}{\alpha}\right) \qquad [7.7.27]$$

$$R = \exp\left(-\frac{t^\beta}{\alpha}\right) \qquad [7.7.28]$$

This is related to the previous form by:

$$\alpha = \eta^\beta \qquad [7.7.29]$$

A third from (Shooman, 1968a) has the characteristics:

$$z = kt^m \qquad [7.7.30]$$

$$f = kt^m \exp\left(-\frac{kt^{m+1}}{m+1}\right) \qquad [7.7.31]$$

$$R = \exp\left(\frac{-kt^{m+1}}{m+1}\right) \qquad [7.7.32]$$

This is related to the first form given by:

$$k = \frac{\beta}{\eta} \qquad [7.7.33]$$

$$m = \beta - 1 \qquad [7.7.34]$$

The Weibull distribution is frequently used in reliability work to fit failure data, because it is flexible enough to handle decreasing, constant and increasing failure rates. This use of the Weibull distribution is considered in more detail below.

The properties of the Weibull distribution are described in the original paper by Weibull (1951) and in standard texts (e.g., Bompas-Smith, 1973; Kapur and Lamberson, 1977).

7.7.8 Rectangular distribution

For the rectangular distribution the characteristics are:

$$z = \frac{1}{a+b-1} \qquad [7.7.35]$$

$$f = \frac{1}{b} \qquad [7.7.36]$$

$$R = \frac{a+b-t}{b} \qquad [7.7.37]$$

for the range $a \le t \le a+b$. These quantities are shown in Figure 7.5(a).

The distribution is also called the ‘uniform distribution’ and has two parameters, the location parameter a and the scaling factor b.

The rectangular distribution is used in reliability work mainly to give random variables a uniform distribution across a specified interval. It is used, for example, in Monte Carlo simulation work. Computers generate pseudo-random numbers with a rectangular distribution. Random numbers with other distributions can be obtained from these, using the inverse cumulative distribution, where available, and other techniques.

7.7.9 Gamma distribution

For the gamma distribution the characteristics are:

$$z = \frac{t^{a-1}\exp(-t/b)}{\int_t^\infty t^{a-1}\exp(-t/b)\,\mathrm{d}t} \qquad [7.7.38]$$

$$f = \frac{1}{b^a\Gamma(a)}t^{a-1}\exp(-t/b) \qquad [7.7.39]$$

$$R = \frac{1}{b^a\Gamma(a)}\int_t^\infty t^{a-1}\exp(-t/b)\,\mathrm{d}t \qquad [7.7.40]$$

for the range $0 \leq \mathrm{t} \leq \infty$, with

$$\Gamma(a) = \int_0^\infty t^{a-1}\exp(-t)\,\mathrm{d}t \qquad [7.7.41]$$

or, if a is an integer,

$$\Gamma(a) = (a-1)! \qquad [7.7.42]$$

The quantities given in Equations 7.7.38–7.7.40 are shown in Figure 7.5(b) for values of the parameter $a = 0.5$ and 2.0.

The distribution has two parameters, the shape factor a and the scaling factor b.

The gamma distribution is another distribution used in reliability work to fit failure data, because it is sufficiently flexible to deal with decreasing, constant and increasing failure rates, but the Weibull distribution is more generally used.

7.7.10 Beta distribution

Use is also sometimes made in reliability engineering of the beta distribution. The properties of the beta distribution are given by Hastings and Peacock (1974). Its characteristics are:

$$f = \frac{x^{v-1}(1-x)^{w-1}}{B(v,w)} \qquad [7.7.43]$$

$$F = \int_0^x \frac{x^{v-1}(1-x)^{w-1}}{B(v,w)}\,\mathrm{d}x \qquad [7.7.44]$$

with

$$B(v,w) = \int_0^1 u^{v-1}(1-u)^{w-1}\,\mathrm{d}u \qquad [7.7.45]$$

for the range $0 \geq x \geq 1$. The distribution has two parameters, v (>0) and w (>0). The beta function is related to the gamma function:

$$\Gamma(v)\tau(w) = B(v,w)\Gamma(v+w) \qquad [7.7.46]$$

for positive values of v and w.

7.7.11 Pareto distribution

For the Pareto distribution the characteristics are:

$$z = \frac{a}{t} \qquad [7.7.47]$$

$$f = at^{-(a+1)} \qquad [7.7.48]$$

$$R = t^{-a} \qquad [7.7.49]$$

for the range $1 \leq t \leq \infty$. These quantities are shown in Figure 7.5(c). The distribution has a single parameter, the shape factor a.

The Pareto distribution is commonly used in reliability work in discrete form to describe the distribution of the numbers of failures in different modes. In this case the independent variable is the failure mode.

7.7.12 Extreme value distribution

For the extreme value distribution the characteristics are:

$$z = \frac{1}{b}\exp\left(\frac{t-a}{b}\right) \qquad [7.7.50]$$

$$f = \frac{1}{b}\exp\left(\frac{t-a}{b}\right)\exp\left[-\exp\left(\frac{t-a}{b}\right)\right] \qquad [7.7.51]$$

$$R = \exp\left[-\exp\left(\frac{t-a}{b}\right)\right] \qquad [7.7.52]$$

for the range $-\infty \leq t \leq \infty$. These quantities are shown in Figure 7.5(d).

Equations 7.7.50–7.7.52 are for the distribution of the smallest extreme. For the distribution of the largest extreme the sign of t should be reversed.

The distribution has two parameters, the location parameter a and the scaling factor b.

The extreme value distribution is used in reliability work to investigate extreme, and therefore very rare, values of phenomena.

7.7.13 Hyperexponential distribution

Another distribution which is sometimes used in reliability engineering is the hyperexponential distribution. This is described by Jardine (1970). Its characteristics are

$$z = \frac{2\lambda\{\sigma^2 + (1-\sigma^2)\exp[-2(1-2\sigma)\lambda t]\}}{\sigma + (1-\sigma)\exp[-2(1-2\sigma)\lambda t]} \qquad [7.7.53]$$

$$\begin{aligned} f = {} & 2\sigma^2\lambda\exp[-2\sigma\lambda t] \\ & + 2\lambda(1-\sigma^2)\exp[-2(1-\sigma)\lambda t] \end{aligned} \qquad [7.7.54]$$

$$F = 1 - \sigma\exp[-2\sigma\lambda t] + (1-\sigma)\exp[-2(1-\sigma)\lambda t] \qquad [7.7.55]$$

for $t \geq 0$ and $0 < \sigma \leq 0.5$. The distribution has two parameters, λ and σ, the former being the mean arrival rate of failures.

The hyperexponential distribution is suitable for the case where the times to failure are either very short or very long.

7.7.14 Error function

A mathematical function which occurs both in some of the distributions described and also in other topics treated here is the error function. Accounts of the error function are given in standard mathematical texts (e.g., Jensen and Jeffreys, 1963; Paradine and Rivett, 1980).

The error function erf is defined as:

$$\mathrm{erf}(x) = \frac{2}{\pi^{1/2}} \int_0^x \exp(-u^2)\,\mathrm{d}u \qquad [7.7.56]$$

The term $(2/\pi^{1/2})$ is a normalizing factor such as to yield

$$\mathrm{erf}(\infty) = 1 \qquad [7.7.57]$$

The error function complement erfc is defined as

$$\mathrm{erfc}(x) = 1 - \mathrm{erf}(x) \qquad [7.7.58]$$

$$\mathrm{erfc}(x) = \frac{2}{\pi^{1/2}} \int_x^\infty \exp(-u^2)\,\mathrm{d}u \qquad [7.7.59]$$

The integral which constitutes the error function is similar in form to those which occur in the distribution function of the normal distribution and in the log–normal distribution, as comparison of Equation 7.7.56 with Equations 7.7.18 and 7.7.21 shows. A similar integral also occurs in the definition of the probit Y described in Chapter 9.

Furthermore, in passive gas dispersion, the gas concentrations follow a normal, or Gaussian, distribution so that the models used for such dispersion are often referred to as 'Gaussian models'. These models are described in Chapter 15.

7.7.15 Error function approximations

The error function may be looked up in the tables given in standard texts on statistics, but it is convenient for computation to have it in analytical function form. A review of approximations of the error function has been given by Karlsson and Bjerle (1980). Two desirable properties of an expression for the error function are that it should represent the function with acceptable accuracy and should be capable of being inverted.

Karlsson and Bjerle give the following approximate expression of their own for the error function:

$$\mathrm{erf}(x) = \frac{2}{\pi^{1/2}} \sin[\sin(x)] \qquad 0 \le x \le 1 \qquad [7.7.60a]$$

$$= \sin(x^{2/3}) \qquad 1 \le x \le 2 \qquad [7.7.60b]$$

$$= 1 \qquad 2 \le x \le \infty \qquad [7.7.60c]$$

They also give the following approximation for the error function inverse

$$\mathrm{erf}^{-1}(y) = \sin^{-1}\left[\sin^{-1}\left(\frac{y\pi^{1/2}}{2}\right)\right] \qquad 0 \le y \le 0.84 \qquad [7.7.61a]$$

$$= [\sin^{-1}(y)]^{3/2} \qquad 0.84 \le y \le 0.995 \qquad [7.7.61b]$$

7.8 Reliability of Some Standard Systems

The reliability of some standard systems is now considered. It is assumed that the exponential failure distribution applies, unless otherwise stated.

7.8.1 Series systems

A series system is one which operates only if all its components operate. It is not implied that the components are necessarily laid out physically in series configuration. For a series system the reliability R is the product of the reliabilities R_i of the components:

$$R = \prod_{i=1}^{n} R_i \qquad [7.8.1]$$

This follows directly from Equation 7.5.19.

For the exponential distribution, if the failure rates of the components are constants λ_i,

$$R_i = \exp(-\lambda_i) \qquad [7.8.2]$$

and hence

$$R = \prod_{i=1}^{n} \exp(-\lambda_i t) = \exp\left(-\sum_{i=1}^{n} \lambda_i t\right) \qquad [7.8.3]$$

If the overall failure rate of the system is a constant λ,

$$R = \exp(-\lambda t) \qquad [7.8.4]$$

and hence

$$\lambda = \sum_{i=1}^{n} \lambda_i \qquad [7.8.5]$$

7.8.2 Parallel systems

A parallel system is one which fails to operate only if all its components fail to operate. Again it is not implied that the components are necessarily laid out physically in a parallel configuration. For a parallel system, the unreliability Q is the product of the unreliabilities Q_i of the components:

$$Q = \prod_{i=1}^{n} Q_i \qquad [7.8.6]$$

Again this follows directly from Equation 7.5.19. The reliability R of the system is:

$$R = 1 - \prod_{i=1}^{n} (1 - R_i) \qquad [7.8.7]$$

Since parallel configurations incorporate redundancy, they are also referred to as 'parallel redundant systems'. For the exponential distribution, Equation 7.8.2 applies, and hence:

$$R = 1 - \prod_{i=1}^{n} [1 - \exp(-\lambda_i t)] \qquad [7.8.8]$$

If the overall failure rate of the system is a constant λ, Equation 7.8.4 is applicable. In this case there is no simple general relationship between the system and component failure rates. But, if the component failure rates are all the same,

$$\frac{1}{\lambda} = \sum_{i=1}^{n} \frac{1}{i\lambda_i} \qquad [7.8.9]$$

If the failure rates are different, then for two components

$$\frac{1}{\lambda} = \frac{1}{\lambda_1} + \frac{1}{\lambda_2} - \frac{1}{\lambda_1 + \lambda_2} \qquad [7.8.10]$$

for three components

$$\frac{1}{\lambda} = \frac{1}{\lambda_1} + \frac{1}{\lambda_2} + \frac{1}{\lambda_3} - \frac{1}{\lambda_1+\lambda_2} - \frac{1}{\lambda_1+\lambda_3} - \frac{1}{\lambda_2+\lambda_3} + \frac{1}{\lambda_1+\lambda_2+\lambda_3} \qquad [7.8.11]$$

and for n components

$$\begin{aligned}\frac{1}{\lambda} = {} & \left(\frac{1}{\lambda_1} + \frac{1}{\lambda_2} + \cdots + \frac{1}{\lambda_n}\right) \\ & - \left(\frac{1}{\lambda_1+\lambda_2} + \frac{1}{\lambda_1+\lambda_3} + \cdots + \frac{1}{\lambda_{n-1}+\lambda_n}\right) \\ & + (\frac{1}{\lambda_1+\lambda_2+\lambda_3} + \frac{1}{\lambda_1+\lambda_2+\lambda_4} + \cdots \\ & + \frac{1}{\lambda_{n-2}+\lambda_{n-1}+\lambda_n}) - \cdots + (-1)^{n-1}\frac{1}{\sum_{i=1}^{n}\lambda_i} \qquad [7.8.12]\end{aligned}$$

7.8.3 *r*-out-of-*n* parallel systems

For a system which has n components in parallel and operates as long as r components survive, the binomial distribution is applicable. Thus for an r-out-of-n system the reliability R is obtained from the component reliability R_x:

$$R(r \le k \le n) = \sum_{k=r}^{n} \binom{n}{k} R_x^k Q_x^{n-k} \qquad [7.8.13]$$

As an illustration, consider the reliability of a 2-out-of-4 system. Expanding

$$(R_x + Q_x)^n = 1 \qquad [7.8.14]$$

for the terms between n and r to get the individual terms of Equation 7.8.13 gives

$$\textit{Probability of } 0 \textit{ failures} = R_x^4$$

$$\textit{Probability of } 1 \textit{ failure} = 4R_x^3 Q_x$$

$$\textit{Probability of } 2 \textit{ failures} = 6R_x^2 Q_x^2$$

The coefficients of the terms may be obtained from Pascal's triangle. The system survives provided no more than two failures occur, and hence

$$R = R_x^4 + 4R_x^3 Q_x + 6R_x^2 Q_x^2 \qquad [7.8.15]$$

An r-out-of-n system reduces in the limiting cases to a series or a parallel system. If all the components must operate for the system to survive, it becomes a series system

$$R = R_x^n \qquad [7.8.16]$$

whilst if it is sufficient for one component to operate for the system to survive, it becomes a parallel system

$$Q = Q_x^n \qquad [7.8.17]$$

7.8.4 Stand by systems

The simplest stand by system is one in which there is one component operating and one or more on stand by, all components have the same failure rate in the operational mode, the stand by components have zero failure rate in the stand by mode, and there is perfect switchover. For this case, the Poisson distribution can be used. Thus, for such a stand by system, the failure rate is λ, the number of failures which the system can withstand is r, and the system reliability R is

$$R(0 \le k \le r) = \exp(-\lambda t)\sum_{k=0}^{r}\frac{(\lambda t)^k}{k!} \qquad [7.8.18a]$$

$$= \exp(-\lambda t)\left[1 + \lambda t + \frac{(\lambda t)^2}{2!} + \cdots + \frac{(\lambda t)^r}{r!}\right] \qquad [7.8.18b]$$

As an illustration, consider the reliability of a stand by system with one component operating and one on stand by, so that the system can survive one failure. Then

$$R = \exp(-\lambda t)(1 + \lambda t) \qquad [7.8.19]$$

It is relatively easy in this case to take into account imperfect switchover. If the reliability of switchover is R_{SW}, the system reliability R is:

$$R = \exp(-\lambda t)(1 + R_{\mathrm{sw}}\lambda t) \qquad [7.8.20]$$

Stand by systems may be more complex than this simple case in a number of ways. The stand by component may be different from the component normally operating and may have a different failure rate in the operational mode. It may also have a finite failure rate in the stand by mode, and there may be imperfect switchover.

7.8.5 Systems with repair

If it is possible to carry out repair on a system, a much higher reliability can be achieved. The repair time which is used here is the total time from initial failure to final repair, and therefore includes any time required for detection of the failure and organization of the repair. Obviously, the determination of the reliability of systems with repair requires data on repair times as well as failure rates.

Repair times, like failure times, may fit various distributions. It is sometimes assumed that the repair time is a constant τ, but a more common assumption is that the repair times τ_{r} have an exponential distribution with constant repair rate μ:

$$f_{\mathrm{r}}(t_{\mathrm{r}}) = \mu \exp(-\mu t_{\mathrm{r}}) \qquad [7.8.21]$$

For the exponential distribution the mean repair time m_{r} is

$$m_{\mathrm{r}} = \frac{1}{\mu} \qquad [7.8.22]$$

Equations 7.8.21 and 7.8.22 are analogous to Equations 7.6.12 and 7.6.25b for failure times and mean life. A more detailed discussion of repair times is given below.

The reliability of some standard systems with repair is now considered. It is assumed that the exponential repair time distribution applies, unless otherwise stated. In particular, this assumption is made in the Markov models described below.

7.8.6 Parallel systems with repair

For a system which has n components in parallel, and which survives provided that at least one component operates, and for which the failure and repair rates are λ and μ, respectively, expressions for the reliability R can be derived using Markov models, as described below. For a parallel system with two components it can be shown that the reliability R is:

$$R = \frac{1}{r_1 - r_2}[(3\lambda + \mu + r_1)\exp(r_1 t) - (3\lambda + \mu + r_2)\exp(r_2 t)] \qquad [7.8.23]$$

with

$$r_1, r_2 = \frac{-(3\lambda + \mu) \pm [(3\lambda + \mu)^2 - 8\lambda^2]^{1/2}}{2} \qquad [7.8.24]$$

7.8.7 Stand by systems with repair

For a stand by system with two components in which there is one component operating and one is on stand by, both components have the same failure rate in the operational mode, the stand by component has zero failure rate in the stand by mode, the switchover is perfect, and there is repair, it can be shown using Markov models that the reliability R is:

$$R = \frac{1}{r_1 - r_2}[(2\lambda + \mu + r_1)\exp(r_1 t) - (2\lambda + \mu + r_2)\exp(r_2 t)] \qquad [7.8.25]$$

with

$$r_1, r_2 = \frac{-(2\lambda + \mu) \pm [(2\lambda + \mu)^2 - 4\lambda^2]^{1/2}}{2} \qquad [7.8.26]$$

7.8.8 Constant repair time

As just described, the usual assumption for repair times is a constant repair rate μ, which implies a distribution of repair times. An alternative assumption is a single constant repair time τ.

For a parallel system of n components with repair, the probability of the system being in the 'as new' condition and then suffering an initial failure a given number of times, is given by the Poisson distribution:

$$\exp(-n\lambda t)\left[1 + n\lambda t + \frac{(n\lambda t)^2}{2!} + \frac{(n\lambda t)^3}{3!} + \cdots\right] = 1 \qquad [7.8.27]$$

The probability of the system failing completely after an initial failure and before repair to the as-new condition is:

$$Q(\tau) = [1 - \exp(-\lambda t)]^{n-1} \qquad \lambda t \ll 1 \qquad [7.8.28]$$

Then the probability of the system suffering one initial failure followed by system failure is:

$$P(t) = \exp(-n\lambda t)n\lambda t Q(\tau) \qquad [7.8.29]$$

The probabilities of the system suffering high numbers of initial failures followed by system failure may be obtained in a similar manner. Hence, it can be shown that the reliability of the system is:

$$R = \exp(-\lambda' t) \qquad [7.8.30]$$

with

$$\lambda' = n\lambda Q(\tau) \qquad \lambda t \ll 1 \qquad [7.8.31]$$

7.8.9 Mean life

Some methods of determining the mean life have been outlined in Section 7.6. The Markov methods described below are a further powerful method for obtaining the mean life and also the variance. The expressions for the mean life of some standard systems, assuming the exponential distribution, are shown in Table 7.4. For systems without repair the expressions allow for different failure rates for each equipment, but for systems with repair they assume the same failure rate. Some expressions for the mean life assuming the Weibull distribution are given by Shooman (1968a).

7.9 Reliability of Complex Systems

7.9.1 System reliability analysis

The reliability analysis of systems is carried out first to obtain an assessment of system reliability and to identify critical features, and then to achieve necessary improvements. A full analysis is likely to require considerable effort. It is important, therefore, to identify those subsystems which particularly affect the overall system reliability. In other words, the direction of effort is assisted by a sensitivity analysis. If the reliability of a particular subsystem does not greatly affect that of the system, it is not necessary to analyse it in great detail.

Reliability calculations require data not only on failure rates but also on repair times. The sensitivity of the system reliability determines the accuracy required in the data in a given case. In some instances it is necessary to obtain a rather accurate estimate from field data. In others an engineering estimate made without any field data may be quite sufficient. The matching of the data to the application is an important element in the art of the reliability engineer.

There are a number of methods which can be used to analyse more complex systems and to decompose them into their subsystems. These techniques may be illustrated by reference to Figure 7.6. Figure 7.6(a) illustrates a system consisting of two intermediate storage tanks and three pumps. Figure 7.6(b) shows the three pumps all in parallel, with complete interchangeability between them. Figure 7.6(c) shows two separate streams, with one tank and one pump in each, and with the third pump available to either stream. The system is defined as successful provided flow is maintained by pumping with at least one pump from one tank.

7.9.2 Reliability graphs

The structure of a system may be represented in terms of simple reliability graphs. Each branch of the graph represents a component. Some examples are given in Figure 7.7. Figure 7.7(a) shows the reliability graph for three components in series, and Figure 7.7(b) shows that for three components in parallel. Figure 7.7(c) shows the reliability graph

***Table 7.4** Mean life for some standard systems assuming exponential failure distribution*

System	*Failure rates*	*Mean life*
Series	Same	$\frac{1}{n\lambda}$
	Different	$\frac{1}{\sum_{i=1}^{n}\lambda_i}$
Parallel	Same	$\frac{1}{\lambda\sum_{i=1}^{n}(1/i)}$
	Different	$\left(\frac{1}{\lambda_1}+\frac{1}{\lambda^2}+\cdots+\frac{1}{\lambda_n}\right)$ $-\left(\frac{1}{\lambda_1+\lambda_2}+\frac{1}{\lambda_1+\lambda_3}+\cdots+\frac{1}{\lambda_{n-1}+\lambda_n}\right)$ $+\left(\frac{1}{\lambda_1+\lambda_2+\lambda_3}+\frac{1}{\lambda_1+\lambda_2+\lambda_4}+\cdots+\frac{1}{\lambda_{n-2}+\lambda_{n-1}+\lambda_n}\right)$ $-\cdots+(-1)^{(n-1)}\frac{1}{\sum_{i=1}^{n}(\lambda_i)}$
Stand by	Same	$\frac{n}{\lambda}$
	Different	$\sum_{i=1}^{n}\left(\frac{1}{\lambda_i}\right)$
r-out-of-*n*	Same	—[a]
Parallel with repair (*n* repairmen)	Same	$\frac{1}{\lambda}\sum_{i=0}^{n-1}\frac{(1+\mu/\lambda)^i}{i+1}$
Stand by with repair (*n* repairmen)	Same	$\frac{1}{\lambda}\sum_{i=0}^{n-1}\frac{n!}{(i+1)(n-(i+1))!}\left(\frac{\mu}{\lambda}\right)^i$

[a] The mean life for this case may be obtained by applying the binomial expansion and using Equation 7.6.20.

for two components in parallel, in series with three components in parallel, which corresponds to the storage tank pump system shown in Figure 7.6(a), assuming the configuration given in Figure 7.6(b). The system reliability may then be determined by computing the reliability of the subsystems and then that of the system itself. Reliability graphs are discussed in more detail by Shooman (1968a).

7.9.3 Logic flow diagrams

The most widely used method of graphical representation is the logic flow diagram, also called the 'logic sequence diagram' or simply the 'logic diagram'. Figure 7.8 shows a logic flow diagram for the storage tank pump system with the configuration shown in Figure 7.6(b). In this case the top event considered is a success, but in other cases it may be a failure. Some typical applications of logic flow diagrams are given in Table 7.5. Logic flow diagrams can be used for systems of considerable complexity. Further examples of logic flow diagrams are given by A.E. Green and Bourne (1972).

One of the most widely used types of logic flow diagram is the fault tree. Fault trees are discussed in Chapter 9. An important development in the area of fault trees is kinetic tree theory, which has been developed by Vesely and co-workers (e.g., Vesely, 1969, 1970b; Vesely and Narum, 1970) and which permits the determination of system characteristics such as reliability and availability in time-varying systems.

7.9.4 Event space method

The event space method involves making a comprehensive list of all the possible states of the system and determining which of these events correspond to success. The events E_i, so listed are mutually exclusive and system reliability R is:

$$R = \sum_{i=1}^{n} P(E_i) \qquad [7.9.1]$$

Table 7.6 gives an event space analysis for a storage tank pump system having the configuration shown in Figure 7.6(b). The events which constitute failure are events 7, 17–19 and 26–32; all other events represent success. Further examples of the event space method are given by Shooman (1968a) and Buffham, Freshwater and Lees (1971).

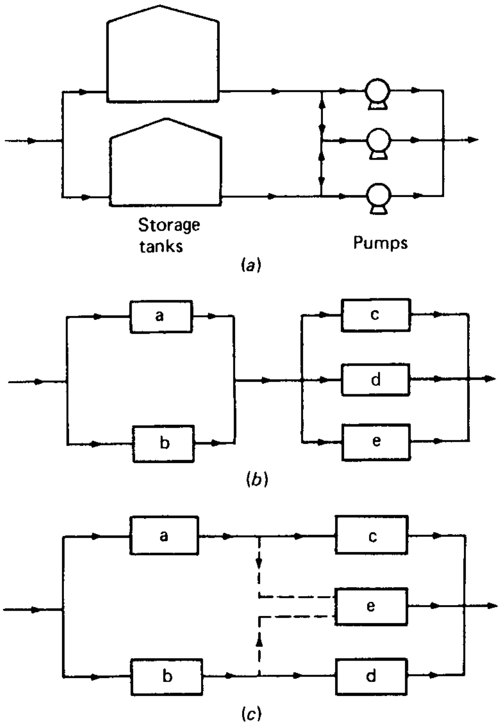

Figure 7.6 *A system to illustrate methods of analysing complex systems: (a) storage tank pump system; (b) system with three pumps in parallel; (c) system with separate streams, but with a common spare pump*

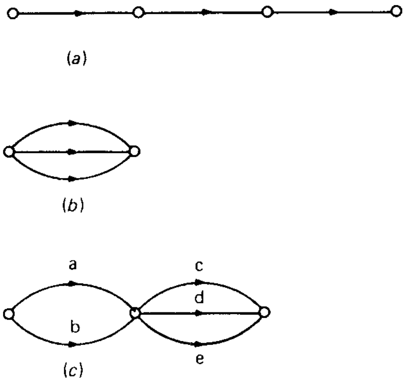

Figure 7.7 *Reliability graphs: (a) for a three-component series system; (b) for a three-component parallel system; (c) for a storage tank pump system (configuration as in Figure 7.6(b))*

7.9.5 Tree diagrams

Another graphical representation is the tree diagram. Figure 7.9 shows such a diagram for a storage tank pump system having the configuration given in Figure 7.6(c). The diagrams can be used for simple cases, but rapidly become rather cumbersome as systems become more complex. Further examples of tree diagrams are given by von Alven (1964) and Breipohl (1970).

7.9.6 Path tracing and tie sets

The path tracing method consists of tracing through the system the paths which constitute success. These paths are known in graph theory as 'tie sets'. System reliability is obtained from the minimum tie sets T_i. These sets of events are not mutually exclusive and the system reliability is given by:

$$R = P\left(\bigcup_{i=1}^{n} T_i\right) \qquad [7.9.2]$$

7.9.7 Path breaks and cut sets

An alternative approach is to determine the sets of events which break all the paths and thus ensure failure. These sets are known in graph theory as 'cut sets'. System unreliability is obtained from the minimum cut sets C_i. Again these sets of events are not mutually exclusive and the system reliability is given by:

$$R = 1 - \left(\bigcup_{i=1}^{n} C_i\right) \qquad [7.9.3]$$

If the event space method is applied to a storage tank pump system having the configuration shown in Figure 7.6(c) rather than that given in Figure 7.6(b), so that paths *ad* and *bc* are not permissible, then the complete cut sets correspond to events 7, 17–19, 22, 24 and 26–32, and are:

$\bar{a}\bar{b}$, $\bar{a}\bar{b}\bar{c}$, $\bar{a}\bar{b}\,\bar{d}$, $\bar{a}\bar{b}\bar{e}$, $\bar{a}\bar{d}\bar{e}$, $\bar{b}\bar{c}\,\bar{e}$, $\bar{c}\bar{d}\bar{e}$,

$\bar{b}\bar{c}\bar{d}\bar{e}$, $\bar{a}\,\bar{c}\bar{d}\bar{e}$, $\bar{a}\bar{b}\bar{d}\bar{e}$, $\bar{a}\bar{b}\bar{c}\,\bar{e}$, $\bar{a}\bar{b}\bar{c}\bar{d}$, $\bar{a}\bar{b}\bar{c}\bar{d}\bar{e}$

However, a cut set which contains within itself a smaller cut set is not a minimum. The minimum cut sets are:

$\bar{a}\bar{b}$, $\bar{a}\bar{d}\bar{e}$, $\bar{b}\bar{c}\,\bar{e}$, $\bar{c}\bar{d}\bar{e}$

Minimum cut sets are important in fault tree work and are considered further in Chapter 9.

7.9.8 System decomposition

It is often possible to simplify the analysis of a system by selecting a key component which makes it possible to decompose the system into subsystems. In such a case, one approach is the use of Bayes' theorem. This theorem is considered in more detail in Section 7.14. Here it is sufficient to note that the theorem may be written in the form:

$$P(\mathrm{A}) = P(A \mid B)P(B) + P(A \mid \bar{B})P(\bar{B}) \qquad [7.9.4]$$

Thus the reliability $R(\mathrm{S})$ of the system is related to the reliability $R(\mathrm{X})$ of the key component as follows:

$$R(\mathrm{S}) = R(\mathrm{S} \mid \mathrm{X})R(\mathrm{X}) + R(\mathrm{S} \mid \bar{\mathrm{X}})Q(\bar{\mathrm{X}}) \qquad [7.9.5]$$

For a storage tank pump system having the configuration shown in Figure 7.6(c) the system unreliability Q is:

$$Q = Q_a Q_b R_e + Q_{ac} Q_{bd} Q_e \qquad [7.9.6]$$

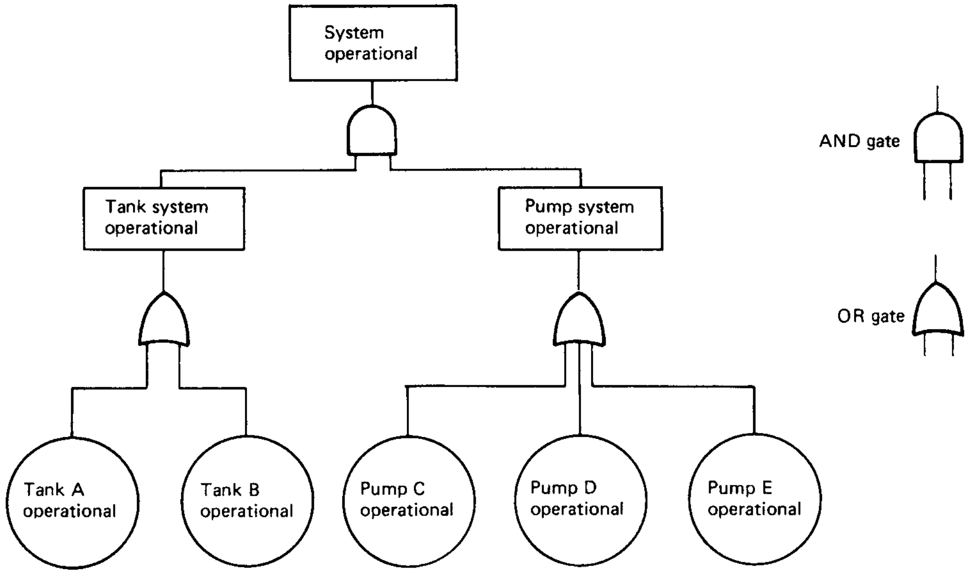

Figure 7.8 *Logic flow diagram for storage tank pump system (configuration as in Figure 7.6(b))*

Table 7.5 *Some typical applications of logic flow diagrams*

Event investigated	*Type of diagram*
Hazardous occurrences	Failure diagram (fault tree)
Trip system operation	Success diagram
Plant availability	Success diagram

with

$$R_{ac} = R_a R_c \quad [7.9.7a]$$

$$R_{bd} = R_b R_d \quad [7.9.7b]$$

Further examples of system decomposition using Bayes' theorem are given by Buffham *et al.* (1971).

7.10 Markov Models

A Markov model is a model of the probabilities of different states of a system as a function of time. It therefore has two variables, state and time. There are thus four possible types of model, since each of these variables may be either discrete or continuous. Accounts of Markov models are given by Sandler (1963), Shooman (1968a) and R.A. Howard (1971). In particular, Sandler (1963) gives solutions of numerous standard cases in reliability and availability. It is the discrete-state, continuous-time model which is most widely used in reliability work.

The state of a system can generally be defined in a number of ways. Thus for a two-equipment system with equipments 1 and 2, one set of states is as follows: no equipments failed, one equipment (either 1 or 2) failed, both equipments failed. Another set of states is as follows: no equipments failed, equipment 1 failed, equipment 2 failed, both equipments failed.

The transitions in the system may be in the forward direction only, that is, from state 0 to state 1, then from state 1 to state 2, etc., or they may be in both forward and backward directions, that is, from state 0 to state 1 and from state 1 to state 0, etc. Also, the transitions may be between adjacent states only or between non-adjacent states.

The transition rates are defined by the states chosen. It is generally desirable to choose the states so that the transition rates correspond to quantities which are known, such as failure and repair rates. The transition rate of a Markov model is a constant. The transition rates may include allowance for imperfect switchover. Thus a transition rate may be a function of both a failure rate and a probability of switchover.

Some examples of Markov models are given below.

7.10.1 Discrete-state, continuous-time models

If a system has $n+1$ possible states and transition is between adjacent states in the forward direction only with transition rates $\lambda_{k-1,k}$ between states $k-1$ and k and $\lambda_{k,k+1}$ between states k and $k+1$, the probability $P_k(t+\Delta t)$ of being in state k at time $t+\Delta t$ is:

$$P_k(t+\Delta t) = \lambda_{k-1,k}\Delta t P_{k-1}(t) + P_k(t) - \lambda_{k,k+1}\Delta t P_k(t) \quad [7.10.1]$$

But

$$\lim_{\Delta t \to 0}\left[\frac{P_k(t+\Delta t) - P_k t)}{\Delta t}\right] = \frac{\mathrm{d}P_k(t)}{\mathrm{d}t} \quad [7.10.2]$$

Hence

$$\frac{\mathrm{d}P_k(t)}{\mathrm{d}t} = \dot{P}_k(t) = \lambda_{k-1,k}P_{k-1}(t) - \lambda_{k,k+1}P_k(t) \quad [7.10.3]$$

Table 7.6 Event space of a storage tank pump system (see Figure 7.6)

1	$abcde$	11	$a\bar{b}\bar{c}de$	20	$\bar{a}b\bar{c}\bar{d}e$	27	$a\bar{b}\bar{c}\bar{d}\bar{e}$
2	$\bar{a}bcde$	12	$a\bar{b}c\bar{d}e$	21	$\bar{a}b\bar{c}d\bar{e}$	28	$\bar{a}b\bar{c}\bar{d}\bar{e}$
3	$a\bar{b}cde$	13	$a\bar{b}cd\bar{e}$	22	$\bar{a}bc\bar{d}\bar{e}$	29	$\bar{a}\bar{b}c\bar{d}\bar{e}$
4	$ab\bar{c}de$					30	$\bar{a}\bar{b}\bar{c}d\bar{e}$
5	$abc\bar{d}e$	14	$ab\bar{c}\bar{d}e$	23	$a\bar{b}\bar{c}\bar{d}e$	31	$\bar{a}\bar{b}\bar{c}\bar{d}e$
6	$abcd\bar{e}$	15	$ab\bar{c}d\bar{e}$	24	$a\bar{b}\bar{c}d\bar{e}$		
		16	$abc\bar{d}\bar{e}$	25	$a\bar{b}c\bar{d}\bar{e}$	32	$\bar{a}\bar{b}\bar{c}\bar{d}\bar{e}$
7	$\bar{a}\bar{b}cde$						
8	$\bar{a}b\bar{c}de$	17	$\bar{a}\bar{b}\bar{c}de$	26	$ab\bar{c}\bar{d}\bar{e}$		
9	$\bar{a}bc\bar{d}e$	18	$\bar{a}\bar{b}c\bar{d}e$				
10	$\bar{a}bcd\bar{e}$	19	$\bar{a}\bar{b}cd\bar{e}$				

Initial conditions are commonly:

$$P_0(0) = 1; \qquad P_k(0) = 0 \quad 0 < k \leq n \tag{7.10.4}$$

As an illustration, consider a system with three states 0, 1 and 2 and transition rates λ_{01} and λ_{12}. The Markov equations are:

$$\dot{P}_0(t) = \lambda_{01} P_0(t) \tag{7.10.5a}$$

$$\dot{P}_1(t) = \lambda_{01} P_0(t) - \lambda_{12} P_1(t) \tag{7.10.5b}$$

$$\dot{P}_2(t) = \lambda_{12} P_1(t) \tag{7.10.5c}$$

Assume the initial conditions given in Equation 7.10.4. Then, rewriting Equations 7.10.5a–c and 7.10.4 in matrix form:

$$\mathbf{P}(t) = \mathbf{A}\mathbf{P}(t) \tag{7.10.6}$$

where

$$\mathbf{A} = \begin{bmatrix} -\lambda_{01} & 0 & 0 \\ \lambda_{01} & -\lambda_{12} & 0 \\ 0 & \lambda_{12} & 0 \end{bmatrix} \tag{7.10.7}$$

and

$$\mathbf{P}(0) = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \tag{7.10.8}$$

Equations 7.10.6–7.10.8 may be solved analytically by taking Laplace transforms, inverting the matrix, and then inverting the transforms. Thus, taking Laplace transforms of Equation 7.10.6:

$$s\mathbf{P} - \mathbf{P}(0) = \mathbf{A}\mathbf{P} \tag{7.10.9}$$

Hence

$$\mathbf{P} = [s\mathbf{I} - \mathbf{A}]^{-1}\mathbf{P}(0) \tag{7.10.10}$$

But

$$[s\mathbf{I} - \mathbf{A}] = \begin{bmatrix} s + \lambda_{01} & 0 & 0 \\ -\lambda_{01} & s + \lambda_{12} & 0 \\ 0 & -\lambda_{12} & s \end{bmatrix} \tag{7.10.11}$$

The inverse of the matrix, $[s\mathbf{I} - \mathbf{A}]^{-1}$, has as its numerator the matrix of cofactors of $[s\mathbf{I} - \mathbf{A}]$ and as its denominator the determinant of $[s\mathbf{I} - \mathbf{A}]$. Thus:

$$[s\mathbf{I} - \mathbf{A}]^{-1} = \frac{\begin{bmatrix} s(s+\lambda_{12}) & 0 & 0 \\ s\lambda_{01} & s(s+\lambda_{01}) & 0 \\ \lambda_{01}\lambda_{12} & \lambda_{12}(s+\lambda_{01}) & (s+\lambda_{01})(s+\lambda_{12}) \end{bmatrix}}{s(s+\lambda_{01})(s+\lambda_{12})} \tag{7.10.12a}$$

$$= \begin{bmatrix} \dfrac{1}{s+\lambda_{01}} & 0 & 0 \\ \dfrac{\lambda_{01}}{(s+\lambda_{01})(s+\lambda_{12})} & \dfrac{1}{s+\lambda_{12}} & 0 \\ \dfrac{\lambda_{01}\lambda_{12}}{s(s+\lambda_{01})(s+\lambda_{12})} & \dfrac{\lambda_{12}}{s(s+\lambda_{12})} & \dfrac{1}{s} \end{bmatrix} \tag{7.10.12b}$$

Then multiplying out Equation 7.10.10 using Equation 7.10.12b:

$$\bar{P}_0(s) = \frac{1}{s+\lambda_{01}} \tag{7.10.13a}$$

$$\bar{P}_1(s) = \frac{\lambda_{01}}{(s+\lambda_{01})(s+\lambda_{12})} \tag{7.10.13b}$$

$$\bar{P}_2(s) = \frac{\lambda_{01}\lambda_{12}}{s(s+\lambda_{01})(s+\lambda_{12})} \tag{7.10.13c}$$

and inverting these transforms gives

$$P_0(t) = \exp(-\lambda_{01}t) \tag{7.10.14a}$$

$$P_1(t) = \frac{\lambda_{01}}{\lambda_{12} - \lambda_{01}}[\exp(-\lambda_{01}t) - \exp(-\lambda_{12}t)] \tag{7.10.14b}$$

$$P_2(t) = 1 - \frac{1}{\lambda_{12} - \lambda_{01}}[\lambda_{12}\exp(-\lambda_{01}t) - \lambda_{01}\exp(-\lambda_{12}t)] \tag{7.10.14c}$$

This example illustrates a number of practical points about Markov models:

(1) The sum of the terms on the right-hand side of all the original model equations is zero.

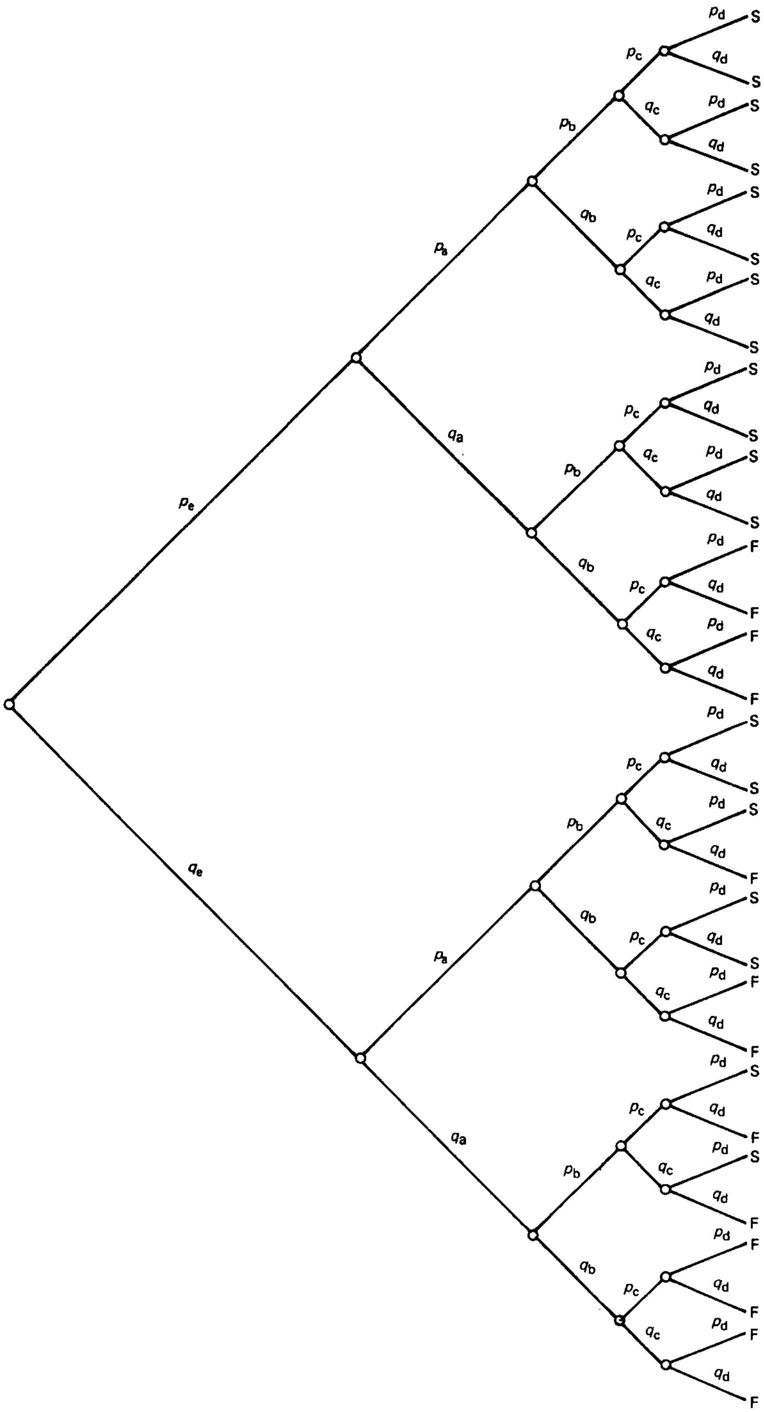

Figure 7.9 *Tree diagram for storage tank pump system (configuration as in Figure 7.6(c)): S, system success; F, system failure*

(2) The sum of the probabilities $P(t)$ is unity and the sum of their transforms $\bar{P}(s)$ is $1/s$.

(3) The initial conditions are frequently $P_0(0) = 1$ and $P_k(0) = 0$ $(0 < k \leq n)$, and in this case only the first column of the matrix $[s\mathbf{I} - \mathbf{A}]^{-1}$ is of interest.

(4) If there are no transitions back from the last state, the equation for this may be omitted and the probability calculated at the end from the other probabilities; this is particularly useful in third- and fourth-order models.

7.10.2 Poisson process

If in Equation 7.10.3 the transition rate from one state to the next is a constant λ, the Markov equations are:

$$\dot{P}_0(t) = -\lambda P_0(t) \qquad [7.10.15a]$$

$$\dot{P}_1(t) = \lambda P_0(t) - \lambda P_1(t) \qquad [7.10.15b]$$

$$\vdots$$

$$\dot{P}_n(t) = \lambda P_{(n-1)}(t) - \lambda P_n(t) \qquad [7.8.15c]$$

Assume the initial conditions given in Equation 7.10.4. Then the solution is:

$$P_0(t) = \exp(-\lambda t) \qquad [7.10.16a]$$

$$P_1(t) = \exp(-\lambda t)\lambda t \qquad [7.10.16b]$$

$$\vdots$$

$$P_n(t) = \exp(-\lambda t)\frac{(\lambda t)^n}{n!} \qquad [7.10.16c]$$

This is a Poisson process.

7.10.3 Two-equipment systems

If a system consists of two components then, whatever its configuration, one formulation of the states in which it can be is as follows: no equipments failed, equipment 1 failed, equipment 2 failed and both equipments failed. Let $P_0(t)$, $P_1(t)$, $P_2(t)$ and $P_3(t)$ be, respectively, the probabilities of: no failures, failure of component 1, failure of component 2, and failure of both components. In addition, let λ_1, λ_2, λ_3 and λ_4 be, respectively, the transition rates from: states 0 to 1, 0 to 2, 1 to 3 and 2 to 3. Then the Markov equations are:

$$\dot{P}_0(t) = -(\lambda_1 + \lambda_2)P_0(t) \qquad [7.10.17a]$$

$$\dot{P}_1(t) = \lambda_1 P_0(t) - \lambda_3 P_1(t) \qquad [7.10.17b]$$

$$\dot{P}_2(t) = \lambda_2 P_0(t) - \lambda_4 P_2(t) \qquad [7.10.17c]$$

$$\dot{P}_3(t) = \lambda_3 P_1(t) + \lambda_4 P_2(t) \qquad [7.10.17d]$$

Assume the initial conditions given in Equation 7.10.4. Then the solution is:

$$P_0(t) = \exp[-(\lambda_1 + \lambda_2)t] \qquad [7.10.18a]$$

$$P_1(t) = \frac{\lambda_1}{\lambda_1 + \lambda_2 - \lambda_3}\{\exp(-\lambda_3 t) - \exp[-(\lambda_1 + \lambda_2)t]\} \qquad [7.10.18b]$$

$$P_2(t) = \frac{\lambda_2}{\lambda_1 + \lambda_2 - \lambda_4}\{\exp(-\lambda_4 t) - \exp[-(\lambda_1 + \lambda_2)t]\} \qquad [7.10.18c]$$

$$P_3(t) = 1 - [P_0(t) + P_1(t) + P_2(t)] \qquad [7.10.18d]$$

Thus far no particular configuration has been assumed. The following cases can be treated to obtain the system reliability $R(t)$:

(1) Series system, failure rates of two equipments identical:

$$\lambda_1 = \lambda_2 = \lambda$$

$$R(t) = P_0(t) = \exp(-2\lambda t) \qquad [7.10.19]$$

(2) Series system, failure rates of two equipments different:

$$R(t) = P_0(t) = \exp[-(\lambda_1 + \lambda_2)t] \qquad [7.10.20]$$

(3) Parallel system, failure rates of two equipments identical:

$$\lambda_1 = \lambda_2 = \lambda_3 = \lambda_4 = \lambda$$

$$\begin{aligned} R(t) &= P_0(t) + P_1(t) + P_2(t) \\ &= 2\exp(-\lambda t) - \exp(-2\lambda t) \qquad [7.10.21] \end{aligned}$$

(4) Parallel system, failure rates of two equipments different:

$$\lambda_1 = \lambda_4 = \lambda; \quad \lambda_2 = \lambda_3 = \lambda'$$

$$\begin{aligned} R(t) &= P_0(t) + P_1(t) + P_2(t) \\ &= \exp(-\lambda t) + \exp(-\lambda' t) - \exp[-(\lambda + \lambda')t] \qquad [7.10.22] \end{aligned}$$

(5) Parallel system, failure rates of two equipments operating together identical, but failure rate of one equipment surviving different:

$$\lambda_1 = \lambda_2 = \lambda; \quad \lambda_3 = \lambda_4 = \lambda'$$

$$\begin{aligned} R(t) &= P_0(t) + P_1(t) + P_2(t) \\ &= \frac{1}{2\lambda - \lambda'}[2\lambda\exp(-\lambda' t) - \lambda'\exp(-2\lambda t)] \qquad [7.10.23] \end{aligned}$$

(6) Stand by system, failure rates of two equipments identical in operating mode, no failure in stand by mode and no switchover failure:

$$\lambda_1 = \lambda_3 = \lambda; \quad \lambda_2 = \lambda_4 = 0$$

$$R(t) = P_0(t) + P_1(t)$$

In this case the expression for $P_1(t)$ is indeterminate since the denominator is zero, but applying de l'Hopital's rule of differentiating both numerator and denominator by λ_1 gives

$$R(t) = \exp(-\lambda t)(1 + \lambda t) \qquad [7.10.24]$$

This example illustrates the versatility of the method.

7.10.4 Single-equipment systems with repair

In the system considered so far the transitions have all been unidirectional towards some failed state. In fact, in most systems there is repair. The transition rate in the reverse direction is the repair rate.

It is normally assumed in Markov models that there is a constant repair rate μ, and hence an exponential distribution of repair times t_r, as given in Equation 7.8.21. If a system comprises a single equipment with repair, there are two possible states it can take. Let $P_0(t)$ and $P_1(t)$ be the probabilities of being operational and failed, respectively, and let λ and μ be the failure and repair rates, respectively. The Markov equations are:

$$\dot{P}_0(t) = -\lambda P_0(t) + \mu P_1(t) \qquad [7.10.25a]$$

$$\dot{P}_0(t) = \lambda P_0(t) - \mu P_1(t) \qquad [7.10.25b]$$

Assume the initial conditions given in Equation 7.10.4. Then the solution is:

$$P_0(t) = \frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu}\exp[-(\lambda + \mu)t] \quad [7.10.26a]$$

$$P_1(t) = \frac{\lambda}{\lambda + \mu} - \frac{\lambda}{\lambda + \mu}\exp[-(\lambda + \mu)t] \quad [7.10.26b]$$

Since there is now transition in both directions, $P_0(t)$ represents the system availability $A(t)$

$$A(t) = \frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu}\exp[-(\lambda + \mu)t] \quad [7.10.27]$$

Thus the availability is, in general, a function of time. But is it usually the steady state availability $A(\infty)$ which is of most interest:

$$A(\infty) = \frac{\mu}{\lambda + \mu} \quad [7.10.28]$$

7.10.5 Reliability and availability formulations

The availability $A(t)$ introduced in the previous section is the probability that the system will be in the operational state. This is not the same as the reliability $R(t)$, which is the probability that the system will not leave the operational state. The difference lies in the fact that, in determining availability, transition back by repair from the non-operational state is permitted. The availability for a given system is always greater than or equal to the reliability:

$$A(t) \geq R(t) \quad [7.10.29]$$

Different Markov models are required for reliability and availability. For reliability, repair transition from the states constituting failure is not permissible, although repair transition from other states is. For availability, repair transition from all states is permitted.

For an r-out-of-n system, in which the states up to and including the $(n - r)$th state give survival, reliability is obtained from the Markov model as:

$$R(t) = \sum_{i=0}^{n-r} P_i(t) \quad [7.10.30]$$

Availability is obtained as

$$A(t) = \sum_{i=0}^{n-r} P_i(t) \quad [7.10.31]$$

when the states 0 to $n - r$ again constitute survival. But the formulation of the equations for the various states is different in the two types of model. For the reliability formulation, the repair transition rates in equations $n - r + 1$ to n are zero.

A state which it is possible to enter but not to leave is an absorbing state. If there is a single absorbing state, the steady state probability of being in that state is unity. The reliability formulations of Markov models have an absorbing state, but availability formulations do not. If the last state of a Markov model is an absorbing state, so that there is no interaction of this state and the preceding states, the last state probability may be omitted in the formulation and determined at the end of the calculation from the other state probabilities. This is particularly useful in the analytical solution or manual calculation of third- and fourth-order models.

7.10.6 Repair rates

The repair rate used in Markov models for systems with more than one equipment needs to be carefully specified. There are two aspects to consider. One is the repair transition rate in systems with n equipments from states in which there is more than one failure. This transition rate will normally lie somewhere in the range μ to $n\mu$. The other aspect is the increase in repair transition rate for a single equipment from μ to $\xi\mu$ which may be obtained by allocating additional effort.

These repair transition rates are often considered in terms of the number of repairmen, it being assumed that the normal case is one repairman for one equipment. Thus for systems with n equipments and with states with multiple failures the repair transition rate in the fully failed state may be $n\mu$. This is often called then 'n repairmen case'. But the number of repairmen may also affect the repair transition rate for a single equipment $\xi\mu$. Thus Sandler (1963) frequently uses $\xi = 1.5$ where two repairmen are available to work on one equipment.

As an illustration, consider a system which consists of two equipments with identical failure rates. Then there are three possible states: no equipments failed, one equipment failed and both equipments failed. Let $P_0(t)$, $P_1(t)$ and $P_2(t)$ be the probabilities of no, one and two failures, respectively, and let λ be the failure rate and μ the basic repair rate. If repair resources allow the repair of only one equipment at a time, that is, the one repairman case, then:

$$\dot{P}_0(t) = -2\lambda P_0(t) + \mu P_1(t) \quad [7.10.32a]$$

$$\dot{P}_1(t) = 2\lambda P_0(t) - (\lambda + \mu)P_1(t) + \mu P_2(t) \quad [7.10.32b]$$

$$\dot{P}_2(t) = \lambda P_1(t) - \mu P_2(t) \quad [7.10.32c]$$

Assume the initial conditions given in Equation 7.10.4. Then the system availability, defined as having both equipments operating, can be shown to be:

$$A(\infty) = P_0(\infty) = \frac{\mu^2}{2\lambda^2 + 2\lambda\mu + \mu^2} \quad [7.10.33]$$

If, on the other hand, the repair resources allow the repair of two equipments simultaneously, that is, the two repairmen case, then:

$$\dot{P}_0(t) = -2\lambda P_0(t) + \mu P_1(t) \quad [7.10.34a]$$

$$\dot{P}_1(t) = 2\lambda P_0(t) - (\lambda + \mu)P_1(t) + 2\mu P_2(t) \quad [7.10.34b]$$

$$\dot{P}_2(t) = \lambda P_1(t) - 2\mu P_2(t) \quad [7.10.34c]$$

and, assuming the same initial conditions and definition of availability,

$$A(\infty) = \frac{\mu^2}{(\lambda + \mu)^2} = \frac{\mu^2}{\lambda^2 + 2\lambda\mu + \mu^2} \quad [7.10.35]$$

It may be noted that there is a difference between the number of repairmen that can usefully be used, depending on whether it is reliability or availability which is being calculated. In a system with n equipments which fails when $n - r + 1$ equipments have failed, it is possible to use n repairmen to maximize availability, but only $n - r$ repairmen to maximize reliability.

7.10.7 Mean life

Markov models offer a powerful method of obtaining the mean life and the variance of the distribution of complex systems. This is discussed in more detail by Sandler (1963).

7.10.8 Discrete-state, discrete-time models

The discrete-state, discrete-time Markov model is also useful in some applications. If a system has a number of possible states and transition occurs between these states over a given time interval, then the vectors of state probabilities before and after the transition **P**(0) and **P**(1) are related by the equation:

$$\mathbf{P}(1) = \mathbf{AP}(0) \qquad [7.10.36]$$

where **A** is the matrix of transition probabilities. Then it can be shown that, as the number of transitions tends to infinity:

$$\mathbf{P}(\infty)\mathbf{A} = \mathbf{P}(\infty) \qquad [7.10.37]$$

The final state probabilities are independent of the initial state probabilities. In addition,

$$\sum \mathbf{P}_i = 1 \qquad [7.10.38]$$

The final states of the system may be obtained by solution of Equations 7.10.37 and 7.10.38.

An account of discrete-state, discrete-time Markov models is given by Sandler (1963). An application involving a discrete-state, discrete-time Markov model is given in Section 7.13.

7.11 Joint Density Functions

An alternative to Markov models is the use of the joint density function approach. The joint density function method is convenient where a failure distribution other than the exponential distribution has to be handled. It is also useful where the failure rate changes depending on the failures which have already occurred. The joint density function method is discussed by Lloyd and Lipow (1962) and Shooman (1968a).

If a system consists of two subsystems and if the second subsystem takes over the system function when the first fails at time τ, then the joint density function of the system $\phi(\tau, t)$ is

$$\phi(\tau, t) = f_1(\tau)f_2(t \mid \tau) \qquad [7.11.1]$$

where $f_1(\tau)$ is a density function, and $f_2(t \mid \tau)$ is a conditional density function. The associated marginal density function $f(t)$ is:

$$f(t) = \int_0^{\infty} \phi(\tau, t)\,\mathrm{d}r \qquad [7.11.2]$$

7.11.1 Parallel systems with variable failure rates

If a system consists of two equipments in parallel and both equipments have the same failure rate λ_1 when both are operating but have a different failure rate λ_2 after the first equipment has failed, then the density functions are:

$$f_1(t) = 2\lambda_1 \exp(-2\lambda_1 t) \qquad [7.11.3]$$

$$f_2(t \mid \tau) = \lambda_2 \exp[-\lambda_2(t - \tau)] \qquad 0 < \tau < t \qquad [7.11.4a]$$

$$= 0 \qquad \tau > t \qquad [7.11.4b]$$

The joint density function is:

$$\phi(\tau,t) = f_1(\tau)f_2(t \mid \tau) \qquad [7.11.5]$$

and the marginal density function is:

$$f(t) = \int_0^t 2\lambda_1 \exp(-2\lambda_1\tau)\lambda_2 \exp[-\lambda_2(t - \tau)]\,\mathrm{d}r \qquad [7.11.6a]$$

$$= \frac{2\lambda_1\lambda_2}{2\lambda_1 - \lambda_2}[\exp(-\lambda_2 t) - \exp(-2\lambda_1 t)] \qquad [7.11.6b]$$

The reliability is

$$R(t) = 1 - \int_0^t f(t)\,\mathrm{d}t \qquad [7.11.7a]$$

$$= \frac{1}{2\lambda_1 - \lambda_2}[2\lambda_1 \exp(-\lambda_2 t) - \lambda_2 \exp(-2\lambda_1 t)] \qquad [7.11.7b]$$

7.11.2 Stand by systems with variable failure rates

If a system consists of two equipments, one operating and one on stand by, with perfect switchover, and if the failure rates of the operating and the stand by equipments are λ_1 and λ_2, respectively, then the density functions are:

$$f_1(\tau) = \lambda_1 \exp(-\lambda_1\tau) \qquad [7.11.8]$$

$$f_2(t|\tau) = \lambda_2 \exp[-\lambda_2(t - \tau)] \qquad 0 < \tau < t \qquad [7.11.9a]$$

$$= 0 \qquad \tau > t \qquad [7.11.9b]$$

and hence

$$f(t) = \frac{\lambda_1\lambda_2}{\lambda_1 - \lambda_2}[\exp(-\lambda_2 t) - \exp(-\lambda_1 t)] \qquad [7.11.10]$$

$$R(t) = \frac{1}{\lambda_1 - \lambda_2}[\lambda_1 \exp(-\lambda_2 t) - \lambda_2 \exp(-\lambda_1 t)] \qquad [7.11.11]$$

7.12 Monte Carlo Simulation

Many practical problems cannot be solved by any of the analytical methods described and are only soluble by simulation. The principal method used is Monte Carlo simulation. Accounts of Monte Carlo simulation include that given in *Method of Statistical Testing. Monte Carlo Method* (Shreider, 1964) and that by Shooman (1968a).

7.12.1 Simulation method

The application of Monte Carlo simulation to the determination of the reliability and/or availability of complex systems proceeds broadly as follows.

The system configuration, the failure and repair characteristics of the components, and the time period of interest are specified. The time period is divided into small increments. The first trial is then carried out covering the time period specified. At the first time increment the probability of failure of the first equipment is calculated. This probability is compared with a random number in the range 0 to 1 generated from a uniform distribution: if the random number is less than or equal to the failure probability the equipment fails, otherwise it survives. The state of all the equipments is computed in like manner. The situation is then reviewed to determine the overall state of the system. If failures have occurred, there may be various changes in the system, such as initiation of repair of failed equipments, alteration in failure rates of more highly loaded surviving equipments, etc. The system behaviour at the second time increment is then computed and the process is continued until the specified time period is complete. This whole calculation constitutes only a single trial.

The result of this trial is that the system either has or has not met its reliability/availability objective. It is then necessary to carry out further trials to obtain the full simulation. The ratio of successful trials to total trials asymptotically approaches a constant value and this is the required system reliability/availability result. The equipment characteristics such as failure and repair rates obtained in the series of simulation trials naturally also approach asymptotically the values originally specified.

7.12.2 Illustrative example

As an illustration, consider the determination of the reliability of a single equipment over a specified period of time, assuming the exponential failure distribution. This simple case is chosen for illustration because there is also an analytical solution which is given by Equation 7.6.11. Let the time period to be considered be 10 months and let the failure rate λ be 0.5 faults/year. Then, in Equation 7.6.11,

$\lambda = 0.5$ faults/year

$t = 10$ months $= 0.83$ year

Hence

$R = 0.66$

Now consider the alternative solution using Monte Carlo simulation. The time period is divided into suitable increments, which in this case are shown as 1 month. The probability of failure q in one time increment δt is then calculated as:

$$-q = \lambda\delta t$$
$$= 0.5 \times 0.0833$$
$$= 0.0417$$

The Monte Carlo simulation is then carried out using a set of random numbers. A suitable series of random numbers, which in this case have been generated by a computer and are therefore strictly pseudo-random numbers, is given in Table 7.7. The first trial is carried out as follows. For the first month the probability of failure q ($= 0.0417$) is compared with the random number v. The occurrence of survival or failure is determined as follows:

$v > q$ survival;

$v < q$ failure.

Thus, taking the random numbers from the first line of the table, in the first month, since $v = 0.0417$, the equipment survives. The same process is repeated for each of the remaining 9 months. Since in all cases $v > q$, the equipment survives the whole 10-month period. This completes the first trial, in which the equipment has survived.

Further trials are then carried out on the same lines. The second, fourth and sixth lines of the random number table contain values of the random number v which are less than q; these are shown underlined in Table 7.7. In the second, fourth and sixth trials, therefore, the equipment fails, but in all the other trials it survives. The trials which constitute survival and failure may then be tabulated as shown in Table 7.8, assigning 1 to a survival and 0 to a failure.

The reliability of the equipment is then determined as the ratio of the number of trials in which the equipment survives to the total number of trials. In this example the ratio is 0.7. Since only 10 trials have been done, the reliability can be calculated only to one place of decimal. This value of the reliability compares with the value of 0.66 calculated earlier from the analytical relationship.

7.12.3 Applications of the method

As an illustration of the sort of problem to which Monte Carlo methods are applicable consider the olefins plant system shown in Figure 7.10. The system consists of four cracking furnaces in parallel followed by a compressor and then by a separation train. The furnaces have the characteristics shown in Table 7.9. The failure rate of the compressor is 0.3 faults/year and that of the separation train is 3 faults/year. The repair characteristics of the equipment are given in Table 7.10. The furnace repair team is able to work on only one furnace at a time, but there is no other restriction on the repair work. The information required from the simulation might be, say: (1) the probability of achieving full availability, (2) the mean availability

achieved, (3) the range of availabilities and the corresponding probabilities, over a period of 90 days.

7.12.4 Features of the method

It will be apparent from this example that it is necessary to resort to Monte Carlo simulation on account of the complexity not so much of the system configuration, which is in fact rather simple, but rather of that of the failure and repair data and other rules and constraints. A single simulation is capable of giving a number of results. Thus in the example quoted the results required were, in effect, the system reliability, its mean availability and its availability density function.

The failure data are frequently provided in the form of a failure histogram. The quantity which is required in the simulation for comparison with the random number is the probability of failure q. If the fraction failing over one time increment is δF, then

$$q = \frac{\delta F}{1 - F} \qquad [7.12.1]$$

Thus consider the failure histogram shown in Figure 7.11. The probabilities of failure for the 4 days obtained from Equation 7.12.1 are 0.2, 0.25, 0.5 and 1.0.

It is often convenient to perform one set of trials, examine the results and then perform further sets. If this is done, however, it is necessary that the subsequent sets should not start with the same random number as the first set, otherwise the effect is simply to repeat that set continuously.

7.12.5 Number of trials

The Monte Carlo method is extremely powerful, but it does have one serious drawback with regard to the number of trials required to obtain an accurate result, especially where the probability investigated is high. The number of trials required to achieve a given confidence level on the probability cannot, in general, be calculated. An approximate estimate of the number of trials can be obtained, however, if certain simplifying assumptions are made. The following method of estimation has been described by Shooman (1968a).

In determining the value of a single probability, such as a reliability, the simulation may be regarded as a series of n trials which have a binomial distribution with a true probability of success p and of failure q. The binomial distribution approaches the normal distribution for $p > 0.5$ and $nq > 5$. The point estimate of the probability of failure q is given by n_f/n, where n_f is the number of failures recorded in n trials. Then the fractional error e between the estimated and true probabilities of failure is:

$$e = \frac{n_f/n - q}{q} \quad [7.12.2]$$

If μ and σ are the expected number of failures and the expected standard deviation, then for a $(1 - \alpha)$ confidence level:

$$P(-\gamma\sigma < n_f - \mu < \gamma\sigma) = 1 - \alpha \quad [7.12.3]$$

where γ is the number of standard deviations corresponding to that level. In terms of the parameters n, p and q of the binomial distribution:

$$\mu = nq \quad [7.12.4]$$

$$\sigma = (npq)^{1/2} \quad [7.12.5]$$

Then

$$P[-\gamma(npq)^{1/2} < n_f - n_q < \gamma(npq)^{1/2}] = 1 - \alpha \quad [7.12.6]$$

$$P[-\gamma(p/nq)^{1/2} < e < \gamma(p/nq)^{1/2}] = 1 - \alpha \quad [7.12.7]$$

Thus at the 95% confidence level, for which $\gamma = 2$:

$$e > 200(p/nq)^{1/2}\% \quad [7.12.8]$$

The very large number of trials required for a system with very high reliability can be seen by considering the number required to give an error of $\not>$5% at a 95% confidence level (see Table 7.11). Thus, despite the undoubted power of the Monte Carlo method, it remains attractive to use and develop analytical techniques wherever possible. A further discussion of the number of trials required in Monte Carlo simulation is given by Shreider (1964).

Monte Carlo simulation also has other applications in reliability work. Its use to generate hazard rates from distributions of hazard rates is described in Chapter 9 in connection with fault tree work.

7.13 Availability

7.13.1 System availability analysis

The availability analysis of systems, like reliability analysis, has as its objectives: (1) to assess system availability and to identify critical aspects; and (2) to effect the required improvements.

It is usually necessary to consider a number of availability characteristics. For process plants these are likely to include: (1) the probability of obtaining nominal output and downtime, (2) the probability of obtaining other outputs and down-times and (3) the probability of infrequent but very long down-times. Long outages are particularly important. It is usually appropriate to deal separately with these. Thus, for example, the frequency of a long outage of 1 year might be about 10^{-4}/year. It is not very meaningful to express this as an additional loss of mean availability of 0.04 days/year.

A full analysis may well involve much effort. Therefore it is important to identify those subsystems which have a particularly strong influence on the overall system availability. Those subsystems which do not greatly affect system availability can be treated in less detail.

There are two main types of availability data which may be used. Sometimes data on the availability of whole subsystems can be obtained. In other cases it is necessary to calculate system availability from failure rate and repair time data. In either case it is important that the accuracy of the data be matched to the sensitivity of the system availability to errors in the data.

As far as possible data on the availability of a process unit should describe the performance of that unit independent of other units. Down-time of the unit due to unavailability of other units or to other extraneous causes should not be included.

Particular attention should be paid to the availability of process raw materials and services. It is also often necessary to consider the availability of other plants which receive from the plant under consideration outputs such as by-products, electricity or steam.

There are a number of methods available for the analysis of more complex systems, and some of these are described below.

7.13.2 The availability function

In general, availability $A(t)$ is a function of time. It may be expressed in terms of the up-time $u(t)$ and down-time $d(t)$:

$$A(t) = \frac{u(t)}{u(t) + d(t)} \quad [7.13.1]$$

The unavailability $V(t)$ is

$$V(t) = 1 - A(t) \quad [7.13.2]$$

$$= \frac{d(t)}{u(t) + d(t)} \quad [7.13.3]$$

The point availability $A(t)$ can be integrated over the time period T to give the mean availability over that period:

$$A(T) = \frac{1}{T}\int_0^T A(t)\,\mathrm{d}t \quad [7.13.4]$$

Often, however, it is the long-term, or steady-state, availability $A(\infty)$ which is of most interest:

$$A(\infty) = \frac{u(\infty)}{u(\infty) + d(\infty)} \quad [7.13.5]$$

The long-term availability may also be expressed in terms of the mean up-time m_u and the mean down-time m_d:

$$A(\infty) = \frac{m_u}{m_u + m_d} \quad [7.13.6]$$

Table 7.11 *Monte Carlo simulation: number of trials required in example to give an error of $\not>$5% at a 95% confidence level*

Probability of success	*No. of trials required*
0.9	14,400
0.99	158,400
0.999	1,598,400

For a single equipment or system with exponential failure and repair distributions, failure rate λ and repair rate μ:

$$m_u = \frac{1}{\lambda} \quad [7.13.7]$$

$$m_d = \frac{1}{\mu} \quad [7.13.8]$$

$$= m_r \quad [7.13.9]$$

Then, from Equations 7.13.6–7.13.9:

$$A(\infty) = \frac{\mu}{\lambda + \mu} \quad [7.13.10a]$$

$$= \frac{1}{1 + \lambda m_r} \quad [7.13.10b]$$

$$= 1 - \lambda m_r \qquad \lambda m_r \ll 1 \quad [7.13.10c]$$

This result was given earlier in Equation 7.10.28, and the long-term unavailability is:

$$V(\infty) = \frac{\lambda}{\lambda + \mu} \quad [7.13.11a]$$

$$= \frac{\lambda m_r}{1 + \lambda m_r} \quad [7.13.11b]$$

$$= \lambda m_r \qquad \lambda m_r \ll 1 \quad [7.13.11c]$$

7.13.3 The repair time density function

It is appropriate at this point to consider the distribution of repair times. The mean repair time m_r is defined as the first moment of the repair time density function $f_r(t_r)$:

$$m_r = \int_0^\infty t_r f_r(t_r)\, dt_r \quad [7.13.12]$$

So far, the repair time distribution which has been considered is the exponential. For this distribution the repair time density function $f_r(t_r)$ is

$$f_r(t_r) = \mu \exp(-\mu t_r) \quad [7.13.13]$$

The repair time distribution function $F_r(t_r)$ is:

$$F_r(t_r) = \int_0^{t_r} f_r(t_r)\, dt_r \quad [7.13.14a]$$

$$= 1 - \exp(-\mu t_r) \quad [7.13.14b]$$

The mean repair time is:

$$m_r = \int_0^\infty t_r \mu \exp(-\mu t_r)\, dt_r \quad [7.13.15a]$$

$$= \frac{1}{\mu} \quad [7.13.15b]$$

For the normal distribution:

$$f_r(t_r) = \frac{1}{\sigma_r (2\pi)^{1/2}} \exp\left(-\frac{(t_r - m_r)^2}{2\sigma_r^2}\right) \quad [7.13.16]$$

where the mean repair time is m_r.

For the log-normal distribution:

$$f_r(t_r) = \frac{1}{\sigma_r t_r (2\pi)^{1/2}} \exp\left(-\frac{[\ln(t_r) - m_r^*]^2}{2\sigma_r^2}\right) \quad [7.13.17]$$

Repair time data often fit a log–normal distribution.

7.13.4 The down-time density function

For a single equipment the repair time and the down-time are the same. For a system it is more usual to speak of the down-time.

So far the down-time used in the expressions for availability has been the mean down-time m_d. But, just as there is a repair time distribution, so there is a down-time distribution. It is possible to define a down-time density function $f_d(d)$ and distribution function $F_d(d)$.

Particularly important are long down-times. In the down-time distribution shown in Figure 7.12, the tail in the distribution is due to infrequent, but long, outages.

7.13.5 The throughput density function

So far it has been assumed that either an item is available or it is not. In fact, however, in the process industries many items may exhibit a range of throughputs. This partial availability can be expressed by a throughput density function $f_w(w)$.

Typical throughput data from a process unit given by G.D.M. Pearson (1975) are shown in Table 7.12 and plotted in Figure 7.13. These data constitute a throughput density function. Similarly, the throughput of a whole plant can be expressed as a throughput density function.

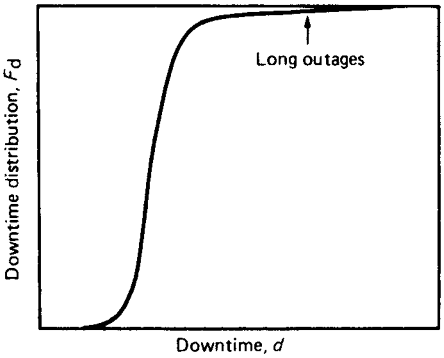

Figure 7.12 *Down-time distribution showing a tail corresponding to infrequent, but long, outages*

7.13.6 Markov models

The derivation of expressions for availability from Markov models has been described briefly above. This method is now considered in more detail.

It is normally assumed in such models that the repair time distribution is exponential with constant repair rate μ. Usually it is the long-term availability which is of interest. In this case the Markov equations become steady-state equations. Thus, for example, Equation 7.10.25 becomes

$$0 = -\lambda P_0 + \mu P_1 \qquad [7.13.18a]$$

but Equation 7.10.25b becomes

$$1 = P_0 + P_1 \qquad [7.13.18b]$$

Equations 7.13.18a,b then yield equation [7.10.28] directly.

The definition of availability used depends on the configuration of the system. Considering systems with n equipments, for a series system only the first state P_0 constitutes survival:

$$A(\infty) = P_0 \qquad [7.13.19]$$

For a parallel system only the last state represents failure:

$$A(\infty) = 1 - P_n \qquad [7.13.20]$$

For an r-out-of-n system the states up to and including the $(n-r)$th state give survival:

$$A(\infty) = \sum_{i=0}^{n-r} P_i \qquad [7.13.21]$$

Long-term availabilities for some standard systems assuming exponential failure and repair time distributions are given in Table 7.13. The availabilities are defined by Equations 7.13.19–7.13.21. The repairman assumption is that each repairman repairs one equipment, so that the repair transition rates between states are limited by the number of repairmen.

Another important and general case is that in which there are n equipments but only m repairmen. If there are k equipments down then, at steady state:

$$0 = (n-k+1)\lambda P_{k-1} - [(n-k)\lambda + k\mu]P_k + (k+1)\mu P_{k+1} \qquad k < m \qquad [7.13.22a]$$

Table 7.13 *Long-term availabilities for some standard systems assuming exponential failure and repair time distributions*

System	*No. of components*	*No. of repairmen*	*Availability*
–	1	1	$\frac{\mu}{\lambda+\mu}$
Series	2	1	$\frac{\mu^2}{2\lambda^2+2\lambda\mu+\mu^2}$
Series	2	2	$\frac{\mu^2}{(\lambda+\mu)^2}$
Series	n	1	$\frac{(\mu/\lambda)^n}{n!\sum_{i=0}^{n}(1/i!)(\mu/\lambda)^i}$
Series	n	n	$\frac{\mu^n}{(\lambda+\mu)^n}$
Parallel	2	1	$\frac{\mu^2+2\lambda\mu}{2\lambda^2+2\lambda\mu+\mu^2}$
Parallel	2	2	$\frac{\mu^2+2\lambda\mu}{\lambda^2+2\lambda\mu+\mu^2}$
Parallel	n	1	$1-\frac{1}{\sum_{i=0}^{n}(1/i!)(\mu/\lambda)^i}$
r-out-of-n	n	n	$\sum_{i=r}^{n}\binom{n}{i}\left(\frac{\mu}{\lambda+\mu}\right)^i\left(\frac{\lambda}{\lambda+\mu}\right)^{n-i}$
Stand by	2	1	$\frac{\mu^2+\lambda\mu}{\lambda^2+\lambda\mu+\mu^2}$
Stand by	2	2	$\frac{2\mu^2+2\lambda\mu}{\lambda^2+2\lambda\mu+2\mu^2}$
Stand by	n	1	$1-\frac{1}{\sum_{i=0}^{n}(\mu/\lambda)^i}$
Stand by	n	n	$1-\frac{1}{\sum_{i=0}^{n}(n/i!)(\mu/\lambda)^{n-i}}$

$$0 = (n-k+1)\lambda P_{k-1} - [(n-k)\lambda + m\mu]P_k + m\mu P_{k+1} \qquad k \geq m \qquad [7.13.22b]$$

$$1 = \sum_{i=0}^{n} P_i \qquad [7.13.22c]$$

Equations 7.13.22a–c have the solution:

$$P_0 = \left[\sum_{k=0}^{m-1}\frac{n!}{(n-k)!k!}\rho^k + \sum_{k=m}^{n}\frac{n!}{(n-k)!m!}\rho^m\left(\frac{\rho}{m}\right)^{k-1}\right]^{-1} \qquad [7.13.23a]$$

$$P_k = \frac{n!}{(n-k)!k!}\rho^k P_0 \qquad k < m \qquad [7.13.23b]$$

$$= \frac{n!}{(n-k)!m!}\rho^m\left(\frac{\rho}{m}\right)^{k-m} P_0 \qquad k \geq m \qquad [7.13.23c]$$

with

$$\rho = \frac{\lambda}{\mu} \qquad [7.13.24]$$

The long-term availability of an r-out-of-n system with m repairmen is given by:

$$A(\infty) = \sum_{i=0}^{n-r} P_i \qquad [7.13.25]$$

using Equations 7.13.23a–c.

These and numerous other cases are treated in more detail by Sandler (1963).

7.13.7 Logic flow diagrams

Logic flow diagrams are often used to represent system availability. Thus the logic flow diagram shown in Figure 7.8 for the storage tank pump system with the configuration given in Figure 7.6(b) is in fact an availability diagram. In order to use the logic flow diagram method it is necessary to represent the plant flow diagram in logical form. It is necessary, therefore, to convert the plant flow diagram into a network of relatively simple blocks such as series or parallel units.

The plant availability determined using a logic flow diagram may be the mean availability or the availability density function. Usually the calculation is limited to the former. There are two main methods of determining the mean availability of the plant. In many cases the availability data are the mean availabilities of the units which constitute the plant. Typical units might be a tank-pump system, a complete distillation column or a set of centrifuges. The mean unavailability of a unit is effectively a fractional dead time or probability of being unavailable. Then the mean availability of the plant may be calculated from the mean unavailabilities of these units.

In other cases the availability data obtainable are the failure rates and repair times of the equipments which constitute the units. Typical equipments are a pump, a heat exchanger or a drier. The mean unavailability, or fractional dead time, of an equipment may be calculated from the failure rate and repair time data using Equation 7.13.10. The fractional dead time of the unit may be calculated from those of the constituent equipments. Then the mean unavailability of the plant may again be calculated from the unavailabilities of the units. The mean repair time of the plant may be determined by calculating the failure rate and the mean unavailability.

It is also possible, however, to express the unit availabilities as throughput density functions, and in this case the plant availability is also a throughput density function. This may be obtained from the logic flow diagram by Monte Carlo simulation in a manner similar to that used in fault tree evaluation, as described in Chapter 9.

7.13.8 Throughput capability method

There is an alternative method, which allows the system availabilities to be expressed as throughput densities and still avoid the use of simulation (G.D.M. Pearson, 1975). The method involves converting the system into a series system and determining successively the limiting throughputs.

As an illustration, consider the distillation plant system flow diagram given by Pearson and shown in Figure 7.14(a). The corresponding availability block diagram is given in Figure 7.14(b). The path (11) affects the operation of paths (2, 6, 7, 9) and (1, 5) and therefore takes the position shown, while side paths (13) and (14) affect the operation of the main forward path and are therefore shown there. The main forward path is also affected by the single supplies of electricity, high pressure steam and cooling water. The units (1–2) can be reduced to an equivalent but simplified block diagram, as shown in Figure 7.14(c). This is a complex subsystem, which cannot be resolved into simple series or parallel systems.

The throughput capability of the system is evaluated by series and parallel state enumeration techniques. The series enumeration technique is as follows. All the stages of the system, that is, the units or the subsystems, are treated together as a series system. The throughput levels of the system are considered in turn, starting at zero throughput and rising to full throughput. At each level there is a stage which has the lowest throughput capability and limits the system throughput capability; this is the 'bottleneck' stage. The probability that the system has this throughput is determined by the probability that this bottleneck stage is in this state. The throughput capability of the bottleneck stage is then increased to its next discrete level. A new bottleneck stage is then identified and the procedure is repeated. Table 7.14 shows the throughput capabilities for a system of 10 identical process units with throughput capabilities as given in Table 7.13. The corresponding plot of system throughput capabilities is illustrated in Figure 7.15. This is the throughput density function of the system. The mean throughput capability of a single unit is 0.943 and that of the system is 0.557.

The parallel path enumeration technique is as follows. Only two stages of the system are considered at a time. The throughput density function of this subsystem is obtained by summing the discrete throughput capabilities of the two stages and multiplying the corresponding probabilities. If in the original system there are more than two stages in parallel, this subsystem and the next parallel stage are then considered and the procedure repeated.

Further details of the throughput capability method, including the application of the state enumeration technique to complex subsystems, are given by G.D.M. Pearson (1975).

7.13.9 Flowsheeting and simulation methods

Flowsheeting methods and, in particular, computer flowsheeting programs, may also be used to determine plant availability. The use of this approach has been described by Holmes (1976).

7.13.10 Storage

Plant availability is affected by storage, which introduces flexibility, and may allow units upstream or downstream of a failed unit to continue in operation for a time. Methods of determining the effect of storage on plant availability have been discussed by Holmes (1976) and by Henley and Hoshino (1977).

There are two main classes of storage tank: (1) raw material and product storage tanks, and (2) intermediate storage tanks. Storage tanks are provided for various reasons, some of which have nothing to do with plant availability. Raw material and product storage tanks are used to smooth deliveries and collections and to blend materials. Intermediate storage tanks are also used to smooth fluctuations and to blend intermediates.

As an illustration, consider the simplest system with intermediate storage capacity of an upstream unit, an intermediate storage tank and a downstream unit. This system and its operating policies have been investigated by Henley and Hoshino (1977).

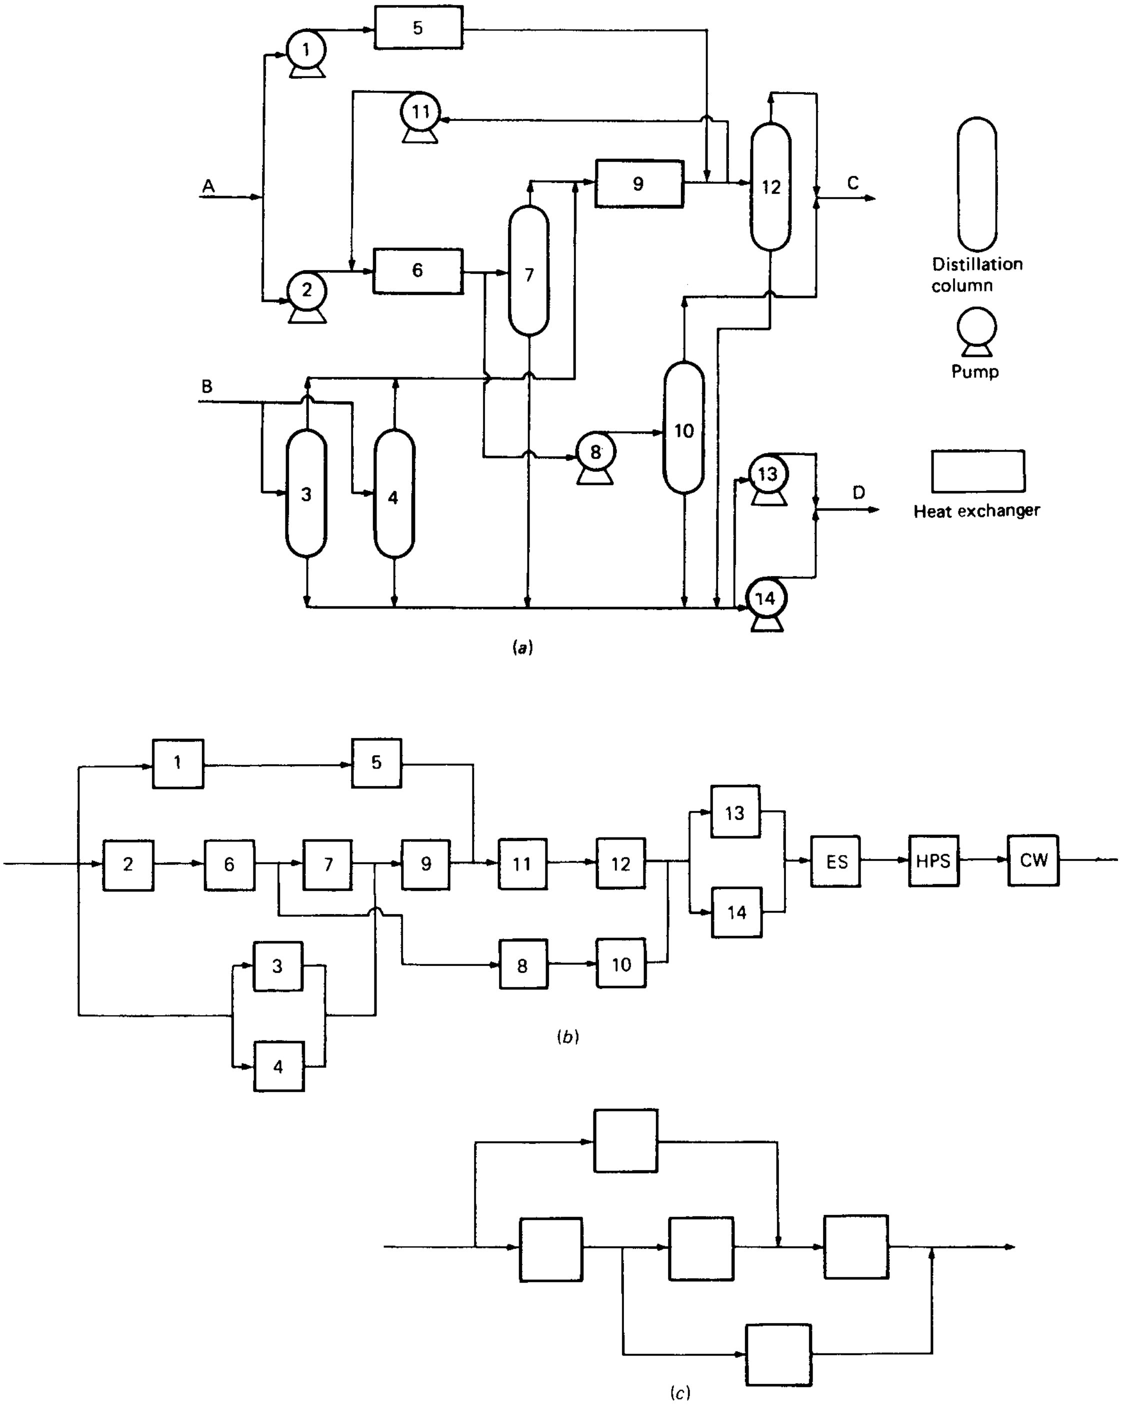

Figure 7.14 *Distillation plant system (G.D.M. Pearson, 1975): (a) flow diagram of system; (b) availability block diagram of system; (c) equivalent block diagram of units 1–2. Throughput capability (fraction of normal throughput)	*Probability*
0	0.300
0.025	0.102
0.050	0.031
0.800	0.006
0.850	0.012
0.900	0.029
0.925	0.038
0.950	0.050
0.975	0.086
1.000	0.349

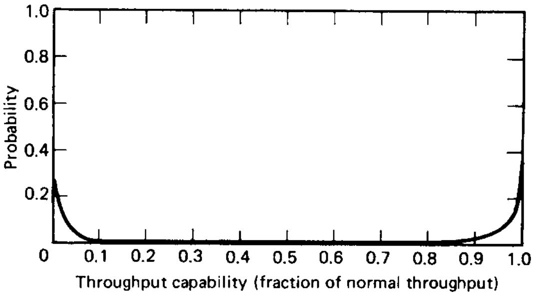

***Figure 7.15** Throughput density for a process system (G.D.M. Pearson, 1975) (Reproduced by permission of the University of Nottingham)*

***Table 7.15** Plant availability example: unit throughput capabilities*

	Throughput capability (m^3/h)	*Probability*
Upstream unit	0	0.02
	95	0.03
	100	0.95
Downstream unit	0	0.04
	90	0.06
	100	0.90

Some basic operating policies are: (1) to keep the tank filled if possible, (2) to keep the tank empty if possible, (3) to keep the tank half full if possible and (4) to allow the tank level to fluctuate. The appropriate operating policy depends on the objectives to be achieved by the use of the storage. It is convenient to consider initially only the improvement of plant availability.

The policy necessary to maximize plant availability depends on the relative maximum capacities and failure rates of the upstream and downstream units. If the capacities and failure rates are equal, the appropriate policy is to run with the tank half full, emptying and filling during unit failures. If the capacity of the upstream unit is higher but its failure rate is also higher, the appropriate policy is to run with the tank full, filling during normal operation or downstream unit failure. If the capacity of the downstream unit is higher, but its failure rate is also higher, the appropriate policy is to run with the tank empty, emptying during normal operation or upstream unit failure. A general principle underlying these policies is that unit production is not interrupted merely in order to fill or empty the tank.

It may be necessary, however, to adopt other policies which have objectives other than improvement of plant availability. Thus, if the shut-down of the downstream unit is relatively hazardous or difficult or if the output of the upstream unit needs to be blended, the policy adopted may be to run with the tank full. On the other hand, if the shut-down of the upstream unit is relatively hazardous or difficult, the policy adopted may be to run with the tank empty.

For certain defined cases, a relatively simple treatment is possible. One such case, described by Henley and Hoshino (1977), is that of an upstream unit with excess capacity. It is assumed that the time required to fill the tank using this excess capacity is much less than the mean time to failure of the upstream unit and that the operating policy is to keep the tank full. Then it can be shown that the following relationships apply:

$$V_s = \frac{\lambda_u m_{ru}}{1 + \lambda_u m_{ru}} \qquad [7.13.26]$$

$$V_{st} = kV_s \qquad [7.13.27]$$

$$k = \exp(-T_e/m_{ru}) \qquad [7.13.28]$$

$$\lambda_{st} = \frac{k[\lambda_u/(1 + \lambda_u m_{ru})]}{1 - k[\lambda_u m_{ru}/(1 + \lambda_u m_{ru})]} \qquad [7.13.29]$$

where m_{ru} is the mean repair time of the upstream unit, T_e is the time required to empty the tank, V_s is the unavailability of the upstream unit, V_{st} is the unavailability of the upstream unit + the tank, λ_{st} is the failure rate of the upstream unit + the tank, and λ_u is the failure rate of the upstream unit.

A fuller treatment of this and other cases is given by Henley and Hoshino (1977).

The problem of the effect of storage has also been treated by Coker (1978), who has extended the throughput capability method of Pearson to take account of storage. The system considered is an upstream unit, an intermediate storage tank and a downstream unit. The states of the storage are defined as discrete levels of storage, or hold-ups. These states are then determined using a discrete-state, discrete-time steady-state Markov model, as described in Section 7.10.

As an illustration of the method, consider the system given by Coker in which the throughput capabilities of the upstream and downstream units are as shown in Table 7.15 and in which the tank capacity is 15 m^3. Then the probability of a net inflow of 100 m^3 into the tank is $0.95 \times 0.04 = 0.038$. The probabilities of the other net inflows may be calculated in a similar manner. It should be noted that a zero net inflow is obtained both for a flow of 0 m^3/h in both units and for one of 100 m^3/h in both units. The probability distribution of net inflow is then as shown in Table 7.16.

Now assume that the states of the tank are defined as hold-ups of 0, 5, 10 and 15 m^3. The transition probabilities, which are the elements of the matrix A in Equation 7.10.37, are determined by considering the possible changes in tank

Table 7.16 *Plant availability example: probability of net inflow*

Net inflow into tank (m^3/h)	*Probability*
100	0.0380
95	0.0012
10	0.0570
5	0.0018
0	0.8558
–5	0.0270
–90	0.0012
–100	0.0180

hold-up and the net flow differences which can produce such changes, and then summing the probabilities of these net flows. Thus for a hold-up 'change' of 0 to 0 m^3 the net flows which can cause this change are 0, −5, −90 and −100 m^3/h. Then the transition probability between an initial hold-up state of 0 m^3 and a final state of 0 m^3 is:

$$0.8558 + 0.027 + 0.0012 + 0.018 = 0.902$$

The other transition probabilities may be calculated in a similar manner. The transition matrix is then:

$$\mathbf{A} = \begin{bmatrix} 0.9020 & 0.0018 & 0.0570 & 0.0392 \\ 0.0462 & 0.8558 & 0.0018 & 0.0962 \\ 0.0192 & 0.0270 & 0.8558 & 0.0980 \\ 0.0192 & 0 & 0.0270 & 0.9538 \end{bmatrix}$$

Then application of Equation 7.10.37 gives the probabilities of tank hold-up listed in Table 7.17.

The throughput capability of the system is now calculated. A throughput capability of 10 m^3/h occurs when the throughput capabilities of the upstream and downstream units are 0 m^3 and 90 or 100 m^3, respectively. The probability of a system throughput capability of 10 m^3/h is:

$$0.02 \times 0.1826 \times (0.06 + 0.90) = 0.0035$$

The other throughput capabilities may be calculated in a similar manner. The result obtained is given in Table 7.18.

7.14 Bayes' Theorem

It frequently occurs in reliability engineering that there is a need to test a hypothesis or to revise an estimate in the light of additional information. A powerful tool for handling such problems is Bayes' theorem. Accounts of Bayes' theorem include those given in *Introduction to Probability and Statistics from a Bayesian Viewpoint* (Lindley, 1965), and those by Savage (1962a), Brand (1980) and Kaplan (1983). Its use in expert systems is discussed by Michie (1979).

7.14.1 Basic formulation

A basic formulation of Bayes' theorem is as follows. Consider the probability of the joint event AB. If the event A has two outcomes A and $\bar{A}$:

$$P(AB) = P(A \mid B)P(B) \quad [7.14.1]$$

$$= P(B \mid A)P(A) \quad [7.14.2]$$

Table 7.17 *Plant availability example: probabilities of tank holdup*

Tank holdup (m^3)	*Probability*
0	0.1722
5	0.0363
10	0.1826
15	0.6089

Table 7.18 *Plant availability example: system throughput capabilities calculated in the example*

Throughput capability of system (m^3/h)	*Probability*
0	0.0433
5	0.0007
10	0.0035
15	0.0167
90	0.0588
95	0.0046
100	0.8774

Then:

$$P(\mathrm{A} \mid \mathrm{B}) = \frac{P(B \mid A)P(A)}{P(B \mid A)P(A) + P(B \mid \bar{A})P(\bar{A})} \quad [7.14.3]$$

In this equation the term $P(A)$ is known as the prior probability, $P(A \mid B)$ as the posterior probability and $P(B \mid A)$ as the likelihood.

Equation 7.14.3 may also be reformulated to accommodate multiple outcomes. If the event A has n outcomes

$$P(A_j \mid B) = \frac{P(B \mid A_j)P(A_j)}{\sum_{i-1}^{n} P(B \mid A_j)P(A_i)} \quad [7.14.4]$$

7.14.2 Hypothesis formulation

Equation 7.14.3 may also be written in terms of a hypothesis H and an event E, which serves to confirm or deny the hypothesis:

$$P(H \mid E) = \frac{P(E \mid H)P(H)}{P(E \mid H)P(H) + P(E \mid \bar{H})P(\bar{H})} \quad [7.14.5]$$

7.14.3 Continuous formulation

There is also a continuous formulation of Bayes' theorem in terms of distributions. If X is a random variable, its density function may be written as $f_X(x)$. Then a formulation of Bayes' theorem in terms of such distributions is:

$$f_{Y|X}(y \mid x) = \frac{f_{X|Y}(x \mid y)f_Y(y)}{f_X(x)} \quad [7.14.6]$$

But

$$f_X(x) = \int_{-\infty}^{\infty} f_{X|Y}(x \mid y)f_Y(y)\,\mathrm{d}y \quad [7.14.7]$$

Hence

$$f_{Y|X}(y \mid x) = \frac{f_{X|Y}(x \mid y)f_Y(y)}{\int_{-\infty}^{\infty} f_{X|Y}(x \mid y)f_Y(y)\,\mathrm{d}y} \quad [7.14.8]$$

7.14.4 Failure rate estimation

A common problem in reliability work is the estimation of a failure rate and the revision of this estimate as more information becomes available. A typical situation might be that the initial estimate is one obtained from the literature which it is desired to revise in the light of works data.

If the failure rate is considered as a random variable, its density function may be written as $f_\Lambda(\lambda)$. The field data are assumed to be available as times to failure $t_1, \ldots, t_n$. Then from Equation 7.14.8, for the first time to failure t_1.

$$f_{\Lambda|T1}(\lambda \mid t_1) = \frac{f_{T1\mid\Lambda}(t_1|\lambda) f_\Lambda(\lambda)}{\int_{-\infty}^{\infty} f_{T1\mid\Lambda}(t_1|\lambda) f_\Lambda(\lambda)\,\mathrm{d}\lambda} \qquad [7.14.9]$$

At this stage the formulation is a general one. Its application may be illustrated by considering the common case of the revision of an initial estimate of the failure rate in the exponential distribution. In the terminology used here the exponential distribution itself may be written in terms of the random variable T:

$$f_T(t) = \Lambda \exp(-\Lambda t) \quad t \geq 0 \qquad [7.14.10a]$$

$$= 0 \quad t < 0 \qquad [7.14.10b]$$

If Λ is now considered to be a random variable, to be estimated on the basis of observed values of T, the exponential distribution just given may be rewritten as

$$f_{T|\Lambda}(t \mid \lambda) = \lambda \exp(-\lambda t) \quad t \geq 0 \qquad [7.14.11a]$$

$$= 0 \quad t < 0 \qquad [7.14.11b]$$

Since the failure rate is to be treated as a random variable, it is necessary to specify the form of the distribution which it follows. The distribution assumed is again the exponential distribution, so that

$$f_\Lambda(\lambda) = \mu \exp(-\mu\lambda) \qquad [7.14.12]$$

where μ is the parameter of this distribution. Its dimensions are time, or lifetime, being the inverse of those of λ.

Then, from Equations 7.14.9, 7.14.11 and 7.14.12

$$f_{\Lambda|T1}(\lambda \mid t_1) = \frac{\lambda \exp(-\lambda t_1) \mu \exp(-\mu\lambda)}{\int_0^{\infty} (\lambda \exp(-\lambda t_1) \mu \exp(-\mu\lambda)\,\mathrm{d}\lambda} \qquad [7.14.13]$$

which yields

$$f_{\Lambda|T1}(\lambda \mid t_1) = \lambda(\mu + t_1)^2 \exp[-(\mu + t_1)\lambda] \quad \lambda \geq 0 \qquad [7.14.14a]$$

$$= 0 \quad \lambda < 0 \qquad [7.14.14b]$$

By extension to further times to failure $t_2, \ldots, t_n$, it can be shown that

$$f_{\Lambda|T1,\ldots,T_n}(\lambda \mid t_1, \ldots, t_n) = \frac{\lambda^n}{n!}\left(\mu + \sum_{i=1}^{n} t_i\right)^{n+1} \exp\left[-\left(\mu + \sum_{i=1}^{n} t_i\right)\lambda\right] \qquad [7.14.15]$$

From this density function the mean value is determined in the usual way, the quantity obtained being the estimate $\hat{\Lambda}$ of the mean:

$$\hat{\Lambda} = \int_0^{\infty} f_{\Lambda|T1,\ldots,T_n}(\lambda \mid t_1, \ldots, t_n)\,\mathrm{d}\lambda \qquad [7.14.16]$$

The required result is thus:

$$\hat{\Lambda} = \frac{n+1}{\mu + \sum_{i=1}^{n} t_i} \qquad [7.14.17]$$

The estimate $\hat{t}$ of the mean life, or MTBF, is obtained as the inverse of that of the failure rate:

$$\hat{t} = \frac{\mu + \sum_{i=1}^{n} t_i}{n+1} \qquad [7.14.18]$$

This equation shows that for the case of the exponential distribution the estimate of the mean life is the average of the prior estimate and of the observed values times to failure.

As an illustration, consider the case where there is for an equipment a prior estimate μ of the time to failure of 8 months which is to be revised in the light of four further measurements ($n = 4$) of the times to failure of 17, 13, 18 and 12 (t_1 to t_4). Then from Equation 7.14.18 the estimated values are:

$$\hat{t} = \frac{8 + (17 + 13 + 18 + 12)}{4 + 1}$$

$$= 13.6 \text{ months}$$

$$\hat{\Lambda} = 0.074 \text{ failures/month}$$

7.15 Renewal Theory

Another technique for the analysis of repairable systems is renewal theory. Accounts of renewal theory are given in *Renewal Theory* (D.R. Cox, 1962) and by Shooman (1968a) and G.H. Mitchell (1972).

Renewal theory is illustrated here by considering the case of a single component system with instantaneous replacement of the component when it fails by another component. The theory is developed initially for the case where each replacement may be by a component with different failure characteristics.

Let system failures occur at time intervals t_1, $t_2, \ldots, t_n$. Then the system operating time τ_n to n renewals is:

$$\tau_n = t_1 + t_2 + \cdots + t_n \qquad [7.15.1]$$

The density function $f_{\tau n}(t)$ of τ_n is obtained by convolution of the individual density functions $f_1(t), f_2(t), \ldots, f_n(t)$. This is handled most easily in the Laplace domain. Then taking Laplace transforms, the convolution becomes:

$$f_{\tau n}(s) = f_1(s) \cdot f_2(s) \cdots f_n(s) \qquad [7.15.2]$$

For simplicity, consideration is now limited to the case where replacement is by identical components. Then Equation 7.15.2 becomes:

$$f_{\tau n}(s) = [f(s)]^n \qquad [7.15.3]$$

The probability that the nth renewal occurs before or at time t is given by the distribution function:

$$F_{\tau n}(t) = \int_0^t f_{\tau n}(t)\,\mathrm{d}t \qquad [7.15.4]$$

The mean, or expected, value of the time for n renewals is:

$$E[\tau_n] = \int_0^\infty t f_{rn}(t)\,\mathrm{d}t \tag{7.15.5}$$

The probability of the number N of renewals occurring exactly at time t is:

$$P(N = n) = F_{\tau n}(t) - F_{\tau n+1}(t) \tag{7.15.6}$$

The mean, or expected, value of N renewals in time t is:

$$E[N] = \sum_{n=0}^{\infty} nP(N = n) \tag{7.15.7}$$

From Equations 7.15.6 and 7.15.7

$$E[N] = \sum_{n=0}^{\infty} n[F_{\tau n}(t) - F_{\tau n+1}(t)] \tag{7.15.8}$$

Expanding the terms in Equation 7.15.8, it can be shown that:

$$E[N] = \sum_{n=1}^{\infty} F_{\tau n}(t) \tag{7.15.9}$$

The application of these relationships may be illustrated by considering the case where the components have an exponential failure distribution with constant failure rate λ, so that the density function is:

$$f(t) = \lambda \exp(-\lambda t) \tag{7.15.10}$$

Taking Laplace transforms

$$f(s) = \frac{\lambda}{s + \lambda} \tag{7.15.11}$$

and then substituting Equation 7.15.11 into Equation 7.15.3 yields

$$f_{\tau n}(s) = \left(\frac{\lambda}{s + \lambda}\right)^n \tag{7.15.12}$$

Inverting back into the time domain gives:

$$f_{\tau n}(t) = \lambda \frac{(\lambda t)^{n-1}}{(n-1)!} \exp(-\lambda t) \tag{7.15.13}$$

This equation is the Erlangian operating time density function.

The distribution function of Equation 7.15.4 may be integrated using the expression for the density function given in Equation 7.15.13. For example, for the first renewal ($n = 1$)

$$f_{\tau 1}(t) = \lambda \exp(-\lambda t) \tag{7.15.14}$$

Hence the distribution function is:

$$F_{\tau 1}(t) = \int_0^t \lambda \exp[-(\lambda t)]\mathrm{d}t \tag{7.15.15}$$

$$= 1 - \exp(-\lambda t) \tag{7.15.16}$$

and from Equation 7.15.5 the mean value

$$E[\tau 1] = \int_0^\infty t\lambda \exp(-\lambda t)\,\mathrm{d}t \tag{7.15.17}$$

$$= 1/\lambda \tag{7.15.18}$$

Furthermore, the probability given in Equation 7.15.6 may be written, by using Equation 7.15.4, as:

$$P(N = n) = \int_0^t f_{\tau n}(t)\,\mathrm{d}t - \int_0^t f_{\tau n+1}(t)\,\mathrm{d}t \tag{7.15.19}$$

Substituting Equation 7.15.13 in this equation yields

$$P(N = n) = \int_0^t \lambda \frac{(\lambda t)^{n-1}}{(n-1)!} \exp(-\lambda t)\,\mathrm{d}t - \int_0^t \lambda \frac{(\lambda t)^n}{n!} \exp(-\lambda t)\,\mathrm{d}t \tag{7.15.20}$$

which can be shown to reduce to

$$P(N = n) = \frac{(\lambda t)^n}{n!} \exp(-\lambda t) \tag{7.15.21}$$

Again, for the case of the first renewal ($n = 1$)

$$P(N = 1) = \lambda t \exp(-\lambda t) \tag{7.15.22}$$

and

$$E[N] = \sum_{n=1}^{\infty} F_{\tau n}(t) \tag{7.15.23}$$

But, using Equation 7.15.4 and then taking Laplace transforms:

$$F_{\tau n}(s) = \frac{f_{\tau n}(s)}{s} \tag{7.15.24}$$

From Equation 7.15.3

$$F_{\tau n}(s) = \frac{[f(s)]^n}{s} \tag{7.15.25}$$

Then

$$E[N(s)] = \frac{1}{s} \sum_{n=1}^{\infty} [f(s)]^n \tag{7.15.26}$$

$$= \frac{1}{s}[f(s) + f(s)^2 + \cdots] \tag{7.15.27}$$

$$= \frac{1}{s} \frac{f(s)}{1 - f(s)} \tag{7.15.28}$$

Substituting from Equation 7.15.11:

$$E[N(s)] = \frac{1}{s} \frac{\lambda/(s + \lambda)}{\lambda/(s + \lambda)} \tag{7.15.29}$$

$$= \lambda/s^2 \tag{7.15.30}$$

Inverting into the time domain:

$$E[N] = \lambda t \tag{7.15.31}$$

7.16 Replacement Models

One of the principal decisions in the maintenance of plant is whether to replace an equipment. Support for such decisions is provided by replacement theory. Treatments of replacement are given by Dean (1963), Hastings (1970), Jardine (1970a,b) and Mitchell (1972).

Some reasons for replacing an equipment are that: (1) it has failed, (2) it is about to fail, (3) it has deteriorated and (4) an improved version has become available.

In most replacement models the quantity sought is the overall economic optimum. Some models treat the problem solely in terms of the equipment, whilst others take into account the effects on the process either of outright failure or of deterioration of the equipment. Another distinction is between models which allow for the time to effect the replacement and those which do not.

A somewhat different model is required where the case considered is that exemplified by the lightbulb replacement problem. Here the cost of the actual replacement actions is high and has a significant influence on the result. This type is known as a 'group replacement model'. Treatments are given by Bartholemew (1963) and Naik and Nair (1965).

Other cases to be considered include replacement as opportunity arises, possibly during a major shut-down, and replacement of an equipment which cannot be repaired to the 'as new' condition.

In general, for simple items which are used in large numbers, what is required is straightforward rules, while for more complex individual equipment a more detailed analysis may be justified.

If the time-scale over which replacement occurs extends over a number of years, it may be necessary to allow for the change in the value of money using a technique such as net present value.

A common type of replacement model is that which considers only the equipment and determines the optimum trade-off between capital cost and operating cost. It is necessarily assumed that the latter increases with time, since if it does not, the best policy is to run the equipment until it fails. A replacement model of this type has been given by G.H. Mitchell (1972) and is as follows:

$$C = \frac{C_c - S}{n} + \frac{1}{n}\int_0^n f(t)\,dt \qquad [7.16.1]$$

where C is the average annual cost of operation, C_c is the capital cost of the equipment, $f(t)$ is the rate of expenditure on maintenance, t is time, and S is the scrap value of the equipment. As just stated, $f(t)$ is taken to increase with time t. Then it can be shown by differentiating Equation 7.16.1 that the average annual cost is a minimum when

$$f(n) = \frac{C_c - S}{n} + \frac{1}{n}\int_0^n f(t)\,dt = C \qquad [7.16.2]$$

Thus the equipment should be replaced when the current maintenance cost becomes equal to the average annual cost to date.

Further replacement models are given by Jardine (1970a) who treats the cases of failure replacement + preventive replacement, where the latter is (1) fixed-term and (2) based on equipment age.

7.17 Models of Failure: Strength–load Interaction

7.17.1 Strength and load

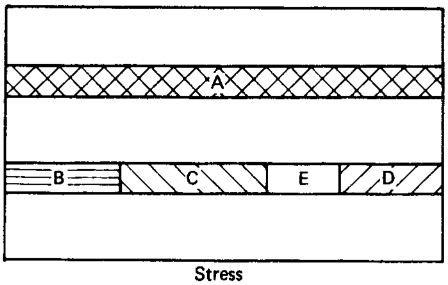
Failure occurs when the load on a component exceeds the strength or, more generally, when the duty exceeds the capability. There are various factors which may cause the load to be higher, or the strength lower, than expected. Factors which increase stress include: internal residual stresses and stress raisers; reductions of cross-sectional area due to size variations in manufacture, wear and corrosion; and applications of the component different from that for which it was designed. Factors which reduce strength include quality variations in manufacture, defects, fatigue and creep.

7.17.2 Safety factor and safety margin

The traditional method of allowing for factors which increase stress or reduce strength is the use of a safety factor. The approach has been to define the safety factor as the ratio of the mean of the strength to that of the load, both mean values being assumed constant. This is a deterministic approach, and increasingly it is being superseded by a probabilistic approach which allows for the variability of both strength and load. This does not mean, however, that concepts of the safety factor, and the associated safety margin, are abandoned, but merely that they are redefined, as described below.

7.17.3 Deterministic approach: mean of strength and load

Traditional safety factors are shown in Figure 7.16. The design safety margin (the difference between the design strength and the design stress) and the design safety factor (the ratio of the design strength and the design stress) are normally substantial. However, by the time account is taken of the margin of ignorance, which is the sum of the increases in stress and the decreases in strength, the actual safety margin and safety factor are greatly reduced.



A Assumed static strength
B Design working stress
C Factors increasing stress: internal residual stresses, stress raisers, size variations in manufacture, wear, corrosion
D Factors reducing strength: quality variations in manufacture, defects, fatigue, creep

Design safety margin = A − B
Margin of ignorance = C + D
Actual safety margin = A − (B + C + D) = E
Design safety factor = A/B
Actual safety factor = A/(B + C + D)

Figure 7.16 *Design and actual safety factors and margins*

This reduction in the design safety factor is important. The actual safety factor is often much less than might be supposed and the potential causes of reduction in the safety factor need to be given close attention. As stated earlier, this approach is based essentially on the means of the strength and of the load.

7.17.4 Probabilistic approach: variability of strength and load

The weakness of the approach just described is that it does not take into account the variability of the strength and of the load. A more realistic representation of failure is shown in Figure 7.17. Both the strength and the load can be expressed as density functions characterized by a mean and a spread. Failure occurs when the tails of the distributions overlap and create an area where the load exceeds the strength.

7.17.5 Interference theory

The effect of this interaction between load and strength can be quantified using interference theory. Accounts of interference theory are given by Lloyd and Lipow (1962) and von Alven (1964). In this subsection an account is given of the basic theory. A failure model based on the interference approach is given in Section 7.17.

The basic approach may be illustrated by considering the case where the variabilities of the load and the strength can each be represented by a normal distribution. Then the joint density function $g(z)$ for the load to exceed the strength is:

$$g(z) = \int_b^a f(x) f(x - z)\, \mathrm{d}x\, \mathrm{d}z \qquad [7.17.1]$$

with

$$z = x - y \qquad [7.17.2]$$

where $f(x)$ is the density function of the load x, $f(y)$ is the density function of the strength y $(= x - z)$, and z is the difference between x and y.

A safety parameter may be defined as:

$$\phi = S/L \qquad [7.17.3]$$

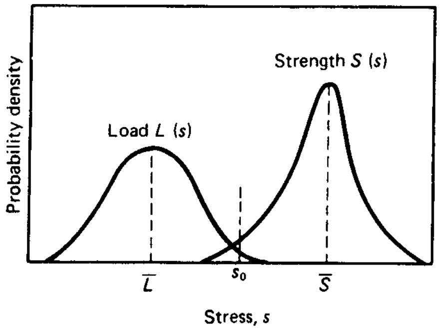


Figure 7.17 *Effect of variability of strength and load on failure (A.D.S. Carter, 1973) (Reproduced by permission of the Institution of Mechanical Engineers)*

where L is the load, S is the strength, and ϕ is the safety parameter. The variability of the load and the strength may be written as:

$$L = m_x + n_x \sigma_x \qquad [7.17.4]$$

$$S = m_y - n_y \sigma_y \qquad [7.17.5]$$

Since the load has a normal distribution, its density function is:

$$f(x) = \frac{1}{\sigma_x (2\pi)^{1/2}} \exp\left[-\frac{(x - m_x)^2}{2\sigma_x^2} \right] \qquad [7.17.6]$$

Similarly, the density function of strength is:

$$f(y) = \frac{1}{\sigma_y (2\pi)^{1/2}} \exp\left[-\frac{(y - m_y)^2}{2\sigma_y^2} \right] \qquad [7.17.7]$$

From Equations 7.17.1, 7.17.6 and 7.17.7, it can be shown that:

$$g(z) = \frac{1}{[2\pi(\sigma_x^2 + \sigma_y^2)]^{1/2}} \exp\left[-\frac{(z + m_y - m_x)^2}{2(\sigma_x^2 + \sigma_y^2)} \right] \qquad [7.17.8]$$

which itself is the density function of a normal distribution with a mean value

$$m_z = m_x - m_y \qquad [7.17.9]$$

and standard deviation

$$\sigma_z = (\sigma_x^2 + \sigma_y^2)^{1/2} \qquad [7.17.10]$$

Then the probability that the load exceeds the strength is given by the distribution function

$$G(z) = \int_0^\infty g(z)\, \mathrm{d}z \qquad [7.17.11]$$

which may be integrated to give

$$G(z) = \frac{1}{(2\pi)^{1/2}} \int_u^\infty \exp(-v^2/2)\, \mathrm{d}v \qquad [7.17.12]$$

with

$$u = \frac{m_y - m_x}{(\sigma_x^2 + \sigma_y^2)^{1/2}} \qquad [7.17.13]$$

$$v = \frac{z + m_y - m_x}{(\sigma_x^2 + \sigma_y^2)^{1/2}} \qquad [7.17.14]$$

As an illustration, consider the example given by von Alven (1964):

$$m_x = 1; \quad \sigma_x = \sigma_y = 0.4; \quad n_x = n_y = 2; \quad \phi = 1.25$$

From Equations 7.17.3–7.17.5,

$$m_y = 3.05$$

and from Equation 7.17.13

$$u = 3.6$$

Then evaluating the distribution function in Equation 7.17.12 using statistical tables for the integral of the distribution function of the normal distribution between 3.6 and ∞, the value is found to be of the order of 0.0001, indicating that the load may be expected to exceed the strength once in every 10,000 loadings.

7.17.6 Carter's rough loading model

A theory of failure based on the overlap of the strength and load distributions has been developed by A.D.S. Carter (1973). The approach is illustrated in Figure 7.17 and is broadly as follows.

Initially, a component has a strength s_0 but this gradually deteriorates so that by the ith application of load the strength is reduced to $s_0 - \Delta s_i$. The probability (P_1) of obtaining a component with initial strength lying between s_0 and $s_0 + \mathrm{d}s$ is:

$$P_1 = S(s_0)\,\mathrm{d}s \qquad [7.17.15]$$

The probability (P_2) of encountering a load which is less than $s_0 - \Delta s_i$ is:

$$P_2 = \int_0^{s_0-\Delta s_i} L(s)\,\mathrm{d}s \qquad [7.17.16]$$

Then the probability (P_3) of encountering a load which is less than the current strength of the component the initial strength of which is s_0 in any of the n applications of load is:

$$P_3 = \prod_{i=1}^{n} \int_0^{s_0-\Delta s_i} L(s)\,\mathrm{d}s \qquad [7.17.17]$$

And the probability (P_4) of obtaining a component of initial strength s_0 and of encountering a load which over n applications is always less than its strength:

$$P_4 = S(s_0)\,\mathrm{d}s \prod_{i=1}^{n} \int_0^{s_0-\Delta s_i} L(s)\,\mathrm{d}s \qquad [7.17.18]$$

Then the reliability of the component is:

$$R(n) = \int_0^{\infty} S(s) \prod_{i=1}^{n} \left[\int_0^{s_0-\Delta s_i} L(s)\,\mathrm{d}s \right] \mathrm{d}s \qquad [7.17.19]$$

The decrements of strength Δs_i may be expressed in terms of a constant scaling factor σ and a shaping factor $f(i)$:

$$\Delta s_i = \sigma f(i) \qquad [7.17.20]$$

with

$$f(i) = (i-1)p \qquad [7.17.21]$$

where $p < 1$ gives a fatigue-type curve; $p = 1$ gives a corrosion deterioration-type curve; and $p > 1$ gives an erosion/wear-type curve.

The hazard rate z is then obtained from the relationship:

$$z(n) = -\frac{1}{R(n)}\frac{\mathrm{d}R(n)}{\mathrm{d}t} \qquad [7.17.22]$$

If preferred, n may be replaced by kt to give the reliability as a function of time.

The quantities in Equation 7.17.19 are not normally known, but the theory can be used to explore the implications of making various assumptions. In Carter's work this was done by expressing $S(s)$ and $L(s)$ as Weibull distributions with the shape factor β given a value of 3.44 to approximate normal distributions. Various values of the means $\bar{S}$ and $\bar{L}$ and standard deviations σ_s and σ_L of the strength and load distributions were investigated. Three regimes were distinguished

$\sigma_L \ll \Delta_s$	smooth loading
$\sigma_L = \sigma_s$	medium loading
$\sigma_L \gg \sigma_s$	rough loading

The following quantities were defined:

$\bar{S}/\bar{L}$	safety factor
σ_L/σ_s	roughness of loading
$\dfrac{\bar{S}-\bar{L}}{(\sigma_s^2+\sigma_L^2)^{1/2}}$	safety margin

This definition of safety margin is different from that conventionally used, as described above.

Some examples of hazard rate curves obtained by Carter are shown in Figure 7.18. The values of σ_s and σ_L were chosen to give a safety margin of six standard deviations and the scaling factor σ was chosen to give $\Delta s_{100} = 2.333$. These results throw considerable doubt on the applicability of the bathtub curve to mechanical components.

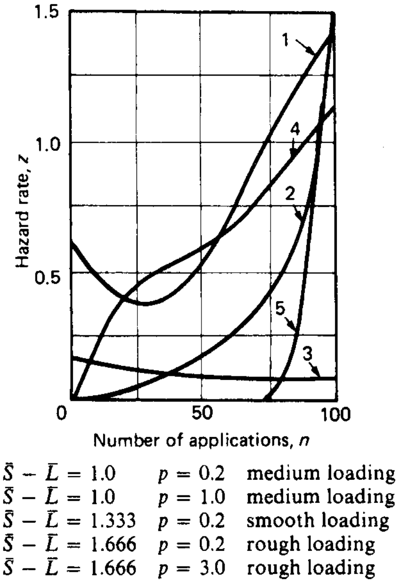

***Figure 7.18** Effect of mean and spread of strength and load on hazard rate (A.D.S. Carter, 1973) (Reproduced by permission of the Institution of Mechanical Engineers)*

7.18 Models of Failure: Some Other Models

7.18.1 Bathtub curve revisited

As already indicated, the original bathtub curve concept has come in for a good deal of criticism. Frequently it appears that it is honoured more in the breach than the observance. The rough loading theory of Carter gives one indication why this should be so.

A modern critique of the concept is that by Moubray (1991), who gives instead the failure patterns shown in Figure 7.19. Moubray states that studies on civil aircraft have shown the following distribution of patterns of failure in terms of the curves in Figure 7.19:

A	4%	*D*	7%
B	2%	*E*	14%
C	5%	F	68%

Discussion of these features is taken up again in Section 7.19.

7.18.2 Lightbulb curve

Systems with large numbers of components often tend to exhibit a constant hazard rate. This is readily understood intuitively in terms of a smoothing out of particular hazard rate characteristics of individual components.

The phenomenon is well illustrated by the so-called 'lightbulb curve' shown in Figure 7.20. If a building is provided with new lightbulbs throughout, then assuming that these fail by wearout with a normal distribution and that the failed bulbs are replaced each day, the number of failures recorded per day will be as shown in the figure. The dotted curves (a)–(e) show the numbers actually failing, and the horizontal full line shows the constant number of failures per day to which the system is tending. Each successive curve has a smaller modal value and higher spread than the previous one. Eventually the number of failures recorded per day will become constant. If the lighting system of the building taken as a whole is considered as a series system, then when the number of bulb failures has become constant, the system hazard rate is also constant, so that the system itself appears to have an exponential failure distribution, although its components have a normal failure distribution.

7.18.3 Drenick's theorem

A theoretical demonstration that systems with many components tend to have a constant hazard rate is given by Drenick's theorem (Drenick, 1960). A modified version of this theorem has been given by Shooman (1968a). For an n-component series system, from Equation (7.6.4):

$$\ln R(t) = -\sum_{i=1}^{n} H_i(t) = -\sum_{i=1}^{n} \int_0^t z_i(t)\,\mathrm{d}t \qquad [7.18.1]$$

Assume that the hazard rates for small values of t can be expressed as

$$z_i = a_i + b_i t^m \qquad [7.18.2]$$

the value of m being the highest found for the n components. Then

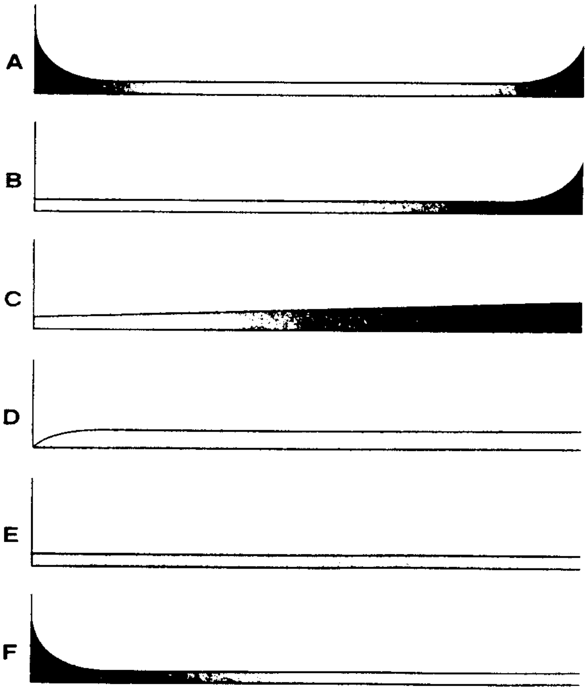

Figure 7.19 Some patterns of equipment hazard rate, including and additional to the bathtub curve (Moubray, 1991) (Courtesy of Butterworth-Heinemann)

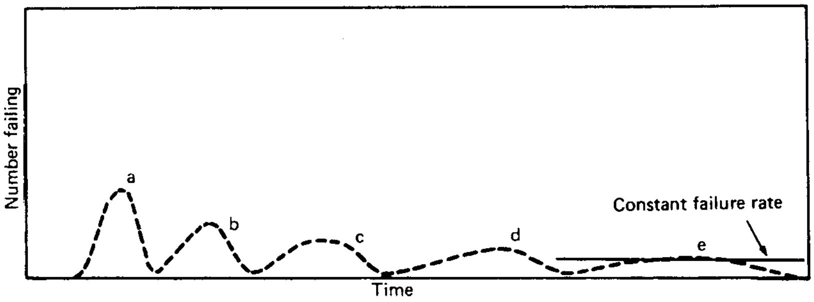

Figure 7.20 *The lightbulb curve*

$$\ln R(\tau) = -\tau - k\frac{\tau^{m+1}}{\bar{\lambda}^m} \qquad [7.18.3]$$

with

$$\bar{\lambda} = \sum_{i=1}^{n} a_i \qquad [7.18.4]$$

$$k = \frac{1}{(m+1)\bar{\lambda}}\sum_{i=1}^{n} b_i \qquad [7.18.5]$$

$$\tau = \bar{\lambda}t \qquad [7.18.6]$$

Assuming that as $n \to \infty$, $\bar{\lambda} \to \infty$, and that k is bounded, then as $n \to \infty$

$$\ln R(\tau) = -\tau \qquad [7.18.7]$$

and hence

$$R(t) = \exp(-\bar{\lambda}t) \qquad [7.18.8]$$

The theorem assumes that the system has a series structure. If the system contains parallel paths, the treatment is pessimistic. In practice, there are many systems which are well fitted by the theorem, but also many which are not.

The equation

$$k = \sum_{i=1}^{n} b_i/(m+1)\bar{\lambda}$$

is bounded, provided at least one $z_i(0) \neq 0$. Its rate of convergence depends, however, on the number of components for which $z_i(0) = 0$. If these are numerous, the convergence is slow.

The implications of this theorem are considered in more detail by Shooman (1968a).

7.19 Failure Behaviour and Regimes

7.19.1 Failure regimes

The measures which can be taken to reduce failure depend very largely on the failure regime of the equipment. The three regimes are: (1) decreasing hazard rate (2) constant hazard rate and (3) increasing hazard rate. The bathtub curve illustrates these three regimes but, as indicated, this model is honoured as much in the breach as in the observance. However, this does not alter the fact that the failure regime must be one or other of those just listed.

The failure regime of an equipment may be identified using the methods described in Section 7.20. In particular, the failure data may be fitted to the Weibull distribution. The relationship between the failure regime and the Weibull shape factor β is:

$\beta < 1$	decreasing hazard rate (early failure);
$\beta = 1$	constant hazard rate (constant failure);
$\beta > 1$	increasing hazard rate (wearout failure).

7.19.2 Catastrophic failure vs tolerance failure

Some failures occur suddenly, whilst others develop much more gradually. In early work the two types were often called ‘catastrophic failure’ and ‘tolerance failure’. These terms were not well chosen. There is no implication that a catastrophic failure has any consequences wider than the failure itself. Nor is there any implication that catastrophic failures occur early in life or tolerance failures late in life.

Tolerance failures are associated with the interaction between the component and the system. Catastrophic failures have a greater tendency to occur independently of the system.

7.19.3 Bimodal failure distributions

Analysis of failure data not infrequently yields a failure density function with two distinct peaks, indicating a bimodal distribution. Such a density function may be written as

$$f(t) = pf_1(t) + (1-p)f_2(t) \qquad [7.19.1]$$

where p is a weighting factor. As described below, early failure can give rise to a bimodal failure distribution.

7.19.4 Wearout failure

Two principal types of failure are wearout failure and early failure. These are now considered in more detail. The discussion here is limited to failure itself and discussion of the determination of the type of failure by data analysis and of maintenance policies appropriate to the types of failure is deferred to later sections.

Failure by wearout is one of the principal failure regimes of industrial equipment. Some of the causes of wearout are: (1) fatigue, (2) wear, (3) corrosion and (4) erosion. It is often associated with contact with process materials.

Wearout failure is a common experience with everyday objects such as clothes and tools. It is natural, therefore, that there should be carried over from this a preconception that it is the dominant mode in industrial equipment but, as just indicated, this can be misleading.

In the results quoted in Section 7.18 for failures in civil aircraft, only some 6% are classified as in some way involving wearout (patterns A and B). In the process industries the overall operating environment is probably conducive to a higher proportion of wearout failures, but how much higher is uncertain.

7.19.5 Early failure

Another of the principal failure regimes of industrial equipment is early failure. Although initially perceived as failure due essentially to premature failure of weak components, there is now better understanding that there is more to early failure than this, and that it can be the dominant mode. In particular, it is now appreciated that early failure in the sense of a decreasing hazard rate is a phenomenon which is not confined to new equipment but is often exhibited by old equipment. The proportion of early failure in the results for civil aircraft quoted in Section 7.18 is 68% (pattern F).

Causes of early failure may be grouped under three headings: (1) those which result in failure of newly commissioned equipment, (2) those which result in failure of equipment which has been operating for some time and (3) those associated with start-up and shut-down stresses, whether on new or old equipment. Among the former causes, in design and commissioning, are: (1) incorrect design specification, (2) incorrect design, (3) incorrect user specification and selection, (4) incorrect manufacture, (5) incorrect installation and (6) incorrect commissioning and initial operation.

Causes of early failure in equipment with a longer operating history, centre on the quality of the maintenance and include: (1) incorrect fault identification, (2) incorrect repair technique, (3) incorrect replacement parts, (4) incorrect reassembly and alignment, (5) dirty working conditions and (6) disturbance to other parts of the equipment. The effect of such failings is that the equipment is not fully restored to the 'as new' condition after repair or overhaul. Underlying these causes of early failure due to maintenance are two more fundamental causes. One is the conduct of unnecessary preventive maintenance (PM). The other is inadequate training and/or discipline of maintenance personnel.

The third group of causes of early failure is the mechanical and thermal stresses associated with plant start-up and shut-down.

Evidence of early failure in process equipment was found in a study by Berg (1977) who investigated some 600 centrifugal and air vacuum pumps and some 200 bottom run-off valves and found values of the shape parameter β ranging from 0.735 to 1.072. Aird (1977b) obtained values of β as low as 0.5 for some mechanical equipment in process plants.

In a further study Sherwin and Lees (1980) found early failure to be prevalent in both process plant equipment and hospital autoclaves. The process plant investigation was done in two stages. In the first stage failure data were collected and analysed and the maintenance tasks were observed. Recommendations were then made for improvement to the conduct of maintenance. In the second stage, 2 years later, further data collection and analysis was carried out. The items of plant equipment studied were: (1) acid pumps, (2) water pumps, (3) vacuum pumps, (4) agitators, (5) screw conveyers, (6) filters, (7) fans, (8) heat exchangers, (9) evaporator flash vessels, (10) other tanks and vessels, (11) pipes and ducts and (12) other items. The failure modes were classified as: (1) blockages, (2) leaks, (3) drives, (4) electrical, (5) holes and breaks, (6) instruments, (7) valves and (8) other faults. The authors found that with few exceptions the failures could be characterized as early failures with β values less than unity. In the first stage, values of β obtained on six types of equipment ranged from 0.61 to 1.07, whilst β values for five failure modes of the acid pumps ranged from 0.48 to 0.76 with the overall value for the eight failure modes being 0.63. As stated, the maintenance work was also observed. The research revealed many of the problems of maintenance work listed above, such as incorrect use of consumables, use of incorrect parts, failure to realign correctly and failure to adjust clearances correctly, as well as working in dirty conditions. Above all, it pointed to a lack of training. Recommendations were made to rectify these shortcomings, in particular proposals on training, and these were acted on. Analysis of the failure data from the second stage found that of the 12 types of equipment, 8 showed improvements in MTBF and 3 deteriorations in MTBF, with one type classed as N/A (not applicable). The MTBFs of the acid, water and vacuum pumps, for example, were increased from 47.5 to 108 days, from 75.8 to 382 and from 57.3 to 117, respectively, and that of the agitators from 910 to 4641 days.

The hospital study was on autoclaves used for sterilization, which were breaking down at an unacceptable frequency. The study yielded results remarkably similar to those on the process plant. Again early failure ($\beta < 1$) was the dominant regime. Recommendations were made and acted on, particularly with respect to training, and the overall failure rate was reduced from 0.065 to 0.014 failures/cycle.

These studies indicate that as a result of early failure the overall failure rate of the equipment is higher than it need be and often never settles down to the lower constant failure rate which might be regarded as the more 'normal' condition. The concept of 'maintenance induced' failure has long been familiar to plant engineers. The investigations described give it statistical support.

7.19.6 Burn-in

In the foregoing discussion wearout and early failure have been viewed as failure regimes. It is also of interest to develop models of failure in these regimes. An account of such modelling is given in *Burn-In* (Jensen and Petersen, 1982).

The starting point is the observation that analysis of failure data for components often gives a bimodal distribution, such that the failure density function exhibits two distinct peaks: the first for 'freak' failures and the second for the main failures. An example is the work of Herr, Baker and Fox (1968) on the failure of electronic components.

Jensen and Petersen have developed a model for the freak failures which is based on two assumptions: (1) the strength of all components deteriorates with time and (2) the strength of weak components deteriorates faster. The more rapid deterioration of the weaker components results in a sharper separation between the peaks of the two failure distributions.

The foregoing refers to components in isolation. Another concept developed by Jensen and Petersen is that once incorporated in a system, the susceptibility to failure of some of the components may be drastically increased. They term this phenomenon 'infant mortality' and treat it as distinct from freak failures. In their terminology, the early failures are made up of the two separate sets of failures (freak and infant mortality). It follows that there is potential for a failure distribution which is not just bimodal but trimodal.

The implications of such concepts of early failure for burn-in policies are discussed in Section 7.25.

7.20 Failure Data Analysis

Guidance on current performance in equipment reliability and on measures which may be taken to improve it can be obtained from the analysis of failure data.

7.20.1 Need for failure data

The application of reliability techniques creates a demand for data on equipment failure and repair time, on other failure-related events and on human error. These data may be obtained from the literature, from data banks or within the works. Usually it is possible to obtain approximate data fairly readily, but the determination of accurate data tends to involve much more effort. It is wasteful, therefore, to seek for greater accuracy in the data than the problem warrants.

The accuracy required in the data varies considerably between different types of reliability calculation and even between different parts of the same calculation. In general, where the reliability problem has a structure, as in a comparison of a simple equipment with a parallel or stand by system or in a fault tree analysis, less accurate data may often be used, at least in some parts of the calculation. Thus in a fault tree study, for example, some branches of the tree may be sensitive to the failure rates used, whilst others may not be. On the other hand, where the problem is a straight comparison, as between the failure rates of two instruments, the accuracy required is clearly greater.

Often, for the solution of the reliability problem to be clear it is sufficient to know that the failure rate lies between certain broad limits. In such cases it may be sufficient to rely on expert judgement or on relatively crude failure data rather than on accurate data.

7.20.2 Types of failure data

The failure information required for reliability work includes not only data on (1) overall failure rates, but also data on (2) failure rates in individual modes, (3) variation of failure rates with time and (4) repair times.

Failure modes can be classified in several ways. Some important categories of failure mode are (1) condition, (2) performance, (3) safety and (4) detection. In the failure classification based on condition, a failure mode is exemplified by a faulty seal on a pump or by a defective gearbox on an agitator. It is the failure classification which is normally used in maintenance. In the classification by performance, illustrations of failure are inability of a heat exchanger to achieve the required heat transfer or of a pump to give the specified head. The safety classification divides failure into fail-safe and fail-to-danger in the context of the process. The detection classification makes a distinction between revealed and unrevealed failure. These different categories of failure mode are particularly important in instruments and are discussed further in Chapter 13.

Generally, information on the variation of failure rate with time is not available and therefore is not used much in ordinary reliability work, but it is important in relation to maintenance problems. It is also necessary to have information on human error rates. This aspect is discussed in Chapter 14.

Other information required relates to other events which have a bearing on failure. Typical examples are the probability of a worker being nearby when an explosion occurs in an equipment, the distance travelled by a vapour cloud before it finds a source of ignition and the time taken for the fire services to reach the scene of a tanker crash.

For availability studies the type of data used varies. In some cases the availability is determined from the failure rates and repair times of the basic equipment. In other cases data on the availability of blocks of plant are used.

Failure rates may be expressed in terms of several parameters. The parameter most commonly used is time, but it may be appropriate to distinguish between operating time and non-operating time, and other measures such as the number of cycles or the number of demands are appropriate in some cases. In this connection it should be emphasized that it is often not known which is the important measure in a particular case. Thus misleading results may be obtained if a particular failure is expressed as failures/year when failures/cycle would be more appropriate.

7.20.3 Failure data sources, data collection and data banks

The sources of failure data are essentially external sources such as the literature and data banks. Alternatively, data may be collected within the works. Often it is the works which is the most dependable source of applicable data, and in this case it is necessary to have some form of data collection system. In other cases, particularly for rare events, it will be necessary to make use of the external sources.

The acquisition of data from these various sources is not straightforward. The data are of use only if they are of the right type, originate from a dependable source and apply to the case in hand. These and other issues related to failure data are discussed in Appendix 14.

7.20.4 Fundamentals of failure data analysis

Analysis of failure data should begin with consideration of the fundamental qualitative factors. One of these factors is the appropriateness of lumping together, as a homogenous set, equipments which may differ in design, manufacture, system function and process environment. Another factor is the parameter by which the failure rate is to be measured. As mentioned, this is usually time, but in some cases another measure such as the number of cycles is more suitable.

The qualitative analysis which can be done depends on the information available. Some items which can be calculated are:

(1) overall failure rates;
(2) failure rates in individual modes;
(3) confidence limits and bounds on failure rates;
(4) failure distributions;
(5) repair time distributions.

Frequently, the only information available is the total number of failures and the total operating time of the equipments, and the analysis is restricted to calculation of the overall failure rate and corresponding mean life.

7.20.5 Failure rates in individual modes

If the failure modes and their relative frequency are available, they are often analysed in the form of a histogram, as shown in Figure 7.21. In many cases there are a few failure modes which have a high relative frequency followed by a larger number of low frequency modes. This is generally referred to as a 'Pareto-type distribution' of failure modes.

It is the failure rates in the individual modes which are the data primarily required for fault tree analysis and for improvement of equipment performance by design and by maintenance.

7.20.6 Confidence limits on failure frequency and mean life

The confidence which can be placed in the estimate of the mean life depends on the number of failures recorded. If this number is small, it may be useful to determine the confidence limits. For the estimate of the mean life in the exponential distribution, the confidence limit may be determined using the χ^2 distribution.

It is necessary to distinguish between the case where the end of the test period T coincides with the final failure n and that where it does not. In the latter case it is conservative to assume that a further failure was just due to occur when the test was terminated.

For the failure-terminated test with replacement, the estimate of the mean life is

$$\hat{m}_1 = \frac{T}{n} \qquad [7.20.1]$$

and the degrees of freedom f are

$$f_1 = 2n \qquad [7.20.2]$$

whilst for the time-terminated test

$$\hat{m}_2 = \frac{T}{n+1} \qquad [7.20.3]$$

and

$$f_2 = 2(n+1) \qquad [7.20.4]$$

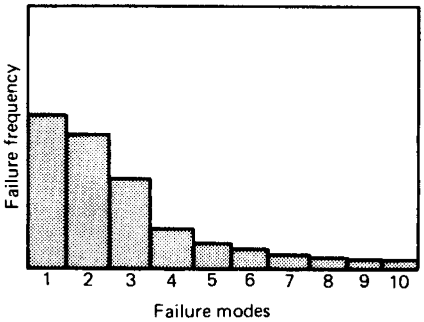

Figure 7.21 *Failure modes of an equipment*

Then for the failure-terminated test it can be shown that the ratio $f_1\hat{m}_1/m$ has a χ^2 distribution. For a two-sided confidence interval at a confidence level $(1-\alpha)$

$$P\left(\chi^2_{1-(\alpha/2):f1} \leq \frac{f_1\hat{m}_1}{m} \leq \chi^2_{\alpha/2:f1}\right) = 1-\alpha \qquad [7.20.5]$$

Then the lower limit L and the upper limit U of the ratio $m/\hat{m}$ are:

$$L\left(\frac{m}{\hat{m}}\right) = \frac{f_1}{\chi^2_{\alpha/2:f1}} \qquad [7.20.6]$$

and

$$U\left(\frac{m}{\hat{m}}\right) = \frac{f_1}{\chi^2_{1-\alpha/2:f1}} \qquad [7.20.7]$$

with

$$\hat{m} = \hat{m}_1 = \frac{T}{n} \qquad [7.20.8]$$

For the time-terminated test it can be shown that:

$$L\left(\frac{m}{\hat{m}}\right) = \frac{f_1}{\chi^2_{\alpha/2:f2}} \qquad [7.20.9]$$

and

$$U\left(\frac{m}{\hat{m}}\right) = \frac{f_1}{\chi^2_{1-(\alpha/2):f1}} \qquad [7.20.10]$$

again with $\hat{m}$ defined by Equation 7.20.8.

Values of the percentage points of the χ^2 distribution may be obtained from standard tables (e.g., Yamane, 1967, p. 879). It should be noted that some tables give the α percentage points and others the $(1-\alpha)$ percentage points. A graph showing the confidence limits on $m/\hat{m}$ according to Equations 7.20.9 and 7.20.10 is given in Figure 7.22.

As an illustration, consider the situation in which 5 failures have been recorded on 10 pumps over a period of half a year, with the final failure occurring before the end of the observation period, and in which it is required to estimate the confidence limits within which the ratio $m/\hat{m}$ lies at a 90% confidence level. Then

$n = 5$ failures

From Equation 7.20.8

$$\hat{m} = \frac{0.5 \times 10}{5} = 1 \text{ year}$$

From Equations 7.20.2 and 7.20.4

$$f_1 = 10$$
$$f_2 = 12$$

For a 90% confidence level, $\alpha = 0.1$. From tables of percentage points of the χ^2 distribution

$$\chi^2_{\alpha/2:f2} = \chi^2_{0.05:12} = 21.0$$
$$\chi^2_{1-(\alpha/2):f1} = \chi^2_{0.95:10} = 3.94$$

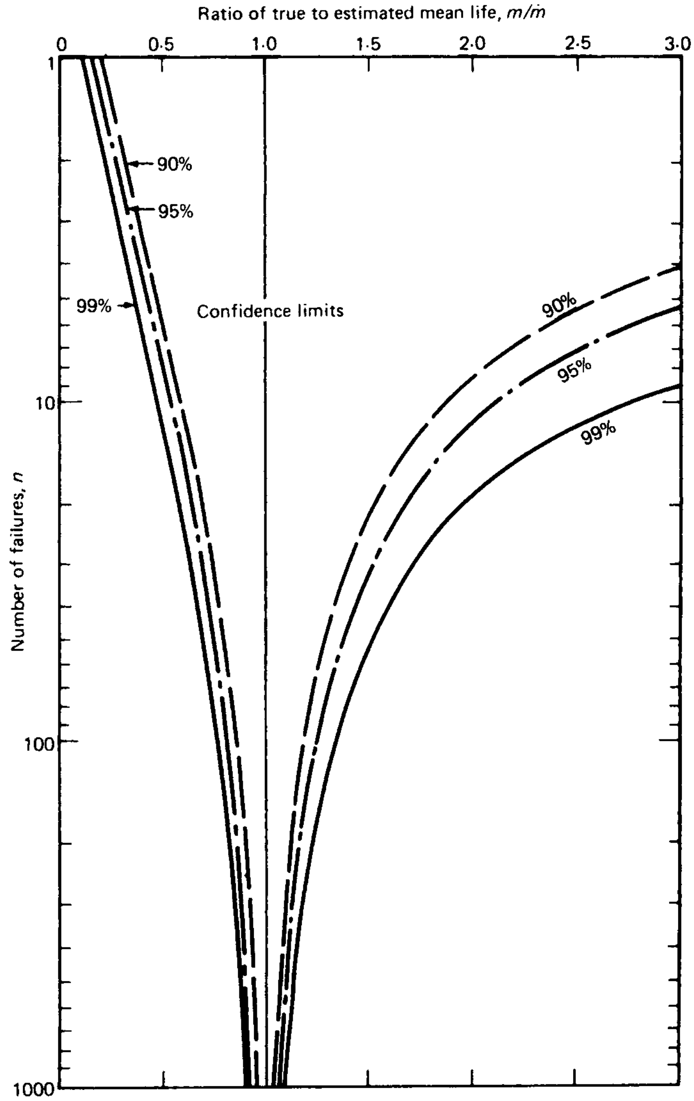

Figure 7.22 Two-sided confidence limits for the ratio of true to estimated mean life m/ṁ vs number of failure n in a time-terminated test with an exponential failure distribution (Buffham, Freshwater and Lees, 1971) (Reproduced by permission of the Institution of Chemical Engineers)

Then from Equations 7.20.9 and 7.20.10, the lower and upper confidence limits on the ratio $m/\hat{m}$ are:

$$L\left(\frac{m}{\hat{m}}\right) = \frac{10}{21.0} = 0.476$$

and

$$U\left(\frac{m}{\hat{m}}\right) = \frac{10}{3.94} = 2.54$$

Alternatively, the confidence limits may be obtained from Figure 7.22. Then

$$L(m) = 0.476 \text{ year}$$

$$U(m) = 2.54 \text{ year}$$

In some cases no failures are observed. Nevertheless, it is still possible to make an estimate of the lower limit of the ratio $m/\hat{m}$. For a one-sided confidence limit at a confidence level $(1 - \alpha)$:

$$L\left(\frac{m}{\hat{m}}\right) = \frac{f_2}{\chi^2_{\alpha:f2}} \qquad [7.20.11]$$

with

$$\hat{m} = \hat{m}_2 = \frac{T}{n+1} \qquad [7.20.12]$$

$$f_2 = 2 \qquad [7.20.13]$$

$$\chi^2_{\alpha:2} = 4.61$$

Then from Equation 7.20.11 the lower confidence limit on the ratio $m/\hat{m}$ is

$$L\left(\frac{m}{\hat{m}}\right) = \frac{2}{4.61} = 0.434$$

and that on the mean life is $L(m) = 4.34$ years.

Further accounts of confidence limits on failure data are given by Bazovsky (1961) and A.E. Green and Bourne (1972).

There is often a quite wide spread in failure rates reported by various sources. The variability of failure rates may be described by a log–normal distribution. Since this distribution has two parameters, it is determined by the end-points of a suitably defined range. This method of describing failure data was extensively used in the *Rasmussen Report* (AEC, 1975). The use of these log–normal distributions in fault trees in this study is discussed in Chapter 9.

7.20.7 Confidence limits on failure probability

The treatment just given refers to failure frequencies. It may also be necessary to determine the confidence limits on failure probabilities. A treatment of this problem is given by von Alven (1964). The approach taken in this case is the use of the binomial theorem. Use may be made of the binomial theorem itself or of charts constructed from it.

Such a plot is given in Figure 7.23, which shows, for the case where there are S successes in N trials, the 95% confidence limits as a function of the ratio S/N, or success probability. As an illustration, consider the case where there are 16 successes in 20 trials. Then the estimated value of the probability of success is 0.8 and the upper and lower confidence limit values are 0.98 and 0.6. The failure probabilities are the complements of these values.

7.20.8 Fitting of failure distributions: graphical methods

Information on the variation of a failure rate with time, that is, the failure distribution, can lead to its reduction through improvement in design and maintenance. The data required for the determination of the failure distribution are the individual times to failure of the equipment.

The procedure is to convert the data to a set of values of the failure distribution $F(t)$ vs times to failure t, and to plot the latter against that function of $F(t)$ on a scale which corresponds to the distribution to be fitted.

For the exponential distribution:

$$F(t) = 1 - \exp(-\lambda t) \qquad [7.20.14]$$

and hence

$$t = \frac{1}{\lambda}\ln\left[\frac{1}{1-F(t)}\right] \qquad [7.20.15]$$

Thus a plot of $1/[1 - F(t)]$ on a log scale vs t on a linear scale gives a straight line.

For the Weibull distribution:

$$\ln(t-\gamma) = \frac{1}{\beta}\ln\left\{\ln\left[\frac{1}{1-F(t)}\right]\right\} + \ln\eta \qquad [7.20.16]$$

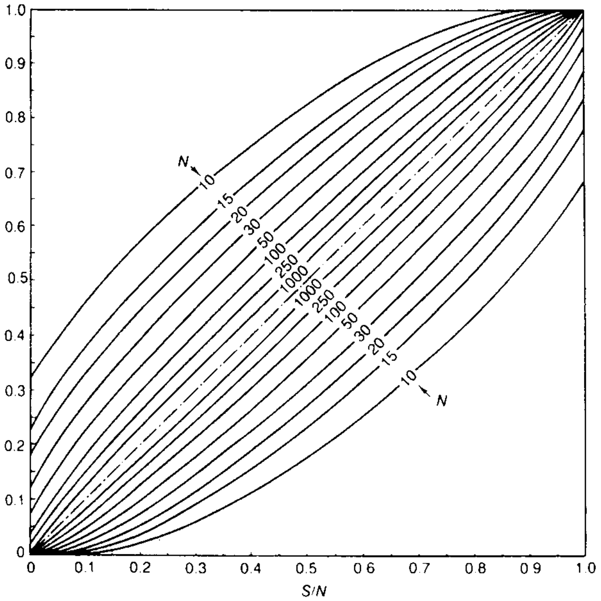

Figure 7.23 *Two-sided 95% confidence limits for the success probability S/N vs number of trials N (Clopper and Pearson, 1934)*

For these common distributions special graph papers are available which allow $F(t)$ vs t to be plotted directly. Figures 7.24–7.27 illustrate such graphs for the exponential, the normal and the Weibull distributions (two cases), respectively.

The determination of the failure distribution $F(t)$ from the experimental data is not entirely straightforward, however, and requires further discussion.

7.20.9 Fitting of failure distributions: ranking

If a test is considered in which n equipments operate without replacement and all fail during the test and if $n_f(t)$ equipments have failed at time t, then intuitively the failure distribution is simply the proportion which have failed:

$$F(t) = \frac{n_f(t)}{n} \qquad [7.20.17]$$

But the matter is not quite so simple. While Equation 7.20.17 holds for the n items tested, it is not the best estimate if these items tested are a sample from a large population. In this case a better estimate is the expected value:

$$F(t) = \frac{n_f(t)}{n+1} \qquad [7.20.18]$$

An alternative approach is the use of ranking. This involves calculating the order number m_j of the jth failure. The following ranking expressions are used:

$$F_{\text{mean}} = \frac{m_j}{n+1} \quad \text{mean rank} \qquad [7.20.19]$$

$$F_{\text{med}} = \frac{m_j - 0.3}{n+0.4} \quad \text{median rank} \qquad [7.20.20]$$

It is usual to calculate the failure distribution $F(t)$ as either the mean rank F_{mean} or the median rank F_{med}. The use of ranking is essential when the number of items n under test is small. The mean is commonly taken as a representative descriptor of a sample from a distribution. In the case of a highly skewed distribution, however, a better description may be the median. A discussion of the difference between mean rank and median rank and of the choice between them is given by Kapur and Lamberson (1977). Illustrative examples involving the use of the mean rank and median rank of a set of failure data are given in Tables 7.19–7.22.

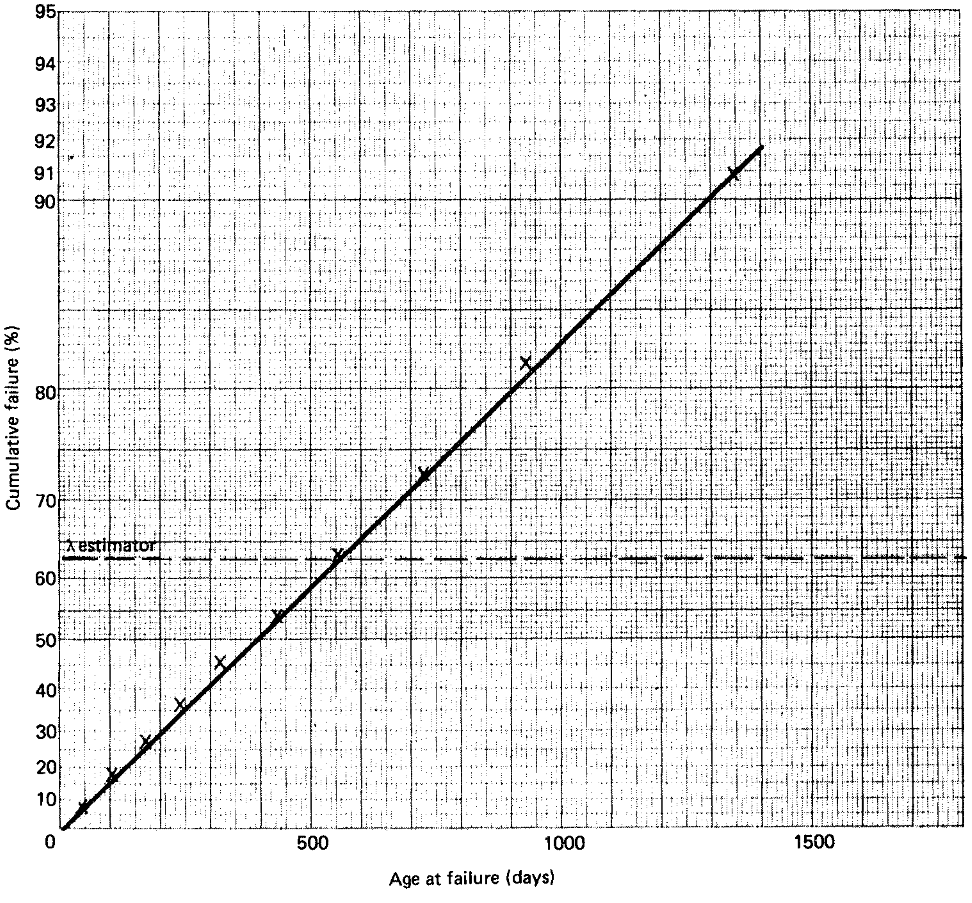

Figure 7.24 *Fitting of failure distributions using special graph paper: exponential distribution (data from Table 7.19)*

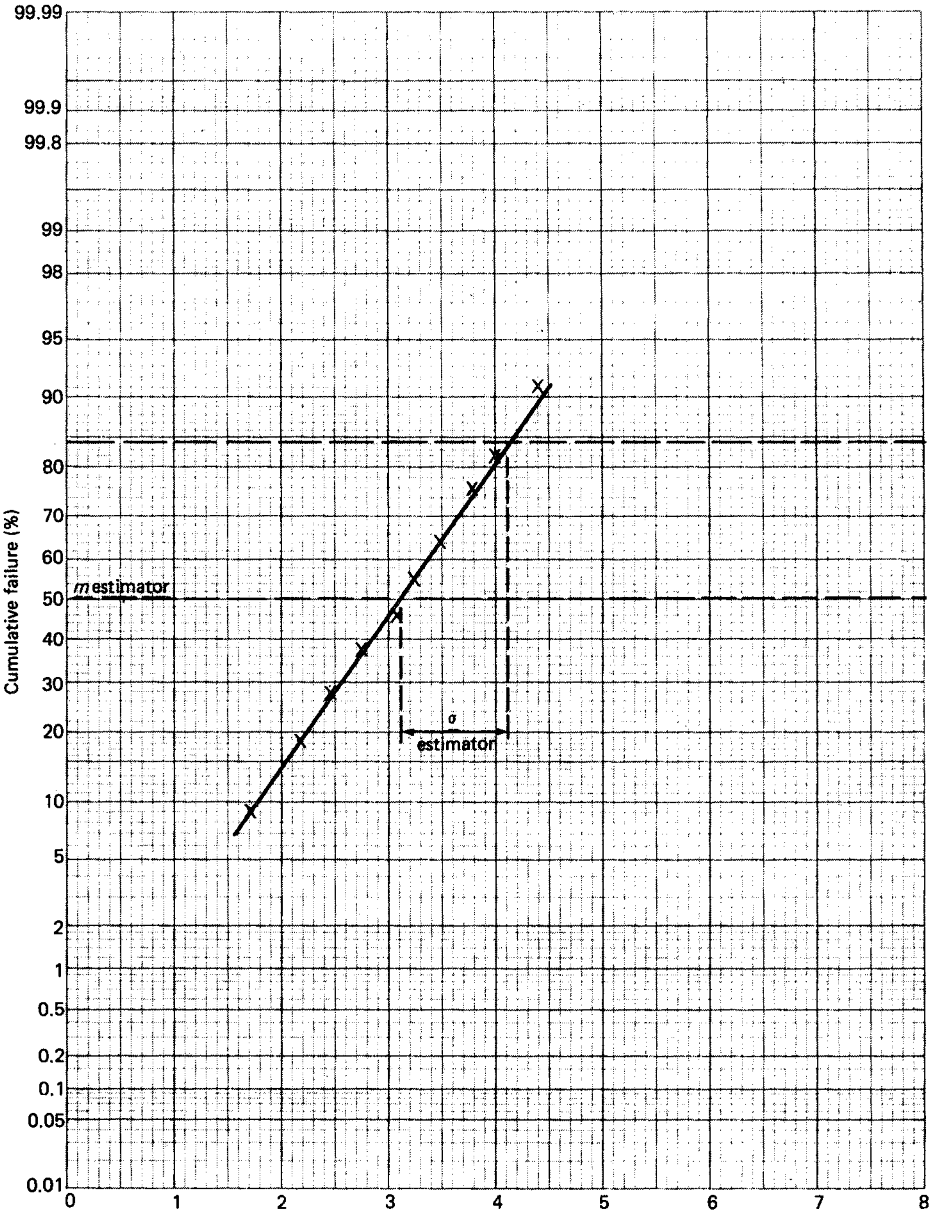

Figure 7.25 *Fitting of failure distribution using special graph paper: normal distribution (data from Table 7.20)*

7.20.10 Fitting of failure distributions: exponential distribution

The data in Table 7.19 correspond to an exponential failure distribution and are plotted in Figure 7.24. The estimator for the parameter failure rate λ in this distribution is given by the point at which the cumulative percentage failure has the value 63.2; the value of λ is then read off as the age at failure at this point, which in this case is 550 days.

7.20.11 Fitting of failure distributions: normal distribution

The data in Table 7.20 correspond to a normal failure distribution and are plotted in Figure 7.25. The estimator for the parameter mean life m is given by the point at which the cumulative percentage failure has a value of 50; the value of m is read off as the age at failure at this point. The estimator for the standard deviation σ is given by the interval between the cumulative percentage failures of 50 and 84;

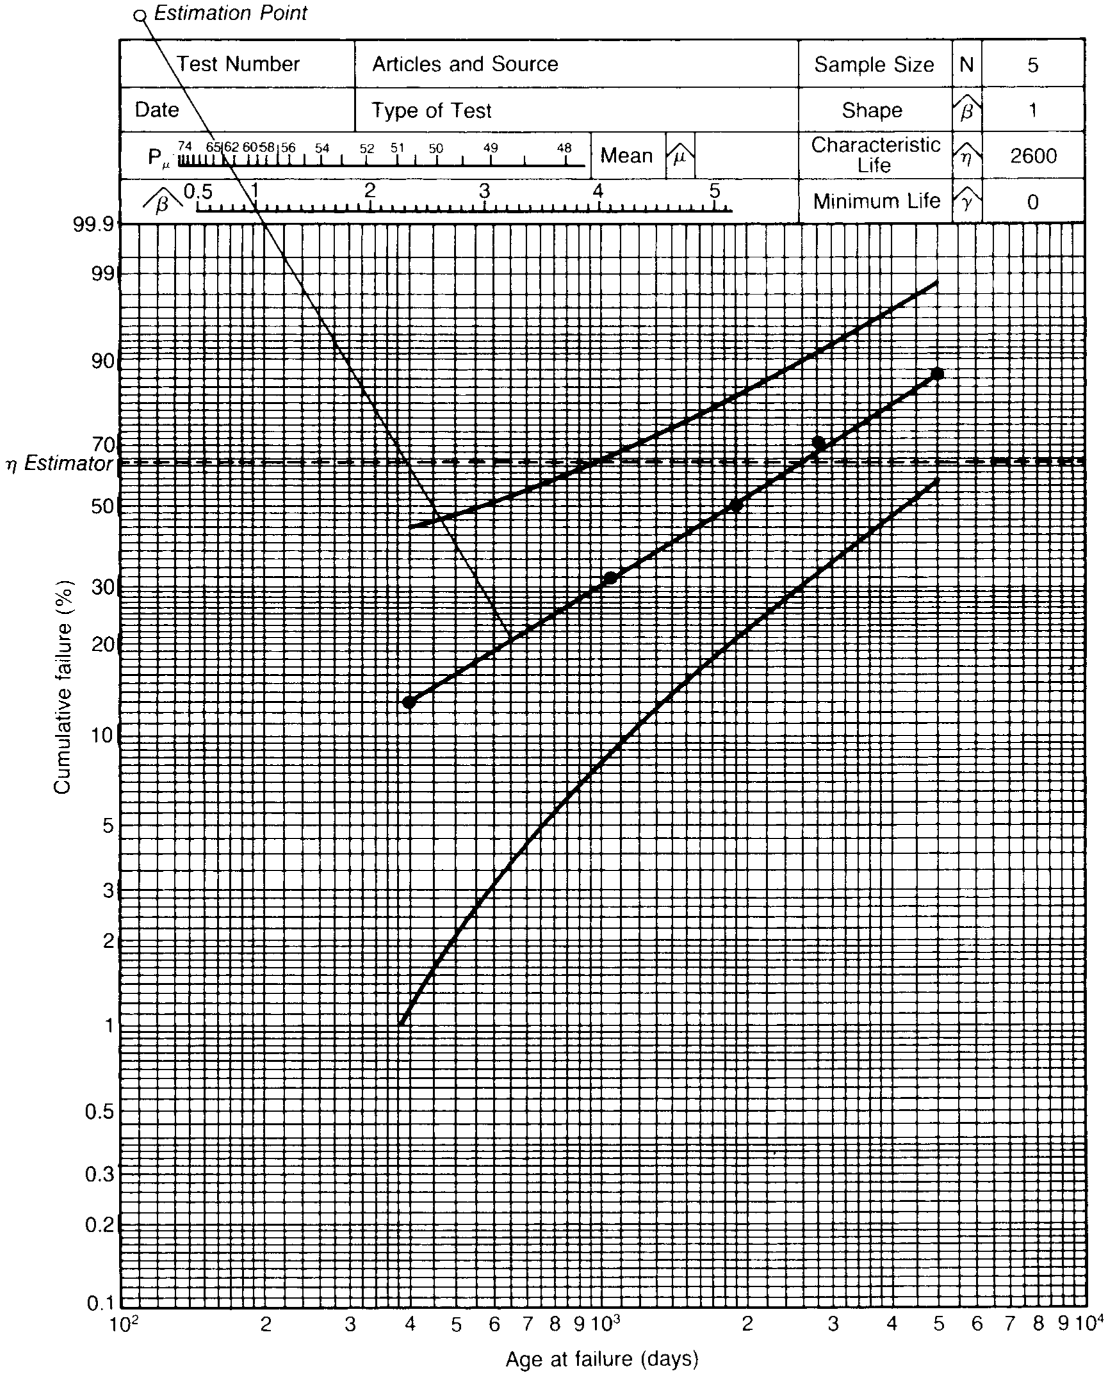

Figure 7.26 *Fitting of failure distributions using special graph paper: Weibull distributions (data from Table 7.21)*

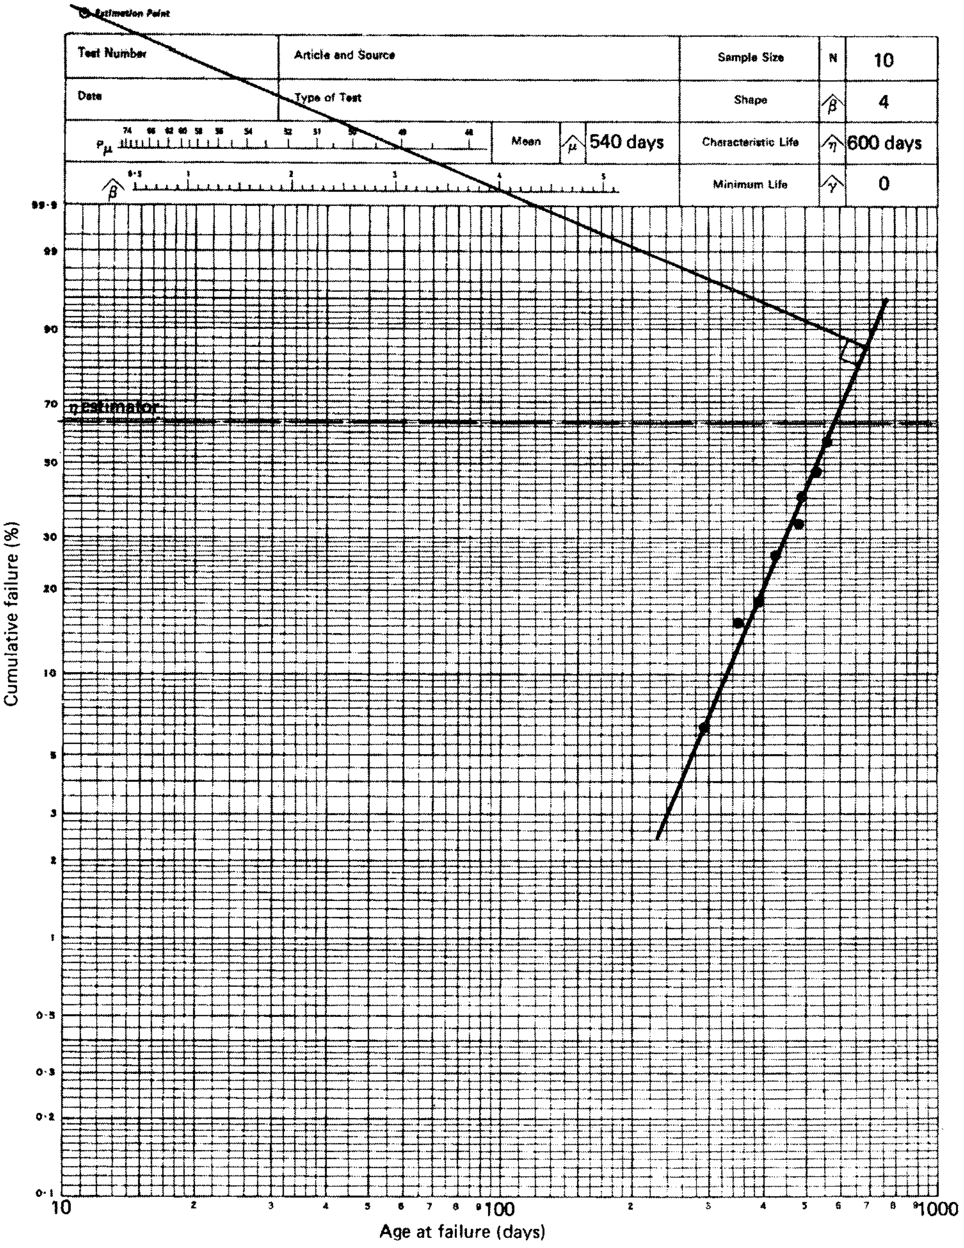

Figure 7.27 Fitting of failure distribution using special graph paper: Weibull distributions (data from Table 7.23)

the value of σ is read off as the interval between the ages at failure at these two points.

7.20.12 Fitting of failure distributions: Weibull distribution

The data in Table 7.21 correspond to a Weibull distribution with $\beta = 1$ and are plotted in Figure 7.26. The estimator for the characteristic life η is given by the point at which the cumulative percentage failure is 63.2; the value of η is read off as the age at failure at this point. The shape parameter β is obtained by constructing a line through the ‘estimation rsquo; point and perpendicular to the line through the experimental points and reading off the value of β on the special scale.

The mean of the distribution may be obtained as follows. The value of the cumulative probability P_μ is read off from the construction line just described. Then the mean of the distribution is obtained by entering the vertical scale at this

4	68.62	34.26	92.36
5	87.06	54.93	98.98

value of P_{μ}, going to the data line and reading off on the horizontal scale.

Also shown in Figure 7.26 are the 90% confidence limits, which are obtained in the following manner. Use is made of the appropriate percentage ranks for the particular sample size. A table of such ranks is given in Appendix VIII of Kapur and Lamberson (1977). The values of the median rank, the 5% rank and the 95% rank for a sample size of $n = 5$ are given in Table 7.22. These values have been used to plot the confidence limits shown.

7.20.13 Fitting of failure distributions: censored data

It frequently happens that items are withdrawn from test before they have failed. The test is then a censored one. Such a test has both failures and survivals. The mean order number m_j is calculated as

$$m_j = m_{j-1} + \Delta m \qquad [7.20.21]$$

$m_0 = 0$ and $m_1 = 1$ if the sequence begins with a failure. The mean order number increment Δm, which is only recalculated for a failure following a survival, is

$$\Delta m = \frac{n + 1 - m_{j-1}}{n + 1 - x} \qquad [7.20.22]$$

where x is the number of items before the jth failure.

An illustrative example of the determination of mean and median ranks of a set of censored failure data is given in Table 7.23. The data in Table 7.23 can be fitted by a Weibull distribution and are plotted in Figure 7.27. The characteristic life η and the shape parameter β are obtained in the same way as in the previous example.

Further discussions of ranking are given by L.G. Johnson (1964) and Bompas-Smith (1973).

7.20.14 Fitting of failure distributions: observation window

These methods are appropriate for test situations, such as the testing of new equipments by the manufacturer. In this case, the equipments are known to be in the new condition at the start of the test.

In the process industries the position is often rather different. Frequently the test situation is that working equipments are observed through a test 'window', as shown in Figure 7.28 (Aird, 1977b). In this case the equipments are not in the 'as new' condition when the test is started. There appears to be no entirely satisfactory method of dealing with this case at present. The difficulty arises in the handling of the period before the first failure of such equipment. It is possible either to neglect this period or to treat it as a time to failure, but neither approach is accurate. The error in the parameters thus estimated increases as the ratio of the observation window to mean life decreases.

7.20.15 Fitting of failure distributions: parameter estimation

Failure data in the form of times to failure or hazard rates may also be fitted to failure distributions by parameter estimation methods. Three principal methods are (1) least squares, (2) moments and (3) maximum likelihood. These methods are considered for the exponential distribution

$$z(t) = \lambda \qquad [7.20.23]$$

Table 7.23 *Failure data from a time-terminated censored test and derived ranked cumulative failure distribution*

[a] Original no. = 10.

and the Weibull distribution

$$z(t) = kt^m \qquad [7.20.24]$$

The least squares method may be applied in various ways. It is often used to fit data in the form of hazard rates. The hazard rate $z(t)$ and the failure density $f(t)$ over each time interval Δt between failures are:

$$z(t) = \frac{1}{n_s \Delta t} \qquad [7.20.25]$$

$$z(t) = \frac{1}{n \Delta t} \qquad [7.20.26]$$

where n and $n_s(t)$ are, respectively, the initial number of equipments and the number of equipments surviving. An illustrative example of the determination of hazard rate and failure density of a set of failure data is given in Table 7.24.

In the least squares method the error e is defined as:

$$e = \sum (z - z_c)^2 \qquad [7.20.27]$$

where z and z_c are the observed and calculated hazard rates. Then if

$$z = f(a_1, \cdots, a_p) \qquad [7.20.28]$$

the parameters a_i are given by the equations:

$$\frac{\partial e}{\partial a_1} = 0 \qquad [7.20.29a]$$

$$\vdots$$

$$\frac{\partial e}{\partial a_p} = 0 \qquad [7.20.29b]$$

A simple relationship for the hazard rate is:

$$z = a + b(t - \bar{t}) \qquad [7.20.30]$$

where $\bar{t}$ is the mean time to failure. From Equation 7.20.27

$$e = \sum_{i=1}^{n} \{z_i - [a + b(t_i - \bar{t})]\}^2 \qquad [7.20.31]$$

Then from Equation 7.20.28

$$a = \frac{1}{n}\sum_{i=1}^{n} z_i \qquad [7.20.32]$$

$$b = \left[\sum_{i=1}^{n}(t_i - \bar{t})z_i\right] \Bigg/ \left[\sum_{i=1}^{n}(t_i - \bar{t})^2\right] \qquad [7.20.33]$$

For the exponential distribution the parameters in Equation 7.20.30 are

$$a = \lambda$$
$$b = 0$$

For the Weibull distribution, from Equation 7.20.27

$$e = \sum_{i=1}^{n}(z_i - kt_i^m)^2 \qquad [7.20.34]$$

$$k = \left(\sum_{i=1}^{n} z_i t_i^m\right) \Bigg/ \left(\sum_{i=1}^{n} t_i^{2m}\right) \qquad [7.20.35]$$

m is obtained from the implicit equation:

$$\sum_{i=1}^{n} z_i t_i^m \ln t_i - \sum_{i=1}^{n} k t_i^{2m} \ln t_i = 0 \qquad [7.20.36]$$

The moments method is used to fit data in the form of times to failure. The moments of the data m_k are:

$$m_k = \frac{1}{n}\sum_{i=1}^{n} t_i^k \qquad [7.20.37]$$

The moments of the distribution μ_k are:

$$\mu_k = \int_0^\infty t_k f(t)\, \mathrm{d}t \qquad [7.20.38]$$

The method is to equate the moments of the data and those of the distribution:

$$\mu_k = m_k \qquad [7.20.39]$$

For the exponential distribution:

$$\mu_1 = \int_0^\infty t\lambda \exp(-\lambda t)\, \mathrm{d}t = \frac{1}{\lambda} = m_1 \qquad [7.20.40]$$

For the Weibull distribution:

$$\mu_k = \int_0^\infty t^k k t^m \exp\left(-\frac{kt^{(m+1)}}{m+1}\right) \mathrm{d}t \qquad [7.20.41a]$$

$$= \left(\frac{k}{m+1}\right)^{-k/(m+1)} \Gamma\left(\frac{k+m+1}{m+1}\right) \qquad [7.20.41b]$$

m and k are obtained from the implicit equations

$$\mu_1 = \left(\frac{k}{m+1}\right)^{-1/(m+1)} \Gamma\left(\frac{m+2}{m+1}\right) = m_1 \qquad [7.20.42a]$$

$$\mu_2 = \left(\frac{k}{m+1}\right)^{-2/(m+1)} \Gamma\left(\frac{m+3}{m+1}\right) = m_2 \qquad [7.20.42b]$$

The maximum likelihood method is also used to fit data in the form of times to failure. The likelihood function L is defined as:

$$L(t_1, \ldots, t_n; a_1, \ldots, a_p)$$
$$= f(t_1; a_1, \ldots, a_p) \cdot f(t_2; a_1, \ldots, a_p) \cdots f(t_n; a_1, \ldots, a_p) \qquad [7.20.43]$$

where f is the density function. Then the maximum likelihood estimate is obtained by maximizing L or $\mathcal{L} = \ln L$ with respect to the parameters a_i

$$\frac{\partial L}{\partial a_i} = 0 \qquad [7.20.44a]$$

or

$$\frac{\partial \mathcal{L}}{\partial a_1} = 0 \qquad [7.20.44b]$$

$$\vdots$$

$$\frac{\partial L}{\partial a_p} = 0 \qquad [7.20.44c]$$

or

$$\frac{\partial \mathcal{L}}{\partial a_p} = 0 \qquad [7.20.44d]$$

For the exponential distribution:

$$L = \prod_{i=1}^{n} \lambda \exp(-\lambda t_i) \qquad [7.20.45]$$

or

$$\mathcal{L} = \ln L = n \ln \lambda - \lambda \sum_{i=1}^{n} t_i \qquad [7.20.46]$$

Then from Equations 7.20.44 and 7.20.46:

$$\frac{\partial \mathcal{L}}{\partial \lambda} = \frac{n}{\lambda} - \sum_{i=1}^{n} t_i = 0 \qquad [7.20.47]$$

$$\lambda = \frac{1}{\frac{1}{n}\sum_{i=1}^{n} t_i} = \frac{n}{\sum_{i=1}^{n} t_i} \qquad [7.20.48]$$

For the Weibull distribution:

$$L = \prod_{i=1}^{n} k t_i^m \exp\left(-\frac{k t_i^{m+1}}{m+1}\right) \qquad [7.20.49]$$

or

$$\mathcal{L} = n \ln k + m \sum_{i=1}^{n} \ln t_i - \frac{k}{m+1} \sum_{i=1}^{n} t_i^{m+1} \qquad [7.20.50]$$

Then from Equations 7.20.44 and 7.20.50:

$$k = \frac{n(m+1)}{\sum_{i=1}^{n} t_i^{m+1}} \qquad [7.20.51a]$$

$$\left[\left(\sum_{i=1}^{n} t_i^{m+1} \ln t_i \right) \Big/ \left(\sum_{i=1}^{n} t_i^{m+1} \right) \right] - \left(\frac{1}{m+1} \right) - \left[\left(\sum_{i=1}^{n} \ln t_i \right) \Big/ n \right] = 0 \qquad [7.20.51b]$$

Once the parameters of the distribution have been estimated by one of the methods described, an assessment can be made of the goodness of fit. A common approach is to use the χ^2 distribution.

7.20.16 Generation of failure distributions

It is sometimes necessary for purposes such as the testing of failure analysis schemes to generate sets of times to failure obtained from particular distributions. This is normally done by rearranging the equation of the failure distribution $F(t)$ to give the time to failure t as a function of the probability, and then generating the set of times to failure by replacing the probability by a set of random numbers v in the range 0 to 1 from the uniform distribution.

For the exponential distribution, from Equation 7.7.14

$$t = -\frac{1}{\lambda} \ln(1 - v) \qquad [7.20.52a]$$

or, since v and $(1 - v)$ are both uniform distributions with the same range,

$$t = -\frac{1}{\lambda} \ln v \qquad [7.20.52b]$$

For the normal distribution, with zero mean and unit variance from Equation 7.7.18, the following approximation may be used:

$$t = \lim_{n \to \infty} \left[\left(\frac{12}{n} \right)^{1/2} - \left(\sum_{i=1}^{n} v_i \right) - \frac{n}{2} \right] \qquad [7.20.53]$$

It is normally sufficient to take $n = 12$, in which case

$$t = \sum_{i=1}^{12} v_i - 6 \qquad [7.20.54]$$

For the Weibull distribution, from Equation 7.7.25

$$t = \eta(-\ln v)^{1/\beta} + \gamma \qquad [7.20.55]$$

The generation of failure distributions is described in more detail by Hastings and Peacock (1974).

7.20.17 Proportional hazards modelling

Another technique useful in failure data analysis is proportional hazards modelling. This is a method of determining the relative effects of influencing factors on the failure rate. Proportional hazards modelling was proposed by D.R. Cox (1972), who suggested that it might have application to data in the fields of medicine and reliability engineering. Its initial development was in the latter. Accounts are given in *The Statistical Analysis of Failure Time Data* (Kalbfleisch and Prentice, 1980) and *Statistical Models and Methods for Lifetime Data* (Lawless, 1982). The application of the method to reliability engineering is described by Bendell (1985) and Dale (1985).

The basic relationship in proportional hazards modelling is:

$$z(t) = z_0(t) \exp\left(\sum_{i=1}^{n} \beta_i z_i \right) \qquad [7.20.56]$$

where $z(t)$ is the hazard rate, z_i the ith influencing variable, or explanatory factor, $z_0(t)$ the baseline hazard function, and β_i the coefficient of z_i.

Thus the action of the explanatory factors on the hazard rate is, in this model, assumed to be multiplicative, in contrast to the more common correlation models, in which it is taken to be additive. A multiplicative effect appears more realistic. The baseline hazard rate $z_0(f)$ is, in principle, distribution free.

Examples of the application of proportional hazards modelling are given by Dale (1985).

7.20.18 Time-varying failure data

The foregoing treatment is based on the assumption that the failure distribution and its parameters do not vary with time. Some guidance on the effect of variation of the failure rate with time is available from work by Blanks (1977). He shows that significant error occurs where failure rates are estimated from exposure periods which are very much less than the representative life, which for the log-normal distribution is the median life and for the Weibull distribution the characteristic life.

This is illustrated in Figure 7.29, which shows that for the Weibull distribution the product (Failure rate ×

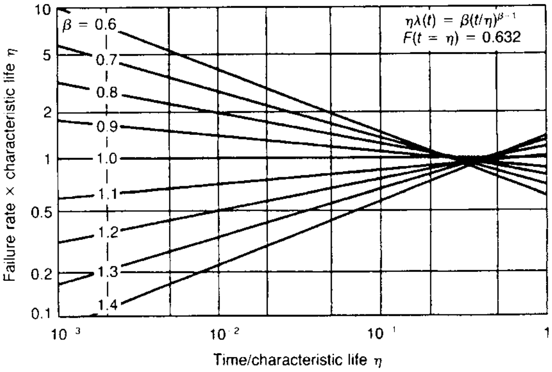

Figure 7.29 Variation of failure rate with observation time, in terms of the Weibull distribution (Blanks, 1977)

Characteristic life) diverges significantly from unity for low values of the time/characteristic life ratio.

7.20.19 Combination of failure data

A common situation is that some failure data are available, typically from the literature, whilst further data have been obtained within the company. A method is needed for combining these two sets of data to produce a single value for the failure rate. In this case use may be made of Bayes' theorem, as described in Section 7.14. The problem is also discussed by the Center for Chemical Process Safety (CCPS, 1989/1).

7.20.20 Role of failure data analysis

Failure data analysis can be a powerful tool for improvement in reliability and in maintenance. It is most effective if used as one prong of an integrated approach. It also has certain limitations. For work on reliability, as opposed to maintenance, the acquisition of data is clearly essential.

For maintenance, at the most elementary level collection and analysis of failure data can highlight which equipments have high failure rates and the most frequent failure modes of such equipment. At a more sophisticated level, determination of failure distributions can identify the failure regime and can point to particular types of remedial action or maintenance policy.

Such an analysis is more effective if it is combined with other methods. In the study by Sherwin and Lees (1980) described above, the authors emphasize the value of combining failure data analysis and observation of the maintenance task. They state that this combination is more powerful than either method on its own.

Failure data analysis has it limitations, however. A works commonly contains a large number of equipments, each with a number, often a large number, of failure modes. The collection and analysis of failure data for these is a serious undertaking. Furthermore, failure data analysis is effectively a form of epidemiology, and is thus subject to criticisms which are directed at the latter, namely that it is a method which comes into play only after failures, and possibly harm, have occurred.

An alternative approach which seeks to get things right first time is that of reliability-centred maintenance (RCM). This is described below. Here it is sufficient to note its critique of failure data analysis. Failure data analysis appears to be of most value in application to significant items of equipment with a few dominant failure modes and perhaps also to lesser items present in large numbers.

7.20.21 Repair times

Information on repair times is also required in reliability work. Repair time data are sometimes difficult to obtain accurately as there is a tendency for nominal repair times to be recorded, particularly when tasks are of short duration. It is frequently found that repair times fit a log–normal distribution.

7.21 Reliability in Design

An outline is now given of the design and development of an equipment which is to have high reliability. It draws largely on accounts of the practice of suppliers and users in high technology industries such as defence and aerospace where the users have stringent reliability requirements.

7.21.1 Design process

An overview of the design process for mechanical systems with specific reference to reliability has been given by A.D.S. Carter (1986). He distinguishes three broad stages: (1) the formulation of objectives, (2) the conventional design process and (3) the development process.

7.21.2 Manufacturer ± user relationship

Before considering the three stages of the design process, it is relevant to recognize that the relationship between the manufacturer and the user can have a strong influence on the reliability requirements. In some cases, such as defence, there may be a single manufacturer and single user who work closely together to define the requirements. At the other extreme there is a market in which there are several manufacturers and numerous users. The users may be imprecise about their requirements so that the manufacturers must take their own view about what is needed.

In principle, a user should be seeking to minimize the life cycle costs. In practice, he may well not do this, but may concentrate on some less global objective such as minimization of the combined capital and operating costs of the equipment, or even of the capital cost alone.

The interests of the manufacturer and user do not necessarily coincide. However, in principle, both parties have an interest in the formulation of the reliability goals and specification.

7.21.3 Reliability targets

The reliability requirement is formulated in the first instance as a set of broad targets. In addition to the normal design considerations targets for reliability, these will include availability and maintainability. The priority accorded to reliability proper, the minimization of outright failure, will depend on the consequences of failure, and in particular on the extent to which the item is safety critical. The targets should ideally include the minimization of life cycle cost, but the extent to which the manufacturer does this will depend on the information about use available to him and on commercial judgement.

7.21.4 Reliability prediction

System design and development need to be supported by a continuous process of reliability prediction. This can be significant activity in its own right, and consideration of this is deferred to the next section.

7.21.5 Reliability feasibility study

Before embarking on detailed specification and design, it is usual to carry out a feasibility study. The purpose of this is to confirm that the proposed design is capable of meeting the reliability goals.

7.21.6 Reliability specification

Once established, the reliability targets need to be converted into reliability specifications. There will be a reliability specification for the system as a whole and further specifications for its component parts. The specification process involves sharper definition of features, such as the precise performance requirements for the system, the limits of the conditions and loads which it is required to withstand and the maintenance requirements and the criteria for success in meeting these various requirements. An account of the practicalities of reliability specification is given by Calabro (1962).

7.21.7 Conventional design

Within his overall account of reliability in design, Carter (1986) gives a detailed description of the conventional design process. The potential system failures should be identified and evaluated. For safety-critical features, techniques such as fail-safe behaviour or redundancy may be appropriate.

In most cases it is possible to make use of an existing design, either unchanged or with relatively minor modification. In this case information should be sought on its reliability in the field under the conditions of interest.

If a new design is indicated, care should be taken to avoid known generic causes of unreliability. These include features which constitute stress raisers, promote corrosion, result in poor connections, allow rupture of pipes, hoses and wires, and so on. The design should be suitable for the environment in which it is to be used. The components should be compatible with each other. A.D.S. Carter gives checklists covering this aspect. Efforts should be made to obtain information on the field reliability of similar designs.

The design should adhere to some basic principles. It should be kept simple. And it should be adequately conservative.

Care should be taken that 'improvements' to an existing or proposed design, whether arising from activities such as value engineering or otherwise, do not in fact result in an unwarranted decrease in reliability.

The maintainability of the system should be considered as well as its reliability.

The components and subsystems used in the design should be fully specified, and there should be inspection and test procedures for them.

Prior to entry into service the system may be subject to handling, packing, transport and storage, which may cause damage or deterioration, and attention should be paid to this aspect.

A quantitative evaluation should be made of the reliability of the system, as much for the sake of stimulating a critical review as for the determination of a numerical value.

7.21.8 Mechanical design

Traditional mechanical design of equipment is based on deterministic methods. It is also possible, however, to take a probabilistic approach using concepts such as those of interference theory. A.D.S. Carter (1986) gives illustrations of the application of this latter approach to problems of stress-rupture phenomena and of fatigue.

7.21.9 Design reviews

The design function should have a formal procedure for the review of the reliability of the systems and equipment under design. This procedure should cover not just the design stage proper but also the testing and development stages, and follow-up at each stage.

7.21.10 Problem identification

The design reviews should make use of the various techniques for problem identification, such as critical examination, checklists, failure modes and effects analysis (FMEA), fault tree analysis, and so on. These methods are described in Chapter 8 and are therefore not discussed further here.

7.22 Reliability Prediction

As just indicated, design for reliability requires the supporting activity of reliability prediction. Reliability prediction is not simply the estimation of numerical values of reliability using suitable models. The term is used to cover the various and much wider range of activities running through the design and development stages, and possibly beyond. Reliability prediction is carried out through this life cycle as a guide to action. Accounts of reliability prediction include those given by von Alven (1964) and D.J. Smith (1985a).

7.22.1 Stages of reliability prediction

Reliability prediction passes through three broad stages, generally characterized as (1) pre-design, (2) interim and (3) final reliability prediction.

7.22.2 Pre-design reliability prediction

The pre-design reliability prediction has to be performed with limited information and involves in particular the feasibility evaluation and the reliability apportionment.

7.22.3 Reliability feasibility study

One of the first reliability prediction activities is the feasibility study. A pre-design estimate is made of the system reliability and is compared with the specification. This indicates whether or not the proposed design is at least within hailing distance of meeting the specification. If it is not, possible responses are modification to the design, or to the specification, or to both. Even if the reliability prediction indicates that the design will meet the specification, it is good practice to explore alternatives. The next step is to set reliability specifications for the subsystems.

7.22.4 Reliability apportionment

The fundamental reliability specification is that for the system as a whole. However, in order to achieve this it is necessary to decompose the system into subsystems and to determine the reliability specifications for the constituent parts. This is known as 'reliability apportionment', or 'reliability allocation'.

There are a number of models which may be used to apportion the reliability targets among the parts, as described by Anderson and Neri (1990). A model for the case where the parts, or subsystems, are similar is:

$$R_x = R^{1/n} \qquad [7.22.1]$$

where n is the number of subsystems, R_x the reliability of the system, and R_x the reliability of a single subsystem. For the case where the subsystems are different one model is:

$$R_x = R^{W_i} \qquad [7.22.2]$$

with

$$w_i = \frac{C_i}{\sum_{j=1}^{n} C_j} \qquad [7.22.3]$$

where C_i is a parameter representing the complexity of the ith subsystem and W_i is the weighting factor for that subsystem.

7.22.5 Interim reliability prediction

Once the design is under way, reliability prediction is used in support. As is usual in design, the process is iterative and involves various trade-offs.

7.22.6 Final reliability prediction

The final reliability prediction is made as part of the overall specification of the product. This prediction also serves as a measure of the success of the design process. There may be complications in producing a single final reliability prediction. The product may come in several versions and, over time, may be subject to modification.

7.23 Reliability Growth, Testing and Demonstration

In the achievement of reliability, design for reliability and reliability prediction need to be complemented by a programme of reliability testing and demonstration. In large part, reliability prediction and testing are directed to the growth in the reliability of the equipment Reliability growth is therefore conveniently considered along with testing.

7.23.1 Reliability testing

In reliability testing a distinction is made between (1) reliability development and demonstration testing, (2) qualification and acceptance testing and (3) operational testing.

Reliability development and demonstration testing is performed to determine (1) whether the design needs improvement, (2) to identify modifications which might lead to improvement and (3) to verify that the modifications made have led to improvement.

In high technology activities it is generally required that a design be accepted as qualified for the intended application. An example is the seismic qualification of equipment for nuclear plants. Similarly, there may be a requirement that the design be qualified with respect to reliability. This is the purpose of qualification testing.

Acceptance testing is concerned with the quality of manufacture of the equipment.

Operational testing provides information on the operation of the equipment, as verification of the design and feedback of information on performance for future use by the designers. This type of testing is less likely to be subject to the continuous process of modification that is characteristic of development testing.

Reliability testing is governed by a formal programme involving subcontractors as well as the lead manufacturer. The programme covers the stages of (1) design concept, (2) production prototype and (3) production testing. It is generally subject to frequent modification.

Further treatment of acceptance testing is deferred to later in the text in order to consider reliability growth.

7.23.2 Reliability growth

If the reliability development programme is effective, it should result in an increase in the reliability of the equipment. Experience with different products shows that the process of reliability growth has certain characteristic features. Accounts of reliability growth are given by Lloyd and Lipow (1962) and D.J. Smith (1985a). A relevant standard is BS 5760: Part 6: 1991 *Guide to Programs for Reliability Growth*.

The situation considered is the development phase of an equipment in which the manufacturer conducts field tests involving a continuous process of feedback of information on reliability performance and modification of the equipment to improve this reliability by reducing design-related failures.

Various models have been developed for reliability growth. Such models may be used to extrapolate in time to the point when the failure rate of an equipment under development should reach the specified value. They may also be used to make estimates of development times.

7.23.3 Duane method

A widely quoted method for the analysis of reliability growth during field testing has been given by Duane (1962). Further discussions of the method are given by Codier (1968), R.C.F. Hill (1977) and D.J. Smith (1985a). Duane found that a log-log plot of cumulative failure rate vs cumulative testing time tended to give a straight line. Codier (1968) modified this plot, replacing cumulative failure rate by cumulative MTBF, as shown in Figure 7.30. A straight line on this plot may be expressed as:

$$\mathrm{MTBF} \propto T^{\alpha} \qquad [7.23.1]$$

The current MTBF is given by:

$$\mathrm{MTBF}_{\mathrm{cur}} = \frac{\mathrm{MTBF}_{\mathrm{cum}}}{1-\alpha} \qquad [7.23.2]$$

where the subscripts cum and cur indicate the cumulative and current values. Values of α tend to lie in the range 0.1–0.65.

The use of cumulative time in the Duane plot means that at long testing times changes in the reliability growth tend to be smoothed out and are difficult to discern.

7.23.4 Reliability acceptance testing

The decision of whether to accept or reject items on reliability grounds needs to be governed by a formal system of acceptance testing. Accounts of acceptance testing are given in texts on quality control (e.g., Burr, 1953; Moroney, 1956; E.L Grant, 1964). Treatments in the context of reliability engineering are given by von Alven (1964), Breipohl (1970) and D.J. Smith (1985a).

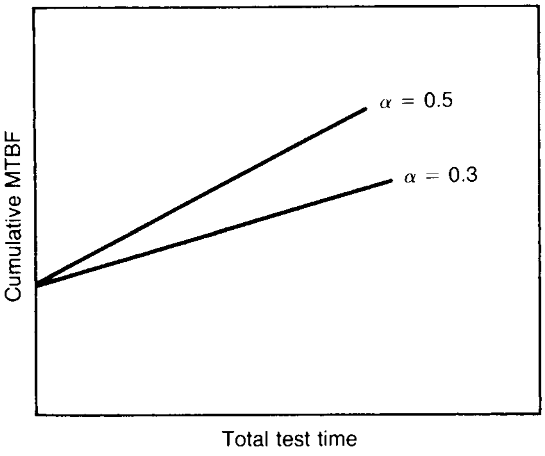

Figure 7.30 *Reliability growth plots: after Duane*

Acceptance testing is generally conducted by reference to an operating characteristic (OC) curve. For the case where such testing is performed by taking a sample of items from a production batch, the operating curve may be constructed from the binomial distribution:

$$P = \sum_{k=0}^{c} \binom{n}{k} q^k p^{n-k} \qquad [7.23.3]$$

where c is the allowable number of defective items in a sample of size n, p and q are the proportions in the batch of good and defective items, respectively ($p + q = 1$) and P is the probability of acceptance. The OC curve is a plot of P vs q for given values of n and c. A typical OC curve of this kind is shown in Figure 7.31(a).

In using a sample as the basis of acceptance, both producer and consumer accept a certain risk. The producer's risk is the probability that the batch is acceptable but fails the test, whilst the consumer's risk is the probability that the batch is unacceptable but passes the test.

The usual procedure is to set values for the acceptable quality level (AQL) and the lot tolerance per-cent defective (LTPD) which are entered on the OC curve as shown in Figure 7.31(a). The AQL is the batch, or lot, quality (q value) for which the probability of acceptance has some (high) specified value. The complement of this probability is the producer's risk (α). A typical value of the AQL is 95%, giving a producer's risk of 5% ($\alpha = 0.05$). Likewise, the LTPD is the lot quality (q value) for which the probability of acceptance has some (low) specified value. This probability is the consumer's risk (β). A typical value of LTPD is 10%, giving a consumer's risk of 10% ($\beta = 0.1$).

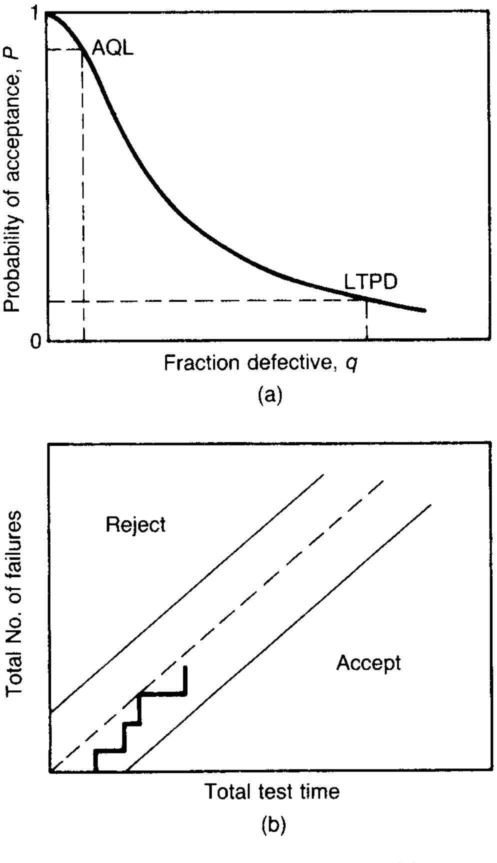

Figure 7.31 *Acceptance testing schemes: (a) operating characteristic curve for sinle sample plan; (b) operating limits for sequential sampling plan*

As just described, this scheme refers to the sampling of a single batch and provides lot quality protection (LQP). If the batch is then to be mixed with other batches, this degree of protection may not be necessary. An alternative scheme may be used which offers average quality protection (AQP).

An approach to acceptance testing for the case where the acceptance criterion is the failure rate of the equipment, which is based on the Poisson distribution, is described by Smith.

The binomial scheme just described involves single sampling. Another approach is the use of sequential sampling in which a series of tests is conducted, the decision after each test being (1) accept, (2) continue testing or (2) reject. This approach is illustrated in Figure 7.31(b).

An important issue in the design of an acceptance testing scheme is the degree of discrimination which it provides. This is discussed by Smith.

7.24 Maintainability

Accounts of reliability engineering generally include as a third theme, in addition to those of reliability and availability, that of maintainability. Maintainability is treated in the main reliability engineering texts cited here and in particular in *Maintainability* (Goldman and Slattery, 1964) and *Reliability, Maintainability and Availability Assessment* (Locks, 1973), and by von Alven (1964) and D.J. Smith (1985a).

The cost of maintaining equipment is a recurring theme in reliability work and was one of the original motivations for it. Although estimates vary, they are generally in agreement that the cost is high. Accounts of maintainability generally treat it as a property of the equipment. 'Maintainability' is therefore not synonymous with maintenance effectiveness, which includes other aspects such as organization and training.

7.24.1 Maintainability measures

The principal measures of maintainability of an equipment are its failure rate and repair time. Attention tends to centre mainly on the repair time, but the overall cost is also strongly influenced by the frequency at which repair is necessary.

The overall repair time is usually decomposed into several parts, a typical division being (1) active repair time, (2) logistics time and (3) administrative time. Essentially, logistics time is that spent waiting for spare parts, and administrative time is the balance of time spent on the repair which is not required for either active repair or logistics.

7.24.2 Maintainability principles

Some basic principles of maintainability are: (1) provision of good access; (2) minimization of the complexity of the task, tools and test equipment; (3) provision of good maintenance manuals; (4) clear criteria for recognition of faults or marginal performance; and (5) optimization of the diagnosis and repair task.

The latter typically involves (1) preparation, (2) malfunction verification, (3) fault location, (4) fault isolation, (5) disassembly, (6) part procurement, (7) part interchange, (8) reassembly, (9) alignment and (10) checkout.

In many cases an approach based on simple checks to identify the malfunctioning module and replacement of that module is an appropriate strategy.

7.24.3 Maintainability prediction

Methods have been developed for the prediction of maintainability as measured by the repair time. The basic approach is to synthesize estimates of the repair time from a data bank of times for element of the repair task. Von Alven (1964) describes a number of data collections developed for this purpose. One is the ASB-4 system. Another system is that developed by the American Institute for Research (AIR).

7.24.4 Maintainability testing and demonstration

Major clients such as the armed services require the supplier to demonstrate maintainability as well as reliability. MIL-STD-471 *Maintainability Demonstration* states requirements for the US Armed Services, and is widely quoted.

Maintainability is generally demonstrated by conducting a series of tests. In the typical test a defined maintenance task is undertaken and measurements are made of the times taken to perform it. A plot is made of the probability of passing the test vs the MTTR (mean time to repair) which is then evaluated against a predefined criterion.

Comparability between tests depends crucially on holding constant the various factors which are known to exert a strong influence. These are listed by D.J. Smith (1985a) as (1) method of selecting the demonstration task, (2) tools and test equipment available, (3) PM given to test system, (4) maintenance documentation, (5) environment during test and (6) skill level and training of test subject.

7.25 Maintenance Activities and Policies

The maintenance analysis of a system has as its objective the identification of failure situations and the formulation of appropriate maintenance policies.

The theory of maintenance is a well-developed aspect of reliability engineering. Accounts are given in *Maintainability* (Goldman and Slattery, 1964), *Maintainability, Principles and Practice* (Blanchard and Lowery, 1969), *Maintenance, Replacement and Reliability* (Jardine, 1973) and *Maintainability Engineering* (D.J. Smith and Babb, 1973).

The management of maintenance is described in *Modern Maintenance* (J.E. Miller and Blood, 1963), *Effective Maintenance Organisation* (Newbrough, 1967), *Maintenance Engineering and Organisation* (Gradon, 1973), *Principles of Planned Maintenance* (Clifton, 1974), *Systematic Maintenance Organisation* (Priel, 1974), *Maintenance Management Techniques* (Corder, 1976), and *Maintenance Management and Terotechnology* (Husband, 1976).

The maintenance of plant to reduce failures and stoppages is discussed below. Some wider aspects of the maintenance function and of the information which it generates are described in Chapter 21.

7.25.1 Maintenance activities

Some maintenance activities which are carried out on process plants have traditionally been:

(1) production assistance – adjusting machine settings;
(2) servicing – replacement of consumables, including lubrication;
(3) running maintenance – running repairs with little interruption to production;
(4) shut-down maintenance – scheduled repair or overhaul with interruption to production;
(5) breakdown maintenance – unscheduled repair with interruption to production.

7.25.2 Failure regimes

Before considering maintenance policies, it is pertinent to consider briefly the issue of failure regimes. The measures which can be taken to reduce failure depend very largely on the failure regime of the equipment. As already discussed, the three regimes are: (1) early failure, (2) constant or random, failure and (3) wearout failure.

If the failure regime is established to be wearout failure, this points to a maintenance policy based on fixed interval replacement.

In many cases the equipment appears to be in the random failure regime. If the failures of the equipment are truly random, then there is little purpose in carrying out scheduled maintenance, because by definition the equipment is just as likely to fail afterwards as before. This is a fundamental point which it is difficult to overemphasize.

On the other hand, failure of an equipment is rarely truly random. If an equipment appears to be in the constant failure regime, it is usually worth probing further. Often the apparent constant failure characteristic is due to the non-constant failure characteristics of the large number of components of which it is constituted. This effect has been discussed in Section 7.18. Thus if the failures of components rather than those of the whole equipment are analysed, non-constant failure regimes may be revealed, although in many cases the number of failures of each component may be so small that analysis is difficult.

If the failure regime is established to be early failure, the choice of maintenance policy is again complex. In formulating a policy, account should be taken of the various factors which contribute to early failure, as described in Section 7.19. One of these may be failure induced by unnecessary scheduled maintenance.

7.25.3 Repair, reconditioning and replacement

Another preliminary matter is the issue of repair, reconditioning and replacement. If an equipment is found to have deteriorated to a point where its condition or performance is unsatisfactory, it is sometimes replaced, but is more often repaired or reconditioned with the aim of restoring it to the ‘as new’ condition.

Often this is not achieved. Failure to make full restoration can be serious. A policy where this tends to be the outcome can result in a higher overall level of faults on the plant. It is essential, therefore, that for equipments with fine tolerances the requirements for repair or reconditioning be properly specified. There should be a written specification for the task. The specification not only should quote the original design information such as a drawing number but also should give the permissible wear tolerances.

It should be borne in mind that maintenance personnel deal with a wide range of equipment. On some of this equipment tolerances may not be particularly critical. It is important that they do not transfer the rough-and-ready methods which may be adequate there to equipment which requires more careful treatment.

Certain equipment designs allow for the rectification of a fault by simply removing a defective module from the equipment and replacing it with a new one. This is then generally the best action.

7.25.4 Maintenance policies

Some policies for maintenance are:

(1) scheduled maintenance:
  (a) inspection;
  (b) minor adjustment;
  (c) replacement;
(2) on-condition maintenance;
(3) opportunity maintenance;
(4) breakdown maintenance.

Maintenance policies can be classed as either PM or breakdown maintenance. All the policies except the last may be regarded as forms of PM.

7.25.5 Planned maintenance

In general, it is desirable that maintenance tasks be planned rather than undertaken *ad hoc*. The term 'planned maintenance' is widely used and refers to any maintenance which is planned. It includes some breakdown maintenance where the latter can be planned in advance.

7.25.6 Scheduled maintenance

A subset of PM policies is that comprising the variations on scheduled maintenance. There are several forms of scheduled maintenance, the distinction between them being the actions prescribed in advance. These may be (1) inspection, (2) adjustment or (3) replacement; the term 'adjustment' covering virtually any action beyond inspection but short of replacement.

If the policy is scheduled inspection and no problem is found, no further action is taken. However, if the inspection indicates that further action is required, it is taken, whether it be adjustment or replacement. Likewise, scheduled adjustment generally includes inspection and may involve replacement if the inspection so indicates.

7.25.7 Scheduled replacement

If it is established that an item exhibits wearout failure, it is possible in principle to determine the failure distribution and to adopt a policy of scheduled replacement based on this. If the parameters of the distribution are known, the probability of failure prior to replacement which is tolerable can be specified and the time interval for replacement read off from the failure distribution function, as shown in Figure 7.32.

Alternatively, the failure distribution may be assumed. In this case a common assumption is that the failure distribution is normal. This assumption together with knowledge of the value of the mean life and a further assumption about the variance allows an estimate to be made of the replacement interval. If the mean life to wearout is m and the corresponding standard deviation is σ, then the maintenance policy is to replace at a time m_0 where

$$m_0 = m - k\sigma \qquad [7.25.1]$$

As a rule-of-thumb the value of σ is often taken as

$$\sigma = 0.1m \qquad [7.25.2]$$

A typical value of k is 6, so that Equation 7.25.1 becomes

$$m_0 = 0.4m \qquad [7.25.3]$$

Thus, for example, bearings are commonly replaced at a proportion of their mean life, the so-called 'B10 life'.

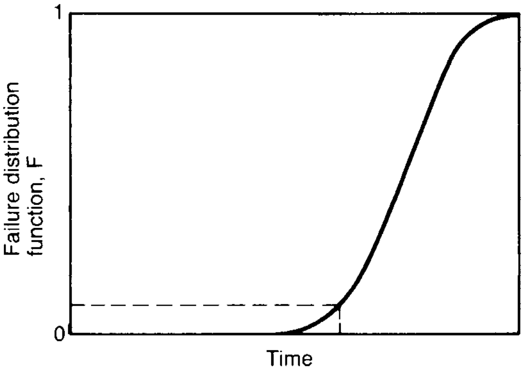

Figure 7.32 *Determination of the scheduled of replacement interval from the failure distribution*

7.25.8 On-condition maintenance

An alternative to scheduled maintenance is on-condition or condition-based maintenance. On-condition maintenance (OCM) involves periodic inspection, and to this extent resembles scheduled inspection. Insofar as a difference can be drawn, the distinguishing features of OCM is that it tends to draw on the many powerful techniques now available for condition monitoring and, when deterioration is detected, to involve prediction of the expected time to failure. OCM has the advantage of averting failures by early action if inspection detects deterioration and of avoiding unnecessary maintenance if inspection reveals no deterioration.

An account of OCM is given by Moubray (1991). The essential conditions for its practice are there is a well-defined potential failure (PF) condition and that it is feasible to construct a dependable PF curve. In a PF diagram the fractional margin of acceptable performance (from 1 to 0) is plotted against time. This PF curve can then be used to predict the time of occurrence of total loss of margin, or failure. The time between first detection of PF and actual failure is the PF interval. For OCM to be practical, the PF curve must be reasonably reproducible. An inspection interval can then be chosen which is less than the PF interval. The time available for action to be taken is the difference between the PF and inspection intervals, or the net PF interval.

Moubray (1991) also gives an appendix containing brief summaries of the various condition monitoring techniques and their applications. A further account of these techniques is given in Chapter 19.

OCM is a feasible policy only if an appropriate inspection or monitoring technique is available, but the development of new techniques is continually widening the scope of items which can be inspected for deterioration. However, since inspection incurs cost, there is an optimum degree of inspection. Optimal inspection policies are dealt with in standard texts on maintenance.

7.25.9 Opportunity maintenance

For equipments which are normally inaccessible, breakdowns or stoppages provide the occasion to practice 'opportunity maintenance'. This consists of doing PM work as and when the item becomes available.

Thus, for example, it is often normal practice that when a pump is opened up a check is made on alignment, bearings, seals and cooling water flow, but this check may be extended to other features such as the casing and the small bore connections.

7.25.10 Burn-in

As described above, one of the causes of early failure in a system with a large number of new components can be the presence of a proportion of weak components. An account of methods for dealing with this problem is given in *Burn-In* (Jensen and Petersen, 1982). These methods might be regarded as another type of maintenance policy. Jensen and Petersen describe a methodology for dealing with this kind of early failure problem by burn-in. Interest centres in large part on the prediction of the burn-in period required.

7.25.11 Selection of maintenance policies

There are considerable differences in the maintenance policies which may be followed on process plant. At one extreme the policy may be one of breakdown maintenance only, whilst at the other the policy may be one of extensive PM.

The terminology used for maintenance policies is defined in BS 3811: 1984 *Glossary of Maintenance Terms Used in Terotechnology.* An account of maintenance policies is given in *Maintenance Aspects of Terotechnology. 1, Planned Maintenance* (Department of Industry (DoI), 1975/4). A decision tree illustrating the relationships between the various forms of maintenance is given in Figure 7.33.

Over the years, maintenance policies have been subject to change, even fashions. Moubray (1991) distinguishes three stages. The first stage is that of breakdown maintenance, characterized by plant which was relatively simple, which was designed with large safety margins and which was usually not safety-critical. The second stage is that of PM, in response to pressures for longer equipment life, high availability and lower costs. The third stage is that of RCM, in response to intensification of the same pressure, as well as those of safety, health and environment.

At one time PM was very much in vogue. It was often taken to uneconomic lengths and, in consequence, the fashion faded. Most present policies in the process industries are a mix of preventive and breakdown maintenance.

If maintenance policies are considered from the safety and loss prevention viewpoint, it is apparent that it is desirable to forestall breakdown as far as possible and that it is prudent to identify critical equipments and to carry out appropriate inspection and PM on them.

Process plants tend to run for long periods between scheduled shut-downs, or turnarounds. There are many equipments, however, which are not accessible for maintenance except at shut-down. Thus the shut-down is extremely important from the maintenance viewpoint. In particular, the shut-down allows an opportunity for the maintenance of plant utilities.

7.25.12 Maintenance information

The formulation of maintenance policies and the monitoring of maintenance activities require that there be a suitable maintenance information system. The maintenance information system has as its main purpose the provision of data on which to base maintenance decision-making, but it also has the further important function of feeding back information on failure to the design department and information on failure and repair to the reliability engineering section.

Some information which is relevant to maintenance includes identification and quantification of (1) failures responsible for hazardous conditions, (2) failures responsible for plant downtime and (3) failures responsible for direct repair costs.

7.25.13 Maintenance effectiveness

Measurement and monitoring of the effectiveness of the maintenance system is necessary, but is often not straightforward. Maintenance costs break down into direct costs and indirect costs. The direct costs are (1) materials and (2) labour. Some indirect costs are those due to (1) plant unavailability, (2) loss of plant throughput, (3) loss of plant efficiency and (4) spares holdings. The overall effect of poor maintenance may result in a degree of disruption, the cost of which can exceeds the apparent sum of these factors.

These considerations are the basis of approaches to maintenance which concentrate on the three 'top tens', these being the top ten items which contribute most in each of the three categories: (1) direct cost, (2) indirect cost and (3) troublesomeness.

7.25.14 Maintenance indices

It is common practice to evaluate maintenance performance in terms of ratios, or indices. Such indices typically measure (1) relative maintenance cost, (2) proportion of PM, (3) plant availability, (4) breakdown rate, (5) breakdown repair time and (6) breakdown cost. Normalizing factors used include (1) plant capital cost, (2) plant operating cost, (3) maintenance man-hours and (4) number of breakdowns.

$$Index\ 1 = \frac{Total\ cost\ of\ maintenance}{Total\ capital\ cost\ of\ plant}$$

$$Index\ 2 = \frac{Total\ cost\ of\ maintenance}{Total\ cost\ of\ plant\ operation}$$

$$Index\ 3 = \frac{Total\ man\text{-}hours\ of\ preventive\ maintenance}{Total\ man\text{-}hours\ on\ all\ maintenance}$$

$$Index\ 4 = \frac{Plant\ up\text{-}time}{Plant\ up\text{-}time + Plant\ down\text{-}time}$$

$$Index\ 5 = \frac{Plant\ up\text{-}time}{Number\ of\ breakdowns} = MTBF$$

$$Index\ 6 = \frac{Plant\ down\text{-}time}{Number\ of\ breakdowns} = MTTR$$

$$Index\ 7 = \frac{Cost\ of\ breakdowns}{Number\ of\ breakdowns}$$

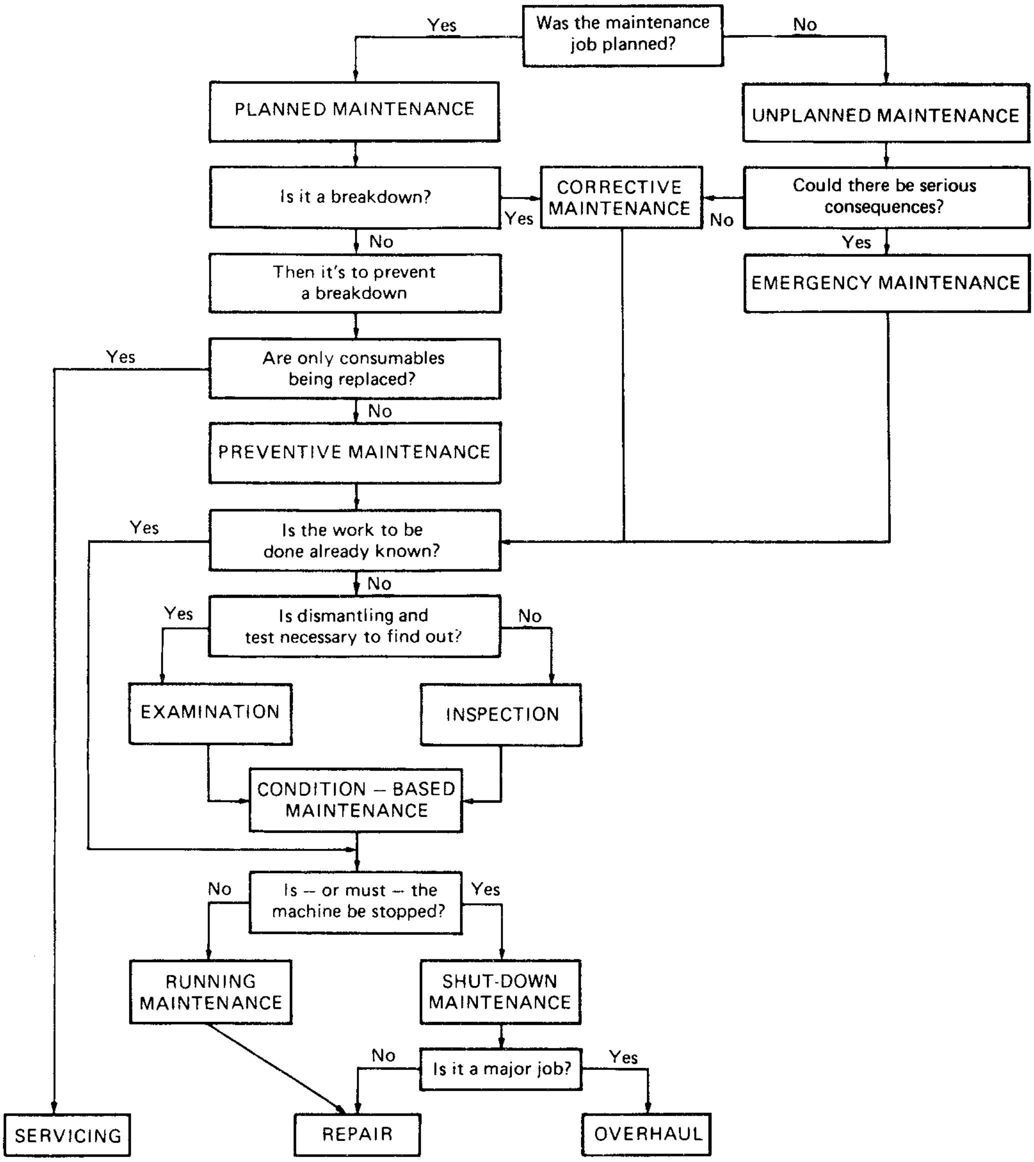

Figure 7.33 *Decision tree illustrating the relationship between the various forms of maintenance (Department of Industry, 1975/4). Terminology used is from BS 3811: 1974*

Such indices can be useful tools, but they may also imply unwarranted assumptions. Index 3, for example, appears to assume that PM is always a good thing, which is not necessarily the case.

A maintenance index may be evaluated by reference either to some absolute criterion value or to the historical trend. Both approaches have their uses.

7.26 Reliability-centred Maintenance

An approach to maintenance which is finding increasing acceptance is RCM. RCM is not a specific maintenance policy such as scheduled replacement or OCM, but an integrated method by which to select such policies. Accounts of this approach to maintenance are given in *Reliability-Centred Maintenance* (Anderson and Neri, 1990) and *Reliability-Centred Maintenance* (Moubray, 1991) and by Nowlan and Heap (1978), Sandtory and Rausand (1991) and Pradhan (1993).

RCM developed within the civil aircraft industry. In 1974, the Department of Defense commissioned a report on maintenance practice in that industry, published as *Reliability-centred Maintenance* (Nowlan and Heap, 1978).

The elements of RCM may be considered under the following headings: (1) functions, (2) function failures, (3) failures modes, (4) failure effects, (5) failure consequences, (6) preventive tasks and (7) default actions. This description suggests that RCM may be regarded as being based on a form of FMEA. This is broadly true, but it takes an approach to FMEA which places particular emphasis on function, function failure and prevention.

As described in the next chapter, FMEA is one of the prime tools of hazard identification used in safety and loss prevention work. Here it is sufficient to note that its growing use in maintenance is a major influence for the integration of safety and loss prevention (SLP) and maintenance.

7.26.1 Functions, functional failures and performance standards

Taking these elements in turn, RCM starts by establishing the functions of the equipment. The equipment will have some primary function which is its *raison d'etre,* but in addition it will generally have secondary functions. Thus, for example, a pump has the primary function of raising the pressure of the liquid, but it also has the secondary function of containing it. Satisfactory performance with respect to safety, health and environment may be treated as other secondary functions.

Increasingly, equipment comes with various kinds of protective device which serve to protect one or other of these functions. Protective devices are used to maintain the primary function by means such as bringing in standby equipment when the main equipment fails or to provide protection in relation to secondary functions such as safety or environment. For each function and each protective device there is a performance standard.

7.26.2 Failure modes and causes

It is necessary to identify the failure modes of the equipment. In general, failure modes may be described in terms of failure of performance or failure of condition. In RCM the former is the failure of function just described and it is the latter which is the failure mode. For example, if a pump becomes incapable of pumping the design flow of liquid, this might be expressed as a failure of pumping capability or a failure due to impeller wear. It is the failure of condition, the impeller wear, which is treated as the failure mode.

In the analysis of the failure modes it is important to uncover the root causes. Typical root causes include incorrect lubrication or maloperation. In the case of the pump impeller wear, the root cause might be cavitation due to partial blockages in the suction line.

7.26.3 Failure effects and consequences

The failure effects describe what happens when the failure occurs. They include the symptoms of failure and the effects on the process, on other equipment, safety and the environment. These failure effects are evaluated in order to assess the failure consequences. Here four types of consequence are distinguished: (1) hidden failure consequences, (2) safety and environmental consequences, (3) operational consequences and (4) non-operational consequences.

The term 'hidden failure' is that generally used in RCM to denote the unrevealed failure of protective devices. Most protective devices tend to fail without signalling the fact. In such cases the device then remains in the failed state until the failure is revealed either because the device is checked or because a demand occurs against which the device no longer provides protection. In other words, protective devices with this characteristic are not fail-safe. The treatment of unrevealed failure of protective devices is discussed in Chapter 13.

A hidden failure means that there is a risk of a demand occurring against which there is no protection, and hence of what in RCM is called 'multiple failure'.

The safety and environmental, operational and non-operational consequences are largely self-explanatory. The latter covers any damage to the equipment

7.26.4 Preventive tasks and default actions

The next step is to determine for each failure mode in turn whether a PM task exists which can eliminate or ameliorate the failure. For main equipment the approach followed is essentially that already described of establishing the failure characteristic (e.g., early failure, wearout failure) and identifying a corresponding appropriate preventive task. Consideration is also given to the appropriateness of OCM. For protective equipment, where the aim is to maintain an adequate availability, the main preventive action is to reduce the failure rate. The alternative measure is to alter the inspection interval, which counts as a default action.

In the RCM context, whether or not a preventive task is appropriate depends first on its technical feasibility and then on its worthwhileness. A task is undertaken only if it is feasible and worthwhile.

It is not appropriate to try to deal with every failure mode by a PM task. Where such a solution is not available, a default action is taken. Principal default actions are (1) redesign, (2) periodic inspection and (3) no action.

The typical account of RCM describes a rather formalized system with decision flow diagrams, FMEA worksheets, and so on. Commonly used abbreviations are: F, failure; FF, function failure; FM, failure mode; H, hidden failure; S, safety; E, environment; O, operation.

7.26.5 Illustrative example

The application of RCM to the process industries is illustrated by an example given by Pradhan (1993). The author deals with the use of RCM on a set of main reactor charge pumps handling vinyl chloride monomer (VCM) on a polyvinyl chloride (PVC) plant. Aims included the improvement of the pump system reliability and avoidance of the need for breakdown maintenance, and the prevention of VCM leaks and fires. He gives sample functions and failure analysis tables akin to those produced in FMEA, discusses in particular the hidden failure of protective devices, and describes the outcomes of the study in terms of the preventive tasks and default actions.

7.27 Life Cycle Costing

The concept of life cycle costing (LCC) is that ownership of an asset involves not only capital but also other costs, and that the aim should be to minimize these costs over the life cycle of the asset. An account of LCC in the context of process plants is given by Lees (1983d).

7.27.1 Management of life cycle costing

The practice of LCC is likely to be effective only if fully supported by management, whose attitude is crucial. Frequently the issue which will reveal management's attitude will be the trade-off between higher initial cost and overall LCC. The role of management is to establish the policy of LCC and to set up formal systems to ensure that the policy is followed.

There are also other ways in which management can promote LCC. One is the rotation of personnel between the plant and the design function, so that plant experience is fed back into design. Failure to achieve such feedback, by this or other means, can be very costly.

There are a number of other activities to which LCC is related. They include (1) reliability and maintainability engineering, (2) value engineering and (3) process economics. It is unlikely that the practice of LCC will flourish unless the organization has a sufficient level of activity in such areas.

A practical policy for LCC needs to define clearly the items to which it is to be applied and needs to avoid excessive complication.

7.27.2 Applicability of life cycle costing

LCC is most readily applied to an asset which is 'free-standing', that is, one whose failure does not cause significant disruption. In this case the optimization of the life cycle cost is essentially a trade-off between the higher capital cost of an equipment with superior performance, including reliability, and the direct costs of inferior performance, including unreliability. Whatever the case with other equipment, and a truly free-standing equipment is perhaps not as common as might appear at first sight, that used in process plant does not fall into this category.

LCC is subject to the law of diminishing returns. A policy for LCC therefore needs to include some sort of stopping rule. The returns are likely to be greatest for two types of equipment: (1) major items and (2) minor items used in large numbers.

7.27.3 Decision process for life cycle costing

It is not uncommon in the acquisition of an asset that the decision is made by the wrong person at the wrong time on the basis of inadequate information, or even that it is made essentially by default. For LCC the decision process covers the stages of (1) specification, (2) design and (3) procurement.

Often the key decisions are those taken early in the project. Thereafter, many of the options which have the strongest influence on the LCC are foreclosed. That said, the importance of the procurement stage should not be underestimated.

7.27.4 Factors contributing to life cycle cost

Some of the factors which contribute to LCC are: for the equipment, (1) capital cost, (2) maintenance cost and (3) equipment life; and, for the plant, (1) plant availability, (2) plant instantaneous throughput, (3) plant efficiency and (4) plant flexibility. Safety, health, environment and other factors act as constraints which may have a strong influence on the LCC.

Often the main elements from this list are (1) capital cost, (2) maintenance cost and (3) plant availability.

7.27.5 Information for life cycle costing

The practice of LCC requires information on *inter alia* (1) failure rate, (2) repair time and (3) plant unavailability.

It is possible to construct a long list of information which in principle bears on LCC. However, not all this information is readily observable, at least without excessive cost. If the acquisition of information is considered in terms of the two attributes of importance and observability, the policy adopted might well be the following:

		Observability	
		High	*Low*
Importance	*High*	Y	?
	Low	?	N

where Y indicates that the information is sought, N that it is not sought and ? that the case is considered on its merits.

7.27.6 Essential and optional equipment functions

The functions of equipment divide into the essential and the desirable. Examples of essential functions include containment by materials of construction, material transfer by pumps and compressors, control by instruments and computers, protection by protective devices and thermal insulation by lagging. Other functions may be less essential, even optional. Examples are equipment for heat recovery or improved process yield.

The computation of LCC in these two cases is different. Where the function is essential, the decision is concerned with the alternative ways of providing the function, but where it is optional the decision is rather whether to provide it at all. The latter decision may well be more self-contained and easier to make.

7.27.7 Euipment functions involving availability

A further distinction to be made is that between those decisions which involve plant availability and those which do not. The effect of an equipment on plant availability is often quite difficult to assess. Intermediate storage is provided to improve plant availability, but its effectiveness is a function of the storage operating policy adopted. Stand by equipment is provided to cut in when the main equipment fails, but its reliability in responding to this demand depends largely on management factors.

A further complication arises when the plant is not operating at full capacity and its availability is at a discount. It is difficult to generalize about this situation, but one point is worth making. It can be of value to demonstrate that the plant can operate dependably at high availability, even if not currently required to do so, since this means that it is known that when demand picks up it can be met from the existing plant, thus allowing expenditure on a further plant to be deferred.

7.27.8 Equipment quality vs system configuration

It often occurs that a particular function can be provided by a single equipment or by several equipments in some-suitable configuration. For a given level of reliability, the single equipment will need to be of higher quality. There is therefore a choice to be made between a single, high quality item and several items which could be of lower quality.

In making this decision, use may be made of simple models of system reliability and availability such as those given above, particularly in Sections 7.8 and 7.13. If the case is considered of a single equipment vs two parallel redundant equipments, the reliability of the single item needs to be very high to match that of a parallel system of two items of moderate reliability.

7.27.9 Assessment of equipment quality

The ability to assess the quality of equipment is clearly crucial to the practice of LCC. Some factors relevant to the assessment are (1) user experience, (2) vendor reputation, (3) design status (new, established), (4) capital cost, (5) material of construction and (6) engineering principles. Engineering principles include (1) the number of subsystems and components, (2) electronic vs mechanical subsystems, (3) moving parts and (4) stressing of parts. Also relevant are any quality assurance arrangements which exist between the vendor and the user.

7.28 Notation

Sections 7.1–7.13

a	constant; parameter in rectangular, gamma, Pareto and extreme value distributions
A	event A
$A(t)$	availability
$\mathbf{A}$	matrices defined by Equations 7.10.6 and 7.10.36
b	constant; parameter in rectangular, gamma and extreme value distributions
B	event B
C	event C; minimum cut set
$d(t)$	down-time
e	error
E	event E
$f(t)$	failure density function
$f_d(d)$	down-time density function
$f_r(t_r)$	repair time density function
$f_w(w)$	throughput density function
$f_1(t), f_2(t)$	failure density function of subsystem
$F(t)$	failure distribution function
$F_d(d)$	down-time distribution function
$F_r(t_r)$	repair time distribution function
$\bar{g}(s)$	Laplace transform of $g(t)$
$H(t)$	cumulative hazard function
$\mathbf{I}$	identity matrix
k	counter; state counter; parameter in Weibull distribution (alternative form); parameters defined by Equations 7.13.28 and 7.18.5
m	mean life; parameter in Weibull distribution (alternative form); mean of normal distribution; number of repairmen
m^*	location parameter in log–normal distribution
m_d	mean down-time
m_i	ith moment (experimental)
m_r	mean repair time; mean of normal distribution of repair times
m_{r^*}	location parameter in log–normal distribution of repair times
m_{ru}	mean repair time of upstream unit
m_u	mean up-time
m_{z^*}	parameter in log-normal distribution of hazard rates
n	counter; number of items; number of states; number or trials; number of repairmen; number of applications of load
$n_f(t)$	number of items failed
n_i	number of times outcome i occurs
$n_s(t)$	number of items surviving
p	probability; probability of success
P	probability; probability of success
$P(\mid)$	conditional probability
P_k	probability of being in state k
$\boldsymbol{P}$	vector of probabilities
q	probability of failure
$Q(t)$	probability of failure, unreliability, failure distribution function
r	counter
$r_1 r_2$	equation roots defined by Equations 7.8.24 and 7.8.26
$R(t)$	probability of success or survival, reliability, reliability function
R_{sw}	probability of switchover
R_x	reliability of component
s	Laplace operator
t	time; failure time
t_r	repair time
T	time period; minimum tie set
T_e	time to empty tank
$u(t)$	up-time
$V(t)$	unavailability
V_s	unavailability of upstream unit
V_{st}	unavailability of upstream unit + tank
w	throughput
$z(t)$	hazard rate
$\mathcal{L}(\,)$	Laplace transform
α	parameter in Weibull distribution (alternative form); confidence level parameter
β	shape factor in Weibull distribution
γ	location parameter in Weibull distribution; number of standard deviations
Γ	gamma function
ζ	event rate
η	characteristic life in Weibull distribution
λ	failure rate; transition rate
λ'	failure rate
λ_{st}	failure rate of upstream unit + tank
λ_u	failure rate of upstream unit
μ	moment; mean number of events; repair rate
μ_i	ith moment (theoretical)
ξ	repair rate enhancement factor
ρ	parameter defined by Equation 7.13.24
σ	standard deviation of normal distribution; shape factor in log–normal distribution
σ_L	standard deviation of loading
σ_r	standard deviation of repair times; shape parameter in log–normal distribution of repair times
σ_s	standard deviation of strength
σ_z	parameter in log–normal distribution of hazard rates
τ	time; repair time; parameter defined by Equation 7.18.6
$\phi(\tau, t)$	joint density function

Superscripts

-	Laplace transform
Λ	estimated value

Section 7.14

E	event
$f_{T1}(t_1)$	density function of t_1
$f_{T1\mid\Lambda}(t_1 \mid \lambda)$	density function of $t_1 \mid \lambda$
$f_X(x)$	density function of x
$f_{X\mid Y}(x \mid y)$	density function of $x \mid y$
$f_Y(y)$	density function of y
$f_{Y\mid X}(y \mid x)$	density function of $y \mid x$

$f_{\Lambda}(\lambda)$	density function of λ
$f_{\Lambda \mid T1}(\lambda \mid t_1)$	density function of $\lambda \mid t_1$
H	hypothesis
n	number of failures
t	time
t_1	specific value of T_1 (time to failure)
T_1	random variable (time to failure)
x	specific value of X
X	random variable
y	specific value of Y
Y	random variable
λ	specific value of Λ (failure rate)
Λ	random variable (failure rate)
μ	parameter in distribution of λ

Superscript

$\hat{}$	estimated value

Section 7.15

$E(\ )$	expected value
f_i	density function of component i
$f_{\tau n}$	density function of τn
$F_{\tau n}$	distribution of function of τn
n	counter for renewals
N	number of renewals
P	probability
s	Laplace operator
t	time
t_i	time to failure of component i

Superscript

$-$	Laplace transform

Section 7.16

C	average annualized cost of operation
C_c	capital cost of equipment
$f(n)$	rate of expenditure on maintenance
$f(t)$	rate of expenditure on maintenance
n	number of years equipment is to be in use
S	scrap value of equipment
t	time equipment is to be in use

Section 7.17

Subsection 7.17.5

$f(x)$	density function of load x
$f(y)$	density function of strength y
$g(z)$	density function of z
$G(z)$	distribution function of z
L	load
m_x	mean value of load x
m_y	mean value of strength y
m_z	mean value of z
n_x	constant in Equation 7.17.4
n_y	constant in Equation 7.17.5
S	strength
u	parameter defined by Equation 7.17.13
v	parameter defined by Equation 7.17.14
x	load
y	strength
z	difference between load and strength
σ_x	standard deviation of load x
σ_y	standard deviation of strength y
σ_z	standard deviation of z
ϕ	safety parameter

Subsection 7.17.6

$f(i)$	shaping factor
L	load
n	number of applications of load
ρ	parameter defining shaping factor in Equation 7.17.21
$R(n)$	probability of survival after n applications of load
s	stress (or strength)
s_0	initial strength
Δs_i	decrement of strength
S	strength
$z(t)$	hazard rate
σ	scaling factor

Section 7.18

a, b	constants
$H(t)$	cumulative hazard function
k	parameter in Weibull distribution (alternative form)
m	parameter in Weibull distribution (alternative form)
$\bar{R}(t)$	probability of success or survival, reliability
$\bar{\lambda}$	parameter defined by Equation 7.18.4
τ	parameter defined by Equation 7.18.6

Section 7.19

$f(t)$	density function
$f_1(t), f_2(t)$	constituent density functions
p	weighting factor

Section 7.20

Subsection 7.20.6

f	degrees of freedom
f_1, f_2	degrees of freedom
$L()$	lower limit
m	mean life
n	number of trials
N	number of trials
S	number of successes
T	period of test
$U()$	upper limit
α	confidence parameter
χ^2	chi square distribution

Superscript

$\hat{}$	estimated value

Subsection 7.20.8

as Sections 7.1–7.13 plus

F_{mean}	mean rank
F_{med}	median rank
m_j	mean order number
m_0	replacement time
Δm	mean order number increment
n	number of items
$n_f(t)$	number of items failed
x	number of items before jth failure

Subsection 7.20.11

as Sections 7.1–7.13 plus

a	parameter
a_i	parameters
b	parameter
L	likelihood function
t	time to failure
z_c	calculated hazard rate
μ_k	kth moment of distribution
$\mathcal{L}$	logarithm of likelihood function $(= \ln \mathrm{L})$

Subsection 7.20.16

as Sections 7.1–7.13 plus

v	random number

Subsection 7.20.17

$z(t)$	hazard rate
z_i	ith influencing variable, or explanatory factor
$z_0(t)$	baseline hazard function
β_i	coefficient of z_i

Section 7.22

as Sections 7.1–7.13 plus

C_i	parameter representing complexity of ith subsystem
W_i	weighting factor for ith subsystem

Section 7.23

Subsection 7.23.3

T	period of test
α	index

Subscripts

cum	cumulative
cur	current

Subsection 7.23.4

c	allowable number of defects
n	number of items in sample
ρ	proportion of good items
P	probability of acceptance
q	proportion of defective items

Section 7.25

k	constant
m	mean life of component
m_0	replacement time of component
σ	standard deviation of life of component

8

Hazard Identification

Contents

The identification of areas of vulnerability and of specific hazards is of fundamental importance in loss prevention. Once these have been identified, the battle is more than half won. Such identification is not a simple matter, however. In many ways, it has become more difficult as the depth of technology has increased. Loss prevention tends, increasingly, to depend on the management system and it is not always easy to discover the weaknesses in this. The physical hazards also no longer lie on the surface, accessible to simple visual inspection. On the other hand, there is now available a whole battery of hazard identification methods which may be used to solve these problems. Selected references on hazard identification are given in Table 8.1.

Different methods are required at different stages of a project. Table 8.2 lists some of these stages and the corresponding hazard identification techniques. The list is illustrative and, in particular, a technique quoted for one stage may also be applicable to another stage. There is no single ideal system of hazard identification procedures. The most appropriate system varies to some extent with the type of industry and process. Thus, for example, a firm involved in the batch manufacture of a large number of organic chemicals is likely to be much more interested in techniques of screening and testing chemicals and reactions than one operating ethylene plants.

The choice of hazard identification technique also depends on the purpose for which the study is done. For the identification of hazards and operating problems on a plant, a hazard and operability (HAZOP) study is suitable, while for the identification of sources of release for a hazard assessment, it is necessary to carry out a specific review of such sources. It is only sensible in hazard identification to make use of past experience. The use of standards and codes, of course, helps to avoid hazards of which people may not even be aware.

Many of the hazard identification techniques used, however, are concerned with situations, which have some element of novelty. Methods for screening and testing are used to detect hazardous runaways and decompositions in new chemicals and reactions. HAZOP studies are used to identify how often familiar hazards may be specifically realized in a new plant.

8.1 Safety Audits

One of the first systematic methods of hazard identification used in the chemical industry was the safety audit. Audits of various types are a normal management tool and are of considerable importance in safety.

An early account of safety audits in the United Kingdom was the BCISC report *Safe and Sound* (1969/9), which drew on the experience of the US chemical industry, where the safety audit was established as a prime means of ensuring safety. A full description of such an audit is given in the BCISC's *Safety Audits* (1973/12). A safety audit subjects every area of the organization's activity to a systematic critical examination. It aims, like other audits, to reveal the strengths and weaknesses and the areas of vulnerability. It is carried out by professionals and results in a formal report and action plan.

Safety Audits draws a distinction between a safety audit and a safety survey, which is a detailed examination of a narrow field such as specific procedures or a particular plant; safety inspection, which is a scheduled inspection of a unit carried out by the unit's own personnel; safety tour, which is an unscheduled tour of a unit carried out by

Dehn (1973); Sheldon and Kochi (1973); Treweekef *et al.* (1973); Bowes (1974b); Carver *et al.* (1974); Groothuizen *et al.* (1974); A.J. an outsider such as the works manager or a safety representative; and safety sampling, which is a specific application of a safety inspection/tour designed to measure accident potential.

A safety audit examines and assesses in detail the standards of all facets of a particular activity. It extends from complex technical operations and emergency procedures to clearance certificates, job descriptions, housekeeping and attitudes. It involves labour relations since people are asked about their training, their understanding of works policy and whether they think they are making their contribution in the right way.

An audit might cover a company-wide problem or a total works situation (say, its emergency procedures or effluent systems) or simply a single plant activity.

At any level an audit is carried out thoroughly by a team made up of people immediately concerned, assisted by experts in various fields and experienced people not connected with the area of audit, to ensure that a fresh and unbiased look is injected into the inspection process.

Safety audits thus cover the following main areas:

(1) site level
  (a) management system;
  (b) specific technical features;
(2) plant level
  (a) management system.

The audit has five main elements;

(1) identification of possible hazards;
(2) assessment of potential consequences of realization of these hazards:
(3) selection of measures to minimize frequency and/or consequences of realization;
(4) implementation of these measures within the organization;
(5) monitoring of the changes.

The audit is conducted in a fairly formal way, using a checklist, although experience-based approaches are used with appropriate protocols. Table 8.3, taken from *Safety*

Table 8.2 *Hazard identification techniques appropriate to different project stages*

Project stage	*Hazard identification technique*
All stages	Management and safety system audits Checklists Feedback from workforce

Research and development	Screening and testing for
	  Chemicals (toxicity, reactivity, explosibility)
	  Reactions (explosibility)
	  Impurities
	Pilot plant

Pre-design	Hazard indices Insurance assessments Hazard studies (coarse scale)

Design	Process design checks
	  Unit processes
	  Unit operations
	  Plant equipments
	  Pressure systems
	  Instrument systems
	Hazard and operability studies (fine scale)
	Safety Integrity Level Studies (SIL, SIS) and Level of Protection
	Chemical Interaction Matrix
	Failure modes and effects analysis
	Fault trees and event trees
	Hazard analysis
	Risk & Reliability assessments
	Operator task analysis and operating instructions

Commissioning	Checks against design, inspection, examination, testing Non-destructive testing, condition monitoring Pre-Startup Safety Review Plant safety audits Emergency planning
Operation	Inspection, testing Non-destructive testing, condition monitoring, corrosion Plant safety audits

Audits, gives a list of activities and activity standards. These standards can be used as the basis of a numerical rating scheme. If a safety audit is conducted, it is essential that the management act on it. This does not necessarily mean that every recommendation must be implemented, but there should be a reasoned response.

Safety audits are an important part of the activity of the safety function. In addition to identifying hazards, they play a major role in educating personnel at all levels. These aspects are discussed in more detail in Chapter 28. Safety audits of the organization and management system at site and at plant level are considered below.

Another form of audit is the insurance survey. Insurance surveys have been described in Chapter 5. Although the insurer is not able to go down to the lower levels of detail, his contribution is valuable in that it represents an independent assessment.

8.2 Management System Audits

The management system is crucial to loss prevention and it is essential that this system itself be monitored. The management system, and its auditing, have been described in Chapter 6. Management audit is so important, however, that a brief, summary account is in order at this point.

The management system may be audited in several ways. These include (1) self-checking procedures, (2) internal audit and (3) external audit. An illustration of a specific check built into the system is a formal requirement that a plant manager audit a proportion of the permits-to-work each week.

The safety audits described above include an internal audit of the overall system. In particular, there are checks on:

(1) overall management attitude, policies, systems and procedures, personnel selection;
(2) plant level management, attitude, systems, training and feedback;
(3) incident reporting, investigation and statistics.

External audit may be carried out by an outside body such as a firm of consultants.

There are now available a number of audit systems, including proprietary systems. Some of these yield quantitative factors applicable in quantitative risk assessment (QRA). Accounts of audit systems are given in Chapters 6, 9 and 28.

Table 8.3 Activity standards for safety audits (British Chemical Industry Safety Council, 1973/12)

Activity	*Poor*	*Fair*	*Good*	*Excellent*
A Organization and administration				
1 Statement of policy, responsibilities assigned	No statement of loss control policy. Responsibility and accountability not assigned	A general understanding of loss control, responsibilities and accountability, but not written	Loss control policy and responsibilities written and distributed to supervisors	In addition to 'good', loss control policy is reviewed annually and is posted. Responsibility and accountability is emphasized in supervisory performance evaluations
2 Safe operating procedures (SOPs)	No written SOPs	Written SOPs for some, but not all, hazardous operations	Written SOPs for all hazardous operations	All hazardous operations covered by a procedure, posted at the job location, with an annual documented review to determined adequacy
3 Employee selection and placement	Only pre-employment physical examination given	In addition, an aptitude test is administered to new employees	In addition to 'fair', new employees' past safety record is considered in their employment	In addition to 'good', when employees are considered for promotion, their safety attitude and record is considered
4 Emergency and disaster control plans	No plan or procedures	Verbal understanding on emergency procedures	Written plan outlining the minimum requirements	All types of emergency covered with written procedures. Responsibilities are defined with back-up personnel provisions
5 Direct management involvement	No measurable activity	Follow-up on accident problems	In addition to 'fair', management reviews all injury and property damage reports and holds supervision accountable for verifying firm corrective measures	In addition to 'good', reviews all investigation reports. Loss control problems are treated as other operational problems in staff meeting
6 Plant safety rules	No written rule	Plant safety rules have been developed and posted	Plant safety rules are incorporated in the plant work rules	In addition, plant work rules are firmly enforced and updated at least annually

B Industrial hazard control

1	Housekeeping storage of materials, etc.	Housekeeping is generally poor. Raw materials, items being processed and finished materials are poorly stored	Housekeeping is fair. Some attempts to adequately store materials are being made	Housekeeping and storage of materials are orderly. Heavy and bulky objects well stored out of aisles, etc.	Housekeeping and storage of materials are ideally controlled
2	Machine guarding	Little attempt is made to control hazardous points on machinery	Partial but inadequate or ineffective attempts at control are in evidence	There is evidence of control which meets applicable Federal and State requirements, but improvement may still be made	Machine hazards are effectively controlled to the extent that injury is unlikely. Safety of operator is given prime consideration at time of process design
3	General area guarding	Little attempt is made to control such hazards as: unprotected floor openings, slippery or defective floors, stairway surfaces, inadequate illumination, etc.	Partial but inadequate attempts to control these hazards are evidenced	There is evidence of control which meets applicable Federal and State requirements – but further improvement may still be made	These hazards are effectively controlled to the extent that injury is unlikely
4	Maintenance of equipment, guards, handtools, etc.	No systematic programme of maintaining guards, handtools, controls and other safety features of equipment, etc.	Partial but inadequate or ineffective maintenance	Maintenance programme for equipment and safety features is adequate. Electrical handtools are tested and inspected before issuance, and on a routine basis	In addition to 'good', a preventive maintenance system is programmed for hazardous equipment and devices. Safety reports filed and safety department consulted when abnormal conditions are found
5	Material handling – hand and mechanized	Little attempt is made to minimize possibility of injury from the handling of materials	Partial but inadequate or ineffective attempts at control are in evidence	Loads are limited as to size and shape for handling by hand, and mechanization is provided for heavy or bulky loads	In addition to controls for both hand and mechanized handling, adequate measures prevail to prevent conflict between other workers and material being moved
6	Personal protective equipment – adequacy and use	Proper equipment not provided or is not adequate for specific hazards	Partial but inadequate or ineffective provision, distribution and use of personal protective equipment	Proper equipment is provided. Equipment identified for special hazards, distribution of equipment is controlled by supervisor. Employee is required to use protective equipment	Equipment provided complies with standards. Close control maintained by supervision. Use of safety equipment recognized as an employment requirement. Injury record bears this out

Table 8.3 *(continued)*

Activity	*Poor*	*Fair*	*Good*	*Excellent*
C Fire control and industrial hygiene				
1 Chemical hazard control references	No knowledge or use of reference data	Data available and used by foremen when needed	In addition to 'fair', additional standards have been requested when necessary	Data posted and followed where needed. Additional standards have been promulgated, reviewed with employees involved and posted
2 Flammable and explosive materials control	Storage facilities do not meet fire regulations. Containers do not carry name of contents. Approved dispensing equipment not used. Excessive quantities permitted in manufacturing areas	Some storage facilities meet minimum fire regulations. Most containers carry name of contents. Some approved dispensing equipment in use	Storage facilities meet minimum fire regulations. Most containers carry name of contents. Approved equipment is generally used. Supply at work area is limited to one day requirement. Containers are kept in approved storage cabinets	In addition to 'good', storage facilities exceed the minimum fire regulations and containers are always labelled. A strong policy is in evidence relative to the control of the handling, storage and use of flammable materials
3 Ventilation – fumes, smoke and dust control	Ventilation rates are below industrial hygiene standards in areas where there is an industrial hygiene exposure	Ventilation rates in exposure areas meet minimum standards	In addition to 'fair', ventilation rates are periodically measured, recorded and maintained at approved levels	In addition to 'good', equipment is properly selected and maintained close to maximum efficiency
4 Skin contamination control	Little attempt at control or elimination of skin irritation exposures	Partial but incomplete programme for protecting workers. First-aid reports on skin problems are followed up on an individual basis for determination of cause	The majority of workmen instructed concerning skin-irritating materials. Workmen provided with approved personal protective equipment or devices. Use of this equipment is enforced	All workmen informed about skin-irritating materials. Workmen in all cases provided with approved personal protective equipment or devices. Use of proper equipment enforced and facilities available for maintenance. Workers are encouraged to wash skin frequently. Injury record indicates good control

5	Fire control measures	Do not meet minimum insurance or municipal requirements	Meet minimum requirements	In addition to 'fair', additional fire hoses and/or extinguishers are provided. Welding permits issued. Extinguishers on all welding carts	In addition to 'good', a fire crew is organized and trained in emergency procedures and in the use of fire fighting equipment
6	Waste – trash collection and disposal, air/water pollution	Control measures are inadequate	Some controls exist for disposal of harmful wastes or trash. Controls exist but are ineffective in methods or procedures of collection and disposal. Further study is necessary	Most waste disposal problems have been identified and control programmes instituted. There is room for further improvement	Waste disposal hazards are effectively controlled. Air/water pollution potential is minimal
D	**Supervisory participation, motivation and training**				
1	Line supervisor safety training	All supervisors have not received basic safety training	All shop supervisors have received some safety training	All supervisors participate in division safety training session a minimum of twice a year	In addition, specialized sessions conducted on specific problems
2	Indoctrination of new employees	No programme covering the health and safety job requirements	Verbal only	A written handout to assist in indoctrination	A formal indoctrination programme to orientate new employees is in effect
3	Job hazard analysis	No written programme	Job hazard analysis (JHA) programme being implemented on some jobs	JHA conducted on majority of operations	In addition, job hazard analyses performed on a regular basis and safety procedures written and posted for all operation
4	Training for specialized operations (fork trucks, grinding, press brakes, punch presses, solvent handling, etc.)	Inadequate training given for specialized operations	An occasional training programme given for specialized operations	Safety training is given for all specialized operations on a regular basis and retraining given periodically to review correct procedures	In addition to 'good', an evaluation is performed annually to determine training needs
5	Internal self-inspection	No written programme to identify and evaluate hazardous practices and/or conditions	Plant relies on outside sources, i.e. Insurance Safety Engineer, and assumes each supervisor inspects his area	A written programme outlining inspection guidelines, responsibilities, frequency and follow-up is in effect	Inspection programme is measured by results, i.e. reduction in accidents and costs. Inspection results are followed up by top management
6	Safety promotion and publicity	Bulletin boards and posters are considered the primary means for safety promotion	Additional safety displays, demonstrations films are used infrequently	Safety displays and demonstrations are used on a regular basis	Special display cabinets, windows, etc., are provided. Displays are used regularly and are keyed to special themes

Table 8.3 *(continued)*

Activity	*Poor*	*Fair*	*Good*	*Excellent*
7 Employee–supervisor safety contact and communication	Little or no attempt made by supervisor to discuss safety with employees	Infrequent safety discussions between supervisor and employees	Supervisors regularly cover safety when reviewing work practices with individual employees	In addition to items covered under 'good', supervisors make good use of the shop safety plan and regularly review job safety requirements with each worker. They contact at least one employee daily to discuss safe job performance
E Accident investigation, statistics and reporting procedures				
1 Accident investigation by line personnel	No accident investigation made by line supervision	Line supervision makes investigations of only medical injuries	Line supervision trained and makes complete and effective investigations of all accidents; the cause is determined; corrective measures initiated immediately with a completion date firmly established	In addition to items covered under 'good', investigation is made of every accident within 24 h of occurrence. Reports are reviewed by the department manager and plant manager
2 Accident cause and injury location analysis and statistics	No analysis of disabling and medical cases to identify prevalent causes of accidents and location where they occur	Effective analysis by both cause and location maintained on medical and first-aid cases	In addition to effective accident analysis, results are used to pinpoint accident causes so accident prevention objectives can be established	Accident causes and injuries are graphically illustrated to develop the trends and evaluate performance. Management is kept informed on status
3 Investigation of property damage	No programme	Verbal requirement or general practice to inquire about property damage accidents	Written requirement that all property damage accidents of US$50 and more will be investigated	In addition, management requires a vigorous investigation effort on all property damage accidents
4 Proper reporting of accidents and contact with carrier	Accident reporting procedures are inadequate	Accidents are correctly reported on a timely basis	In addition to 'fair', accident records are maintained for analysis purposes	In addition to 'good', there is a close liaison with the insurance carrier

The HSE is also concerned with auditing the management system. Indeed, it is fair to say that this is its most important function. When visiting a factory, an Inspector is very much concerned with the way the system works in practice. Audit by the HSE is another aspect discussed in Chapter 6.

8.3 Checklists

One of the most simplistic tools of hazard identification is the checklist. Like a standard or a code of practice, a checklist is a means of passing on lessons learned from experience. It is impossible to envisage high standards in hazard control unless this experience is effectively utilized. The checklist is one of the main tools available to assist in this.

Checklists are applicable to management systems in general and to a project throughout all its stages. Obviously the checklist must be appropriate to the stage of the project, starting with checklists of basic materials properties and process features, continuing on to checklists for detailed design and terminating with operations audit checklists.

There are a large number of checklists given in the literature – indeed a paper on practical engineering is quite likely to include a checklist. Selected references on checklists are given in Table 8.4, but these are only a tiny fraction of those available. A number of checklists are given in the present volume. These are collated in the index. A checklist should be used for just one purpose only – as a final check that nothing has been neglected. Also, it is more effective if the questions cannot be answered by a simple 'yes' or 'no' but require some thought in formulating an answer.

Table 8.4 *Selected references on checklists*

Statutory approvals: J.C. Rose *et al.* (1978)

Chemical reactors: Gorbell (1982)

Dust-handling plant: Anon. (1990 LPB 95, p. 7)

Utilities: Gorbell (1982)

Pressure systems design: Spiegelman (1969); Gorbell (1982); D. Scott and Crawley (1992)

Pressure relief: Gorbell (1982)

Instrumentation: Gorbell (1982)

Human factors, human error: SRD, Human Factors in Reliability Group (1985 SRD R347); HSE (1989 HS(G) 48); Brazendale (1990 SRD 510)

Training: FPA (1974/23)

Fire and fire protection: Dow Chemical Co. (1964, 1966a,b, 1976, 1980, 1987, 1994); FPA (1965/3, 1974/23); Wells (1980); Gorbell (1982); D. Scott and Crawley (1992)

Plant commissioning: Matley (1969); Buyers (1972); J.D. Baker (1974); Mackey (1974); Turnbull *et al.* (1974); Unwin *et al.* (1974); L. Pearso (1977a,b); J.C. Rose *et al.* (1978); Wells (1980); D. Scott and Crawley (1992)

Plant start-up and shut-down: Wells (1980); D. Scott and Crawley (1992)

Plant operation: D. Scott and Crawley (1992)

Plant maintenance: D. Scott and Crawley (1992)

Demolition: Stuart (1974)

Plant modifications: Henderson and Kletz (1976); Wells (1980); Anon. (1994 LPB 120, p. 13)

Storage: Dow Chemical Co. (1964, 1966a,b, 1976, 1980, 1987, 1994); Spiegelman (1969); Balemans *et al.* (1974); Drewitt (1975); Jager and Haferkam (1992)

Transport: Spiegelman (1969)

Personal safety: Gorbell (1982)

Pilot plants: Carson and Mumford (1989 LPB 89)

Incident investigation: M.E. Lynch (1967, 1973)

Checklists are effective only if they are used. There is often a tendency for them to be left to gather dust on the shelf. This is perhaps part of the reason for the development of other techniques such as HAZOP studies, as described below.

8.4 Materials Properties

8.4.1 Physical and chemical properties

It is obviously necessary to have comprehensive information on all the chemicals in the process: raw materials, intermediates and final products. A list of some important physical and chemical properties of any chemical is given in Table 8.5. The significance of most of the items in the list is self-evident.

Compilations of properties of hazardous substances are typically found in accompanying Material Safety Data Sheets (MSDSs). Other sources include those by the NFPA (NFPA 704) and the NIOSH.

Corrosivity, flammability, toxicity and radioactivity are considered in more detail in Chapters 12, 16, 18 and 25, respectively. Reactivity, instability and explosibility and

Table 8.5 *Some important physical and chemical properties of a chemical*

General properties	Molecular structure Freezing point Vapour pressure, boiling point Critical pressure, temperature, volume Vapour density, specific heat, viscosity, thermal conductivity Liquid density, specific heat, viscosity, thermal conductivity Latent heats of vaporization and fusion Dielectric constant, electrical conductivity
Flammability	Flammability limits Flash point Autoignition temperature Minimum ignition energy Maximum experimental safe gap Self-heating
Corrosion	Corrosiveness to materials of construction Incompatibility with particular materials
Polymerization, decomposition	Polymerization characteristics Decomposition, hydrolysis characteristics
Impurities	Impurities in: raw material plant material Mutual solubilities with water
Reaction, explosion	Heats of formation, combustion, decomposition Energy hazard potential Thermal stability Impact sensitivity
Toxicity	Threshold limit values, emergency exposure limits Lethal concentration LC_{50}, lethal dose LD_{50} Exposure effects (inhalation, ingestion, skin and eye contact) Long-term low exposure effects Warning levels (smell)
Radioactivity	Radiation survey α-particle, β- , γ- ray exposures

process chemical reactions are dealt with in the following sections.

8.4.2 Materials safety data sheets

Information on the physical and chemical properties of chemicals and on the associated hazards and the appropriate precautions cast in standard format is available in the form of MSDSs.

Safety data sheet compilations are prepared by various organizations and are available on the Internet.

An EC Directive (91/155/EEC) lays down the contents of a safety data sheet. In the United Kingdom, this is implemented by the Chemical Hazard Information and Packaging (CHIP) Regulations. HSE guidance: *Safety Data Sheets for Substances and Preparations Dangerous for Supply* (1993) has been amended on a regular basis since its inception and further guidance is available in *The EC Safety Data Sheet Directive* by CONCAWE (1992 92/55).

The Directive requires that the contents of a safety data sheet cover:

(1) identification of the substance/preparation and company;
(2) composition/information on ingredients;
(3) hazards identification;
(4) first-aid measures;
(5) firefighting measures;
(6) accidental release measures;
(7) handling and storage;
(8) exposure controls/personal protection;
(9) physical and chemical properties;
(10) stability and reactivity;
(11) toxicological information;
(12) ecological information;
(13) disposal considerations;
(14) transport information;
(15) regulatory information;
(16) other information.

Both the guides mentioned give detailed guidance on the material to be included under each of these heads. It is the responsibility of the supplier of a chemical to supply the safety data sheet.

8.4.3 Impurities

Impurities, foreseen or unforeseen, can have serious adverse effects on many aspects of process operation, including safety and loss prevention. These effects are discussed in more detail in Chapter 11. Here consideration is confined to the identification of possible problems with impurities.

There is no established methodology of identifying impurities which may arise in the process, that is comparable with that for checking the reactivity of a chemical. Reliance usually has to be placed on the literature and on experience. As discussed below, however, indication of possible impurities and of their adverse effects is one of the particularly valuable features of a pilot plant.

8.5 Pilot Plants

Scale-up from laboratory to full-size plant has always been a difficult problem in the chemical industry. Indeed it is this problem which in large part is responsible for the profession of chemical engineering. An important tool for tackling the problem is the pilot plant. In the words of L.H. Baekeland, the philosophy of the pilot plant is: 'Make your mistakes on a small scale and your profits on a large scale'.

There are many reasons beside safety for using a pilot plant. They include the determination of the most economic design and operating parameters, the production of product for evaluation and trial marketing. Nevertheless, safety considerations constitute a substantial part of the case for the pilot plant.

A pilot plant is used principally to assist in the scale-up of the process design rather than the mechanical design, for example, reaction conditions rather than pump specifications.

Some types of information relevant to safety which a pilot plant may yield include:

(1) operating conditions (e.g. pressure, temperature);
(2) design parameters (e.g. reaction rates, heat transfer coefficients);
(3) reactor problems;
(4) unit operations problems;
(5) materials handling problems (e.g. foaming, solids handling, catalyst handling);
(6) decomposition;
(7) impurities;
(8) corrosion;
(9) fouling;
(10) analytical problems;
(11) operating problems;
(12) working environment problems (e.g. toxics);
(13) effluent and waste disposal problems.

Impurities can cause many problems, and a pilot plant is one of the most effective means of identifying these. There may be impurities in the feedstock which give unexpected effects. Impurities may arise through side reactions, decomposition or polymerization. Leaks into the system may bring in other impurities such as pump lubricant and seal fluids or heat transfer media, including water. Air and water from other sources are common impurities or sources of impurity. Impurities which in a one-pass process might not be significant can build up if there is recycle. The product may be contaminated with any of these impurities. Impurities may cause fouling, blockages, etc. Some impurities can explode or catalyse explosive reactions. Problems may arise in effluent disposal due to impurities. Operation of a pilot plant offers a high probability of detecting impurities problems. Similarly, a pilot plant often reveals corrosion problems. These are frequently associated not with the main materials and bulk chemicals, but with minor components such as gaskets and diaphragms or with impurities in the bulk chemicals.

If a pilot plant is used, it is essential, of course, that due attention be paid to safety in its design and operation. This rather different aspect is dealt with in Appendix 10.

8.6 Hazard Indices

There are a number of hazard indices which have been developed for various purposes. Mention has already been made at the level of the material processed of indices of energy hazard potential. There are other indices which are applicable to the process and plant as a whole. Some principal indices of process and plant hazard are the Dow Index, the Mond Index and the IFAL Index. Another technique of ranking hazards is that of rapid ranking.

8.6.1 Dow's Index

The Dow *Guide* was originally published in 1964 and has gone through seven editions (Dow Chemical Company, 1964, 1966a; AIChE, 1973, 40; Dow Chemical Company, 1976, 1980; AIChE, 1987, 1994). Descriptions of the first and third editions have been given by Pratt (1965) and van Gaalen (1974), respectively.

The original purpose of the Dow Fire and Explosion Index (F&EI) was to serve as a guide to the selection of fire protection methods. The index in the first edition was a modification of the Factory Mutual Chemical Occupancy Classification guide. In the first three editions, the methods of determining the index were developed and refined. Changes in the fourth edition were that the index was simplified and that two new features were introduced, the maximum probable property damage (MPPD) and a Toxicity Index. The fifth edition changes included a new framework for making the risk evaluation, improvements in the method of calculating the index and several new features, including Loss Control Credits and Maximum Probable Days Outage (MPDO), and omission of the Toxicity Index. In the sixth edition, a risk analysis package, including business interruption (BI) and a toxicity penalty to reflect emergency responses, was introduced. The seventh edition up-dates the sixth edition with respect to codes and to good practice, but includes no major conceptual changes.

The following account gives an overview of method. The figures are from the *Guide*, but the tables are summaries only. The account is intended to provide an understanding of the Dow *Guide*, but the guide itself should be consulted for determination of the index and, in particular, for fuller explanations, qualifications and illustrative examples.

The overall structure of the method is shown in Figure 8.1. The procedure is to calculate the F & EI and to use this to determine fire protection measures and, in combination with a Damage Factor, to derive the base MPPD. This is then used, in combination with the loss control credits, to determine the actual MPPD, the MPDO and the BI loss.

The procedure may be summarized as follows. The basic information required for the F & EI is the plot plan and flow sheet of the plant. For the economic losses, it is also necessary to know the value of the plant per unit area, or the 'capital density', and the monthly value of production.

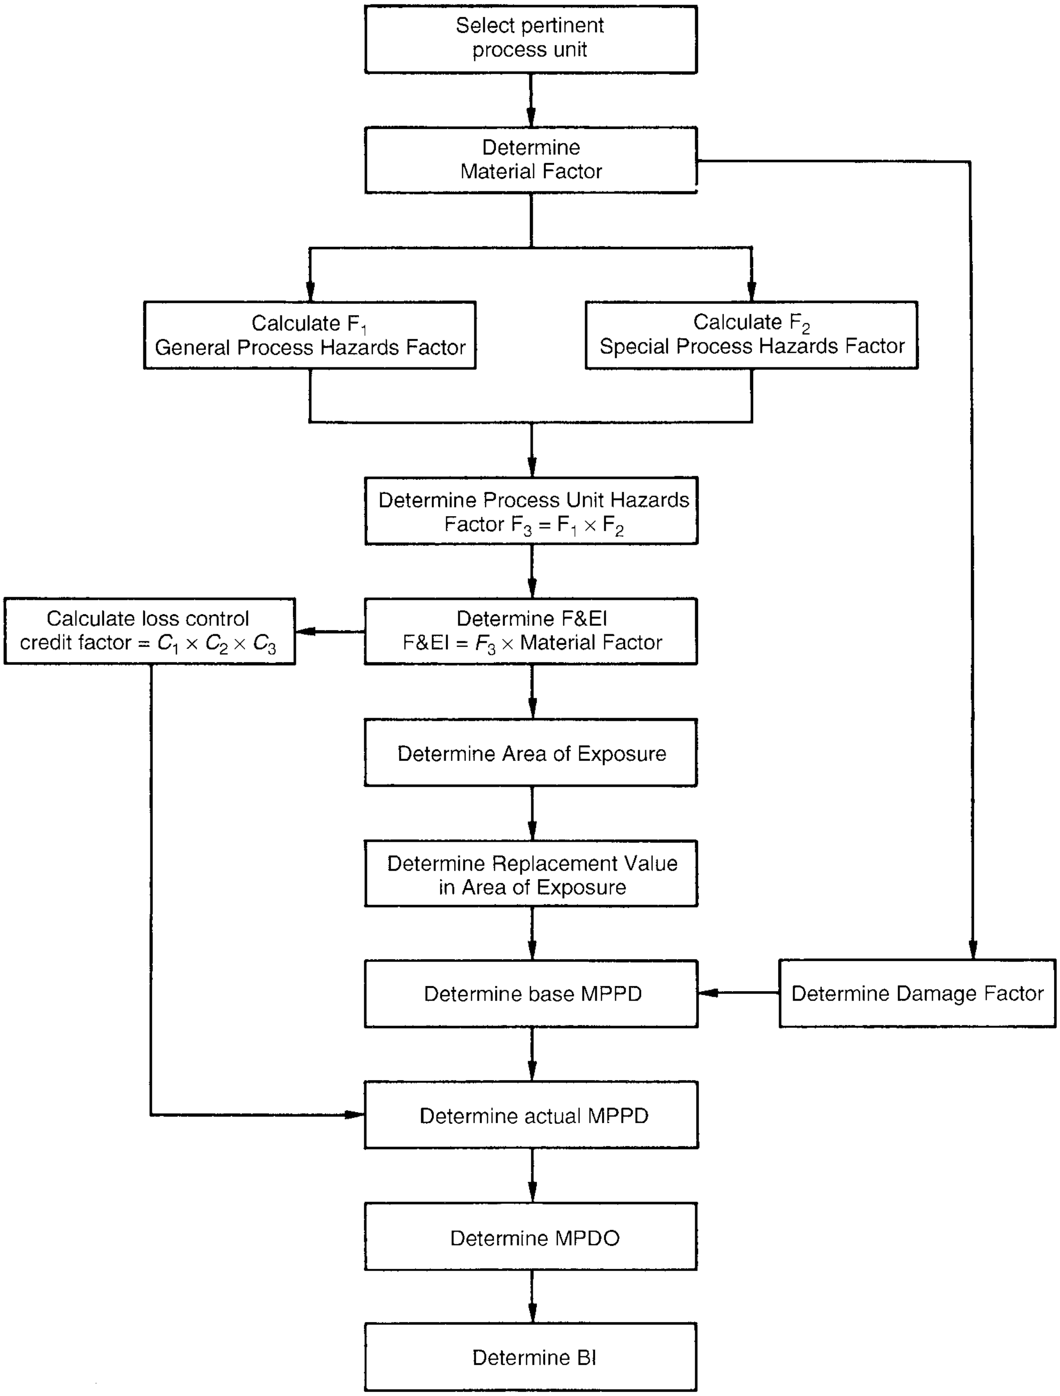

Figure 8.1 *Dow Fire and Explosion Index: procedure for calculating the Fire and Explosion Index and other quantities (Courtesy of the American Institute of Chemical Engineers)*

The plant is first broken down into process units. A process unit is an item of process equipment such as a reactor, distillation column, absorption column, compressor, pump, furnace, storage tank, etc. The process units are then identified which could have the most serious impact on the process area. The factors which identify a pertinent process unit include the inventory, chemical energy potential, operating conditions, capital density, loss history and potential for BI. Where equipment is arranged to give a single train, the decision on whether to treat the whole train or just a single vessel as a process unit is determined by the type of process. It is also necessary to make a judgement on the most appropriate stage of plant operation for the determination of the F&EI.

The F&EI is then determined for the process units. It should not normally be necessary to determine the F&EI for more than three or four process units in a single process area.

The F&EI assumes a minimum inventory of 5000 lb or 600 USgal of flammable, combustible or reactive material. If the inventory is less than this, the risk will generally be overstated.

The F&EI is calculated as follows. First a material factor (MF) is obtained. Then two penalty factors (F_1 and F_2), one for general process hazards (GPHs) and one for special process hazards (SPHs), respectively, are determined, and the process unit hazards factor (PUHF) (F_3), which is the product of these, is calculated. The product of the MF and PUHF is the F&EI. The assessment form used to calculate the index is shown in Figure 8.2.

The MF is a measure of the potential energy release from the material. It is obtained by considering the flammability and reactivity of the material and has a value in the range 1–40. Values of the MF for some 216 materials are given in Appendix A of the Dow *Guide* and values for selected chemicals are given in Table 8.6. For materials not listed, the procedure used to determine the MF is summarized in Table 8.7. Use is made of the NFPA fire rating N_F and reactivity rating N_R. Detailed guidance on the calculation of the MF using the procedure in the table is given in the Dow *Guide*.

The base MF is a measure of the hazard of the material at ambient temperature and pressure. If these are not the conditions applying, the base MF needs to be adjusted. The correction for temperature is shown in Table 8.8. Pressure is taken into account through the SPH. The Dow *Guide* also gives a method for the determination of the MF for a mixture.

The penalty factors applicable for GPHs and for SPHs are given in Tables 8.9 and 8.10 and Figure 8.3, respectively. The GPH factor (f_1) is the sum of all the GPH penalties, and the SPH factor (F_1) is the sum of all the SPH penalties. The PUHF factor (F_3) is the product of the GPH and SPH factors:

$$F_3 = F_1 \times F_2 \qquad [8.6.1]$$

The F&EI is the product of the MF and the PUHF:

$$\mathrm{FEI} = F_3 \times \mathrm{MF} \qquad [8.6.2]$$

The F&EI is of importance in its own right as a guide to the fire and explosion hazard.

The degree of hazard implied by the F&EI is shown by the relationships given in Table 8.11. The further use of the F&EI to undertake a process risk analysis, covering property damage and BI, is then as follows. The F&EI is used by itself to obtain the exposure radius (ER) and hence the area of exposure. The value of the area of exposure (VAE) is obtained from the area of exposure and the capital density, as described below. The F&EI and the PUHF are used in combination to obtain the damage factor (DF). The base MPPD is then obtained as the product of the VAE and the damage factor.

The exposure radius is a linear function of the F&EI, being 0 and 168 at values of the F&EI of 0 and 200, respectively. In other words:

$$\mathrm{ER} = 0.84 \times \mathrm{FEI} \qquad [8.6.3]$$

The value of the area of exposure is obtained as follows. The original value (OV) is obtained as the product of the area of exposure and the original capital density. The replacement value (RV) is then a function of the OV and the escalation factor (EF):

$$\mathrm{RV} = 0.82 \times \mathrm{OV} \times \mathrm{EF} \qquad [8.6.4]$$

where 0.82 is an allowance for the cost of items which will not require replacement. The Dow *Guide* gives detailed guidance on the appropriate costs to use.

The damage factor is a function of the F&EI and the PUHF, as shown in Figure 8.4.

Then,

$$\text{Base MPPD} = \mathrm{VAE} \times \mathrm{DF} \qquad [8.6.5]$$

A credit factor (CF) is then obtained as the product of three individual loss control credit factors (C_1–C_3). The product of the base MPPD and the credit factor is the actual MPPD. The MPDO is a function of the actual MPPD. The BI is then obtained from the MPDO and the value of production per month (VPM). The credit factor is:

$$\mathrm{CF} = C_1 \times C_2 \times C_3 \qquad [8.6.6]$$

The three loss control credit factors C_1–C_3 are each the product of a set of individual loss control credits. The ranges of these credit items are given in Table 8.12. Detailed guidance on the precise value of each credit within the range in Table 8.11 is given in the Dow *Guide*. Then

$$\text{Actual MPPD} = \mathrm{CF} \times \text{Base MPPD} \qquad [8.6.7]$$

The MPDO is a function of the actual MPPD as shown in Figure 8.5. It is intended that judgement be exercised in selecting the line to be used in this figure. The upper and lower lines correspond to the cases where there are factors which would increase or reduce the period of interruption, respectively, and the central line corresponds to the case where neither of these applies. The BI is:

$$BI = 0.7 \times \frac{MPDO}{30} \times VPM \qquad [8.6.8]$$

where 0.7 is a factor which represents fixed costs plus profits, and 30 converts the number of days to months. The Dow *Guide* describes a risk analysis package which comprises: the simplified block flow sheet; the plot plan

[a] This is the net heat of combustion, which is the value obtained when the water formed is considered to be in the vapour state.

[b] Heat of combustion H_c is equivalent to six times the heat of decomposition H_d.

showing areas of exposure, emergency isolation valves, and fire and gas detection equipment; the F&EI forms completed for the highest F&EI, the highest actual MPPD and the highest MPDO and BI; a risk analysis summary for the plant, based on the process units analyses as shown in Figure 8.2; and BI data. It recommends that each site maintain such a package for each of its plants.

The Dow *Guide* contains in Appendix C a set of basic preventive and protective features for fire protection. It states that many of the features should be provided regardless of the size of the F&EI, and that where they are not the hazard exposure will be greater than the F&EI indicates. These features are listed and discussed in Chapter 16.

There appears, in the successive editions, to be more emphasis on the use of the F&EI itself for risk management purposes and perhaps rather less on its use for the selection of fire protection measures. The Dow *Guide* also gives in Appendix D an extensive loss prevention checklist.

The current edition of the guide gives the correlations in terms of both graphical and equation form. The equations necessary for the determination of the F&EI are quoted here, but not those for MPPD, etc., for which the *Guide* should be consulted.

*The account given in this subsection is based on the seventh edition by permission of the Dow Chemical Company. The company accepts no liability for results of actions following the use of the *Guide*.

8.6.2 Mond Index

The Mond Fire, Explosion and Toxicity Index is an extension of the Dow Index. The index was developed at the Mond Division of ICI and the original version was described by D.J. Lewis (1979).

The principal modifications to the Dow method made in the Mond Index are:

(1) to enable a wider range of processes and storage installations to be studied;
(2) to cover the processing of chemicals which are recognized as having explosive properties;
(3) to offset difficulties raised by high heat of combustion per unit mass of hydrogen and to enable distinctions to be made between processes where a given fuel is reacted with different reactants;

Table 8.7 *Dow Fire and Explosion Index: Material Factor determination guide (Courtesy of the American Institute of Chemical Engineers)*

Liquids & gases flammability or combustibility[a]	*NFPA 325M or 49*	*Reactivity or instability*				
		$N_R = 0$	$N_R = 1$	$N_R = 2$	$N_R = 3$	$N_R = 4$

	N_F	St	N_R
(a) Enter N_F (St for dusts) and N_R			
(b) If temperature less than 140°F (60°C), go to (e)	▨	▨	▨
(c) If temperature above flash point or if temperature greater than 140°F (60°C), enter 1 under N_F		▨	▨
(d) If temperature above exotherm start or autoignition, enter 1 under N_R	▨	▨	
(e) Add each column but enter 4 where total is 5			
(f) Using (e) and Table 8.7 determine Material Factor (MF) and enter on F&EI Form and Manufacturing Unit Risk Analysis Summary			

[a] 140°F (60°C) can be reached in storage due to layering and solar heat.

(4) to include a number of additional special process type of hazard considerations that have been shown by a study of incidents to affect the level of hazard signifcantly;

(5) to allow aspects of toxicity to be included in the assessment;

(6) to include a range of offsetting factors for good design of plant and control/safety instrumentation systems to enable realistic hazard levels to be assessed for plant units under varying levels of safety features;

Table 8.9 *Dow Fire and Explosion Index: penalties for General Process Hazards (Courtesy of the American Institute of Chemical Engineers)*

A Exothermic chemical reactions

For reactions taking place in a reactor:

(1) Mild exotherms, e.g. hydrogenation, hydrolysis, isomerization, sulfonation and neutralization, penalty = 0.30
(2) Moderate exotherms, e.g. alkylation, esterification, oxidation,[a] polymerization, condensation, addition reactions,[b] penalty = 0.50
(3) Critical-to-control exotherms, e.g. halogenation, penalty = 1.00
(4) Particularly sensitive exotherms, e.g. nitration, penalty = 1.25

B Endothermic processes

(1) Endothermic process taking place in a reactor, penalty = 0.2
(2) Endothermic process taking place in a reactor where energy source is provided by combustion of solid, liquid or gaseous fuel, e.g. calcination, direct- fired pyrolysis, penalty = 0.4

C Material handling and transfer

For hazard of fire involving process unit during handling, transfer and warehousing of materials:

(1) Loading and unloading of Class I flammable liquids or liquefied petroleum gas (LPG)-type materials where transfer lines are connected and disconnected, penalty = 0.50
(2) Processes where introduction of air during manual addition may create a flammable mixture or reactivity hazard, e.g. centrifuges, batch reactions or batch mixing, penalty = 0.50
(3) Warehousing and yard storage:
    (a) Flammable liquids or gases $N_F = 3$ or 4,[c] penalty = 0.85
    (b) Combustible solids $N_F = 3$, penalty = 0.65
    (c) Combustible solids $N_F = 2$, penalty = 0.40
    (d) Combustible liquids (closed cup flash point > 100°F (37.8°C) and <140°F (60°C), penalty = 0.25

If any of (a)–(d) are stored on racks without in-rack sprinklers, add 0.20 to penalty

D Enclosed or indoor process units

For enclosed area, defined as any roofed area with three or more sides or an area enclosed by roofless structure with walls on all sides:

(1) Dust filters or collectors in an enclosed area, penalty = 0.50
(2) Process in which flammable liquids are handled above flash point in an enclosed area, penalty = 0.30; for quantities in excess of 10 M lb., penalty = 0.45
(3) Process in which LPG or flammable liquids are handled above boiling point in an enclosed area, penalty = 0.60; for quantities in excess of 10,000 lb (4536 kg), penalty = 0.90

If properly designed mechanical ventilation is installed, reduce penalties in (l) and (3) above by 50%

E Access

For inadequate access[d]

(1) Process area > 10,000 ft^2 (925 m^2) with inadequate access, penalty = 0.35
(2) Warehouse > 25,000 ft^2 (2312 m^2) with inadequate access, penalty = 0.35

F Drainage and spill control

For a flammable material in a process unit with a flash point <140°F or being processed above its flash point:

(1) Diking which exposes all equipment within dike to potential fire, penalty = 0.50
(2) Flat area around process unit which allows spills to spread, exposing large areas to potential fire, penalty = 0.50
(3) Diking around process unit which surrounds three sides of the area and directs spills to an impounding basin or non-exposing drainage trench, no penalty provided:
    (a) Slope to basin or trench is at least 2% for earthen surfaces or 1% for hard surfaces
    (b) Distance to equipment from nearest edge of trench or basin is at least 50 ft (15 m). This distance can be reduced if a firewall is installed
    (c) The impounding basin must have a capacity at least equal to the combined volume of flammable liquid and fire water[e]
(4) Basin or trench which exposes utility lines or does not meet distance requirements, penalty = 0.5

[a] In oxidation reactions involving combustion processes or vigorous oxidizing agents such as chlorates, nitric acid, hypochlorous acids and salts, etc., increase penalty to 1.00.
[b] When the acid is a strong reacting material, increase penalty to 0.75.
[c] This includes drums, cylinders and aerosol cans.
[d] For access to be adequate, there should be access from at least two sides. At least one of these should be a roadway. A monitor nozzle, which would remain easily accessible and operational during a fire could be considered a second access. Strong consideration should be given to this penalty for process units in an enclosed area.
[e] This volume is the sum of volume of the flammable liquid, which for process and storage facilities is 100% of the capacity of the unit's largest tank + 10% of the capacity of the next largest tank, and of the volume of a 30 min flow of firewater.

(7) to indicate how the results of using the method can be applied logically in the design of plants having a greater degree of 'inherent safety'.

The Mond Index was developed from the 1973 version of the Dow Index and the comparisons between the two given here relate to that version. Since then, there have been a number of developments in the Dow Index itself, in particular, the introduction of the loss control credit factors.

The Mond method involves making an initial assessment of hazard in a manner similar to that used in the Dow Index, but taking into account additional hazard considerations. The potential hazard is expressed in terms of the initial value of a set of indices for fire, explosion and toxicity. A hazard factor review is then carried out to see if there is scope to reduce the hazard by making

Table 8.10 Dow Fire and Explosion Index: penalties for Special Process Hazards (Courtesy of the American Institute of Chemical Engineers)

A Toxic materials

Penalty of $0.2 \times N_h$ is applied for a process involving toxic materials[a]

B Subatmospheric pressure[b]

Penalty of 0.5 is applied for processes in which air inleak could create a hazard and which operate at an absolute pressure $<$ 500 mmHg[c]

C Operation in or near flammable range

For processes where air might enter the system and form a flammable mixture:

(1) Tank storage of $N_F = 3$ or 4 flammable liquids where air can be breathed into the tank during pump-out or sudden cooling of the tank, penalty = 0.50
For open vent or non-inert gas padded operating pressure-vacuum relief system, penalty = 0.50
Storage of combustible liquids above closed cup flash point, penalty = 0.50
No penalty is applied if an inerted, closed vapour recovery system is used and its air-tightness is assured
(2) Process equipment or process storage tanks which could be in or near the flammable range only in the event of instrument or equipment failure,[d]
penalty = 0.30
(3) Processes or operations which are by nature always in or near the flammable range either because purging is not practical or because it was elected not to purge,
penalty = 0.8

D Dust explosion[e]

For any process unit involving dust handling operations such as transferring, blending, grinding, bagging, etc.

Particle size[f] (mm)	*Tyler mesh size*	*Penalty*[g]
175+	60–80	0.25
150–175	80–100	0.50
100–150	100–150	0.75
75–100	150–200	1.25
<75	>200	2.00

E Relief pressure

For a process operating at a pressure above atmospheric, a penalty is applied which is a function of the operating pressure. Two pressure ranges are considered. For operating pressures in the range 0–1000 psig, the penalty is obtained using Figure 8.3(a)[1] in the manner described below. For pressures above 1000 psig, the penalty is

Pressure (psig)	*Penalty*
1000	0.86
1500	0.92
2000	0.96
2500	0.98
3000–10,000	1.0
>10,000	1.5

For the lower pressure range, the curve shown in Figure 8.3(a)[1] gives an initial penalty which is applicable for flammable and combustible liquids with flash point <140 °F (60 °C). For other materials, the initial penalty given by the curve is adjusted by a material adjustment factor as follows:

(1) Highly viscous materials,[h] multiply penalty by 0.7
(2) Compressed gases used alone or flammable liquids pressurized with any gas above 15 psig, multiply penalty by 1.2
(3) Liquefied flammable gases,[i] multiply penalty by 1.3
The actual penalty is obtained as follows. First determine from Figure 8.3(a)[1] the penalties associated with the operating pressure and with the set pressure of the relief device. Divide the operating pressure penalty by the set pressure penalty to obtain the final pressure penalty adjustment factor. Now multiply the operating pressure by the material adjustment factor given in (1)–(3) above and then by the final pressure penalty adjustment factor to obtain the final pressure penalty.

Example:
Vessel design pressure = 150 psig
Normal operating pressure = 100 psig; initial penalty = 0.31 (from Figure 8.3(a)[1])
Rupture disc set pressure = 125 psig; initial penalty = 0.34 (from Figure 8.3(a)[1])
Process with viscous material; penalty adjustment = 0.70
Adjusted initial penalty = $0.7 \times 0.31 = 0.22$
Actual penalty = $0.22 \times (0.31/0.34) = 0.20$

F Low temperature

For a process for which it has not been shown that there is no possibility of temperatures below the transition temperature due to normal or abnormal operating conditions:

(1) Process utilizing carbon steel and operated at or below the ductile/brittle transition temperature,[j]
penalty = 0.30
(2) Process utilizing materials other than carbon steel where the operating temperature is at or below the transition temperature, penalty = 0.20

G Quantity of flammable and unstable material

A process involving flammable or unstable materials is classed as either:

(1) Liquids or gases in process;
(2) Liquids or gases in storage;
(3) Combustible solids in storage or dust encountered in process
and a single penalty is applied based on the material selected for the MF as follows:

The penalty is a function of the quantity of material which it is estimated might be released within 10 min.

For case (3) above, this quantity is used directly, whilst for cases (1) and (2) above, it is used in the form of the potential heat release.

Liquids or gases in process
This category applies to:

(a) Flammable liquids and those combustible liquids with flash point <140°F (60°C)
(b) Flammable gases

(c) Liquefied flammable gases
(d) Combustible liquids with closed cup flash points >140°F (60°C)
(e) Reactive materials, regardless of flammability

The penalty is a function of the potential heat release, which is the product of the quantity of material which it is estimated might be released within 10 min[k] and of the heat quantity H_c (BTU/lb),[l] as given in Figure 8.3(b)[1].

Liquids or gases in storage
This category applies to liquids or gases in storage and thus outside the process area. The penalty is a function of the potential heat release, which is the product of the quantity of material in storage[m] and of H_c[n] as given in Figure 8.3(c)[1].[o]

Combustible solids in storage or dust encountered in process
This category applies to combustible solids in storage and to dust in a process unit. The penalty is a function of the quantity of material[p] as given in Figure 8.3(d)[1].

H Corrosion and erosion[q]

For a corrosion rate, defined as the sum of the external and internal corrosion rates:

(1) Corrosion rate < 0.5 mil/year (0.127 mm/year) with risk of pitting or local corrosion, penalty = 0.10
(2) Corrosion rate > 0.5 mil/year (0.127 mm/year) and <1 mm/year, penalty = 0.20
(3) Corrosion rate > 1 mil/year (0.254 mm/year), penalty = 0.50
(4) Risk of stress corrosion cracking developing, penalty = 0.75
(5) Lining required to prevent corrosion,[r] penalty = 0.20

I Leakage – joints and packing

(1) Pump and gland seals are likely to give some leakages of a minor nature, penalty = 0.10
(2) Process known to give regular leakage problems at pumps, compressors and flange joints, penalty = 0.30
(3) Process in which thermal and pressure cycling occurs, penalty = 0.3
(4) Process material penetrating in nature or an abrasive slurry which causes intermittent problems of sealing, and process utilizing a rotating shaft seal or packing, penalty = 0.40
(5) Process with sight glasses, bellows assemblies or expansion joints, penalty = 1.50

J Use of fired equipment

For a process unit which is in the vicinity of a fired heater or which is itself a fired heater, a penalty is applied which is a function of the distance from the air intake of the fired heater to a probable leak point as given in Figure 8.3(e)[1]. The two curves A-1 and A-2 are applied as follows, where the material referred to is the material of the MF:

Curve A-1 is used for:

(a) A process unit in which the material could be released above its flash point;
(b) A process unit in which the material is a combustible dust.

Curve A-2 is used for:

(a) a process unit in which the material could be released above its boiling point;

Note: If the material is below its flash point, the only situation which attracts a penalty is where the fired heater itself is the process unit being evaluated. In this case, the distance from the possible leak source is zero and even if the material is below its flash point, a penalty of 1.0 is applied.

K Hot oil exchange system

The penalty in this section is not applied:

(1) If the hot oil exchange system is the process unit being evaluated;
(2) If the hot oil is non-combustible or, if combustible, is always used below its flash point.

Otherwise, for a process unit utilizing a hot oil exchange system in which the heat exchange fluid is combustible:

Quantity[s] (US gal)	(m^3)	*Penalty oil > flash point*	*Oil ≥ flash point*
<5000	<18.9	0.15	0.25
5000–10,000	18.9–37.9	0.30	0.45
10,000–25,000	37.9–94.6	0.50	0.75
>25,000	>94.6	0.75	1.15

Note: (1) It is recommended that the F&EI also be determined for the hot oil system itself, including the process tank, pumps and distribution/return piping, but not the storage tank. (2) If a fired hot oil heat exchange system is actually located in the area of the process unit, the penalty in Section J applies.

L Rotating equipment[t]

Penalty of 0.5 is applied for a process unit, which utilizes, or is

(1) A compressor in excess of 600 hp;
(2) A pump in excess of 75 hp;
(3) Agitators and circulating pumps in which failure could produce a process exotherm;[u]
(4) Other large, high speed rotating equipment with a significant loss history, e.g. centrifuge

---

[a] For mixtures, the highest N_H value of the individual components should be used.
[b] If the penalty is applied, the penalty specified in Section C or E should not be duplicated or repeated.
[c] The main process units in this category are most stripping operations, some compressor operations and a few distillation operations.
[d] For a process unit which relies on inert purge to keep it out of the flammable range, penalty = 0.30. This penalty also applies to padded barges or tank cars. (*Note*: no penalty is applied here if the penalty in Section B has already been taken).
[e] Penalties should be applied unless it has been shown by testing that no dust explosion hazard exists.
[f] The particle size to be used is the 10% particle size, i.e. that at which 90% of the dust is coarser and 10% finer.
[g] If the dust is handled in an inert gas, the penalty should be halved.
[h] This includes materials such as tars, bitumen, heavy lubricating oils and asphalts.
[i] This includes all other flammable materials stored above their boiling point.
[j] If no data are available, a 50°F (10°C) transition temperature should be assumed.
[k] This figure should be based on the user's own judgement but, as a guide, experience shows that a reasonable estimate is the larger of

the quantity of material (1) in the process unit or (2) in the largest connected unit, disregarding any connected unit which can be isolated by an emergency isolation valve;

[l] For most materials, H_c is the heat of combustion, but for unstable materials ($N_r > 2$), it is six times the heat of decomposition or the heat of combustion, whichever is larger.

[m] In the case of portable drums, the relevant quantity is the total quantity in all the drums, and in the case where two or more vessels are in a common dike which would not drain adequately into an impounding basin, it is the quantity in all the vessels.

[n] See footnote l.

[o] If there is more than one class of material, the total heat release should be utilized in conjunction with the highest curve applicable to any of the individual materials.

[p] For unstable materials ($N_R > 2$), the quantity which should be used is the actual mass multiplied by six and the curve to be used is curve A.

[q] The *Guide* gives guidance on situations where corrosion or erosion is likely.

[r] This penalty does not apply if the lining is simply to prevent discolouration of the product.

[s] This quantity is defined as follows. It is the lesser of (1) a 15-min spill caused by a break in the lines servicing the process unit or (2) the oil inventory within the active circulating hot oil system, where the portion of the exchange system classed as storage is not included unless it is connected much of the time to the process unit.

[t] Formulae have not been developed for all types and sizes of rotating equipment, but there is evidence that equipments above a certain size are liable to contribute to an incident.

[u] Where the exotherm is due to lack of cooling from interrupted mixing or circulation of coolant or to interrupted and resumed mixing.

design changes, and intermediate values of the indices are determined. Offsetting factors for preventive and protective features are applied and the final values of the indices, or offset indices, are calculated.

In outline, the method of determining the Mond Index is as follows. The plant is divided into units, the demarcation between units being based on the feasibility of locating a separating barrier (open space, wall or floor) between the unit and its neighbours.

The material factor is determined as in the Dow method, but in addition, special material hazard factors are introduced. Again as in the Dow method, use is made of factors for GPHs and SPHs although the particular factors are different. A quantity factor, based on the inventory of material, and layout hazard factors are also introduced. There are also factors for toxicity hazard. The features taken into account in these factors are shown in Table 8.13.

The indices calculated are:

(1) overall index;
(2) fire load index;
(3) unit toxicity index;
(4) major toxicity incident index;
(5) explosion index;
(6) aerial explosion index;
(7) overall risk rating.

The degree of hazard associated with these indices is shown in Table 8.14.

The overall risk rating is then evaluated. If further action is judged appropriate, a hazard review is carried out to determine the scope for design modifications. Some examples of changes, which might be considered are given in Table 8.15. If design changes are made, the indices are recalculated.

The offsetting features shown in Table 8.16 are then brought into account. Some of these are preventive, reducing the frequency of incidents, and some are mitigating, reducing the consequences. Using the corresponding offsetting factors, final values of the indices are calculated.

The features to be taken into account in calculating the various factors are specified in detail in the *Technical Manual*, which contains a wealth of practical information, particularly in respect of the offsetting features.

As already mentioned, the plant is divided into individual units on the basis of the feasibility of creating separating barriers and one of the factors taken into account in the index is plant layout. The use of the method to assist in layout design is an important application. It is considered in more detail in Chapter 10.

8.6.3 IFAL Index

The IFAL index is a separate index developed by the Insurance Technical Bureau primarily for insurance assessment purposes. Accounts have been given by J. Singh and Munday (1979), Munday *et al.* (1980) and H.B. Whitehouse (1985). Calculation of the index is described in the *IFAL p Factor Workbook* (Insurance Technical Bureau, 1981).

The index was developed in order to provide a means of assessment that was more scientifically based and satisfactory than the historical loss record, which tends to be subject to chance fluctuations. An outline flow chart of the method is shown in Figure 8.6.

The method involves dividing the plant into blocks and examining each major item of process equipment in turn to assess its contribution to the index. The main hazards which contribute to the index are

(1) pool fires;
(2) vapour fires;
(3) unconfined vapour cloud explosions;
(4) confined vapour cloud explosions;
(5) internal explosions.

For hazards (2)–(5), emission frequency and hole size distributions are used, and for each case, emission, ignition, fire and explosion are modelled and the damage effects are estimated.

The IFAL Index is the product of the process factor p and of two modifying factors, the engineering factor e and the management factor m. For a process engineered and managed to 'standard good practice', the last two factors are unity and the IFAL Index equals the p factor.

In contrast to the Dow and Mond Index methods, the IFAL Index method is too complex for manual calculation and is carried out using a computer program.

Table 8.17 shows some results obtained using the IFAL method. Section A gives some relative p factors for 100,000 te/year petrochemical plants, and Section B gives the relative contribution of the five hazards to losses on an ethylbenzene plant.

8.6.4 Dow Chemical Exposure Index

As stated earlier, the main Dow Index contained at one time a Toxicity Index. Dow now uses a separate Chemical Exposure Index (CEI). An account of this index is given in *Dow's Chemical Exposure Index Guide* (AIChE 1994/39) (the Dow *CEI Guide*).

The CEI is a measure of the relative acute toxicity risk. It is used for initial process hazard analysis (PHA), in the calculation of its Distribution Ranking Index (DRI) and in emergency response planning.

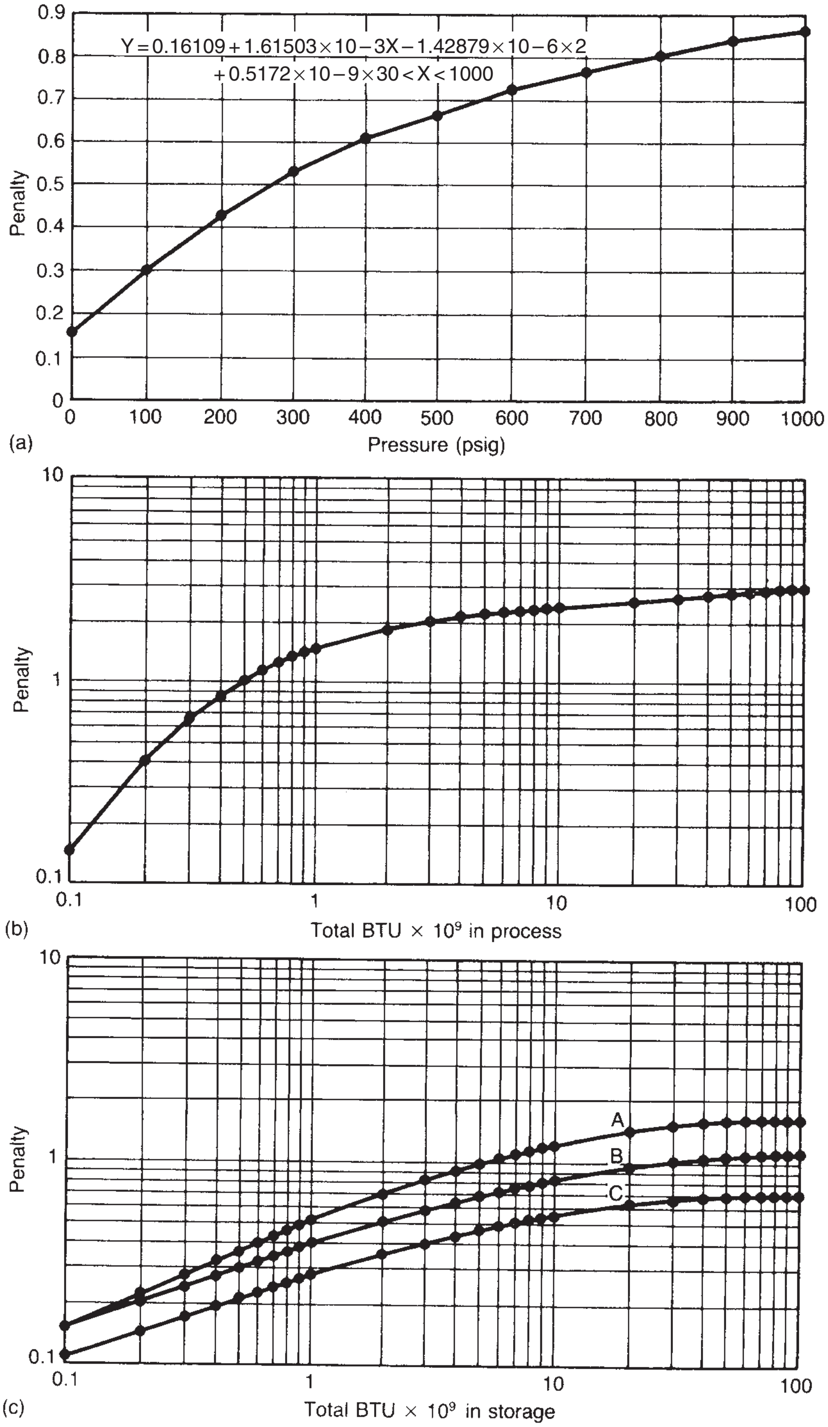

Figure 8.3 *Continued*

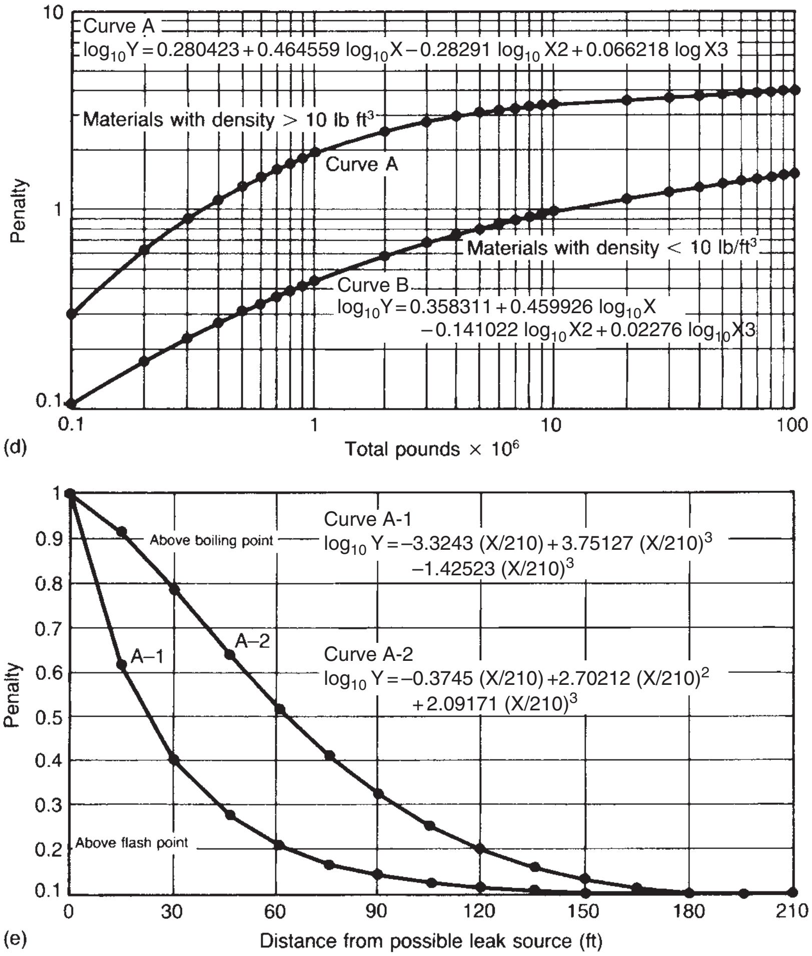

Figure 8.3 *Dow Fire and Explosion Index: penalties for special process hazards 1994: (a) penalty for pressure of flammable and combustible liquids; (b) penalty for potential heat release for liquids or gases in process; (c) penalty for potential heat release for liquids or gases in storage; (d) penalty for quantity of combustible solids in storage/dust in process; (e) penalty for location of fired equipment (Courtesy of the American Institute of Chemical Engineers)*

Table 8.11 *Dow Fire and Explosion Index: degree of hazard*

F&E index range	*Degree of hazard*	
	4th edition	*5–7th editions*[a]
1–50	1–60	Light
51–81	61–96	Moderate
82–107	97–127	Intermediate
108–133	128–158	Heavy
≥134	≥159	Severe

[a] Increase in range is due to new contribution factors and a correction for penalties in three contributing factor charts.

The information needed for the calculation of the CEI is: the physical and chemical properties of the material; a simplified process flow sheet, showing vessels and major pipework with inventories; and an accurate plot plan of the plant and the surrounding area.

It is also necessary to have toxicity limits in the form of the American Industrial Hygiene Association (AIHA) Emergency Response Planning Guidelines (ERPGs) for the material. There are three levels of ERPG (ERPG-1, ERPG-2 and ERPG-3), which are essentially the maximum airborne concentrations below which it is believed that nearly all individuals could be exposed without experiencing some defined effect, the effects being: for level 1, experience of something more than a mild transient health effect or odour; for level 2, serious or irreversible health effects; and for level 3,

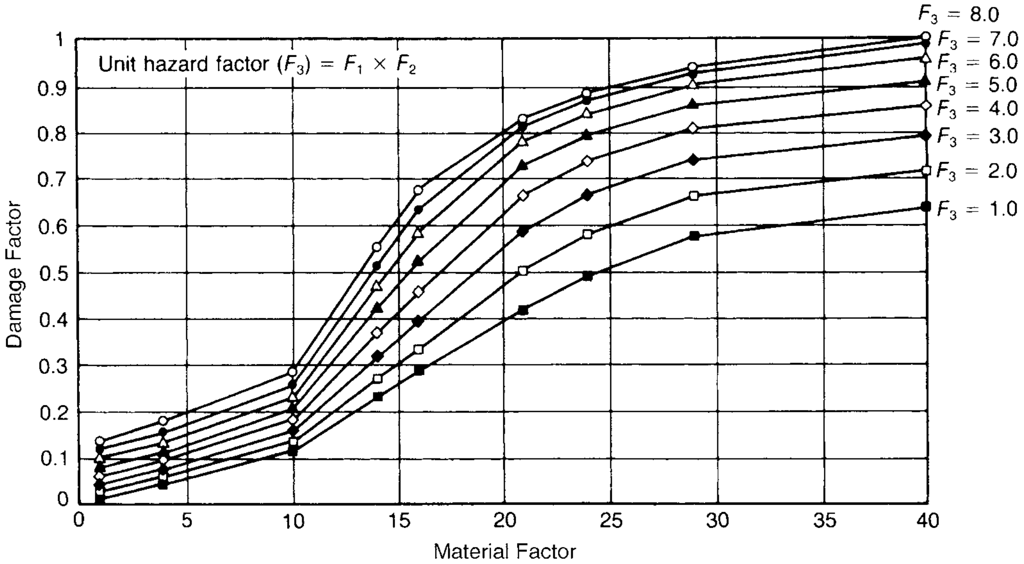

Figure 8.4 *Dow Fire and Explosion Index: damage factor (Courtesy of the American Institute of Chemical Engineers)*

Table 8.12 *Dow Fire and Explosion Index: loss control credit factor (Dow Chemical Company, 1994) (Courtesy of the Dow Chemical Company)*

A Process control (C_1)			
(a) Emergency power	0.98	(f) Inert gas	0.94–0.96
(b) Cooling	0.97–0.99	(g) Operating procedures	0.91–0.99
(c) Explosion control	0.84–0.98	(h) Reactive chemical review	0.91–0.98
(d) Emergency shut-down	0.96–0.99	(i) Other process hazard analysis	0.91–0.98
(e) Computer control	0.93–0.99		
B Material isolation (C_2)			
(a) Remote control valve	0.96–0.98	(c) Drainage	0.91–0.97
(b) Dump/blowdown	0.96–0.98	(d) Interlock	0.98
C Fire protection (C_3)			
(a) Leak detection	0.94–0.98	(f) Water curtains	0.97–0.98
(b) Structural steel	0.95–0.98	(g) Foam	0.92–0.97
(c) Water supply	0.94–0.97	(h) Hand extinguishers/monitors	0.93–0.98
(d) Special systems	0.91	(i) Cable protection	0.94–0.98
(e) Sprinkler systems	0.74–0.97		

life-threatening effects. ERPGs are considered further in Chapter 18.

The procedure for the calculation of the CEI is to determine (1) the release scenarios, (2) the ERPG-2, (3) the airborne quantities, (4) the CEI and (5) the hazard distance. The CEI is based on the scenario giving the largest airborne quantity (AQ).

The Dow *CEI Guide* gives a set of rules for defining release scenarios and of equations for estimating the AQ based on gas or liquid flow from vessels and pipes, liquid flash-off, and pool formation and evaporation. These, in effect, constitute a release model, description of which is deferred to Chapter 15.

The CEI is then calculated from the relationship:

$$\mathrm{CEI} = 655.1\left(\frac{\mathrm{AQ}}{\mathrm{ERPG\text{-}2}}\right)^{1/2} \qquad [8.6.9]$$

where AQ is the airborne quantity (kg/s) and ERPG-2 is the relevant toxic limit (mg/m^3). If the calculated value of the CEI is greater than 1000, the CEI is set equal to 1000.

Table 8.13 *Mond Index: hazard factors (after D.J. Lewis, 1979)*[a]

A Special material hazards

Oxidizing materials
Reacts with water to produce a combustible gas
Mixing and dispersion characteristics
Subject to spontaneous heating
Subject to rapid spontaneous polymerization
Ignition sensitivity
Subject to explosive decomposition
Condensed phase properties
Other

B General process hazards

Handling and physical changes only
Single continuous reactions
Single batch reactions
Multiplicity of reactions or different process operations carried out in same equipment
Material transfer
Transportable containers

C Special process hazards

Low pressure (below 15 psia)
High pressure
Low temperature:
  1: Carbon steel +10°C to −10°C
  2: Carbon steel below −10°C
  3: Other materials
High temperature:
  1: Flammability
  2: Construction materials
Corrosion and erosion
Joint and packing leakages
Vibration, load cycling, etc.
Processes or reactions difficult to control
Operation in or near flammable range
Greater than average explosion hazard
Dust or mist hazard
High strength oxidants
Process ignition sensitivity
Electrostatic hazards

D Layout hazards

Structure design
Domino effect
Below ground
Surface drainage
Other

E Toxicity hazards

TLV value
Material form
Short exposure risk
Skin absorption
Physical factors

[a] This table lists the hazard factors but not the associated numerical values. See *Technical Manual* (D.J. Lewis, 1979) for full details.

The hazard distance is then determined as:

$$HD = 6551\left(\frac{AQ}{ERPG}\right)^{1/2} \qquad [8.6.10]$$

where HD is the hazard distance (m) and ERPG is any one of three ERPG toxic limits (mg/m^3). If the calculated value of HD is greater than 10,000 m, HD is set equal to 10,000 m. There is thus a set of three HD values corresponding to the three levels of ERPG.

The Dow *CEI Guide* contains tabulations of relevant physical properties and ERPG values. It also gives CEI values for releases of different chemicals from a 2 in. hole together with worked examples. It provides a containment and mitigation checklist.

8.6.5 Mortality index

Another index which should be mentioned here is the Mortality Index proposed by V.C. Marshall (1977b). This is an index of the lethality of materials with major hazard potential, and is defined as the number of deaths per tonne of material involved. The index is discussed in Chapters 16–18.

8.7 Hazard Studies

There are now a number of methods that have been developed for the identification of hazards. A brief overview of these is given in this section, and a more detailed account of each method is then presented in the succeeding sections.

Overviews of hazard identification methods are available from numerous sources. Two primary information sources are the Chemical Industries Association (CIA) *HAZOP: Guide to Best Practice* (CIA, 1999) and *Guidelines for Hazard Evaluation Procedures* (AIChE/CCPS, 1992, 2nd edition).

Some of the methods described are complete methods. Methods in this category are What If? analysis, Preliminary Hazard Analysis (PHA), screening analysis techniques, HAZOP studies, and FMECA. Of these, PHA and screening analysis are designed for use at an early stage in the design.

Other methods, such as event tree, fault tree analysis, sneak analysis, computer control and human error analysis (known as CHAZOP), are specialist techniques used to complement or support more comprehensive methods. Scenario development and consequence analysis are part of hazard identification, but are also major features in hazard assessment.

The process safety system described in Subsection 8.7.12 combines a number of these techniques in an integrated system. Other aspects considered are the choice of method, the filtering and follow-up of the study results and formal safety review systems.

8.7.1 What if? analysis

An early method of hazard identification is to review the design by asking a series of questions beginning with What If? The method is a team exercise and typically makes use of pre-determined questions, but otherwise tends not to be highly structured. An account is given in Section 8.8.

8.7.2 Event tree and fault tree analysis

Event trees and fault trees are logic diagrams used to represent, respectively, the effects of an event and the

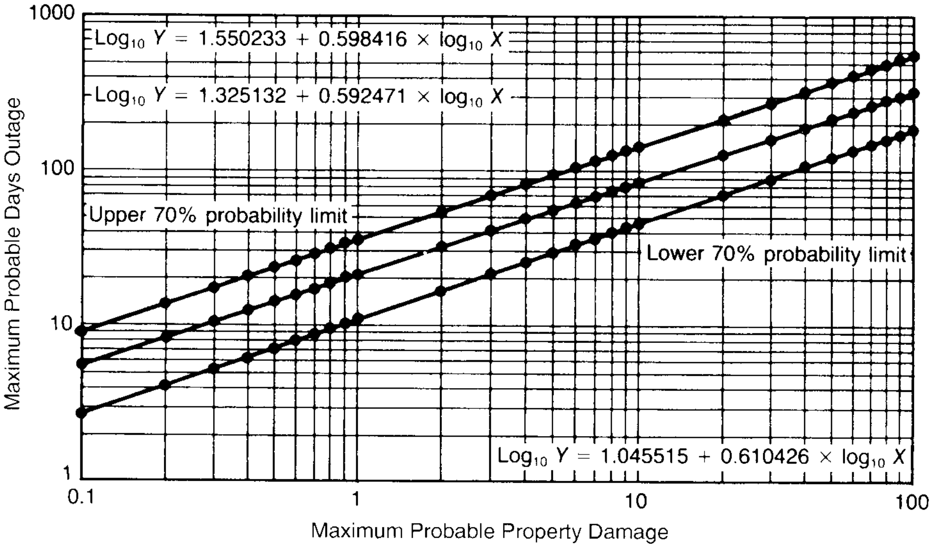

Figure 8.5 *Dow Fire and Explosion Index: maximum probable days outage. The MPPD is given as the actual MPPD in 10^{12} US$, 1986 basis. To update to 1993 basis, multiply by 359.9/318.4 = 1.130 (based on Chemical Engineering Plant Cost Index) (Courtesy of the American Institute of Chemical Engineers)*

contributory causes of an event. Accounts of event tree and fault tree analysis are given in Section 8.9 and Chapter 9.

8.7.3 Preliminary hazard analysis

'Preliminary hazard analysis' is a term normally used to describe a qualitative technique for identifying hazards relatively early in the design process. It is to be distinguished from the detailed hazard analysis, which employs a quantitative risk ranking technique. An account of PHA is given in Section 8.10.

8.7.4 Screening analysis techniques

A method of identifying hazards early in the design is through a screening analysis of anticipated hazards such as fire, explosion, reactivity, toxicity, etc. An account of screening techniques is given in Section 8.11.

8.7.5 Hazard and operability study

A method widely used by the process industries for the identification of hazards at, or close to, the engineering line diagram (ELD) stage is the HAZOP study. This technique is a development from critical examination. It is a team exercise, which involves examining the design intent in the light of guidewords. The technique has itself been subject to numerous variations.

For the process industries, the HAZOP study might fairly be described as the jewel in the crown of hazard identification methods. An account of the HAZOP study is given in Section 8.12.

8.7.6 Failure modes, effects and criticality analysis

Another method of hazard identification is the FMECA. It involves the analysis of the failure modes of an entity, their causes, effects, and associated criticality of the failure. An account of the FMECA technique is given in Section 8.13.

8.7.7 Sneak analysis techniques

There are a number of ways in which a hazard can 'sneak' into a complex electromechanical system. Sneak analysis is essentially a set of techniques for dealing with the various types of sneak. It is a complementary rather than a comprehensive method. An account of sneak analysis is given in Section 8.14.

8.7.8 Computer control and human error analysis

The conventional HAZOP study was developed for plants in which the control system was based on analogue controllers. It is not itself oriented to failures associated with computer control systems. CHAZOP has been developed to augment the process HAZOP in this respect. An account of CHAZOP is given in Section 8.15.

8.7.9 Human error analysis

It is well established that human actions play a large role in accidents. Human error analysis is used to take this aspect into account. As a hazard identification technique, human error analysis is qualitative, although a similar term is also sometimes used to describe a quantitative method. An account of human error analysis is given in Section 8.16.

8.7.10 Consequence analysis and modelling

Examination of different scenarios of plant disturbance and loss of containment is a central activity in hazard identification. The scenarios may relate to the events before release or to events involved in escalation after release. Hazard identification, therefore, includes methods of developing and structuring scenarios. Accounts of scenario development are given in Sections 8.17 and 8.19.

8.7.11 Process safety system

Hazard identification and hazard assessment are a part of the safety management system developed by the American

Table 8.14 *Mond Index: evaluation of index (after D.J. Lewis, 1979)*

A Overall index D

Range	*Overall degree of hazard*
0–20	Mild
20–40	light
40–60	Moderate
60–75	Moderately heavy
75–90	Heavy
90–115	Extreme
115–150	Very extreme
150–200	Potentially catastrophic
> 200	Highly catastrophic

B Fire load index F

Fire load (10^3 BTU/ft^2)	*Expected fire duration* (h)	*Category*	*Comments*
0–50	0.25–05	light	
50–100	0.5–1	Low	Dwellings
100–200	1–2	Moderate	Factories
200–400	2–4	High	Factories
400–1000	4–10	Very high	Maximum for occupied buildings
1000–2000	10–20	Intensive	Rubber warehouses
2000–5000	20–50	Extreme	
5000–10000	50–100	Very extreme	

C Explosion indices

Internal unit explosion index, E range	*Aerial explosion index, A range*	*Category*
0–1	0–10	Light
1–2.5	10–30	Low
2.5–4	30–100	Moderate
4–6	100–500	High
>6	>500	Very high

D Toxicity indices

Unit toxicity index, U range	*Major toxicity incident index, C range*	*Category*
0–1	0–20	Light
1–3	20–50	Low
3–6	50–200	Moderate
6–10	200–500	High
>10	>500	Very high

E Overall risk factor R

Range	*Category*
0–20	Mild
20–100	Low
100–500	Moderate
500–1100	High (Group 1)
1100–2500	High (Group 2)
2500–12,500	Very high
12,500–65,000	Extreme
>65 000	Very extreme

Table 8.15 *Mond Index: some examples of potentially beneficial design changes (after D.J. Lewis, 1979)*

1. Changes to process whereby the key material is diluted by an inert at all times and so reducing the material factor
2. Use of effective stabilizer in all parts of the unit where polymerization hazards can exist
3. Alteration in process conditions (i.e. pressure, temperature or mixture composition) to avoid Special Material Hazards such as explosive decomposition, gaseous detonation (e.g. acetylene), condensed phase behaviour, etc.
4. Separation of unit into two or more units of reduced capacity or into units carrying out separate stages when such smaller units can be effectively separated from each other
5. Elimination of heated two phase storages
6. Elimination of multiple reactions within the same equipment
7. Replacement of removable connection systems by fixed fully closed pipework
8. Avoidance of use of open or semi-open equipment
9. Operation under less arduous pressure conditions (either vacuum or high pressure)
10. Selection of less arduous temperature conditions (avoidance of low temperature and high temperature operational hazards)
11. Use of materials of construction having reduced corrosion potential for vessels, pipework and fittings
12. Reduction in numbers of joint and packing leakage points and use of superior joint and packing designs and materials
13. Changes in design to reduce vibration or thermal cycling effects (e.g. elimination of bellows)
14. Adoption of more effective and safe control systems for the process
15. Change in operation to take conditions further away from flammable range
16. Use of some inert diluents where high strength oxidants are involved (i.e. oxygen enriched air in place of oxygen)
17. Selection of equipment requiring a smaller inventory of the key material in the unit
18. Changes to eliminate as much high level or below ground storage of flammable materials within the unit plan area as possible
19. Separation of as much storage capacity from process operations as possible
20. Placement of specific items behind blast or fire resistant walls
21. Addition of effective second containment walls to storage units
22. Changes to unit ventilation requirements

Petroleum Institute (API RP 750) and later evolved into the process safety management system enacted by USDOL OSHA (1992). An account of the hazard identification segments of the system is given in Section 8.19.

8.7.12 Choice of method

The number of techniques available for hazard identification is large and is still growing. Each has its own field of application. One relevant distinction is between methods

Table 8.16 *Mond Index: offsetting factors (after D.J. Lewis, 1979)*[a]

A Containment system

Pressure vessels
Non-pressure vertical storage tanks
Transfer pipelines
Additional containment vessels, sleeves and bund walls
Leakage detection systems and response
Disposal of relief, vented or dumped material

B Process control

Alarm systems
Emergency power supplies
Process cooling systems
Inert gas systems
Hazard study activities
Safety shut-down systems
Computer control
Explosion and incorrect reaction protection
Operating instructions
Plant supervision

C Safety attitude

Management involvement in safety
Safety training
Maintenance and safety procedures

D Fire protection

Structural fire protection
Fire walls, barriers and equivalent devices
Equipment fire protection

E Material isolation

Valve systems
Ventilation

F Fire fighting

Fire alarms
Hand fire extinguishers
Water supply
Installed sprinkler, water spray or monitor systems
Foam and inerting installations
Fire brigade attendance
Site cooperation in firefighting
Smoke ventilators

[a] This table lists the offsetting factors but not the associated numerical values. See *Technical Manual* (D.J. Lewis, 1979) for full details.

which are comprehensive and those which are not but which supplement the former. Another is between methods for use early and late in the design. A third is in the type of problem to which a method is best suited. Guidance on choice of method is given in Section 8.20.

8.7.13 Ranking and hazard resolution

Further aspects of hazard identification are the filtering or ranking of the hazard identified to determine those on which action is prioritized, and the recording and follow-up resolution of these actions. An account of filtering and follow-up is given in Section 8.21.

8.7.14 Safety review systems

The arrangements for hazard identification need to be embodied in a formal system, which ensures that the necessary studies are done and which covers the life cycle of the plant. An account of safety review systems is given in Section 8.22.

8.8 What If? Analysis

The What If? method involves asking a series of questions beginning with this phrase as a means of identifying hazards. Apart from checklists, What If? analysis is possibly the oldest method of hazard identification. The method is to ask questions such as,

> What if the pump stops?
> What if the temperature sensor fails?

The questions posed need not necessarily all start with What If?; other phrases may be used.

The method involves review of the whole design by a team using questions of this type, often using a list of pre-determined questions. A checklist for use in What If? analysis is given by Burk (1992) and is shown in Table 8.18

Table 8.19 gives an example of the results from a What If? study reported by Kavianian, Rao and Brown (1992).

8.9 Event Tree and Fault Tree Analysis

The event tree and fault tree methods may be used either qualitatively or quantitatively. The concept of the fault tree was introduced in Chapter 7 and a fuller treatment of both event trees and fault trees, including their application to quantitative assessment, is given in Chapter 9. Here it is sufficient to draw attention to the value of tree methods, particularly fault trees, in hazard identification.

An event tree involves the development of the consequences (outcomes) of an event. The overall approach is similar to that adopted in FMEA, which is described below.

A fault tree involves the development of the contributing causes of an undesirable event, often a hazard. The possibility of this event must be foreseen before the fault tree can be constructed. What the fault tree helps to reveal are the possible causes of the hazard, some of which may not have been foreseen.

Fault trees are used extensively in hazard assessment, but they are also of great value in hazard identification. In many cases, it is sufficient to be able to identify the fault paths and the base events, which can give rise to the top event, it being unnecessary to quantify the frequency of occurrence of these events.

In an FMEA or an event tree, the approach is 'bottom up', while in a fault tree, it is 'top down' (deductive). The HAZOP method involves both approaches, starting with the deviations and tracing down to the causes and up to the consequences.

8.10 Preliminary Hazard Analysis

PHA is a method for the identification of hazards at an early stage in the design process. Accounts of PHA are given in the CCPS *Hazard Evaluation Guidelines* and by Kavianian, Rao and Brown (1992). PHA is a requirement of the MILSTD-882D Standard Practice for System Safety.

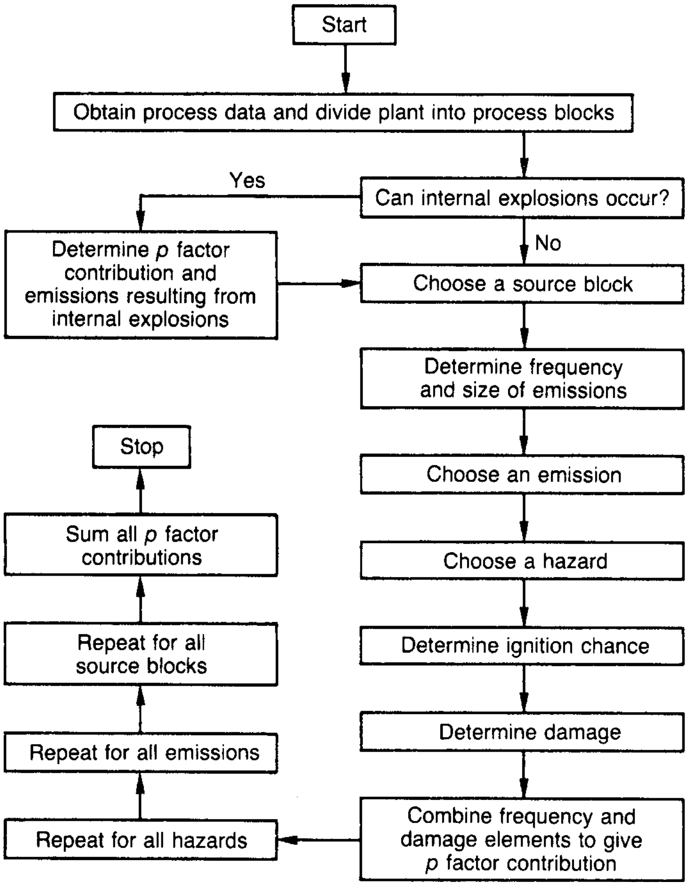

Figure 8.6 *IFAL Index: procedure for calculating p factor contributions (Munday et al., 1980)*

Since the early identification of hazards is of prime importance, many companies have some sort of technique for this purpose, a portion of which are called PHA; the use of the term tends to be fairly loose.

The CCPS *Guidelines* state that PHA is intended for use only in the preliminary stage of plant development, in cases where past experience provides little insight into the potential hazards, as with a new process. The information required for the study is the design criteria, the material and equipment specification, and so on. The *Guidelines* list the entities examined for hazards as: (1) raw materials, intermediates and final products; (2) plant equipment; (3) facilities; (4) safety equipment; (5) interfaces between system components; (6) operating environment and (7) operations (maintenance, testing, etc.).

The results from a PHA are illustrated in Table 8.20 (Kavianian, Rao and Brown, 1992).

8.11 Screening Analysis Techniques

One of the principal methods of identifying process hazards is the HAZOP study. Before describing this, however, it is appropriate to consider first the method developed for use in conjunction with, but earlier than the HAZOP.

The screen analysis is done at an early stage in the design where there is a block layout of plant items. The objective is to determine whether there are problems in areas such as data on the chemicals, information about the hazards, basic features of the process design, or layout and siting of the plant.

There are a number of advantages to be gained from conducting screening prior to the HAZOP study itself. It assists in the identification of those hazards and other problems which are quite basic and which are therefore capable, in principle, of being identified at this earlier stage. It reveals deficiencies in the design information. And it exposes hazards due to interactions between the plant and other plants or the environment, at which the HAZOP study is less effective. These features contribute to removing potential delays on the critical path of the project.

The conduct of a screening analysis involves compilation of two lists: (1) a database of hazards and nuisance properties of the material and (2) a list of potential hazards, nuisances and other matters of concern. The study

Table 8.17 IFAL Index: value of index and relative contributions of hazards (after Munday et al., 1980)

A Relative values of p factor for some 100,000 te/year plants

Plant	*p*
Acetic acid	1.7
Ethanol	2.4
Ethyl benzene	1.1
Ethylene oxide	2.1
Isopropanol	1.6
Styrene (1)	1.9
Styrene (2)	1.0
Vinyl chloride monomer	3.3

B Relative contribution of hazards on an ethylbenzene plant

Event	*Contribution (%)*
Pool fires	20
Vapour fires	30
Unconfined vapour cloud explosions	50
Confined vapour cloud explosions	0
Internal explosions	0

therefore covers, albeit in a different way from a HAZOP study, the two essential features of the design intent: (1) materials and (2) equipment and activities.

Use is made of a list of suitable guidewords. Guidewords may be generated by considering:

(1) energy sources;
(2) chemical interactions;
(3) environment.

Each of these headings may be broken down further. A suitable energy set is a list of the main forms of energy.

(1) People
(2) Materials
(3) Equipment.

The study results in a set of work assignments to follow-up the queries raised. As an illustration, the block layout might show a storage tank containing flammable liquids. The application of the guideword 'fire' to this tank might raise a number of queries. Amongst those that may be considered are (1) frequency of fire, (2) detection of fire, (3) access for firefighting, (4) method of firefighting, (5) source and disposal of fire water, (6) use of alternative firefighting agents, (7) nature of combustion products, (8) effects of radiant heat and (9) need for a disaster plan.

8.12 Hazard and Operability Studies

The HAZOP study is carried out when the ELD (piping and instrument diagram) of the plant becomes available. Accounts of HAZOP studies are given in the CIA *HAZOP: Guide to Best Practice* (CIA 1999), in HAZOP and Hazan (Kletz, 1983d, 1986d, 1992b), Guidelines for Hazard Evaluation Procedures (CCPS, 1985/1, 1992/9) (the CCPS *Hazard Evaluation Guidelines*) and *A Manual of Hazard and Operability Studies* (Knowlton, 1992), and by Kletz (1972a), S.B. Gibson (1974, 1976b,e), Lawley (1974a,b) and Kavianian, Rao and Brown (1992).

The following description is based on those given in the CIA *HAZOP: Guide to Best Practice* and by Lawley (1974b). The study is carried out by a multi-disciplinary team, which reviews the process to discover potential hazards and operability problems using a guideword approach. It is essentially an application of the technique of critical examination.

The basis of such a study may, in principle, be a process flow diagram (PFD), piping and instrument diagram (P&ID) or other information, which reveals the design intent. The basis of a HAZOP study is generally the ELD (P&ID) supplemented, as appropriate, by other information such as operating instructions, MSDSs, details of metallurgy, process control information, etc.

The HAZOP study technique is not a substitute for good design. There is something fundamentally wrong if the application of the method consistently reveals too many basic design faults.

8.12.1 Origins of HAZOP studies

The origins of HAZOP studies were in ICI in the 1960s. As with many techniques, there is more than one source which can lay claim to have been influential in its development. Accounts of the development of HAZOP have been given by Kletz (1986d) and in the Chemetics *Manual* (Knowlton, 1992).

The techniques, which eventually grew into HAZOP, developed at a time when the applications of method study, including critical examination, were being explored. Accounts of work in the Heavy Organic Chemicals Division of ICI (Binsted, 1960) and in the Mond Division (Elliott and Owen, 1968) describe the development of HAZOP in terms of critical examination.

8.12.2 Principle of HAZOP studies

The basic concept of the HAZOP study is to take a full description of the process and to question every part of it to discover what deviations from the intention of the design can occur and what the causes and consequences of these deviations may be. This is done systematically by applying suitable guidewords. Thus important features of the study are:

(1) design intent;
(2) deviations from intent;
(3) causes of deviations;
(4) consequences
  (a) hazards,
  (b) operating difficulties.

8.12.3 Design intent and entities examined

The design intent is examined in respect of the following entities:

(1) material;
(2) activity;
(3) equipment;
(4) source;
(5) destination.

In some applications, other relevant entities are:

(6) time;
(7) space.

***Table 8.18** What if method?: checklist for simplified process hazard analysis (Burk, 1992) (Courtesy of the American Institute of Chemical Engineers)*

Storage of raw materials, products, intermediates	
Storage tanks	Design separation, Inerting, Materials of construction
Dikes	Capacity, Drainage
Emergency valves	Remote control-hazardous materials
Inspections	Flash arresters, Relief devices
Procedures	Contamination prevention, Analysis
Specifications	Chemical, Physical, Quality, Stability
Limitations	Temperature, Time, Quantity
Materials handling	
Pumps	Relief, Reverse rotation, Identification of materials of construction
Ducts	Explosion relief, Fire protection, Support
Conveyors, Mills	Stop devices, Coasting, Guards
Procedures	Spills, Leaks, Decontamination
Piping	Rating, Codes, Cross-connections, Materials of construction
Process equipment, facilities and procedures	
Procedures	Start-up, Normal, Shut-down, Emergency
Conformance	Job audits, Shortcuts, Suggestions
Loss of utilities	Electricity, Heating, Coolant air, Inerts, Agitators
Vessels	Design, Materials, Codes, Access, Materials of construction
Identification	Vessels, Piping, Switches, Valves
Relief devices	Reactors, Exchangers, Glassware
Review of incidents	Plant, Company, Industry
Inspections, Tests	Vessels, Relief devices, Corrosion
Hazards	Hang-fires, Runaways
Electrical	Area classification, Conformance, Purging
Process	Description, Test authorizations
Operating ranges	Temperature, Pressure, Flows, Ratios, Concentrations, Densities, Levels, Time, Sequence
Ignition sources	Peroxides, Acetylides, Friction, Fouling, Compressors, Static electricity, Valves, Heaters
Compatibility	Heating media, Lubricants, Flushes, Packings
Safety margins	Cooling, Contamination
Personnel protection	
Protection	Barricades, Personal, Shower, Escape aids,
Ventilation	General, Local, Air intakes, Rate
Exposures	Other processes, Public environment
Utilities	Isolation: Air, Water, Inerts, Steam
Hazards manual	Toxicity, Flammability, Reactivity, Corrosion, Symptoms, First aid
Environment	Sampling, Vapours, Dusts, Noise, Radiation
Controls and emergency devices	
Controls	Ranges, Redundancy, Fail-safe
Calibration, Inspection	Frequency, Adequacy
Alarms	Adequacy, Limits, Fire, Fumes
Interlocks	Tests, Bypass procedures
Relief devices	Adequacy, Vent size, Discharge, Drain, Support
Emergencies	Dump, Drown, Inhibit, Dilute
Process isolation	Block valves, Fire-safe valves, Purging
Instruments	Air quality, Time lag, Reset windup, Materials of construction
Waste disposal	
Hatches	Flame traps, Reactions, Exposures, Solids
Vents	Discharge, Dispersion, Radiation, Mists
Characteristics	Sludges, Residues, Fouling materials
Sampling facilities	
Sampling points	Accessibility, Ventilation, Valving
Procedures	Pluggage, Purging
Samples	Containers, Storage, Disposal
Analysis	Procedures, Records, Feedback
Maintenance	
Decontamination	Solutions, Equipment, Procedures
Vessel openings	Size, Obstructions, Access
Procedures	Vessel entry, Welding, Lockout

Table 8.18 (continued)

Fire protection	
Fixed protection	Fire areas, Water demands, Distribution system, Sprinklers, Deluge, Monitors, Inspection, Testing, Procedures, Adequacy
Extinguishers	Type, Location, Training
Fire walls	Adequacy, Condition, Doors, Ducts
Drainage	Slope, Drain rate
Emergency response	Fire brigades, Staffing, Training equipment

Table 8.19 *What if? method: results for a high pressure/low density polyethylene plant (Kavianian, Rao and Brown, 1992)*

What if	*Consequence/hazard*	*Recommendations*
Coolant pump to reactor fails	Runaway condition in reactor explosion/fatality	• Provide accurate temperature monitoring in reactor • Employ backup pump/high temperature alarm • Relieve reactor pressure in reactor through automatic control to stop reactions • Provide automatic shut off of ethylene flow
Coolant temperature to jacket is high	Eventual runaway condition in reactor	• Provide adequate temperature control on coolant line • Use heat exchanger flow control to adjust inlet temperature
Runaway condition in reactor	Explosion; fire/fatality	• Provide adequate temperature control on coolant line • Use heat exchanger flow control to adjust inlet temperature • Install rupture disk/relief valve to relieve pressure to stop reactions • Emergency shut-down procedure
Recycle gas compressor 1 or 2 fails	None likely	• Provide spare compressor or shut-down procedure
Melt pump fails	High level in reactor causing more polymerization: runaway reaction eventually exceeds design pressure	• Provide level and flow control schemes to activate spare pump or shut the flow of monomer • Shut-down procedure if no spare pump
Leak at suction or discharge of compressors	Fire; explosion	• Use monitoring devices to ensure no flammable gas is released
Ethylene leaks out of process lines	Fire; explosion	• Provide adequate flammable gas monitoring devices
Monomer/initiator ratio out of control	Eventual runaway reaction causing fire and explosion	• Provide flow control on the initiator and monomer lines

8.12.4 Guidewords

To each of these above entities, there is applied a basic set of guidewords. These guidewords and their meanings are:

NO or NOT	Negation of intention
MORE	Quantitative increase
LESS	Quantitative decrease
AS WELL AS	Qualitative increase
PART OF	Qualitative decrease
REVERSE	Logical opposite of intention
OTHER THAN	Complete substitution

The application of these guidewords is illustrated by some of the examples discussed below. It is usually possible to apply all the guidewords intelligibly to activities and, with the possible exception of REVERSE, to substances.

In applying the guidewords to time, the following aspects may be relevant: duration, frequency, absolute time and sequence. The guidewords MORE and LESS are applicable for duration or frequency, while the guidewords SOONER and LATER may be more applicable than OTHER THAN for absolute time or sequence.

Similarly, in applying the guidewords to space, or place, the following aspects may be relevant: position, source and destination. The guidewords HIGHER or LOWER may be more applicable than MORE or LESS for elevation, while the guideword WHERE ELSE may be more applicable than OTHER THAN for position, source or destination.

Table 8.20 *Preliminary hazard analysis (Kavianian, Rao and Brown 1992)*

Hazard	*Cause*	*Major effects*	*Corrective/preventive measures*
Damage to feed reactor tubes	Feed compressor failure (no endothermic reactions in reactor)	Capital loss, down-time Damage to the furnace coils due to high temperature	• Provide spare compressor with automatic switch-off control • Develop emergency response system
Explosion, fire	Pressure build-up in the reactor due to plug in transfer lines	Fatalities, injuries	• Provide pressure relief valve on the reactor tubes • Provide warning system for pressure fluctuations (high-pressure alarm) • Provide auxiliary lines with automatic switch off
	Violent reaction of H_2 to acetylene converter with air in presence of ignition source	Potential for injuries and fatalities due to fire or explosion	• Provide warning system (hydrogen analyser) • Eliminate all sources of ignition near hydrogen gas storage area • Develop emergency fire response • Automatically shut off the H_2 feed • Provide firefighting equipment
Flammable gas release	Ethane storage tank ruptures	Potential for injuries and fatalities due to fire or explosion	• Provide warning control system (pressure control) • Minimize on-site storage • Develop procedure for tank inspection • Develop emergency response system • Provide gas monitoring system
Flammable gas release	CH_4 storage tank (line) leak/rupture (fuel for the furnace)	Potential for injuries and fatalities due to fire or explosion	• Provide warning system • Minimize on-site storage • Develop procedure for tank inspection • Develop emergency response system • Provide gas monitoring system
Flammable gas release	Radiant tube rupture in the furnace	Potential for injuries and fatalities due to fire	• Improve reactor materials of construction • Monitor design vs operating reactor temperature • Provide temperature control instrument
Employee exposure to benzene (carcinogen)	Leak in knock-out pots or during handling benzene	Chronic health hazard	• Install warning signs in the area • Provide appropriate PPE • Develop safety procedures for handling and cleanup • Monitor concentration of benzene in area to meet TLV requirements
Fire/explosion in acetylene converter	Runaway reaction (exothermic)	Fatality, injury, or loss of capital	• Install temperature control on converter • Install pressure relief on reactor responding to temperature control
Flammable atmosphere	Leak in transfer lines	Fire/explosion	• Install combustible gas meter in sensitive areas • Provide adequate firefighting equipment • Provide for emergency shut-down • Educate and train personnel on emergency procedures

Some additional guidewords include

STARTING
STOPPING
CONTROLLING
ISOLATION
INGRESS
ESCAPE
DECONTAMINATION

8.12.5 Illustrative example: reactor transfer system

The following example is given, which serves to illustrate both the basic examination principle and the detailed use of the guidewords. The flow sheet of a reactor system shows that raw material streams A and B are transferred by pump to the reactor, where they react to give product C. The flow of B should not exceed that of A, otherwise an explosion may occur. The flow sheet thus shows an intention to TRANSFER A to the reactor at the design flow. Applying the first guideword NO, NOT or DONT to this intention gives:

DON'T TRANSFER A

This is a deviation from intent. Some causes might be that the supply tank is empty, that the pipe is fractured or that an isolation valve is closed. A consequence might be an explosion due to an excess of B. Thus, the examination has discovered a hazard. The study is continued using further guidewords such as MORE, LESS, etc.

The application of the guidewords may be illustrated by the example already described: TRANSFER A. The guidewords may be applicable to either the word TRANSFER or to the word A. Thus, for this case, the meanings might include the following:

NO or NOT	No flow of A
MORE	Flow of A greater than design flow intent
LESS	Flow of A less than design flow intent
AS WELL AS	Transfer of some component other than A Occurrence some operation event additional to TRANSFER
PART OF	Failure to transfer all components of A Failure to achieve all that is implied by TRANSFER
REVERSE	Flow of A in direction opposite to design direction
OTHER THAN	Transfer of some material other than A Occurrence of some operation event other than TRANSFER

8.12.6 Organization and conduct of HAZOP studies

The stages in the conduct of a HAZOP study are:

(1) Definition of objectives and study scope;
(2) Selection of multi-disciplined team;
(3) Preparation;
(4) Conduct/facilitate;
(5) Record/document study;
(6) Preparation of HAZOP study report.

In general, the objectives of a HAZOP study as originally defined are to check the design intent and the operating procedures/conditions in order to identify hazards and operability problems, to which, increasingly, are added environmental issues.

Closely associated with these are checks on (1) information still lacking, (2) particular equipments, (3) supplier information, (4) plant phases (start-up, shut-down) and (5) maintenance procedures, and on entities to be protected such as (1) persons working on the unit, (2) others on the site, (3) the public, (4) the plant and (5) the environment.

A multi-disciplinary team is used to conduct the HAZOP study. The team should contain people from design and from operations who can cover the main relevant disciplines, who are senior enough to make on-the-spot decisions and who personally attend all the meetings, but the team size should be kept fairly small.

A good deal of preparation is needed prior to the HAZOP study. This includes (1) deciding on the type of study required, (2) acquisition of the information, (3) validation of the information, (4) conversion of the information to suitable form, (5) planning of the study sequence and (6) arrangement of the schedule of meetings. The detailed sequence of an examination is illustrated in Figure 8.7.

There are a number of factors, which are important for the success of the method. The study should have a clearly defined objective. The study leader (facilitator) should be experienced in the analysis technique but not necessarily in the particular process. The role of the study leader is crucial and the study leader must be adequately trained. The preparative work should be done carefully so that all the necessary documents are to hand and are accurate and up-to-date.

The study uses a formal, even mechanistic, approach and the questions raised may in some cases appear unrealistic or trivial. It is important to emphasize, however, that the approach is intended as an aid to the imagination of the team in visualizing deviations and their causes and consequences. The effectiveness of the technique depends very much on the spirit in which it is done.

More complete and detailed discussions of the organizational aspects of HAZOP studies are given in the CIA *Guide*.

8.12.7 Parametric method

As so far described, the focus of a HAZOP study is on the design intent. There is also a 'parametric method', distinguishable from the classic form, which concentrates on the deviations from design conditions.

This approach was originally developed in ICI Mond Division in response to the need to carry out a large number of HAZOP studies on existing plants. The method uses a hazard guide sheet. An early version of this guide sheet was reproduced in the first edition of this book, a later version from ICI is shown in Figure 8.8.

8.12.8 Illustrative example: continuous plant

As an illustration of a HAZOP study of a continuous process, consider the example given by Lawley (1974b). The proposed design is shown in Figure 8.9.

The process description is:

> An alkene/alkane fraction containing small amounts of suspended water is continuously pumped from bulk intermediate storage via a half-mile pipeline section into a buffer/settling tank. Residual water is settled out prior to passing via a feed/product heat exchanger and preheater to the reactor section. The water, which has an adverse effect on the dimerization reaction, is run off manually from the settling tank at intervals. Residence time in the reaction section must be held within closely

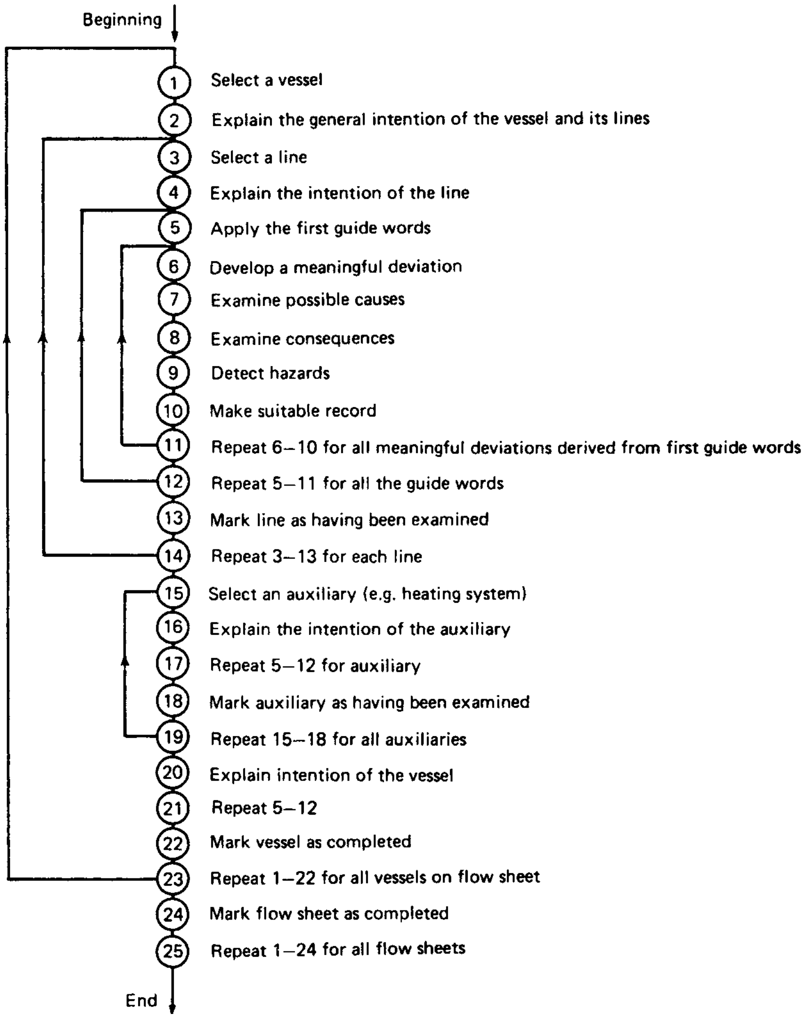

Figure 8.7 *Hazard and operability studies: detailed sequence of examination (Chemical Industry Safety and Health Council, 1977/3)*

defined limits to ensure adequate conversion of the alkene and to avoid excessive formation of polymer.

A summary of the results of a study for the first line section from the intermediate storage up to the buffer/settling tank is given in Table 8.21. A further table showing the results for the second line section is given in Lawley's paper.

For a continuous plant, the study should include the operability of the plant during commissioning and during regular start-up and shut-down. There are generally a number of operations, which are carried out only during these periods.

8.12.9 Time in HAZOP studies: sequences/batch processes

The HAZOP technique is applicable both to batch processes and to sequential operations on continuous plants such as start-up, shut-down and emergency shut-down. This introduces time as an additional factor to be taken into account. An adaptation of the set of guidewords applicable to time has been given in Section 8.12.4.

For batch and sequential operations, the following classification of activities are considered:

(1) make ready;
(2) key;
(3) put away.

'Key' is the activity which progresses the process, 'make ready' is the activity needed to prepare for the key activity, and 'put away' is the activity needed on completion of the key activity.

8.12.10 Illustrative example: batch plant

For a batch plant, the working documents comprise not only the flow diagram but also the operating procedures. Several documents may be needed to cover the latter, such

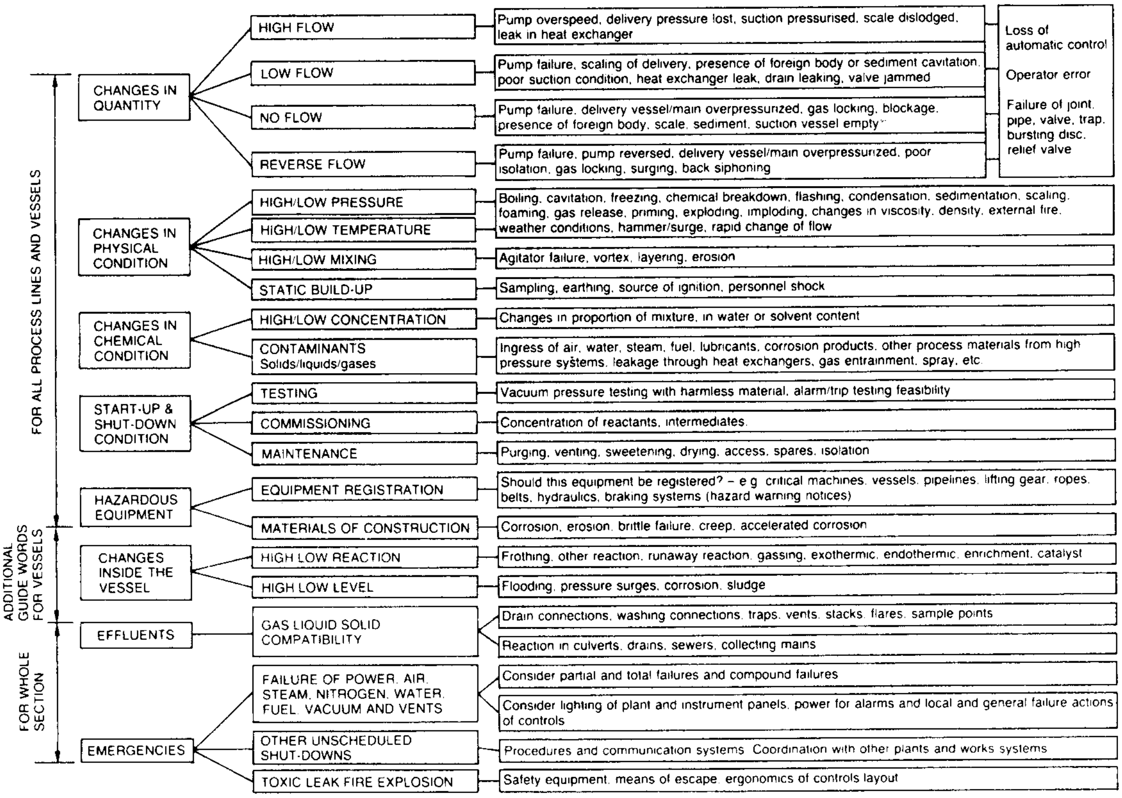

Figure 8.8 *Hazard and operability studies: hazard guide sheet (Imperial Chemical Industries Ltd, 1994)*

as tables giving the operating sequences, bar charts showing the states of equipment during the cycle and flow charts indicating the operator's movements.

As an illustration of a HAZOP study of a batch plant, consider the following example. The design is shown in a simplified diagram in Figure 8.10. The plant consists of two measure vessels, four reaction vessels, a condenser, an absorption tower with its circulation system and a Nutsche filter with its filtrate receiver.

The development of the study depends on the kind of sequence to be followed. In this case it is possible to follow a sequence derived from the flow diagram or one derived from the operating instructions. Assuming that the latter is used, an instruction part way through the sequence might be:

Instruction 23 Charge 100 1 of material C from drum to the general purpose vessel using the air ejector.

Such an instruction is quite adequate for operational purposes, but it is too complex for the generation of deviations in the study, and needs to be broken down into the part dealing with the air ejector and that dealing with the liquid transfer. Thus the leader may ask a member of the team to describe the purpose of the air ejector, which might be stated as: 'Remove some air from measure vessel'. The guidewords may then be applied to the statement.

A summary of the results of a study of this batch plant for the operation 'Remove some air from measure vessel' is given in Table 8.22.

8.12.11 Illustrative example: proprietary equipment

As an illustration of a study of proprietary equipment, consider a sterilization autoclave design example given in Figure 8.11. The process description is:

> Sterilization of stillage-loaded materials is achieved by treatment with steam humidified sterilizing gas in a jacketed autoclave chamber under specified conditions. Two entries are provided to the chamber – from the sterile and from the non-sterile working areas of the facility.
>
> Steam is admitted to the chamber via a letdown system and sterilizing gas via a vaporizer. The chamber may be evacuated via a cooler either directly to drain or via a luted sealed catchpot to a vent stack. Filtered atmospheric air may be admitted via a non-return valve. A relief valve is fitted to the chamber, which exhausts to the vent stack and may be by-passed by opening a vent valve if it is required to dump the contents to stack. Water is circulated through the jacket and heated indirectly by means of steam.
>
> Once the autoclave is charged and the doors closed, automatic sequence control takes over and programmes the process as shown in Figure 8.12. The machine itself checks the progress of the process cycle, monitoring the status of the chamber and auxiliaries. Certain checks [see

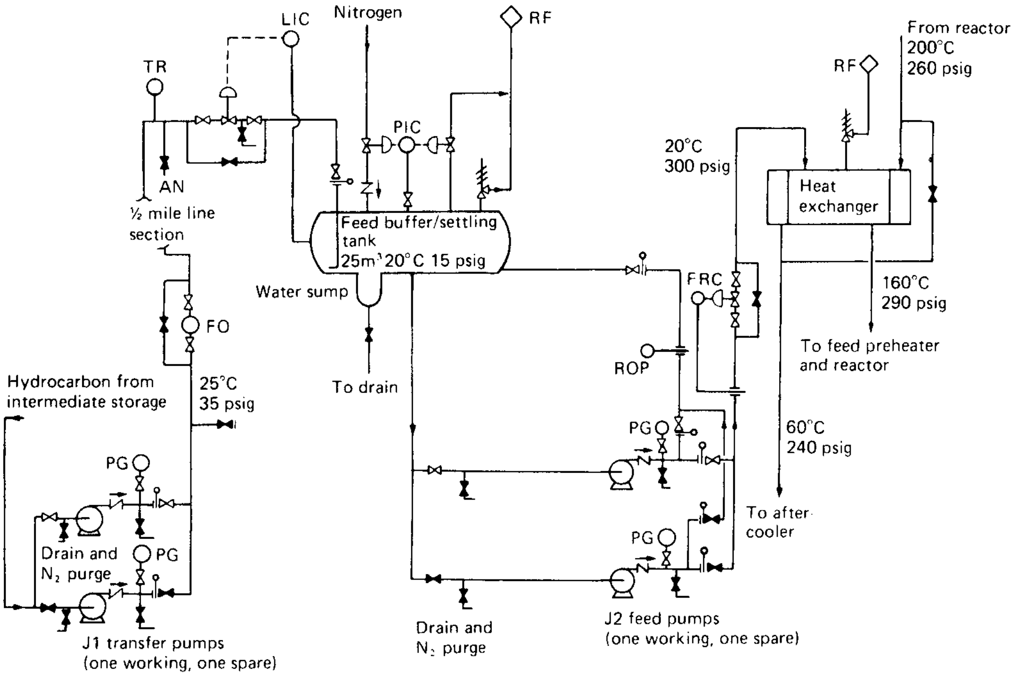

Figure 8.9 *Hazard and operability studies: feed section of proposed alkene dimerization plant (Lawley, 1974b) (Courtesy of the American Institute of Chemical Engineers)*

Figure 8.12: Autochecks] control progress in association with timers.

For an equipment of this kind, it is also possible to produce a flow process chart for the different operations of the cycle. A chart for the operation 'Charging autoclave' is shown in Figure 8.13.

The development of this study again depends on the choice of sequence to be followed. In this case there are a number of possible sequences that might be followed. Three of these are the flow diagram, the sequence diagram (dot chart) and the flow process chart shown in Figures 8.11–8.13, respectively.

A summary of the results of a study of this equipment for the operation 'Humidify autoclave chamber' derived from the flow diagram is given in Table 8.23.

8.12.12 Space and interactions in HAZOP studies: hybrid studies

In their classic form, HAZOP studies are essentially concerned with conditions inside the plant, including loss of containment from it. They do not address, however, any interaction in space between the plant and other plants nearby or the environment.

A technique for dealing with such problems is a hybrid approach, utilizing both creative checklists and guidewords. The method involves nominating a 'top event', which is then examined to identify its causes, using both a checklist of potential causes and guidewords.

8.12.13 Critical examination and HAZOP studies

As stated at the outset, HAZOP studies developed from the technique of critical examination. In some applications it may be useful to revert to the latter. A critical examination may be carried out by examining the design intent in respect of material, activities, equipment, source and destination.

The classic guidewords of critical examination may include:

WHAT	The design intent
HOW	Method and resources: materials, activities, equipments
WHEN	Time aspects: sequence, frequency, duration, absolute time
WHERE	Space aspects: relative location, sources and destinations, dimensions, absolute location
WHO	Persons or controls: person, skills, organization, control system

8.12.14 Control systems in HAZOP studies

The HAZOP study methodology was developed originally for plants operating under the control of analogue controllers. The methodology may be adapted to the examination of a plant operated through Distributive Control System (DCS).

8.12.15 Electrical systems in HAZOP studies

The treatment of electronic control and interlock systems and electrical distribution systems in a HAZOP is described by Mitchell (1992 LPB 105).

The headings used in his account for electronic control and interlock systems are: current, voltage, temperature, contamination, high current protection, instruments,

Table 8.21 *Hazard and operability studies: results for feed section of proposed alkene dimerization plant from intermediate storage to buffer/settling tank (Lawley, 1974b) (Courtesy of the American Institute of Chemical Engineers)*

Guide word	*Deviation*	*Possible causes*	*Consequences*	*Action required*
NONE	No flow	(1) No hydrocarbon available at intermediate storage	Loss of feed to reaction section and reduced output. Polymer formed in heat exchanger under no flow conditions	(a) Ensure good communications with intermediate storage operator. (b) Install low level alarm on settling tank LIC
		(2) J1 pump fails (motor fault, loss of drive, impeller corroded away, etc.)	As for (1)	Covered by (b)
		(3) Line blockage, isolation closed in error, or LCV fails shut	As for (1) J1 pump overheats	Covered by (b) (c) Install kick-back on J1 pumps (d) Check design of J1 pump strainers
		(4) Line fracture	As for (1) Hydrocarbon discharged into area adjacent to public highway	Covered by (b) (e) Institute regular patrolling and inspection of transfer line
MORE OF	More flow	(5) LCV fails open or LCV bypass open in error	Settling tank overfills	(f) Install high level alarm on LIC and check sizing relief opposite liquid overfilling (g) Institute locking off procedure for LCV bypass when not in use
			Incomplete separation of water phase in tank, leading to problems on reaction section	(h) Extend J2 pump suction line to 12 in. above tank base
	More pressure	(6) Isolation valve closed in error or LCV closes, with J1 pump running	Transfer line subjected to full pump delivery or surge pressure	(j) Covered by (c) except when kick-back blocked or isolated. Check line, FQ and flange ratings, and reduce stroking speed of LCV if necessary. Install a PG upstream of LCV and an independent PG on settling tank
		(7) Thermal expansion in an isolated valved section due to fire or strong sunlight	Line fracture or flange leak	(k) Install thermal expansion relief on valved section (relief discharge route to be decided later in study)
	More temperature	(8) High intermediate storage temperature	Higher pressure in transfer line and settling tank	(l) Check whether there is adequate warning of high temperature at intermediate storage. If not, install

Table 8.21 *(continued)*

Guideword	*Deviation*	*Possible causes*	*Consequences*	*Action required*
LESS OF	Less flow	(9) Leaking flange or valved stub not blanked and leaking	Material loss adjacent to public highway	Covered by (e) and the checks in (j)
	Less temperature	(10) Winter conditions	Water sump and drain line freeze up	(m) Lag water sump down to drain valve, and steam trace drain valve and drain line downstream
PART OF	High water concentration in stream	(11) High water level in intermediate storage tank	Water sump fills up more quickly. Increased chance of water phase passing to reaction section	(n) Arrange for frequent draining off of water from intermediate storage tank. Install high interface level alarm on sump
	High concentration of lower alkanes or alkenes in stream	(12) Disturbance on distillation columns upstream of intermediate storage	Higher system pressure	(o) Check that design of settling tank and associated pipework, including relief valve sizing, will cope with sudden ingress of more volatile hydrocarbons
MORE THAN	Organic acids present	(13) As for (12)	Increased rate of corrosion of tank base, sump and drain line	(p) Check suitability of materials of construction
OTHER	Maintenance	(14) Equipment failure, flange leak, etc.	Line cannot be completely drained or purged	(q) Install low point drain and N_2 purge point downstream of LCV. Also N_2 vent on settling tank

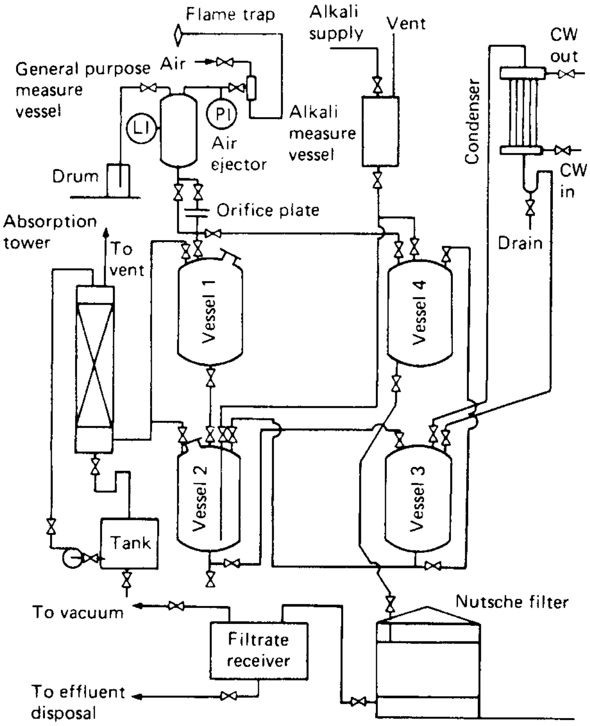

Figure 8.10 Hazard and operability studies: batch plant (simplified diagram) (Chemical Industry Safety and Health Council, 1977/3)

Table 8.22 Hazard and operability studies: results for batch plant for operation 'Remove some air from measure vessel' (Chemical Industry Safety and Health Council, 1977/3)

Deviations	*Causes*	*Consequences*
DON'T REMOVE AIR	No air supply Faulty ejector Value shut	Process inconvenience but no hazard
REMOVE MORE AIR	Completely evacuate measure vessel	Can vessel stand full vacuum?
REMOVE LESS AIR	Insufficient suck to transfer contents of drum	Process inconvenience but no hazard
AS WELL AS REMOVE AIR	Pull droplets of material C or other materials from drums or vessels 1 or 4 along exhaust line	Fire hazard? Static hazard? Corrosion hazard? Blocked flame trap? Will material be a hazard after leaving the flame trap? Where does it go?
REMOVE PART OF AIR	Remove oxygen or nitrogen only: not possible	
REVERSE REMOVAL OF AIR	If line form air ejector is blocked, compressed air will flow into measure vessel	Overpressure vessel? Blow air into drums and spray out contents? Put air into vessels 1 or 4?
OTHER THAN REMOVE AIR	Put air ejector on when measure vessel full	Spray contents along line and out through flame trap. Similar hazards to AS WELL AS

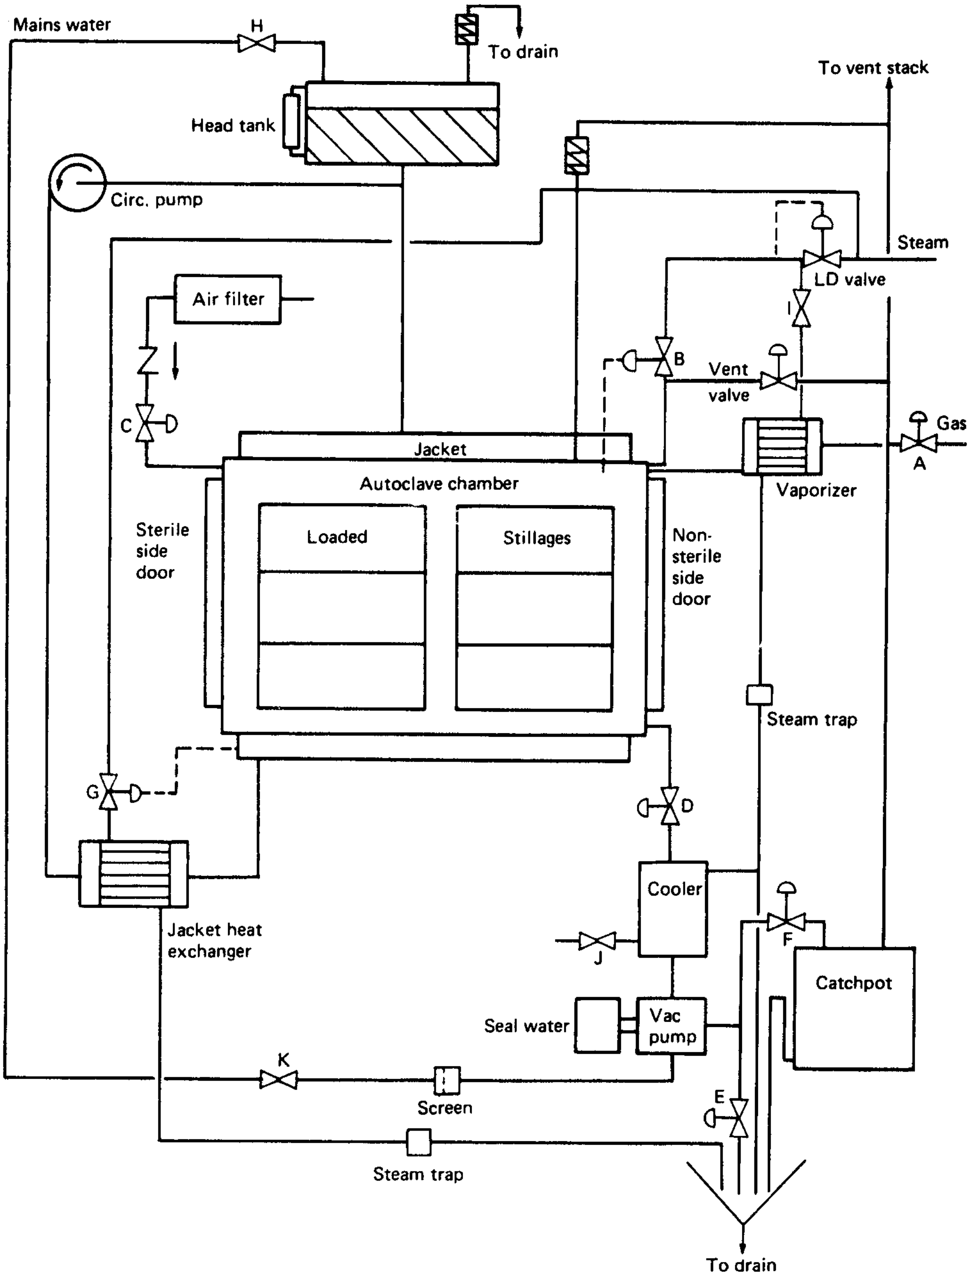

Figure 8.11 *Hazard and operability studies: autoclave arrangement (Chemical Industry Safety and Health Council, 1977/3)*

sampling, corrosion, services failure, maintenance, abnormal operations, spares, static electricity and safety. A short checklist is given under each heading. Where appropriate, as with current and voltage, guidewords such as NO, REDUCED, INCREASED, etc., are used. A basically similar list is used for electrical distribution systems.

8.12.16 Additional parameters and guidewords

Wider application of the HAZOP approach, to systems such as materials handling systems, has led to the creation of further lists of parameters and guidewords such as the one shown in Table 8.24, derived from the work by Tweeddale (1993e).

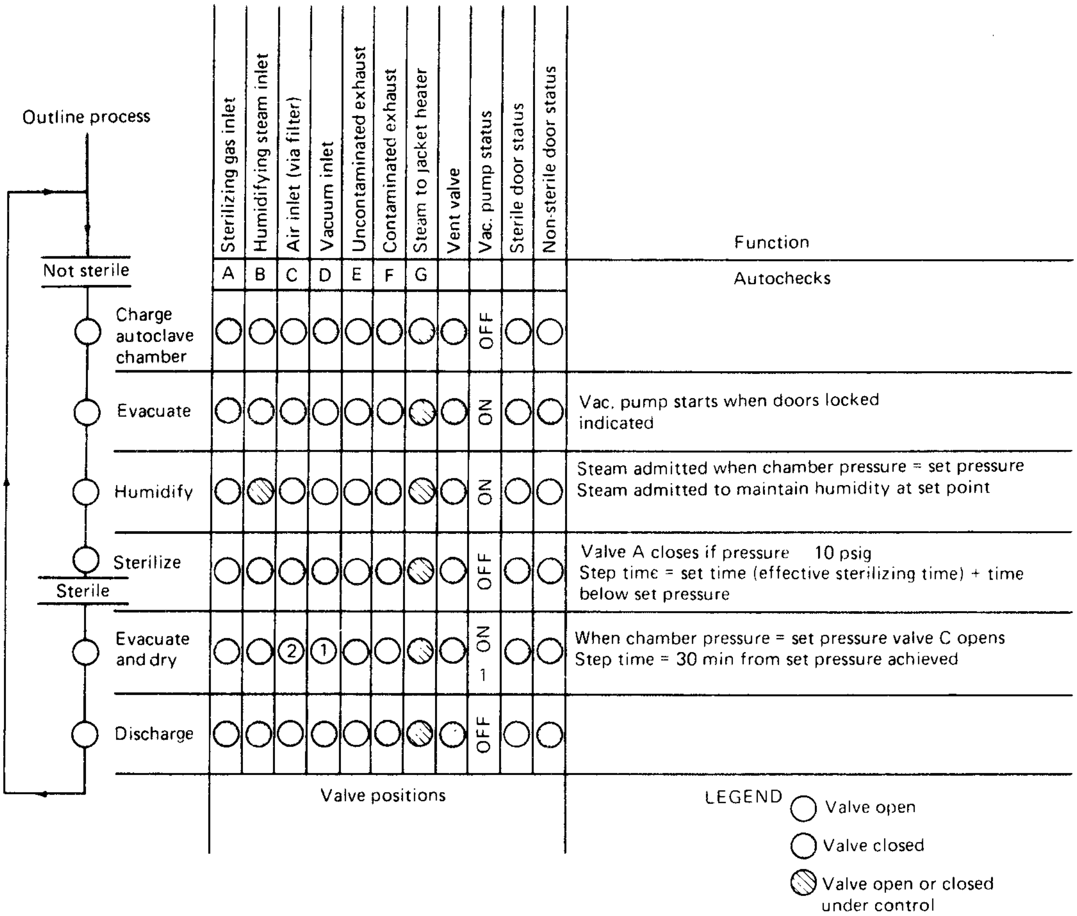

Figure 8.12 *Hazard and operability studies: sequence diagram (dot chart) for autoclave arrangement (Chemical Industry Safety and Health Council, 1977/3)*

8.12.17 Timing of HAZOP studies

The timing of a HAZOP study is an important issue. The disadvantages of an early study are that some of the information necessary to its effective conduct is not available and that there is a greater risk of design changes being made to the detriment of operability and/or safety. The advantages are that it is easier to incorporate in the design any changes arising out of the study and, in particular, to achieve an inherently safer design.

Conversely, the disadvantages of a late study are that the design response options will have been rendered more difficult and expensive to implement, or sometimes foreclosed altogether, and consequently there is a stronger tendency to solve safety problems by 'add-on' measures.

8.12.18 Documentation for hazard studies

As the design progresses, the documentation produced, including the process and plant diagrams becomes firmer and more detailed.

The most primitive document is a block diagram of the whole process, in which each block represents some operation, possibly a whole plant. Addition of flow quantities and utility usages to this diagram turns it into a quantities flowsheet.

Next come, for each of the blocks in the block diagram, the various versions of the PFD, these typically being concept, preliminary and final versions. The PFD shows the main items of equipment, utilities and effluents, and control loops.

As the design firms up, the ELD is produced, showing the in-line items, the materials of construction, the equipment sizings, the line specifications and sizings, the equipment and line code numbers, and more details of instrumentation and control loops, as well as of pipework features such as drains and lutes.

An ELD with full information on the instrumentation constitutes the P&ID.

The firm ELD or P&ID is the preferred diagram for a HAZOP study, but in some cases it may be necessary to initiate the study at some earlier stage. For a continuous process, the minimum documentation required is the ELD and the outline operating procedures. For a batch process, these need to be augmented by the operating sequence.

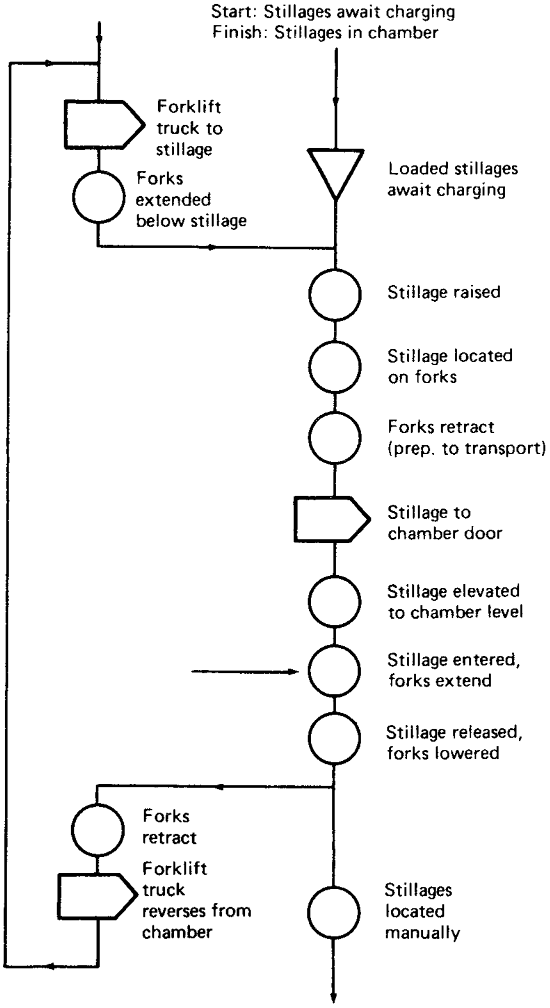

Figure 8.13 *Hazard and operability studies: flow process chart for autoclave arrangement for operation 'Charging autoclave' (Chemical Industry Safety and Health Council, 1977/3)*

8.12.19 Personnel involved in HAZOP studies

As stated earlier, a multi-disciplinary team performs the HAZOP. The team is normally composed of personnel responsible for design, commissioning and operation, but the detailed composition varies both between companies and with the type of project within a given company.

A typical team might comprise the study leader (facilitator), the project engineer, a process engineer, an instrument engineer and the commissioning manager. Other personnel who are often included, depending on the nature of the project, are a chemist, a civil engineer, an electrical engineer, a materials technologist, an operations supervisor, an equipment supplier's representative, and so on.

The technical team members provide the technical input in response to the guidewords. They are also able to amplify the information about the plant design given in the plant diagrams, operating instructions, etc. They may receive work assignments arising from the meetings and, as indicated below, one of their numbers may be appointed to act as the follow-up coordinator.

8.12.20 Leadership of HAZOP studies: the Facilitator

The role of the study leader is to act as a facilitator to bring to bear the expert knowledge of the technical team members in a structured interaction. It is not his role to identify hazards and operability problems, but rather to ensure that such identification takes place.

The study leader should be someone not directly involved in the design, but with skills as a HAZOP leader. The effectiveness of a HAZOP study is highly dependent on the skill of the study leader. Trained and experienced leaders are crucial.

The study leader is responsible for the definition of the project HAZOP; for the preparation of the meetings to be held; for arranging the schedules of meetings, and hence their timing and pacing; for assembling an appropriate team and ensuring that they understand their role, and receive training if necessary; for the provision to each study meeting of the necessary documents and other information; for the conduct and recording of the meetings; and for follow-up of matters raised during the meetings.

At the definition stage, the study leader should ensure that there is a satisfactory liaison with the client such that the latter will follow-up the results emerging from the study.

In the preparation stage, the study leader should review the extent to which the plant under consideration is similar to one already studied and how this should affect the study to be conducted. In many cases, the design is not a completely new one but constitutes a modification of an existing design. The study leader will then define the features, which are novel – raw materials, plant equipment, materials of construction, environmental conditions, etc. – and decide whether examination of certain parts can be omitted as unproductive. He should also ensure as part of the preparation that the necessary information is available and is correct.

The most elusive skill of the study leader lies in the conduct of the HAZOP meeting itself. One essential requirement is to ensure that the examination neither becomes too superficial nor gets bogged down in detail so that it identifies all the hazards but within a reasonable time-scale. Another is to manage the personal interactions between the team members, to obtain balanced contributions and to minimize the effect on individuals when the design is subject to criticism. These requirements are easily stated but constitute a significant skill.

8.12.21 Follow-up of hazard studies

The output of a HAZOP study is a set of queries concerning the design. There needs to be a formal arrangement to ensure that these are followed up. One method of doing this is to arrange that at each meeting every question raised is assigned to a specific individual to follow up and, in addition, to appoint a follow-up coordinator, preferably a member of the study team, to ensure that this is done. A common practice is to assign to this role a person with line responsibility such as the project manager.

Follow-up is one of the prime functions of computer packages developed to assist HAZOP.

Table 8.23 *Hazard and operability studies: results for autoclave arrangement for operation 'Humidify autoclave chamber' (Chemical Industry Safety and Health Council, 1977/3)*

Deviations	*Causes*	*Consequences*
DON'T HUMIDIFY	Valve B not open LD valve closed Steam line choked Vent valve open All steam to vaporizer Line fractured	Hazard to product – sterilizing gas not effective dry
MORE HUMIDIFY	Too much steam – LD valve failed open	Could chamber be overpressured? Is relief valve sized for full bore ingress of steam to chamber?
	Too high steam pressure/temperature	Is product temperature/pressure sensitive? Effect of high temperature and pressure on sealing components of autoclaves, e.g. door seals?
LESS HUMIDIFY	Too little steam, too low steam pressure/temperature	Is condensation on product deleterious?
AS WELL AS HUMIDIFY	Contaminants in steam, e.g. CO_2, condensation, air, rust, etc.	Effect on product?
	Sterilizing gas (valve A passing)	Waste gas by evacuation. Gas into plant atmosphere – is second isolation valve required?
	Air (valve C passing)	Reduces effectiveness of humidification
	Contaminants from vent stack (vent valve passing)	Might induce gases from other autoclaves
	Plant atmosphere (door seals leaking)	No hazard at this stage, but could be leak at sterilizing stage
	Vacuum pump fails	Contaminants from drain enter autoclave
PART OF HUMIDIFY	Steam in but loss of vacuum pump (or valve D closes)	Chamber will be partly pressurized. Load very wet, temperature too high. Chamber partly filled with water. Cycle will continue and sterilizing gas may not enter due to back pressure
	Vacuum, but no steam in	Cycle will continue; if lack of humidity is not detected and action taken, load will *not* be sterile
REVERSE HUMIDIFY	Vacuum drying	No steam in, as above
OTHER THAN HUMIDIFY	Sterilize by omission of humidifying step	Cycle will continue – load will not be sterile (as above)

8.12.22 Computer aids for HAZOP studies

There are a number of computer programs available to assist in the housekeeping aspects of HAZOP studies. These are covered in Chapter 29. These programs are distinct from codes, which perform hazard identification by emulating HAZOP studies. Developments in this area are described in Chapter 30.

8.12.23 Experience and further development of HAZOP studies

The HAZOP study has been found to be an effective technique for discovering potential hazards and operating difficulties at the design stage. Reductions of at least an order of magnitude in the number of hazards and problems encountered in operation due to such studies have been claimed.

The technique has become firmly established in the process industries, in small as well as large companies, as a prime, or the prime, method of hazard identification. In those companies where the method is used, HAZOP studies have tended to become an appreciable proportion of the design effort.

The account of the technique given above has followed the original emphasis on the deviations of process variables. Application of the technique has led to its extension particularly to the various activities of operation and maintenance, which are the source of many other deviations.

Not surprisingly, the widespread use of the technique has also led to the development of local variants and to adaptations to the needs of the particular companies using it. The HAZOP study technique has also been extended to cover other concerns such as the environment. In some cases, the same study is used to cover, on the one hand, safety and operability and, on the other, environment. Some HAZOP studies given in the literature are listed in Table 8.25.

Table 8.24 *Hazard and operability studies: some additional parameters and guidewords (after Tweedale, 1993e)*

Process variables	Flow	High; low; reverse; two-phase; leak
	Level	High; low
	Temperature	High; low
	Pressure	High; low; vacuun
	Load	High; low
	Viscosity	High; low
	Quality	Concentration/proportion; impurities; cross-contamination, side reactions; particle size; viscosity; water content; inspection and testing
Plant states	Commissioning and start-up	Statutory approvals; compliance checking; sequence of steps; supervision, training
	Shut-down	Isolation; purging; cleaning
	Breakdown	Fail-safe response; loss of utilities; emergency procedures
Production	Throughput	Sources of unreliability/unavaliability; bottlenecks
	Efficiency	
Materials of construction		Corrosion; erosion; wear; chilling; compatibility; sparking
Plant layout	Access	Operation; maintenance; escape; emergency response
	Space	(For housekeeping, work in progress, escape) Cramped; wasted
	Electrical safety	Hazardous area classification; electrostatic discharge and earthing: lightning protection
Utilities		Air; nitrogen; steam; electrical power; water: process, hot/cold, demineralized, drinking: drainage
Machinery	Machinery	Overload; malfunction; foreign body; rotation: fast, slow; jamming/seizing; frictional overheating; mechanical failure/fracture; impact; valve blockage: mechanical, low temperature; interlocks
	Assembly	Component missing, extra, or wrong; assembly sequence wrong; screwed wrong: (too tight, too loose): crossed/contaminated thread; shielding
	Incompatibility	Tools and equipment material: foreign objects
Materials handling	Speed	Fast; slow; unbalanced
	Packaging	Filling (over, under); damage (external, internal); poor sealing: legal requirements; labelling
	Physical damage	Impact; dropping; vibration
	Stoppages	Breakage; blockage; jamming; loss of feed; loss of packaging; advance warning; rectification
	Direction	Upwards; downwards: to one side; reverse
	Spillage	Spillage: into product, into other materials. Spillage: outside equipment, outside plant
	Location	Wrong: vertical, horizontal; orientation
Stockholding	Stockholding	Failed stock rotation: poor storage (water, vermin); storage of consumables (spares, tools, paints/solvents); storage of raw materials
Hazards	Fire and explosion	Prevention; detection; separation; protection; control
	Toxicity	Acute; long-term; ventilation; control
	Ignition	Friction: impact: static electricity; degraded electricals; failed earthing; mechanical sparling: misalignment; high temperature; dropped objects
	Environment	Housekeeping; dust, spillage, scrap/residues: humidity high, low; ventilation failure
	Environmental control	Effluents: gaseous, liquid, solid; noise; monitoring
Targets	Severity	Quantity exposed; protection and adequacy; venting; personnel escape: unplanned exposure: dust, maintenance, protection malfunction, propagation via duct
	Operator injury	Heavy lifting; repetitive motion; exposure: dust, fume, heat; falling, slipping, tripping
Reactions	Reaction rate	Fast; slow
Control and protection	Control	Sensor and display location; response speed; interlocks
	Protection	Response speed; element common with control loop: sensor, valve, operator; remote actuation; venting; testing
	Safety equipment	Personal equipment; showers
Sequences	Timing	Duration/dwell; rate of approach; sequence; start too early, late: stop too early, late
Testing	Testing	Raw materials; products; equipment; protective instrumentation: alarms, interlocks, trips; protective equipment

Table 8.25 *Selected hazard and operability studies*

Author(s)	*Subject of study*
Lawley (1974b)	Feed section of olefine dimerization plant
Lawley (1976)	Ethylene oxide feed system for batch reactors
CIHSC (1977/3)	Reactor transfer system; feed section of olefine dimerization plant; batch plant; autoclave
Rushford (1977)	Section of cracker unit
Austin and Jeffreys (1979)	Reactor section
Sinnott (1983)	Reactor section of nitric acid plant
Piccinini and Levy (1984)	Ethylene oxide reactor system
Kletz (1985e)	Liquid propane cross-country pipeline
Ozog (1985)	Flammable liquid storage tank
Flothmann and Mjaavatten (1986)	Refrigerated liquid ammonia storage
Kavianian, Rao and Brown (1992)	High pressure/low density polyethylene plant; metal organic chemical vapour deposition process
Knowlton (1992)	Reactor transfer system; batch plant; autoclave; interstage cooler; emergency shut-down and blowdown system; gas supply and oil storage system (hybrid study)

8.12.24 Activities in HAZOP studies

It is of interest to know the actual activities that are undertaken in a HAZOP study, particularly for the development of the HAZOP technique, including computer-aided activities (Table 8.26).

Figure 8.14 gives a flow chart for a typical study. A large proportion of the protocol consisted, in addition to selection of the item of plant and the parameter deviation for study, of the following activities:

(1) generation of possible causes and consequences of initial deviation;
(2) explanation of features of process material or plant item;
(3) estimation of quantitative aspects of plant dynamics, plant reliability and availability, hazard and risk;
(4) checks on features of design and operation and of potential HAZOP problems, including detectability of deviations/faults and final consequence hazards and methods for starting, controlling and stopping the operation;
(5) specification of any action to be taken.

The activity of generating causes and consequences triggered by the application of the guideword to the parameter was relatively unsystematic. The team explored fault paths as they occurred to individuals.

Explanation of features of process materials or plant items emerged as a significant activity. Generally, in a design there are (1) features that are ambiguous, (2) features that have to be modified and (3) features that have characteristics, which have not been considered. These features may require further explanation for several reasons: (1) the information may be documented but it is more convenient to retrieve it by verbal explanation, for example, philosophy of the design calculation; (2) the information is, or should be, part of the design, but it is not yet documented, for example, intended operating procedure; (3) the information is generated by the HAZOP team during the study. Some topics on which explanations were given are shown in Table 8.27, Section C.

Another significant activity was estimation of quantitative or semi-quantitative aspects of plant dynamics, plant reliability and availability, and hazard and risk. Some features on which estimates were made are given in Table 8.27, Section D.

The central activity was checks on features of design and operation and on hazards and operability problems. Some of these checks are listed in Table 8.27. The checks given are limited to those arising directly or indirectly from use of the guidewords, which were not instantly dismissed. An important class of check was those on the detectability of deviations/faults. A large proportion of operability problems are problems of deviation/fault detection. Some of the checks of this type are listed in Table 8.27, Section E.

Most of the hazards listed in Table 8.27 are intermediate events rather than final consequences. Table 8.27, Section F, gives some of the principal final consequences of ultimate interest in the study.

Some of the hazards considered would be identified only if two deviations/faults were to occur simultaneously. Some of the decisions made on such simultaneous deviations/faults are given in Table 8.27, Section G. In four out of the five cases shown in the table, the probability of simultaneous occurrence was assessed as negligible. In the fifth case, one of the faults is failure of a low flow alarm system. This type of failure could occur well before the low flow deviation but remain unrevealed so that the probability of 'simultaneous' deviations/faults could be much higher in this case unless the instrument was proof tested. The problem of unrevealed failure was evidently recognized by the team in assessing this risk as not negligible.

The analysis revealed several problems of design communication. Some of these are shown in Table 8.27, Section H.

8.12.25 Filtering in HAZOP studies

The account given so far of HAZOP studies has emphasized primarily the generation of deviations. But HAZOP is not in fact a pure identification technique. A significant part of the activity in a HAZOP is concerned with the filtering of the deviations identified. It is not the function of the HAZOP team to carry out 'instant design'. But it is a proper function to carry out a coarse filtering process on the deviations generated in order to prevent the design systems being swamped with insignificant items. The contribution of experienced people is probably at least as much in filtering as in generation.

8.12.26 Quality assurance

A survey of HAZOP studies conducted as part of the safety case for oil platforms in the North Sea has been

Table 8.26 *Hazard and operability studies: activities in a study[a] (Roach and Lees, 1981)*

A Features of design and operation

- Plant and pipework configuration:
  - Potential alternative pipework configuration
  - Pipework configuration relative to intended flow
- Equipment capacity, underdesign:
  - Condenser
  - Distillation column trays
  - Pipe (6)
  - Pressure relief valve
  - Vent
- Equipment overdesign:
  - Pump
  - Valve (2)
- Plant turndown (2)
- Materials of construction:
  - Corrosion (2)
  - High temperature
  - Low temperature effect on lined pipe
  - Low temperature embrittlement
  - Product discolouration
- Lagging:
  - Frost protection (5)
  - Heat conservation
  - Personnel protection (4)
- Equipment features and facilities:
  - Access
  - Analysis point (5)
  - Break tank
  - Bund
  - Disengagement space
  - Drain point (2)
  - Droplet knockout facilities
  - Drying facilities
  - Gas balancing
  - Isolation (4)
  - Lute (4)
  - NPSH
  - Purging facilities (2)
  - Self-draining:
    - Consenser fall
    - Pipe fall (3)
    - Restrictor orifice, effect of
  - Siphon breaker (2)
  - Slip plate facilities
  - Spool piece (3)
  - Venting facilities (3)
  - Warming facilities
- Instrumentation and control:
  - Alarms on pumps
  - Alarm dynamic response
  - Alarm setting
  - Flow measurement – full bore flow in pipe
  - Interlocks (3)
  - Potential correction
  - Pressure deviation – effect on distillation column controllers
  - Temperature measurement - full immersion of probe
  - Trip dynamic response
  - Trip setting
- Pressure equipment:
  - Pressure relief
  - Pressure vessel design assumptions
  - Pump delivery pipework rating for high pump suction pressure
  - Rating of vessel as a pressure vessel
- Pumps:
  - Automatic vs manual changeover
  - Configuration and layout
  - Kickback
  - Maintenance error–pump wrongly piped up
  - Operating instructions
  - Overdesign
  - Pressure relief valve (positive displacement pump)
  - Replacement error – pump of twice design capacity installed
- Valves:
  - Action on air failure
  - Valve and bypass:
    - Interlock
    - Operating instructions
  - Valve lock open
  - Valve selection – isolation valve vs instrument valve
  - Valve trim size
- Power supply
- Earthing, electrical continuity
- Plant layout:
  - Access (3)
  - Floor levels, relative to operations
  - Goggles area
  - Manholes
  - Overflows
- Operating instructions:
  - Additives
  - Distillation column high level
  - Effluent system operation
  - Lute maintenance
  - Pipe function and flow
  - Pump maximum flow
  - Pump operation
  - Reverse flow hazard
  - Valve and bypass
- Sequential operations:
  - Charging of acid and water
- Additives:
  - Operation instructions
  - Pipework
  - Pump interlocks
- Pressure system register:
  - Hazardous pipelines (3)
  - Pipe acting as vent
  - Vent
- Maintenance, maintainability:
  - Column repacking
  - Equipment removal
  - Pressurized equipment (2)

B Hazards and operability problems

- Air ingress (3)
- Blockage (6)
  - Freezing (2)
  - Icing
  - Polymerization
- Chemical reaction
- Decomposition
- Effluents
  - Impurities
  - Vented materials, fate of
- Erosion
- Explosion
- Explosive impurities
- External fire
- Flammable atmosphere
- Fluid flow phenomena:
  - Boiling (2)
  - Entrainment
  - Erosion
  - Flashing
  - Flooding:
    - Condenser
    - Distillation column (2)
    - Gas absorption column
- Frothing
- Gas breakthrough
- Gas evolution from liquid (2)
  - Gas, Vapour lock (2)
  - Hammerblow
  - Inert gas blanketing of heat transfer surface
  - Layering
  - Liquid slugs, surges (2)
  - Pressure surges (2)
  - Reaction forces
  - Siphon (3)
  - Suction due to high downflow
  - Suckback
  - Vortexing
- Heat effects:
  - Heat of mixing (3)
- Impurities:
  - Effluents
  - Process water
  - Product
- Leaks:
  - to environment
  - within heat exchanger (4)
  - through Valve (3)
- Lutes
- Maloperation:
  - Pumping of fluid from one pump back through another
- Material deposits
- Sample points:
- Access (2)
  - Air ingress
  - Liquid circulation
  - Pressurized system
  - Wrong location
- Sabotage
- Static electricity (2)
- Trip action effects
- Utilities failure:
  - Cooling water (3)
  - Electrical power
  - Instrument air
  - Nitrogen
- Vacuum:
  - Absorption of soluble vapour
  - Collapse of pipe lining
- Valves:
  - Heating up of fluid trapped between two closed valves
  - Installed or replaced wrong way round
  - Leaks
- Water ingress (2)

[a] The categories listed are not all mutually exclusive, and a small proportion of checks are listed under more than one entry.

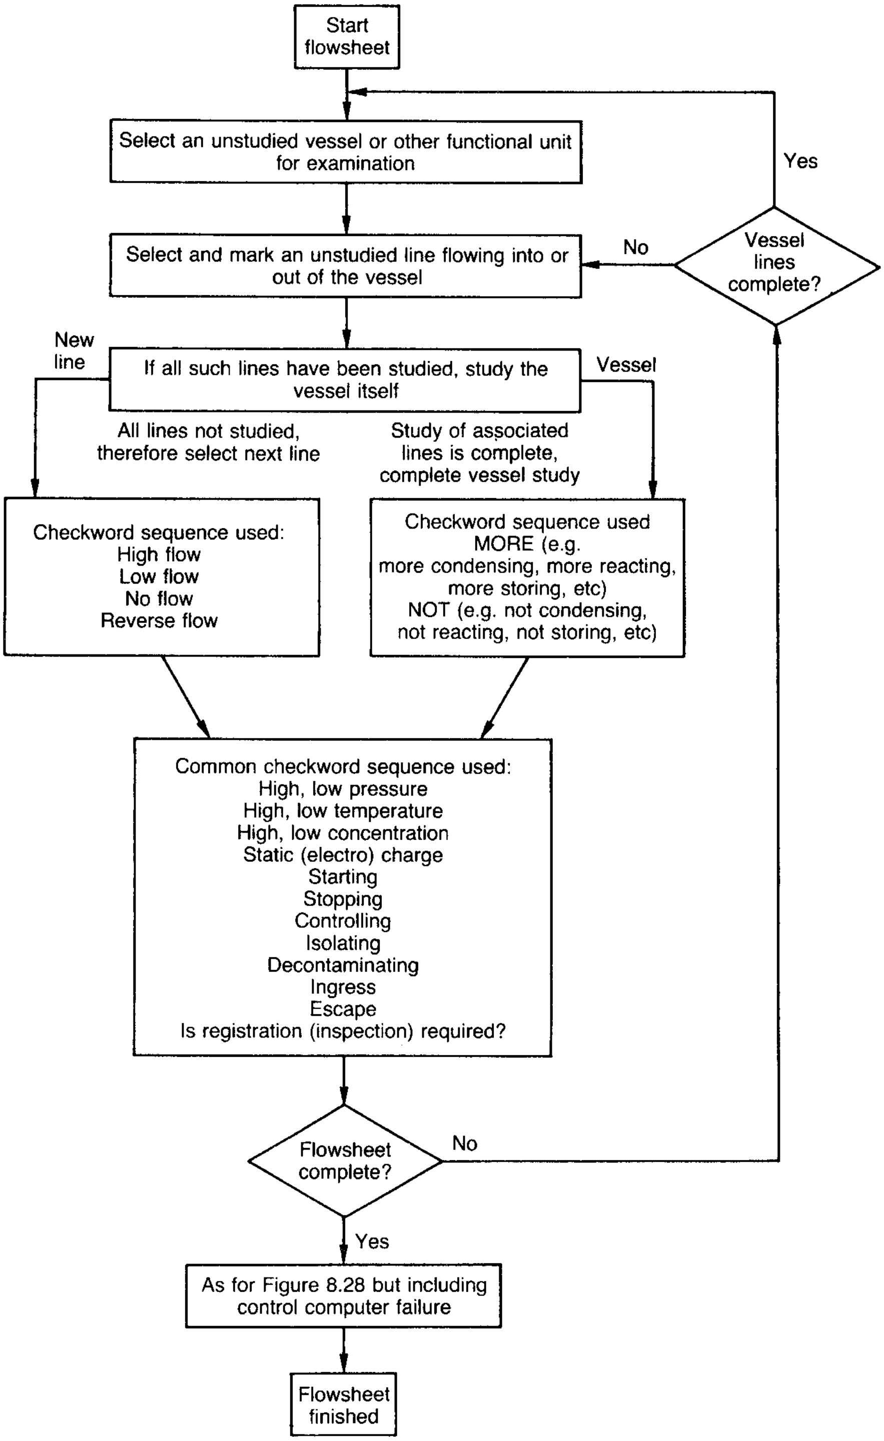

Figure 8.14 *Hazard and operability studies: sequence of activities in a study (Roach and Lees, 1981) (Courtesy of the Institution of Chemical Engineers)*

***Table 8.27** Hazard and operability studies: checks made in a study[a] (Roach and Lees,1981) (Courtesy of the Institution of Chemical Engineers)*

A Check words applicable to deviation of process variables

NO, NOT	Negation of intention
MORE	Quantitative increase
LESS	Quantitative decrease
AS WELL AS	Qualitative increase
PART OF	Qualitative decrease
REVERSE	Logical opposite of intention
OTHER THAN	Complete substitution

B Other check words

- STARTING
- STOPPING
- CONTROLLING
- ISOLATION
- ESCAPE
- DECONTAMINATION
- INGRESS

C Some topics on which explanations are given

- Flowsheet discrepancies
- Function of a unit:
  - Drain/flushing point
  - Valve
- Modes of operation of unit
- Design capacity/overdesign of unit
- Materials of construction
- Lagging
- Physical characteristics of process materials:
  - Miscibility
  - Solubility
- Chemical characteristics/reactions of process materials:
  - Decomposition
- Additives, functions of
- Impurities, fate of pressures and pressure drops:
  - Gravity vs pumped flows (2)
  - Units atmospheric pressure
- System arrangements:
  - Bypasses (2)
  - Gas balancing
  - Inserting/purging
  - Isolation
  - Lutes
  - Purging (2)
  - Sampling (2)
  - Venting
- Instrumentation, control and protection
  - Conventional control system configuration, logic and behaviour (3)
  - Computer control configuration logic and behaviour (3)
  - Manual control loops
  - Trip vs alarm setting
  - Trip or pressure relief setting
- Quality standards:
  - Products
  - Effluents (2)
- Potential deviation:
  - Pressure
- Failure effects:
  - Flow meter failure
  - Pump corrosion
  - Pump start failure
  - Pump valve configuration errors
- Failure data:
  - Failure rate
  - Repair time
- Company practices:
  - Lagging
  - Overpressure protection
- Statutory requirements
  - Break tank

D Some features on which estimates are made

- Fraction of time spent by unit in different operational modes
- Magnitude of deviations (4)
- Steady-state gain relating consequences
- Time for deviation/fault to give rise to consequences (3) and cause deviations
- Time for deviation/fault to be detected (2)
- Performance of plant unit in face of deviation
- Failure rate:
  - Utilities (2)
- Event rate
- Repair time
- Fractional dead time (3)
- Degree of hazard/inoperability (4)
- Frequency/probability of hazard/inoperability (8)

E Checks on detectability of deviations/faults and of correct operation

Deviations/faults checked for detectability

- Process variable deviations:
  - High flow (2)
  - Low flow
  - Reverse flow (2)
  - High level (4)
  - Low level (3)
  - High pressure
  - Low pressure (2)
  - High temperature
  - Low temperature
- Contamination (3)
- Additive deviations
- Blockages:
  - Blockages (3)
  - Freezing (3)
- Leaks
- Flooding
- Utility failures:
  - Cooling water (2)
  - Refrigeration set
  - Steam
- Instrument failure
- Pump failure (2)
- Valve fails open
- Valve misdirected shut (2)
- Valve installation errors on pump
- Lute problems

Flow at pumps and valves checked for detectability

- Pumps
- Valves

F Principal final and intermediate consequences of deviations/faults

- Overpressure (5)
- Underpressure, vacuum collapse (2)
- Overtemperature (3)
- Undertemperature (2)
- Corrosion (5)
- Explosive mixture, confined
- Explosion, confined
- Equipment damage
- Overflow (liquids) (11)
- Boilover
- Escape (gases)
- Escape (liquids)
- Product contamination (4)
- Effluent (flow normally exists):
  - Contamination (3)
  - High flow
  - High temperature
  - pH deviation (2)
- Effluent, (occasional venting flow occurs) (3):
  - High flow (2)
- Forced shut-down:
  - Manual
  - Automatic trip (2)
  - Equipment failure
- Personnel injury (6)

G Decisions on simultaneous deviations/faults

- One of two pump motors down for maintenance AND electrical supply phased – no action
- Process upset AND cooling water failure – no action
- Steam flow high AND cooling water failure – no action
- Pump failure AND low flow alarm failure – further investigation
- Deviation in pH AND deviation in chemical decomposition with consequent possibility of SO_2 generation – no action

H Uncommunicated features, ambiguities and variations in the design

- Uncommunicated design features
- Uncommunicated design changes
- Ambiguity about vessel design pressure
- Equipment designed for throughputs other than flow sheet one
- Potential variations in methods of plant operation not communicated

[a] Numbers in parentheses indicate the number of times an item occurs in the protocol. If no number is given, an item occurs once. Entries followed by a colon are headings, not specific items.

described by Rushton *et al.* (1994). The survey covered the context, policy, practical aspects and quality assurance of HAZOP.

A more detailed account of possible approaches to the quality assurance of HAZOP is given in a further report by Rushton (1995).

Quality assurance is discussed further in Sections 8.27–8.29.

8.12.27 Limitations of HAZOP studies

The HAZOP technique has been widely adopted and is the centrepiece of the hazard identification system in many companies. It does, however, have some limitations.

These limitations are of two kinds. The first type arises from the assumptions underlying the method and is an intended limitation of scope. In its original form, the method assumes that the design has been carried out in accordance with the appropriate codes. Thus, for example, it is assumed that the design caters for the pressures at normal operating conditions and intended relief conditions. It is then the function of HAZOP to identify pressure deviations which may not have been foreseen.

The other type of limitation is that which is not intended, or desirable, but is simply inherent in the method. HAZOP is not, for example, particularly well suited to deal with spatial features associated with plant layout and their resultant effects.

8.12.28 Variants of HAZOP studies

There are a large number of variants on the original HAZOP study. Many, perhaps most, companies have adapted the technique to their own needs. Many of these adaptations extend the method in respect of non-normal operation or of other activities such as maintenance, or to take account of other concerns such as environmental effects. Another type of variant is the application of the basic technique of HAZOP to systems other than process vessels and pipework. Some of these are described in Section 8.12.29. In this regard it should be remembered that HAZOP itself was an application of method study, and it may often be better to step back to this origin and then forward again from there rather than to try to apply HAZOP *per se*.

8.12.29 Other applications of HAZOP methodology

The methodology of HAZOP, or its parent critical examination, has been applied to a number of other situations, many of which are of interest in the process industries. These include (1) plant modification, (2) plant commissioning, (3) plant maintenance, (4) emergency shut-down and emergency systems, (5) mechanical handling, (6) tanker loading and unloading, (7) works traffic, (8) construction and demolition and (9) buildings and building services.

8.13 Failure Modes, Effects and Criticality Analysis

Another method of hazard identification is FMEA and its extension FMECA.

Accounts of FMEA and of FMECA are given in the CCPS *Hazard Evaluation Guidelines* (1985/1, 1992/9) and by Recht (1966b), J.R. Taylor (1973, 1974c, 1975a), Himmelblau (1978), Lambert (1978a), A.E. Green (1983), Flothmann and Mjaavatten (1986), Moubray (1991), Kavianian, Rao and Brown (1992), D. Scott and Crawley (1992) and Goyal (1993). A relevant code is BS 5760, which is described below.

FMEA involves reviewing systems to discover the mode of failure, which may occur, and the effects of each failure mode. The technique is oriented towards equipment rather than process parameters. Table 8.28 shows a set of typical results from an FMEA study on a process plant given by Recht (1966b).

8.13.1 BS 5760

Guidance on FMEA is given in BS 5760 *Reliability of Systems, Equipment and Components*, Part 5:1991 *Guide to Failure Modes, Effects and Criticality Analysis* (FMEA and FMECA). BS 5760: Part 5: 1991 deals with the purposes, principles, procedure and applications of FMEA, with its limitations and its relationship to other methods of hazard identification, and gives examples.

FMECA is an enhancement of FMEA in which a criticality analysis is performed. Criticality is a function of the severity of the effect and the frequency with which it is expected to occur. The criticality analysis involves assigning to each failure mode a frequency and to each failure effect a severity.

The purpose of an FMEA is to identify the failures which have undesired effects on system operation. Its objectives include: (1) identification of each failure mode, of the sequence of events associated with it and of its causes and effects; (2) a classification of each failure mode by relevant characteristics, including detectability, diagnosability, testability, item replaceability, compensating and operating provisions; and, for FMECA, (3) an assessment of the criticality of each failure mode.

The standard lists the information required for an FMEA, under the headings: (1) system structure; (2) system initiation, operation, control and maintenance; (3) system environment; (4) system modelling; (5) system software; (6) system boundary; (7) system functional structure; (8) system functional structure representation; (9) block diagrams and (10) failure significance and compensating provisions.

Core information on the items studied is the (1) name, (2) function, (3) identification, (4) failure modes, (5) failure causes, (6) failure effects on system, (7) failure detection methods, (8) compensating provisions, (9) severity of effects and (10) comments.

The main documentation used in an FMEA is the functional diagram. Use may also be made of reliability block diagrams.

The identification of the failure modes, causes and effects is assisted by the preparation of a list of the expected failure modes in the light of (1) the use of the system, (2) the element involved, (3) the mode of operation, (4) the operation specification, (5) the time constraints and (6) the environment.

The failure modes may be described at two levels: generic failure modes and specific failure modes. The standard gives as an example a set of generic failure modes: (1) failure during operation, (2) failure to operate at a prescribed time, (3) failure to cease operation at a prescribed time and (4) premature operation. As examples of specific failure modes, the standard gives: (1) cracked/fractured, (2) distorted, (3) undersized, and so on.

The failure causes associated with each mode should be identified. BS 5760 gives a checklist of potential failure causes under the headings: (1) specification, (2) design, (3) manufacture, (4) installation, (5) operation, (6) maintenance, (7) environment and (8) uncontrollable forces.

Table 8.28 *Failure modes and effects analysis: result for a process plant (after Recht, 1966b; Himmelblau, 1978)*

Component	*Failure or error mode*	*Effects on other system components*	*Effects on whole system*	*Hazard class*[a]				*Failure frequency*	*Detection methods*	*Compensating provisions and remarks*
				1	*2*	*3*	*4*			
Pressure relief valve	Jammed open	Increased operation of temperature sensing controller, and gas flow, due to hot water loss	Loss of hot water; greater cold water input, and greater gas consumption	1				Reasonably probable	Observe at pressure-relief valve	Shut off water supply, reseat or replace relief valve
	Jammed closed	None	None	1				Probable	Manual testing	Unless combined with other component failure, this failure has no consequence
Gas valve	Jammed open	Burner continues to operate. Pressure-relief valve opens	Water temperature and pressure increase. Water → steam			3		Reasonably probable	Water at faucet too hot. Pressure-relief valve open (observation)	Open hot water faucet to relieve pressure. Shut off gas supply. Pressure-relief valve compensates
	Jammed closed	Burner ceases to operate	System fails to produce hot water	1				Remote	Observe at output (water temperature too low)	
Temperature measuring and comparing device	Fails to react to temperature rise above preset level	Controller gas valve, burner continue to function 'on'. Pressure-relief valve opens	Water temperature too high. Water → steam			3		Remote	Observe at output (faucet)	Pressure-relief valve compensates. Open hot water faucet to relieve pressure. Shut off gas supply
Temperature measuring and comparing device	Fails to react to temperature drop below preset level	Controller, gas valve, burner continue to function off	Water temperature too low	1				Remote	Observe at output faucets	
Flue	Blocked	Incomplete combustion at burner	Inefficiency. Production of toxic gases				4	Remote	Possibly smell products of incomplete combustion	No compensation built in. Shut-down system
Pressure-relief valve and gas valve	Jammed closed	Burner continues to operate, pressure increases	Increased pressure cannot bleed at relief valve.				4	Probable	Manual testing of relief valve	Open hot water faucet. Shut off gas supply.
	Jammed open		Water → steam If pressure cannot back up cold water inlet, system may rupture violently					Reasonably probable	Observe water output	Pressure might be able to back into cold water supply, providing pressure in supply is not greater than failure pressure of system
								Reasonably probable	Temperature too high	

[a] 1, Negligible effects; 2, marginal effects; 3, critical effects; 4, catastrophic effects.

The failure effects involve changes in the operation, function or status of the system and these should be identified by the analysis. Failure effects can be classified as local or as end effects. Local effects refer to the consequences at the level of the element under consideration and end effects to those at the highest level of the system.

Where FMEA is to be applied within a hierarchical structure, it is preferable to restrict it to two levels only and to perform separate analyses at the different levels. The failure effects identified at one level may be used as the failure modes of the next level up, and so on.

BS 5760: Part 5: 1991 contains in Appendix B a number of tables illustrating the results of FMECAs conducted on various types of system. They include analysis of a subsystem of a motor generator set and of the fire protection system of an electric locomotive. Taking the latter as being most representative of process applications, the table is headed by a declaration that the system considered is the fire protection system and that its function is to detect and extinguish a fire within the locomotive. The columns of the table are headed as follows: (1) item, (2) item failure mode, (3) failure cause, (4) block function description, (5) functional failure mode, (6) effect on subsystem outputs, (7) effect on system reliability, (8) effect on system safety, (9) preventive action (design), (10) preventive action (quality assurance), (11) comment, (12) severity and (13) failure rate. Item failure mode is exemplified by ‘failed to open circuit conditions’, and functional failure mode by ‘detection of false fire’.

FMEA is an efficient method of analysing elements which can cause failure of the whole, or of a large part, of a system. It works best where the failure logic is essentially a series one. It is much less suitable where complex logic is required to describe system failure.

FMEA is an inductive method. A complementary deductive method is provided by fault tree analysis, which is the more suitable where analysis of complex failure logic is required.

BS 5760: Part 5: 1991 states that FMEA can be a laborious and inefficient process unless judiciously applied. The uses to which the results are to be put should be defined. FMEA should not be included in specifications indiscriminately.

8.13.2 Application of FMEA

The range of applications of FMEA is very wide. At one end of the spectrum, A.E. Green (1983) has applied it to a pneumatic differential pressure transmitter, whilst at the other, Aldwinkle and Slater (1983) have described its application to a liquefied natural gas terminal. Table 8.29 lists some of the FMEA studies given in the literature.

8.14 Sneak Analysis

In contrast to general methods such as HAZOP and FMECA, there are also niche methods. One of these is sneak analysis. Accounts of sneak analysis are given by E.J. Hill and Bose (1975), J.R. Taylor (1979, 1992), Rankin (1984), Dore (1991), Hahn *et al.* (1991), Hokstad, Aro and Taylor (1991) and Whetton (1993b).

Sneak analysis originated in sneak circuit analysis (SCA), a method of identifying design errors in electronic circuits (E.J. Hill and Bose, 1975). The technique was developed within a particular company and was slow to spread. An early use in the process industry was in the work of J.R. Taylor (1979) on sneak path analysis. A lead in encouraging the wider use of sneak analysis has been taken by the European Space Agency (ESA), as described by Dore (1991).

Table 8.29 *Failure modes and effects analysis: selected studies*

Author(s)	*Subject of study*
Recht (1966b)	Hot water system
C.F. King and Rudd (1972)	Heavy water recovery plant
Eames (1973 UKAEA SRS/GR/12) Lambert (1978a)	Nuclear instrumentation
Aldwinkle and Slater (1983)	Liquified natural gas terminal
A.E. Green (1983)	Pneumatic differential pressure transmitter
Flothmann and Mjaavatten (1986)	Refrigerated liquid ammonia storage
BS 5760: Part 5:1991	Fire protection system of an electric locomotive; subsystem of a motor generator set
Kavianian, Rao and Brown (1992)	Metal organic chemical vapour deposition process

A review of sneak analysis is given by Whetton (1993b), who gives as a rough definition: ‘A sneak is an undesired condition which occurs as a consequence of a design error, sometimes, but not necessarily, in conjunction with a failure’.

In sneak analysis generally, four recognized categories of sneak have emerged: (1) path, (2) indication, (3) label and (4) timing. Whetton refers to the following categories, which have developed from process work: (1) flow, (2) indication, (3) energy, (4) procedure, (5) reaction and (6) label.

8.14.1 Types of sneak

The different types of sneak which can occur are discussed by Whetton, with examples.

Sneak flow

Sneak flow is unintended flow from a source to a target. An example is the case where two vessels containing liquids, one at higher pressure than the other, are connected to a common drain header. If the bottom outlet valves on both vessels are open at the same time, liquid can flow from the higher to the lower pressure vessel.

Sneak indication

A sneak indication is one which is incorrect or ambiguous. An example is the power-operated relief valve (PORV) at Three Mile Island, where there was displayed an indication of ‘Valve position’ which was in fact the signal to, rather than the actual position of, the valve.

Sneak label

Likewise, a sneak label is one which is incorrect or ambiguous.

Sneak energy

Sneak energy is the unintended presence or absence of energy. An example is the energy release attendant on the restart of agitation in a reactor where the agitator has been temporarily switched off.

Sneak reaction

Sneak reaction is an unintended reaction. Examples are a side reaction in a reactor and an undesired reaction between a fluid and a material of construction.

Sneak procedure or sequence

A sneak procedure or sequence is the occurrence of events in an unintended or conflicting order.

8.14.2 Sneak analysis methods

Whetton distinguishes three basic methods of sneak analysis: (1) topological, (2) path and (3) clue.

The original sneak analysis method was based on decomposing electrical circuits into standard subnetworks. According to Whetton, the method has proved difficult to adapt to process plants in that successful application depends on the ability of the analyst to cast process phenomena in the form of electrical analogues.

Sneak path analysis, developed by J.R. Taylor (1979, 1992), is the investigation of unintended flow between a source and a target. It is performed in a systematic manner by decomposing the P&ID into functionally independent sections and identifying sources and targets, source–target pairs and paths between sources and targets. One method of doing this is the use of coloured markers to trace the various paths, sometimes known as the 'rainbow' technique.

The clue method involves the use of a structured checklist. It is applicable to all types of sneak and examines each type by means of a question set.

8.14.3 Sneak-augmented HAZOP

Sneak analysis may be used as an enhancement of HAZOP. The techniques used are the path and clue methods. Whetton gives a detailed procedure for the conduct of a sneak-augmented HAZOP. All drawings used should be 'as built'. Information on labels should cover the as-built condition. Essentially, the sneak analysis aspect of the procedure involves an examination of the various types of sneak against the appropriate clue list. Among the other points made are the following:

Sneak flow

Examine all paths including utilities and drains, sewers and vents

Examine, in turn, all plant states such as normal operation, start-up, shut-down, etc.

Examine for each valve in turn the effect of unintended deviation in valve state.

Sneak indications

Examine each instrument

Examine control room, including humble lamps.

Sneak labels

Examine consistency of labels against as-built drawings

Examine consistency of labels on instruments.

Sneak procedures

Examine all procedures, including start-up, shut-down, etc., and maintenance.

Sneak energy

Examine, in turn, for all plant states, including start-up, shut-down, etc., and maintenance.

8.15 Computer HAZOP

The HAZOP study method just described was developed for plants in which predominantly the control system was based on analogue controllers. The advent of computer control has created the need for some method, which addresses the specific problems of this form of control.

In recent years, process engineers have increasingly chosen to use Programmable Logic Controllers (PLCs), DCSs and computers for process control. While these systems provide flexibility and close control of the process, they introduce an additional mode of failure to the plant. Modern HAZOP techniques including CHAZOP are used to consider such systems. This is quite distinct from computer-aiding of HAZOP.

An early expression of concern was that by Kletz (1982g), who highlights the human problem associated with computer control. The HSE has identified this as a topic requiring attention. One outcome has been its work on programmable electronic systems, leading to the HSE *PES Guide*, which deals with the reliability of the computer system itself, but the concern is wider than this, as described by P.G. Jones (1991).

8.15.1 Checklist and guideword methods

A method for CHAZOP that has the same general approach as conventional HAZOP has been described by Andow (1991). Like HAZOP, it is intended to be carried out by a multi-disciplinary team following a systematic methodology and using standard guidewords and questions.

Andow describes a two-part study format, comprising a preliminary study and then the main study. The purpose of the preliminary study is to identify critical features early in the design. The study covers (1) system architecture, (2) safety-related features, (3) system failure and (4) utilities failure. In the full study, attention is directed to (1) the computer-system environment, (2) input/output signals and (3) complex control schemes.

Study of the computer system environment involves examination of the machine itself and of cabinet, crates, etc.; control, input/output cards; communication links; operator consoles; power supplies; watchdog timers; and other utilities. It uses questions to establish design intent and then a question set to investigate failures:

(1) Does it matter?
(2) Will the operator know?
(3) What should he do?

The input/output signals are studied following rather more closely the HAZOP format, with examination of items such as the signal using guidewords such as LOW, HIGH, INVARIANT, DRIFTING and BAD followed up with the failure question set just quoted. Another item examined is the actuator.

Complex control schemes are examined using a list of potential weak points and corresponding problems:

Control tuning	Initialization and windup
Points of operator access	Set-points, cascades that may be made or broken
Interaction with other	schemes Start-up, normal operation, shut-down; synchronization and timing issues; expected or required operator actions

The approach described by Burns and Pitblado (1993) also follows that of HAZOP; it applies to features, such as signal or information, guidewords such as NO, MORE, LESS and WRONG.

8.15.2 Task analysis method

A quite different approach is that described by Broomfleld and Chung (Broomfleld and Chung, 1994; Chung and Broomfleld, 1994). The methodology developed by these authors is based on an analysis of some 300 incidents in two organizations – one a process industry and one an avionics company. As an example of a process industry incident, they quote the premature start of a control sequence due to inadequate specification of the preconditions for initiation.

The underlying premise of the method is that most incidents are the result of deficiencies in the software-hardware interface. The authors state that attempts to conduct separate analyses of the hardware and the software in order to simplify the task, actually complicates it.

This interface is represented by four concentric functional levels. Each level is associated with certain system components. Each component has a defined task. Starting at the periphery and working in to the centre, these are as follows:

Functional level	*Component*	*Task*
Intervention	Utility	Intervention
	Operator	Intervention
Input/output	Sensor	Input
	Human input device	Input
	Actuator	Output
	Display	Output
Communication	Communication link	Communication
Control and processing	Computer	Control and processing

There is for each task a guideword and question set. Those for the intervention task are shown in Table 8.30

8.16 Human Error Analysis

An important source of hazards and losses is maloperation of the plant, and other forms of operator error. There are a number of methods for addressing this problem. One of these is the HAZOP study which, as just described, utilizes aids such as the sequence diagram to discover potential for maloperation. Other methods which may be mentioned here are task analysis and action error analysis (AEA). The problem of human error is, however, very complex. It is considered in more detail in Chapter 14.

8.16.1 Task analysis

Task analysis is a technique, which was originally developed as a training tool. As applied to the process operator, it involves breaking down the task of running the plant into separate operations carried out according to a plan. The objective is to discover potential difficulties, and hence errors, in executing the individual operations or the overall plan. A detailed account is given in Chapter 14.

Clearly such task analysis also ranks as a hazard identification technique. Task analysis has been applied to process plants with good results, but is not in widespread use. It may also be noted in passing that the writing of operating instructions constitutes a less formalized type of task analysis, and may likewise serve to identify hazards.

8.16.2 Action error analysis

Another technique of identifying operating errors is AEA, developed by J.R. Taylor (1979). This is a method of analysing the operating procedures to discover possible errors in carrying them out.

The actions to be carried out on the process interface are listed in turn, each action being followed by its effects on the plant, so that a sequence is obtained of the form:

Action – Effect on plant – Action – Effect on plant …

The actions are interventions on the plant such as pushing buttons, moving valves, etc.

The errors handled in the method are shown in Table 8.31. The effects of possible errors are then examined using guidewords for action. The main guidewords are:

TOO EARLY
TOO LATE
TOO MUCH
TOO LITTLE
TOO LONG
TOO SHORT
WRONG DIRECTION
ON WRONG OBJECT
WRONG ACTION

In analysing the effects of an error, an important consideration is whether the effect can be observed and corrected.

It is necessary to limit the scope of the analysis. Consideration of actions on wrong objects may be confined to those, which are physically or psychologically close to the correct object. The number of wrong actions to be considered has to be kept small.

Multiple errors are considered only to a limited extent. Thus, in a large operating procedure, it would normally be practical to take into account only single initial errors, but in a few cases it may be possible to use heuristic rules to identify double errors, a factor which H is worthwhile to explore. For example, one error may result in material being left in a vessel, while a second error may result in an accident arising from this.

The technique of AEA appears to have been quite widely used in Nordic countries, but much less so elsewhere.

8.17 Scenario Development

8.17.1 Release scenarios

The methods just described are concerned with HAZOP problems, which occur on most plants. A rather different question is the identification of potential sources of major release of hazardous materials, which may pose a risk to the workforce and/or the plant, and in unfavourable circumstances may even affect the public.

Information on release sources is required for hazard assessment and for emergency planning. In order to identify such sources, it is necessary to carry out a review.

Table 8.30 *Computer hazop: task considerations and attributes for task 'intervention' (Chung and Broomfield, 1994)*

Task	*Task consideration*	*Task attributes*	*Questions*	*Incidents*
Intervention	Specification	Definition	. . .	. . .
		Objective	. . .	. . .
		Options	. . .	. . .
		Input/outputs	. . .	. . .
		Timing/control	. . .	. . .
		. . .	. . .	. . .
	Association	Tasks	. . .	. . .
		Devices	. . .	. . .
	Implementation	Selection	. . .	. . .
		Installation	. . .	. . .
		Testing	. . .	. . .
		Maintenance	. . .	. . .
		Environment	. . .	. . .
		Utilities	. . .	. . .
	Fail safe/protection	Failure detection	. . .	. . .
		Interlocks	. . .	. . .
		Trips	. . .	. . .
		Recovery procedure	. . .	. . .
		. . .	. . .	. . .
	Failure modes	Not initialized	. . .	. . .
		Incorrectly executed	. . .	. . .
		Not terminated	. . .	. . .
		. . .	. . .	. . .

Table 8.31 *Action error analysis: errors handled (J.R. Taylor, 1979)*

Cessation of a procedure
Excessive delay in carrying out an action or omission of an action
Premature execution of an action – timing error
Premature execution of an action – preconditions not fulfilled
Execution on wrong object of action
Single extraneous action
In making a decision explicitly included in a procedure, taking the wrong alternative
In making an adjustment or an instrument reading, making an error outside tolerance limits

Table 8.32 *Some sources of release on a plant*

- Pipework:
  - Pipe rupture
  - Pipe flanges
  - Valves
  - Hoses
- Compressors
- Pumps
- Agitators
- Vessels and tanks:
  - Vessel/tank rupture
  - Vessel/tank overfilling
- Reactors
- Drain points
- Sample points
- Drains
- Relief devices:
  - Pressure relief valves
  - Bursting discs
- Vents
- Flares
- Operational release
- Maintenance release

In principle, virtually all elements of the pressure system (vessels, pumps, pipework) are points at which a release may occur. Table 8.32 gives a list of some of these release sources. A more detailed checklist of release sources is given in the CCPS *QRA Guidelines* (1989/5). The identification of release sources in a hazard assessment is illustrated by the studies given in the *Rijnmond Report* described in Appendix 8.

The role of the HAZOP study in identifying such sources merits mention. A HAZOP study starts from the assumption that the plant is basically well designed mechanically and concentrates primarily on process parameter deviations. The type of release which a HAZOP study might identify would be overfilling of a tank as a result of maloperation, or brittle fracture of a pipe due to contact with cold liquefied gas, but the study is not normally concerned with mechanical failures which occur while the process parameters are within their design range. The points on the plant at which a release may occur can generally be identified by the release source review. What the HAZOP study does is to identify specific credible realizations of release from these points. For a potential release, it is necessary not only to identify a source but also to decide on the nature of the release, which could occur. The tendency is to assume that the fluid released is at its design conditions. A HAZOP study may reveal that this is not so. For example, materials may be released from a storage tank as a result of a chemical reaction in the tank, which causes the liquid to heat up considerably above its storage temperature, and hence when released to give a much larger fraction of vapour.

8.17.2 Escalation scenarios

The identification process should not stop at the point where a release occurs, but in principle should be continued to embrace the consequences of the release and the failures and other events, which may allow these consequences to escalate. In practice, this aspect is usually treated as part of the hazard assessment. Whilst this is a reasonable approach, there is a danger that, unless the identification of the escalation modes is treated with a thoroughness matching that applied to the identification of the release modes, features which permit escalation and against which measures might be taken will be missed. The identification of the modes of escalation appears to be a rather neglected topic.

8.18 Consequence Modelling

For major hazard plants, it is common practice, following the development of the scenarios just described, to carry out some degree of quantitative modelling of the consequences. Such consequence modelling is described in more detail in the next chapter. Here it is sufficient to note its effect in giving a much better understanding of the likely development of the release and its potential for the identification both of hazards and of mitigatory measures.

8.19 Process Safety Review System

It is convenient at this point to consider under the heading of process safety reviews the family of techniques for hazard identification, hazard assessment, audit and accident investigation developed by Wells and co-workers.

8.19.1 General incident scenario

The next element is a method of defining incident scenarios, which is a necessary part of both hazard assessment and accident investigation. An account of this is given by Wells (1992) *et al.* The general incident scenario (GIS) described by these authors is a structure intended to be applicable to any incident.

The logic of an incident is also represented by the general incident structure shown in Figure 8.15. The GIS may be used for hazard identification, PHA or incident investigation.

8.19.2 Preliminary safety analysis

The GIS provides the basis for a set of techniques for PSA. Accounts of PSA are given by Wells, Wardman and Whetton (1993) and Wells, Phang and Wardman (1994). The PSA methods described are:

(1) concept safety review (CSR);
(2) concept hazard analysis (CHA);
(3) critical examination (CE);
(4) preliminary consequence analysis (PCA);
(5) preliminary hazard analysis (PHA).

These methods are now considered in turn, based on the account by Wells, Wardman and Whetton (1993).

8.19.3 Concept safety review (CSR)

The CSR is carried out as early as practical, possibly during the process development stage. Features of the CSR are review of the process and the alternatives, the safety, health and environment (SHE) information requirements, any previous incidents within the company and elsewhere, movement of raw materials and products, and organizational aspects.

8.19.4 Concept hazard analysis (CHA)

The CHA is an examination of the hazards of the process and is commenced as soon as the preliminary PFD becomes available. A checklist of keywords for a CHA is given in Table 8.33. Wells, Wardman and Whetton (1993) distinguish between a hazard and a hazardous condition. The former is purely qualitative, but the latter has a quantitative element. For example, a hazardous material constitutes a hazard.

The hazardous condition is determined by the quantity of the material. The CHA is akin to a coarse hazard study.

8.19.5 Critical examination (CE)

The CE of system safety is in large part a critical examination of the inherent safety of the system, and is therefore different from the critical examination involved in conventional HAZOP. The CE examines how the proposal is to be achieved and, in particular, (1) the materials, (2) the method and (3) the equipment. It also examines any dangerous condition and its cause. A checklist of keywords for the CE is shown in Table 8.34.

8.19.6 Preliminary consequence analysis (PCA)

The PCA, which may be started when the preliminary PED becomes available, is a hazard assessment kept at a fairly simple level. The main hazardous events considered are: (1) fire; (2) explosion, including missiles and (3) toxic release. The analysis covers the effects on the environment as well as on humans.

The analysis seeks to identify worst-case scenarios, to establish whether these could have impact outside the site and to define the types of emergency which might arise. The results from a PCA are illustrated in Table 8.35.

8.19.7 Preliminary hazard analysis (PHA)

The PHA is an analysis, which centres on the dangerous disturbance entry in the GIS. It involves estimating the frequency/probability of certain events and thus, in contrast to some other PHAs described in Section 8.10, it is a simplified form of conventional hazard analysis.

The results of a PHA are presented in tabular form, the core of which is the events:

(1) significant event to be prevented;
(2) failure to recover the situation;
(3) dangerous disturbance;
(4) inadequate emergency control or action;
(5) hazardous disturbances;

together with expansions at both ends, into causes of the set of hazardous disturbances and into escalation of the significant event. For each event, an estimate is given of the frequency/probability.

8.19.8 Short-cut risk assessment (SCRAM)

The SCRAM is essentially an extension of the PHA. It is described by Allum and Wells (1993). The SCRAM generates a set of significant events to be prevented, or top events, each of which is described in a risk evaluation

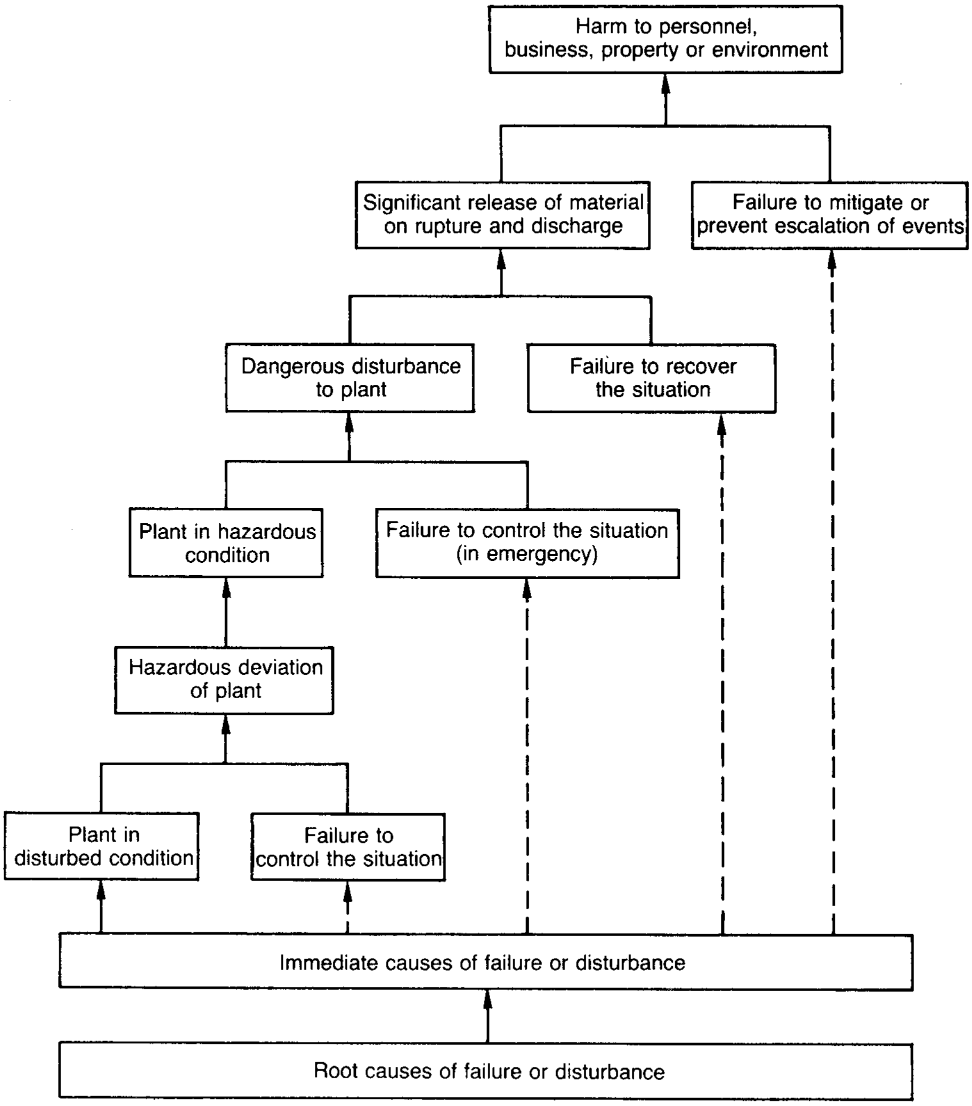

Figure 8.15 *Process safety review system: general incident structure (Wells et al., 1992) (Courtesy of the Institution of Chemical Engineers)*

sheet, which is essentially the tabulation of the PHA as just outlined. The risk assessment is developed using:

(1) target risk;
(2) severity categories;
(3) priority categories.

The target risk (TR) is defined as:

$$\mathrm{TR} = L + S \qquad [8.19.1]$$

where L is the exponent of likelihood as measured by frequency, and S is the severity category (described below).

The likelihood L is thus a negative number. If the frequency of the event is 10^{-2}, the likelihood has the value -2. The severity is the severity category number, which lies in the range 1–5. The authors give guidance on the estimation of event frequencies. This includes the adjustments to be made where the case under consideration is judged to depart from the average condition, as shown in Table 8.36. The target risk is taken as acceptable only if it is zero or less.

The severity categories are shown in Table 8.37. The severity category assigned to a given incident scenario is based on the highest level indicated by the entries in the category. The categories 'catastrophic' and 'severe' relate to very rare events, with a frequency of less than, say, 10^{-5}/year. The severity categories are not to be interpreted as implying that an event in a lower category is less serious

Table 8.33 *Process safety review system: concept hazard analysis – checklist of keywords (Wells, Wardman and Whetton, 1993)*

Keywords	*Undesired event*	*Consequences/problems*
Flammables	Release on rupture	Fire: flash, torch, pool
Ignition	Release by discharge	Chemical explosion
Fire	Entry of vessels	Physical explosion
Explosion	Handling	Vapour cloud explosion
	Ignition	Electrical explosion
Chemicals	Release on rupture	Absorption, inhalation, ingestion
Toxicity	Release by discharge	Contamination of environment
Corrosion	Entry of vessels	Disposal, incineration, storage, landfill
Pollutants	Handling	Asphyxia
Emissions	Fugitive emissions	Acidity, alkalinity, exposure effects
Effluents	Periodic emissions, washings	Separation or accumulation after discharge
Waste	Emergency emissions	
Health hazards	Human contact with chemicals	Effects of toxicity, biological activity
	Human contact with heat or cold	Effects of fire, contact with hot bodies, cold surfaces
	Noise	Effects of exceeding acceptable noise levels
	Illumination	Effect of glare, mist, fog, contrast, smoke
	Radiation	Effect of radioactive materials
External threats	Accidental impact, vibration	Harm, damage and removal of equipment
	Act of God, natural causes	Harm, damage and death of personnel
	Abnormal environmental extreme	Release of material
	External interference, loosening	Adverse discharge
	Drop, fail	Loss of supply
	Theft, hooliganism	Loss of services
	Force majeure, sabotage	Item breaks on impact
	External energetic events	
	External toxic events	
	External contamination	
	Corrosion, erosion	
Reactions	Unintended reactions	Release of material
	Difficulties with intended reactions	Dangerous disturbances
	Presence of dangerous (toxic) substances	Release of reaction energy
	Products of combustion	Defective materials
	Corrosion, etc.	
Thermodynamic hazards	Overpressure	Rupture of equipment
Overpressure	Underpressure	Impulse blows
Underpressure	Over-temperature	Weakening of materials of construction
Over-temperature	Under-temperature	Failure or damage of equipment
Under-temperature	Overheating	
	Overcooling	
	Fluid jet effects	
Abnormal opening to atmosphere	Inadequate mechanical integrity	Release of material
	Corrosion, erosion	Change in planned or emergency discharge
	Wrong status of equipment, valves, emergency relief, etc.	
Mechanical hazards	Overload/stress/tension	Rupture of equipment, change in material properties
Structural hazards	Mechanical energy/inertia	Failure of equipment or structure, transient effects, forces
Collapse, drop	Mechanical weakness	Impulse blows, fragility, vibration
	Loss of structural integrity	Failure of structure, collapse, object dropped
Electrical hazards	Charge, current, magnetism	Explosion, spark, shock, heat transfer, ionization
	High voltage	Shock to personnel

Table 8.33 *(continued)*

Keywords	*Undesired event*	*Consequences/problems*
Equipment problems	Dangerous disturbances or incident initiators	Release of material Off-specification material
Mode of operation Start-up Shut-down Maintenance Abnormal Emergency	Any notable disturbances or incident initiators Loss of supply Loss of services	Release of material Common cause failures Off-specification material

Table 8.34 *Process safety review system: critical examination – checklist of keywords (Wells, Wardman and Whetton, 1993) (Courtesy of Butterworth-Heinemann)*

Keyword	*Examples of use*
Eliminate	Eliminate by a completely different method or part of a method Eliminate certain chemicals, change the route, use a lean technology Eliminate additives, solvents, heat exchange mediums, additives Change the equipment or processing method Eliminate leakage points; use a weld not a bolted fitting, etc. Eliminate a prime mover or heat exchange or agitator Eliminate a separation stage or step Eliminate intermediate storage Eliminate an installed spare Eliminate manual handling Eliminate sneak paths, openings to atmosphere Eliminate waste Eliminate entry into vessels or disconnection Eliminate products that are harmful in use Eliminate an ignition source, particularly permanent flame
Avoid	Avoid extremes of operating conditions Avoid operating in a flammable atmosphere Avoid possible layering of materials, inadequate mixing Avoid flashing liquids, particularly in extensive heat exchanger networks Avoid production of large quantities of dangerous intermediates Avoid unwanted reactions within and outside reactors Avoid operating near extremes of materials of construction Avoid operating conditions leading to rapid deterioration of plant Avoid maintenance on demand and in short time periods Avoid items of plant readily toppled by explosions Avoid stage, step or activity by doing something as well as or instead of
Modify	Modify any topics above Modify batch operation to continuous operation, or vice versa
Prevent	Prevent emissions and exposure by totally enclosed processes and handling systems Prevent exposure by use of remote control
Increase	Increase heat transfer and separation efficiency or capacity Increase conversion in reactions
Reduce	Reduce inventory; less storage, hold-up, smaller size of equipment, less piping Reduce amount of energy in system Reduce pressure and temperature above ambient Reduce emissions and exposure by improved containment, piped vapour return, covers, condensation of return, use of reactive liquids, wetting dust Reduce frequency of opening, improve ventilation, change dilution or mixing Reduce size of possible openings to atmosphere
Segregate	Segregate by distance, barriers, duration and time of day Segregate plant items to avoid certain common-mode failures Segregate fragile items from roads, etc.
Isolate	Isolate plant by shut-down systems, emergency isolation valves
Improve	Improve plant integrity, reliability and availability Improve control or computer control; use user-friendly controls Improve response Improve quality of engineering, construction, manufacture and assembly

than one in a higher category. The categorization is for use solely as a practical design tool.

The priority categories are a function of the likelihood values and the severity categories. They are:

None	No action
A	Immediate attention needed
B	Further study probably required
C	Further study may be necessary

Table 8.35 *Process safety review system: results from a preliminary consequence analysis (Wells, Wardman and Whetton, 1993)*

What if undesired event?	*FR/PR*	*GA*	*Failure to mitigate*	*PR*	*L*	*S*	*P*	*Consequences*
Significant release of material: catastrophic failure of methanator circuit	10^{-3}	And	Countermeasures for a release fail: insufficient time for response	1	3	1		Release causes hazardous condition: cloud of flammable material
Ignition of flammable mixture: ignition and torch fire	0.5	And	Countermeasures fail to control fire: fire too great to be put out immediately	1	4	3	B	Escalation by torch fire
Escalation by fire: further spread of fire to pipe rack	0.2	And	Countermeasures fail to control fire: fire brigade fails to put out fire (no barrier)	0.5	5			Escalation by further release of material
Ignition of flammable mixture: ignition and pool fire	1.0	And	Countermeasures fail to control fire: fire brigade fails to put out fire	0.2	6	3	C	Escalation by pool fire, generating possible explosion with missiles
Escalation by explosion: missiles land on C plant	0.2	And	Countermeasures for a release fail	1	6	4	C	Escalation by further release of flammable material Aromatics washed into sewer

Note: GA, gate; FR, frequency; L, likelihood; P, priority; PR, probability; S, severity.

Table 8.36 *Process safety review system: short-cut risk assessment – adjustments to frequency estimates to allow for non-average conditions (Allum and Wells, 1993) (Courtesy of the Institution of Chemical Engineers)*

- Determine whether the plant conditions represent:
  - (a) Average duty or appropriate baseline failure rate data
  - (b) Excellent case conditions in which the internal duty is clean and maintenance performance is good on a well-established plant
  - (c) Worst-case conditions in which the duty is severe or maintenance performance poor or the plant is of novel technology or various combinations of similar effects
- Adjust the *likelihood* of failure in average duties as follows:
  - (a) In the worst case, multiply by 10
  - (b) In an average case, multiply by 1
  - (c) In an excellent case, multiply by 0.5
- Modify the *ineffectiveness* probabilities of control and mitigation:
  - (a) If a protective system is in the failed state, $P = 1$.
  - (b) In the worst case, *increase* values as follows: 0.01 → 0.1; 0.1 → 0.5; 0.5 → 0.9
  - (c) In an average case, do not adjust probabilities
  - (d) In an excellent case, *reduce* values as follows: 0.001 (no change); 0.01–0.005; 0.1–0.05; 0.5–0.1

The prioritization of risk is

Severity category	*Value of risk*			
	−2	−1	0	1
1	None	None	None	C
2	None	None	C	B
3	None	C/B	A/B	
4	C	B/C	B	A
5	B	B/C	A	A

The SCRA provides guidance on priorities to be addressed in the design. It also provides an indication as to whether more detailed QRA is appropriate.

8.19.9 Goal-oriented failure analysis (GOFA)

The GOFA technique is another based on the CIS checklists. An account is given by Reeves, Wells and Linken (1989). The method is described as a combination of fault tree analysis and checklists. The example given by the authors is loss of containment, the causes of which are traced through the checklist structure.

8.19.10 Socio-technical systems analysis

A socio-technical systems analysis is used to examine the preconditions for failure. An account is given by Wells, Phang and Wardman (1994). These authors describe the procedure and give the primary checklist. The main headings of this list are:

(1) system climate;
(2) communication and information systems;
(3) working environment;
(4) organization and management;
(5) management control;
(6) operator performance;
(7) external systems;
(8) procedures and practice;
(9) site and plant facilities;
(10) equipment integrity.

They also give the subsidiary checklist for external systems.

8.19.11 Illustrative example: methanator system

Some of the techniques which constitute the process safety review system just described have been illustrated by Wells and co-workers using the methanator system shown in Figure 8.16. Treatments which include examples involving the methanator system are given by Wells *et al.* (1992), Wells, Wardman and Whetton (1993) and Allum and Wells (1993).

***Table 8.37** Process safety review system: short-cut risk assessment – severity categories (Allum and Wells, 1993) (Courtesy of the Institution of Chemical Engineers)*

Catastrophic consequences: Severity 5
Catastrophic damage and severe clean-up costs
On-site: loss of normal occupancy $>$ 3 months
Off-site: loss of normal occupancy $>$ 1 month
Severe national pressure to shut-down
Three or more fatalities of plant personnel
Fatality of member of public or at least five injuries
Damage to Site of Special Scientific Interest or historic building
Severe permanent or long-term environmental damage in a significant area of land

Acceptable frequency 0.00001 per year

Severe consequences: Severity 4
Severe damage and major clean-up
Major effect on business with loss of occupancy up to 3 months
Possible damage to public property
Single fatality or injuries to more than five plant personnel
A 1-in-10 chance of a public fatality
Short-term environmental damage over a significant area of land
Severe media reaction

Acceptable frequency 0.0001 per year

Major consequences: Severity 3
Major damage and minor clean-up
Minor effect on business but no loss of building occupancy
Injuries to a maximum of five plant personnel with a 1-in-10 chance of fatality
Some hospitalization of public
Short-term environmental damage to water, land, flora or fauna
Considerable media reaction

Acceptable frequency 0.001 per year

Appreciable consequences: Severity 2
Appreciable damage to plant
No effect on business
Reportable near miss incident under CIMAH[a]
Injury to plant personnel
Minor annoyance to public

Acceptable frequency 0.01 per year

Minor consequences/near miss: Severity 1
Near-miss incident with significant quantity released
Minor damage to plant
No effect on business
Possible injury to plant personnel
No effect on public, possible smell

Acceptable frequency 0.1 per year

[a] Control of Industrial Major Accident Hazards Regulations 1984.

The methanator is a reactor, the feed to which contains H_2 97%, oxides of carbon 2% and methane 1%, and in which the oxides of carbon are converted to methane in a reaction which is exothermic. On occasion, the oxides of carbon in the feed can rise to 10–15%. In the examples quoted, the two dangerous disturbances explored for the reactor are overtemperature and overpressure.

The results of a concept hazard analysis for the system are shown in Table 8.38, those of a critical examination in Table 8.39 and those of a PHA in Table 8.40, as given by Wells, Wardman and Whetton (1993). The latter leads in to the risk evaluation sheet, given by Wells *et al.* (1992), shown in Table 8.41.

8.20 Choice of Method

A variety of methods of hazard identification applicable at the different stages of the project have been described. An overview of these methods is given in Table 8.2. In many cases, the aspect of hazard identification covered by a particular method is self-evident, but in others it is not. Some methods are alternatives or are complementary. Table 8.42 lists some of the principal methods as a guide to selection. The table gives the prime purpose(s) of each method. With regard to checklists, the applications shown in the table are limited, but some of the other methods such as HAZOP may also make use of a checklist specific to that method.

8.21 Filtering and Follow-up

Although it is convenient for purposes of exposition to treat hazard identification and assessment separately, the two are often interwoven. A process of filtering of the hazards takes place. Two forms of filtering, which occur with many of the identification methods described, may, be mentioned. The first involves discarding a hazard, which is considered to be unrealizable.

In the second form of filtering, a hazard is discarded if it is considered not to be sufficiently important. A measure of the need for action on an identified hazard which is widely used, albeit often not explicitly, is the product of the magnitude and frequency of the event. It is this criterion, which underlies the method of ranking described in Section 8.19.9. It is also used in task analysis as a stopping rule to decide how far to carry the process of subdivision of the task.

Filtering is an important feature of a HAZOP study. In such a study, a filtering process occurs whereby the hazards identified are assessed on the spot and only a proportion is passed on for further assessment.

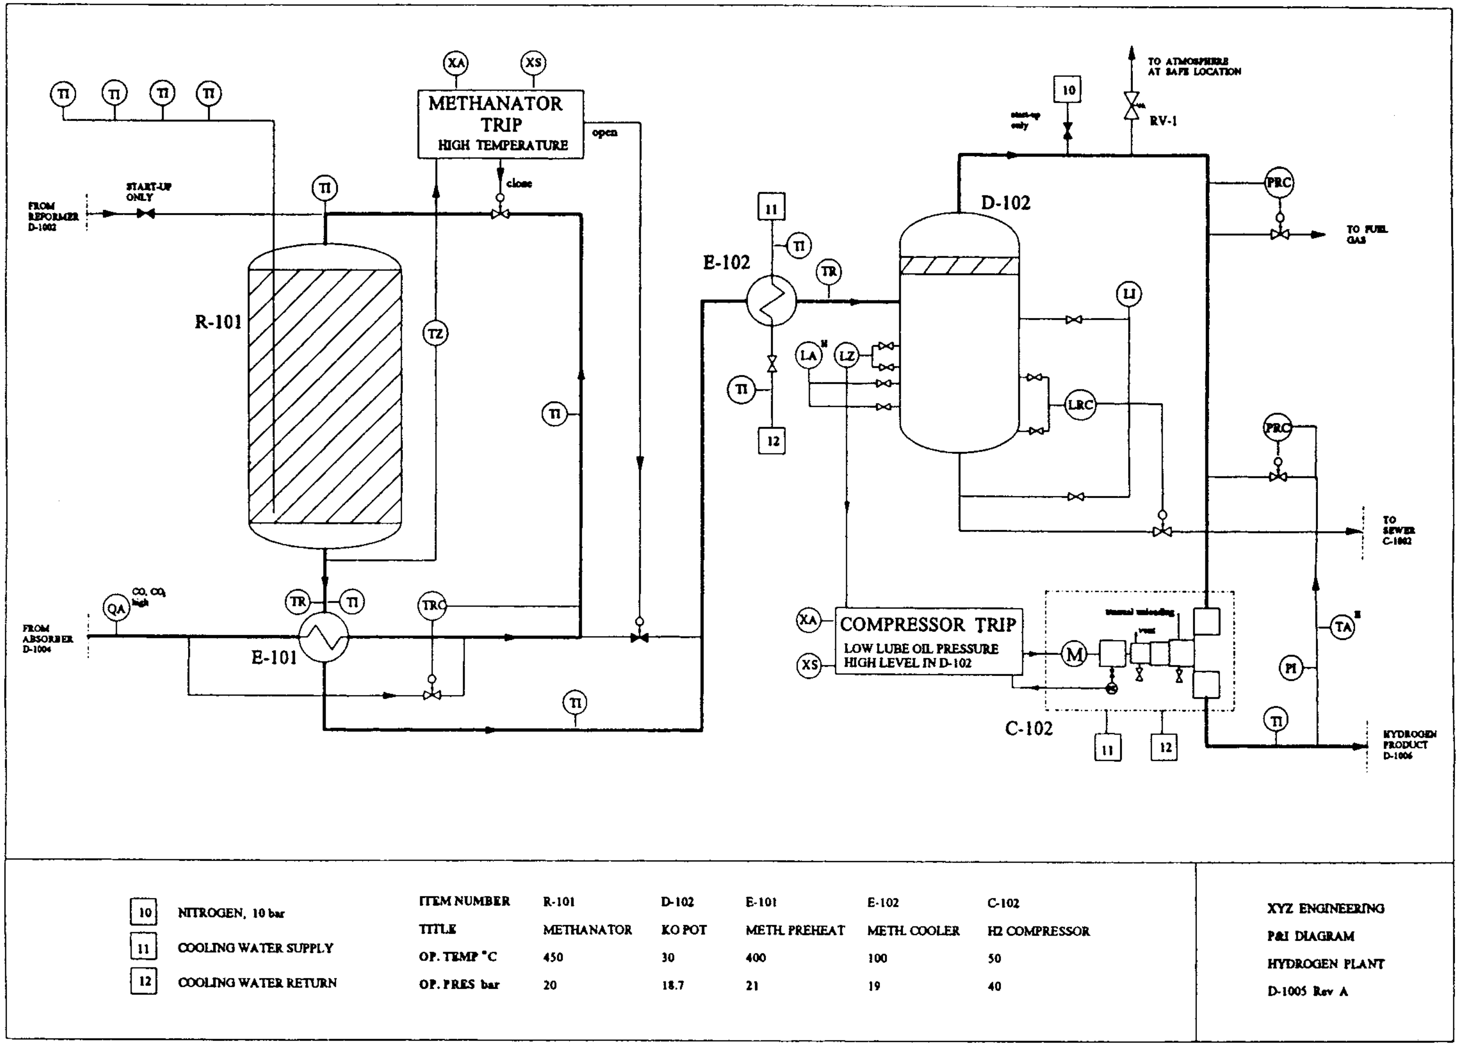
Once a hazard has been identified and accepted, as worth further consideration, it is necessary to decide what to do about it. Figure 8.17 indicates four principal outcomes of the identification process. In many cases, once the problem has been identified, the solution is obvious or is known from experience. In many others it is taken care of by codes of practice. In a small proportion of cases, it may be appropriate to carry out a hazard analysis.

8.22 Safety Review Systems

Formal systems for the conduct of safety reviews appropriate to the stages of the project are now widespread in the process industries. These systems go by different names.

8.22.1 Hazard study systems

The system used in Mond Division of ICI has been described by several authors (N.C. Harris, 1975; S.B. Gibson, 1976a; Hawksley, 1984) and is shown in Figure 8.18 and Table 8.43. The system involves six hazard studies.



ITEM NUMBER	R-101	D-102	E-101	E-102	C-102
TITLE	METHANATOR	KO POT	METH. PREHEAT	METH. COOLER	H2 COMPRESSOR
OP. TEMP °C	450	30	400	100	50
OP. PRES bar	20	18.7	21	19	40

Figure 8.16 *Process safety review system: illustrative example – simplified piping and instrument diagram of a methanator system (Wells et al., 1992) (Courtesy of the Institution of Chemical Engineers)*

Table 8.38 *Process safety review system: methanator system – results of a concept hazard analysis (extract) (Wells, Wardman and Whetton, 1993)*

Ref. No	*Keyword*	*Dangerous disturbance*	*Consequences*	*Suggested safeguards*	*Comments/action*
1	Flammables	Release on rupture	Release may self-ignite torch fire. Escalation to pipe rack likely. Missile could affect C plant	Segregation by distance. Depressure or steam purge	Study best way of reducing damage
2	Flammables	Release on emergency discharge	Release at safe height: possible ignition and fire	Segregation by distance	Check possible radiation levels
3	Flammables	Normal discharge to sewer	Chemical explosion in sewer	Vent sewer with standpipes	Check other plants for incidents
4	Reaction	Exothermic runaway reaction in methanator	High level of oxides of carbon cause runaway with rupture and possible physical explosion	More robust design of absorber. Trip methanator on high temperature. Alarms on temperature and CO_2 high	Check action if trip fails
5	Reaction	Air in combustion vessels	Combustion in vessels. Causes chemical explosion	Purge plant before start-up. Ensure catalyst covered by N_2 as replaced	Get more information on catalyst
6	Reaction	Inadequate reaction Catalyst failure Low temperature feed Methanator bypassed	Off-specification H_2 to downstream plant. This can cause runaway reaction with chemical explosion	Alarm on high CO_2 outlet. Vent if off-specification and shut-down compressor. Ensure methanator warm enough to start-up. Connect methanator trip to compressor trip	Design heat exchanger circuit to preheat methanator
7	Pollutants	Effluent to sewer	Water with high sodium salts	Sewer to effluent treatment	Check effect on current treatment
8	Pollutants	Effluent caused by firewater	Fire-water will flood. River receives minor contamination		Check other sewers in area for contamination
9	Pollutants	Noise	Noise in compressor area	Building would cause explosion hazard	Operators to wear protection in danger area
10	Overpressure	Overpressure in hydrogen plant	High pressure caused by inadequate release of excess gas to fuel gas or blockage or incorrect valve status causes explosion	Two relief valves in circuit. High pressure alarm	Flare may be needed on fuel gas if demand low
11	Overtemperature	Overtemperature in methanator	Runaway reaction (see above)		
12	Overtemperature	Overtemperature in compressor	Excess recycle of hydrogen around compressor can result in physical explosion	High temperature alarm on loop	Evaluate as no safeguard provided
13	Mechanical hazard: overload	Overload of compressor	Stress in compressor caused by two phase feed due to liquid blowby from KO Pot can result in physical explosion	Trip on high level in KO Pot. Level alarm in KO Pot	Explosion unlikely but note compressor may be damaged
14	Abnormal opening	Vibration at compressor	Loosening of flange gives release. Possible torch fire	Vibration probe	
15	Abnormal opening	Spurious relief	Loss of material to safe point. Could ignite as minor torch fire		Consider need for lock open valve after RVs or bursting disc before RVs

Table 8.39 *Process safety review system: methanator system – results of a critical examination (Wells, Wardman and Whetton, 1993)*

DESIGN INTENT: A fixed-bed catalytic reactor, operating at 20 bar, 400°C inlet, 450°C outlet, converts the small amounts of oxides of carbon (maximum 2%) in a stream of hydrogen into a hydrogen product stream containing 10 ppm maximum of oxides of carbon

Query proposal	*Response*	*Generate alternatives*	*Comments*	*Recommendations*
Why remove oxides of carbon?	Oxides of carbon affect downstream catalyst on aromatics plant	Eliminate methanator here and install on aromatics plant only	No real saving on risk overall	Reject or change downstream catalyst
Why this process?	No addition of further materials	Alter by using pressure-swing adsorption system upstream	Lower yield of hydrogen but cheaper plant	Review for plant after next
Why at 400°C?	Optimized design for this catalyst	Alter the catalyst or use a larger size of bed	No safety advantage	Reject
Dangerous condition	*Cause*	*Modification/control*	*Comments*	*Recommendations*
Reactor runaway due to excess oxides of carbon in feed leading to reactor	Failure of absorption system	Increase capacity of absorption unit using an absorption train	Expensive but robust solution	Evaluate using quantitative risk analysis
		Isolate the methanator by shut-down system	Requires the diversion of upstream flow from methanator by shut-down system	Install bypass and vent off-specification material
Catastrophic failure of methanator circuit	Overtemperature due to reactor runaway	Improve metallurgy of reactor to withstand maximum temperature during upset condition	Long-term effort required	Review later
		Increasing cooling of reactor by external quench	Weakness in circuit may well not be the reactor	Consider under preliminary hazard analysis

Hazard Study I is the first formal study, carried out at the project exploration stage. Its purpose is to ensure that there is full understanding of the materials involved in the process and their potential interactions, and also the constraints on the project due to the particular site, not only in terms of safety but also in terms of environmental factors, including pollution and noise. This type of study was referred to above as a 'coarse hazard study'.

Hazard Study II is performed using the PFDs. Each section such as reaction, distillation, etc., is studied in turn and potential hazardous events such as fire, explosion, etc., are identified. At this stage it is often possible to eliminate such a hazard by means of design changes or to protect against it by the use of protective systems. In some instances, it may be necessary to study an event further. In this case, use may be made of fault tree analysis, with the hazardous event as the top event in the tree.

Hazard Study III is the HAZOP study, which has already been described.

Hazard Study IV involves a review of the actions generated in Hazard Studies I–III by the plant or commissioning manager, who also ensures that operating procedures, safe systems of work and emergency procedures are available.

Hazard Study V is the plant inspection carried out to ensure that the plant complies with the legal requirements on such matters as access and escape, guarding, emergency equipment, etc.

Hazard Study VI is undertaken during the commissioning and early operation of the plant and involves a review of changes made to the plant and its operating procedures, and of any differences between design intent and actual operation.

Once in operation, the plant is subject to further audits, but these fall outside the system as described.

8.22.2 Project safety review system

A broadly similar system is the project safety review system operated by BP. The reviews conducted in this system are:

(1) pre-project review;
(2) design proposal review;
(3) detailed design review;
(4) construction review;
(5) pre-commissioning review;
(6) post-commissioning review.

The two sets of safety review systems described above typify those in use.

Table 8.40 *Process safety review system: methanator system – preliminary hazard analysis (Wells, Wardman and Whetton, 1993)*

PROJECT: TOMHID	REFERENCE: GLW	*Priority*			
PLANT: HYDROGEN	LOCATION: SHEFFIELD				
UNIT: METHANATOR SECTION	EQUIPMENT: METHANATOR/PREHEAT	*C*			
FUNCTION: Fixed bed reactor converting oxides of carbon to hydrogen		*S*	*L*	*S*	*L*
Consequences of escalation	Fire escalates to pipe rack and C plant	4	E−6[a]	4	7
Failure to prevent further escalation	Failure to avoid domino due to lack of time and ineffective firefighting		0.01		0.01
Consequences of significant event	Torch fire on section of plant	3	E−4	3	E−5
Failure to mitigate or avoid escalation	Failure to avoid ignition: self-ignites as hot and release not attenuated in 15 min	3			1

Significant event to be prevented	Release through overtemperature	E−4	Release through overpressure	E−5
Failure to recover the situation	Operator fails to stop all plant flows	*	Operator action to depressure fails	0.1
		0.1		
Plant in danger: dangerous disturbance	Overtemperature in reactor	E-3	Overpressure in reactor	E−4
Inadequate emergency control or action	Failure of operator to stop flow to methanator	0.1	Pressure relief system fails	0.01
	Failure of shut-down system	0.2		
Hazardous disturbance	High temperature in reactor	0.1	High pressure in section	E−2
Inadequate control or action	Operator fails to reduce trend on TAH	1		0.01
Immediate causes	High inlet temperature (slow propagation)	E−1	Downstream blockage (clean duty)	E−4
Hazardous disturbance				
Inadequate control or action	Operator fails to reduce trend on CO_2 alarm or TAH	0.8	PRC closed	
			Fuel gas overpressure	0.01
Immediate causes	High CO_2 in stream from absorber	E−1	Lack of demand for product	E−0
Hazardous disturbance				
Inadequate control or action	Operator fails to reduce trend on CO_2 alarm or TAH or PAH	0.1	PRC closed	0.01
			Fuel gas overpressure	0.01
Immediate causes	Impurities in feed: sneak path down start-up line	E−2	Off-specification product	E−0

Recommendations/comments/actions: 1. Public not affected by domino escalation. 2. Business damage would be extensive if spread to complex. *The operator can increase the probability of a release by wrong action and special supervision is required on any methanator problem.	1. Do not depressurize on high temperature unless sure of no flow through methanator. 2. Operator alert by several alarms. New TAH in and out. 3. Check if start-up line needed if heat exchange circuit modified. 4. Alter outlet location of start-up line. Add PAH and TR. Double block and bleed. 5. Check catalyst activation. 6. Improve absorber design to enhance reliability.	1. Operator also alerted by PAH. 2. Two relief valves in system and hydrogen is exceptionally free-flowing. 3. Add RV-1 and depressuring valve: locate before methanator.

8.23 Hazard Ranking Methods

There are available a number of hazard ranking methods for assigning priorities among hazards. Accounts include those of Gillett (1985), Ashmore and Sharma (1988), Rooney, Turner and Arendt (1988), Casada, Kirkman and Paula (1990), Eraser, Bussey and Johnston (1990) and Keey (1991).

8.23.1 Rapid ranking

Typical of these methods is that of rapid ranking described by Gillett (1985). The basis of the method is a trade-off between the consequence and the frequency of the event considered. The more serious the consequence, the lower the frequency, which is tolerable for the event. In principle, therefore, the criterion for action may be taken, as a first approximation, as some threshold level of the product of consequence and frequency.

The rapid ranking method actually utilizes a mixture of quantitative and qualitative measures. The cost of damage to the plant and the frequency of occurrence are expressed quantitatively and the other consequences qualitatively.

In the method, five hazard categories are defined. Table 8.44 defines the hazard categories in terms of the consequences. In determining the features of a particular hazard for comparison with the entries in the table, it is intended that the damage costs be estimated and that the other entries be obtained from expert judgement. The table also gives both relative guide frequencies and typical absolute frequencies for each hazard category.

For a particular hazard, a hazard category is obtained on the basis of the consequences. If different consequences yield different hazard categories, judgement must be exercised. The estimated frequencies derived from historical data are then compared with the absolute guide frequencies given in Table 8.44 and a hazard ranking obtained using Table 8.45.

Examples of the technique are given by Mumford and Lihou (1984 LPB 59). As an illustrative example, consider the hazard of fire in a pipe trench. In a particular application, it is estimated that a pipe trench fire will cause on average £10,000, damage and the following estimates are made of the frequency of the two hazards – (1) a fire without operator fatality and (2) a fire with a chance of an operator fatality:

Frequency of pipe trench fires without operator fatality $= 0.5$/year

Frequency of pipe trench fires with 1 in 10 chance of operator fatality $= 1.5 \times 10^{-2}$/year

Hazard 1, with an estimated damage cost of £10,000, is given by Table 8.44 as hazard category 2 and therefore has guide frequency of 10^{-1}/year. The expected frequency is 5×10^{-1}/year and thus exceeds the guide value by a factor of 5.

***Table 8.43** Rapid ranking of hazards: hazard categories (Gillet, 1985) (Courtesy of Process Engineering)*

Area at risk	*Description of risk*	*Hazard category*				
		1	*2*	*3*	*4*	*5*
Plant	Damage	Minor <£2000	Appreciable <£20,000	Major <£200,000	Severe <£2m	Total destruction > £2m
	Effect on personnel	Minor injuries only	Injuries	1 in 10 chance of a fatality	Fatality	Multiple fatalities
Works	Damage	None	None	Minor	Appreciable	Severe
Business	Business loss	None	None	Minor	Severe	Total loss of business
Public	Damage	None	Very minor	Minor	Appreciable	Severe
	Effects on people	None (smells)	Minor	Some hospitalization	1 in 10 change of public fatality	Fatality
	Reaction	None/ mild	Minor local outcry	Considerable local and national press reaction	Severe local and considerable national press reaction	Severe national (pressure to stop business)
Relative guide frequency of occurrence	–	1	10^{-1}	10^{-2}	10^{-3}	10^{-4}
Typical[a] judgmental values for a plant/small works (years)	–	1	1/10	1/100	1/1000	$1/10^4$

[a] These typical comparative figures are given for illustration and should not be taken as applicable to all situations or taken to indicate absolute levels of acceptability.

From Table 8.45, the hazard ranking is A. Hazard 2, with the same damage cost but a 1 in 10 chance of fatality, is hazard category 3 and therefore has a guide frequency of 10^{-2} /year. The estimated frequency is 1.5×10^{-1} /year and thus exceeds the guide value by a factor of 1.5. The hazard ranking is again A, but only just. Action is indicated in both cases.

8.24 Hazard Warning Analysis

In some cases, analyses are carried out to identify the lesser events, which may serve as precursors to, or warnings of, more serious events. Such analyses clearly rank as hazard identification techniques. One such method is the technique of hazard warning analysis described by Lees (1982b). Like fault tree analysis, on which it is based, this technique may be used to obtain quantitative results. It is therefore described in the next chapter.

8.25 Plant Safety Audits

The conduct of some form of plant safety review is a normal part of plant commissioning. Traditionally this is a joint inspection by the plant manager and the plant safety officer and is concerned mainly with checking that the company complies with the legal and company safety requirements. Attention is directed to features such as: access and means of escape; walkways, stairs and floors; and firefighting and protective equipment.

There has developed from this, however, the more comprehensive plant safety audit. There is no uniform system for such audits. The BCISC publications *Safe and Sound* (1969/9) and *Safety Audits* (1973/12) give information on several systems. D. Williams (1971) gives a detailed des-cription of one system, including a comparison of one of the audits from *Safe and Sound* with a later audit by the same company, which illustrates the evolution of the method.

The general approach is on the following lines. The plant safety audit is conducted by a small, interdisciplinary team which is not connected with the plant. The members may come from the same works or from other works. The team may be led by a quite senior manager. The audit is carried out first during the plant commissioning, but is also repeated later at intervals. Typical intervals are a year after initial start-up and every 5 years thereafter.

The topics covered by the audit are illustrated by the checklists given in Tables 8.46 and 8.47. The former gives topics listed in *Safety Audits*. The latter is a checklist for both audits and surveys given by Williams. As already emphasized, it is essential that management act on any audit made.

8.26 Other Methods

8.26.1 Feedback from workforce

It is the responsibility of the management to create systems and attitudes which lead to the effective identification of

Table 8.44 *Rapid ranking of hazards: hazard ranking (Gillett, 1985) (Courtesy of Process Engineering)*

Hazard category (from Table 8.43)	*Expected frequency compared with guide frequency*			
	Smaller (−)	*Same (=)*	*Greater (+)*	*Uncertain (U)*
1	D	D	D/C at team's discretion	D/C at team's discretion
2	D	Normally C, but if upper end of frequency/ potential raised to B at team's discretion	Equally damaging hazard as those below, A, but if lower end of frequency/potential could be lowered to B at team's discretion	B Frequency estimate should not be difficult at this category; may be a lack of fundamental knowledge which requires research
3	C	B	A Major hazard	A/B at team's discretion. Such potential should be better understood
4 & 5	B/C at team's discretion	B, but can be raised to A at team's discretion	A Major hazard	A Such potential should be better understood

Table 8.45 *Checklist for a plant safety audit (after British Chemical Industry Safety Council, 1973/12)*

(1) Statutory requirements in the area under consideration
(2) Methods of process operation. Hazards of the materials involved and of the technology in use
(3) Material handling
(4) Tools, machinery, maintenance equipment
(5) Permit-to-work system, schedules for regular inspection of emergency equipment
(6) Personal protective equipment, its condition, care and suitability
(7) Plant tidiness, condition of floors, stairs, walkways, cleanliness of toilets and washing facilities, environmental factors, waste disposal
(8) Fire prevention and protection, alarm systems, emergency exits, flammable material storage
(9) Unsafe practices
(10) Arrangements for treating injuries, condition of safety showers, eye- and hand-wash cabinets, resuscitation equipment
(11) Involvement of employees in safety activities, their knowledge of the safety organization, attitudes, condition of displays and notices

Also
Electrostatic hazards
Alarms and trip systems and testing
Pressure vessels and relief valve inspections
Cable protection
Radiation hazards
Operation and maintenance of internal and external transport
Occupational health and hygiene standards
Electrical equipment maintenance
Major emergency arrangements
New projects and processes
Adherence to codes of practice (of internal or external origin)
Equipment faults
Labelling of products
Adherence to approved work and operational procedures
Training procedures/programmes and their effectiveness
Adequacy of safety procedures in office, administrative and ancillary buildings
Methods of communication and their success
Receipt, storage and transportation of chemicals and other materials
Extensions/alterations to existing production and storage facilities
Pollution/environmental control methods
Liaison with outside contractors
Safety standards in research, development and laboratory work
Consideration of safety and loss prevention at the design stage
Security arrangements covering the storage and issue of harmful substances
Safety advisory service to customers, covering products, their handling and use

Table 8.46 *Checklist for a plant safety audit or survey (D. Williams, 1971) (Courtesy of the Institution of Chemical Engineers)*

Buildings and surroundings:

(1) Are emergency exits adequate and accessible?
(2) Is lighting adequate for operations, walking, material handling?
(3) Is firefighting equipment adequate and accessible?
(4) Are aisles large enough? Marked? Clear?
(5) Is floor free of tripping or slipping hazards?
(6) Are floor loads within safe working loads? Are safe loading limits posted where necessary?
(7) Is general ventilation sufficient?
(8) Are stairs and platforms free of tripping hazards? Equipped with necessary guard rails?
(9) Are there any openings in fire walls? Are fire doors operable?
(10) Are hazardous areas provided with adequate explosion venting?
(11) Does building electrical service appear adequate? Does visual inspection reveal any maintenance problems?
(12) Is building trim (window sash, doors, rain gutters, fire escapes, etc.) in safe condition?
(13) Are lifts regularly inspected and adequately maintained between inspections? Are safe lifts loads posted? Adhered to?
(14) Are building approaches (outside steps, platforms, paths, etc.) in a safe condition?
(15) Are safety signs adequate and in good condition?

Equipment:

(1) Are danger points adequately guarded? Rotating parts? Pinch or nip points? Belts? Cutting edges? Hot surfaces? Open flames?
(2) Are operating controls positioned for safe use?
(3) Is there room for the operator to work safely?
(4) Are valves, switches, instruments, and other operating controls clearly identified? Are pilot lights working?
(5) Are safety alarms properly identified and tested regularly?
(6) Do automatic controls fail safe? (Can a hazardous condition be created by the failure of automatic controls?)
(7) Do wiring and piping appear to be in good condition and adequate for intended use?
(8) Is equipment rated and inspected for the service in which it is used? (Area engineers to provide list of pressure equipment rating.)
(9) If process presents corrosion problems, is equipment inspected regularly to anticipate and prevent failure in service?
(10) Are pressure relief devices adequately sized and accessible for inspection?
(11) Are overflow lines and breather vents adequate and clear? Equipped with flame arresters, liquid seals where needed? Do overflows and vents discharge at a safe location?
(12) Does equipment conform to grounding policy? Are grounds tested regularly? (Area supervisor to specify frequency of test.)
(13) Are drop lights and extension cords in good condition? Meet electrical standards?
(14) Are hand tools, portable tools and ladders inspected regularly? Are they proper for the intended use? In good condition?
(15) Can equipment be made safe for routine maintenance work? Electric lockouts? Lines blanked? Sufficient safe working area for mechanics? Adequate room and facilities for rescue?

Process:

(1) Is process safe under normal conditions?
  (a) Are toxic vapours normally present? Are safeguards adequate?
  (b) Are flammable vapours normally present? Are vapours confined? Are sources of ignition controlled?
  (c) Are operators or other employees normally exposed to toxic, corrosive or hot liquids? Is protective equipment properly stored, maintained and used? Are special physical examinations of employees conducted as recommended by the medical department?
  (d) Are sampling procedures safe?
  (e) Are safe storage conditions provided for hazardous raw materials and intermediates?
(2) Are abnormal conditions provided for?
  (a) Loss of utilities: Electricity – agitation, circulation, controls and instruments, light. Steam – heating, vacuum, pumps, steam snuffers. Air – instruments, pumps. Water – cooling, quenching. Gas – inert and illuminating.
  (b) Mechanical failures.
  (c) Operator errors – what can happen?
  (d) Are emergency venting facilities adequate? Inspected?
  (e) What sources of ignition may develop in this process? Are they guarded against?
  (f) Can a fire be controlled in this process?
  (g) Are operators or other employees unnecessarily exposed to serious injury in event of probable fire, explosion, large spills or mechanical failures?

Table 8.46 *(continued)*

(h) Are operators protected from probable leaks of steam, toxic or corrosive chemicals?
(i) Is quantity of exposed flammable or toxic liquids in populated areas kept to an absolute minimum consistent with production requirements?
(j) Is process subject to abnormal reactions?

ARE THERE ANY HAZARDS, WHICH WE HAVE NOT GUARDED AGAINST AND FROM WHICH OUR ONLY PROTECTION IS THE LAW OF CHANCE?

Operating instructions:
(1) Are operating instructions available in a written, legible, easily identified form?
(2) Are they up to date?
(3) Is there a procedure for keeping them up to date?
(4) Are they reviewed regularly with each employee?
(5) Are they accessible to operators for reference?
(6) Do the operating instructions spell out hazards of job and how to avoid them?
(7) Do operating instructions provide definite procedures for emergency situations where required?
(8) Is operator's performance checked regularly by supervision?
(9) Is there an effective system for notifying operators of non-standard conditions?
(10) Are operators permitted to take unauthorized short cuts in operations without reprimand?
(11) Are operators working in isolated locations checked regularly by supervision or the guard force?
(12) Do department supervisors know immediate first aid treatment required for exposure to toxic chemicals used in their departments?

Table 8.47 *System of hazard studies (after N.C. Harris, 1975; S.B. Gibson, 1976a; Hawksley, 1984)*

Study	*Project phase*	
I	Exploratory	Carried out at inception of project. Review of hazards of materials and process, of effluent and environmental problems and of site
II	Definition, preliminary design	Completed before sanction is sought. Examination of process flowsheets and assessment of ability of design to meet specifications
III	Detailed design	Takes place about time plant is sanctioned. Critical examination of hazards and operability of plant using Piping and instrument diagram, operating instructions, maintenance procedures, etc.
IV	Construction	Takes place during later stages of construction and early stages of commissioning. Review to ensure provisions of previous studies have been implemented
V	Commissioning	Carried out before initial start-up. Inspection to ensure safety systems are installed and operate as intended
VI	Operation	Carried out within a year of handover to operating team. Review of plant modifications, operating instructions, documentation

hazards, but it is the responsibility of everyone involved in the design and operation of the process to play his role in identifying and reporting any hazard of which he becomes aware.

This aspect has already been considered in the context of total loss control in Chapter 1 and of the safety system in Chapter 6, and is discussed again in Chapters 11 and 28.

8.26.2 Process design checks

There is an enormous amount of experience on the hazards associated with unit processes, unit operations, plant equipment, pressure systems, instrumentation, etc., and it is essential that this be utilized. It is not enough, therefore, to rely only on generalized methods of hazard identification. Full use needs to be made of what is already known. This may be done by methods such as the use of checklists for such processes, operations, etc. This aspect is discussed in more detail in Chapter 11.

8.26.3 Plant equipment checks

There are numerous types of check which are carried out on the plant equipment at various stages in the project. There are checks done before and during plant commissioning, including testing in manufacturers' works, checking the correct installation of the equipment, testing *in situ*, etc. There is a whole range of inspection and examination techniques, including non-destructive testing and condition monitoring, which are applied both during commissioning and in operation. Many items are checked or tested on a scheduled basis. While the results of some tests are unambiguous, others require careful interpretation and the application of sophisticated inspection standards.

8.26.4 Emergency planning

If a works contains hazardous plant, it is essential to plan for possible emergency situations. The first step in emergency planning is identification of those hazards, which are sufficiently serious to warrant such planning. Such a study is not necessarily an exercise separate from the other hazard identification procedures, but it does emphasize particular aspects, especially the development and scale of the emergency, the effects inside and outside the works boundary, the parties involved in dealing with the situation, etc. Emergency planning is treated in Chapter 24.

8.27 Quality Assurance

The quality of the hazard identification system should be assured by a suitable system of quality assurance. Normally this will be part of an accredited system covering the quality assurance of all aspects of company operation. Principles of quality assurance are discussed in Chapters 1 and 6 are therefore not repeated here, but it is appropriate to consider some aspects which apply to hazard identification.

There should be a formal system for hazard identification. For each stage of a project, a set of hazard identification techniques should be selected. The system should then ensure that these techniques are used.

Quality assurance may be based on inputs and process and/or outputs. It is generally prudent to utilize both. Inputs and process for hazard identification include: the qualifications, training, experience and plant knowledge of the team performing the task; the methods of hazard identification used and their suitability; the project documentation available, its comprehensiveness and accuracy; and the time available for the task.

Outputs include the whole range of information generated by the team. They are therefore not confined just to items such as release scenarios or deviations with associated causes and consequences, but extend also to the statements of scope, the report on the analysis and the follow-up measures.

Quality assurance of hazard identification requires documentation both of the hazard identification system and of the hazard identification activities conducted in a particular project. It should leave an audit trail which can be followed later if necessary.

8.28 Quality Assurance: Completeness

The quality of hazard identification virtually parallels the completeness of identification. It is of interest, therefore, to consider attempts made to assess the completeness of hazard identification. Some identified hazards are discarded as unrealizable. In discarding such hazards, discrimination is exercised. It is desirable to have some measure of this also.

A study of completeness and discrimination in hazard identification has been made by J.R. Taylor (1979; 1981 LPB 46). It is possible to specify a list of hazards which is complete. According to Taylor, process plant hazards are covered by the following list: fires, explosions, toxic releases, asphyxiations, drownings, and mechanical impact and cutting accidents. However, the price paid for completeness is a list so general that it is of little practical use. As soon as the list is developed into more specific categories, the degree of completeness is liable to decrease.

8.28.1 Criteria of completeness

The following criteria of completeness are defined:

Criterion	*Definition*
1	N_{id}/N_{tot}
2	$(N_{id})_m/N_{chl}$
3	$(\sum f_i c_i)_{id}/(S f_i c_i)_{chl}$
4	N_{rl}/N_{id}

where c is a measure of consequence, f is the frequency of occurrence, and N is the number of hazards and where subscripts refer to the following:

id	identified
chl	identified in a case history list
m	identified by method m
rl	realizable
tot	total existing

Criterion 1 is the simple measure of completeness. Criterion 2 is a more practical criterion, which measures completeness obtained by a particular method in relation to hazards, which are ascertainable as having occurred historically. This requires the use of a large list of case histories.

Some hazards are expressly excluded from consideration in order to reduce the work involved. This is the case where a cut-off is applied to exclude combinations of hazards of order higher than 1 or 2. Criterion 3 is intended for use in such situations.

Some hazard identification methods possess internal completeness. They treat a specific class of hazard, which is logically complete. This is the case with a FMEA, where the set of failure modes is complete. Sources of incompleteness in such a method are errors in using the method or hazards, which lie outside the scope of the method.

Criterion 4 is a measure of discrimination. A hazard which has been identified may actually not be realizable, as may be demonstrated by further analysis.

There is a degree of conflict in the attempt to achieve both completeness and discrimination, particularly in industrial work where the time available for analysis is limited.

8.28.2 Studies of completeness

Taylor has extended this work to encompass a comparative study of the completeness of hazard identification on particular plants. The investigation covered four full-scale risk analysis projects plus a research study on a batch distillation plant.

In the batch plant study, various hazard identification techniques were applied successively. Starting with the HAZOP method, using a supporting checklist, the number of hazards identified was 30. A further two were identified by making some use of fault trees to explore causes and of consequence diagrams to explore consequences. Application of AEA then identified a further 82 hazards. Inspection of the actual plant using checklists identified a further 10 hazards. This gives a total of 124 hazards identified. A further three hazards were identified from disturbances during commissioning, making a total of 127.

The completeness of hazard identification was checked against a generic fault tree based on case histories. A further two hazards were identified using the tree. On this basis, therefore, the completeness of hazard identification obtained using the HAZOP, AEA and inspection was 97%.

Taylor also describes evaluation of completeness using manually and automatically constructed fault trees. For the former, he quotes a completeness of 80% as typical for analysis of a piping diagram, but states that the degree of completeness is much less for sequential operations and operating problems. For the latter, work was still in progress, but he quotes a completeness at the time of writing of some 94%.

The HAZOP method used in the study was based on vessels rather than lines and appears not to have been a version adapted for sequential operations, so that, as the author states, the results do not do justice to the HAZOP method.

8.29 Quality Assurance: QUASA

A formal method for quality assessment assurance of safety analyses (QUASA) has been developed by Rouhiainen (1990). The method covers both qualitative and quantitative aspects, but with emphasis on hazard identification, and it is therefore appropriate to consider it at this point.

8.29.1 Safety analysis

The content of safety analysis is considered in terms of four main elements: (1) hazard identification, (2) QRA (3) remedial measures and (4) resources.

The quality assessment examines fitness for purpose. The purposes of safety analysis considered include: assessment of risks in relation to plant siting; identification, elimination or reduction, and control of hazards in design of a new plant; and the same for an existing plant.

Safety analysis has potential deficiencies which it is the function of quality assessment to uncover. Some of these deficiencies are listed by Rouhiainen, as shown in Table 8.48.

Table 8.48 *Some potential deficiencies in a safety analysis (Rouhiainen, 1990)*

Phase of analysis	*Examples of possible deficiencies*
System definition	Correlation between the plant and its descriptions not checked Important parts of the production system not included in the analysis Important production situations not taken into account
Hazard identification	Important hazard types omitted Methods used do not cover all hazards
Accident modelling	Important accident chains not modelled Important contributing factors omitted
Estimation of accident frequencies	The data used inaccurate Incorrect subjective judgements used Accuracy of the results not evaluated
Estimation of accident consequences	Simplifications made incorrect Model used not suitable to the situation studied
Risk estimation	More reliable toxicity data might be available Emergency provisions overestimated or underestimated
Documentation	Description of the object inadequate Initial assumptions not presented
Measures after the analyses	Measures presented not implemented No plan for updating the analysis

8.29.2 QUASA

QUASA is based on quality theory. In accordance with this theory, methods for the assessment of the quality of a safety analysis may be based essentially on inputs and process and/or on outputs. The features assessed in QUASA are given in Table 8.49. As stated earlier, they include not just the immediate results of the hazard identification and risk assessment, but other features such as the statements of scope, the report on the analysis and the follow-up measures. The emphasis in the method is thus on outputs, broadly defined.

A core feature of the method is the assessment of the quality of the hazard identification and the QRA. Here consideration is confined to hazard identification, the treatment of the QRA in the method being deferred to the next chapter. The quality assessment in QUASA may be made by a single assessor or by a group of assessors.

8.29.3 Assessment models

Rouhiainen gives the following model of the accident process:

Hazard → Exposure → Consequences

with contributory factors influencing each stage. Two types of contributory factors are distinguished: determining factors and deviations. Essentially, determining factors are those governing the design of the system, and deviations are excursions in its operation.

For the assessment of a safety analysis, use is made of the further model shown in Figure 8.19, which gives an overview of limitations and deficiencies of the safety analysis process, cast in the form of a cause–consequence diagram.

8.29.4 Assessment checklist

The QUASA method is based on the checklist shown in Table 8.49. The checklist covers the various stages of the safety analysis, its preparation and initiation, conduct, reporting and follow-up. It draws on the method given in ISO 9002: 1987 for the assessment of the quality assurance system of a subcontractor.

8.29.5 Assessment measures

Assessment of quality involves a comparison of actual performance against some performance standard. Performance standards for some parts of the safety analysis are difficult to define. This is true particularly for hazard identification, since the complete list of hazards is not

Table 8.49 *Checklist for quality assessment of a safety analysis (Rouhiainen, 1990)*

(1) Preparation of the analysis
  (a) Selection of the object
  (b) Restriction and definition of the object
  (c) Definition of the goals
  (d) Organization of the safety analysis
(2) Initiating the safety analysis
(3) Selection of methods and performance of the analysis
  (a) Identification of hazards
    (i) General aspects
    (ii) Equipment
    (iii) Processes and materials
    (iv) Organization of the object
    (v) Human activities
  (b) Modelling of accidents
  (c) Estimation of accident frequencies
  (d) Estimation of consequences
    (i) Calculation of consequences
    (ii) Emergency preparedness
  (e) Estimation of risk
  (f) Planning of remedial measures
(4) Report of the safety analysis
  (a) Description of the object
  (b) Description of the analysis
  (c) Results of the analysis
  (d) Description of the proposed measures
(5) Measures after the analysis
  (a) Measures to be taken in the object under analysis
  (b) Information about analysis results
  (c) Plans for reviewing and updating the analysis
  (d) Follow-up

known. The approach taken in QUASA is to use a number of complementary methods of generating data alternative to that yielded by the original safety analysis with which the latter can then be compared. Some methods of generating such information for assessment of the hazard identification outputs include:

(1) parallel analysis
  (a) complete,
  (b) partial;
(2) comparison with operating experience;
(3) comparison with incident case histories.

Parallel analysis involves repeating the analysis using another analyst, either completely or in part. Full repeat analyses are time consuming and are rarely undertaken except in benchmark exercises, but sampling of the problem and partial analysis are more common.

A comparison may be made between the hazards identified in the safety analysis and incidents drawn from the operating experience of the plant. Since these cannot be expected to give the full range of potential incidents, particularly for rare events, a further comparison may be made by drawing on incident case histories for plants with similar features.

The safety analysis identifies deficiencies which in a proportion of cases will lead to incidents, but does not predict incidents as such. The same applies to the quality assessment of the safety analysis. The quality assessment, therefore, has to proceed by making a judgement as to which deficiencies have caused a particular incident. This then establishes the link between deficiencies and incidents.

8.29.6 Safety analysis performance

Thus, in general, there will be a number of deficiencies identified in the safety analysis, which may be compared with two other sets of identified deficiencies: those found by the quality assessor(s) and those inferred from incidents. There is no guarantee that these three sets comprise the total universe of deficiencies, but nevertheless the comparison gives a useful indicator of quality.

8.29.7 Assessor performance

Two indices of assessor performance are used which apply when there is more than one assessor. If a group of assessors is used, it is possible to compare the performance of the individual assessors. An interassessor reliability for a given assessor is defined as the ratio of the number of deficiencies identified by that assessor to the total number identified by all the assessors. The other index used is that of validity. This is defined as the ratio of the number of incidents illustrating deficiencies in the analysis identified by a given assessor to the total number identified by all the assessors. A high score by an assessor in interassessor reliability and a low score in validity means that a large proportion of the deficiencies identified are not significant causes of incidents.

8.29.8 Assessment studies

Four quality assessment studies were conducted and used to improve the checklist. The studies covered: (1) a pulp manufacturing process; (2) a chlorine liquefaction plant; (3) an liquefied petroleum gas storage and distribution system and (4) the First Canvey Report. All the studies involved quality assessment of the safety analysis as a whole, but in the first three the emphasis was on the quality of hazard identification, whilst in the fourth it was on the quality of the quantitative risk analysis.

In the original safety analysis of the pulp manufacturing process, the hazard identification methods used had been potential problem analysis (PPA), HAZOP and AEA. The PPA identified 30 hazards. The HAZOP identified over 150 hazards and gave 120 proposals for improvement. The AEA identified 25 opportunities for human error and gave 22 improvements.

In the quality assessment of this safety analysis, assessments were made by three assessors. The total number of deficiencies identified by the three assessors was as follows: system definition, 11; hazard identification, 24; accident modelling, 1; estimation of accident frequencies, 1; estimation of accident consequences, 3; risk estimation, 3; documentation, 9; and follow-up measures, 5. Assessor A found 36 deficiencies, assessor B found 17 of these same deficiencies and 13 new ones, assessor C found 20 of the deficiencies found by A and B and 8 new ones.

As far as concerns the checklist, out of the 138 questions, 70 were useful in revealing deficiencies in the safety analysis. Of these, 45 led to identification of deficiencies by one assessor, 28 to identification by two assessors and only 2 to identification by all three assessors.

The performance both of the safety analysis and of the quality assessors was checked against data obtained on operating experience on the plant. From these data, the assessors identified some 280 trivial incidents, which they classified under five headings, and 112 non-trivial

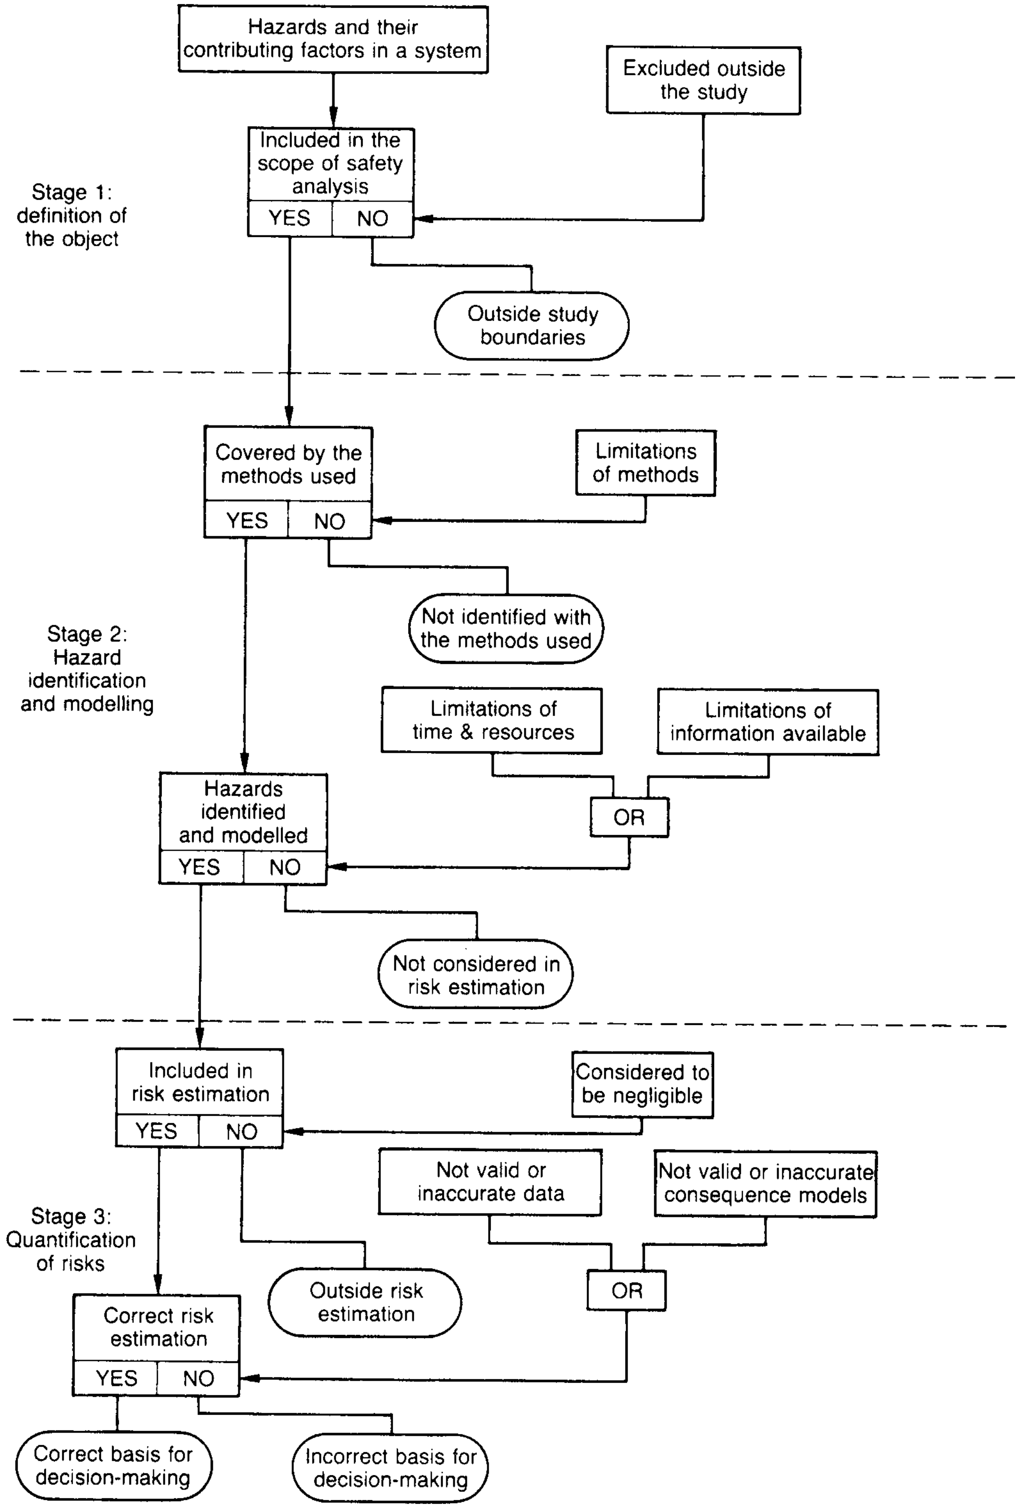

Figure 8.19 *Some potential limitations and deficiencies in a safety analysis (Rouhiainen, 1990)*

Table 8.50 *Identification of factors contributing to incidents by safety analysts and by quality assurance assessors: study of 117 incidents (after Rouhiainen, 1990)*

	Identified in safety analysis	*Not identified in safety analysis*		*Total*
		Identified by at least one assessor	*Not identified by any assessor*	
Physical subsystem	49	63	15	127
Environmental subsystem	7	4	2	13
Human subsystem	4	5	0	9
Managerial subsystem	2	10	1	13
Total	62	82	18	162
N	44	59	14	117

Table 8.51 *Some principal deficiencies in the First Canvey Report identified in two quality assessments (Rouhiainen, 1990)*

Author[a]	*(Analysis . . . 1980)*
Definition of the object	
– Definition of the area not clear	– Geographical limits should be applied only to fixed installations
– No definition of the residual regions	
– Employees and minor accidents excluded	– Minor events ignored
	– Office and factory workers excluded
Definition of the goals	
– No definition of the concept 'major interaction'	
– No definition of the types of hazards excluded	
– No criteria for choosing the accidents modelled	
– Cut-off criteria for risks which can be excluded not presented	– The analysis could have gone further
Organization of the risk analysis and methods used	
– Background of the team members not presented	
– Knowledge and experience of the team not presented	
– Incident statistics of the plants not used	– Comparison with accident statistics should have been made
Identification of hazards	
– Hazard identification not systematic	– Reference presents two hazards overlooked
– Not all factors affecting event-chains considered	– Smaller initiating events not considered
– Hazards caused outside the area not studied	– The same deficiency noted
– Not all materials taken into account	– Not all toxic chemicals included in the report
Estimation of accident frequencies	
– Not all assumptions and simplifications presented	– Assumptions and calculations criticized
– Reference for the data used not presented	– Noted that this prevents assessment of the data
– Statistical data used may in some cases be incorrect	– Reference presents examples of incorrect failure frequencies
– Effect of speed limit overestimated	– Noted as a source of inaccuracy
	– Basis of subjective judgements incorrect
	– Frequencies overestimated
Estimation of consequences	
– Not all principles and limitations of the models used presented	– Calculation methods not presented in enough detail
– Estimation based only on average amounts of materials	– Reference presents many mistakes in the assumptions, simplifications and methods
– The effect of the changes in the source term not estimated	
Estimation of risks	
– Not all assumptions, simplifications and calculations presented	– Many mistakes presented
	– Some serious arithmetic errors noted

Table 8.51 *(continued)*

– Cryogenic commission of LNG[b] tankers excluded	– The same deficiency noted
– Risk estimated only for some regions	– Avoiding action of people not taken into account
– Not all aspects concerning emergency planning studied	
Report of the risk analysis	
– Some characteristics of the analysis object not described	– The same deficiency noted – Results not presented in enough detail
– Accuracy of the results not presented	– No logical basis for selecting the remedies – No guidance for the future – The total impact of the hazards not estimated

[b] Liquefied natural gas.

incidents, giving a total number of 117 different incidents in all. Of these 117 incidents, 73 had not been identified in the safety analysis.

Rouhiainen (1990) gives evaluations of the interassessor reliability and of the validity. The interassessor reliabilities were 58%, 53% and 49%. With regard to validity, of the 117 incidents, 59 illustrated deficiencies identified by at least one assessor and 30 deficiencies identified by all three assessors.

The number of factors considered to have contributed to these 117 incidents is given in Table 8.50.

The physical subsystem covered failures and malfunctions, structural defects, leaks within and from the system, pipe blockage and conveyor jamming, and process disturbances. The environmental subsystem covered environmental factors, weather and impurities.

Further aspects of the incidents identified were also analysed. Of the total 177 incidents, the effects on personnel safety were found to be as follows: leak of hazardous substance, 12; another immediate accident hazard, 5; hazard with a parallel failure, 19; increase in probability of hazard, 25; and no direct effect on safety, 56. The effects on plant operation were as follows: shut-down of whole plant, 8; shut-down of part of plant, 53; operating disturbance, 40; decrease in quality of pulp, 4; extra work only, 8; and no effect on production, 4. The account given by Rouhiainen (1990) of the other two plant studies follows this broad pattern.

After the second study, the checklist was revised. The aim of the revisions was to repair omissions, overlaps and obscurities and variability in level of detail.

The study of the Canvey Report was concerned with the quality of the QRA rather than with hazard identification. The checklist was applied by a single assessor and the deficiencies identified, which are shown in Table 8.51 were compared with those given in other critiques of the report, including the Second Canvey Report.

8.30 Notation

Section 8.6

AQ	airborne quantity (kg/s)
BI	Business interruption loss
C	Loss control credit factor
CEI	Chemical exposure index
CF	Credit factor
DF	Damage factor
EF	Escalation factor
EPRG	toxic limit (mg/m^3)
ER	Exposure radius
F_1	GPH factor
F_2	SPH factor
F_3	PUHF factor
F&EI	Fire and explosion index
GPH	General process hazard
HD	Hazard distance (m)
MF	Material factor
MPDO	Maximum probable days outage
MPPD	Maximum probable property damage
OV	Original value
PUHF	Process unit hazards factor
RV	Replacement value
SPH	Special process hazard
VAE	Value of the area exposed
VPM	Value of production per month

Section 8.19

L	Exponent of likelihood (where latter is expressed as a frequency)
S	severity category
TR	target risk

Section 8.28

c	measure of consequence
f	frequency of occurrence
N	number of hazards

Subscripts

chl	identified in a large case history list
id	identified
m	identified by method m
rl	realizable
tot	total existing

9

Hazard Assessment

Contents

In the previous chapter, an account was given of the process of identifying hazards, of the methods available and of the follow-up. For the great majority of hazards the action to be taken is clear once the hazard is known. There are, however, some hazards that require further assessment. Originally, such hazard assessment was undertaken in order to assist in making engineering decisions in the 'grey' areas where further investigation is needed in order to decide on the most cost-effective measures. This is still the prime purpose of hazard assessment, but increasingly in recent years, this activity has been enlarged to deal with major hazards which are realized only very rarely but which present a threat to the public.

The aims and nature of these two activities are somewhat different. The terminology used to describe them also differs. In the United Kingdom, the practitioners of the first type of hazard assessment have tended to call it 'hazard analysis' (HAZAN). The second type is often called 'probabilistic risk analysis' (PRA), a term which came into use in the US nuclear industry, or simply 'risk analysis'.

Hazard assessment is introduced here, therefore, with an account of how it has developed historically. The use of hazard analysis as an aid to engineering decision-making is then described. As this account shows, the methods used in hazard analysis are often relatively simple.

Risk assessment is a more complex undertaking, as the account given indicates. The starting point is the identification of the hazards and definition of the hazard scenarios to be considered. For each hazard, the frequency and consequences are then estimated. The estimation of frequency may require the use of fault trees, event trees and/or cause–consequence diagrams. The estimation of the consequences involves the study of a sequence of events. Usually this is an emission of hazardous material which gives rise to certain physical effects. The estimation of these effects involves the use of a wide range of hazard models.

Some hazard assessments terminate at this point. If a full risk assessment giving risks to the public is required, however, it is necessary also to have models that define the characteristics of the population at risk, in order to allow for factors such as shelter and escape, which modify exposure to the physical effects, and then to estimate the proportion of people who suffer injury.

There are a number of forms in which the results of a risk assessment may be presented. It is desirable that information be presented on the degree of confidence in the results of the risk assessment. This is important both because there are inherent uncertainties in risk assessment and because the methodology is still developing. Although the numerical estimates produced by a quantitative hazard assessment may not be the most important outputs, it is necessary to have risk criteria by which to evaluate them.

Model hazard assessments for major hazards have been carried out by the Health and Safety Executive (HSE) to assist in land-use planning and by the Chemical Industries Association (CIA) to assist in emergency planning and in preparation of a safety case. The impact of a hazard on the surrounding area may be estimated using a hazard impact model.

A full risk assessment is a major undertaking. Various simplified techniques have been developed, involving a greater or lesser degree of approximation. These range from short-cut versions of the normal method to very simple and approximate methods. A major accident is usually preceded by a number of lesser events which may serve as warnings. The hazard warning structure may be analysed and used to enhance confidence that the hazard is under control.

A number of major risk assessments have been carried out, notably the two *Canvey Reports* and the *Rijnmond Report*. These are described in Appendices 7 and 8, respectively. Selected references on hazard assessment are given in Table 9.1.

9.1 Background

An understanding of the way in which hazard assessment has developed historically is important in appreciating its present role. Hazard analysis was developed in the 1960s as part of the response to the problems that stimulated the development of loss prevention in general, as described in Chapter 1.

One problem area was the availability of large, single stream chemical plants. Application of the techniques of reliability engineering was one of the measures taken to correct this. Closely related was the problem of high hazard plants. Several major protective systems were implemented. These were designed using fault trees and instrument failure data, and risk criteria were devised to evaluate them. Another matter of concern was the increasing quantity of chemicals being transported around the country by road, rail and pipeline. Assessments were made of these operations.

The industry was initially assisted in the use of reliability engineering by the UK Atomic Energy Authority (UKAEA), but soon began to develop its own approach. One innovation introduced was the use of the hazard and operability study as a means of identifying hazards. This technique was developed by the chemical industry. The industry also developed a rather distinctive approach to hazard assessment. It was clear that in order to improve plant reliability and safety it was necessary to modify the plant designs, by using more reliable equipment and/or configurations and by incorporating additional protective devices. There was a severe problem, however, in selecting from the large number of measures which might be taken, those which were most cost-effective.

In many cases, once a hazard had been identified, it was clear what action should be taken, but there were sometimes 'grey' areas where the decision was not clear-cut. This is the problem which hazard analysis addresses. Typically, the use of hazard analysis involves estimating the frequency of realization of the hazard without and with some protective measure, and then evaluating the results using an appropriate criterion. The frequency of the hazard is usually estimated directly from data for that event, but it sometimes has to be synthesized from a fault tree using data for events lower down the tree.

The spirit in which the early hazard analysis was developed was to use quantitative methods but to keep it simple. Fault trees were used, but they were usually nothing like as complex as those developed for nuclear plants. Often the calculations were almost of a 'back of the envelope' type. In this, the approach had much in common with that of early operational research. Some examples of such hazard analysis are given in the next section. They are estimates made in support of engineering decision-making.

9.2 Hazard Analysis

Hazard analysis is now a well-established method for aiding engineering decision-making. An account is given in *Hazop and Hazan: Notes on the Identification and Assessment of Hazards* (Kletz, 1983d, 1986d, 1992b). The activity of hazard analysis may best be described in terms of illustrative examples. A collection of such examples has been given by Kletz (1971). Before giving these examples, however, it is necessary to describe the risk criterion used in them.

9.2.1 Fatal Accident Rate criterion

A risk criterion is required for the evaluation of the estimates made in hazard analysis. The criterion which was developed in the original work and which is still in almost exclusive use is the Fatal Accident Rate (FAR). The FAR is defined as the number of fatalities per 10^8 exposed hours. The meaning of the FAR may perhaps be best understood by saying that if the actual FAR is, say, 4, and if 1000 men go into a chemical works at the age of 20 years, then at the age of 60 years 996 men will leave the works alive. At the time when it was developed as a criterion, the actual FAR for the UK chemical industry was about 3.5.

The way in which the FAR is applied is then as follows. The total FAR is divided into 10 parts. Five of these are allocated for everyday hazards such as falling downstairs or having a spanner dropped on the head. The other five parts are allocated to technological hazards specific to the plant on which the employee works. It is assumed that there are no more than five of these on a given plant. This then gives one part available for each technological hazard on that plant. Thus if, for example, the actual overall FAR of 3.5 is also taken as the overall target value which is not to be exceeded, the target FAR for a single, specific technological hazard will be 0.35.

The FAR was originally called the Fatal Accident Frequency Rate (FAFR), but since this is tautologous, the term Fatal Accident Rate (FAR) is preferred. The FAR criterion is discussed further in Section 9.21.

9.2.2 Pipeline fracture

A hazard identified on one particular plant was contact of refrigerated liquefied gas with a mild steel pipeline, leading to brittle fracture. One method of avoiding this hazard was to use stainless steel, which would be very expensive. A much cheaper method was to use a trip system to prevent the cold gas from contacting the line. The use of hazard analysis to tackle this problem is described by Kletz (1971) as follows:

> Using data on the reliability of the various components of the trip system and assuming the operator will ignore the initial alarm system on one occasion out of four, the 'fractional dead time' of the whole system (that is, the fraction of time it is not operating) was calculated. This depends on the frequency with which the trips are tested. The 'demand rate' on the system, the number of times per year it is called on to operate, was estimated from previous experience.

The failure rate of the whole system was then estimated as once in 10,000 years or once in 2500 years for the whole plant which contained four similar systems.

It was assumed that one tenth of the occasions on which the cold gas reached mild steel would result in a leak, an explosion and a fatality – almost certainly an overestimate. A fatality will then occur once in 25,000 years giving an FAFR of 0.45. It was therefore agreed that the control system was satisfactory and it was not necessary to replace the mild steel by stainless steel.

It might be argued that the latter course is preferable as it is 100% safe, the FAFR is zero. Had we done this, the cost of reducing the hazard rate to zero would have been equivalent to £150,000,000 per life saved.

This example illustrates many of the characteristic features of hazard analysis. The aim of the analysis is to select a measure to deal with a hazard. An estimate is made of the frequency of realization of the hazard, based on a simple calculation using field data. The estimate made is somewhat conservative. The result is evaluated using the FAFR criterion, this criterion not being applied slavishly but with regard to the uncertainty in the estimate. A further check is done on the value of a life implied by the decision alternatives.

9.2.3 Crankcase explosions

Another example is the problem of possible crankcase explosions in a building housing 25 compressors. Data obtained from a survey showed that there was one explosion per 500 machine-years. In order to achieve an FAR of 0.35 the proportion of explosions causing fatalities would not have had to exceed 1 in 1650. As there were normally several men in the building, the risk was clearly too high. The risk had to be reduced; the method actually used being to fit a suitable relief valve.

9.2.4 Hazardous area classification

A third example relates to hazardous area classification. Flameproof or intrinsically safe electrical equipment is required in Division 1 areas in which flammable gas or vapour is likely to be present under normal operating conditions. Totally enclosed 'non-sparking' equipment may be used in Division 2 areas, in which flammable gas or vapour is likely to be present under abnormal conditions. It is more economic to use this latter type of equipment and it is therefore desirable to apply the Division 1 classification only to those areas where it is really necessary. Records indicate that Division 2 motors develop a fault that causes them to spark or overheat at a rate of once per 100 years. Observation indicates that the probability of a man being within 10 ft (3 m) of a given motor in a plant area is 1 in 20. If it is assumed that anyone within this distance is killed when an explosion occurs, that on half the occasions when a flammable atmosphere occurs there is no explosion because diffusion into the equipment is slow and short-lived concentrations of gas/vapour can be ignored and that there are 100 motors on the plant, then an area may be classed as Division 2 if it has a flammable mixture for less than 10 h/year. This is the figure that corresponds to an FAR of 0.35.

9.3 Risk Assessment

The hazards considered in hazard analysis as just described are typically accidents with the potential to cause one or two fatalities. By contrast, quantitative risk assessment (QRA), also known as probabilistic risk assessment (PRA) or probabilistic safety assessment (PSA), usually deals with major hazards that could cause a high death toll.

A full risk assessment involves the estimation of the frequency and consequences of a range of hazard scenarios and of individual and societal risk. This is a major undertaking. An outline of the classical procedure of risk assessment is given in Figure 9.1. The diagram shows the principal elements and the broad structure, but there are variations and there is a degree of iterations, which is not shown. A risk assessment should be undertaken only if the purpose of the study has been well defined. If this is not done, it is unlikely that full value will be derived from the results obtained.

Identification of the hazards is the essential first step. The quality of the assessment depends crucially on the comprehensiveness of the hazard identification. Techniques of hazard identification have been discussed in Chapter 8. The method most relevant to risk assessment is the review of release sources. It is also necessary to identify the vulnerable targets, both persons and property.

A scenario is then developed for each potential release. The scenario defines the nature of the release and thus determines the subsequent chain of consequences. Since there is an infinite number of potential releases, it is necessary to arrange them in a limited number of groups of broadly similar nature. Some factors affecting the scenarios include the hole size and the duration, which may depend on any emergency shut-off. This procedure gives the source terms.

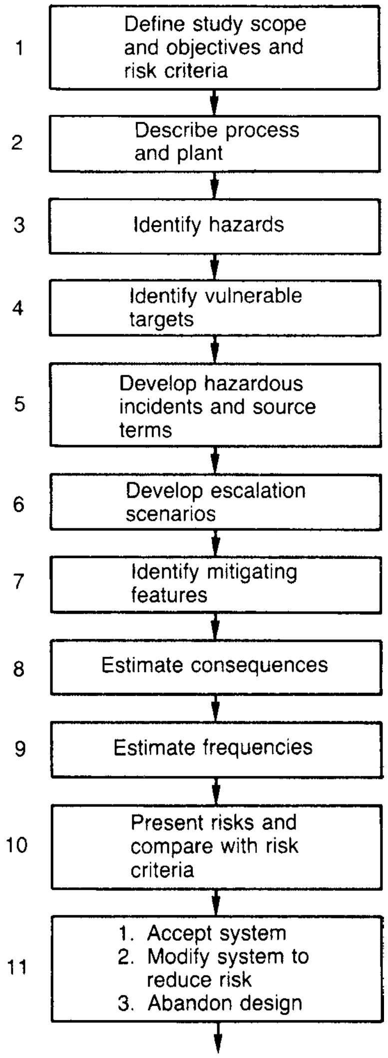

Figure 9.1 *The risk assessment process*

For each release scenario, a set of consequence chains is developed showing the escalation of the event. The different chains arise from the influence of conditions that affect the development of the event, such as the wind direction and velocity and stability conditions and, for flammables, the ignition sources. A typical consequence chain is shown in Figure 9.2. The dotted line in the figure represents the widening of the confidence bounds as the successive events become more remote from the initial release.

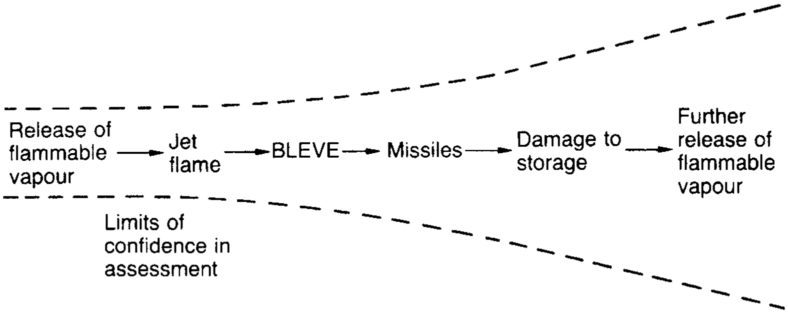

Figure 9.2 *A consequence chain*

Table 9.2 *Typical sequences of events in a risk assessment*

A	Flammable release
	Emission Vaporization (if liquid) Air entrainment Gas dispersion Ignition Flash fire or vapour cloud explosion
B	**Toxic release**
	Emission Vaporization Air entrainment Gas dispersion

The set of consequence chains is conveniently represented in the form of an event tree. Each of the branches of the event tree represents a single consequence chain. The outcomes are generally defined as events such as flash fire, vapour cloud explosion or toxic cloud. It is then necessary to identify any features that may mitigate the effects of these events on people or property. Factors that modify the exposure of the people include shelter, escape and evacuation.

In order to estimate injury or damage, it is necessary to model the sequence of events leading up to each outcome. Two typical chains of events are shown in Table 9.2, one for a flammable release and the other for a toxic release. Physical models are required which describe each stage in the sequence. Using these hazard models for the successive stages of the chain, the intensity of the physical effect is estimated.

The effect of a given outcome event on persons or property is estimated from the intensity of the harmful physical effect. These effects include:

(1) thermal radiation;
(2) explosion
  (a) overpressure,
  (b) impulse;
(3) toxic concentration
  (a) dosage,
  (b) concentration–time function.

The risk of injury is determined using injury relations that give the probability of a defined degree of injury as a function of the intensity of the physical effect. Similar procedures apply to property damage. Some hazard assessments are terminated at this point. The consequences are evaluated.

In other cases, an estimate is made of the frequencies of some or all of the outcomes. This involves first the estimation of the frequency of the release scenario. It may be possible to do this directly from failure data or it may be necessary to synthesize a value using fault tree methods. Then, using the event tree framework, an estimate is made of the probability of the various events constituting the branch points in the event tree and hence the frequencies of the outcomes. Other hazard assessments are terminated at this stage. The frequencies of the various consequences are evaluated.

Alternatively, the assessment is continued to provide a full risk assessment yielding individual and societal risks. Societal risk is expressed as a set of points representing increasingly serious events and relating the numbers of persons affected to the frequencies of the events. Estimation of societal risk involves determining the population at risk. The results of the assessment may be presented in a number of different forms such as risk contours on a map of the site or tables or graphs of individual and societal risks. Each stage of the assessment is attended by uncertainty. It is necessary, therefore, to provide measures of this uncertainty. Thus, the frequency of an outcome may be expressed as a frequency distribution or range of values rather than as a single figure. Finally, the results so obtained are evaluated using risk criteria.

The foregoing account is a simplified one. In particular, the information from a particular stage may lead to modification of the design and an iteration in which the results from that stage are recalculated. As indicated, the hazard assessment may be terminated short of a full risk assessment following assessment of the consequences. The consequences may be judged tolerably low for any foreseeable frequency.

In the scheme outlined, the estimation of the frequencies is deferred until a relatively late stage. An alternative approach is to perform this stage rather earlier. The hazard assessment may also be terminated following assessment of the frequencies. The frequencies may be judged tolerably low for any foreseeable consequences.

The individual aspects of QRA are discussed in more detail in the following sections.

There are differences of view on the value of such risk assessments. Some criticisms are directed to the basic philosophy underlying the methodology, others to the evaluation of the risk estimates generated. An account of the debate on risk assessment is given in Section 9.28.

9.3.1 NRC *PRA Procedures Guide*

Initially, guidance on the conduct of risk assessments had to be sought mainly in published studies such as the two *Canvey Reports*, the *Rijnmond Report* and the *Rasmussen Report*. More formal guidance appeared in the *PRA Procedures Guide* of the Nuclear Regulatory Commission (NRC, 1982). The coverage of the *PRA Procedures Guide* is indicated by the list of contents given in Table 9.3.

9.3.2 IAEA *PSA Procedures Guide*

A more recent nuclear industry guide is *Procedures for Conducting Probabilistic Safety Assessment of Nuclear Power Plant* by the International Atomic Energy Agency (IAEA, 1992). This guide is particularly strong on the development of accident scenarios.

9.3.3 CONCAWE *Guide*

Outline guidance for the process industries was published in *Methodologies for Hazard Analysis and Risk Assessment in the Petroleum Refining and Storage Industry* by CONCAWE (1982 10/82).

9.3.4 CCPS *QRA Guidelines*

A much more detailed QRA guide is given in *Guidelines for Chemical Process Quantitative Risk Analysis* by the Center for Chemical Process Safety (CCPS, 1989/5) (the CCPS *QRA Guidelines)*. The principal contents of the CCPS *Guidelines* are shown in Table 9.4 together with the location in this book where they are treated.

The *Guidelines* are oriented to the QRA practitioner. Discussion of the various consequence models and frequency estimation techniques typically has the following structure: (1) background (purpose, philosophy/ technology, application), (2) description (description of technique, theoretical foundation, input requirements and availability, outputs, simplified approaches), (3) sample problem and (4) discussion (strengths and weaknesses, identification and treatment of errors, utility, resources needed, available computer codes).

9.3.5 QRA in safety cases

In the United Kingdom, one of the principal applications of QRA in the process industries is in the safety case. An account of safety cases and, in particular, of the extent to which QRA is required is given in Chapter 4.

9.3.6 QRA and decision-making

A review by the HSE of the role of QRA in decision-making is given in *Quantified Risk Assessment: Its Input to Decision-making* (HSE, 1989c). The document is part of the HSE's response to the *Layfield Report* (Layfield, 1987) on Sizewell B, which called for studies both of the tolerability of risk from nuclear power stations and of the relationship of safety standards in the nuclear industry to those in other industries. It deals with the second of these topics, the first being treated in *The Tolerability of Risks from Nuclear Power Stations* (HSE, 1988c).

The study considers some 16 cases of the use of QRA. They include: in the process industries, the *Canvey Reports* (HSE, 1978b, 1981a), the St Fergus to Moss Morran pipeline (HSE, 1978a), the Moss Morran/Braefoot Bay development (HSE, 1983e), housing development near an ammonium nitrate plant in the Goole–Hook plan, major retail development near a chemical plant at Ellesmere Port, a harbour with a liquefied petroleum gas (LPG) shipping risk, an explosives wharf, a sulfonation reactor and a plastics injection moulding machine; in the nuclear industry, the Heysham/Torness AGR and Sizewell B; in civil engineering, Ronan Point and the River Thames Flood Defence scheme; in mining, Markham Colliery and, in the United States, Sunshine Mine; and in rail transport, automatic level crossings. In all cases, except apparently Sunshine Mine, the QRA was used as an input to decision-making. Details of these cases are given in Appendix 2 of the study.

There is, in general, considerable variation between one QRA and another. One cause of variation is the nature of the problem addressed. This may be, for example, a single machine, a whole plant or even a complex of plants. Another cause is the degree of conservatism in the estimates made. Furthermore, QRA is subject to quite large margins of error. The study makes the point that a QRA does not necessarily have to be a complex exercise. In some cases, a relatively simple QRA suffices.

In the cases considered, the main forms in which the risks were presented are individual fatal risk and societal fatal risk, the latter in the form of frequency–number (FN) curves. The study emphasizes the need to distinguish between the different bases on which FN curves are constructed. An FN curve may be based on (1) historical data, (2) design requirements or (3) predicted values. These three bases are quite different, and this needs to be borne in mind when using the curves derived.

The two latter types are illustrated by considering two FN curves produced for Sizewell B. One curve, by Harbison and Kelly (1985), is based on design requirements implied in the safety assessment principles of the Nuclear Installations Inspectorate (NII). The other curve, produced by the Central Electricity Generating Board (CEGB) (G.N. Kelly and Hemming, 1983) represents the predictions arising from the actual design. Another difference in the basis of FN curves is the fatalities on which the curve is based, which may be confined to immediate deaths or may also include delayed deaths.

The study gives a review of risk criteria, dealing in particular with the HSE criterion for a major civil nuclear

accident and the Advisory Committee on Major Hazards (ACMH) criterion for a major accident. The HSE nuclear criterion may be summarized as the requirement that an uncontrolled release from any of a family of reactors nationwide capable of giving doses of 100 mSv at 3 km, which pessimistically might cause eventual deaths of about 100 people, should be no more frequent than 10^{-4}/year and the ACMH major hazard criterion that a major accident such as Flixborough, involving say ≥ 10 deaths, should occur nationwide with a frequency no greater than 10^{-4}/year.

In Appendix 1, the study lists some 42 factors that seem important in judging the tolerability of risk, under the four headings of: (1) the hazard, the consequential risk and the consequential benefits, (2) the nature of the assessment, (3) the factors of importance to those generating the risk, to government or to regulators, and (4) public attitudes.

Although the results of a QRA are typically expressed in terms of deaths or of casualties, appropriately defined, there are generally other consequences that need to be considered. The study lists (1) the write-off of the plant, (2) the impact on the surrounding area, (3) the anxiety factor, (4) consequential detriments and (5) the 'What if?' factor. The write-off of a plant such as occurred at Three Mile Island or Chernobyl is costly in itself and harms the whole industry. The impact on the surrounding area can be severe, especially where land is rendered radioactive, and there may be consequent detrimental outcomes such as the increased number of miscarriages that took place after Seveso. The occurrence of a major accident may lead to concern arising from asking 'What if an even larger scale one were to occur?'

For the cases described, the study reviews the nature of the decision to be made, the risk estimates yielded by the QRAs and the decisions taken. Many of the decisions concerned the granting of planning permission. Others related to the safety of particular equipment or civil engineering designs. Two, Canvey and Sizewell, were much more complex than might appear. Canvey started from a planning application for a new plant but grew into an examination of the risks from an existing complex. Sizewell inevitably became a generic inquiry into the case for nuclear power in general and the pressurized water reactor (PWR) design in particular.

The study tabulates the QRA estimates of individual risk and gives for the societal risk estimates a FN curve in which the curves differ widely. For example, the frequency of ≥ 10 deaths varies from 10^{-1}/year for the historical data for flats of the Ronan Point type to somewhat over 10^{-7}/year for the implied design requirements of Sizewell B, with most cases clustering between about 10^{-3} and 10^{-4}/year.

The decision outcomes, as a decision proper or advice on a decision, include: granting of planning permission to a new development, without or with improvements (e.g. St Fergus to Moss Morran pipeline; Moss Morran Braefoot Bay development, harbour with LPG shipping, explosives wharf); requirement to make improvements to existing situation (e.g. Canvey); acceptance of a design (sulfonation reactor); and rejection of a design (e.g. Ronan Point).

Principal conclusions of the study are as follows. First, QRA is an element that cannot be ignored in decision-making about risk since it is the only discipline capable, however imperfectly, of enabling a number to be applied and comparisons of a sort to be made, other than of a purely qualitative kind. This said, the numerical element must be viewed with great caution and treated as only one parameter in an essentially judgmental exercise. Moreover, since any judgement upon risk is distributional, risk being caused to some as an outcome of the activity of others, it is therefore essentially political in the widest sense of the word. Second, QRA illuminates some important components of a safety assessment but needs to be supplemented by other approaches particularly in the areas of management and human factors. Third, the fact that other factors need to be taken into account does not detract from the value of QRA as a decision input. Fourth, it is not legitimate to 'read across' QRA-derived risk figures from one hazardous situation to another. It follows that it is not possible to specify a universal upper limit for all societal risks. Fifth, it needs to be borne in mind that, although QRA sometimes gives predictions of very severe accidents, such accidents do occur, as instanced by events such as Mexico City, Bhopal and Piper Alpha.

9.4 Event Data

The methods that are used to estimate the frequency of an event depend somewhat on the nature of the event. The aim is usually to base the estimate on historical experience, but the precise way in which this is done varies.

In the simplest case, there may be available frequency data that apply directly to the event in question. This is likely to be the case if the event of interest is one that does sometimes occur, for example, the failure of a single item of equipment such as a pipeline fracture or pump leak. In other cases it may not be possible to obtain such direct data. This tends to be the case for complex systems and/or systems with multiple layers of protection. Thus the frequency of failure of a nuclear power reactor is a case in point. The presence of the protective systems has the effect both of rendering each system more or less unique and of reducing the frequency of system failure to a very low value. For both these reasons historical data on failure frequency are lacking. The frequency therefore has to be synthesized using a fault tree. Again historical data are used, but in this case the data are for the base events in the tree and so are used indirectly.

The choice of method for the estimation of frequency depends on the hazard under consideration. This is illustrated very clearly in the different methodologies used in the *Canvey Reports* and the *Rasmussen Report*. In the former, the typical events of interest were emissions from vessels, pipelines and pumps. For these events historical frequency data exist and were used. In the latter study, however, the events of interest were accidents on nuclear power plants. Historical data for the frequency of these events did not exist and estimates had to be synthesized. Thus, whereas the *Canvey Reports* contain very few fault trees, the *Rasmussen Report* has an appendix several centimetres thick and full of fault trees.

A particularly difficult problem is posed by the estimation of the frequency of a rare event where this is not amenable to synthetic methods. A typical example is the outright failure of a high quality pressure vessel. In many cases the estimates required are probabilities rather than frequencies. In the following, most of the comments made about frequency apply also to probability. Similarly, it is convenient to refer to failure frequency, but the account given applies in most instances to the frequency of other events.

There are a number of sources of historical data that can be used to obtain a frequency estimate. They include the literature, the works and data banks. The data which are often most easily obtained are the total number of events over a given time period. These do not in themselves give an event rate. To determine the event rate it is necessary to know the total number of items to which the data apply. It can be quite difficult to determine this inventory.

Given that these data are available, frequency is typically estimated by dividing the total number of events by the total number of equipment-years. The assumption underlying this procedure is that a constant event rate, or the exponential distribution, applies.

Where failure data are concerned, it is often necessary to have information not only on the overall frequency of failure but also on the composition of this frequency in terms of the individual failure modes. In hazards work the fail-to-danger mode is usually required.

The estimation of the frequency from historical data is in some cases straightforward, but in others not. Areas of difficulty include

(1) inapplicability of data;
(2) sparseness of data;
(3) status of data.

The first point that has to be ascertained is whether the data available are applicable to the case in hand. There are various reasons why they may not be. The data may apply to equipment and/or conditions that are out of date. There may be significant differences between the equipment and/or its situation.

The design and environment in which equipment is used have a major influence on its failure rate. High failure rates can occur if equipment is highly rated or used in the wrong application. Operating practices affect the failure rate. Above all, failure rates can vary widely, depending on the maintenance regime.

In some instances, it is possible to identify specific ways in which the situation to which the data apply differs from that under consideration. A not uncommon case is in which a particular failure mode is known to be much less frequent or even inapplicable. For example, pipeline failures due to corrosion have been much reduced by the use of cathodic protection. Similarly, changes to the design of rail tank cars for hazardous materials in the United States have reduced the probability of impact damage. It is, in principle, legitimate to adjust an estimate based on historical failure data to allow for changed conditions, although this should be done with care.

Another common problem is that the data available are sparse. As described in Chapter 7, methods exist which allow estimates to be made of the confidence bounds on such data, but the bounds may be wide, and in any case uncertainty in the basic data complicates the assessment.

Usually the frequency data used come from a number of different sources and have varying statuses. Data statuses include

(1) historical data
    (a) numerous,
    (b) sparse;
(2) synthesized values;
(3) expert judgements
    (a) amenable to improvement,
    (b) unamenable to improvement.x

If it is not practical to obtain direct data on the frequency of an event, it is often possible to obtain a value indirectly by synthesis using tree methods. The most commonly used method is the fault tree, but the event tree can also be used.

A fault tree is typically used to estimate the frequency where the failure is such that the system or situation which gives rise to it is sufficiently complex as to render it relatively unique. In such a case historical failure data will not be available. One important feature that tends to render a system unique is the use of protective systems. Fault tree methods are described in Section 9.5.

Events that present a threat to the public are also relatively rare and unique, and again it may be necessary to resort to synthesis to obtain a value for the frequency. Such an event is the outcome of a chain of events following a release. The frequency may be obtained using an event tree. Event tree methods are described in Section 9.6.

In some cases historical data are not obtainable. In this case an approach that is increasingly used is that of expert judgement. Expert judgement methods are described in Section 9.9.

9.5 Fault Trees

A fault tree is used to develop the causes of an event. It starts with the event of interest, the top event, such as a hazardous event or equipment failure, and is developed from the top-down.

Accounts of fault trees are given in *Reliability and Fault Tree Analysis* (Barlow, Fussell and Singpurwalla, 1975), *Fault Tree Handbook* (Vesely *et al.*, 1981), *Engineering Reliability* (Dhillon and Singh, 1981), *Reliability Engineering and Risk Assessment* (Henley and Kumamoto, 1981), *Designing for Reliability and Safety Control* (Henley and Kumamoto, 1985) and *Probabilistic Risk Assessment, Reliability Engineering, Design and Analysis* (Henley and Kumamoto, 1992), and by Vesely (1969, 1970a,b), Vesely and Narum (1970), Fussell (1973a, 1975, 1976, 1978b), Lawley (1974b, 1980), Lapp and Powers (1977a, 1979), Vesely and Goldberg (1977b) and Kletz and Lawley (1982).

The fault tree is both a qualitative and a quantitative technique. Qualitatively it is used to identify the individual paths that led to the top event, while quantitatively it is used to estimate the frequency or probability of that event.

The identification of hazards is usually carried out using a method such as a hazard and operability (hazop) study. This may then throw up cases, generally small in number, where a more detailed study is required, and fault tree analysis is one of the methods that may then be used.

Fault tree analysis is also used for large systems where high reliability is required and where the design is to incorporate many layers of protection, such as in nuclear reactor systems.

With regard to the estimation of the frequency of events, the first choice is generally to base an estimate on historical data, and to turn to fault tree analysis only where data are lacking and an estimate has to be obtained synthetically.

9.5.1 Fault tree analysis

The original concept of fault tree analysis was developed at the Bell Telephone Laboratories in work on the safety evaluation of the Minuteman Launch Control System in the early 1960s, and wider interest in the technique is usually dated from a symposium in 1965 in which workers from that company (e.g. Mearns) and from the Boeing Company (e.g. Haasl, Feutz, Waldeck) described their work on fault trees (Boeing Company, 1965).

Developments in the methodology have been in the synthesis of the tree, the analysis of the tree to produce minimum cut sets for the top event, and in the evaluation of the frequency or probability of the top event. There have also been developments related to trees with special features, including repair, secondary failures, time features, etc.

A general account of fault tree methods has been given by Fussell (1976). He sees fault tree analysis as being of major value in

(1) directing the analyst to ferret out failures deductively;
(2) pointing out the aspects of the system important in respect of the failure of interest;
(3) providing a graphical aid giving visibility to those in system management who are removed from system design changes;
(4) providing options for qualitative or quantitative system reliability analysis;
(5) allowing the analyst to concentrate on one particular system failure at a time;
(6) providing the analyst with genuine insight into system behaviour.

He also draws attention to some of the difficulties in fault tree work. Fault tree analysis is a sophisticated form of reliability assessment and it requires considerable time and effort by skilled analysts. Although it is the best tool available for a comprehensive analysis, it is not foolproof and, in particular, it does not of itself assure detection of all failures, especially common cause failures (CCFs).

9.5.2 Basic fault tree concepts

A logic tree for system behaviour may be oriented to success or failure. A fault tree is of the latter type, being a tree in which an undesired or fault event is considered and its causes are developed. A distinction is made between a failure of and a fault in a component. A fault is an incorrect state that may be due to a failure of that component or may be induced by some outside influence. Thus fault is a wider concept than failure. All failures are faults, but not all faults are failures.

A component of a fault tree has one of two binary states: essentially it is either in the correct state or in a fault state. In other words, the continuous spectrum of states from total integrity to total failure is reduced to just two states. The component state that constitutes a fault is essentially that state which induces the fault that is being developed.

As a logic tree, a fault tree is a representation of the sets of states of the system that are consistent with the top event at a particular point in time. In practice, a fault tree is generally used to represent a system state that has developed over a finite period of time, however short. This point is relevant to the application of Boolean algebra. Strictly, the implication of the use of Boolean algebra is that the states of the system are contemporaneous.

Faults may be classed as primary faults, secondary faults or command faults. A primary fault is one that occurs when the component is experiencing conditions for which it is designed, or qualified. A secondary fault is one that occurs when the component is experiencing conditions for which it is unqualified. A command fault involves the proper operation of the component at the wrong time or in the wrong place.

A distinction is made between failure mechanism, failure mode and failure effect. The failure mechanism is the cause of the failure in a particular mode and the failure effect is the effect of such failure. For example, failure of a light switch may occur as follows:

Failure mode – high contact resistance
Failure mechanism – corrosion
Failure effect – switch fails to make contact

Some components are passive and others active. Items such as vessels and pipes are passive, whilst those such as valves and pumps are active. A passive component is a transmitter or recipient in the fault propagation process, an active one can be an initiator. In broad terms, the failure rate of a passive component is commonly two or three orders of magnitude less than that of an active component.

There is a distinction to be made between the occurrence of a fault and the existence of a fault. Interest may centre on the frequency with which or probability that a fault occurs, that is, on the unreliability, or on the probability that at any given moment the system is in a fault state, that is, on the unavailability. The distinction between reliability and availability was discussed in detail in Chapter 7.

The simplest case is the determination of the reliability of a non-repairable system. This is sometimes known as the 'mission problem': the system is sent on a mission in which components that fail are not repaired. The obvious example is space missions, but there are cases in the process industries that may approximate to this, such as remote pumping stations or offshore subsea modules. The availability of a non-repairable system may also be determined, but the long-term availability, which is usually the quantity of interest, tends to zero.

Generally, however, process systems are repairable systems, and for these both reliability and availability may be of interest. If concern centres on the frequency of realization of a hazard, it is the reliability that is relevant. If, on the other hand, the concern is with the fractional downtime of some equipment, it is the availability that is required.

A fault tree may be analysed to obtain the minimum cut sets, or minimum sets of events that can cause the top event to occur. Discussion of minimum cut sets is deferred to Section 9.5.8, but it is necessary to mention them at this point since some reference to them in relation to fault tree construction is unavoidable.

9.5.3 Fault tree elements and symbols

The basic elements of a fault tree may be classified as (1) the top event, (2) primary events, (3) intermediate events and (4) logic gates.

The symbols most widely used in process industry fault trees are shown in Table 9.5. The British Standard symbols are given in BS logic 5760 *Reliability of Systems, Equipment and Components*, Part 7: 1991 *Guide to Fault Tree Analysis*. For the most part the symbols shown in Table 9.5 correspond to those in the Standard, but in several cases the symbols in the table are the Standard's alternative rather than preferred symbols.

The top event is normally some undesired event. Typical top events are flammable or toxic releases, fires, explosion and failures of various kinds.

Primary events are events that are not developed further. One type of primary event is a basic event, which is an event that requires no further development. Another is an undeveloped event, which is an event that could be developed, but has not been. One common reason for not developing an event is that its causes lie outside the system boundary. The symbol for such an undeveloped event is a diamond and this type is therefore often called a 'diamond event'. A third type of primary event is a conditioning event, which specifies conditions applicable to a logic gate.

Table 9.5 *Fault tree event and logic symbols*

A Events

Symbol	
	Primary, or base, event – basic fault event requiring no further development
	Undeveloped, or diamond, event – fault event which has not been further developed
	Intermediate event – fault event which occurs due to antecedent causes acting through a logic gate
	Conditioning event – specific condition which applies to a logic gate (used mainly with PRIORITY, AND and INHIBIT gates)
	External, or house, event – event which is normally expected to occur[a]

Table 9.5 *(continued)*

B Logic gates, etc.

Symbol	*Alternative symbol*	
		AND gate – output exists only if all inputs exist
		OR gate – output exists if one or more inputs exists
		INHIBIT gate – output exists if input occurs in presence of the specific enabling condition (specified by conditioning event to right of gate)
		PRIORITY AND gate – output exists if all inputs occur in a specific sequence (specified by conditioning event to right of gate)
		EXCLUSIVE OR gate – output exists if one, and only one, input exists
		VOTING gate – output exists if there exist *r*-out-of-n inputs[b]
		TRANSFER IN – symbol indicating that the tree is developed further at the corresponding TRANSFER OUT symbol
		TRANSFER OUT – symbol indicating that the portion of the tree below the symbol is to be attached to the main tree at the corresponding TRANSER IN symbol

[a] This is the definition given by Vesely *et al.* (1981). Other authors such as Henley and Kumamoto (1981) use this symbol for an event which is expected to occur or not to occur.

[b] See Chapter 13.

A fourth type of event is an external event, which is an event that is normally expected to occur.

Intermediate events are the events in the tree between the top event and the primary events at the bottom of the tree.

Logic gates define the logic relating the inputs to the outputs. The two principal gates are the AND gate and the OR gate. The output of an AND gate exists only if all the inputs exist. The output of an OR gate exists provided at least one of the inputs exists. The probability relations associated with these two gates are shown in Table 9.6, Section A. Other gates are the EXCLUSIVE OR gate, the PRIORITY AND gate and the INHIBIT gate. The output of an EXCLUSIVE OR gate exists if one, and only one, input exists. The output of a PRIORITY AND gate exists if the

Table 9.6 Probability and frequency relations for fault tree logic gates (output A; inputs B and C)

A Basic probability relations[a]

Logic symbol	*Reliability graph*	*Boolean algebra relation*	*Probability relations*
		A = BC	$P(A) = P(B)P(C)$
		A = B + C	$P(A) = P(B) + P(C) - P(B)P(C)$

B Relations involving frequencies and/or probabilities[a]

Gate	*Inputs*	*Outputs*
OR	P_{B} OR P_{C} F_{B} OR F_{C} F_{B} OR P_{C}	$P_{\mathrm{A}} = P_{\mathrm{B}} + P_{\mathrm{C}} - P_{\mathrm{B}}P_{\mathrm{C}} \approx P_{\mathrm{B}} + P_{\mathrm{C}}$ $F_{\mathrm{A}} = F_{\mathrm{B}} + F_{\mathrm{C}}$ Not permitted
AND	P_{B} AND P_{C} F_{B} AND F_{C} F_{B} AND P_{C}	$P_{\mathrm{A}} = p_{\mathrm{B}}p_{\mathrm{C}}$ Not permitted; reformulate $F_{\mathrm{A}} = F_{\mathrm{B}}P_{\mathrm{C}}$

[a] F, frequency; P, probability.

inputs occur in the sequence specified by the associated conditioning event. The output of an INHIBIT gate exists if the (single) input exists in the presence of the associated conditioning event. There are also symbols for TRANSFER IN and TRANSFER OUT, which allow a large fault tree to be drawn as a set of smaller trees.

9.5.4 AND gates

One of the two principal logic gates in a fault tree is the AND gate. AND gates are used to represent a number of different situations and therefore require further explanation. The following typical situations can be distinguished:

(1) output exists given an input and fault on a protective action;
(2) output exists given an input and fault on a protective device;
(3) output exists given faults on two devices operating in parallel;
(4) output exists given faults on two devices, one operating and one on standby.

In constructing the fault tree the differences between these systems present no problem, but difficulties arise at the evaluation stage.

As already described, the probability p_0 that the output of a two-input AND gate exists, given that the probabilities of the inputs are p_1 and p_2, is

$$p_0 = p_1 p_2 \qquad [9.5.1]$$

The occurrence of events may be expressed quantitatively in terms of frequency or of probability. Failure of equipment is normally expressed as a frequency and failure of a protective action or device as a probability. A protective device is normally subject to unrevealed failure and needs therefore to be given a periodic proof test. Data for the failure of such a device may be available either as probability of failure on demand, or as frequency of failure. As described in Chapter 13, it can be shown that, subject to certain assumptions, the relationship between the two is

$$p = \lambda\tau_{\mathrm{p}}/2 \qquad [9.5.2]$$

where p is the probability of failure, λ is the failure rate and τ_{p} is the proof test interval.

Then for a Type 1 situation the frequency λ_0 of a fault is

$$\lambda_0 = \lambda_{\mathrm{p}} \qquad [9.5.3]$$

where p is the probability of failure of the protective action, λ is the frequency of the input event and λ_0 is the frequency of the output event.

For a Type 2 situation, Equation 9.5.3 is again applicable, with the probability p of failure of protective action in this case being obtained from Equation 9.5.2.

The evaluation of a Type 3 situation is less straightforward. For this, use may be made of the appropriate parallel system model derived from either the Markov or joint density function methods, described in Chapter 7. These give the probability of the output event given the frequency of the input events. Where applicable, the rare event approximation may be used to convert from probability to frequency:

$$\lambda = p/t \qquad [9.5.4]$$

Similarly, for a Type 4 situation use may be made of the appropriate standby system model.

9.5.5 Fault tree construction

The construction of a fault tree appears a relatively simple exercise, but it is not always as straightforward as it seems and there are a number of pitfalls. Guidance on good practice in fault tree construction is given in the *Fault Tree Handbook*. Other accounts include that in the CCPS *QRA Guidelines*, and those by Lawley (1974b, 1980), Fussell (1976) and Doelp *et al.* (1984).

An essential preliminary to construction of the fault tree is definition and understanding of the system. Both the system itself and its bounds need to be clearly defined. Information on the system is generally available in the form of functional diagrams such as piping and instrument diagrams and more detailed instrumentation and electrical diagrams. There will also be other information required on the equipment and its operation, and on the environment. The quality of the final tree depends crucially on a good understanding of the system, and time spent on this stage is well repaid.

It is emphasized by Fussell (1976) that the system boundary conditions should not be confused with the physical bounds of the system. The system boundary conditions define the situation for which the fault tree is to be constructed. An important system boundary condition is the top event. The initial system configuration constitutes additional boundary conditions. This configuration should represent the system in the unfailed state. Where a component has more than one operational state, an initial condition needs to be specified for that component. Furthermore, there may be fault events declared to exist and other fault events not to be considered, these being termed by Fussell the 'existing system boundary conditions' and the 'not-allowed system boundary conditions', respectively.

Fault trees for process plants fall into two main groups, distinguished by the top event considered. The first group comprises those trees where the top event is a fault within the plant, including faults that can result in a release or an internal explosion. In the second group, the top event is a hazardous event outside the plant, essentially fires and explosions.

If the top event of the fault tree is an equipment failure, it is necessary to decide whether it is the reliability, availability, or both, which is of interest. Closely related to this is the extent to which the components in the system are to be treated as non-repairable or repairable.

As already described, the principal elements in fault trees are the top event, primary events and intermediate events, and the AND and OR gates. The *Handbook* gives five basic rules for fault tree construction:

Ground Rule 1	Write the statements that are entered in the event boxes as faults; state precisely what the fault is and when it occurs.
Ground Rule 2	If the answer to the question, 'Can this fault consist of a component failure?' is 'Yes', classify the event as a 'state-of-component fault'. If the answer is 'No', classify the event as a 'state-of-system fault'.
No Miracles Rule	If the normal functioning of a component propagates a fault sequence, then it is assumed that the component functions normally.
Complete-the-Gate Rule	All inputs to a particular gate should be completely defined before further analysis of any one of them is undertaken.
No Gate-to-Gate Rule	Gate inputs should be properly defined fault events, and gates should not be directly connected to other gates.

Each event in the tree, whether a top, intermediate or primary event, should be carefully defined. Failure to observe a proper discipline in the definition of events can lead to confusion and an incorrect tree.

The identifiers assigned to events are also important. If a single event is given two identifiers, the fault tree itself may be correct, if slightly confusing, but in the minimum cut sets the event will appear as two separate events, which is incorrect.

For a process system, the top event will normally be a failure mode of an equipment. The immediate causes will be the failure mechanisms for that particular failure. These in turn constitute the failure modes of the contributing subsystems, and so on.

The procedure followed in constructing the fault tree needs to ensure that the tree is consistent. Two types of consistency may be distinguished: series consistency within one branch and parallel consistency between two or more branches. Account needs also to be taken of events that are certain to occur and those that are impossible.

The development of a fault tree is a creative process. It involves identification of failure effects, modes and mechanisms. Although it is often regarded primarily as a means of quantifying hazardous events, which it is, the fault tree is of equal importance as a means of hazard identification. It follows also that fault trees created by different analysts will tend to differ. The differences may be due to style, judgement and/or omissions and errors.

It is generally desirable that a fault tree has a well-defined structure. In many cases such a structure arises naturally. It is common to create a 'demand tree', which shows the propagation of the faults in the absence of protective systems, and then to add branches, representing protection by instrumentation and by the process operator, which are connected by AND gates at points in the demand tree. An example of a fault tree constructed in this way has been given in Figure 2.2. Essentially the same fault tree may be drawn in several different ways, depending particularly on the location of certain events that appear under AND gates.

9.5.6 Dependence

A fundamental assumption in work on reliability generally, and on fault trees in particular, is that the events considered are independent, unless stated otherwise. Formally, the events are assumed to be statistically independent, or 's-independent'. In practice, there are many types of situation where events are not completely independent. In fault tree work this problem was originally known as 'common mode failure' (CMF), then as 'common cause failure', and now more usually as 'dependent failure'.

The problem is particularly acute in systems, such as nuclear reactor systems, where a very high degree of reliability is sought. The method of achieving this is through the use of protective systems incorporating a high degree of redundancy. On paper, the assessed reliabilities of such systems are very high. But there has been a nagging worry that this protection may be defeated by the phenomenon of dependent failure, which may take many and subtle forms. Concern with dependent failure is therefore high in work on fault trees for nuclear reactors.

Dependent failure takes various forms. In most cases it requires that there be a common susceptibility in the component concerned. Some situations which can cause dependent failure include: (1) a common utility; (2) a common defect in manufacture; (3) a common defect in application; common exposure to (4) a degrading factor, (5) an external influence, or (6) a hazardous event; (7) inappropriate operation and (8) inappropriate maintenance.

Perhaps the most obvious dependency is supply from a common utility such as electric power or instrument air. Equipment may suffer common defects either due to manufacture or to specification and application. Common degrading factors are vibration, corrosion, dust, humidity and extremes of weather and temperature. External influences include such events as vehicle impacts or earthquakes. An event such as a fire or explosion may disable a number of equipments. Equipment may suffer abuse from operators or may be maintained incorrectly. It will be clear that in such cases redundancy may be an inadequate defence.

Generally, a common location is a factor in interpreting this fairly broadly. But it is by no means essential. In particular, incorrect actions by a maintenance fitter can disable similar equipments even though the separation between the items is appreciable.

A type of dependent failure that is important in the present context is that resulting from a process accident. A large proportion of equipments, including protective and fire fighting systems, may be susceptible to a major fire or explosion, just at the time when they are required.

There is some evidence that dependent failure is associated particularly with components where the fault is unrevealed. Thus a study of nuclear reactor accident reports by J.R. Taylor (1978b) showed that of the dependent failures considered only one was not associated with a standby or intermittently operated system.

Not all dependent failures involve redundant equipment. Another significant type of dependent failure is the overload that can occur when one equipment fails and throws a higher load on another operating equipment. Failures caused by domino effects, and escalation faults generally, may also be regarded as dependent failures.

Dependent failure, then, is a crucial problem in high reliability systems. A more detailed account is therefore given in Section 9.8. Here further discussion is confined to fault tree aspects.

Dependent failure can be taken into account in a fault tree only if the potential for it is first recognized. Given that this potential has been identified, there are two ways of representing it in the tree. One is to continue to enter each fault separately as it occurs in the tree, but ensuring that each such entry is assigned the same identifier, so that the minimum cut sets are determined correctly. The other approach is to enter the effect as a single fault under an AND gate higher up the tree. A further measure that may be taken to identify dependent failure is to examine the minimum cut sets for common susceptibilities or common locations.

9.5.7 Illustrative example: instrument air receiver system

As an illustration of fault tree analysis, consider the system shown in Figure 9.3(a). The vessel is an air receiver for an instrument air supply system. Air is let down from the receiver to the supply through a pressure reducing valve. The pressure in the receiver is controlled by a pneumatic control loop that starts up an air compressor when the receiver pressure falls below a certain value. The instrument air supply to the control loop is taken from the instrument air supply described, and if the pressure in the supply system falls below a certain value this too causes the control loop to start up the compressor. There is a pressure relief valve on the receiver. There is also a pressure relief valve (not shown) on the instrument air supply system. The design intent is that the pressure relief valve on the air receiver is sized to discharge the full throughput of the compressor and is set to open at a pressure below the danger level and that the pressure reducing valve is sized to pass the full throughput of the compressor if the instrument air pressure downstream falls to a very low value. One of the main causes of failure in the system is likely to be dirt.

The top event considered is the explosion of the air receiver due to overpressure. A fault tree for the top event of 'Receiver explosion' is shown in Figure 9.3(b).

One fault event occurs in two places – 'Pressure reducing valve partially or completely seized shut or blocked'. This is drawn as a subtree. One primary failure event appears at several points in the tree – 'Dirt'. As shown, this is treated in the tree as separate primary failures for the pressure reducing valve and the pressure relief valve.

Two of the events in the tree are mutually exclusive. These are 'Instrument air system pressure abnormally high' and 'Instrument air pressure abnormally low'. These events are denoted by B and B*, respectively.

The analysis of this fault tree to obtain the minimum cut sets and the probability of occurrence of the top event is described below.

9.5.8 Minimum cut sets

A fault tree may be analysed to obtain the minimum cut sets. A cut set is a set of primary events that is of basic or undeveloped faults, which can give rise to the top event. A minimum cut set is one that does not contain within itself another cut set. The complete set of minimum cut sets is the set of principal fault modes for the top event.

The minimum cut sets may be determined by the application of Boolean algebra. The procedure may be illustrated by reference to the fault tree shown in Figure 9.3(b). This may be represented in Boolean form as:

$$T = (A + B + C + D)(B^* + F)(G + H + I) \qquad [9.5.5]$$

Then substituting

$$B^* = C + D + E$$

and noting that: $BB^* = 0$

$$CC = C; DD = D$$

$$AC, CD, CE, CF \subset C$$

$$AD, DC, DE, DF \subset D$$

gives

$$T = (AE + AF + BF + C + D) \cdot (G + H + I) \qquad [9.5.6a]$$

$$= [A \cdot (E + F) + BF + C + D] \cdot (G + H + I) \qquad [9.5.6b]$$

and thus the minimum cut sets are:

A E G	A E H	A E I
A F G	A F H	A F I
B E G	B F H	B F I
CG	CH	CI
DG	DH	DI

A simplified fault tree that corresponds to Equation 9.5.6b is shown in Figure 9.3(c).

Since fault trees for industrial systems are often large, it is necessary to have systematic methods of determining the minimum cut sets. Such a method is that described by Fussell (1976). As an illustration of this method, consider the motor system which is described by this author and which is shown in Figure 9.4(a). The top event considered is the overheating of the motor. The fault tree for this event is shown in Figure 9.4(b). The structure of the tree is:

Gate	*Gate type*	*No. of inputs*	*Input code*	*No.*
A	OR	2	1	B
B	AND	2	C	2
C	OR	2	4	3

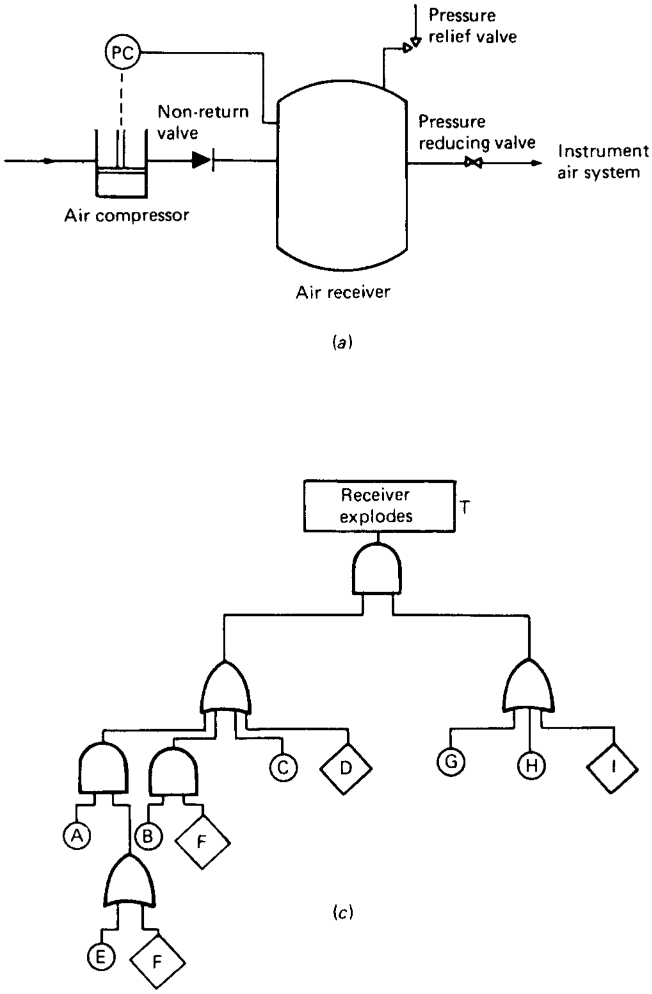

Figure 9.3 *continued*

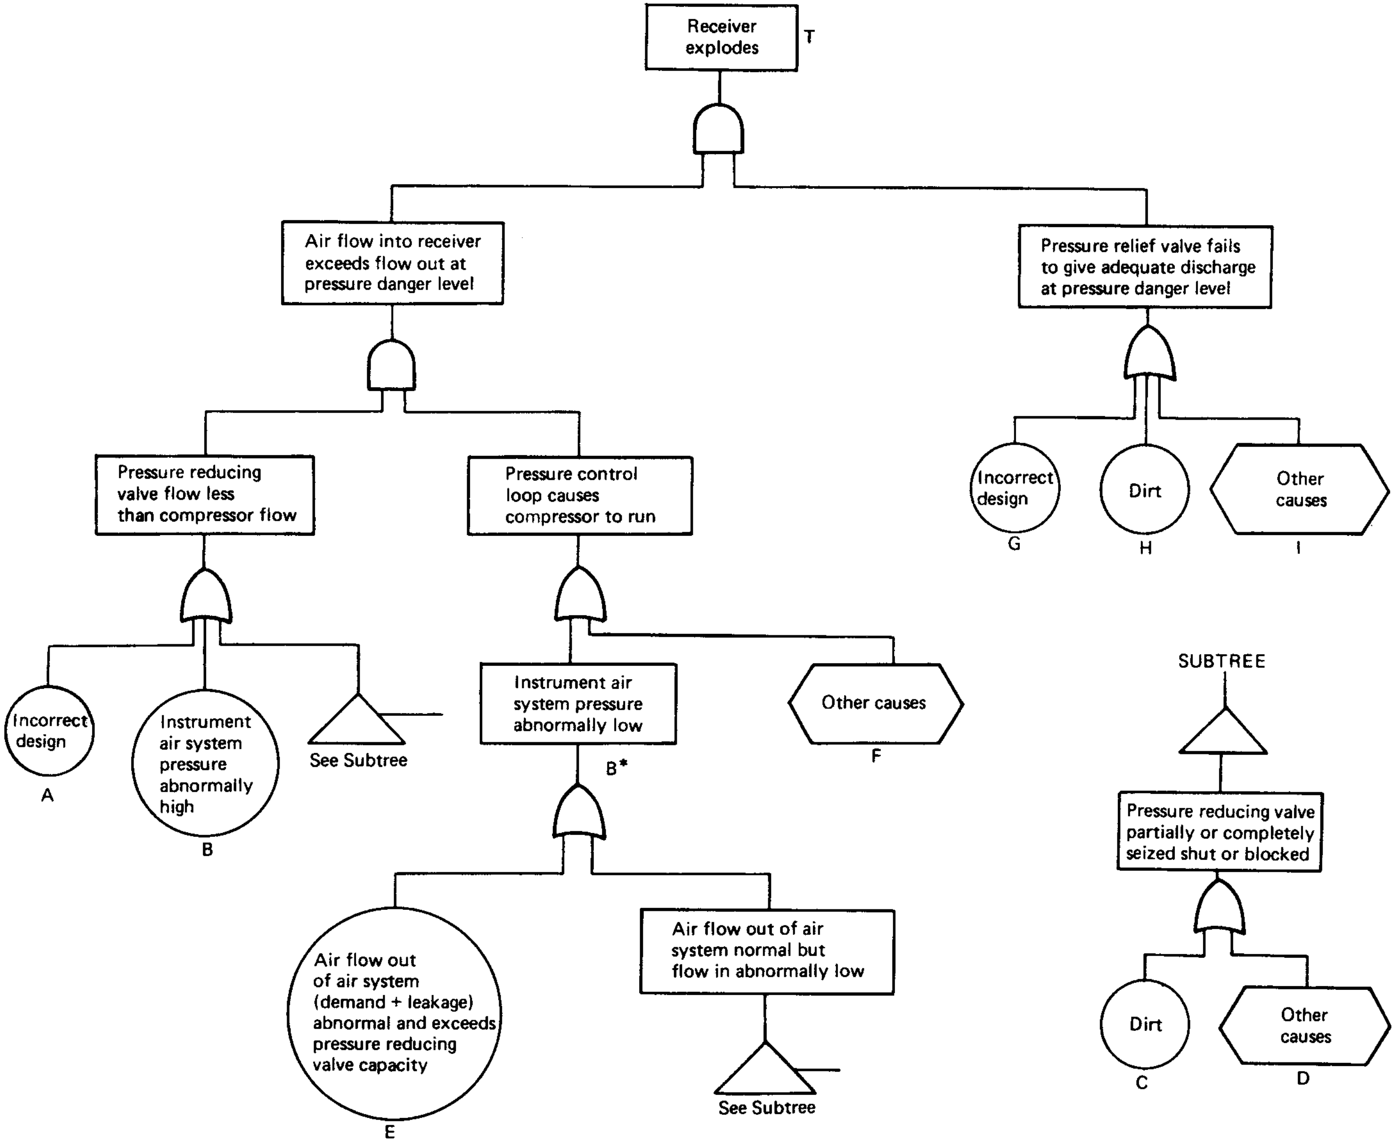
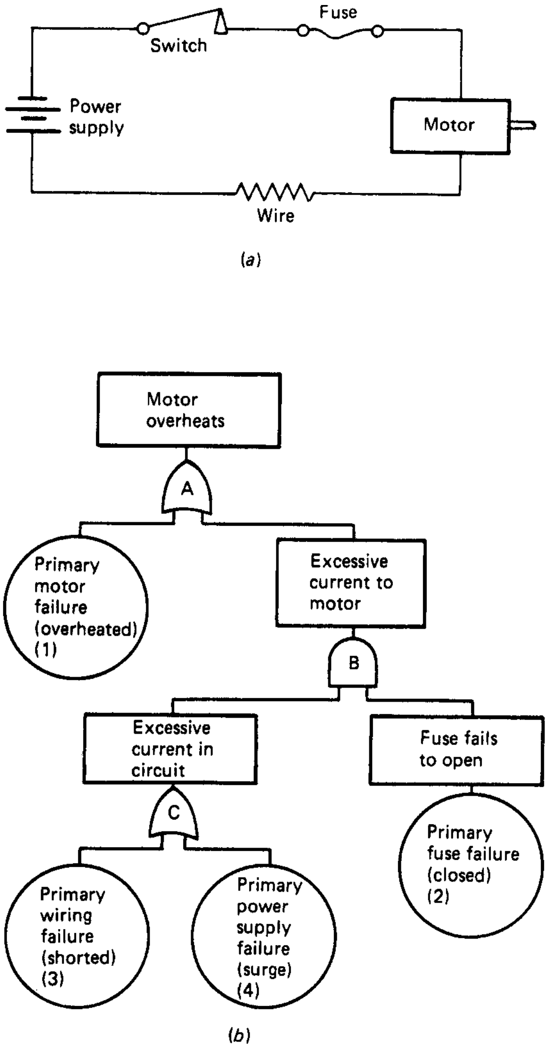


(b)

Figure 9.3 *Instrument air receiver system: flow diagram and fault trees for the explosion of an air receiver: (a) instrument air receiver system; (b) fault tree for top event 'Receiver explodes'; (c) equivalent but simplified fault tree for top event 'Receiver explodes'*



(*a*)

(*b*)

Figure 9.4 *Motor system: system diagram and fault tree for overheating of the motor (Fussell, 1976): (a) motor system; and (b) fault tree for top event 'Motor overheats' (Courtesy of the Sijthoff and Noordhoff International Publishing Company)*

The procedure is based on successive elimination of the gates. The analysis starts with a matrix containing the first gate, gate A, in the top left-hand corner:

A	

A is an OR gate and is replaced by its inputs listed vertically:

1	
B	

B is an AND gate and is replaced by its inputs listed horizontally:

1	
C	2

C is an OR gate and is replaced by its inputs listed vertically:

1	
4	2
3	2

It should be noted that when C is replaced by 4 and 3, the event 2, which is linked to C by an AND gate, is listed with both events 4 and 3. The minimum cut sets are then:

(1); (4,2); (3,2)

There are now a large number of methods available for the determination of the minimum cut sets of a fault tree. Methods include those described by Vesely (1969, 1970b), Gangadharan, Rao and Sundararajan (1977), Zipf (1984) and Camarinopoulos and Yllera (1985).

There are also a number of computer codes for minimum cut set determination. One of the most commonly used is the code set PREP and KITT. Another widely used minimum cut set code is FTAP.

9.5.9 Coherence of tree

The structure of a fault tree is either coherent or non-coherent. The property of coherence has been developed by Esary and Proschan (1963) as follows.

They define a structure function $\phi(\mathbf{x})$ such that it has three properties.

Property 1:

$$\phi(\mathbf{x}) \geq \phi(\mathbf{y}) \qquad \mathbf{x} \geq \mathbf{y} \qquad [9.5.7]$$

Property 2:

$$\phi(\mathbf{x}) = 1 \qquad \mathbf{x} = 1 \qquad [9.5.8]$$

Property 3:

$$\phi(\mathbf{x}) = 0 \qquad \mathbf{x} = 0 \qquad [9.5.9]$$

where $\mathbf{x}$ is the vector $[x_1, x_2, \ldots, x_n]$ and $\mathbf{y}$ the vector $[y_1, y_2, \ldots, y_n]$. For each component i, x_i has the value 1 if the component is functioning and 0 if it is failed; $\mathbf{x} \geq \mathbf{y}$ signifies $x_i \geq y_i$ for all i. A structure that has such a structure function is coherent or monotonic. In plain language, this means that:

(1) *Property 1* If sufficient components are functioning for the system to be functioning, the functioning of an additional component will not cause the system to fail; and if sufficient components are failed for the system to be failed, the failure of an additional com-ponent will not cause the system to function.
(2) *Property 2* If all the components are functioning, the system is functioning.
(3) *Property 3* If all the components are failed, the system is failed.

Coherence is of interest to reliability engineers because, given the property of coherence, it is possible to derive a number of useful relationships for bounds on the behaviour of large systems.

For fault trees the property of coherence depends partly on the logic gates and partly on the events. A fault tree structure which consists exclusively of AND and OR gates is generally coherent, but one which includes other types of gate may not be. Thus the presence of an EXCLUSIVE OR gate can render a structure non-coherent. For example for a two-input EXCLUSIVE OR gate, if one input fault to the gate exists, the output fault exists, but if a second input fault occurs, the output fault disappears.

However, coherence is also affected by the nature of the events. A structure that contains a secondary failure is generally non-coherent. As already described, a secondary failure is one that occurs because the component is overstressed. This component is not necessarily restored by restoration of the other components.

An EXCLUSIVE OR gate was used in the classic nitric acid cooler problem considered by Lapp and Powers (1977a, 1979), which has been the subject of comment by Locks (1979) and others. A review of non-coherent structure and its bearing on fault tree work has been given by Johnston and Matthews (1983 SRD R245).

9.5.10 Fault trees and digraphs

A fault tree is one type of model of the propagation of faults in a process plant. The construction of the tree may be aided by the use of other models of fault propagation. A widely used method of constructing fault trees is to develop first a directed graph, or digraph, representing the fault propagation in the plant. A single digraph may be used to construct a number of fault trees, depending on the top events selected. Accounts of the use of digraphs for fault tree construction include those by Lambert (1975), Lapp and Powers (1977a, 1979), Chamow (1978), Andrews and Morgan (1986) and Kohda and Henley (1988).

9.5.11 Fault tree evaluation

A fault tree is a graphical representation of the fault paths and logic of a system and is of value as such. There are, however, a number of methods of fault tree evaluation that greatly enhance its utility. These methods are both qualitative and quantitative.

Qualitative evaluation is largely based on the determination of the minimum cut sets. The minimum cut sets and methods for their determination have been described in Section 9.5.8. One form of qualitative evaluation that is particularly useful is the determination of the importance of the primary events. This is described in Section 9.5.12.

Quantitative evaluation of a fault tree requires that numbers be put to the frequency or probability of the primary events. Given these quantitative data, there are several options for the evaluation of the frequency or probability of the top event.

Three methods of evaluation are considered here. These are the use of (1) the minimum cut sets, (2) the gate-by-gate method and (3) Monte Carlo simulation.

In the first of these methods, the probability of the top event may be evaluated from the probabilities of the minimum cut sets C_i

$$P(\mathrm{T}) = P\left(\bigcup_{i=1}^{n} \mathrm{C}_i\right) \qquad [9.5.10]$$

The events are not mutually exclusive and, therefore, strictly

$$\begin{aligned} P(\mathrm{T}) = {} & P(\mathrm{C}_1) + P(\mathrm{C}_2) + \cdots + P(\mathrm{C}_n) - P(\mathrm{C}_1)P(\mathrm{C}_2) \\ & - P(\mathrm{C}_1)P(\mathrm{C}_3) - \cdots - P(\mathrm{C}_{n-1})P(\mathrm{C}_n) \\ & + P(\mathrm{C}_1)P(\mathrm{C}_2)P(\mathrm{C}_3) + P(\mathrm{C}_1)P(\mathrm{C}_2)P(\mathrm{C}_4) \\ & + \cdots + P(\mathrm{C}_{n-2})P(\mathrm{C}_{n-1})P(\mathrm{C}_n) \\ & + \cdots + (-1)^{n-1} \prod_{i=1}^{n} P(\mathrm{C}_i) \qquad [9.5.11] \end{aligned}$$

But usually it is sufficient to use the low probability, or rare event, approximation

$$P(\mathrm{T}) = \sum_{i=1}^{n} P(\mathrm{C}_i) \qquad [9.5.12]$$

Equation 9.5.12 always gives a higher probability than Equation 9.5.11 and thus for failure oriented logic it is conservative.

As an illustration, consider the evaluation of the probability of the top event in the fault tree for the instrument air receiver system as given in Figure 9.3(c). The minimum cut sets have been listed above. Assume that

$P_\mathrm{A} = 10^{-5}$ $\quad P_\mathrm{D} = 2 \times 10^{-3}$ $\quad P_\mathrm{G} = 10^{-3}$
$P_\mathrm{B} = 3 \times 10^{-5}$ $\quad P_\mathrm{E} = 10^{-3}$ $\quad P_\mathrm{H} = 8 \times 10^{-3}$
$P_\mathrm{C} = 2 \times 10^{-3}$ $\quad P_\mathrm{F} = 5 \times 10^{-4}$ $\quad P_\mathrm{I} = 2 \times 10^{-3}$

Then, for the first minimum cut set AEG,

$$\begin{aligned} P(\mathrm{C}_1) &= P_\mathrm{A} P_\mathrm{E} P_\mathrm{G} \\ &= 10^{-5} \times 10^{-3} \times 10^{-3} \\ &= 10^{-11} \end{aligned}$$

and so on for the other 14 cut sets. Alternatively, from Equation 9.5.12,

$$
\begin{aligned}
P(\mathrm{T}) = \sum_{i=1}^{n} P(\mathrm{C}_i) &= [P_\mathrm{A}(P_\mathrm{E} + P_\mathrm{F}) + P_\mathrm{B}P_\mathrm{F} + P_\mathrm{C} + P_\mathrm{D}] \\
&\quad \times (P_\mathrm{G} + P_\mathrm{H} + P_\mathrm{I}) \\
&= [10^{-5}(10^{-3} + 5 \times 10^{-4}) \\
&\quad + (3 \times 10^{-5} \times 5 \times 10^{-4}) \\
&\quad + (2 \times 10^{-3} + 2 \times 10^{-3})] \\
&\quad \times (10^{-3} + 8 \times 10^{-3} + 2 \times 10^{-3}) \\
&= 4.4 \times 10^{-5}
\end{aligned}
$$

This form of the minimum cut set method is applicable where the occurrence of the primary events can be characterized by simple probabilities. More commonly the occurrence of these events is characterized by a mix of frequencies and probabilities. Furthermore, it may be necessary to take into account repair of components. An account of an approximate method of handling systems in which event rates are expressed as frequencies and which involve repair is given in Section 9.5.15.

The second method is to work up the tree gate-by-gate from the bottom calculating the frequency or probability of the output event of each gate from those of the input events. The procedure is straightforward except where there occur at the gate, some input faults which are expressed in terms of frequency rather than probability.

The output–input relations which are permitted and those that are not are given for a two-input gate in Table 9.6, Section B. The main problem arises where the two inputs to an AND gate both have the dimensions of frequency. The output from the gate must also have the dimension of frequency. It is not permissible to multiply the two frequencies together.

The handling of an AND gate where the two inputs both have the dimension of frequency is discussed in Section 9.5.4. Two main situations occur: one is where both the components whose faults are the inputs to the gate are operating, and the other is where one component is operating and the other is on standby. As indicated in the Section 9.5.4, both situations can be handled by the use of suitable models derived from Markov modelling.

Use may also be made of the alternative model given in Equations 7.8.28–7.8.31, which in effect utilizes a repair time to convert one of the frequencies to a fractional downtime, or probability.

Accounts of the gate-by-gate method are given in the CCPS *QRA Guidelines* and by Doelp *et al.* (1984). The method is illustrated in the fault trees given by Lawley (1974b, 1980), one of which is described in Section 9.5.14.

There are advantages and disadvantages to both the gate-by-gate and minimum cut set methods. The former is the method traditionally used in manual evaluation of trees. It gives an evaluation of all the intermediate events as well as of the top event, which can be valuable. On the other hand, it tends to be error prone and becomes tedious for large trees.

The third method is the use of Monte Carlo simulation. The basic principle of this method has been described in Chapter 7. Its application to fault tree evaluation involves a series of trials. In a given trial each primary event either does or does not occur, the occurrence being determined by sampling, where the values returned by the sampling are, on average, in accordance with the frequency or probability data supplied. The outcome of each trial is the occurrence or non-occurrence of the top event. Provided a sufficient number of trials are used, the frequency or probability of the top event is then given by the proportion of trials in which it occurs. An account of the use of this method for fault tree evaluation has been given by Hauptmanns and Yllera (1983).

The use of Monte Carlo simulation is virtually unavoidable if the primary events are characterized by a range of values of probability, or frequency. The probability of a failure may be given not by a point probability value but by a probability density function. Obviously if the probabilities of the other events are expressed as density functions, then the probability of the top event must be expressed as a density function also.

A given Monte Carlo trial generates a set of probabilities for the primary failure events. The probability of the top event may then be evaluated by an analytical method, such as the minimum cut set method. The result of the series of trials is a probability density function for the top event. The principle of the method is illustrated in Figure 9.5. Monte Carlo simulation was used extensively for fault tree evaluation in the *Rasmussen Report*.

9.5.12 Importance of events

Since the number of primary events that, either serially or in combination, can cause the top event to occur can be large, it is very desirable to have means of assessing their relative significance. Primary events have the property of 'importance'. There are a number of measures of importance. Some of these rely solely on structural considerations, while others are based on probabilities. In other words, there are both qualitative and quantitative measures.

A simple approach to structural importance may be illustrated by the following minimum cut sets of events given in Section 9.5.8: (1); (4, 2); (3, 2).

The order of importance is then: events in one-event minimum cuts, events common to two-event minimum cut sets, events in two-event minimum cut sets, and so on. Thus, in the example given, the order of importance is:

1
2
3,4

There are a number of quantitative measures of importance that may be calculated if frequency or probability data are available. These include the Birnbaum criterion, which is the incremental reduction in the probability of the top event where the probability of the primary event is reduced incrementally, and the Vesely–Fussell criterion, which is the probability that a cut set containing the primary event has occurred given that the top event has occurred.

Formal methods of determining importance have been given by Lambert and Oilman (1977a,b), who have developed the computer code IMPORTANCE for such analysis.

9.5.13 Illustrative example: pressure tank system

As another illustration, consider the fault tree for the pressure tank system described by Vesely *et al.* (1981).

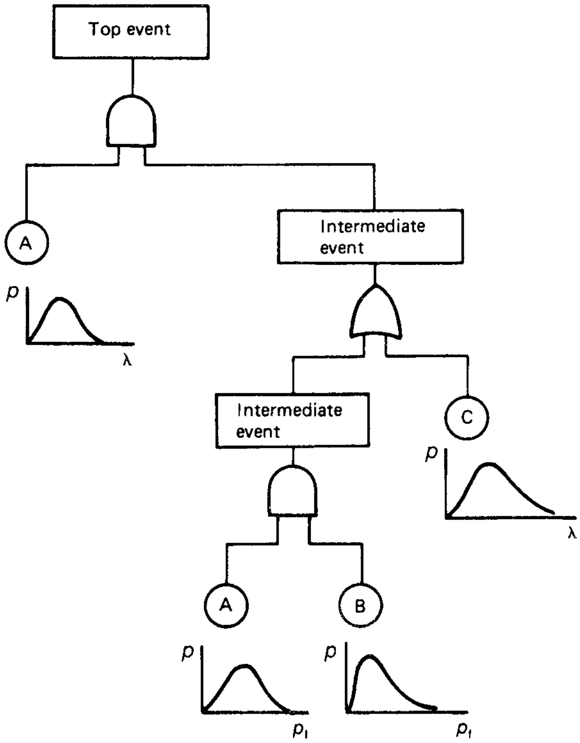


Figure 9.5 *Fault tree illustrating the principle of probabilities expressed in the form of density functions and of evaluation by Monte Carlo simulation, λ, Failure frequency; p_f, failure probability; p, probability of given value of λ or p_f*

This system is shown in Figure 9.6. The authors describe the system as follows:

> The function of the control system is to regulate the operation of the pump. The latter pumps fluid from an infinitely large reservoir into the tank. We shall assume that it takes 60 seconds to pressurize the tank. The pressure switch has contacts that are closed when the tank is empty. When the threshold pressure has been reached, the pressure switch contacts open, removing power from the pump, causing the pump motor to cease operation. The tank is fitted with an outlet valve that drains the entire tank in a negligible time; the outlet valve, however, is not a pressure relief valve. When the tank is empty, the pressure switch contacts close and the cycle is repeated.
>
> Initially the system is considered to be in its dormant mode: switch S1 contact open, relay K1 contacts open, and relay K2 contacts open: i.e., the control system is de-energized. In this de-energized state the contacts of the timer relay are closed. We will also assume that the tank is empty and the pressure switch contacts are therefore closed.
>
> System operation is started by momentarily depressing switch S1. This applies power to the coil of relay K1, thus closing relay K1 contacts. Relay K1 is now electrically self-latched. The closure of relay K1 contacts allows power to be applied to the coil of relay K2, whose contacts close to start up the pump motor.
>
> The timer relay has been provided to allow emergency shutdown in the event that the pressure switch fails closed. Initially the timer relay contacts are closed and the timer relay coil is de-energized. Power is applied to the timer coil as soon as relay K1 contacts are closed. This starts a clock in the timer. If the clock registers 60 seconds of *continuous* power application to the timer relay coil, the timer relay contacts open (and latch in that position), breaking the circuit to the K1 relay coil (previously latch closed) and thus producing system shutdown. In normal operation, when the pressure switch contacts open (and consequently relay K2 contacts open), the timer resets to 0 seconds.

The top event considered is 'Rupture of pressure tank after the start of pumping'. The fault tree developed by Vesely *et al.* for this event is shown in Figure 9.7. The detailed development of this fault tree is described by Vesely *et al.* and need not be given here, but the following points may be noted.

If the undeveloped events are disregarded, this fault tree reduces to that indicated by the events E1–E5, K1, K2, R, S, S1 and T shown in Figure 9.7. The top event E1 and the intermediate events E2–E5 in this tree are:

E1	pressure tank rupture
E2	excessive pressure to tank
E3	current to K2 relay coil for too long
E4	circuit B carries current for too long
E5	current to K1 relay coil for too long

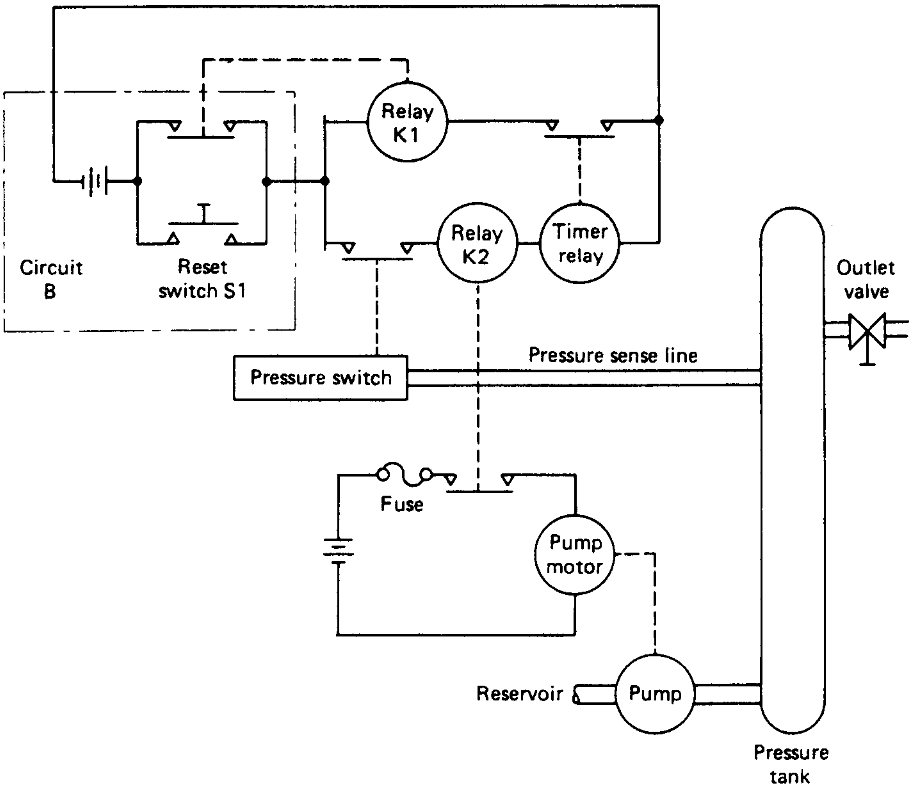

Figure 9.6 *Pressure tank system: system diagram (Vesely et al., 1981)*

E2 is equivalent to K2 relay contacts closed for too long, and E5 to timer relay contacts failing to open when pressure switch contacts have been closed for too long. The cut sets for the top event of this fault tree may be obtained by applying Boolean algebra. Starting with the top event E1:

$$
\begin{aligned}
\mathrm{E1} &= \mathrm{T} + \mathrm{E2} \\
&= \mathrm{T} + (\mathrm{K2} + \mathrm{E3}) \\
&= \mathrm{T} + \mathrm{K2} + (\mathrm{S} \cdot \mathrm{E4}) \\
&= \mathrm{T} + \mathrm{K2} + \mathrm{S} \cdot (\mathrm{S1} + \mathrm{E5}) \\
&= \mathrm{T} + \mathrm{K2} + (\mathrm{S} \cdot \mathrm{S1}) + (\mathrm{S} \cdot \mathrm{E5}) \\
&= \mathrm{T} + \mathrm{K2} + (\mathrm{S} \cdot \mathrm{S1}) + \mathrm{S} \cdot (\mathrm{K1} + \mathrm{R}) \\
&= \mathrm{T} + \mathrm{K2} + (\mathrm{S} \cdot \mathrm{S1}) + (\mathrm{S} \cdot \mathrm{K1}) + (\mathrm{S} \cdot \mathrm{R})
\end{aligned}
$$

There are therefore five minimal cut sets: T, K2, (S·S1), (S·K1) and (S·R).

Analysis of the tree at this stage gives qualitative information about the design of the system. The pressure tank system has in effect a single protective device, the timer relay, which protects against failure of the pressure switch. This is reflected in the fault tree which has a single AND gate.

With regard to the qualitative importance of the events, K2 and T both occur in single event cut sets, but K2 is an active failure and T a passive one, and hence K2 ranks higher than T. Events S, S1, K1 and R each occur in two-event cut sets, but of these S occurs in all three cut sets, whereas the other three faults each occur only in one cut set and hence S ranks higher than the other three, which all rank equally. The order of importance is thus: K2; T; S; and S1, K1 and R.

The failure probabilities given by Vesely *et al.* are:

Component	*Symbol*	*Failure probability*
Pressure	T	5×10^{-6}
Relay K2	K2	3×10^{-5}
Pressure	S	1×10^{-4}
Relay Kl	K1	3×10^{-5}
Timer relay	R	1×10^{-4}
Switch SI	S1	3×10^{-5}

Then the probabilities of the minimum cut sets are:

$$P(\mathrm{T}) = 5 \times 10^{-6}$$

$$P(\mathrm{K2}) = 3 \times 10^{-5}$$

$$P(\mathrm{S} \cdot \mathrm{K1}) = 1 \times 10^{-4} \times 3 \times 10^{-5} = 3 \times 10^{-9}$$

$$P(\mathrm{S} \cdot \mathrm{R}) = 1 \times 10^{-4} \times 1 \times 10^{-4} = 1 \times 10^{-8}$$

$$P(\mathrm{S} \cdot \mathrm{S1}) = 1 \times 10^{-4} \times 3 \times 10^{-5} = 3 \times 10^{-9}$$

and the probability of the top event is the sum of these

$$P(\mathrm{E1}) = 3.5 \times 10^{-5}$$

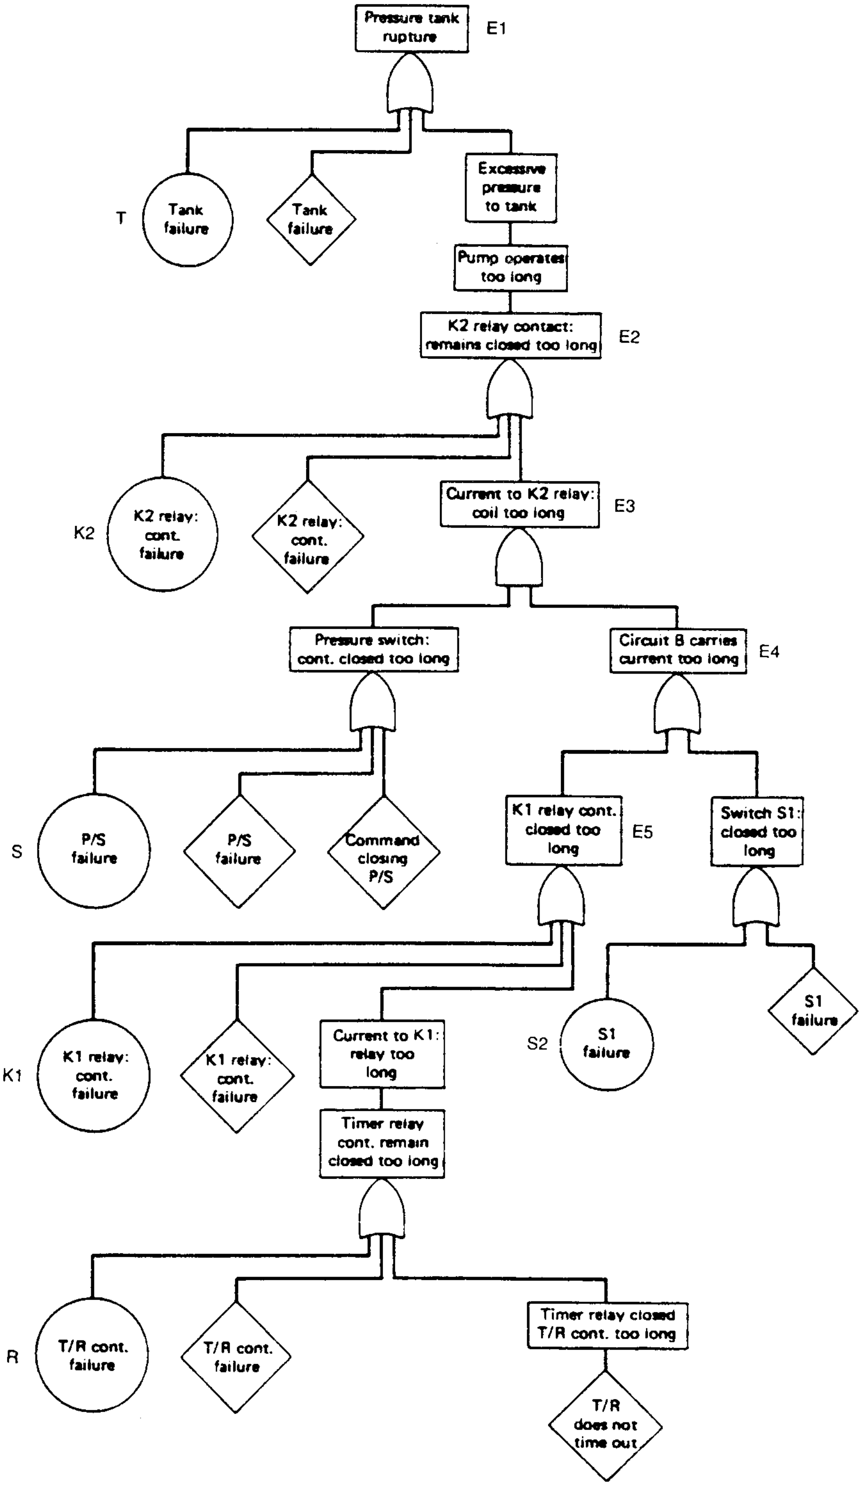

Figure 9.7 *Pressure tank system: fault tree for rupture of pressure tank (after Vesely et al., 1981; Henley and Kumamoto, 1981)*

The contribution of these minimum cut sets to the top event is a measure of their quantitative importance, and is:

Cut set	*Importance* (%)
T	14
K2	86
Other	<0.1

9.5.14 Illustrative example: crystallizer system

As a third illustrative example, consider the proposed crystallization plant system described by Lawley (1974b). This system is shown in Figure 9.8. The problem is to estimate the expected frequency of emission of the toxic and corrosive crystallizer slurry via the stack to the atmosphere. There are two ways in which this can occur – by discharge at about atmospheric pressure or by discharge at high pressure – but only the former is considered here. If the stack base and luted drain are properly designed for the flow from the three reactors, a discharge of slurry at only a few pounds per square inch pressure would normally pass via the pressure control valve (PCV) header or the relief header to the stack and hence to the drain. If a blockage occurs in the stack or the drain, the discharge from the crystallizer will result in a build-up of liquid in the stack and eventually to entrainment of the slurry to the atmosphere.

The top event considered is 'Low pressure discharge of slurry to the atmosphere'. The fault tree developed by the author for this event is shown in Figure 9.9. The tree is constructed by working from the top-down, but it is convenient here to explain it from the bottom-up. The level in No. 1 crystallizer can rise only if the outflow to No. 2 crystallizer is restricted. This can occur in three ways:

(1) Discharge line choked with slurry; frequency estimated from plant experience of similar materials, 5 occasions/year.
(2) Crystallizer level control valve (LCV) on discharge line shut or misdirected shut; frequency estimated from literature data, 0.5 occasions/year.
(3) Manual isolation valve on discharge line shut in error; frequency estimated from general plant experience, 0.1 occasions/year.

Thus the estimated frequency of restricted outflow is 5.6 occasions/year. The level will continue to rise only if:

(1) The operator fails to take action opposite a rising level signal; frequency estimated 4% of occasions.
(2) The level meter fails dangerous; failure rate estimated 2 failures/year, downtime 4 h/failure, dead time $2 \times 4 = 8$ h/year, fractional dead time $8/8760 \approx 0.1\%$ of time.

The slurry will only overflow into the PCV header and thence to the stack if

(1) The operator fails to take action opposite a high-level alarm signal; frequency estimated 3% of occasions.
(2) The high level alarm fails dangerous; fractional dead time estimated 1.25% of time.

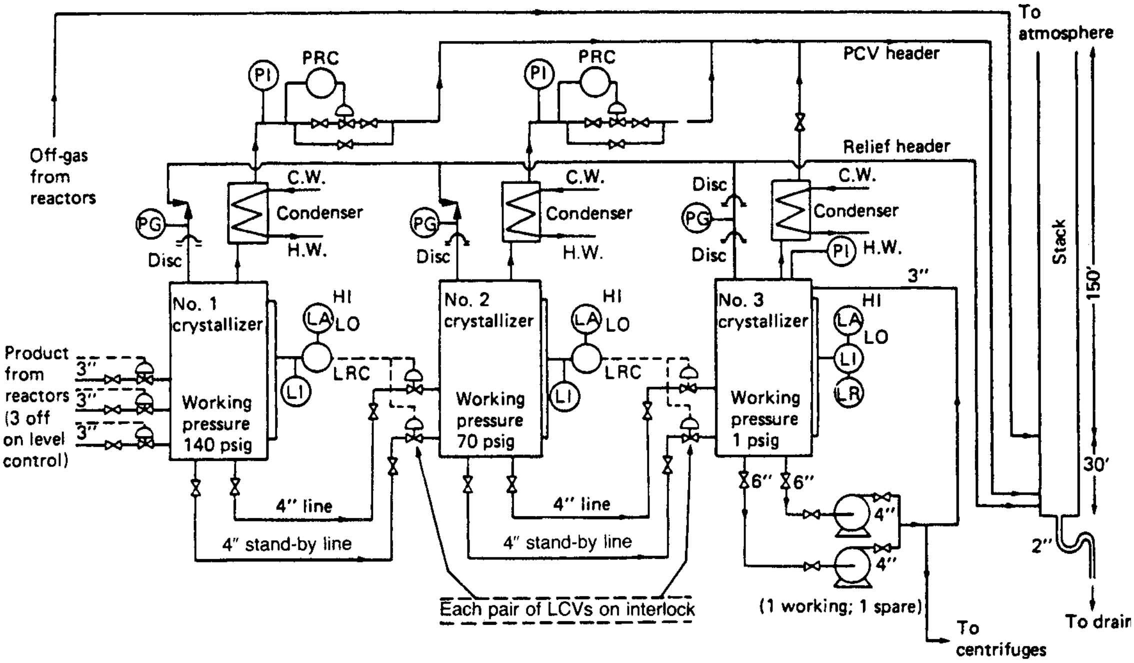

Figure 9.8 *Proposed crystallization plant: flow diagram (Lawley, 1974b) CW, cold water; HI, high; HW, hot water; LA, Level alarm; LO, low; LRC, level recorder controller; PCV, pressure control valve; PG, pressure gauge; PI, pressure indicator; PRC, pressure recorder controller (Courtesy of the American Institute of Chemical Engineers)*

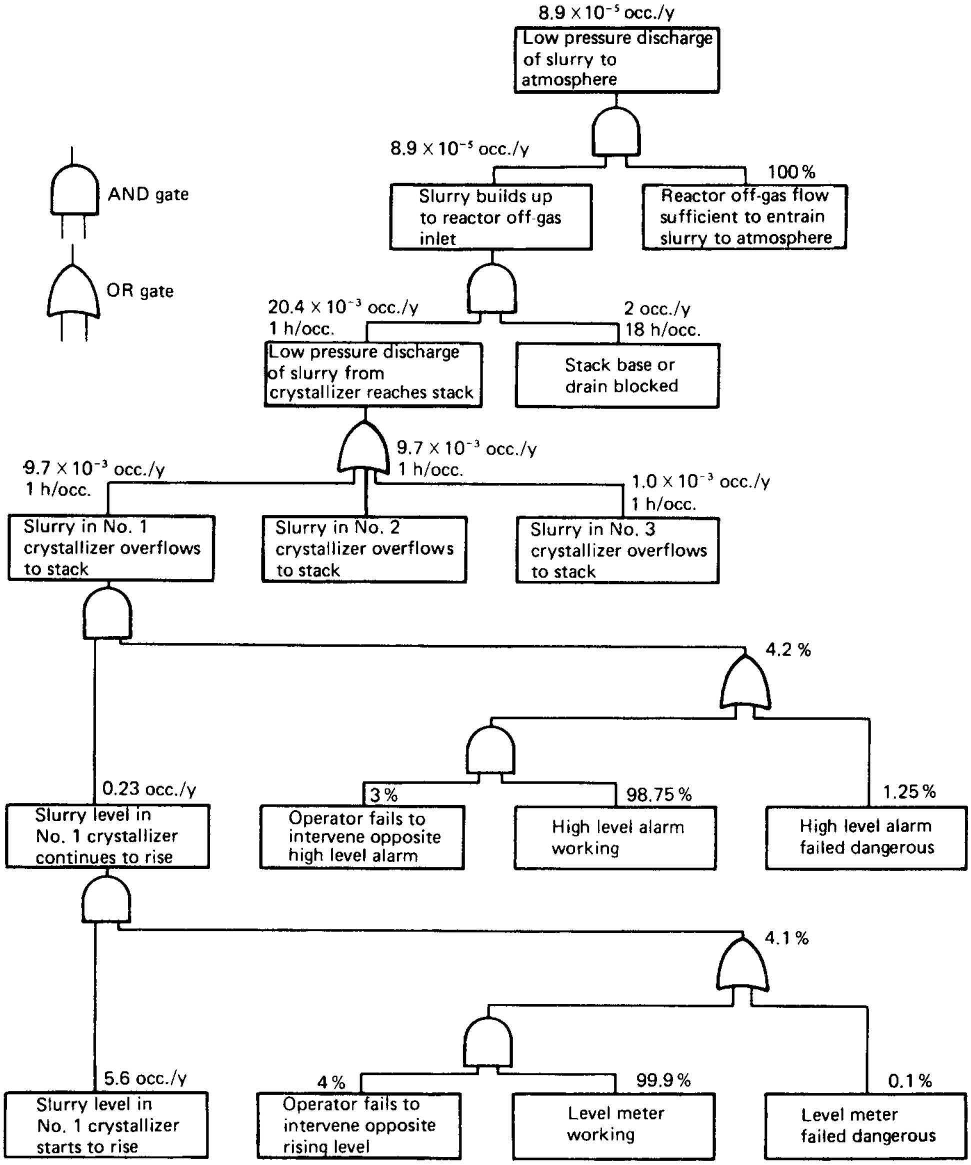

Figure 9.9 *Proposed crystallization plant: fault tree for low pressure discharge of crystallizer slurry to stack and entrapment to atmosphere (Lawley, 1974b) (Courtesy of the American Institute of Chemical Engineers)*

This fractional dead time calculation is as follows. The failure rate of the high level alarm (excluding the meter) is estimated as 0.2 failures/year and the proof test interval is 6 weeks. Thus the fractional dead time is:

$$\frac{1}{2}\times 0.2\times\frac{6}{52} = 1.15\times 10^{-2}$$
$$= 1.15\%$$

The fractional dead time of the meter has already been given as 0.1%. Thus the fractional dead time of the level meter and the high level alarm together is 1.25%.

If the slurry overflows, it is assumed that it continues to pass to the stack for up to 2 h maximum and thus for 1 h/occasion, on average.

Similarly, the level in No. 2 crystallizer can rise only if the outflow to No. 3 crystallizer is restricted. The treatment is identical to that for No. 1 crystallizer.

The level in No. 3 crystallizer can rise only if the outflow is restricted. This can occur in four ways:

(1) Discharge line or centrifuge feed line blocked; frequency estimated from plant experience of similar materials, 0.2 occasions/year.
(2) Failure of online circulation pump followed by failure to commission standby circulation pump in time; frequency estimated, 0.1 occasion/year.
(3) The operator fails to reduce the feed to the reaction section when there are problems on the centrifuges; frequency estimated 0.2 occasions/year.
(4) Manual isolation valve on discharge line shut in error; frequency estimated 0.1 occasion/year.

Thus the estimated frequency of restricted outflow is 0.6 occasions/year.

Since No. 1 crystallizer has restricted outflow on 5.6 occasions/year and overflow on 9.7×10^{-3} occasions/year, No. 3 crystallizer, which has restricted outflow on 0.6 occasions/year, will have overflow on:

$$\frac{0.6}{5.6} \times 9.7 \times 10^{-3} = 1 \times 10^{-3} \text{ occasions/year}$$

Thus the low pressure discharge of slurry from one of the crystallizers reaches the stack via the PCV header on

$$2 \times 9.7 \times 10^{-3} + 1 \times 10^{-3} = 20.4 \times 10^{-3} \text{ occasions/year}$$

Noxious discharge from the top of the stack occurs only if the stack base or drain is blocked. It is estimated that blockage will occur on 2 occasions/year. The stack drain is checked for blockage once per day so that, on average, a blockage would be unrevealed for 12 h. Allowing 6 h for clearing the blockage gives a mean downtime for the drain of 18 h/occasion. Then the low pressure discharge of slurry to atmosphere is

$$2 \times 20.4 \times 10^{-3}\left(\frac{1+18}{8760}\right) = 8.9 \times 10^{-5} \text{ occasions/year}$$

This is a fairly typical illustration of an industrial fault tree analysis. Some additional examples related to protective systems are given in Chapter 13.

9.5.15 Repairable systems

The treatment given so far has not taken into account the repair of failed components. For lack of exact solutions, approximate treatments have been developed which give the upper bounds on reliability and availability. A method of determining the reliability and availability for the top event that is based on this approach and that is suitable for manual calculation has been described by Fussell (1975).

The method is based on the crucial minimum cut sets, or collection of minimum cut sets that can be taken as adequately representing for quantitative evaluations the top event fault logic. It utilizes the rare event approximation, the principal condition being $0.1 < \lambda_i t$, where λ_i, is the failure rate of component i. The account given here is confined to the presentation of the results obtained by Fussell; full derivations are given by that author.

For the primary events:

$$\bar{r}_i \le \lambda_i t \quad \text{non-repairable and repairable components} \qquad [9.5.13]$$

$$\bar{a}_i \le \lambda_i t \quad \text{non-repairable components} \qquad [9.5.14a]$$

$$= r_i \qquad [9.5.14b]$$

$$\bar{a}_i \le \lambda_i \tau_i \quad \text{repairable components} \qquad [9.5.15]$$

where, for component i, a_i and $\bar{a}_i$ are the availability and unavailability, r_i and $\bar{r}_i$ the reliability and unreliability, and λ_i, is the failure rate and τ is the restoration time. For the minimum cut sets:

$$\bar{A}_k = \sum_{i=1}^{n_k} \bar{a}_i \qquad [9.5.16]$$

$$f_k \le \bar{A} \sum_{i=1}^{n_k} \frac{\lambda}{\bar{a}_i} \qquad [9.5.17]$$

$$\bar{R}_k = \int_0^t f_k(t')\mathrm{d}t' \qquad [9.5.18]$$

$$\Lambda_k = f_k/\bar{R} \qquad [9.5.19]$$

And for the top event

$$\bar{A}_t \le \sum_{k=1}^{N} \bar{A}_k \qquad [9.5.20]$$

$$\bar{R}_t \le \sum_{k=1}^{N} \bar{R}_k \qquad [9.5.21]$$

$$\Lambda_t \approx \sum_{k=1}^{N} \bar{\Lambda}_k \qquad [9.5.22]$$

where, $\bar{A}$ is the unavailability, f the failure density function, $\bar{R}$ the unreliability, Λ the failure rate, n_k the number of primary events in minimum cut set k, and N the number of crucial minimum cut sets; subscripts k and t refer to the minimum cut set and top event, respectively. For importance:

$$I_{ia} \approx \left(\sum_{k=1}^{m_i} \bar{A}_k\right) \Big/ \bar{A}_t \qquad [9.5.23]$$

$$I_{ir} \approx \left(\sum_{k=1}^{m_i} \bar{R}_k\right) \Big/ \bar{R}_t \qquad [9.5.24]$$

where, for event i, $I_{i\mathrm{a}}$ is the importance with respect to availability and $I_{i\mathrm{r}}$ is the importance with respect to reliability, and m_i is the number of minimum cut sets containing event i.

9.5.16 Illustrative example: pump set system

As a fourth illustrative example, consider the use of the relationships just given to determine the reliability of a pump set, consisting of two streams, each with a pump and a control valve (CV).

The basic components, their failure rates and restoration times, and hence their unavailabilities, obtained from

Equation 9.5.15, are:

Component	*Component no.*	*Failure rate,* λ_i (year^{-1})	*Restoration time,* τ_i		*Unavailability,* $\bar{a}_i$
			hours	(years)	
Power supply	1	0.08	1	1.1×10^{-4}	8.8×10^{-6}
Pump 1	2	2	6	6.8×10^{-4}	1.36×10^{-3}
Pump 2	3	2	6	6.8×10^{-4}	1.36×10^{-3}
Control valve 1	4	0.02	3	3.4×10^{-4}	6.8×10^{-6}
Control valve 2	5	0.02	3	3.4×10^{-4}	6.8×10^{-6}

The minimum cut sets are:

Minimum cut set no.	*Component failure no.*
1	1
2	2, 5
3	2, 3
4	3, 4
5	4, 5

Then from Equations 9.5.16 and 9.5.17:

$$f_1 = \bar{a}_1\lambda_1/\bar{a}_1 = \lambda_1 = 0.08$$

$$f_2 = \lambda_2\bar{a}_5 + \lambda_5\bar{a}_2 = 2.86 \times 10^{-5}$$

$$f_3 = \lambda_2\bar{a}_3 + \lambda_3\bar{a}_2 = 5.44 \times 10^{-3}$$

$$f_4 = \lambda_3\bar{a}_4 + \lambda_4\bar{a}_3 = 2.86 \times 10^{-5}$$

$$f_5 = \lambda_4\bar{a}_5 + \lambda_5\bar{a}_4 = 2.72 \times 10^{-7}$$

From Equation 9.5.18 for a time period of one year ($t=1$), $R_k = f_k t$ is numerically equal to f_k. Then, from Equation 9.5.21,

$$\bar{R}_t \leq 0.085$$

9.5.17 Phased mission systems

In some cases the system passes through more than one phase of operation. Such a system is referred to as a 'phased mission system'. Typically, phased mission systems occur where the same equipment is used at different times in different configurations for different tasks.

Certain emergency core cooling systems (ECCSs) in US nuclear reactors are phased mission systems. After a loss-of-coolant accident (LOCA) the ECCS may have to go through the phases of (1) initial core cooling, (2) suppression pool cooling, and (3) residual heat removal (Burdick *et al.*, 1977). Similarly, on certain liquefied natural gas (LNG) installations the same equipment is used in different modes for normal operation and peak load operation.

In effect, therefore, the top event of the fault tree for a phased mission system is the output of an OR gate, the inputs to which are the top events of the several phases of the mission. This particular OR gate differs, however, from the conventional type in that its inputs are separated in time.

Although a phased mission system can be treated by constructing fault trees for the separate phases, there are certain problems which arise at the boundaries. Such a treatment is not conservative.

For non-repairable systems only, Esary and Ziehms (1975) have developed a transformation that converts the fault tree under the special type of OR gate just mentioned to a conventional fault tree. This transformation is not applicable, however, to repairable systems.

9.5.18 Protective systems

A large proportion of fault tree applications are for protective systems. The determination of the characteristics of systems of this type is therefore of particular interest. A treatment of this problem has been given by Kumamoto, Inoue and Henley (1981). The method given treats the system as a whole rather than the individual protective devices.

The states of the system are: 0, operational; 1, under a normal trip; 2, under a spurious trip; and 3, subject to destructive hazard. The system may then be described by the following equations:

$$\omega_{01}(t) = f_{01}(t,0) + \int_0^t f_{01}(t,u)[v_{10}(u) + v_{20}(u)]\,\mathrm{d}u \qquad [9.5.25]$$

$$\omega_{02}(t) = f_{02}(t,0) + \int_0^t f_{02}(t,u)[v_{10}(u) + v_{20}(u)]\,\mathrm{d}u \qquad [9.5.26]$$

$$\omega_{03}(t) = f_{03}(t,0) + \int_0^t f_{02}(t,u)[v_{10}(u) + v_{20}(u)]\,\mathrm{d}u \qquad [9.5.27]$$

with

$$v_{10}(u) = \omega_{01}(u - \tau_\mathrm{n}) \qquad [9.5.28]$$

$$v_{20}(u) = \omega_{02}(u - \tau_\mathrm{s}) \qquad [9.5.29]$$

where: $F_{0j}(t, u)$ is the probability at time t that the system is in state j given that it entered state 0 at time u; $f_{0j}(t, u)$ is the time differential of $F_{0j}(t, u)$; $v_{j0}(t)$ is the transition rate, or intensity, at time t from state j to state 0; $w_{0j}(t)$ is the transition rate, or intensity, at time t from state 0 to state j; τ_n is the restoration time after a normal trip; and τ_s is the restoration time after a spurious trip. Then the expected numbers of the transition events are as follows:

$$N_\mathrm{n} = \int_0^t \omega_{01}(u)\,\mathrm{d}u \qquad [9.5.30]$$

$$N_\mathrm{s} = \int_0^t \omega_{02}(u)\,\mathrm{d}u \qquad [9.5.31]$$

$$N_\mathrm{h} = \int_0^t \omega_{03}(u)\,\mathrm{d}u \qquad [9.5.32]$$

where N_h is the number of realized destructive hazards, N_n is the number of normal trips and N_s is the number of spurious trips.

Equations 9.5.25–9.5.27 are solved by numerical integration. The authors have written a code, PROTECT, for this purpose. An application of this method, using PROTECT, has been described by Kumar, Chidambaram and Gopalan (1989).

9.5.19 Fault tree applications

Reviews of work on fault trees have been given by Arendt and Fussell (1981) and W.S. Lee *et al.* (1985). Accounts of industrial application of fault trees include those of Caceres and Henley (1976), Lihou (1980a,b), Pilz (1980a), Prugh (1981, 1982, 1992a) and Schreiber (1982). Some fault tree applications described in the literature are listed in Table 9.7.

9.6 Event Trees

An event tree is used to develop the consequences of an event. It starts with a particular initial event such as a power failure or pipe rupture and is developed from the bottom-up. The event tree is both a qualitative and a quantitative technique. Qualitatively it is used to identify the individual outcomes of the initial event, while quantitatively it is used to estimate the frequency or probability of each outcome.

An event tree is constructed by defining an initial event and the possible consequences that flow from this. The initial event is usually placed on the left and branches are drawn to the right, each branch representing a different sequence of events and terminating in an outcome. The main elements of the tree are event definitions and branch points, or logic vertices. The initial event is usually expressed as a frequency (events/year) and the subsequent splits as probabilities (events/demand), so that the final outcomes are expressed also as frequencies (events/year).

Each branch of the event tree represents a particular scenario. The tree is a means of estimating the frequency of the outcome for that scenario. It is used in conjunction with a set of hazard models for the determination of the physical consequences of that scenario. For example, for a flammable release, a typical series of models might be those for emission, gas dispersion, ignition, explosion and explosion injury.

Table 9.7 *Some fault trees for process industry systems*

System	*Reference*
Ethylene oxide plant trip system	R.M. Stewar (1971)
Pressure tank system	Fussell (1973a,b); Vesely *et al.* (1981)
Crystallization plant	Lawley (1974b)
Reactor system	Powers and Tompkins (1974a)
Nitric acid cooler	Lapp and Powers (1977a, 1979); Shaewitz, Lapp and Powers (1977)
Sulfur trioxide reactor	Lambert (1977)
Liquid propane pipeline system	Lawley (1980)
Motor system	Vesely *et al.* (1981)
Distillation column system	Kletz and Lawley (1982)
Power distribution network	Cummings, Lapp and Powers (1983)
Storage tank system	Ozog (1985)
Butane vaporizer system	Andrews and Morgan (1986)

In constructing an event tree, the normal convention is to use binary rather than multiple splits. For example, consider the representation of a release for which the immediate outcomes are that (a) the vapour cloud is ignited at the point of release, (b) it drifts towards housing and (c) it drifts away from housing, where the probabilities p_a, p_b and p_c of these three outcomes are 0.2, 0.2 and 0.6, respectively. Figure 9.10 shows two ways of representing this situation, but it is Figure 9.10(b) that is the preferred form. It should be noted that in this case the probability p_2 is obtained from

$$p_2 = p_b/(1 - p_a) \qquad [9.6.1]$$

In certain cases one event tree can be reduced to another, equivalent event tree. Examples of such reduction have been given by Schreiber (1982).

Figures 9.11–9.13 show event trees for the response of an operator to a nuclear reactor transient, a loss of grid power supply and a release of LPG, respectively. In the plant power supply system analysed in the event tree in Figure 9.12, power is supplied to a plant from the National Grid, but in the event of grid loss a standby generator is started up to supply power. The problem is to estimate the frequency of loss of power to the plant. In the event of diesel failure, a backup power supply is brought in. It is assumed in the example that the frequency of grid loss is 1×10^{-1} events/year, that the probability of diesel failure is 2.1×10^{-2} failures/ demand, made up of 2×10^{-2} failures/demand for start-up and 1×10^{-3} failures/demand for running for the required period, and that the backup power supply failure probability is 1×10^{-2} failures/demand. The event tree shows that the frequency of works power loss is 2.1×10^{-5} events/year.

Figure 9.13 shows an event tree analysis of a release of LPG near a detergent alkylate plant (DAP). The possibilities for the development of the release are then as follows. The release may ignite and, if it does, it will either explode or give a fireball. If it does not ignite, it may be borne by the wind towards the DAP and may then ignite and explode at the DAP. Alternatively, the cloud may drift in some other direction. The estimates are:

Frequency of large LPG release $1 = 68 \times 10^{-6}$/year

Probability of ignition $p_1 = 0.9$

Probability of explosion given ignition $p_2 = 0.1$

Probability of wind to DAP $p_3 = 0.4$

Probability of ignition and explosion at DAP $p_4 = 0.9$

Then the probabilities of the outcomes are:

Probability of hydrogen fluoride (HF) release (independent of wind direction) $p_5 = p_1 p_2 = 0.9 \times 0.1 = 0.09$

Probability of fireball $p_6 = p_1 \times (1 - p_2) = 0.9 \times 0.9 = 0.81$

Probability of HF release drifting north-east $p_7 = (1 - p_1) \times p_3 \times p_4 = 0.1 \times 0.4 \times 0.9 = 0.036$

Probability of drifting cloud $p_{10} = p_8 + p_9 = (1 - p_1) \times [p_3 \times (1 - p_4) + (1 - p_3)] = 0.1 \times (0.4 \times 0.1 + 0.6) = 0.064$

The outcome frequencies are then obtained by multiplying the initial event frequency by these outcome frequencies. Thus

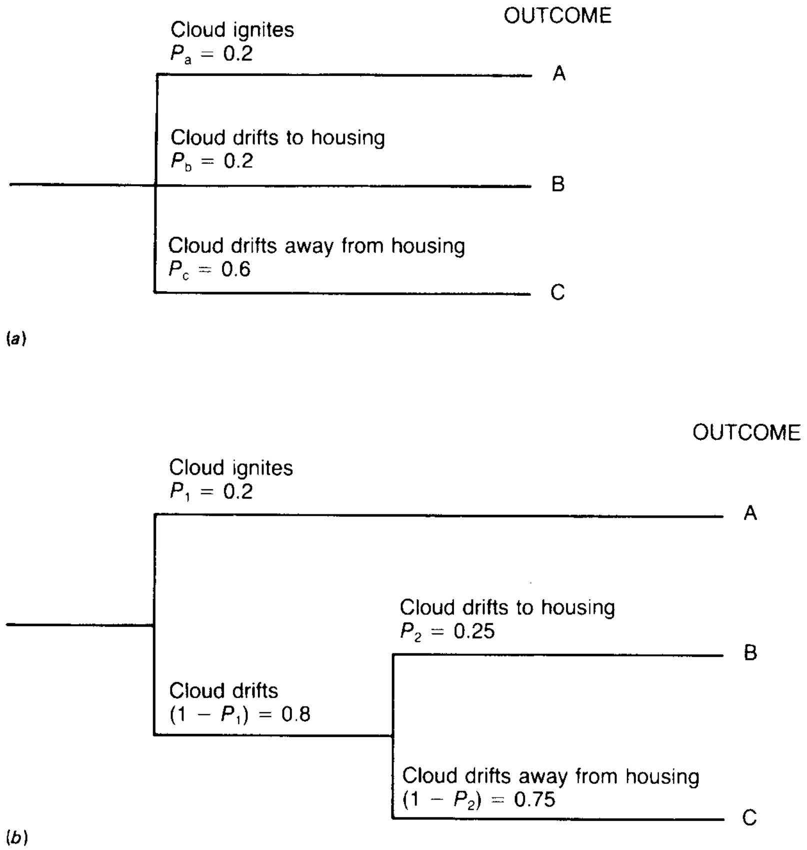

Figure 9.10 *Construction of an event tree: (a) multiple splits; (b) binary splits*

Frequency of HF release (independent of wind direction)

$\lambda_5 = 0.09 \times 68 \times 10^{-6} = 6.1 \times 10^{-6}$/year

and so on.

The outcome probabilities should sum to unity and the outcome frequencies to that of the initial event.

This last example also illustrates the need for care in the definition and interpretation of events. Outcome C is an HF release drifting north-east, but this is not the only outcome where this occurs. It occurs implicitly also in outcome A, so that the frequency of such a release is that of outcome C plus a contribution from that of outcome A.

Event trees are used particularly, but not exclusively, to analyse failures of utilities and outcomes of releases from plants. Other event trees are given in the literature (e.g. von Alven, 1964; N.C. Rasmussen, 1974; AFC, 1975; HSE, 1978b, 1981a; Cross, 1982; Rijnmond Public Authority, 1982).

9.7 Cause–Consequence Diagrams

A third technique that incorporates features both of the fault tree and of the event tree is the cause–consequence diagram. The cause–consequence diagram has been developed by D.S. Nielsen (1971, 1974, 1975) and by J.R. Taylor (1974d, 1978a).

A cause–consequence diagram is constructed by defining a critical event and then developing the causes and consequences of this event. The forward development has the features of an event or a decision tree and the backward development those of a fault tree. The main elements of the diagram are therefore event and conditions definitions and logic gates and vertices.

Some cause–consequence diagram symbols are given in Table 9.8. The logic symbols include both gates, which describe the relations between cause events, and vertices, which describe the relations between consequences. The event and condition symbols describe the type of event or condition. The symbols given are those that have been used by Nielsen and by Taylor.

The main logic gates are the AND gate and the OR gate. There are corresponding logic vertices in the form of the AND vertex and the OR vertex.

The EITHER/OR vertex, or decision box, is also very useful. It is utilized in particular to determine the effect of an event or condition on the paths that the system takes. If, as is often the case, the 'No' output from the decision box is the result of an abnormal condition, then the fault tree for this condition is developed. Thus fault trees occur on the diagram not only for the critical event but also for abnormal conditions throughout the diagram.

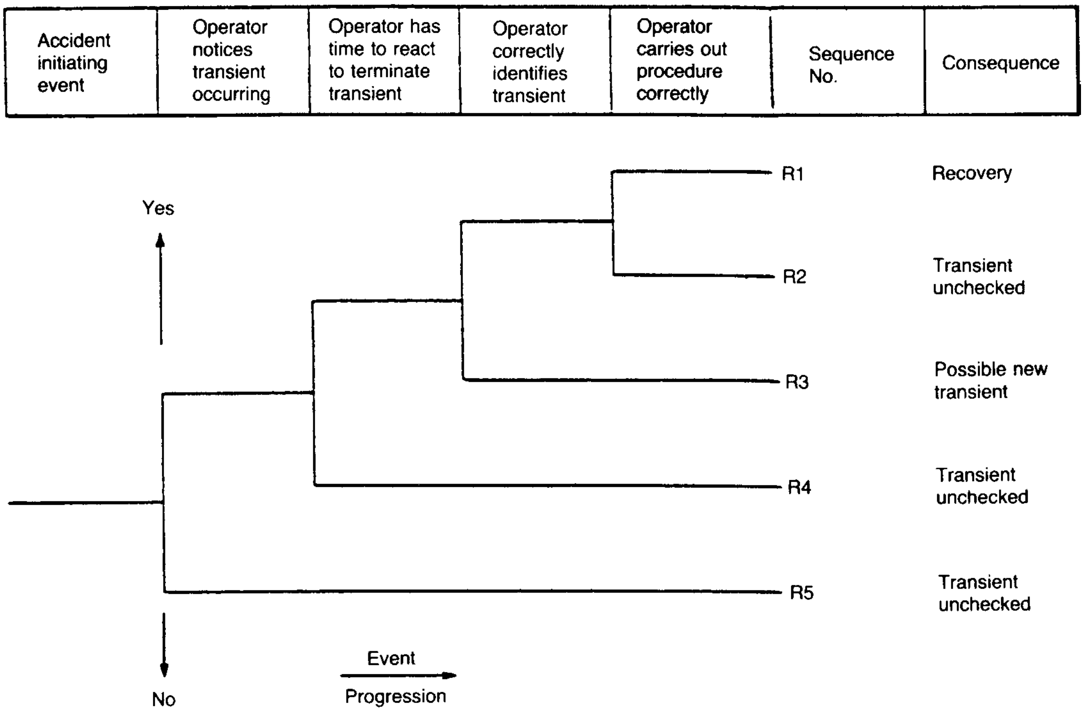

Figure 9.11 *Event tree for response of operator to nuclear reactor transient (Welsh and Lundberg, 1980) (Courtesy of Elsevier Science Publishers)*

Some important features of the cause–consequence diagram are its ability to handle alternative consequence paths and time delay and time order.

Examples of the use of cause–consequence diagrams in hazard assessment have been given by Nielsen and by Taylor. As an illustration consider the example of the surge tank system shown in Figure 9.14(a), which is adapted from a similar example by J.R. Taylor (1978a). The problem is to develop the diagram for the critical event of 'Flow controller fails'. The cause–consequence diagram is shown in Figure 9.14(b).

The cause–consequence diagram may also be used for quantitative assessment.

9.8 Dependent Failures

In the design of systems for reliability, use is made of redundancy and diversity of subsystems and components. In principle, the use of redundancy allows very high reliability to be obtained. The condition for this, however, is that the failures that occur are independent. If this is not so, then the design intent is defeated and the reliability may be less, sometimes dramatically less. In other words, the phenomenon of dependent failure tends to set a limit on the reliability that can be achieved. It is therefore a major concern for designers of high reliability systems.

Work on dependent failures has been described in *A Study of Common Mode Failures* (Edwards and Watson, 1979 SRD R146) and on defences against it in *Defences Against Common Mode Failures in Redundancy Systems* (Bourne *et al.* 1981 SRD R196) and *SRD Dependent Failure Procedures Guide* (Humphreys and Johnston, 1987 SRD R418).

The terminology used in the field has changed somewhat over the years. Initially, the term generally used was 'common mode failure' (CMF). The term 'common cause failure' (CCF) then gained currency. Some debate arose as to the difference between the two. The term 'dependent failure' (DF) is now preferred. A set of definitions is given by Humphreys and Johnston. They define dependent failure as 'the failure of a set of events, the probability of which cannot be expressed as the simple product of the unconditional failure probabilities of the individual events'. They treat CMF as a subset of CCF in which the failures are in the same mode and due to the same cause. They also refer to and include a fourth category, cascade failures or propagating failures.

9.8.1 Occurrence

Dependent failures are liable to occur in all sorts of ways. One of the most obvious is loss of a utility, such as failure of the power supply and hence simultaneous loss of power to all the instruments in a particular system. Another readily envisaged type of dependent failure is that due to some influence from the external environment. This may be freezing due to cold weather, or shock caused by an earthquake.

There are other causes of dependent failure which are less readily appreciated but which are just as important. One of these is human error, specifically systematic error. A systematic error in maintenance or testing may disable a complete system of redundant devices.

In general, a particular component will be potentially subject to a number of types of dependent failure. Typical

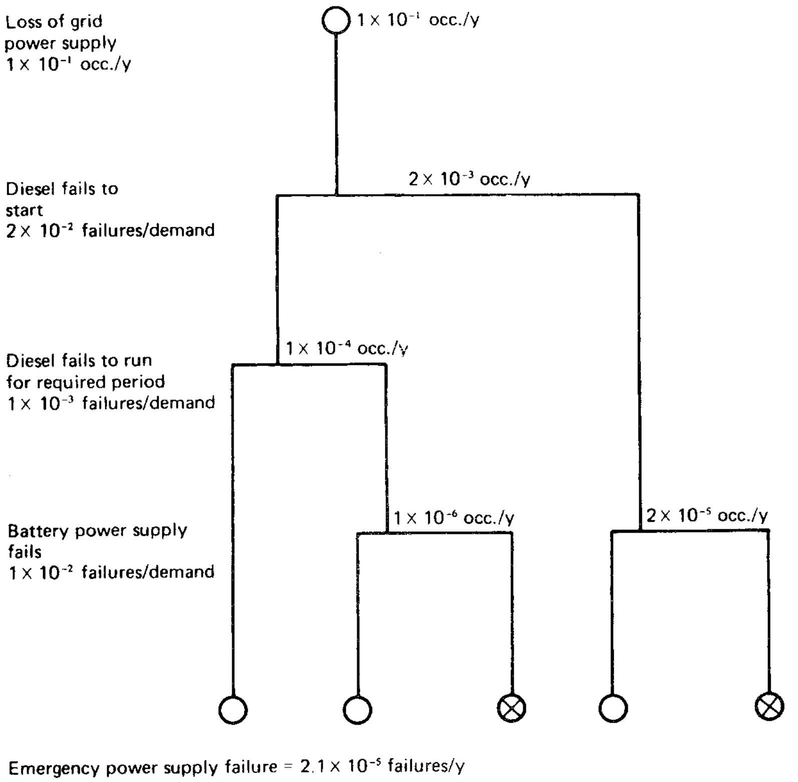

Figure 9.12 *Event tree loss of grid power supply (after Andow, 1976)*

dependencies are manufacture, maintenance and external events. Another form of dependent failure is damage caused by the accident event itself.

9.8.2 Significance

The significance of dependent failures is readily appreciated. There is a limit to the degree of reliability that can be achieved in a system by the use of single items of high reliability. For high system reliability it is necessary to exploit redundancy and diversity. In the absence of dependent failures, very high system reliabilities can be achieved by these means. The effect of dependent failures, however, is to set a limit to the increase in reliability that is obtainable in practice.

One type of system where this is important is protective, or trip, systems. High reliability protective systems tend to utilize more than one channel, typical configurations being $\frac{1}{2}$ systems and $\frac{2}{3}$ voting systems. Dependent failures can cause a significant increase in the probability of failure on demand for such systems.

Another type of system where the effect of dependent failures is significant is standby systems. There can be an appreciable increase in the probability of failure on demand due to dependent failures. One type of standby equipment where this effect has been repeatedly demonstrated is standby diesel generator sets for emergency power supply, where reliabilities have frequently fallen well below those estimated neglecting dependent failures.

9.8.3 Classification

A classification of causes of CMFs has been given by Edwards and Watson (1979 SRD R146) and is shown in Figure 9.15. Engineering failures are classed as those of design (ED), which is subdivided into functional deficiencies (EDF) and realization (EDR), and those of construction (EC), subdivided into manufacturing faults (ECM) and installation and commissioning faults (ECI). Operations failures are classed as procedural (OP), subdivided into maintenance and test (OPM) and operation (OPO), and environmental (OE), subdivided into normal extremes (OEN) and energetic events (OEE). Each of these classes is broken down into further detailed categories.

9.8.4 Failure data

Edwards and Watson review the data available on CMFs. Most of these data relate to aircraft systems and to nuclear reactor systems in the United States, France, Germany and the United Kingdom.

Data on abnormal occurrences in US nuclear power plants are available in the form of Licensee Event Reports (LERs). Two reactor systems for which high reliability is required are the automatic protective system (APS) and the emergency core cooling system (ECCS). The authors analyse the reports to identify CMFs.

CMF also figures prominently in the *Rasmussen Report* (AEC, 1975). This report contains (in Appendix III) CMFs identified in various data sources on reactor incidents and

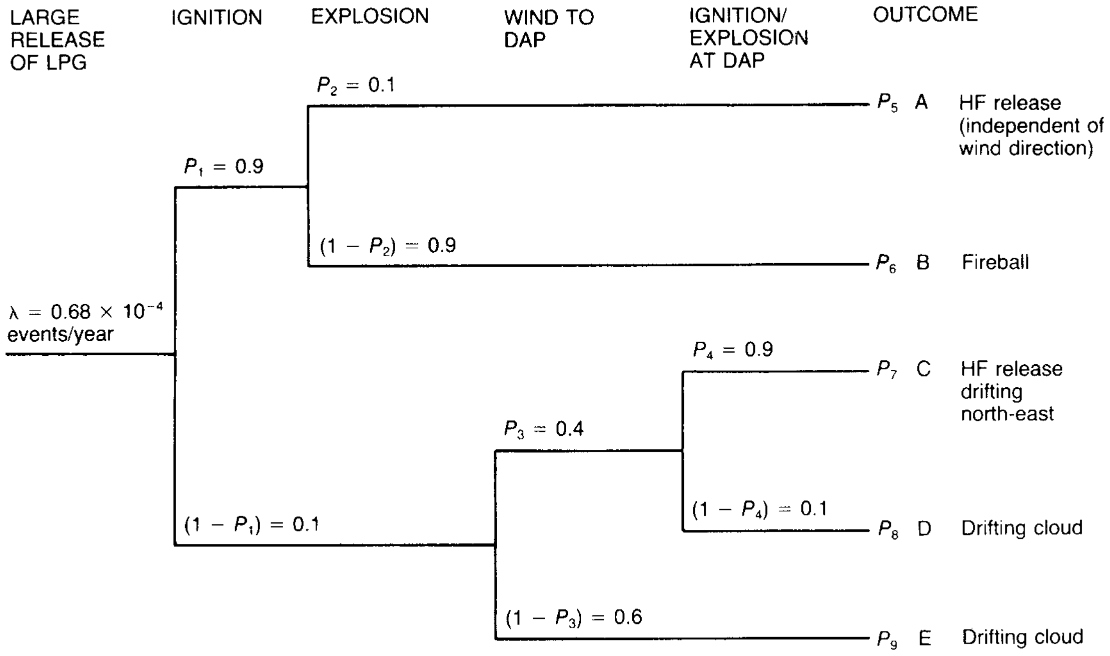

Figure 9.13 *Event tree for release of LPG (after HSE, 1981a)*

operation. Analysis of the data in the *Rasmussen Report* shows that of a total of 303 faults some 32 were CMFs. The causes of these CMFs include EDR (12 faults), OPM (6 faults) and OEN (5 faults).

Further discussions of data on dependent failures are given by Humphreys (1987) and G.T. Edwards (1988).

9.8.5 Beta factor

A quantitative measure of the prevalence of dependent failure is the ratio β of the dependent failures to the total failures, introduced by Fleming (1974). It is defined as:

$$\beta = \frac{\lambda_d}{\lambda_i + \lambda_d} + \frac{\lambda_d}{\lambda} \qquad [9.8.1]$$

with

$$\lambda = \lambda_i + \lambda_d \qquad [9.8.2]$$

where λ is the overall failure rate, λ_d is the rate of dependent failure, and λ_i is the rate of independent failure.

The beta factor may be used to quantify the contribution of dependent failures to overall system failure. Edwards and Watson have analysed the data and derived values of the beta factor for a number of subsystems and components. Particularly important are protective systems with redundancy. For such redundant systems typical values of the beta factor are 0.05 to 0.25.

Another important item is diesel generator sets for emergency power supply. In their study the authors identified 24 nuclear power plants that yielded usable data. For the diesel generators in these plants there were 67 failures recorded over a period of 238 operating years. There were six dependent failures over a period of 118 operating years. Each diesel generator was broken down into eight subsystems. The overall subsystem failure rate was therefore 0.035 failures/year (67/(8 × 238)) and the dependent failure rate 0.0064 (6/(8 × 118)). The resultant value of β is 0.18 (0.0064/0.035).

A further study of beta factors has been described by Humphreys (1987).

9.8.6 Protective systems

The type of system for which dependent failures are of particular concern is protective systems with a high degree of redundancy. The characteristics of such systems have been discussed by Bourne *et al.* (1981 SRD R196). The authors recognize five basic types of configuration for such systems: (1) a single channel, (2) a redundant system, (3) a partly diverse system, (4) a fully diverse system and (5) two diverse systems.

Thus, considering the measurement channels for a trip system, the authors give as an example of a redundant system a system with *n* identical redundant channels and *m*/*n* majority voting. As examples of partly diverse and fully diverse systems they give systems with two parallel channels, in which the channels are partly diverse and fully diverse, respectively. Two diverse systems are exemplified by a system with two complete subsystems in parallel, each of which is a half-identical redundant channel subsystem.

Bourne *et al.* gave the following approximate ranges for the probability of failure of these configurations, based on a typical proof test interval of 1–3 months:

Single channel	>0.5 to 5×10^{-3}
Redundant system	5×10^{-2} to 5×10^{-4}
Partly diverse system	10^{-2} to 5×10^{-5}

***Table 9.8** Cause–consequence diagram logic and event symbols (after D.S. Nielsen, 1974; J.R. Taylor (1974d)) (Courtesy of the Danish Atomic Energy Commission)*

Logic symbol	*Meaning of symbols*
	AND gate
	OR gate
	AND vertex
	Mutually exclusive, exhaustive OR vertex
	Mutually exclusive OR vertex (used after time delays)
	EITHER/OR vertex, decision box
	Condition vertex
Event and condition symbols	
	Basic condition
	Initiating event (may be critical event)
	Event
	Significant consequence
	Condition
	Fixed time delay
	Variable time delay

Fully diverse system	10^{-3} to 5×10^{-5}
Two diverse systems	5×10^{-5} to $< 10^{-6}$

The probabilities of failure of the systems therefore show considerable overlap.

9.8.7 Modelling for redundancy

A number of methods have been developed for the modelling of dependent failures in redundant systems. Accounts of such modelling are given by Edwards and Watson (1979 SRD R146), G.T. Edwards (1987a,b) and Humphreys and Johnston (1987 SRD R418). The methods include the beta factor method, the multiple Greek letter method, the binomial failure rate method and the Marshall–Olkin method. An account of these and other methods is given by Humphreys and Johnston.

One of the most widely used is the beta factor method. This has a single parameter β. Some of the other methods have several parameters. The use of a single parameter has the merit that only one parameter needs to be estimated from the data, but the corresponding limitation that it cannot, in principle, model the data as accurately as a multiple parameter method.

9.8.8 Beta factor method

As just stated, one of the most widely used models of dependent failure is the beta factor method of Fleming (1974). The beta factor was defined in Section 9.8.5. For a single component the overall failure rate may be written in terms of the beta factor as:

$$\lambda = \lambda_{\mathrm{i}} + \lambda_{\mathrm{d}} \qquad [9.8.3]$$

Then, writing

$$\lambda_{\mathrm{i}} = (1 - \beta)\lambda \qquad [9.8.4]$$

$$\lambda_{\mathrm{d}} = \beta\lambda \qquad [9.8.5]$$

Gives

$$\lambda = (1 - \beta)\lambda + \beta\lambda \qquad [9.8.6]$$

The simplest system to which CCF is applicable is the two-component parallel redundant system shown in Figure 9.16(a). The failure rate for a single component is λ. Then, applying the beta method and separating out the contributions of independent and CCFs, gives the system shown in Figure 9.16(b). The system now consists of a two-component parallel subsystem in series with a single component subsystem. The failure rate for the system λ_{s} is then given by the relation:

$$\lambda_{\mathrm{s}} = \frac{1}{(1/(1-\beta)\lambda) + (1/(2-\beta)\lambda)} + \beta\lambda \qquad [9.8.7]$$

The fault trees for the two cases are given in Figures 9.16(c) and (d), respectively.

Models such as the beta model are applied particularly to protective systems. For such a system consisting of multiple redundant items in parallel, which is normally not operational but which is required to operate when a demand is placed on it, the probability of failure is equal to its unavailability, or fractional dead time. Since the probability of failure increases with time and since for such a

system the failure will normally be unrevealed, it is necessary to perform a proof test at some fixed interval.

The application of the beta model may be illustrated as follows. It is shown in Chapter 13 that, subject to certain conditions, the fractional dead time for a single channel system is $\phi = \lambda\tau_p/2$ and that for a system of two parallel redundant channels it is $\phi = (\lambda\tau_p)^{2/3}/3$, where ϕ is the fractional dead time and τ_p the proof test interval. The corresponding expression for the latter case in terms of the beta factor is:

$$\phi = \frac{[(1-\beta)\lambda\tau_p]^2}{3} + \frac{\beta\lambda\tau_p}{2} \qquad [9.8.8]$$

The use of the beta factor method requires that a suitable value of β be known. As stated earlier, typical values for redundant systems are 0.05 to 0.25.

9.8.9 Geometric method

Another method of handling CCF is the geometric method. This utilizes the upper and lower bounds of failure of the system. The lower bound λ_l of the system failure rate is that assuming that there are no failures due to a CCF, and the upper bound λ_u is that assuming that all failures are due to the common cause. The system failure rate λ_s is

$$\lambda_s = (\lambda_l^n \times \lambda_u)^{1/(n+1)} \qquad [9.8.9]$$

where n is an index. The value of n is a function of the diversity of the components in the system and its value usually lies in the range 1–4.

9.8.10 Partial beta factor method

The partial beta factor method is not actually a separate method but rather a method of obtaining a more accurate value of the beta factor. The method is described by Humphreys and Johnston (1987 SRD R418). The authors suggest that a practical limit of the beta factor in a redundant subsystem is about 2×10^{-2} and that in a diverse subsystem is about 10^{-3}. They take the latter as the lower limit for a subsystem for which very high reliability is required and in which all defences are exploited.

The beta factor is decomposed into a set of partial beta factors, each of which corresponds to a particular defence. The beta factor is computed as the product of the partial beta factors. The procedure is as follows. For each partial beta factor, a minimum value β_{pm} is assigned. The product of the minimum values is 10^{-3}. Then for each partial beta factor the user assigns an actual value β_{pa}. The maximum in each case is unity, so that if this maximum is assigned in every instance, the product of these values is unity. Thus, in general, the beta value computed from the partial beta values will lie between 10^{-3} and 1.0.

The authors give a proforma for the determination of the beta factor from the partial beta factors, in which account is taken both of the causes of, and defences against, dependent failures. A further discussion of the partial beta factor method is given by B.D. Johnston (1987a,b).

9.8.11 Multiple Greek letter method

The beta factor method does not distinguish between different levels of redundancy in a subsystem. This deficiency is overcome in the multiple Greek letter method, in which a separate Greek letter is introduced for each component after the first. Thus for a four-component system one would use the letters β, γ and δ, where β is the conditional probability that a cause of component failure will be shared by one or more components, γ is the conditional probability that the cause of component failure which is shared by one or more components will be shared by two or more components, and δ is the conditional probability that the cause of component failure which is shared by two or more components will be shared by all components. It should be noted that the definition of β used here differs from that in the conventional beta factor method.

Humphreys and Johnston (1987 SRD R418) state that typical values of β, γ and δ are 0.1, 0.76 and 0.82, and that system failure probabilities computed by this method typically differ from those obtained by the conventional beta factor method by a factor of about 1.5.

9.8.12 Binomial failure rate method

In the binomial failure rate model developed by Vesely (1977a) and modified by Attwood (1991), multiple dependent failures in a redundant subsystem are treated as being either probabilistic (binomial) or deterministic (global) in nature. In this model, the external event is referred to as a 'shock'. Shocks are divided into non-lethal and lethal, the former being those which have a certain probability of causing subsystem failure and the latter being those which are certain to do so:

$$\lambda = \lambda_{\mathrm{si}} + p\mu + \omega \qquad [9.8.10]$$

where p is the conditional probability that the external event will cause subsystem failure, λ is the overall failure rate of the subsystem, λ_{si} is the overall failure rate of the subsystem for independent failures, μ is the occurrence rate of non-lethal shocks, and ω is the occurrence rate of lethal shocks.

9.8.13 Revealed and unrevealed failure models

In the account given so far the emphasis has been on dependent failures in protective systems where failures are unrevealed when they occur and are detected only by proof testing. The probability of failure is a function of the failure rate and of the proof test interval.

In most plant systems, however, where an equipment is required to perform some active function on a continuous basis, failures are detected by the fact that this function is no longer being performed. In this case the failures are revealed. The probability of being in a failure state is a function of the failure rate and of the repair time, taking this as the total time for detection and repair. An example of a system in which failures are revealed is two pumps each of 50% capacity operating in parallel.

The models for the probability of failure in systems with revealed failures and in systems with unrevealed failures are different. Treatments are given in Chapters 7 and 13, respectively. Standby systems are an intermediate case. In the standby mode the failures are unrevealed, whilst in the operating mode they are revealed.

9.8.14 Diversity and its modelling

Diversity is recognized as one of the principal defences against dependent failures. A system with diversity is much less vulnerable to many of the events that can cause dependent failures in redundant systems. The modelling of diversity is, however, much less well developed than that of redundancy, and it is therefore less easy to obtain quantitative results for subsystems embodying diversity.

9.8.15 Fault tree analysis

One of the principal tools for the analysis of high reliability systems is fault tree analysis. The type of system to which fault tree analysis is typically applied is one in which undesirable events are protected against by the use of control loops and trip systems. In systems where very high reliability is required, use is generally made of redundancy in some of the trip systems. The benefit of redundancy may be negated if there is dependency between failures.

In fault tree analysis, dependent failures may be handled in two different ways. One is to construct the tree as normal, without explicit regard to dependency, but to flag each group of base events where a dependency exists and to deal with this dependency at the cut set stage. The alternative approach is to represent the dependent failure part of the subsystem failure as an explicit failure in its own right.

The two approaches are illustrated in Figure 9.17, which shows a fault tree for a system in which a measurement is made using a half-redundant system. The top event X is the failure of the measurement function. In Figure 9.17(a), the events A and B are defined as failure of measurement channel 1 and failure of channel 2, respectively. These failures include both independent and dependent failure contributions. If the dependency of A and B were to be dealt with at the cut set stage, the events would be flagged in some way.

In Figure 9.17(b), the failure that causes failure of the two channels, that is, the dependent failures, is isolated as event C. The events A and B are now redefined as, respectively, the failures of channels 1 and 2, excluding the dependent failure contribution. In this tree, the event C is shown accompanying both event A and event B. In the alternative, but equivalent, configuration shown in Figure 9.17(c), event C is separated out and shown only once.

Computer codes for the analysis of dependent failures have been described by Humphreys and Johnston (1987 SRD R418) and by B.D. Johnston (1987a,b). An account of these codes is given in Chapter 29.

9.8.16 Effect on reliability

The effect of dependent failures is seen most markedly in protective systems with a high degree of redundancy, where it can dominate. This may be illustrated by considering the half-redundant protective system described earlier. The expression for the fractional dead time ϕ of such a system is Equation 9.8.8. Typical values of the parameters are given by Humphreys and Johnston (1987 SRD R418) as follows: $\lambda = 10^{-6}$ failures/h; $\tau_{\mathrm{p}} = 10^3$ h; and $\beta = 0.1$. The fractional dead time is then:

$$\phi = 0.27 \times 10^{-6} + 0.5 \times 10^{-4}$$

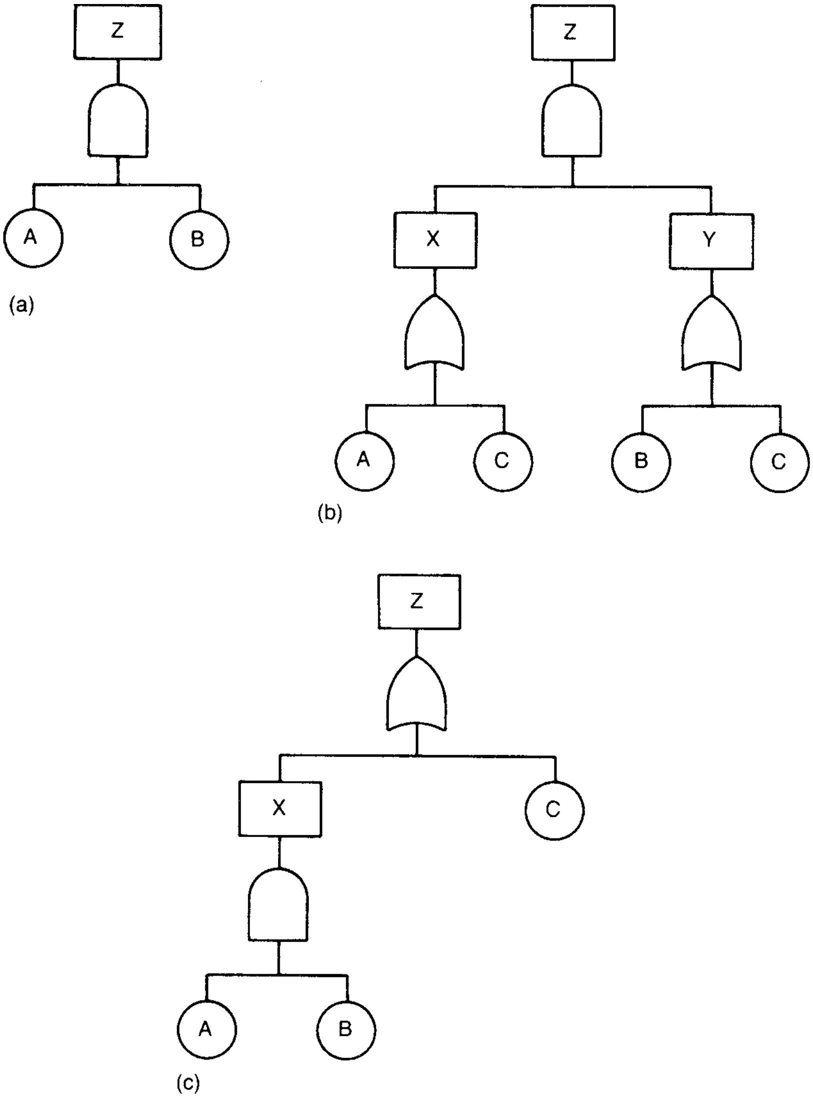

Figure 9.17 *Treatment of dependent failures in fault tree analysis: (a) tree with events A and B treated as independent events; (b) tree with events A and B treated as dependent on event C; (c) alternative form of tree in (b)*

where the first term is the contribution of the system for independent failures and the second that for dependent failures. The dominant contribution is that of the dependent failures.

The impact of dependent failures can be even greater. In the example just given the redundancy was minimal. Systems with higher degrees of redundancy are relatively even more vulnerable to dependent failures. One early study, by Epler (1969), stated that dependent failures might be dominant by a factor as high as 10^5.

9.8.17 Benchmark study

A benchmark study of CCF is described in *Common-cause Failure Reliability Benchmark Exercise* (*Gohnston* and Crackett, 1985 SRD R383). The study is one of a series of benchmark exercises conducted by the Commission of the European Communities (CEC) and organized by JRC-Ispra. A summary of this study is given by Humphreys and Johnston (1987 SRD R418). The situation investigated was dependent failures on the feedwater system of a PWR under emergency conditions. Of the ten teams whose studies are listed, five used the multiple Greek letter method and four the Marshall–Olkin method. The system is characterized by redundancy rather than diversity, and for this situation agreement was reasonably good. The three most structured presentations estimated the probability of failure as lying in the range 10^{-4} to 5×10^{-5}. The treatment of the rather limited amount of diversity in the system exhibited greater discrepancies.

9.8.18 Cascade failures

Cascade failures occur when a fault propagates through the plant and induces further failures. The conditions created by the fault may include abnormal process conditions, equipment overload, loss of potential correction on control loops, activation of trip systems and actions by the operator in response. The cascade failure problem appears to have received relatively little attention.

9.8.19 Defences

The defences available against dependent failures are described by Edwards and Watson (1981 SRD R146) and are further developed by Bourne *et al.* (1981 SRD R196) and Humphreys and Johnston (1987 SRD R418). The headings of the list given by Edwards and Watson are:

1.0 Design
  1.1 Administration
  1.2 Functional diversity
  1.3 Equipment diversity
  1.4 Fail-safe design
  1.5 Redundancy and voting logic
  1.6 Protection and segregation
  1.7 Proven design and standardization
  1.8 Equipment derating and simplicity
  1.9 Operational interfaces
  1.10 Quality control
  1.11 Design review
2.0 Operation
  2.1 Administration
  2.2 Maintenance procedures
  2.3 Proof testing
  2.4 Operating procedures
  2.5 Reliability performance monitoring
3.0 Reliability assessment

Detailed accounts of the elements of each of these defences are given by the three sets of authors quoted. Bourne *et al.* (1981 SRD R196) describe an overall defence strategy in terms of (1) general strategy, (2) management aspects and (3) technical aspects. The general strategy should be based on good administrative controls of both design and operations. There should be a specification for the reliability requirements of the system with particular reference to dependent failures (DFs). The design should be subject to reviews of dependent failures at appropriate stages. There should be an independent assessment of reliability in which dependent failures are considered. During the operational life of the plant, the continued effectiveness of the defences against dependent failures should be periodically reviewed.

Management should ensure that there is awareness of the problem of dependent failures among all personnel who have a contribution to make in minimizing it, and should give a lead. It should make defence against dependent failures an explicit objective in both design and operations stages. It should make it clear where the need for such defence imposes requirements additional to those of the regular standards and codes. It should assure the necessary reviews and independent assessment.

Technical aspects cover a wide range of measures. Probably the most effective is functional diversity, which is generally used only at system level. This defence may be enhanced by equipment diversity. Within subsystems fail-safe design may be exploited. Other measures are: redundancy and voting logic; protection and segregation; proven design and standardization; and equipment derating and simplicity. These design measures need to be complemented by adequate systems and procedures for defence during operations.

Bourne *et al.* suggest the following priorities. As the most significant contributors to dependent failures are errors in design and in maintenance and testing, the first priority should be the management of the design process and of design and operational tasks in relation to dependent failures. Of the technical measures, fail-safe characteristics offer the greatest potential for reliability enhancement. Next come measures to minimize human error at the interfaces of tasks such as maintenance and testing.

The defences most commonly applied are protection and segregation. Protection guards against influences from the external environment and segregation can be effective against most causes of dependent failure. Both have a contribution to make, but it is not a predominant one. The authors state that other design defences considered (redundancy and voting, proven design and standardization, derating and simplicity) are of less significance, but have a role to play.

9.9 Expert Judgement

It is sometimes difficult to obtain data on event frequency or probability. In such cases, a possible solution is the use of expert judgement to obtain the required estimates. This approach has been used particularly to obtain estimates for human error rates (HERs), where it is especially difficult to obtain field data, and for equipment failure rates, but it also has other applications.

An account of expert judgement is given in *Eliciting and Analysing Expert Judgement: A Practical Guide* (M.A. Meyer and Booker, 1990). A review of five areas of application of expert judgement methods is given by Mosleh, Bier and Apostolakis (1987). Further guidance on knowledge representation and elicitation is available in the literature on expert systems, though there the emphasis is generally more on expert rules rather than on quantification. Expert systems are discussed in Chapter 30.

9.9.1 Scope

Some purposes for which expert judgement has been used are given by M.A. Meyer and Booker (1990) as:

(1) to provide estimates on new, rare, complex or otherwise poorly understood phenomena;
(2) to forecast future events;
(3) to integrate or interpret existing data;
(4) to learn an expert's problem-solving processes or a group's decision-making processes;
(5) to determine what is currently known, what is not known, and what is worth learning in a field of knowledge.

A study in which expert judgement has been used for all these purposes in the context of the NUREG-1150 project is *Analysis of Core Damage Frequency from Internal Events: Expert Judgement Elicitation* by Wheeler *et al.* (1989).

9.9.2 Expert problem-solving

In solving a problem the tasks which an expert has to perform are essentially to (1) understand the question,

(2) retrieve the relevant information, (3) make a judgement and (4) formulate and report an answer.

It is to be expected that the results of an expert judgement exercise will be affected by bias. One form of bias is that arising from the elicitation process and from the expert's involvement with the project. Another form is a discrepancy between the expert's knowledge and some sort of norm. These two forms of bias are sometimes termed 'motivational bias' and 'cognitive bias', respectively.

Some forms of motivational bias are social pressure, misinterpretation or misrepresentation by the interviewer, and overoptimism by the expert. Forms of cognitive bias include inconsistency, anchoring, availability and underestimation of uncertainty. Anchoring is failure to make sufficient adjustment to an initial opinion in the light of further evidence. Availability is the difference in ease of retrieval of different types of information, infrequent catastrophic events being more readily retrieved than more frequent mundane ones.

The handling of bias is not well developed, but there are certain measures that can be taken. The elicitation process can be planned so as to minimize it. The expert can be made aware of the potential for bias. The elicitation process can be monitored for bias and, if necessary, adjustments made to counter it. The results can be analysed for the effect of bias.

9.9.3 Formulation of questions

The elicitation process involves asking the expert a number of questions. The quality of the results obtained depends in large part on the formulation of these questions. This involves defining the objectives of the project, selecting the general question areas and formulating the specific questions. Closely related to this is the selection of the experts who are to try to answer the questions. These may be in-house and/or external experts. Different options exist on the extent to which the experts are involved in the selection of the question areas and the formulation of the questions.

The questions are then refined by structuring them. Some aims of the refinement process are: to focus attention on what is required and to minimize misinterpretation; to present the question in a form that is assimilable by the expert; and to make the question acceptable to him. Some ways in which questions may be refined include decomposition, phrasing and use of representational aids such as diagrams.

There are certain circumstances in which the involvement of external experts in question refinement is critical. These are given by M.A. Meyer and Booker (1990) as those where the purpose is to capture the experts' problem-solving process, where there is evidence that the experts may not accept the questions, and where outside reviewers are likely to be concerned about bias in the questions.

9.9.4 Selection of experts

A basic distinction in the selection of the experts is between applications where the output is to be the experts' answers and those where the output is to be insight into the experts' problem-solving process. In most cases, it is the experts' answers that are of interest. In order to select an expert it is necessary to have some idea of what is to be regarded as constituting expertise. Two types of expertise are distinguished. One is the expert's experience in the domain, or substantive expertise. The other, or normative, expertise is his knowledge of the response mode, or form in which he is to be asked to give his answers, for example, as probabilities, odds or rankings. Both types of expertise are needed for satisfactory results. For certain projects, the credibility of the expert in the world at large may be a factor.

It is normally advisable to use multiple and diverse experts. Diversity of experts guards against the excessive influence of a single individual, and is particularly effective in face-to-face meetings. The number of experts is typically five to nine, the lower figure being about the minimum needed to obtain diversity and the upper one about the maximum that can be readily handled.

The diversity of expertise achieved depends on the selection of experts from the expert population; this is essentially a sampling problem. It is necessary to guard against overrepresentation of any particular tendency.

The success of the exercise depends on the motivation as well as the selection of the experts, and measures should be taken to motivate those participating.

9.9.5 Elicitation methods and planning

In designing the elicitation it is necessary to consider (1) the elicitation method, (2) the response mode and dispersion measures, (3) the aggregation of response, (4) the problem-solving process and (5) the documentation.

There are three principal methods of elicitation: the individual interview, the interactive group and the response of experts operating in isolation (the Delphi method). Each method has its advantages and disadvantages. The individual interview is the main method for obtaining detailed responses and insight into the expert's problem-solving process, but does not give interaction between experts and is time-consuming. The interactive group is claimed to give more accurate responses and to generate more ideas, but it can suffer from group bias. The Delphi method is freer from group bias. It can be framed so as to offer some insight into problem-solving or interaction.

Some response modes which may be used are: single probability values; odds ratios; sets of probability values, effectively a probability distribution; location on a continuous scale; location on a discrete scale, with ranking or rating; paired comparisons; and revisions of estimates. The expert may provide an indication of the uncertainty in the response in the form of a dispersion measures such as a range, or standard deviation.

Methods available for eliciting the expert's problem-solving process include verbal protocol, verbal probe and the ethnographic method. The first requires the expert to think aloud, the second is the questioning of the expert about his problem-solving process immediately after he has given his answer and the third involves transposing the expert's answers into questions, which draw from the expert elaboration of his answers. The use of verbal protocol avoids interviewer bias but is liable to disturb the expert's skilled problem-solving behaviour.

The answers given by a group of experts are likely to differ and need to be aggregated in order to obtain an overall response. This may be done by the experts themselves or by a mathematical technique.

The documentation required from the exercise should be specified. It may record the answers only, the answers and the problem-solving process or something intermediate such as the answers with a short explanation of the underlying reasoning.

The planning of the elicitation includes the logistics of involving the experts, the structuring of the elicitation process, the precautions against bias and the specification of the documentation to guide and record the elicitation. There will normally need to be some training and practice, probably with pilot testing, prior to the main elicitation exercise.

9.9.6 Analysis of responses

The data obtained from the elicitation normally consist of (1) answers to questions and (2) ancillary information. The latter is essentially information about (1) the experts and (2) the expertise.

The data obtained should be examined for two features in particular. One is the degree of detail, or granularity. Variations in the level of granularity can adversely affect the results. It is desirable in principle to operate in the analysis with a single level of granularity. There is, however, a loss of information in passing from the particular to the general and this may act as a constraint.

The other feature is conditionality. Answers are conditioned by the path by which they have been reached and it is desirable to make this explicit. Meyer and Booker comment that: 'Two experts could arrive at exactly the same final answer but for very different reasons, or two experts could arrive at different answers for exactly the same reasons'.

The analysis of the data is facilitated if they can be converted to quantitative form. There are a number of methods of doing this. One approach is to convert qualitative descriptors into values on some kind of scale. Another is to merge separate categories into a small number of broader ones. Another is the combination of quantitative data using weighting.

The data may be analysed to obtain relationships between different answers, between different ancillary variables and/or between answers and ancillary variables. One major aspect of such analysis is that concerned with lack of independence between experts' answers, or correlation, and with bias in these answers. There are various factors which experts may have in common, such as shared training, similar work experience and exposure to the same data sources. The biases that may be present include motivational and cognitive bias, as described earlier.

Another aspect of data analysis is the modelling of the experts' answers in terms of the ancillary data on the expert and his expertise.

A third aspect of the analysis is the application of aggregation methods to combine the answers of a number of experts into a single value or distribution of values. One particular application of aggregation occurs where there is a decision-maker and a single expert. The elements in this situation are the decision-maker's prior estimate, his choice of the expert, the aggregation of the prior estimate with the expert's information, and the inference. There are several quite different potential outcomes. Thus, the decision-maker may consider both items of information as valid and combine them, he may prefer one or the other or he may decide to adopt a range of values. Another situation occurs where there is a decision-maker and *n* experts. The potential outcomes are similar, but it is more likely that the decision-maker will not simply prefer his own prior.

A fourth aspect of the analysis is the handling of uncertainties in the data. Some sources of uncertainty are definitions, errors associated with small samples, non-sampling errors such as missing data, and deficiencies in scientific and modelling techniques. Methods are available which assist in the measurement, modelling and control of such uncertainties.

The purpose of the analysis is to reach conclusions by making inferences from the responses and analysis of these responses. What an expert judgement exercise does is to sample the world of experts and their expert knowledge. It does not sample the real world and the conclusions drawn may or may not represent the true state of nature. The validity of these conclusions depends very much on the quality of expert knowledge about the domain in question.

Critiques of expert judgement refer to the subjective nature of such judgement. The validity of subjective judgement is considered in more detail in Chapter 7.

9.9.7 Interviews

One of the main techniques of elicitation used in expert judgement work is the individual interview. There is a large literature on interview and questionnaire techniques. Guidance on interviewing is given by Kahn (1957), by Oppenheim (1966) and by Gorden (1987) and also in texts on expert systems.

9.9.8 Delphi method

Another of the principal techniques of expert judgement is the Delphi method. As already described, this method involves the use of multiple experts operating in isolation. This method is described in *The Delphi Method* (B. Brown, 1964), and by Linstone and Turoff (1975) and Dalkey (1969). The Delphi method was used for the estimation of failure rates in IEEE Standard 500:1984, which gives an appendix on the procedure used.

9.9.9 Ranking and scaling

Work on ranking and scaling of expert judgement has been described by Thurstone (1927, 1931) and by Kendall (1948, 1955, 1970). An account of scaling methods has been given in *Theory and Method of Scaling* (Torgerson, 1967).

In general, the overall approach in expert judgement work is first to rank the items. From this ranking the items are then located on a numerical scale. If absolute values are known for some of the items on the scale, these may be used to calibrate the scale and thus obtain absolute values for the other items.

A distinction is made between psychological and probability scales. The responses from the judges lie on a psychological scale and have to be converted to a probability scale. The theory underlying the conversion of rankings to locations on the psychological scale is complex, but essentially, it is based on the concept that the responses for a particular item exhibit a Gaussian distribution about some point on the scale. Then if two items are located close together, there will be an overlap between the two distributions and hence a higher frequency of disagreement between judges, while if they are located far apart there will be little or no overlap between distributions and little or no disagreement between judges. The key result obtained by Thurstone is that

$$\mu_{k-j} \approx x_{kj} \qquad [9.9.1]$$

where μ_{k-j} is the mean separation on the scale between item j and item k, and x_{kj} is the unit normal deviation corresponding to the probability that k will be ranked above j. This is the basis for the conversion of the rankings of the bench of judges into locations on the psychological scale.

9.9.10 Method of paired comparisons

A major difficulty in asking an expert to rank a number of items is that his preferences may not lie on a linear scale. If the interviewer insists on a simple ranking, the responses may be forced into too rigid a framework. This problem can be mitigated by asking the expert to express preferences between pairs of items only. This is the basis of the method of paired comparisons.

The method of paired comparisons was proposed by Thurstone (1927) and developed by Kendall (1948, 1955, 1970). Further accounts of the method are given by Guilford (1954), Keats (1971) and Hunns (1980, 1982).

In the method of paired comparisons, a bench of m judges is asked to rank a set of n items. The response of a single judge is considered first. For each item pair, say A and B, the judge is asked to express a preference. A preference for A over B is denoted by A → B or B ← A. An $n \times n$ matrix of responses is produced, as shown in the following illustrative example given by Kendall (1970):

$$\begin{array}{ccccccc}
 & A & B & C & D & E & \mathrm{F} \\
A & - & 1 & 1 & 0 & 1 & 1 \\
B & 0 & - & 0 & 1 & 1 & 0 \\
C & 0 & 1 & - & 1 & 1 & 1 \\
D & 1 & 0 & 0 & - & 0 & 0 \\
E & 0 & 0 & 0 & 1 & - & 1 \\
F & 0 & 1 & 0 & 1 & 0 & -
\end{array}$$

The diagonals are blocked out. An entry 1 in column Y, row X signifies X → Yand is therefore accompanied by the entry 0 in column X, row Y. In this example, A → B, A → C and A ← D. This $n \times n$ matrix provides the basic data from a single judge.

The responses of a judge often exhibit some degree of inconsistency. This is seen in its simplest form where a set of three pairs, or triad, is inconsistent, or circular. For example, the responses F → G → H → F are inconsistent.

In making paired comparisons, on n items a judge takes $n(n{-}1)/2$ decisions. The maximum number of circular triads is $(n^3{-}n)/24$ if n is odd and $(n^3{-}4n)/24$ if n is even. The minimum number is zero. A coefficient of consistency ζ for a single judge may then be defined

$$\zeta = 1 - 24d/(n^3 - n) \qquad n \text{ odd} \qquad [9.9.2a]$$

$$= 1 - 24d/(n^3 - 4n) \qquad n \text{ even} \qquad [9.9.2b]$$

where d is the observed number of circular triads. This may be obtained from the

$$d = \frac{n}{12}(n-1)(2n-1) - \frac{\sum a_i^2}{2} \qquad [9.9.3]$$

where a_i, is the sum of entries in row i.

The number of triads may also be analysed, as described by Kendall, using the chi-square distribution to determine the probability that the responses are random and could have arisen by chance.

The measure of agreement between the bench of judges is the coefficient of agreement u:

$$u = \frac{8\sum}{m(m-1)n(n-1)} - 1 \qquad [9.9.4]$$

where $\sum$ is the sum of agreements between pairs of judges. The maximum possible value *of* u is 1. The minimum possible value is not –1 but $-1/m$ for m odd and $-1/(m{-}1)$ for m even.

9.9.11 Saaty's method

One method for paired comparisons is that of Saaty (1977, 1980). His method is part of a methodology described in his book *The Analytic Hierarchy Process* (AHP) (Saaty, 1980). The problem is cast in hierarchical form and the paired comparison technique is then used at the successive levels of the hierarchy.

The following scheme is used in making the paired comparisons:

Number	*Description*
1	The two items are of equal importance or equally likely
3	A slight favouring of the first item over the second
5	A strong favouring of the first item over the second
7	A demonstrated dominance of the first over the second
9	An absolute affirmation of the first over the second

Values 2, 4, 6, 8 are used where the comparison is assessed as a case intermediate between the above descriptions. The comparsions are expressed as the number 1, for no preference, or the fractions 1/3, 1/5, 1/7, and 1/9 for positive preferences. Thus, for example, and entry 1/3 means that there is a slight preference for the second item over the first.

The expert proceeds by making all the possible comparisons and recording them in a $n \times n$ matrix with 1s down the diagonal and the comparisons in the upper triangular portion of the matrix. The reciprocals of the entries in the upper triangular portion are entered in the lower triangular portion. The relative weights of the n items are then obtained. These weights are the normalized eigenvectors of the principal eigenvalue of the matrix.

An index of consistency is obtained based on the deviation of the principal eigenvalue from the theoretical eigenvalue of a perfectly consistent matrix. If the consistency ratio is greater than 0.10, inconsistency is indicated.

As an illustration of Saaty's method, consider the example given by M.A. Meyer and Booker (1990). It is required to rank the following meteorological conditions in respect of the likelihood that they will cause a loss of off-site power to a plant:

(1) flash flooding at plant site with 0.5 to 2 in. of water;
(2) flash flooding with 2 to 4 in.;
(3) flash flooding with more than 4 in.;
(4) direct hit of lightning on power lines;
(5) direct hit by tornado;

(6) winds between 20 and 40 mph;
(7) winds higher than 40 mph.

The expert makes the following judgements:

1 vs 2........1/3
1 vs 3........1/4
1 vs 4........1/5
1 vs 5........1/5
1 vs 6........1/3
1 vs 7........1/4

2 vs 3........1/2
2 vs 4........1/3
2 vs 5........1/3
2 vs 6........1/2
2 vs 7........1/3

3 vs 4........1/2
3 vs 5........1/2
3 vs 6........1
3 vs 7........1/2

4 vs 5........1/3
4 vs 6........1/5
4 vs 7........1/4

5 vs 6........5
5 vs 7........4

6 vs 7........1/2

and produces the following matrix:

	1	2	3	4	5	6	7
1	1	1/3	1/4	1/5	1/5	1/3	1/4
2	3	1	1/2	1/3	1/3	1/2	1/3
3	4	2	1	1/2	1/2	1	1/2
4	5	3	2	1	1/3	1/5	1/4
5	5	3	2	3	1	5	4
6	3	2	1	5	1/5	1	1/2
7	4	3	2	4	1/4	2	1

Eigenvalue analysis of this matrix gives the principal eigenvalue as 8.001. The weights for the seven items are obtained by normalizing the seven terms in the corresponding eigenvector. For this example the respective weights of the seven items are: 0.03, 0.06, 0.11, 0.11, 0.35, 0.15 and 0.19.

However, the consistency check gives a value of 0.13, indicating a degree of inconsistency. Examination of the initial judgements shows that the inconsistencies include the following: 1 vs 4 is the same as 1 vs 5; 2 vs 4 same as 2 vs 5; 3 vs 4 same as 3 vs 5; 6 vs 4 same as 6 vs 5 and 7 vs 4 same as 7 vs 5. These judgements imply that 4 and 5 are the same, but 4 vs 5 is given as 1/3. Furthermore they imply that $6 < 7$, but the judgements 4 vs 6 and 4 vs 7 imply that $6 > 7$. There may be other inconsistencies, but these three are major. The following corrections are made:

Comparison	*Correction*	*Objective*
4 vs 5	1	To make 4 and 5 the same
4 vs 6	5	To match 5 vs 6
4 vs 7	4	To match 5 vs 7

This now gives a consistency ratio of 0.06, which is much more acceptable, and yields the following revised weights: 0.03, 0.07, 0.11, 0.28, 0.28, 0.08 and 0.15.

These weights are to be interpreted solely as indicating the relative ranking. Thus the items judged most likely to cause loss of power are 4 and 5, whilst that judged least likely to do so is item 1. The weights must not be used to draw quantitative conclusions. It is not correct to infer that item 7 (weight 0.15) is five times as likely as item 1 (0.03).

Saaty's method has the advantages that it is easily used by an expert and that it monitors consistency. It is used primarily where the overall problem can be formulated to have a hierarchical structure. It has been widely used in decision analysis.

Many problems, however, are not readily cast in hierarchical form. Moreover, the forcing of a problem into such form is contrary to a philosophy of letting the data suggest the methods of analysis and the models to be used.

9.9.12 Hunns' method

A method for paired comparisons that allows items to be not only ranked but also scaled has been given by Hunns (1980, 1982). In order to calibrate the scale in terms of probability it is necessary to know the relationship between the scale units and the relative probability. Hunns suggests that there is evidence that this is a logarithmic one. Some support for the existence of a logarithmic scale has been given by Pontecorvo (1965) in a study involving comparison of expert judgements on repair times with field data. The relation may be expressed as:

$$\log_{10} P_x = k_1 + k_2 S_x \qquad [9.9.5]$$

where P is the relative probability of an item, S the scale value of the item, k_1 and k_2 are constants and the subscript x refers to item x.

Taking one scale unit to correspond to a ratio r of probabilities the following relations then apply:

$$\frac{P_u}{P_l} = r^{(S_u - S_l)} \qquad [9.9.6]$$

$$\frac{P_x}{P_l} = r^{(S_x - S_l)} \qquad [9.9.7]$$

$$= \left[\frac{P_u}{P_l}\right]^{(S_x - S_l)/(S_u - S_l)} \qquad [9.9.8]$$

Hence

$$r = \left[\frac{P_u}{P_l}\right]^{1/(S_u - S_l)} \qquad [9.9.9]$$

and

$$k_1 = \log_{10}(P_l r^{-S_l}) \qquad [9.9.10]$$

$$k_2 = \log_{10} r \qquad [9.9.11]$$

where subscripts l and u are to lower and upper.

If absolute probability values are known for two items on the scale, Equations 9.9.6–9.9.11 may be used to obtain absolute values for the others.

The application of Hunns' method is now described using the illustrative example given by him. A bench of 20 judges is asked to rank four items A, B, C and D. The results obtained are recorded in the raw frequency matrix **F**, which for this example is as follows:

	A	*B*	*C*	*D*
A	–	6	7	11
B	14	–	12	20
C	13	8	–	14
D	9	0	6	–

The entries give the number of judges out of 20 expressing the preference in question. An entry n in column Y, row X signifies that n judges prefer X to Y. Thus in this example all 20 judges prefer B to D. The entries on the diagonal are left blank. For an entry n in the upper triangular portion of the matrix there is an entry $20-n$ in the corresponding location in the lower triangular portion.

Next the probability matrix **P** is obtained by dividing the entries in the **F** matrix by 20 and thus normalizing them:

	A	*B*	*C*	*D*
A	–	0.30	0.35	0.55
B	0.70	–	0.60	1.0
C	0.65	0.40	–	0.70
D	0.45	0	0.30	–
Σ	1.80	0.70	1.25	2.25

The entries in each column are then summed as shown in the bottom additional row.

The transformation matrix **X** is then obtained as follows. The order of the columns is rearranged in the numerical order of the values of Σ in the **P** matrix, starting with the highest value. The entries in the **X** matrix are obtained by replacing the probability values from the **P** matrix by the values of the unit normal deviates. Thus for each entry value P the probability P' is obtained as follows:

$$\begin{aligned} P' &= P & P &\le 0.5 \\ &= P - 0.5 & P &> 0.5 \end{aligned}$$

From the value of P' the unit normal deviate is then determined. For this use is made of a table of the cumulative normal distribution function (e.g. A.E. Green and Bourne, 1972, p. 554). Thus for the entry in column A, row B in the **P** matrix, which has the value 0.70, the value of P' is 0.20 (=0.70 − 0.50) and that of the unit normal deviate is 0.53. The **X** matrix is:

	D	*A*	*C*	*B*
A	0.13	–	−0.38	−0.53
B	?	0.53	0.25	–
C	0.53	0.38	–	−0.25
D	–	−0.13	−0.53	?

The query signs occur where the judges were unanimous, namely in preferring B to D.

The column difference matrix **Z** is then obtained by taking the differences between entries in the adjacent columns of the **X** matrix:

	D–A	*A–C*	*C–B*
A	0.13	0.38	0.15
B	?	0.28	0.25
C	0.15	0.38	0.25
D	0.13	0.40	?
Σ/n	0.14	0.36	0.22

The entries in each column are then averaged as shown in the bottom additional row. These latter entries are the scale values that are used to locate the items on the ranking scale.

The range of the scale in this example, as given by the bottom additional row of the **Z** matrix, is 0.72 ($= 0.14 + 0.36 + 0.22$). Item D has the lowest preference rating and is at the bottom of the scale and item B is at the top of the scale. The intervals between D and A, A and C, and C and C are, respectively, 0.14, 0.36 and 0.22.

This psychological scale may then be calibrated as a relative probability scale, as described above, and if the necessary absolute probability values are available for some of the items, absolute probabilities for the others may be calculated as described above. In performing this conversion, it is necessary to ensure that the upper limit of the scale is unity and to set some lower limit. For the latter Hunns uses a value of 10^{-6}. Hunns describes an application of his method but does not claim it to be well tested. It is, however, one of the methods referred to in the literature.

9.9.13 Applications

The use of expert judgement is now a well-established approach. A critical review of some principal applications has been given by Mosleh, Bier and Apostolakis (1987). Five types of application are reviewed.

The first is the assessment of component failure rates and other reliability parameters. Examples of the estimation of failure rates considered are those in the *Rasmussen Report* (AEC 1975), in IEEE Standard 500: 1984, and in the Seabrook Station PRA (Pickard, Lowe and Garrick, 1983).

The second type is the assessment of seismic hazard rates as exemplified in the studies by the Electrical Power Research Institute (EPRI, 1986) and Veneziano, Cornell and O'Hara (1984).

The third type is the assessment of nuclear reactor containment phenomenology as instanced by the work of the Steam Explosion Review Group of the NRC (1985 NUREG/CR 1116) and the Surry Station PRA by Benjamin *et al.* (1986).

The fourth type is modelling for the assessment of HERs. Examples considered here are: the approach described in the *Handbook of Human Reliability Analysis* (Swain and Guttman, 1983); the human cognitive reliability (HCR) model of Hannaman *et al.* (1986); the SLIM-MAUD method of estimating HERs of Embrey (1984); and, again, the Seabrook Station PRA.

The fifth type is studies of precursor events, which have been carried out by Minarick and co-workers (Minarick and Kukielka, 1982; Cottrell, Minarick *et al*, 1984; Minarick *et al.*, 1985).

These applications covered cases with a wide range of characteristics, including the following:

(1) cases involving single, as well as multiple, experts;
(2) cases involving structured group processes as well as unstructured ones;
(3) cases with a wide range of substantive problem areas;
(4) cases with and without availability of relevant empirical data;
(5) cases of varying degrees of complexity;
(6) cases involving varying degrees of mathematical sophistication in the aggregation of responses;

Some of the conclusions of the study are as follows. (1) An improvement in the quality of the results may often be obtained by decomposition of the problem into a set of more elementary problems. (2) Where experts are used to make estimates without the aid of formal methods, they tend to produce under- or overestimates and to underestimate the degree of uncertainty in these estimates. (3) Two effective techniques for reducing overconfidence are calibration training of the experts and exercises in which the experts are required to identify contrary evidence. (4) A structured group meeting tends to give better performance than an unstructured one. (5) Aggregation of multiple opinions tends to yield a more accurate result than the opinion of a single expert. (6) For aggregation of the opinions of multiple experts, mathematical methods of aggregation are to be preferred to behavioural methods of reaching a consensus.

Decomposition is identified as an effective strategy. The approach suggested by the authors is to enlist the experts in the decomposition process.

The use of multiple experts as opposed to a single expert is well established. But the methods of combining the responses of multiple experts need more development. Combination by an unstructured group does not give accurate results. On the other hand, the highly structured group used in the Delphi method seems cumbersome. The authors suggest the multiple team approach used by EPRI in the seismic hazard work.

9.9.14 Failure rates

As just described, one of the principal applications of expert judgement has been the estimation of failure and event rates. Experience in applications of this sort has been discussed by Apostolakis (1986). He distinguishes three general situations in which judgement is very prominent. These are where: (1) the probability distribution is developed solely from non-statistical knowledge, for example, human error distributions; (2) the advice of experts is incorporated, for example, generic failure rates in the *Rasmussen Report* and fragility curves in seismic work; and (3) the statistical evidence if available but subject to different interpretations. The author discusses some of the detailed features of the generic failure rate estimates in the *Rasmussen Report* and IEEE Standard 500: 1984.

Expert judgement may also be used in the utilization of such generic data. A common situation is in which plant data are available to supplement the generic data and it is then necessary to aggregate them. This may be done using Bayes' theorem. The generic data constitute the prior information that is adjusted using the plant data to obtain the posterior distribution.

Apostolakis draws attention to the fact that in some cases of failure rate estimation when this Bayesian approach is used, it is found that the posterior distribution lies in the tail region of the prior distribution on the high side, indicating bias in the prior distribution. He suggests that this points to the need to broaden the prior distribution, but acknowledges that this is a matter of debate (e.g. Apostolakis, 1982, 1985a; Martz, 1984).

9.10 Rare Events and External Threats

One of the most difficult problems in event frequency estimation is that of rare events. Such events come under the following headings:

(1) equipment failure;
(2) external events
    (a) natural,
    (b) man-made.

Usually it is necessary to take into account rare events only where the potential consequences may be very serious. The rare event problem is therefore essentially associated with major hazards.

9.10.1 Equipment failure

The failure rate of equipment is usually estimated from historical data. The difficulty in using this approach is that for rare events such data are sparse. This may render it necessary to resort to making an alternative estimate based on engineering principles.

It is not uncommon that the historical record appears to show there to be some cases of the event of interest, but that it is judged that many, or even all, of these do not apply to the particular situation of interest. Discarding of failures that are considered inapplicable reduces the data set further.

In the process, and nuclear, industries the rare event that has received most attention is almost certainly pressure vessel failure. The historical record shows only a handful of failures and some of these have been judged inapplicable for vessels designed to and operated at high standards.

Statistics exist which allow an estimate to be made of the failure rate of a device even if the data are limited to just a few, or even one, failure. The confidence limits, however, are a function of the number of failures, and if there are only one or two of these the bounds are wide. It is also possible to make an estimate of the failure rate, or rather its upper bound, even if there have been no failures, based on the number of failure-free years of the equipment. For a rare but high hazard event, however, it is generally necessary to accumulate a rather large number of years without failure before the failure rate estimate begins to approach an acceptable value, and often the number of equipment-years recorded is insufficient. Similarly, statistics exist which allow estimates to be made of failure probability on demand for a device, both with and without recorded failures. The appropriate statistics are given in Chapter 7.

If a statistical approach is considered inappropriate, it is necessary to resort to an attempt to make an estimate based on engineering principles. For example, for a pressure vessel use is made of estimates based on fracture mechanics and inspection considerations.

A prime example of equipment failure as a rare event is the failure of the nuclear reactor pressure vessel considered at the Sizewell inquiry, which is described in Appendix 26.

9.10.2 Natural hazards

There are various natural hazards that pose a threat to plant. Some of these are listed in Table 9.9. The relative importance of a particular natural hazard varies between different countries and between different locations within a country.

For some natural hazards, particularly those due to weather, there are historical records that for certain sites at least may allow a frequency estimate to be made. Others such as those involving surface instability tend to be one-off events that are not amenable to prediction. A third class are those involving subterranean stress where the probability of the event may increase over time until the stress is relieved and where the prediction techniques are still developing.

Information on recurring natural hazards is generally of two kinds. The hazard may be a discrete event that either occurs or does not occur and in this case, the data required are the frequency of occurrence. For such events the usual default assumption is that occurrence is random and that the data fit a Poisson distribution.

The other situation is where the hazard is an event that has associated with it a variable that has a range of values. In this case, the data required are the maximum values of the variable. For example, for wave hazard the required data are maximum wave heights. Data of this latter kind may relate either to maxima of events occurring at random or, where a number of such events always occur within a year, to annual maxima.

The statistical treatment of natural hazards is given in *Statistics of Extremes* (Gumbel, 1958). Descriptions are available of the application of such statistics to various natural hazards such as floods, hurricanes, waves and earthquakes. Further treatments are given by Perry (1981) and Schueller (1982).

In considering such natural phenomena the point of interest is to know the probability that a given value x of the variable, say wind speed or wave height, will be equalled or exceeded – this is the 'exceedance probability'. If the event occurs at random, then for an event rate λ and time period t the number of trials v in which exceedance may occur is

$$v = \lambda t \qquad [9.10.1]$$

If the event is the annual event for which the variable is the annual maximum, the number of trials θ equals the number of years in the time period t.

***Table 9.9** Some natural hazards which pose a threat to plant*

Subterranean stress:
Earthquakes
Volcanoes
Tsunamis

Surface instability:
Landslides and avalanches
Ground surface collapse

Weather:
Wind, storm
Tornadoes
Hurricanes
Floods

Fires

Considering first a general treatment, define $P(x)$ as the distribution of the probability that exceedance does not occur and p as the probability that in a single trial it does occur. Then,

$$p = 1 - P(x) \qquad [9.10.2]$$

Furthermore,

$$q = 1 - p \qquad [9.10.3]$$

$$= P(x) \qquad [9.10.4]$$

where q is the complement of p. The probability $W(v)$ of exceedance in v trials is

$$W(v) = 1 - q^v \qquad [9.10.5]$$

The mean number of trials $\bar{v}$ at which exceedance occurs is

$$\bar{v} = 1/p \qquad [9.10.6]$$

From Equations 9.10.3, 9.10.5 and 9.10.6:

$$W(v) = 1 - (1 - 1/\bar{v})^v \qquad [9.10.7]$$

$$= 1 - \exp(-v/\bar{v}) \qquad 1/\bar{v} = p << \phi \qquad [9.10.8]$$

A return period $T(x)$ may be defined as the mean time between exceedances, so that

$$T = \bar{v}$$

Then, from Equations [9.10.8] and [9.10.9]

$$W(v) = 1 - \exp(-v/T) \qquad 1/T << \o \qquad [9.10.10]$$

$$\approx v/T \qquad v/T << \o \qquad [9.10.11]$$

Equation 9.10.10 is independent of the form of the distribution $P(x)$.

Turning now to the assignment of a specific distribution to the event of interest, Gumbel gives a number of distributions, but that most commonly referred to as the 'Gumbel distribution' is as follows. For $P(x)$ he gives

$$P(x) = \exp\{-\exp[-\alpha(x - u)]\} \qquad [9.10.12]$$

where u is a location parameter and α is a scale parameter. This is the distribution of the probability that exceedance does not occur. The distribution of the probability that exceedance does occur is

$$F(x) = 1 - \exp\{-\exp[-\alpha(x - u)]\} \qquad [9.10.13]$$

It should be noted that Gumbel uses $F(x)$ for the distribution which is here denoted by $P(x)$. Since exceedance is akin to failure, $F(x)$ has been reserved here for the complement of $P(x)$ so that it is akin to the failure distribution functions given in Chapter 7.

Equation 9.10.13 is a form of the extreme value distribution that is described in Chapter 7. This distribution is the appropriate one to use for extreme values of a variable that follows the exponential distribution.

Observed values of the variable of interest may be plotted on special extreme value distribution graph paper, or 'Gumbel paper'. The vertical axis is a linear scale for the values of the variable. The horizontal axis is the probability scale. The observed values are first ordered in ascending order of magnitude. The ranks are then determined from

$$r = m/(n+1) \qquad [9.10.14]$$

where m is the order number, n the number of readings, and r the rank. The rank r is then equivalent to $P(x)$.

As an illustrative example, consider the determination of the distribution parameters for the wind gust data given in Table 9.10, where the data are already ordered and the rank calculated. The data are shown plotted in Figure 9.18. From this graph, at the 0.10 and 0.99 probability points (equivalent to $P(x)$) the values x of the wind speeds are 51 and 95 knots, respectively. Then the parameters u and α are 57.9 and 0.124, respectively.

The return period T of a particular wind speed is obtained as the reciprocal of $F(x)$ $(=1-P(x))$. Consider the return period of a wind speed of 95 knots. Since for this wind speed $P(x) = 0.99$, the probability of exceedance $F(x)$ is 0.01 and the wind speed has a return period of 100 years. This value is extrapolated from 23 data points in which the maximum observed wind speed is 81 knots and is about the limit of extrapolation.

If Gumbel paper is not available, the horizontal scale may be constructed using the reduced variate $y = -\ln(-\ln P(x))$, as shown in Figure 9.18.

Table 9.10 *Annual maximum wind gust velocities at Cardington 1932–54 (after Perry, 1981) (Courtesy of George Allen & Unwin)*

Order no. (m)	*Highest gust* (knots)	*Year*	*Rank (r)*
1	48	1953	0.042
2	51	1950	0.083
3	52	1941	0.125
4	53	1951	0.167
5	54	1952	0.208
6	55	1937	0.250
7	55	1939	0.292
8	56	1942	0.333
9	57	1933	0.375
10	58	1949	0.417
11	59	1948	0.458
12	60	1945	0.500

14	63	1934	0.583
15	63	1944	0.625
16	66	1954	0.667
17	68	1943	0.708
18	68	1946	0.750
19	71	1932	0.792
20	72	1936	0.833
21	75	1938	0.875
22	77	1935	0.917
23	81	1947	0.958

9.10.3 Man-made hazards

Man-made hazards also pose a threat to plant. Some of these are listed in Table 9.11. The estimation of the frequency of events of this type is usually based on the use of historical data together with detailed consideration of the application of the data to the plant in question.

For example, an estimate of the frequency of aircraft crash on a plant would be made by using general data on aircraft crash frequency in combination with information for the particular location about such factors as aircraft flight paths at any nearby airport, deviations from such paths, etc.

9.11 Human Factors and Human Error

Human error and, more generally, human factors is a wide and complex topic and the treatment here is limited to the bare essentials necessary for a balanced treatment of hazard assessment. A more detailed account is given in Chapter 14. The account given there includes details of available techniques. The discussion in this section tries to set these techniques in the context of hazard assessment.

9.11.1 Human error in hazard assessment

Analyses of failures in technological systems generally conclude that in the vast majority of cases human error has played a predominant role. Insofar as any failure can be attributed to some form of human failing, human error in its broadest sense becomes, by definition, the basic cause of failures. An exception to this can occur in the case where a risk has been assessed and, after evaluation, accepted, but where the hazard nevertheless materializes, as statistically it must in a proportion of instances.

It is well appreciated by hazard analysts that it is necessary to take human error into account in hazard assessment work. The problem has been how to achieve this. As with other aspects of hazard assessment, there are two main motivations for investigating human error. One is to reduce it by identifying defects in the human factors environment and effecting improvements. The other is to obtain the data required to be able to quantify the human aspects of the assessment.

The implications of these two motivations for the hazard assessment as a whole are different. The purpose of hazard assessment is to assist decision-making. There is a danger that the second approach will furnish data for quantification, but that it may be relatively ineffective in indicating improvements in the human factors area.

It is fair to say that interest in human error in the process industries has been driven by the perceived need to address human error in hazard assessment, and in particular to obtain the human error data required for quantification.

9.11.2 Human error in operation

Historically, in hazard assessment most attention has been focused on human error in process operation. In the operation of a plant, human error may contribute to an incident either as an initiating or enabling cause or as a failure to achieve some form of prevention or mitigation.

Much of the early work on human error was concerned with estimating error rates in relatively well-defined activities such as detecting a signal, pressing a button or opening a valve. Work then moved on to human error in executing a whole task using a relatively well-defined plan. Both activities and plans may be relevant to either causation or prevention of an incident.

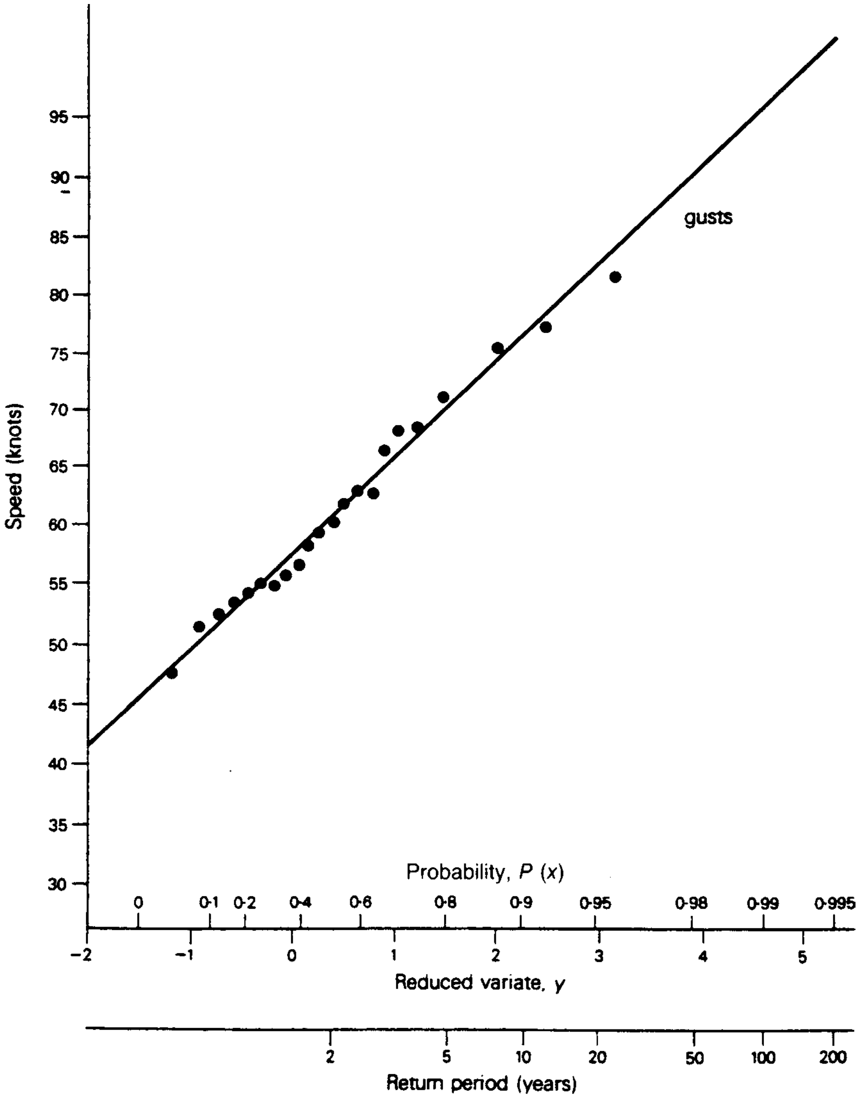

Figure 9.18 *Annual maximum gust velocities given in Table 9.10 plotted on extreme probability (Gumbel) paper (after Perry, 1981)*

Table 9.11 *Some man-made hazards that pose a threat to plant*

Dam bursts
Vehicle crashes
Aircraft crashes
Fires
Explosions

One method was to break a task down into its constituent elements, to collect data on the probability of error in the performance of these elements and to store these data in a human error data bank. This approach, however, tends to do less than justice to the operator's information processing and decision-making which are generally critical to the performance of the task. An alternative method, therefore, is to treat the task as a whole and to collect data on the probability of error in the performance of the task.

Both approaches make allowance for the influence of the work situation in which the task is performed by identifying performance shaping factors. The application of such factors requires the development for each factor of a measure of the strength of the factor and a relationship between the factor and the probability of error.

The most widely quoted method is the THERP technique developed by Swain and Guttman (1983). This technique makes widespread use of estimates of the probability of error in individual actions. A method that gives error estimates for whole tasks is the SLIM technique described by

Embrey (1983a,b). These and other methods are described in Chapter 14.

Human error often occurs in the development of a branch of a fault tree. The typical application of the methods just described is to obtain an estimate of the probability of failure, or error, for use at this point.

Another application of these methods is in the development of the branches of an event tree. Again the methods described have been used to estimate the probability of error at the branch points of an event tree. In particular, interest has centred on the prevention by the operator of escalation of the incident. The operator action event tree (OAET) is a particular form of event tree in which the branch points are defined in terms of failure of operator action.

As so far described, the assessment of operator error occurs within essentially predefined structures such as fault trees and event trees. In some cases, the situation is more complex. One such case is where the operator makes some fundamental error in assessing the situation and performs a series of actions, which may be quite complex, and which cause an incident. This is probably the most difficult case to handle and only limited progress has been made. One area where there has been some progress is in respect of communication errors, as described below.

Another case is where the operator is, in principle, able to prevent an incident but only by making a correct assessment of the situation and performing a series of actions, which may be quite complex and may involve initiative. This situation is sometimes dealt with by making a global estimate of the probability of no effective action. The probability is usually taken as a function that decreases quite strongly with time.

9.11.3 Human error in maintenance

Human error in maintenance has received rather less attention, although there is growing interest in it. Some maintenance errors result in an incident during plant operation. Insofar as the operations function has overall responsibility for safe operation, these may generally be regarded as operational failures. Other maintenance errors lead to an incident while the plant is shut-down. Maintenance errors are also an influencing factor on the failure rate of plant equipment.

9.11.4 Human error in communication

Analysis of incidents shows that an important contribution comes from errors of communication. It is fair to say that so far this work has contributed more to defining good practice in communications that to quantifying this aspect of human error.

9.12 Management Aspects

The prime determinant of the control over a hazard is the quality of management. The influence of management is all pervasive. In other words, it is a powerful cause of failure and has many of the features of a common cause. It is clearly desirable, therefore, to take the quality of management into account in any hazard assessment.

The first point to be made is that if the quality of management falls below a certain level, then there is generally little point in doing a hazard assessment at all. Hazard assessment should be able to start from the assumption that management meets at least some minimum standard of quality, particularly for major hazard installations. If this is not so, the effort would be better employed in remedying the defects than in estimating the probable results of those defects.

A second important point is that the use of management quality as an explicit input in a hazard assessment is a sensitive issue. This is so whether the assessment is being conducted by analysts within the organization concerned or by an outside body.

In general, the realization of a hazard involves the occurrence of an initial event followed by escalation of that event. Management influences both the frequency of the initial event and the effectiveness of measures taken to prevent its escalation.

9.12.1 Quantification of management influence

The attempt to make allowance for the effect of management quality involves both devising a measure of quality and a model for the impact of that quality on event frequency and escalation. Discussions of allowance for management quality in hazard assessment has been given by R.A. Cox and Comer (1982), Pitblado, Willliams and Slater (1990) and J.C. Williams and Hurst (1992).

Some limited progress has been made in this area. Aspects of the quality of management are considered in Chapter 6. Indices of quality may be devised for this specific purpose or, alternatively, use may be made of other indices such as the International Safety Rating System (ISRS).

The most straightforward application of such indices is to failure rates. Generic equipment failure rates may be regarded as being derived from organizations with 'average' quality management. These base failure rates may be adjusted according to the assessment made of management quality.

9.12.2 MANAGER model

The MANAGER model developed by DnV Technica and described by Pitblado, Williams and Slater (1990) exemplifies this approach.

A review was conducted of systems that might be adapted to provide modifiers for generic failure data to take into account management factors (MFs). Systems reviewed included the ISRS (Bird and Germain, 1985), the Management Oversight and Risk Tree (MORT) (W.G. Johnson, 1980) and the Technique for Human Error Rate Prediction (THERP) (Swain and Gutmann, 1983). The first two are described in Chapter 28 and the last in Chapter 14. It was concluded that ISRS would be relatively slow and costly to use and that it would not fit well with QRA, and that the strength of MORT is in accident investigation and that of THERP is in assessing the human error contribution in fault tree analysis. A requirement was defined for a modification of risk (MOR) method that would be simpler to use than human reliability assessment.

The properties that such a method should have were identified as the following. It should: (1) be based on a review of the role of safety management in actual accident causation, (2) address all areas shown to be important in accident causation, including human factors, (3) confirm that widely accepted management principles are suitably embedded in all key elements of the safety management system and (4) provide both a qualitative overview of safety management and an indication of quantitative modification to generic failure rates.

MANAGER is based on a questionnaire that utilizes the concept of performance shaping factors, which are described in Chapter 14. The four most significant for this purpose were identified as (1) resources (manning, instrumentation), (2) system norms (incident reporting, safety policy, training), (3) communications (information flow, written documentation) and (4) pressures (stress, boredom). The questions are structured to conform with loss prevention principles as well as with these human factors influences. The questionnaire is structured into 12 broad topics, as shown in Table 9.12.

The responses to the questionnaire are scored as the proportion P which are rated as industry average (P_A), better than average (P_G) or worse than average (P_B) Use is made of a triangular diagram with these three proportions P_A, P_G and P_B at its corners. Values of a MF are located on the triangular diagram. A completely average plant ($P_A = 1$) has a value of MF = 1. This same value of the MF is also obtained by a plant with only good and bad responses ($P_A = 0$) at $P_G = 0.74$ and $P_B = 0.26$. A completely good plant has MF = 0.1 and for a completely bad plant MF = 100. In some 30 plant audits, values of MF ranged from 0.5 to 8.0.

The MF may then be used in QRA as a modifier for generic failure rates:

$$F_{\mathrm{est}} = \mathrm{MF} \times F_{\mathrm{gen}} \qquad [9.12.1]$$

where F_{est} is the modified failure frequency and F_{gen} is the generic failure frequency.

A case study of the application of MANAGER has been described by J.C. Williams and Hurst (1992). A comparative investigation was made of two technically similar major hazard sites. The comparison was between the number of incidents reported under the RIDDOR regulations and the computed MF. The numbers of RIDDOR incidents per 1000 employees over the periods April 1986–March 1987, April 1987–March 1988 and January–March 1991 were 8.7, 7.3 and 5.9 for company A and 12.5, 10.3 and 8.0 for company B. The computed MFs were 0.9 for company A and 1.7 for company B. Thus at site B the occupational incident rate was almost twice that at site A, and likewise the risk at site B as given by the MF was nearly twice that at site A. QRA showed that an individual risk of 10^{-5}/year occurred at site B at a distance of 400 m but at site A at 290 m. Further studies would be required to confirm the generality of the correlation.

As the study just described indicates, MANAGER may also be used for audit purposes.

Table 9.12 *Twelve topic areas of MANAGER questionnaire (after Pitblado, Williams and Slater, 1990)*

11. Other human factors influences
12. Fire protection systems

9.12.3 STATAS model

Another model that is relevant here is STATAS. This has been developed for the purposes of audit. However, just as MANAGER may also be applied to audit, so STATAS has a potential use in making allowance for MFs in QRA. It is described in Chapter 6.

9.13 Hazard Models

The estimation of the physical effects of a particular release scenario involves the use of a series of hazard, or consequence, models. Some of the models required are shown in Table 9.13. Most of the entries are straightforward,

Table 9.13 *Some principal hazard models*

Emission
Holes:
  Gas flow
  Liquid flow
Two-phase flow
Vessel rupture
Pipeline rupture
Vents
Relief valves
Vaporization
Flashing liquids
On land:
  Spreading liquid
  Volatile liquid
  Cryogenic liquid
On sea:
  Spreading of immiscible liquid
  Mixing of miscible liquid
  Volatile liquid
  Cryogenic liquid
Air entrainment
(for each emission situation)
Source term
Gas cloud dispersion
Neutral density clouds
Heavy gas clouds
Buoyant gas clouds
Plumes
Neutral plumes
Heavy gas plumes
Buoyant plumes
Jets
Momentum jets
Fires
Pool fires
Fireballs
Flash fires
Jet flames
Engulfing fires
Explosions
Physical explosions of plant
Combustion explosions inside plant
Vapour cloud explosions
Explosions in buildings
Boiling liquid expanding vapour explosions

but the references to air entrainment and source term require some further explanation.

The models for emission allow an estimate to be made of the amount of material that is released or the rate at which it is released, but they do not in themselves necessarily give any information on the extent to which the emission entrains and mixes with the air. Dispersion models can be sensitive to the amount of air that mixes with the initial emission. It is necessary, therefore, to make some estimate of this.

The emission constitutes the source term for the dispersion models. A real emission does not usually correspond exactly to idealized source terms such as pure instantaneous or continuous sources, and a source term has to be selected which represents the situation as closely as possible but is suitable as input to the dispersion model.

Consequence models are described mainly in Chapters 15–17.

9.14 Domino Effects

Another aspect that needs to be taken into account in hazard assessment is the possibility of knock-on or 'domino' effects, leading to escalation. An event at one unit may be the cause of a further event at another unit, and so on.

The possibility of domino effects was one of the principal concerns that led to the hazard assessment of the complex of installations at Canvey, which was the subject of the two *Canvey Reports* described in Appendix 7.

The incident at Feyzin in 1968 (Case History A38) in which a fire on one storage sphere led to a series of fires and explosions involving other spheres illustrates the danger. Other subsequent incidents in which a domino effect has played an important role include Mexico City in 1985, Pasadena in 1988 and Piper Alpha in 1988. These incidents are described in Appendices 4, 6 and 19, respectively.

A method of handling potential domino effects in hazard assessment has been described by Bagster and Pitblado (1991). Table 9.14 shows a matrix of interactions between the process areas of two different operators obtained from the *Canvey Report* and quoted by these authors. A domino event may be treated either as an increase in the consequences of the event at the initiating unit, or as an increase in the frequency of events at the victim unit. The method described in this work adopts the latter approach.

Five events are included in the treatment: pool fire, explosion, boiling liquid expanding vapour explosion (BLEVE) giving rise to a fragment, jet fire and delayed explosion of a vapour cloud. The escalation is described in terms of a loss of containment at the victim unit. The following relation is used to describe loss of containment at unit *j* due to an event at the initiating unit *i*:

$$p_{\mathrm{loc};j;i} = \left[1 - \frac{r}{r_{\mathrm{lim};i}}\right]^2 \qquad [9.14.1]$$

where $p_{\mathrm{loc};j;i}$ is the probability of loss of containment at unit *j* due to an event at unit *i*, *r* is the distance of unit *j* from unit *i*, and $r_{\mathrm{lim};i}$ is the maximum distance at which the event at unit *i* can cause damage.

The basic relation for the frequency of loss of containment at the unit *j* due to an event at unit *i* is

$$F_{\mathrm{loc};j;i} = P\mathrm{I}_i \left(F_{\mathrm{cat};i} \sum_{m=1}^{3} p_{\mathrm{loc};j;i;m} P_{m;i} M_{m;i} + F_{\mathrm{leak};i} \sum_{m=4}^{5} p_{\mathrm{loc}rm;j;i;m} P_{m;i} M_{m;i} \right) \qquad [9.14.2]$$

with

$$M_{1:i} = M_{2:i} = 1 \qquad [9.14.3]$$

where $F_{\mathrm{cat};i}$ is the frequency of a catastrophic failure at unit *i*, $\mathrm{F}_{\mathrm{leak};i}$ is the frequency of a leak failure at unit *i*, $F_{\mathrm{loc};j;i}$ is the frequency of loss of containment at unit *j* due to an event at unit *i*, $M_{m;i}$ is the factor for mitigation of the event at unit *ı* due to its directionality, $p_{\mathrm{loc};j;i;\mathrm{m}}$ is the probability of loss of containment at unit *j* due to an event at unit *i* of type *m*, $P_{m;i}$ is the probability that the event at unit *ı* is an event of type *m* and PI_i is the probability of ignition following failure at unit *i*. The five events are pool fire (PF; $m = 1$), explosion (EX; $m = 2$), BLEVE fragment (BF; $m = 3$), jet fire (JF; $m = 4$) and delayed explosion (DEX; $m = 5$). The same probability of ignition is used for both types of failure and for all types of event.

In addition to this escalation of the primary event at unit *i* into a secondary event at unit *j*, the method also takes into account escalation of the latter into a tertiary event at unit *k*. In order to do this, it is necessary to make some assumption about the probability distribution of the failures induced at unit *j*. The assumption made is that the distribution between catastrophic failures and leak failures at unit *j* is the same as that at unit *i*. The relation for the probability of loss of containment at unit *k* due to an event at unit *j*, itself due to an event at unit *i*, is then

$$P_{\mathrm{loc};k;j;i} = \mathrm{PI}_{j\mathrm{loc};j;i} \left[\phi_j \sum_{m=1}^{3} p_{\mathrm{loc};k;j;m} P_{m;j} M_{m;j} + (1 - \phi_j) \sum_{m=4}^{5} p_{\mathrm{loc};k;j;m} P_{m;j} M_{m;j} \right] \qquad [9.14.4]$$

with

$$\phi_j = \frac{F_{\mathrm{cat},j}}{F_{\mathrm{cat},j} + F_{\mathrm{leak},j}} \qquad [9.14.5]$$

$$M_{1;j} = M_{2;j} = 1 \qquad [9.14.6]$$

where $M_{m;j}$ is the factor for mitigation of the event at unit *j* due to its directionality, $P_{\mathrm{loc};k;j;i}$ is the probability of loss of

Table 9.14 *Matrix of potential interactions of process area explosions for two installations at Canvey: frequency of massive release of LPG per 10^6 years (Bagster and Pitblado, 1991) (Courtesy of the Institution of Chemical Engineers)*

Explosion at	*Fire spreading to LPG storage at*

containment at unit k due to an event at unit j, itself due to an event at unit i, $p_{\mathrm{loc};k;j;m}$ is the probability of loss of containment at unit k due to an event at unit j of type m, $P_{m};j$ is the probability that the event at unit j is of type m, PI_j is the probability of ignition following failure at unit j, and ϕ_j, is the probability that the failure at unit j is catastrophic.

It is also necessary to take into account the fact that the damage zone of the event at unit j may be partially or totally within the damage zone of the event at unit i, or vice versa. This is taken into account by utilizing for each type of event a correction factor S_m. This correction factor is applied to the frequency of loss of containment at unit j for an event at unit i of type m. In effect, this is a correction to allow for overlap of the damage zones and thus to avoid double counting of the damage.

The three situations that are possible if overlap occurs are shown in Figure 9.19. An overlap factor q_m is defined which has the values

$q_m = 1$	damage zone of event i lies entirely within that of event j
$q_m = 1/2$	damage zones of event i and j partially overlap
$q_m = 0$	damage zone of event j lies entirely within that of event i

The overlap correction factor S_m is then

$$S_m = \frac{\sum_{m=1}^{5} P_m M_m q_m}{\sum_{m=1}^{5} P_m M_m} \qquad [9.14.7]$$

where M_m is the probability of mitigation of an event at unit j of type m, P_m is the probability that the event at unit j is an event of type m and q_m is the overlap factor for an event at unit j of type m.

The authors give the following illustrative example. They investigate the domino effects for two alternative layouts of a plant consisting of four items – an atmospheric storage tank, two storage spheres and a compressor. In one configuration the items are laid out in a square and in the other they are in a line. Details of the units are given in Table 9.15, Section A. The frequencies of loss of containment for three levels of escalation in the square layout case are shown in Table 9.15, Section B, and the corresponding first-order domino matrix in Section C. The results given in the domino matrix show, for example, that for unit 1 the base failure frequency of 6×10^{-6}/year is augmented by 0.893×10^{-6}/year due to domino effects.

9.15 Hazard Model Systems

There are a number of hazard model collections and complete hazard assessment systems. These include:

(1) the vulnerability model;
(2) the '*Yellow Book*';
(3) plant layout model;
(4) SAFETI system;
(5) WHAZAN system.

These are now described in turn.

9.15.1 Vulnerability model system

One major hazard assessment system is the vulnerability model (VM), later renamed the population vulnerability model (PVM), developed under contract for the US Coast Guard to investigate the possible effects of hazardous material spills. The basic VM is described by Eisenberg, Lynch and Breeding (1975) in a report entitled *Vulnerability Model: A Simulation System for Assessing Damage Resulting from Marine Spills*. Specific models developed in support of the VM are given by Raj and Kalelkar (1974). The second stage of the development of the VM is described by Rausch, Eisenberg and Lynch (1977) and the third stage by Rausch, Tsao and Rowley (1977). Modifications to the VM are described by Tsao and Perry (1979) and by Perry and Articola (1980) and a users' guide is given by Rowley and Rausch (1977). The VM and its applications have been reviewed by Parnarouskis, Perry and Articola (1980).

The VM is a consequence assessment system. It consists of a set of hazard models and injury/damage relations which are used in conjunction with meteorological and population data for a given site to assess the effects of specified releases of hazardous materials. The overall structure of the VM is shown in Figure 9.20. Within this structure, there are a number of decision trees for the selection of the scenarios and the corresponding hazard models. The decision tree for the behaviour of the cargo on release is shown in Figure 9.21. The information required by and obtained from the model is shown in Table 9.16. Figure 9.22 illustrates the simulation of a vapour cloud from a marine spill.

Some of the principal elements in the VM are shown in Table 9.17. As the table indicates, the VM is a prime source both of hazard models and of injury relations for both flammable and toxic releases. Many of these are considered in later chapters.

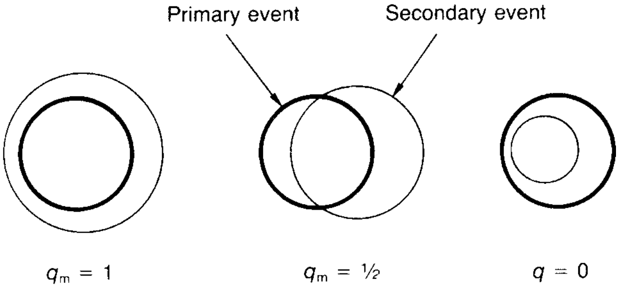

Figure 9.19 *Relationship between primary and secondary events in a domino incident (Bagster and Pitblado, 1991) (Courtesy of the Institution of Chemical Engineers)*

Table 9.15 *Illustrative example of potential interactions for four plant items on a single site (after Bagster and Pitblado, 1991) (Courtesy of the Institution of Chemical Engineers)*

A Data

Plant item number	1	2	3	4
Plant type	Atmospheric storage tank	Sphere	Sphere	Compressor
Toxic?	No	No	No	No
FC_{kt} (per million years)	1.0	1.0	1.0	50
F_{leak} (per million years)	5.0	1.0	1.0	100

[a] 0.061 + 0.070 + 0.762.

The injury relations in the VM, given in the form of probit equations, have proved of particular interest, owing to the paucity of information on this aspect. The VM studies did pioneering work in defining the form of the causative factor and in deriving constants for the probit equations. Inevitably, some of these require modification in the light of more recent work. Table 9.18 lists some of the original probit equations in the model. In the later work, revisions and additions were made to the probits for toxic gases, as described in Chapter 18.

The principal application of the VM is consequence assessment for planning purposes. It is used to estimate for a particular site the effects of hazardous releases, to determine whether particular releases would cause casualties, and to give a hazard ranking. The VM is also used to compare the hazards of specified releases at different sites. For example, comparisons have been made of the relative hazards of LNG terminals at Point Conception and Oxnard in California.

9.15.2 '*Yellow Book*' models

A major collection of hazard models is given in *Methods for the Calculation of the Physical Effects Resulting from Release of Hazardous Material* by the Committee for the Prevention of Disasters (CPD, 1992a) in the Netherlands. The report is published by the Dutch Labour Inspectorate and the work was done by Toegepast-Natuurwetenschappelijk Onderzoek (TNO). It is usually referred to as the '*yellow Book*'. The principal contents of the *Yellow Book* are shown in Table 9.19.

9.15.3 Plant layout models

A set of hazard models for use in plant layout has been given in *Process Plant Layout* (Mecklenburgh, 1985). These models are listed in Table 9.20.

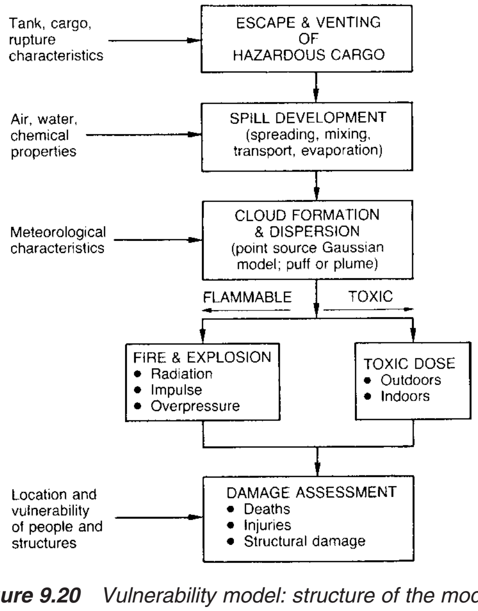

Figure 9.20 *Vulnerability model: structure of the model (Parnarouskis, Perry and Articola, 1980)*

9.15.4 SAFETI computer code

Another major collection of hazard models is that in the SAFETI computer code for risk assessment developed by Technica. The hazard models used, as described by Pitblado and Nalpanis (1989), are as follows. For gas dispersion, four regimes are recognized. These are (1) turbulent jet dispersion, (2) hydrid dispersion with both turbulent jet and dense gas behaviour, (3) dense gas cloud, and (4) passive dispersion. The dense gas dispersion model used is that of R.A. Cox and Carpenter (1980).

The other models cover: (1) vaporization from a pool using the model of O.G. Sutton (1953) or, for liquids with boiling points below ambient, that of Drake and Reid (1975); (2) vapour cloud explosion using the TNO correlation model by Opschoor (1979); (3) fireball, or BLEVE, based on the model of Moorhouse and Pritchard (1982); (4) pool fire, using an in-house model; and (5) jet flame, using the TNO free jet model to obtain the jet length combined with the American Petroleum Institute (API) model for thermal radiation. There is no flash fire model as such; it is assumed that the fire is co-terminus with the cloud and in determining injury a small additional increment is added to this contour to allow for the thermal radiation close to the cloud. Probit equations are used for injury and damage effects.

9.15.5 WHAZAN computer code

A set of hazard models is the core of another computer code WHAZAN developed by Technica for the World Bank. The package is described in *Manual of Industrial Hazard Assessment Techniques* (World Bank, 1985). This system allows the user to explore interactively the consequences of a set of release scenarios. The frequency of occurrence of the scenarios is not estimated and the hazard models are relatively simple. The package is not intended for probabilistic risk assessment.

The models used are given in Table 9.21 and a typical event tree which the user can explore using WHAZAN is illustrated in Figure 9.23. These relate to the initial version of the program. WHAZAN is therefore a much simpler package than SAFETI. It is described further in Chapter 29.

9.16 Population Characteristics

Information on the characteristics of the exposed population is frequently required in a hazard assessment. The people exposed consist of two groups, those working on the site and those living and/or working in the area around the site.

It is usually a straightforward matter to obtain the necessary information on the on-site workforce, but this is not so for the off-site population. Here the data required include

(1) population density;
(2) population composition;
(3) population changes by time of day;
(4) vulnerable population;
(5) population outdoors.

For estimation of societal risk information is required on all these items, but even for estimation of individual risk only it is still necessary to have data on the vulnerable population and the population outdoors.

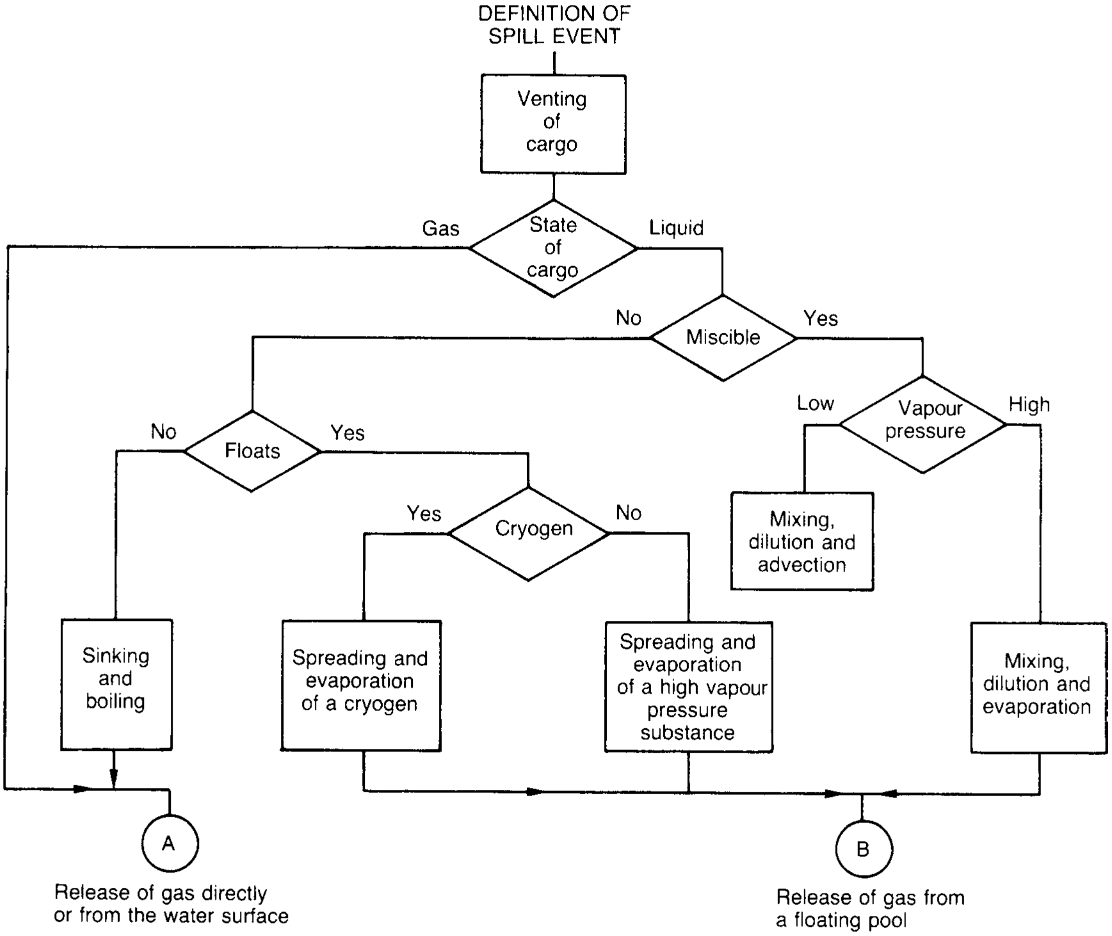

Figure 9.21 *Vulnerability model: decision tree for behaviour of cargo on release (Eisenberg, Lynch and Breeding, 1975)*

The accuracy of estimation of the density and other characteristics of the population should broadly match that of the other stages of the hazard assessment. A very refined estimate of the population characteristics will often not be justified. On the other hand, it should be borne in mind that some of the factors that characterize the population are not independent. Thus the number of people at home during the day is less than at night, but the proportion of vulnerable people is greater.

A method for the determination of the population characteristics for Britain has been given by Petts, Withers and Lees (1987). The method is intended primarily for use in estimating the societal risk of fatalities for sets of scenarios where typically in a large proportion of cases the fatal effects may not extend sufficiently far for more approximate methods of estimating population density to give sufficient accuracy.

9.16.1 Population density

Estimates of off-site population density have been made in the two *Canvey Reports* and in the *Rijnmond Report*. The *Canvey Reports* are mainly concerned with the off-site population, but the *Rijnmond Report* gives estimates of the on-site population density. For the on-site population, data on the number of workers at each site were obtained and the numbers present during the working day N_d and at other times N_n were determined. Then assuming three-shift, 7-day working, the number of manshifts worked per week is $5\,N_d + 16\,N_n$, and assuming that each employee has n_h weeks off for holidays and sickness, etc., and therefore works $(52 - n_h)$ weeks per year, the average number N_s of employees on site is

$$N_s = ((5N_d + 16N_n) \times 52)/(5 \times (52 - n_h)) \qquad [9.16.1]$$

The average number on site in the daytime for the six sites in this study was found to be 200 persons/km^2. The site area used in this computation appears from the map of the area to be filled with process plant and storage and does not contain much open space.

For the off-site population in the First *Canvey Report* the general approach is to define the built-up areas on the map and to use for these areas a uniform population density of

Table 9.16 Vulnerability model: outline of information required by and obtained from the model (after Perry and Articola, 1980)

A Information required
Characteristics of the cargo (e.g. chemical composition, size of tank, temperature of cargo)
Size and location of the rupture
Characteristics of the spill environment (e.g. marine characteristics and weather conditions)
Geographical location of the spill
Location and characteristics of the vulnerable resource (people and property) in the vicinity of the spill
B Information obtained
Size and characteristics of the spill
Disposition of the hazardous materials (e.g. mixing, sinking, dilution, vaporization, diffusion, dispersion)
Concentrations and hazardous effects of spilled material as a function of position and time (e.g. toxic concentration and dose, thermal intensity and dose, overpressure)
Number of people killed and injured and amount and value of property damage

4000 person/km^2. The population profile was obtained in some cases up to 32 km from the hazard source. In some of the studies in the report, however, there are variations. In Appendix 3, use is made of population densities of 5000 and 100 persons/km^2 for urban and rural areas, respectively. In Appendix 14, use is made of census data on the number of people in 100 m squares. In the Second *Canvey Report* it is this latter method that is used.

The *Rijnmond Report* also makes use of census data on the number of people in grid squares, in this case 500 m squares. This grid covered an area of some 75 km^2. Uniform population densities were assumed outside the grid.

The method for the estimation of the population density for British conditions given by Petts, Withers and Lees is as follows. Use is made of national census population data. In Britain, there is a full census every decade, the then most recent being in 1971 and 1981. The 1981 Census (OPCS, 1981a) is available as is the official user guide (OPCS, 1981b) and a further guide (Rhind, 1983). Other useful documents are the 1981 Labour Force Survey (OPCS, 1981c) and the Annual Abstract of Statistics (CSO, 1985). The basic small geographical unit for the census is the enumeration district (ED), which is an area of land defined in terms of the number of households representing a suitable census workload. The average population of an ED in England and Wales is about 500 in urban areas and 150 in rural areas. The local geography of the census in Scotland is slightly different in that EDs are built up from the Post Office postcode areas. The main small unit statistical output from the census is the small area statistics (SAS), which are supplied by the Census Office on magnetic tape, on microfilm or as paper copy. There are delays of several years in the publication of some census data. Naturally, the data become out of date, and this needs to be borne in mind.

The estimation of the population density off site requires the use of Ordnance Survey maps. Four principal map sizes relevant here are the 1 : 25,000, 1 : 10,000, 1 : 2500 and 1 : 1250 scale series. The 1 : 10,000 scale is that normally used by local authorities. It is also the size on which the census EDs are recorded and maps showing the boundaries of the EDs are available from the Census Office as paper copies of microfilmed 1 : 10,000 scale maps. The 1 : 2500 and 1 : 1250 scale maps can be useful in locating more accurately the boundaries between EDs; unfortunately the whole country is not covered by these series. These maps give the most detailed record of buildings. In the 1 : 10,000 and 1 : 25,000 series there is some loss of detail and accuracy with respect to buildings.

The method that gives the most accurate results for population density is the use of the census data. This should therefore be used where it is practical to do so. There may, however, be reasons for not using census data for the whole area of interest. One is that it can be time-consuming. Another is that the census may have become out of date.

In these circumstances, a rapid estimate of population may be made using a map to identify the built-up areas and assuming population densities of 4000 persons/km^2 for large built-up areas, 100 persons/km^2 for other inhabited areas, and zero population for uninhabited areas.

For more accurate work, a more detailed approach is necessary. It is recommended by Petts, Withers and Lees that three zones be defined around the hazard source, delimited by distances of 400 and 1000 m. For the outer zone (>1000 m) the rapid estimation method should be used. For the intermediate zone (400–1000 m) the map should be used to identify three types of residential area and the uninhabited area. These three types of residential development are: dense, usually in-town, terraced housing (and high-rise flats); semi-detached housing, usually suburban; and sparse, detached housing. Population densities of 15,000, 10,000 and 1000 persons/km^2, respectively, should be used.

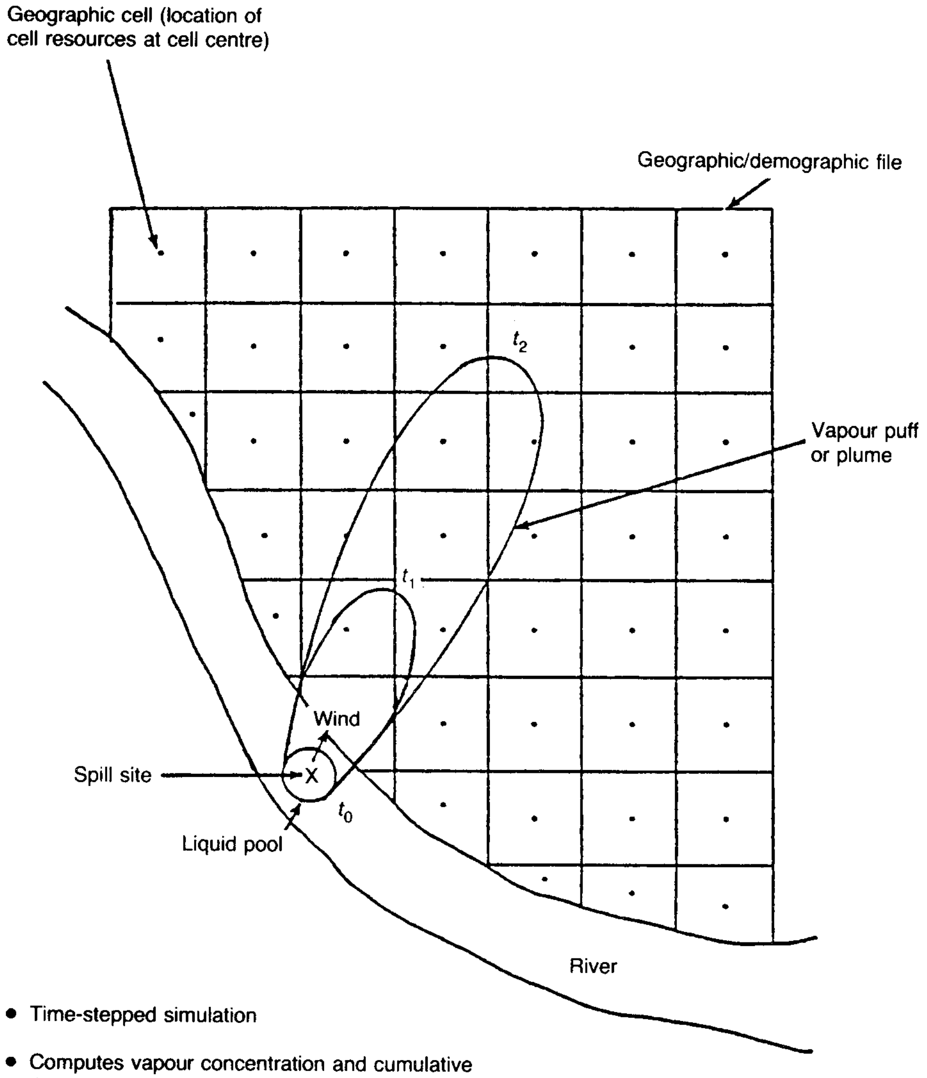
For the inner zone (<400 m) the population should be estimated from census ED data. It is recommended, however, that for this inner zone this estimate should be checked against visual inspection and local inquiry. The radius of the inner zone was originally set at 250 m, but site inspection indicated that this may be too short a distance for acceptable accuracy. The distance of 400 m is therefore preferred as the boundary of the inner zone. This method for the estimation of the density of the population around a hazard source is summarized in Table 9.22.

It is necessary to define the point from which the circles defining these zones are drawn. There appears at present to be some difference of practice. In some cases this point is taken to be the plant itself, in others the site boundary. The former makes more sense for a plant at a specific point, but the latter allows for relocation of the plant within the site boundary.

The accuracy of the method described for the estimation of the population density in the middle zone was checked against the 1981 Census data for three hazardous sites. The average difference in the estimates of the numbers of people was 14%, one estimate being low and two high.

The use of the census data is not entirely straightforward. The approach used by the authors was first to identify the codes of the required EDs from 1 : 10,000 scale maps provided by the Census Office and then to obtain the ED data by interrogating the Census computer data bank.

There are in existence several computer programs that process population data. These use data on the numbers of people in each 100 m square. This information was provided in the 1971 Census, but is not available in the 1981 Census.



- Time-stepped simulation
- Computes vapour concentration and cumulative dose at each cell
- For flammable vapours, simulation stops when ignition occurs, and fire or explosion damage to each cell is computed at that time
- Ignition occurs if cell contains ignition source and concentration is above lower flammable limit

Figure 9.22 *Vulnerability model; simulation of vapour release from a marine spill (Parnarouskis, Perry and Articola, 1980)*

The basic case for the off-site population is the nighttime population. It is this that is given by the census data and by the method just described. An approximate estimate of the number of people over the whole 24 h is 80–85% of this value. However, the probability of some hazards may be a function of time of day and it then becomes necessary to estimate population by time of day also. The daytime population may be estimated more accurately, as described below.

Attention is drawn by Petts, Lees and Withers to the fact that errors in drawing the boundaries between areas of different population densities can easily lead to errors which are as great or greater than those which are due to errors in estimating those densities.

9.16.2 Population composition

In order to obtain a more detailed picture of the population it is necessary to define the population composition. This is relevant to the probability that an individual is at his home base, that he is a member of a more vulnerable population and/or that he is outdoors.

Information on population categories is available in the 1981 Labour Force Survey (OPCS, 1981c) as shown in Table 9.23. From these data Petts, Withers and Lees have derived the population composition model given in Table 9.24.

In order to use this population composition model it is necessary to define the times of day. The set of times of day used by the authors is shown in Table 9.25, Section A. These are to be used with the population categories at home by time of day given in Table 9.25, Section B.

9.16.3 Population change by time of day

Using the definitions of population composition and of times of day just given, estimates may be made of the population changes by time of day. The estimates based on the data given in Table 9.25, Sections A and B, are given in Section C of the table. It was found that for random sections of the Canvey and Rijnmond populations, the proportions of the nighttime population who were at home during the day were 42% and 46%, respectively.

9.16.4 Vulnerable population

Some members of the population are likely to be more vulnerable to the hazard than others and it may be necessary to take this into account. In general, it is children, old people and infirm people who tend to be most vulnerable, and the proportion of vulnerable people may be estimated as a first approximation by determining the proportion in these categories. However, vulnerability must be a function of the particular hazard. For example, children

Distance from hazard source (m)	*Method*	*Population density* (persons/km^2)
<400	Use of Census data	From enumeration district data
400–1000	Use of Ordnance Survey maps	Dense terrace housing: 15,000 Semi-detached housing: 10,000 Sparse detached housing: 1000 Uninhabited areas: 0
>1000	Use of Ordnance Survey maps	Built-up areas: 4000 Other inhabited areas: 100 Uninhabited areas: 0

Table 9.23 *Population categories and composition based 1981 Labour Force Survey (after Petts, Lees and Withers, 1987) (Courtesy of Elsevier Science Publishers)*

	Number (thousands)	*No. per household*
Adults in full-time employment	16,595	0.85
Adults in part-time employment	4,042	0.21
Self-employed	2,164	0.11
Unemployed	2,447	0.13
Housewives	7,092	0.36
Children: 0–4 years	3,222	0.17
Children: school age	8,753	0.45
Students	1,415	0.07
Retired	6,266	0.32
Others (including permanently sick and disabled)	1,100	0.06
Total	53,096	2.73
Total no. of households	9,442	

may actually recover better from some burns than adults, and persons with respiratory disease are likely to be more susceptible to irritant toxic gas, but not necessarily to thermal radiation.

As a first approximation, therefore, the population may be divided into two broad groups: (1) adults of working age and older children and (2) young children and old people. The first group is some 75% and the second some 25% of the population. In general, the latter is the more vulnerable group, although for some hazards it may be necessary to have a more specific definition. In this case, the proportion of vulnerable people may be assessed in relation to the particular hazard considered using the population composition model given in Table 9.24.

Mention may be made here of estimates of the proportion of vulnerable people given by other workers. Table 9.26 shows some estimates made by Hewitt (1976) for the proportion of people vulnerable to a toxic irritant gas such as chlorine.

9.16.5 Population outdoors

Very little information was found by Petts, Withers and Lees on the proportion of the population which is outdoors at different times of the day. In the *Rijnmond Report*, the proportion of people indoors was taken in the context of toxic gas hazard as 99%, allowing for the fact that some people would seek shelter from this hazard indoors.

The population location model derived by the authors is shown in Table 9.27. It was assumed that the regular and vulnerable groups spend 1 and 1/2 h/day outdoors, respectively, that the proportion of the total population outdoors at night (18.30–08.00 h) is 1%, and that those outdoors are drawn exclusively from the regular population. Then the time outdoors and the proportions outdoors by day, by night and overall may be calculated for the regular, vulnerable and total populations. A partial cross-check on the model or, more specifically, a crosscheck on the lower bound of the proportion of the population outdoors, was obtained from wartime data on V-2 rocket bomb casualties.

9.17 Modification of Exposure

The characteristics of the population at risk may need to be modified to take account of changes in the exposure of the population that occur if there is warning of the hazard. There are a number of ways in which an individual who becomes aware of a hazard may modify his exposure. He may seek shelter indoors or he may try to distance himself from the hazard, either by individual escape or by participating in an organized evacuation.

While these are the principal actions, they are by no means the only ones. There are others that are more specific to the hazard concerned. For example, an individual may seek shelter from the thermal radiation of a fireball behind some

Table 9.24 Population composition model (after Petts, Lees and Withers, 1987) (Courtesy of Elsevier Science Publishers)

A Unemployment 5%

	No. per household	*Proportion* (%)

Total	2.71	100.0

structure. Or he may try to reduce his vulnerability to the blast from an explosion by adopting a different body posture.

Some aspects of modification of exposure by escape and evacuation are considered here. Other aspects such as modification by shelter are treated in the chapters on particular hazards. Organized evacuation as part of emergency planning is discussed in Chapter 24.

9.17.1 Reaction

The most basic feature bearing on modification of exposure is the response time of humans.

Estimates of human response time in emergencies have been made by the British Compressed Gases Association (BCGA, 1984) in relation to response to ignition of clothing in an oxygen-enhanced atmosphere. Work on human factors (e.g. Denison and Tonkins, 1967) is quoted, to the effect that the time taken by humans to respond to an unexpected situation varies between 5 and 20s. The BCGA obtain from this the following response model:

(1) 5% of the population (i.e. babies and disabled persons) are incapable of any reaction
(2) 95% of the population are capable of reaction, of whom it is assumed: 80% can react within 15 s, 25% can react within 10 s, 10% can react within 7.5 s.

It is taken that none of the population can react within 5 s.

Table 9.25 *Population composition at home by time of day (after Petts, Lees and Withers, 1987) (Courtesy of Elsevier Science Publishers)*

A Time-of-day categories

	Time of day	*Duration*	
		(h)	(%)
School day	08.00–16.00	8	33
Work day	08.00–18.30	10.5	44
Night	18.30–08.00	13.5	56

B Population categories at home

	Categories
School day	1(b), 2(b), 3, 4(b), 5(b), 6(b), 7–9
Work day	All except 1(a)
Night	All

C Proportion of population at home

	Proportion at home (%)	
	Unemployment 5%	*Unemployment* 10%
School day	46.5	49.1
Work day	67.2	69.0
Night	100.0	100.0

9.17.2 Escape

A systematic treatment of individual escape is difficult. The principal case where this has been attempted is for escape from toxic gas by walking out of the cloud. The treatment of this problem given in the First *Canvey Report* is described in Appendix 7.

9.17.3 Evacuation

Organized evacuation is more readily analysed. A simple model for evacuation is:

$$\phi(t) = 1 \qquad t < t_d \quad [9.17.1a]$$

$$= \phi(\infty) + [1 - \phi(\infty)]\exp[-\lambda(t - t_d)] \qquad t \geq t_d \quad [9.17.1b]$$

where t_d is the time lag before any evacuation starts, λ is a constant, $\phi(t)$ is the fraction of population which has not evacuated at time t, and $\phi(\infty)$ is the fraction of population which does not evacuate at all. The constant λ is related to the evacuation half-life $t_{1/2}$ as:

$$\lambda = 0.693/t_{1/2} \quad [9.17.2]$$

This model has been used by Solomon, Rubin and Okrent (1976) to allow for the effect of evacuation in hazard assessments of large toxic releases. Most other workers appear to have used a similar model.

A study of evacuation effectiveness in actual emergencies has been made by Hans and Sell (1974), who give details of evacuation from transportation, hurricane and flood emergencies. The transportation emergencies include the incidents shown in Table 9.28. The overall conclusion of these investigators is that behaviour in such emergencies is less irrational and more effective than is often supposed.

Table 9.26 *Vulnerable members of population (after Hewitt, 1976)*

	No. per 1000 people
Children:	
<6 months	8
<12 months	8
12 months–5 years	75
5–9 years	82
Old people (>70 years)	85
People with chronic heart trouble	5
People with respiratory diseases	9
People with restricted mobility	4
Blind people	2
Healthy youngsters and adults	722

The data presented in this work were analysed in the *Rasmussen Report* (AEC, 1975). The evacuation speed and time for each type of incident were found to be correlated by the equations:

$$v = kd^n \quad [9.17.3]$$

$$t = d/v \quad [9.17.4]$$

where d is the evacuation distance (mile), t is the evacuation time (h), v is the evacuation speed (mile/h), k is a constant and n is an index.

The type of incident that is most relevant in the present context appears to be the transportation emergency. For such incidents

$$v = 0.3\mathrm{d}^{1.02} \quad [9.17.5]$$

The evacuation speeds were found to fit a log–normal distribution with the density function

$$f = \frac{1}{\sigma v(2\pi)^{1/2}}\exp\left[-\frac{(\ln v - m^*)^2}{2\sigma^2}\right] \quad [9.17.6]$$

where m^* and σ are parameters in the log–normal distribution.

For transportation incidents $m^* = 0.20$ and $\sigma = 1.64$ and hence the modal and mean values of v are 0.08 and 4.7 mile/h, respectively.

There have been a number of more recent major evacuations. One of the largest was at Mississauga, Toronto, where a leaking chlorine rail tank car led to the evacuation of some 223,000 people (Case History A97). Another large evacuation took place at Bhopal, but in this case there was no chance of averting a major disaster. Bhopal is described in Appendix 5. At Chernobyl, after a delay in deciding to evacuate, some 40,000 people were evacuated in about 2 h. Chernobyl is described in Appendix 22.

The value of evacuation in modifying exposure was investigated in the First *Canvey Report*, as described in Appendix 7. Opportunity to evacuate depends on the hazard and on the way in which the incident develops. Although some hazards, such as a single, unexpected explosion may give little warning, in other cases there may be a substantial degree of warning. One example is an initial explosion in a works followed by a fire that may lead to further explosions and fires. Another is derailment of a rail tank car with the possibility of fireballs and toxic release. In both such cases evacuation may be beneficial.

***Table 9.27** Population outdoor exposure model (after Petts, Lees and Withers, 1987) (Courtesy of Elsevier Science Publishers)*

Population	*Time outdoors* (h/week)			*Proportion outdoors* (%)		
	Day	*Night*	*Overall*	*Day*	*Night*	*Overall*
Regular	0.81	0.19	1.0	7.70	1.33	4.17
Vulnerable	0.5	0	0.5	4.8	0	2.08
Total	0.74	0.14	0.88	7.05	1.0	3.67

***Table 9.28** Evacuation in some major transport emergencies (after Hans and Sell, 1974)*

Date	*Location*	*Incident*	*Number evacuated*	*Area evacuated* ($mile^2$)	*Evacuation distance* (mile)	*Evacuation period* (h)
1965	Baton Rouge, LA	Chlorine barge, no chlorine escape	150,000	8	30	2
1969	Glendora, MI[a]	Vinyl chloride escape from rail tankers	35,000	1200	20	4
1972	Louisville, KY	Chlorine barge, no chlorine escape	4,000	0.35	1	3
1973	Morgan City, LA	Chlorine barge, no chlorine escape	3,000	1.8	2	4

[a] The Glendora incident is described in Case History A43.

9.17.4 Incident control

Avoidance of casualties also has another aspect. Besides getting people who are exposed out of the danger zone, it is often necessary also to keep others from entering the danger zone. In particular, an incident may tend to attract spectators who thereby put themselves at risk. In 1947, ammonium nitrate explosions aboard the *Grandcamp* and the *High Flyer* in the harbour in Texas City killed 552 people (Case History A16). The explosion on the *Grandcamp* killed everyone in the dock, many of whom were spectators. Spectators also constituted a large proportion of the death toll of more than 150 at Caracas in 1982, when burning oil from a storage tank on fire at the top of a hill flowed down into a crowd below (Case History A102).

9.18 Injury Relations

The estimation of the injury or damage caused by a physical effect such as heat radiation intensity, overpressure or toxic concentration requires the use of injury or damage relations.

The normal method of formulating such relations is in three stages. The first is the determination of the causative (or injury or damage) factor which best correlates the data. The second is the determination of the probability distribution for this factor. The third is the conversion of this distribution into the more convenient form of a probit equation.

These steps are now described. In the account given reference is primarily to injury rather than damage relations, but the principles are the same for the latter. Injury and damage relations may be expressed in forms other than probit equations and these also are briefly mentioned.

9.18.1 Injury factors

The starting point for the derivation of an injury relation is a set of data giving the probability of a specified degree of injury as a function of some physical effect. Some typical physical effects are:

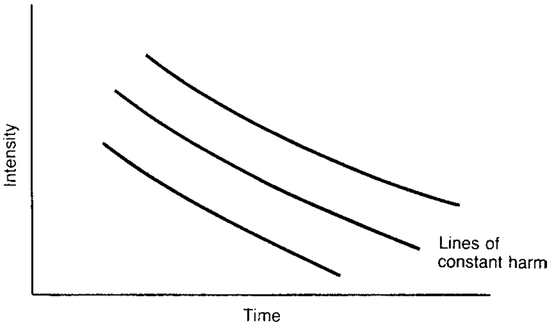

***Figure 9.24** Determination of the form of the injury factor*

Fire	Thermal radiation intensity	I
Explosion	Overpressure	p°
	Impulse	J
Toxic gas	Concentration	C
	Dosage	Ct

where t is time.

The probability of injury may or may not correlate directly with the physical effect. In some cases the correlation is with some power or time function of the effect. For example, probability of eardrum rupture does correlate with explosion overpressure p°, but probability of burn death correlates with the radiation intensity time function $I^{4/3}t$. The first step, therefore, is to determine the appropriate injury factor. It may be helpful to plot a graph of the form shown in Figure 9.24.

9.18.2 Injury distributions

Next it is necessary to determine the probability distribution of the injury factor. The distribution usually considered first is the log–normal distribution. The fit of the data to this distribution may be tested by plotting on log–probability paper. A plot of this type is shown in Figure 9.25.

The reason that data on probability of injury tend to give a log–normal distribution is that this distribution fits the case where the population contains a proportion of individuals who are unusually resistant. For example, the distribution is widely used to correlate the toxicity of an insecticide, where the dosage required to kill off the last few individuals is relatively high.

9.18.3 Probit equations

The injury distribution just described gives the information required on the probability of injury as a function of the injury factor. It is possible, however, to carry out a transformation that casts it in the more convenient form of a probit equation. An account of the probit method is given in *Probit Analysis* (Finney, 1971). One of the first major applications of the method to hazard assessment in the process industries was in the VM of Eisenberg, Lynch and Breeding (1975). The probit Y is an alternative way of expressing the probability P of injury. It is defined by the relation:

$$P = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{Y-5} \exp(-u^2/2)\,\mathrm{d}u \qquad [9.18.1]$$

The probit is a random variable with a mean 5 and variance 1. The probability range (0–1) is generally replaced in probit work by a percentage (range 0–100). The relationship between percentages and probits is shown in Table 9.29 and in Figure 9.26.

It is shown below that for an injury factor x which fits the log–normal distribution the probit equation has the form:

$$Y = k_1 + k_2 \ln x \qquad [9.18.2]$$

A typical probit transformation is illustrated in Figure 9.27. The sigmoidal curve of the log–normal distribution is transformed into the straight line of the probit. This makes it easier both to correlate the data in the first place and then to use the correlation.

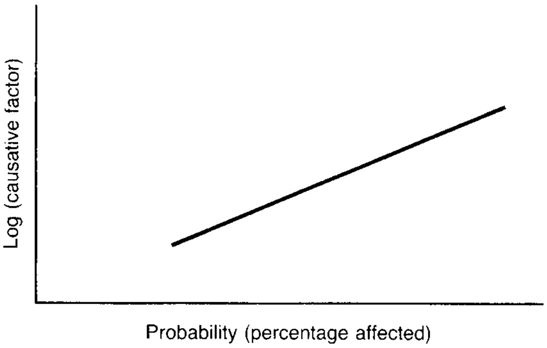

Figure 9.25 *Determination of the distribution of the injury factor*

The derivation of an equation of the general type given in Equation 9.18.2 is conveniently shown by considering first a normal distribution. The density function f is

$$f = \frac{1}{(2\pi)^{1/2}\sigma} \exp\left[-\frac{(x-m)^2}{2\sigma^2}\right] \qquad [9.18.3]$$

The distribution function F is

$$F = \int_{-\infty}^{x} f(x)\,\mathrm{d}x \qquad [9.18.4]$$

But the distribution function F is the same as the probability P of injury, so that entering Equation 9.18.3 in Equation 9.18.4 gives:

$$P = \frac{1}{(2\pi)^{1/2}\sigma} \int_{-\infty}^{x} \exp\left[\frac{-(x-m)^2}{2\sigma^2}\right] \mathrm{d}x \qquad [9.18.5]$$

Then equating Equation 9.18.5 with Equation 9.18.1 gives

$$u = (x - m)\sigma \qquad [9.18.6]$$

and

$$Y - 5 = u \qquad [9.18.7]$$

Hence

$$Y = (5 - m/\sigma) + (1/\sigma)x \qquad [9.18.8]$$

$$= k_1' + k_2' x \qquad [9.18.9]$$

Similarly, for the log–normal distribution:

$$Y = k_1 + k_2 \ln x \qquad [9.18.10]$$

with

$$k_1 = 5 - m^*/\sigma \qquad [9.18.11a]$$

$$k_2 = 1/\sigma \qquad [9.18.11b]$$

Equation 9.18.10 is the usual form of the probit equation.

The derivation of a probit equation from a set of data giving the probability of a specified injury as a function of the injury factor may be illustrated using the following data for eardrum rupture due to overpressure given by Eisenberg, Lynch and Breeding:

Percentage affected	*Probit*	*Peak overpressure* ($\mathrm{N/m^2}$)
1	2.67	16.5×10^3
10	3.72	19.3×10^3
50	5.00	43.5×10^3
90	6.28	84.3×10^3

The corresponding probit equation given by these authors is

$$Y = -15.6 + 1.93 \ln p^{\circ} \qquad [9.18.12]$$

***Table 9.29** Transformation of percentages to probits (Finney 1971) (Courtesy of Cambridge University Press)*

%	*0*	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*
0	–	2.67	2.95	3.12	3.25	3.36	3.45	3.52	3.59	3.66

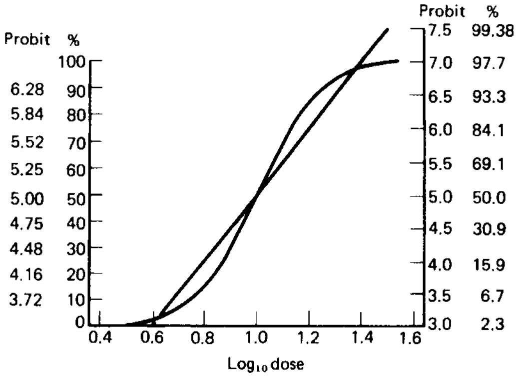

***Figure 9.27** Effect of the probit transformation (Finney, 1971). The figure illustrates a typical experiment on the toxicity of an insecticide. The logarithm of the lethal dose fits a normal distribution. The figure shows the distribution function and the corresponding probit function (Courtesy of Cambridge University Press)*

Probit equations for some major hazards given by Eisenberg, Lynch and Breeding are shown in Table 9.18. The derivation of these equations is discussed in more detail in Chapters 16–18.

It is emphasized that the probit equations given in Table 9.18 were early examples and were avowedly tentative and approximate, as will be clear from their derivations. They were developed essentially for use in the VM. Some have been superseded by improved equations. They are given here primarily as an illustration of the general form of injury factors and probit equations.

Probit equations were used in the *Canvey Reports* and the *Rijnmond Report* and have been widely used in many hazard assessments since then.

With respect to probit equations, there are several points that need to be borne in mind. First, any injury or damage correlation is only as good as the original data. Second, a check should be made that the data do actually fit the distribution implied, generally the log–normal distribution. Third, it is desirable to allow for the fact that data for probabilities in the middle of the probability range are likely to be more accurate than those for probabilities at the extremes of the range.

9.18.4 Probit equations: data weighting

Taking up this latter point, it is the case that given data for probabilities P near the centre of the range (say $P = 0.5$) and at an extreme of the range (say $P = 0.01$ or 0.99) obtained from samples of the same size, the level of confidence will be higher in the former. Or, to put the matter another way, for the same level of confidence it is necessary to have a larger sample size at an extreme of the range than near the centre.

This problem arises particularly in laboratory work on the toxicity of, say, pesticides. It has been addressed by Fisher and Yates (1957), who give a set of weighting coefficients for use in probit analysis. Table 9.30, Section A, gives a set of weighting coefficients interpolated from their values.

A technique described by Gilbert, Lees and Scilly (1994a) which is convenient in dealing with a set of data points and which gives an essentially similar weighting is to multiply each point by the weighting factor shown in Section B of Table 9.30. The point is discussed further in Chapter 18.

Table 9.30 *Weighting factors for construction of probit equations*

A Weighting coefficient (after R.A. Fisher and Yates, 1957)

Probability (%)[a]	*Probit*	*Weighting coefficient*
1	2.7	0.072
5	3.4	0.224
10	3.7	0.342
20	4.2	0.490
30	4.5	0.575
40	4.7	0.621
50	5.0	0.637

B Number of entries (after Gilbert, Lees and Scilly, 1994a)

Probability range (%)	*No. of times in which point is entered*
40–60	6
30–40; 60–70	5
20–30; 70–80	4
10–20; 80–90	3
5–10; 90–95	2
<5; >95	0

[a] The weighting coefficient for a percentage x greater than 50% may be obtained from that for $100 - x$.

9.18.5 Other relations

Not all correlations of injury and damage are in terms of probability distributions and probit equations. In particular, certain effects of explosions are often correlated in other ways. Among these effects are damage to plant and buildings, injury due to building collapse and damage and injury due to missiles. The treatment of explosion effects is described in Chapter 17.

9.18.6 Multiple injury and double counting

It is appropriate at this point to draw attention to some of the problems associated with multiple injury and double counting of injuries.

A treatment of double counting is given in the *Green Book*, (CPD, 1992b), which identifies three basic types of double counting. In double counting of the first type, a single injury mechanism due to a single event creates victims with several, successively more severe, degrees of injury. A problem arises where the number of victims with a lower degree of injury is also included in the number with the higher degree(s) of injury. The correct procedure is to subtract the number of victims with the higher degree(s) of injury from the number with the lower degree of injury.

In double counting of the second type, several injury mechanisms due to a single event create victims with the same degree of injury. The problem here is that a proportion of victims are injured by more than one of these mechanisms and that, mathematically, it is incorrect to obtain the probabilities of injury by simply summing the probabilities for each mechanism. The correct procedure mathematically is to utilize the expressions for the probability of a joint event, as given by Equations 7.5.5–7.5.8.

In double counting of the third type, several events, occurring in succession, each theoretically injure to a given degree the same person, whereas in reality the first event produces such injury that any subsequent event has no additional injurious effect. In this case, the correct procedure mathematically is to subtract the number of persons suffering this degree of injury after the first event from the population at risk for subsequent events.

This approach to the avoidance of double counting is essentially a mathematical one. It is valid for double counting of the first type and also for double counting of the second and third types where the degree of injury concerned is fatal injury. However, for degrees of injury that are less than fatal it fails for the second and third types to make sufficient allowance for physiological as opposed to mathematical factors.

As far as physiological factors are concerned, it is difficult to generalize. Each case needs to be considered on its merits. It might be thought that from a physiological rather than a mathematical viewpoint the overall probability of a given degree of injury from more than one event capable of causing that degree of injury might be greater, rather than less, than the sum of the individual probabilities, and also that there might be escalation to a more severe degree of injury, but this may not always be so.

Thus, on the one hand there is some evidence from battle casualties that the physiological effect of fragment wounds is not necessarily proportional to the number of fragments involved. On the other hand, the severity of burn wounds increases with the proportion of the body surface that is affected. A further discussion of combined injuries is given by R.K. Jones (1971).

9.18.7 Overview

It is peculiarly difficult to obtain injury relations for humans, since the normal method of establishing a correlation, that is direct experimentation, is ruled out. The approaches taken have often been opportunistic, seeking data wherever it may be found. For example, the correlation for burn injury that has long held the field is based on data on injuries caused by the atomic bombs at Hiroshima and Nagasaki. Not surprisingly, the derivation and use of injury relations has been subject to some criticism. Critiques include those of V.C. Marshall (1989b), Turner and Fairhurst (1989 HSE SIR 21) and R.F. Griffiths (1991b).

A general criticism is the relatively high uncertainty in injury relations. This is inherent in the problem and there is not very much that can be done about it. The degree of uncertainty may be quantified if it is possible to determine confidence bounds, but often it is not obvious how this is to be done. It may well be possible to give bounds for, say, the concentrations of a toxic gas which are lethal to a particular animal species, but these data have then to be extrapolated to humans, an operation which involves a good deal of judgement.

Another criticism concerns extrapolation from the region of 50% probability to those of 5% and or even 1%. Here there are two distinct problems. One is the confidence that can be placed in the slope of the probit relation on which such extrapolation is based. The other is the possibility that at low values of the physical effect the injury mechanisms that come into play may be qualitatively different. Since the level of physical effect which applies to the 5% or 1% probabilities is relatively low and thus applies to the far field, the area affected is large and differences in the value of the effect for these probability levels can have a significant impact on the estimate of the number injured.

Although in principle a similar problem of extrapolation exists for the region of 95% or 99% probability, in practice this is of less importance, because these probability values apply in the near field where the area affected is relatively small and because in consequence the difference in numbers of injured between estimated values of, say, 90% and 95% is not great.

9.19 Presentation of Results

There are a number of different outputs that may be obtained from a hazard assessment. These outputs may be, and often are, in the form of risk estimates, but other outputs may also be used. The results are sometimes presented in terms of the distance at which the hazard will cause a defined effect. Such a hazard range may be based on a worst-case scenario or on some less serious scenario. In the latter case there is an implied cut-off for the frequency of the event.

Alternatively, the results are presented in terms of risk. One form of risk is the frequency of a defined effect. In this case, no explicit computation is made of harm to people. If the risk to people is determined, the exercise becomes a full risk assessment. The risk may be expressed in terms of fatalities only, or of fatalities and injuries.

The risk of damage to property may also be determined, although such assessment appears to be less common as an end in itself than as a means of estimating the risk to people.

9.19.1 Types of risk to people

As just described, the results presented from a risk assessment may be confined to risk of death or may embrace risk of injury. Relying on the concept of a more or less fixed ratio of injuries to fatalities, the engineer may well consider that a risk profile of the plant formulated in terms of fatalities is usually sufficient as an aid to decision-making. As described below, however, risk of injury is also taken into account. In particular, the HSE are interested in the risk of receiving a 'dangerous dose'. This dose translates into different risks of death for vulnerable and non-vulnerable people.

9.19.2 Forms of presentation

There are a number of ways in which the results of a risk assessment may be presented. Some of the forms of presentation are shown in Table 9.31. For a fixed installation the risk will relate to some event that might occur on the site in question. The risk is generally measured from a particular point within the site. In some cases, the risk may be presented simply as the frequency of a defined event, usually a major accident, at the installation.

For individual risk to the workforce, the usual form is either an annual risk or the FAR. There is a straight conversion between the two. It is not usual to derive for the workforce any form of collective risk equivalent to the societal risk for the public described below.

The forms of presentation for risk to the public are more varied. For land-use planning, contours and transects (plan and elevation, respectively) may be given. These contours and transects may represent the frequency of a given intensity of a physical effect, or alternatively the frequency of individual fatality, or individual risk. Such contours and transects may relate to a single hazard or to the combined results of several hazards.

Table 9.31 *Forms of presentation of results of a risk assessment*

A Risk of workforce

Annual risk
Fatal accident rate (FAR)

B Risk to public

- Physical effects
  - Contours on site map
  - Transects on site map
- Individual risk
  - Contours on site map
  - Transects on site map
  - Annual risk at fixed location
- Societal risk
  - FN table
  - FN curve
- Equivalent annual fatalities

Note: Risk may be risk of fatality or injury, or other risk such as that of HSE dangerous dose.

Individual risk to members of the public may be presented as a function of distance from the site, but is more usually given as the average risk to groups at different locations around the site.

The main form in which societal risk is presented is as a relation between incidents that cause some number N or more fatalities and the frequency F of such incidents. These data may be given in tabular form, but are also often plotted as a FN curve. The basic FN data may be integrated to obtain a value for the equivalent annual fatalities. One use of this statistic is to compare the risks of different activities, for example coal mining vs nuclear energy. It is generally regarded as less appropriate for a hazard on a particular site, since it lumps together small incidents with relatively high frequency and large incidents with relatively low frequency. However, for such a hazard it is of some value in assessing the relative contribution of high frequency and low frequency events to the overall risk.

9.19.3 Risk contours and transects

The use of risk contours and transects is illustrated in Figures 9.28 and 9.29. Figure 9.28 gives overpressure risk contours for a natural gas liquids (NGL) plant and refrigeration facility. Figure 9.29 gives a risk transect for interaction between a vapour cloud from a pipeline and the public.

9.19.4 FN tables and curves

Table 9.32 shows some results of the risk assessment given in the First *Canvey Report*. Figure 9.30 shows the corresponding FN curve. This was one of the first FN curves published for the process industries. Also shown in Figure 9.30 are other curves given in the two *Canvey Reports*.

Figure 9.31 shows a set of FN curves given by the HSE for accidents, in the chemical and petrochemical industries, in the United Kingdom and worldwide.

If the FN relation is a straight line, it may be written as:

$$fN^{\alpha} = r = \text{Constant} \qquad [9.19.1]$$

where f is the frequency, N is the number of fatalities, r is a constant and α is an index.

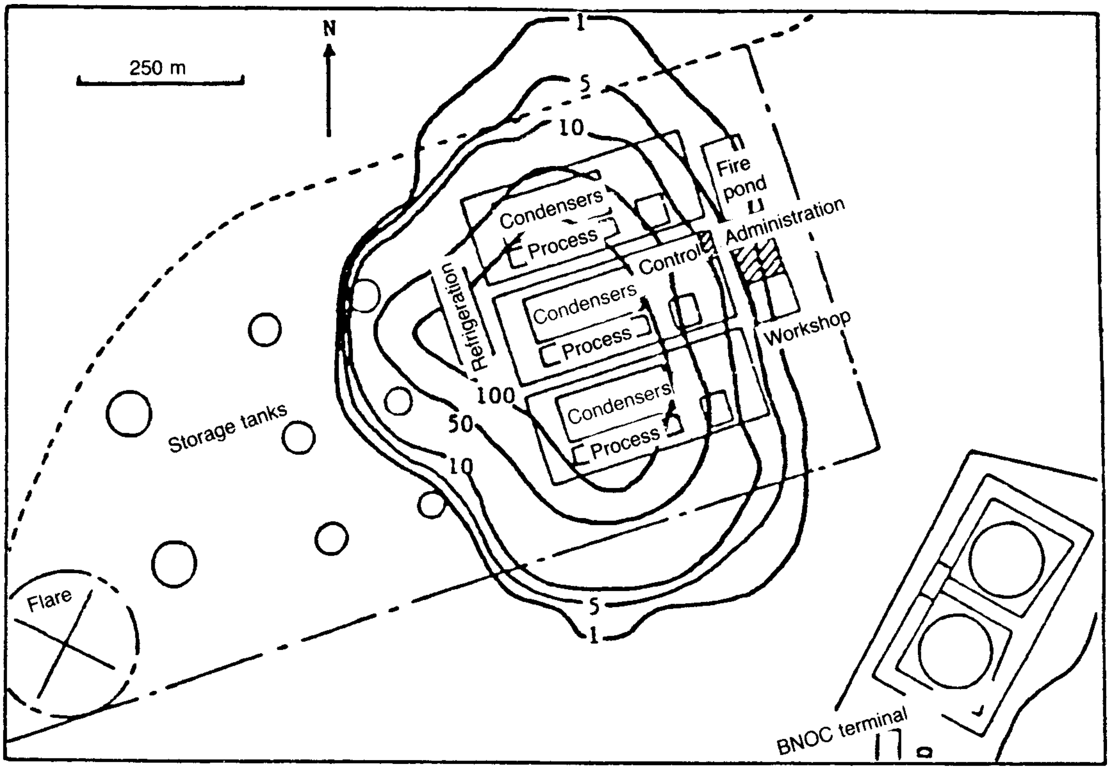

Figure 9.28 Risk contours for a NGL plant and refrigeration facility (Ramsay, Sylvester-Evans and English, 1982) (Courtesy of the Institution of Chemical Engineers)

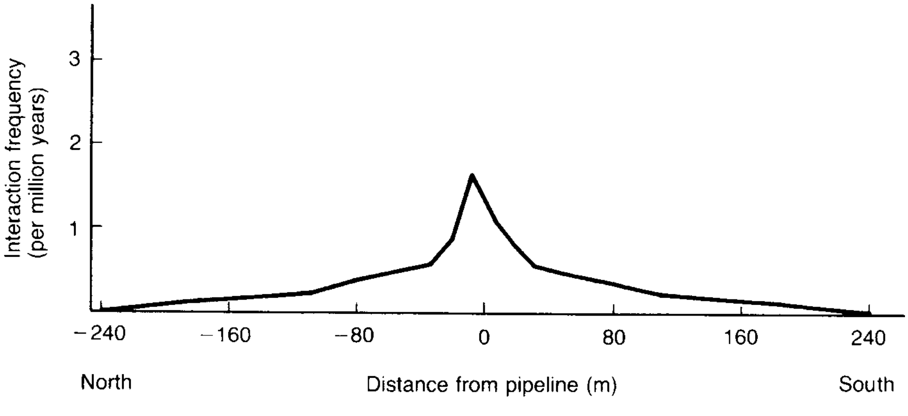

Figure 9.29 Risk transect for interaction between a vapour cloud from a pipeline and the public (Ramsay, Sylvester-Evans and English, 1982) (Courtesy of the Institution of Chemical Engineers)

9.19.5 Risk aversion in FN curves

Generally, society is more averse to a single very large accident than to a number of small ones. Such risk aversion has been discussed in Chapter 4. In simple terms, risk aversion exists if society regards a single accident with 100 fatalities as in some sense worse than 100 accidents with a single fatality each.

Risk aversion is seen most clearly in FN curves, where the slope of the curve indicates the degree of risk aversion. If the FN relation is in fact a straight line, its slope

Table 9.32 *Assessed risks for some principal hazards given in the First Canvey Report (before proposed modifications (after Lees, 1982b) Courtesy of the Institution of Chemical Engineers)*

Hazard	*Frequencies of initiating event* (10^{-6}/year)	*Frequenceis* (10^{-6}/year) *for number of offsite casualties exceeding*

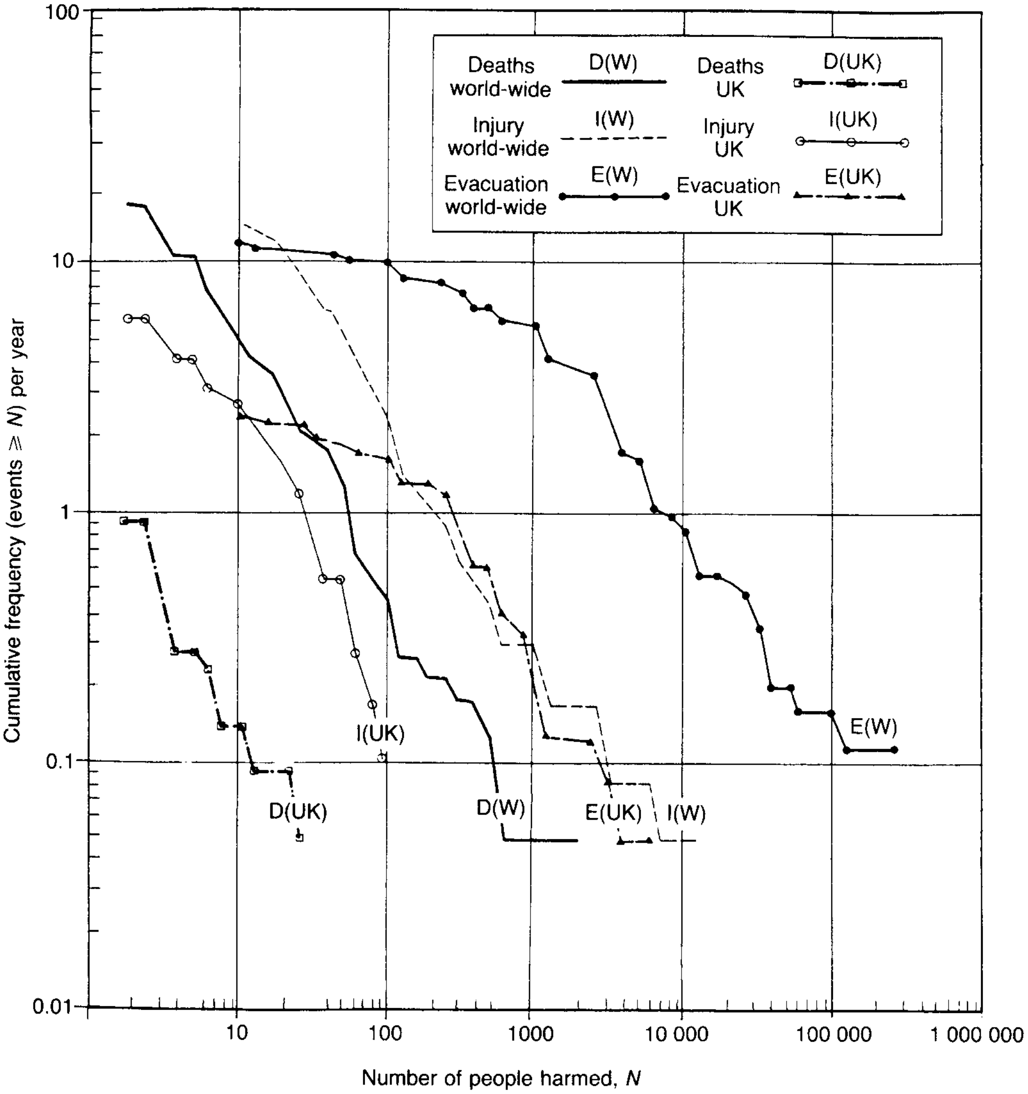

__Figure 9.31__ Some FN curves for accidents in the chemical and petrochemical industries, in the United Kingdom and worldwide (HSE, 1989e) (Courtesy of the HM Stationery Office)

is directly related to the parameter α, which is therefore known as the 'risk aversion index'.

9.19.6 Characteristics of FN curves

In order to make full use of the information given in FN curves and also to avoid certain misunderstandings that have arisen in their use, it is necessary to consider some of the characteristics of such curves. Accounts of FN curves include those given by R.F. Griffiths (1981e), the Royal Society Study Group (1983) and Hagon (1984).

As already stated, the normal FN curve is a plot of the frequency F of N or more events. Use has been made, however, particularly in early work, of alternative forms. The best known of these is the Farmer curve (F.R. Farmer, 1967b). This is a risk criterion curve and description of it is deferred until Section 9.21. However, it is appropriate to consider here the characteristics of the curve itself, that is whether the curve represents actual risk or a risk criterion. In a curve of this type, the consequence quantity plotted against frequency is not a cumulative quantity. There has been some confusion as to what this quantity should be. Accounts are given by R.F. Griffiths (1981e) and D.C. Cox and Baybutt (1982). The interpretation of Farmer himself is that it is a range of consequences, or a consequence interval, as shown in Figure 9.32. However, this type of curve is now rarely used.

Accounts of the relations underlying FN curves include those by R.F. Griffiths (1981e), D.C. Cox and Baybutt (1982) and Hagon (1984). The following treatment is based on the work of the latter.

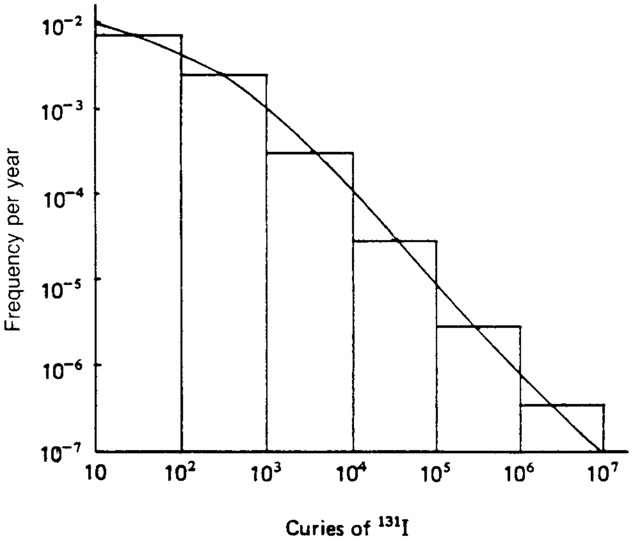

Figure 9.32 *Interpretation of the Farmer curve (R.F. Griffiths, 1981e) (Courtesy of Manchester University Press)*

From Equation 9.19.1, the following relations may be stated for cumulative frequency F:

$$F_1^K = \sum_{N=1}^{N=K} f \qquad [9.19.2a]$$

$$= r\sum_{N=1}^{N=K} (1/N^{\alpha}) \qquad [9.19.2b]$$

Defining

$$S(K,\ \alpha) = \sum_{N=1}^{N=K} (1/N^{\alpha}) \qquad [9.19.3]$$

gives

$$F_1^N = rS(N,\ \alpha) \qquad [9.19.4]$$

Also

$$F_{N_1}^{N_2} = r[S(N_2,\ \alpha) - S(N_1 - 1,\ \alpha)] \qquad [9.19.5]$$

Values of $S(N, \alpha)$ computed for ranges of values of N and α are shown in Figure 9.33.

The total annual fatalities D may be obtained in a similar manner:

$$D_1^K = \sum_{N=1}^{N=K} fN \qquad [9.19.6a]$$

$$= r\sum_{N=1}^{N=K} (1/N^{\alpha-1}) \qquad [9.19.6b]$$

$$D_1^N = rS(N,\ \alpha - 1) \qquad [9.19.7]$$

$$D_{N_1}^{N_2} = r[S(N_2,\ \alpha - 1) - S(N_1 - 1,\ \alpha - 1)] \qquad [9.19.8]$$

If f is treated as a continuous function of N, the following relations apply:

$$F_1^K = \int_1^K f\,\mathrm{d}N \qquad [9.19.9]$$

$$D_1^K = \int_1^K fN\,\mathrm{d}N \qquad [9.19.10]$$

The relations for these integrations are shown in Table 9.33. The relations change at $\alpha = 2$. The values based on the assumption that N is continuous are not accurate for N less than approximately 30.

The application of these equations to a set of FN curves given in an actual risk assessment has also been described by Hagon. Figure 9.34 shows the FN curves concerned which are for the ammonia storage sphere in the *Rijnmond Report*.

Also shown in Figure 9.34 is a dotted line that corresponds to

$$\alpha = 2$$

$$F_1^N = 10^{-3}$$

Then for r taking some large value of N, say 5000,

$$r = F_1^N / S(N,\ \alpha)$$

From Figure 9.30, for $N = 5000$

$$S(5000,\ 2) \approx 1.65$$

Hence

$$r = 10^{-3}/1.65 = 0.61 \times 10^{-3}$$

Then the cumulative frequency of accidents and expected annual fatalities may be estimated. Values of these quantities derived from (1) the exact relations and (2) the approximate relations given in Table 9.33 are shown in

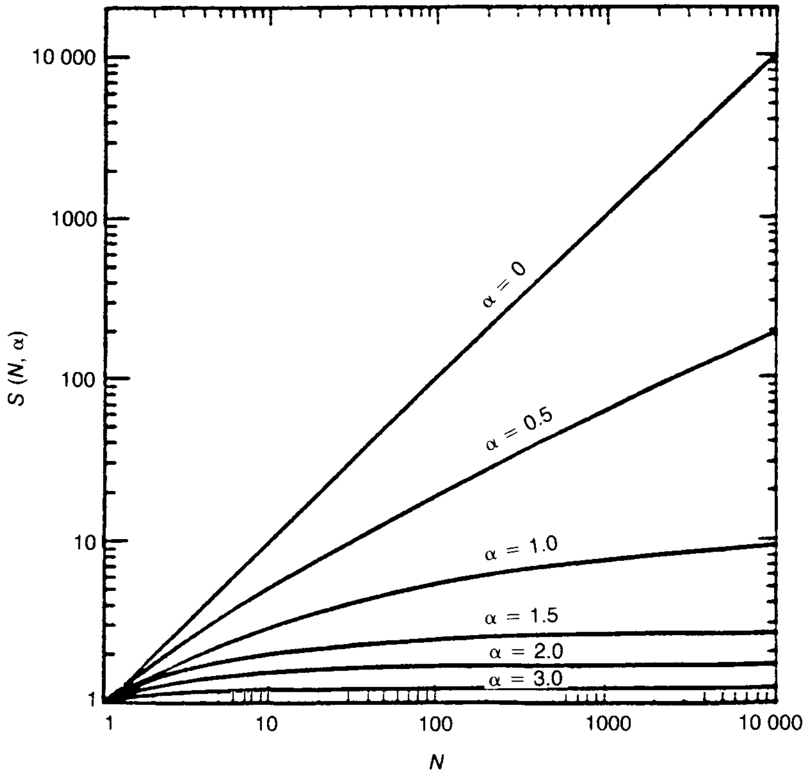

Figure 9.33 *Values of parameter S(N, α) (Hagon, 1984) (Courtesy of the Institution of Chemical Engineers)*

Table 9.33 *Approximate relations for cumulative frequencies and expected annual fatalities (Hagon, 1984). These relations approximate to the exact relations (Equations (9.19.3)–(9.19.6)) if N > 30 and limits are taken as N_2 + 0.5, N – 1 – 0.5 (Courtesy of the Institution of Chemical Engineers)*

Aversion index	*Cumulative frequency*		*Total deaths/year*
	$(F)_{N_1}^{N_2}$	$F_N = (F)_N^{\alpha}$	$(D)_{N_1}^{N_2}$
$\alpha = 1$	$r \ln \frac{N_2}{N_1}$	∞	$r(N_2 - N_1)$
$1 < \alpha < 2$	$\frac{r}{\alpha - q}\left(\frac{1}{N_1^{\alpha-1}} - \frac{1}{N_2^{\alpha-1}}\right)$	$\frac{r}{\alpha - 1}\left(\frac{1}{N^{\alpha-1}}\right)$	$\frac{r}{2-\alpha}\left(N_2^{2-\alpha} - N_1^{2-\alpha}\right)$
$\alpha = 2$	$r\left(\frac{1}{N_1} - \frac{1}{N_2}\right)$	$\frac{r}{N}$	$r \ln \frac{N_2}{N_1}$
$\alpha > 2$	$\frac{r}{\alpha - 1}\left(\frac{1}{N_1^{\alpha-1}} - \frac{1}{N_2^{\alpha-1}}\right)$	$\frac{r}{\alpha - 1}\left(\frac{1}{N^{\alpha-1}}\right)$	$\frac{r}{\alpha - 2}\left(\frac{q}{N_1^{\alpha-2}} - \frac{1}{N_2^{\alpha-2}}\right)$
			$= \frac{r}{\alpha - 2}$ for $N_2 = \infty, N_2 = 1$

Note: The above relations approximate to the exact Equations 9.20.4, 9.20.5, 9.20.6 and 9.20.7 if $N > 30$ and limits are taken to be $N_2 + 0.5$, $N_1 - 0.5$.

9.20 Confidence in Results

The results of a hazard assessment are subject to uncertainty and it is necessary therefore to be able to estimate the extent of this uncertainty. Discussions of uncertainty in hazard assessment include those by Nussey (1983), Goosens, Cooke and van Steen (1989) and Chhibber, Apostolakis and Okrent (1991).

9.20.1 Sources of uncertainty

Sources of uncertainty in a hazard assessment may be classified under the following broad headings:

(1) scenarios for initial event;
(2) scenarios for escalation;
(3) event frequency, probability;
(4) models for physical events;
(5) models for injury;
(6) models for mitigation.

These sources of uncertainty are amplified in Table 9.35. An account of sources of uncertainty with special reference to toxic release has been given by Nussey (1983).

9.20.2 Characterization of uncertainty

Uncertainty may attach to a single event or to a chain of events. The approach taken to the characterization of uncertainty depends on the complexity of the problem. The conventional analytical approach to uncertainty in the frequency, or probability, of a single event is to utilize not a point value but a distribution of values. A distribution that is widely utilized is the log–normal distribution, described below.

Table 9.35 *Some sources of uncertainty in hazard assessment*

A Scenarios for initial event

Some uncertainties in the scenarios for the initial event, and thus the source term are:

Release sources and, for each source
- Size
- Orientation
- Flash, rainout
- Initial air entrainment
- Duration

B Scenarios for escalation

- Pool vaporization
- Gas dispersion
- Ignition
- Jet flames
- Pool fires
- Fireballs
- Flowing, burning liquid
- BLEVEs
- Missiles
- Failure of emergency shut-down
- Failure of fire protection system
- Structural collapse

C Event frequency, probability

- Failure frequency
- Leak frequency
- Ignition probability
- Explosion probability

D Models for physical events

- Flash fires
- Pool fires
- Fireballs
- Jet flames
- BLEVEs
- Missiles

E Models for injury

- Heat radiation
- Explosion effects
  - Direct blast effects
  - Housing collapse
  - Missiles
- Toxic effects

F Models for mitigation

- Human behaviour
- Escape
- Shelter

Continuing with an analytical approach, the propagation of uncertainty is handled by utilizing relationships for the combination of distributions, principally relations for the sum and product of distributions. The result obtained is a distribution of the frequency, or probability, of the event of interest.

If the problem is too complex for analytical solution, use may be made of techniques such as Monte Carlo simulation to obtain frequencies and probabilities. Again a frequency, or probability, distribution is obtained. The Monte Carlo method was described in Chapter 7.

Moving on to uncertainty in the models, for physical effects, injury and mitigation, the analytical approach is to derive relations for the sensitivity of the results to changes in the models. One method is to determine the first derivative of the output of the model to its inputs, in other words the gains. Another is to express the parameters of the model as distributions rather than point values. A formal method of investigating the sensitivity of results to the parameters of physical models and injury relations is the hazard impact model, described in Section 9.23.

If again the problem is too complex to be handled analytically, the sensitivity of the results to the models may be investigated by Monte Carlo simulation or other methods. Again the parameters in the model may be given in the form of distributions.

The characterization of uncertainty in the scenarios is less well developed. One approach is to utilize expert judgement, as described below.

9.20.3 Log–normal distribution and error factor

A distribution which is widely used to characterize the spread of values of a variable is the log–normal distribution. The properties of the log–normal distribution were described in Chapter 7.

This distribution is used in particular for event frequency λ and probability p. For a failure rate λ, the log–normal distribution may be written as

$$f(\lambda) = \frac{1}{(2\pi)^{1/2}\sigma\lambda}\exp\left[-\frac{(\ln\lambda - m^*)^2}{2\sigma^2}\right] \qquad [9.20.1]$$

where m^* is the location parameter and σ the shape parameter.

The distribution is also frequently characterized in terms of the median λ_{med} and the shape parameter σ. The median λ_{med} of the distribution is

$$\lambda_{\text{med}} = \exp m^* \qquad [9.20.2a]$$

$$m = \ln\lambda_{\text{med}} \qquad [9.20.2b]$$

The mean λ_{mn} is

$$\lambda_{\text{mn}} = \exp(m^* + \sigma^2/2) \qquad [9.20.3]$$

where subscripts med and mn indicate the median and mean, respectively.

An important property of the log–normal distribution is its associated error factor. For lower and upper confidence bounds λ_{l} and λ_{u}, respectively, the median λ_{med} is related to the bounds by the error factor ϕ:

$$\lambda_{\text{med}} = \phi\lambda_{\text{l}} \qquad [9.20.4a]$$

$$= \lambda\text{u}/\phi \qquad [9.20.4b]$$

Hence

$$\lambda_{\text{med}} = (\lambda_{\text{l}}\lambda_{\text{u}})^{1/2} \qquad [9.20.5]$$

The relation between the spread parameter σ and the error factor ϕ is

$$\sigma = \ln \phi / k \qquad [9.20.6]$$

where k is a constant. The values of k for 90% and 95% of values that lie within the range are 1.64 and 1.96, respectively.

These equations have been written for further reference in terms of event frequency λ but they could equally well be written in terms of any variable x. In particular, they are also applicable to event probability p, and are so utilized below.

9.20.4 Propagation of uncertainty

A broad outline of approaches to the propagation of uncertainty was given above. An account is given here of the propagation of uncertainty in event rates.

Since a combination of events is considered, it is more appropriate to work in terms of probability p rather than frequency λ. For a variable p_3, which is the product of two independent variables p_1 and p_2 so that

$$p_3 = p_1 p_2 \qquad [9.20.7]$$

it can be shown that if variables p_1 and p_2 are log–normally distributed, the distribution of p_3 is also log–normal and the relations between the location parameters and the variances are

$$m_3^* = m_1^* + m_2^* \qquad [9.20.8]$$

$$\sigma_3^2 = \sigma_1^2 + \sigma_2^2 \qquad [9.20.9]$$

where subscripts 1–3 indicated events 1–3, respectively. Then it follows from Equations 9.20.2, 9.20.3, 9.20.8 and 9.20.9 that the median and mean of p_3 are given by:

$$p_{3,\mathrm{med}} = p_{1,\mathrm{med}} \times p_{2,\mathrm{med}} \qquad [9.20.10]$$

$$p_{3,\mathrm{mn}} = p_{1,\mathrm{mn}} \times p_{2,\mathrm{mn}} \qquad [9.20.11]$$

The propagation of uncertainty in a fault tree is considered in Section 9.20.7.

9.20.5 Scenarios

The basis of a hazard assessment is a set of scenarios. Both the completeness and the realism of these scenarios are subject to uncertainty.

Usually in hazard assessment the scenarios relate to loss of containment. There are then two sets of scenarios to be considered. The first set relates to the release itself. The second set relates to the escalation. Both release and escalation scenarios are subject to uncertainty.

In principle, completeness of the release scenarios may be achieved by considering release from each item of equipment. For this purpose, certain categories of equipment may be lumped together. On the other hand, it is necessary to consider not just a single size of release, but also a size distribution. There is, however, a further uncertainty concerning the geometry of the release. The material will not necessarily come out as, say, a free jet, but may issue at a downwards angle and hit the ground or may impinge on other equipment.

Completeness of the escalation scenarios is probably a more difficult problem. Much attention has been focused on the release and dispersion of flammable or toxic gas clouds. The generation of scenarios for such a hazard has not proved particularly difficult. However, the concentration on this rather stereotyped situation has perhaps masked the problem of defining the escalation in other, more varied, cases. Such a situation is exemplified by an offshore module.

Uncertainty concerning scenarios shades over into uncertainty concerning models, as described below.

9.20.6 Event rate

For an event rate, a frequency or probability, uncertainty may be taken into account by treating the event rate as a random variable with a distribution of values. This approach was used in the *Rasmussen Report* and since then has been widely adopted. In this study, data for both failure frequencies and probabilities were correlated using the log–normal distribution, as described in Section 9.20.3.

The procedure adopted was to consider for each equipment the available data on failure frequency or probability and to determine by expert judgement the lower and upper bounds for the range of values covering 90% of cases. The tables of failure data quote the lower and upper bounds, the median and the error factor.

9.20.7 Fault trees

It is also necessary to be able to obtain the probability distribution of the frequency of an event that has been synthesized using a fault tree. Where a measure of the uncertainty in the frequency estimate is made in a risk assessment, this is generally done numerically using Monte Carlo simulation. The frequencies of the base events in the tree are expressed in terms of probability distributions of frequency, such as the log–normal distribution as just described. Each simulation trial generates a set of frequencies for the base events. These are combined according to the tree structure to obtain a frequency of the top event. The result of a series of such trials is the probability density function for the top event. The principle of the method is illustrated in Figure 9.5.

Analytical treatments of the propagation of uncertainty through the logic gates of a fault tree are also available for certain defined cases. This approach is illustrated here by the work of Keey and Smith (1984). The problem considered is the combination at OR and AND gates of inputs which are normally distributed. Taking first an OR gate, consider two inputs whose frequencies take random values λ_1 and λ_2 with corresponding mean values $\bar{\lambda}_1$ and $\bar{\lambda}_2$ and standard deviations σ_1 and σ_2. The frequency λ of the output from the OR gate is

$$\lambda = \lambda_1 + \lambda_2 \qquad [9.20.12]$$

and the corresponding mean frequency $\bar{\lambda}$ is

$$\bar{\lambda} = \bar{\lambda}_1 + \bar{\lambda}_2 \qquad [9.20.13]$$

But mean values can be expressed as expected values. Then Equation 9.20.13 can be rewritten as

$$E[\lambda] = E[\lambda_1] + E[\lambda_2] \qquad [9.20.14]$$

The variance of the output becomes

$$\sigma^2 = E\left[\lambda^2\right] - (E[\lambda])^2 \qquad [9.20.15]$$

Then, from the properties of expected values.

$$E\left[\lambda^2\right] = E\left[\lambda_1^2 + 2\lambda_1\lambda_2 + \lambda_2^2\right] \qquad [9.20.16]$$

$$= E\left[\lambda_1^2\right] + E[2\lambda_1\lambda_2] + E\left[\lambda_2^2\right] \qquad [9.20.17]$$

Also

$$(E[\lambda])^2 = \bar{\lambda}^2 = \bar{\lambda}_1^2 + 2\bar{\lambda}_1\bar{\lambda}_2 + \bar{\lambda}_2^2 \qquad [9.20.18]$$

From Equations 9.20.15 and 9.20.17

$$E\left[\lambda^2\right] = E\left[\bar{\lambda}_1^2 + \sigma_1^2\right] + E\left[\bar{\lambda}_2^2 + \sigma_2^2\right] + 2\bar{\lambda}_1\bar{\lambda}_2 \qquad [9.20.19]$$

Substitution of Equations 9.20.18 and 9.20.19 into Equation 9.20.15 gives

$$\sigma^2 = \left(\bar{\lambda}_1 + \sigma_1^2\right) + \left(\bar{\lambda}_2 + \sigma_2^2\right) - \left(\bar{\lambda}_1 + \bar{\lambda}_2\right) \qquad [9.20.20]$$

$$= \left(\sigma_1^2 + \sigma_2^2\right)^{1/2} \qquad [9.20.21]$$

A measure of spread of the frequency is the coefficient of variation C:

$$C_i = \sigma_i/\lambda_i \qquad [9.20.22]$$

The coefficient of variation of the output is

$$C = \sigma/\bar{\lambda} = (\sigma_1^2 + \sigma_2^2)^{1/2}/\left(\bar{\lambda}_1 + \bar{\lambda}_2\right) \qquad [9.20.23]$$

One limiting case is where the two inputs have the same mean value ($\lambda_0 = \lambda_1 = \lambda_2$) and the same standard deviation ($\sigma_0 = \sigma_1 = \sigma_2$). Then

$$C = (2\sigma_0^2)^{1/2}/2\bar{\lambda}_0 = 2^{1/2}\sigma_0/2\bar{\lambda}_0 \qquad [9.20.24]$$

or

$$C = C_0/2^{1/2} \qquad [9.20.25]$$

Another limiting case is which one input becomes single valued ($\sigma_1 = 0$) and very small ($\lambda_1 \ll \lambda_2$):

$$C = (\sigma_2^2)^{1/2}/(\bar{\lambda}_1 + \bar{\lambda}_2) = \sigma_2/\bar{\lambda}_2 \qquad [9.20.26]$$

or

$$C = C_2 \qquad [9.20.27]$$

Hence the output coefficient of variation has the range:

$$(1/2^{1/2})\min(C_1, C_2) < \Psi < \mu\alpha\xi(\Psi_{\oslash}, \Psi) \qquad [9.20.28]$$

Equation 9.20.18 shows that for an OR gate the coefficient of variation of the output is less than the larger of the coefficients of variation of the inputs, and that in this sense this gate reduces the uncertainty in the input data.

For an AND gate with an input of frequency λ_1 and another input of probability p_2, with corresponding standard deviations σ_1 and s_2, respectively, the frequency λ of the output is

$$\lambda = \lambda_1 p_2 \qquad [9.20.29]$$

The corresponding mean frequency $\bar{\lambda}$ is related to the mean frequency $\bar{\lambda}_1$ and probability $\bar{p}_2$ of the inputs:

$$\bar{\lambda} = \bar{\lambda}_1\bar{p}_2 \qquad [9.20.30]$$

Then

$$E\left[\lambda^2\right] = E\left[\lambda_1^2 p_2^2\right] \qquad [9.20.31a]$$

$$= E\left[\lambda_1^2\right] \cdot E\left[p_2^2\right] \qquad [9.20.31b]$$

$$= \left(\bar{\lambda}_1^2 + \sigma_1^2\right)\left(\bar{p}_2^2 + s_2^2\right) \qquad [9.20.31c]$$

Also

$$(E[\lambda])^2 = \bar{\lambda}^2 = \bar{\lambda}_1^2 p_2^2 \qquad [9.20.32]$$

Then, from Equation 9.20.15, the standard deviation of the output σ is

$$\sigma^2 = \left(\bar{\lambda}_1^2 + \sigma_2^2\right)\left(\bar{p}_2^2 + s_2^2\right) - \bar{\lambda}_1^2\bar{p}_2^2 \qquad [9.20.33]$$

Hence

$$\sigma = \left(\sigma_1^2 s_2^2 + \bar{\lambda}_1^2 s_2^2 + \sigma_1^2\bar{p}_2^2\right)^{1/2} \qquad [9.20.34]$$

The output coefficient of variation is then

$$C = \sigma/\bar{\lambda} = \left(\sigma_1^2 s_2^2 + \bar{\lambda}_1^2 s_2^2 + \sigma_1^2\bar{p}_2^2\right)^{1/2}/\bar{\lambda}_1^2\bar{p}_2 \qquad [9.20.35]$$

Noting that

$$C_2 = s_2/\bar{p}_2 \qquad [9.20.36]$$

Equation 9.20.35 can be recast in terms of the input coefficients of variation

$$C = (C_1^2 + C_2^2 + C_1^2 C_2^2)^{1/2} \qquad [9.20.37]$$

One limiting case is where both input coefficients have the same value ($C_0 = C_1 = C_2$)

$$C = C_0(2 + C_0^2)^{1/2} \qquad [9.20.38]$$

Another limiting case is in which one input coefficient becomes very small. Hence the output coefficient of variation has the range

$$C_{\mathrm{m}} < \Psi < \Psi_{\gtrless}(+\Psi_{\gtrless})^{\oslash} \qquad [9.20.39]$$

with

$$C_{\mathrm{m}} = \max(C_1, C_2) \qquad [9.20.40]$$

Relation 9.20.39 shows that for an AND gate the coefficient of variation of the output is more than the larger of the coefficients of variation of the inputs, and that in this sense this gate increases the uncertainty in the input data.

These results show that strictly in terms of error propagation for a sizeable fault tree a large number of initiating events may produce an outcome for which the uncertainty is relatively low, while a large number of mitigating or protective features may produce one for which the uncertainty is relatively high.

9.20.8 Event trees

An event tree consists of a series of binary splits. Each branch of the tree constitutes a separate escalation scenario. Uncertainty attaches both to the set of escalation scenarios and then, assuming that the set is correct, to the probability of each branch. The question of uncertainty in the escalation scenarios was discussed in Section 9.20.5. The probability distribution for the occurrence of a given branch may be obtained from probability distributions for each of the branch points.

9.20.9 Scenarios, models and parameters

The uncertainty in models has been discussed by Chhibber, Apostolakis and Okrent (1991), in the context of modelling of the fate of chemicals in the environment, particularly in geohydrochemical systems. They consider especially the following areas of uncertainty: (1) completeness of scenarios, (2) completeness of chains of consequences, (3) validity of individual models and (4) parameters in these models, with particular reference to expert judgement.

The formulation of scenarios by experts has been the subject of study. *The Reactor Risk Reference Document* of the Nuclear Regulatory Commission (NRC) (1989 NUREG-1150) gives an account of the expert treatment of scenarios in terms of 'issues' and levels' for a nuclear incident. The issues concern the scenarios that are credible. The levels represent different sets of assumptions about these scenarios.

Likewise, the models, whether for physical phenomena or for injury, may be based on a wide variety of assumptions and may thus be very disparate. Up to a certain point, variation may be handled by assigning different values to the parameters in the model, but beyond this point the model can be stretched no more, and a different model has to be used. There can be a thin dividing line between models and parameters.

Similarly, the value assigned to a parameter may depend on the model used. A well-known case is particle diameter, which may be characterized in different ways, depending on the situation being modelled. The relationships between models are a problem area. The models are not necessarily exclusive, exhaustive or independent.

9.20.10 Physical models

In general, the question of uncertainty in the models of physical phenomena is a relatively neglected one. Whereas treatments are available for uncertainty in event data and fault trees, there is no real equivalent for models. The problem is considered here first in terms of certain general principles. The role of expert judgement in selecting models is then described.

It is possible to identify certain features of models that bear on the degree of uncertainty. Models may be

(1) theoretical;
(2) empirical;
(3) semi-empirical.

They may also be

(1) deterministic;
(2) probabilistic.

The characteristics of these different types of model are well known. A theoretical model may have the weakness that it fails to take into account some relevant phenomenon. It may contain parameters to which it is difficult to assign accurate values or which it is impractical to quantify at all. The weakness of an empirical model may be that it has a limited, and poorly defined, range of applicability. A semi-empirical model, incorporating some combination of theory and experiment, may go some way to overcoming these weaknesses. Alternatively, a straight theoretical model may be validated by experiments.

A comprehensive model incorporates knowledge of the relevant regimes, the ranges of these regimes, and, in each regime, the mechanisms and the values of the parameters. Some factors that bear on the confidence that can be placed in a model include:

(1) theoretical basis;
(2) experimental validation;
(3) range of applicability;
(4) variety of tests;
(5) origin of model;
(6) life of, and interest in, model;
(7) number and convergence of competing models.

Confidence in a model must be greater if it has a theoretical basis. Equally, experimental validation increases confidence. It is, however, the quality of these two factors that matters. It is not uncommon that a theoretical model with some experimental support later proves inadequate.

The range of applicability is therefore important. Greater confidence can be placed in a model that covers a wide range and has been tested over this range. Testing using a variety of methods also increases confidence.

In assessing quality, the origin of the model is a crucial factor. Notwithstanding the challenge to conventional thinking that sometimes occurs from a previously unknown author, confidence is clearly greater if the worker(s) concerned are well established.

Where there is a single model, confidence should in principle increase with time. This will be true, however, only if there is some interest in the model so that the passage of time does actually result in activities which provide some degree of support for it.

A more encouraging situation is where there are a number of competing models that over a period of time yield results which converge. Whilst this by no means gives a guarantee of correctness, it does nevertheless build confidence.

These points are illustrated by the history of the development of models for heavy gas dispersion. In the early days, the models used for gas dispersion were neutral density models. These had both a strong theoretical basis and extensive experimental support. They originated largely from the Meteorological Office and had a good scientific pedigree. It was shown by experiment, however, that the behaviour of a heavy gas cloud is quite different from that of a neutral density gas. It has some of the characteristics of the flow of a liquid, but differs in that air is entrained at the top and the edge of the cloud. This led to the development of a number of models for heavy gas dispersion.

Estimates of the travel distance of a flammable cloud were given in an early study, *Transportation of Liquefied Natural Gas* by the Office of Technology Assessment (OTA) of the US Congress (1977). The following estimates were quoted for the maximum downwind distance for a cloud from a 25,000 m^3 instantaneous spill of LNG onto water in a 5 mile/h wind for dilution to 5% concentration:

Travel distance (miles)	*Source*
0.75	Federal Power Commission
1.2[a]	Science Applications Inc.
5.2	American Petroleum Institute
16.3	US Coast Guard
25.2–50.3	US Bureau of Mines

[a] 37,500 m^3 release in a 6.7 mile/h wind.

The figures illustrate the wide spread given by the different early models. As the field has become more mature, this wide spread has disappeared. There are now available heavy gas dispersion models that have emerged from a large field of competitive models and for which there is experimental underpinning from both large-scale field trials and wind tunnel tests.

9.20.11 Injury relations

Many of the same general considerations that apply to physical models apply also to injury relations, but in addition the latter have some characteristics of their own. In general, an injury relation is obtained either from laboratory work on animals or from incident data affecting humans. In the former case, confidence limits are usually given for the results. Uncertainty arises, however, concerning the applicability of the results to man. If the data relate to an incident, there may be uncertainty concerning both the physical phenomenon and the exposure of humans to it. It is difficult to provide confidence limits. The uncertainty tends to be greatest at the two extremes of very low and very high probability of the injury effect and least at the 50% probability level. Often the injury relations are expressed as probit equations. The remarks just made apply equally to these.

9.20.12 Expert judgement

The choice of models to be used is normally made by a single expert. One of the main methods available to assess the uncertainty in the models is that of expert judgement, using a panel of experts.

Several studies of expert judgement in assessment of models have been made. One is the NRC study already mentioned (NUREG-1150).

Another is the work of Goossens, Cooke and van Steen (1989). This addresses uncertainty in the relative likelihood of different phenomena and in the values of parameters. The areas of application include failure rates, physical models and injury effects.

Models are developed by a domain expert. The uncertainty in the models may be assessed by a normative expert, whose expertise resides in such assessment.

One way of quantifying the uncertainty in a model is the error factor method. The error factor was described in Section 9.20.3. Consider a deterministic reference model (DRM) that yields some variable T. Then using an error factor E, T may be written as

$$T = ET_{\mathrm{DRM}} \qquad [9.20.41]$$

where T_{DRM} is the value of given by the DRM. The error factor is external to the model. It may be updated whilst the model remains unchanged. This error factor approach has been applied by Siu and Apostolakis (1985) in the context of fire growth in a building. It is described further by Chhibber, Apostolakis and Okrent (1991).

It can occur that experimental data become available that might be used to modify a model. In principle, such updating may be effected using Bayesian methods, but this may not be straightforward. In order to apply the Bayesian approach it is necessary to formulate a likelihood function and for a complex model it may not be easy to do this. In this case, one approach may be to use expert judgement methods to formulate a suitable likelihood function.

9.20.13 Results

The results of a hazard assessment should in principle include not only the best estimate of the risk but also a measure of the uncertainty that attaches to this estimate. There are, however, problems associated with providing such measures of uncertainty. These include: the difficulties of principle in assigning uncertainty, particularly to models; the effort required to compute the measures, which may be comparable with that of making the basic estimate; and an inability to make effective use of this additional information in decision-making.

9.21 Risk Criteria

In order to evaluate a risk assessment it is necessary to have appropriate risk criteria. Some of the more philosophical aspects of risk are considered in Chapter 4. The treatment here is confined to a consideration of some of the principles that should underlie the choice of risk criteria and of some of the types of criterion, systems and numerical criterion values used or proposed. Accounts of risk criteria include those given in *Dealing with Risk* (R.F. Griffiths, 1981c), *Risk Assessment. A Report of a Royal Society Study Group* (Royal Society Study Group, 1983) (the RSSG Report), the *Third Report of the Advisory Committee on Major Hazards* (Harvey, 1984), *The Tolerability of Risk from Nuclear Power Stations* (HSE, 1988c) and *Risk Criteria for Land-use Planning in the Vicinity of Major Industrial Hazards* (HSE, 1989c). Selected references on risk criteria are given in Table 9.36.

9.21.1 Royal Society Study Group

The *RSSG Report* sets out some possible quantitative guidelines for risk. It prefaces these by a number of qualifications. The risks considered are primarily risks of death, but in addition some suggestions are also made for criteria for non-fatal risks.

The RSSG define an upper bound of risk above which the risk is ‘unacceptable in essentially all circumstances’,

except perhaps for activities entered into voluntarily or in wartime. It also defines a lower bound below which risks may 'legitimately be regarded as trivial by the decision-maker'. Between these two bounds there lies a region in which the risk needs to be assessed and all reasonably practicable steps taken to reduce it. This is referred to here as the 'three-region approach', as opposed to the point value, approach.

The RSSG suggest that most people regard as insignificant a risk of death below about 10^{-6}/year. This therefore constitutes a lower bound. For the upper bound the RSSG state that few would dissent from the proposition that imposing a continuing risk of 10^{-2}/year is unacceptable. The position is less clear with regard to a risk of 10^{-3}/year. For males only, those between 1 and 20 years of age have an annual risk of death markedly less than this. Therefore pre-existing levels of risk are more likely to cause death than a new imposed risk. The RSSG argue that an imposed risk of 10^{-3}/year can therefore hardly be called totally unacceptable provided that the individual is aware of the situation. The RSSG finally take this value of 10^{-3}/year as the upper bound. The central region contained within these bounds is therefore that where the risk lies between 10^{-6}/year and 10^{-3}/year. It is in this region that the concept of reducing risk 'as far as reasonably practicable' applies. As indicated, the upper bound of 10^{-3}/year is evidently associated with situations in which there is a degree of voluntary acceptance.

The risk criteria described are those that may be used by the decision-maker, particularly the central decision-maker in government. The categorization of a risk as insignificant does not necessarily imply that it will be perceived as such by those affected, but relates rather to the action that the decision-maker should require.

9.21.2 Advisory Committee on Major Hazards

In its First *Report* (Harvey, 1976), the ACMH made the statement

> If, for instance, such tentative conclusions indicated with reasonable confidence that in a particular plant a serious accident was unlikely to occur more often than once in 10,000 years (or – to put it another way – a 1 in 10,000 chance in one year), this might perhaps be regarded as just on the borderline of acceptability . . .

Insofar as the committee was set up following the Flixborough disaster, in which 28 people were killed, it may be assumed to have had in mind a similar accident, say one involving 30 fatalities. The above statement has been taken by a number of parties as a starting point for the development of criteria for societal risk. Otherwise, however, the ACMH proposed little by way of quantitative risk criteria. It did, however, in its Third *Report* (Harvey, 1984) state a number of principles, including the following:

1. The risk from a major hazard to an individual employee or member of the public should not be significant when compared with other risks to which a person is exposed in everyday life.
2. The risk from any major hazard should, whenever reasonably practicable, be reduced.
3. Where there is a risk from a major hazard, additional hazardous development should not add significantly to the existing risk.
4. If the possible harm from an incident is high, the risk that the incident might actually happen should be made very low indeed.

9.21.3 HSE nuclear installations risk criteria

The HSE have published two documents outlining their approach to the development of risk criteria. The first of these is *The Tolerability of Risk from Nuclear Power Stations* (HSE, 1988c). This document gives the following treatment of risk of death to workers and to members of the public. A distinction is made between risk from normal operation, due essentially to radiation dose, and risk from a nuclear accident.

At nuclear installations the actual risk to workers from the average levels of radiation dose lies between about 10^{-4}/year and 2.5×10^{-4}/year. A very small number of workers are exposed to a risk some ten times greater. The figure of 2.5×10^{-4}/year happens to correspond to the risk to workers in heavy manufacturing and mineral extraction and that of 10^{-4}/year to the average for manufacturing industry. The HSE conclude that, broadly, the limit of tolerable risk to a worker is 10^{-4}/year.

On the basis that the risk to a member of the public should be at least an order of magnitude lower than that to a worker, the limit of tolerable risk to a member of the public is taken as 10^{-4}/year. The risk to a member of the public that might be regarded as acceptable, as opposed to tolerable, is then taken 10^{-6}/year. This appears to be a level at which in general a risk causes little concern. It happens to be approximately the risk of being electrocuted at home and one hundredth of the risk of dying in a traffic accident.

The actual risk to a member of the public from normal operation of a nuclear installation is well below 10^{-5}/year and that from a nuclear accident at an installation designed to Nuclear Installation Inspectorate (NII) principles is about 10^{-6}/year. The risk to a member of the public from both causes is assessed as 10^{-6}/year for most people in the vicinity of the installation, but for a small number it is about 10^{-5}/year and for a very few it may exceed this.

The document does not give a criterion for societal risk in terms of FN curves or the equivalent. Instead, it takes as a measure of societal risk three scenarios: (1) a limiting design basis accident, (2) an uncontrolled release and (3) an uncontrolled release large enough to produce doses of 100 mSv within 3 km. It suggests that the limit of tolerable risk of a considerable uncontrolled release anywhere in the United Kingdom might be about 10^{-4}/year. The assessed risk quoted for such a release is in fact 10^{-6}/year.

9.21.4 The ALARP principle

The HSE nuclear risk document also deals with the question of reducing the risk to a level that is as low as reasonably practicable (ALARP). The reduction of risk in accordance with the ALARP principle is a basic requirement of the Health and Safety at Work etc. Act 1974.

The ALARP principle is illustrated in Figure 9.35. There is some level, above which the risk is intolerable. Above this level, the risk cannot be justified on any grounds and must be reduced. There is another level below which the risk is negligible and no action is required, not even demonstration that the ALARP principle has been applied. Between these two levels lies the region in which there is a requirement to apply the ALARP principle.

9.21.5 HSE land-use planning risk criteria

The other HSE publication on risk criteria is *Risk Criteria for Land-use Planning in the Vicinity of Major Industrial Hazards* (HSE, 1989c). The risk criteria described in this document are strictly for land-use planning of new developments around major hazard installations. They are not intended to be used for (1) siting of a new major hazard installation, (2) new activities on an existing site or (3) an existing major hazard installation and existing development.

As described in Chapter 4, the basic approach to land-use planning adopted by the HSE is to divide the area around a hazardous installation into three zones. In the top zone risk is a major factor, in the bottom zone it is treated as insignificant and in the middle zone it is a consideration and further assessment is indicated.

The risk criteria given are largely determined by the use to which they are put in land-use planning and differ from the conventional criteria, which tend to be for risk of death. Instead the HSE have developed the concept of a 'dangerous dose'. This dangerous dose is effectively an injurious load imposed by some physical phenomenon such as thermal radiation, explosion overpressure or toxic concentration. The dangerous dose is that which will result in the death of a small proportion of the exposed population. It is

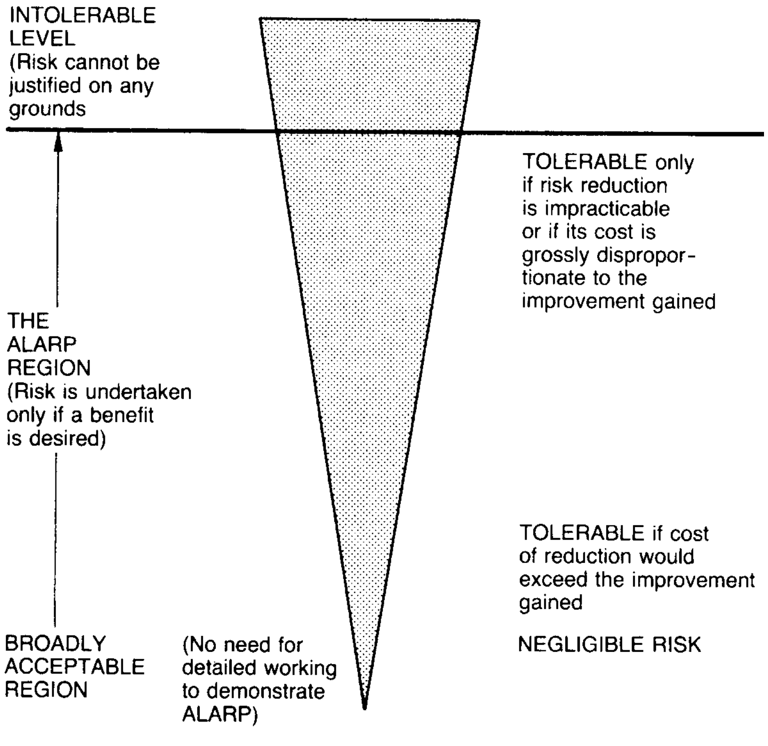

Figure 9.35 *The ALARP principle (HSE, 1988c) (Courtesy of HM Stationery Office. Copyright All rights reserved)*

assumed that the risk to a vulnerable person is an order of magnitude greater than that to the average person.

For the exposed population as a whole, the HSE take as the upper bound for the risk of a dangerous dose or worse 10^{-5}/year and as the lower bound 10^{-6}/year. This implies that these figures are also approximately the risk of death for vulnerable people. For the case where the exposed population contains a high proportion of vulnerable people the lower bound is taken instead as 0.33×10^{-6}/year. The upper bound risk is about one-tenth of the risk of death in a road traffic accident. The lower bound risk is about ten times the risk of death from lightning.

With regard to societal risk, the HSE rehearse the problems of risk aversion and of FN curves. Instead they elect to use a 'judgmental approach', in which qualitative factors are more prominent. The starting point is the individual risk. The element of societal risk is taken into account by applying a harsher judgement to larger developments in the middle zone. These risk criteria are intended to be used in conjunction with a risk assessment based on the 'cautious best estimate' approach.

The application of these criteria to various types of development, which is given in the document, is described in Chapter 4.

9.21.6 Factors restricting choice of individual risk criteria

A difficulty in the selection of risk criteria is that the choice of criteria is liable to appear arbitrary. The description just given of some systems of risk criteria hints at the fact that when account is taken of the various relevant factors, the scope for arbitrary choice is quite severely restricted. This aspect is now explored in more detail.

Considering risk of death, the average risk to a worker in manufacturing industry is about 3×10^{-5}/year. On the assumption that a new plant should be three times safer than the current average, the risk criterion for a worker on a new plant might be taken as 10^{-5}/year.

It is reasonable to assume that the risk to a worker on a potentially affected plant other than the plant under consideration should be less than that to a worker on the latter, and an order of magnitude reduction is often used. On this assumption, the risk criterion for a worker on another plant would be 10^{-6}/year.

Adopting the usual assumption that the risk to a member of the public should be less than that to a worker, the figure of 3×10^{-5}/year might also be taken as an upper bound for a member of the public. The risk of being killed by lightning, which is 10^{-7}/year, is often taken as one that causes little concern. On this basis, the lower bound for risk to a member of the public might be taken as 10^{-6}/year.

A further factor that needs to be taken into account is the risk from a complex of plants. It is assumed that where there is such a complex the risk is increased by a factor of 3.

Then, taking into account (1) new vs existing plants and (2) single plants vs a complex of plants, the risks obtained for a member of the public are as follows:

Single plant		*Complex*	
New plant	*Existing plant*	*New plant*	*Existing plant*
10^{-6}/year	3×10^{-6}/year	10^{-5}/year	3×10^{-5}/year

The highest and lowest risks here correspond exactly to the upper and lower bounds given above.

The foregoing account is given not primarily to suggest a further set of risk criteria, although the values given do not differ greatly from criteria often proposed, but rather to illustrate the fact that by the time account is taken of the relevant factors, the scope for arbitrary choice narrows appreciably.

9.21.7 FN curve criteria of societal risk

Given that a formal risk criterion is used at all for societal risk, the criterion most commonly used is the FN curve. The basic characteristics of FN curves were described in Section 9.19. The account given here is concerned with the parameters to be used in a risk criterion curve.

Like other forms of risk criterion, the FN curve may be cast in the form of a single criterion curve or of two criteria curves dividing the space into three regions – where risk is unacceptable, where it is negligible and where it requires further assessment. The latter approach corresponds to application to societal risk of the ALARP principle and is much to be preferred.

The characteristics of a FN relation are most easily appreciated by considering an FN line. The two defining parameters of such a line are the frequency of a single fatality accident, or intercept on the *F* axis, and the slope of the line. A characterization of FN curves, whether for actual risks or as risk criteria, has been given by Hagon (1984).

9.21.8 Farmer curve

Before considering the more usual type of FN curve, it is appropriate to refer to the risk criterion curve given by F.R. Farmer (1967b), which pioneered this form of criterion. Figure 9.36 shows the Farmer curve.

As explained in Section 9.19, the quantity plotted on the ordinate of this curve is accident intervals rather than accidents equal to or greater than the defined size.

The argument supporting this criterion (as developed in 1967) is roughly on the following lines. A release of a few thousand curies of ^{131}I constitutes an accident that could cause fatalities and would probably provoke public outcry. Programmes of reactor installation in several countries

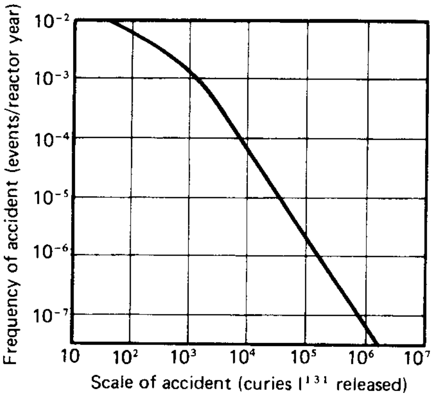

Figure 9.36 *Accident scale–frequency criterion for nuclear power reactors (the Farmer curve) (after F.R. Farmer, 1967b) (Courtesy of the British Nuclear Energy Society)*

will accumulate about 100 reactor-years operation before the turn of the century. The risk of one such event during this period is probably the limit of acceptability. This therefore gives one point on the graph, at the frequency of 10^{-3} accidents per reactor year. The slope of the main part of the graph, for large accidents, is –1.5 (on the log–log plot). This slope implies that if the severity of an event increases by two orders of magnitude, its frequency decreases by three orders of magnitude. This represents a weighting to reduce the probability of large-scale accidents that may be expected to give rise to severe public reaction. The curve on the graph in the smaller accident region represents a reduction in the frequency of small incidents, since numerous small incidents are also likely to cause public concern.

9.21.9 Criteria expressing risk aversion

Reference has already been made to risk aversion in respect of societal risk. The Farmer curve just described is an early illustration of such risk aversion. As mentioned above, a measure of risk aversion is the parameter α defined in Equation 9.19.1. This quantity is known as the 'risk aversion index'. Considering a FN line on a log–log plot, if the slope of the line is $-x$ the risk aversion index α is $1 + x$. A number of authors have discussed the appropriate value of this index, including Okrent (1981), D.C. Cox and Baybutt (1982) and Hagon (1984).

It is argued by Okrent that it is unlikely that society demands a value of $\alpha \geq 1.5$, that one of $\alpha = 2$ is certainly excessive and that even one of $\alpha = 1.2$ may not be of general applicability. On the other hand, as described below, Hagon has shown that at values of α of less than 2 the contribution of large accidents to the average risk tends to become relatively large, or even predominant.

9.21.10 Groningen FN curve risk criterion

An early societal risk criterion utilizing FN curves was that promulgated by the Provinciale Waterstaat Groningen (PWG, 1979), the 'Groningen criterion'. The Groningen criterion is illustrated in Figure 9.37. There are three zones and two bounding curves. In one zone the risk is unacceptable, in one it is acceptable and in one further assessment is required. For accidents with, on average, more than one fatality ($N > 1$) the slope of the two bounding curves corresponds to a degree of risk aversion in which the consequence is raised to the power 2 (N^2).

Some further characteristics of the Groningen criterion have been given by Hagon (1984), using his relations given in Section 9.19. For the upper curve over the range $N = 1$ to $N = 1000$

$$F_1 = 10^{-2}$$

$$F_{1000} = 10^{-8}$$

The risk aversion is therefore given by

$$FN^2 = \text{Constant}$$

$$\alpha = 3$$

Beyond $N = 1000$ the curve is vertical so that $\alpha = \infty$. For the lower curve over the range $N = 1$ to $N = 10$

$$F_1 = 10^{-6}$$

$$F_{10} = 10^{-8}$$

with the same degree of risk aversion. Beyond $N = 10$, the curve is again vertical.

9.21.11 Hagon FN curve risk criteria

Hagon has used his FN curve relations to describe the characteristics of several well known FN curves. His treatment of the Groningen criterion has just been described. For those given in the Second *Canvey Report*, shown in

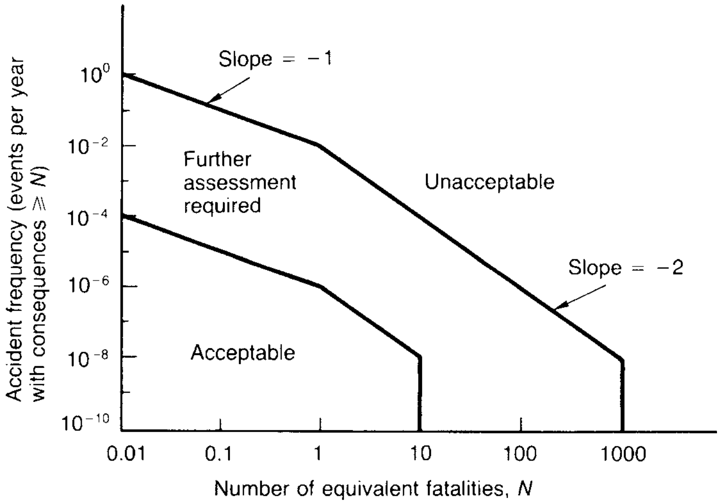

Figure 9.37 *Groningen FN curve risk criterion (Hagon, 1984; after PWG, 1979) (Courtesy of the Institution of Chemical Engineers)*

Figure 9.30 which gives a curve approximating to a straight line, for events up to $N > 1000$ he obtains:

$$F_{10} = 10^{-3}/\text{year}$$
$$F_{1000} = 2 \times 10^{-4}/\text{year}$$
$$\alpha = 1.35$$

This is a low degree of risk aversion.

For the ammonia storage sphere in the *Rijnmond Report*, the FN curves for which are shown in Figure 9.34, Hagon sets a bounding line characterized by $F_1 = 10^{-3}$/year and $\alpha = 2$. He then obtains:

$$F_3^{30} = 2.2 \times 10^{-3}$$
$$F_{30}^{300} = 2.2 \times 10^{-5}$$

and

$$D_1^{30} = 2.4 \times 10^{-3}$$
$$D_1^{3000} = 5.2 \times 10^{-3}$$

This indicates that large accidents are a significant contributor to the average risk of death.

Hagon takes as a prime determinant of the risk aversion index α the parameter F_N^M, which is the frequency of all accidents between one with N fatalities and one with the maximum number M of fatalities. Figure 9.23 shows that F_N^M increases only slowly with N, provided that $\alpha > 1.5$.

Hagon takes as another determinant of α the parameter D. From Figure 9.33 the increase of D with N is slow, provided that $\alpha > 2$.

With regard to the choice of F_N^M, Hagon takes as his starting point the Flixborough disaster, in which 28 men died. If there are assumed to be nationwide in the United Kingdom some 500 installations capable of giving an event such as Flixborough, and if such an event should occur no more often than once in 100 years, then for a single installation:

$$F_N^M = \frac{1}{500 \times 100} = 2 \times 10^5/\text{year}$$

The number of fatalities at Flixborough was 28. He takes the range of fatalities for a major hazard as 30–300, and thus sets $F_{30}^{300} = 2 \times 10^{-5}$/year. He sets $\alpha = 2$, and obtains for single fatality accidents and for total deaths due to the major hazard risk:

$$F_1 = 6.5 \times 10^{-4}/\text{year}$$
$$D_1^{300} = 4.1 \times 10^{-3}/\text{year}$$

9.21.12 Dutch risk criteria

Two more recent sets of risk criteria are the Dutch criteria and the Advisory Committee on Dangerous Substances (ACDS) FN curve. Provisional risk criteria according to Dutch law are quoted by Ale (1991). They are shown in Figure 9.38

9.21.13 ACDS FN curve

The ACDS *Transport Hazards Report* (1991) also gives a FN curve, shown in Figure 9.39. Arguments in support of the curve are given in detail in Appendix 6 of the report.

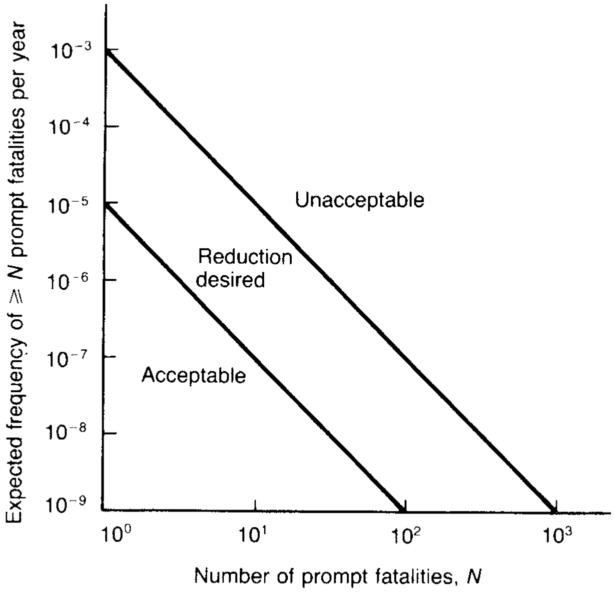

Figure 9.38 Some risk criteria for the Netherlands (after Ale, 1991; Pasman, Duxbury and Bjordahl, 1992) (Courtesy of Elsevier Science Publishers)

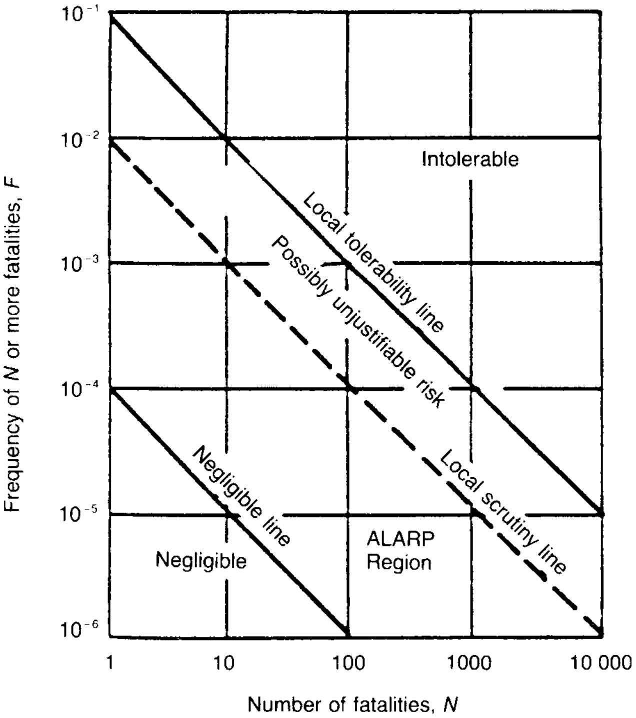

Figure 9.39 *ACDS FN curve risk criterion (after Advisory Committee on Dangerous Substances, 1991)*

9.21.14 Need for criteria in hazard assessment

In the method of hazard assessment described by Kletz (1971) he effectively recognizes four situations in respect of the probability of an event leading to a hazard:

(1) The probability of the event is low.
(2) The probability of the event can be made low by application of a standard or code of practice.
(3) The probability of the event can be made low by the application of measures that can be shown by a simple risk analysis to be of equivalent safety to the normal standard or code of practice.
(4) The probability of the event must be assessed quantitatively and must be reduced to conform to the risk criteria by measures indicated by the analysis. For a straightforward case use is make of a simple risk analysis while for a more complex one it is necessary to resort to a more detailed method such as fault tree analysis.

Risk criteria are needed mainly for the fourth case. The second and third cases are considered first.

9.21.15 Standards and codes

If the probability of the event that may lead to realization of the hazard is not intrinsically low, nevertheless it may often be reduced to a low level by the use of an appropriate standard or code of practice.

An example given by Kletz is that there is some probability of overpressure in a pressure vessel, but the use of pressure relief valves as specified in standards and codes for pressure vessels reduces this probability to a low level. Another example is that electrical equipment has some probability of acting as a source of ignition, but the application of codes for hazardous area classification and equipment safeguarding results in a low value of this probability.

The main *caveat* to be made here is that where major hazards are concerned it should not be assumed that the use of the standards and codes is sufficient.

9.21.16 Equivalent risk

It is sometimes not appropriate, or even possible, to use a standard or code. In this case it may be possible to devise an alternative method that can be shown to have a degree of safety at least equivalent to the standard or code. A simple risk analysis is carried out to demonstrate this. The analysis by Kletz (1974a) of the use of trips instead of pressure relief valves described in Chapter 13 is a case in point.

9.21.17 Individual and average risk

Before considering the evaluation of the more complex analyses mentioned using suitable risk criteria, there are some further preliminary points to be made.

In considering risk, it is necessary to distinguish between the average risk run by a group of people, whether employees or public, and the higher risk that may be run by some individuals within the group. Thus some employees may be exposed to a higher risk because the plant on which they work is more hazardous and some members of the public may be exposed to a higher risk because they live nearer the works. There is fairly general agreement that there should be a limit to the risk run by any individual.

Thus it is not sufficient to achieve a low average risk; it is necessary also to reduce to a minimal level the risk to the most exposed individual. In other words the risk to that person should not be 'lost' by combining it with the risk to a larger group most of whom are much less exposed.

9.21.18 Death and injury

Most treatments of risk deal primarily with the risk of death. This may appear somewhat arbitrary, but there is justification for this approach. Data on fatalities are recorded and are relatively straightforward. For other levels of injury, however, there can be problems. Often the data are not available, but even if they are, there tend to be difficulties in interpreting them. Moreover, for any given activity in industry there tends to be a relationship between fatalities and other injuries. The work of Heinrich (1959) on this ratio has been described in Chapter 1.

Measures that reduce deaths from a particular hazard tend to reduce injuries in proportion and it is this reduction that is important. The use of death rate as the main practical criterion does not therefore imply any disregard of the personal tragedy arising from serious injury.

Several indices of industrial injury risk are used in the literature. The lost time accident rate is expressed as the number of accidents per 10^5 exposed hours; this period corresponds approximately to a working lifetime. Fatal accidents are much less frequent and in order to avoid inconveniently small numbers the FAR is defined as the number of deaths per 10^8 exposed hours; this roughly corresponds to the number of deaths over a working lifetime of 1000 persons. Another index that is useful in relation to general fatality risks is the death rate per annum.

It should be recognized, however, that the use of fatality risk is not universally accepted as the most appropriate approach, and there is considerable literature on the subject. Some hazards are particularly likely to give rise to delayed, as opposed to prompt, deaths or to serious injury. A release of radioactivity from a nuclear reactor may have the potential to cause many deaths that are predominantly delayed.

9.21.19 Engineering feasibility

There is obviously a limit to the degree of plant reliability that can be achieved even by the best engineering practice and, equally important, to the degree of confidence that can be placed in estimates of that reliability.

A figure frequently quoted for the reliability to which plants can be engineered is a hazard rate for a major accident of 10^{-5} events/year. This is the figure given by J.H. Bowen (1976) from a nuclear industry perspective. The reason that it is difficult to achieve lower hazard rates is that at this level the risk begins to be affected by rather improbable failures and by dependent failures.

In this respect, a distinction may be made between a risk which is assessed as 10^{-5}/year as a single figure and a one which is also assessed as 10^{-5}/year but as the product of two separate risks of 10^{-2}/year and 10^{-3}/year; insofar as the two latter values represent figures that are known to be achievable in engineering terms, the second of the two risks of 10^{-5}/year may be considered to be a more robust estimate.

9.21.20 Value of a life

One criterion for evaluating measures available to reduce risk is the value of a life. A general discussion of this concept, and its difficulties, has been given in Chapter 4. The account here is confined to an overview of the principal approaches and of the values that emerge from them.

The cost of accidents and the cost-effectiveness of safety measures were major concerns of the Robens Committee (Robens, 1972). The *Robens Report* itself attempted to assess the cost of industrial accidents to the nation. The committee also supported work by Sinclair, Marstrand and Newick (1972a,b) on the cost-effectiveness of approaches to industrial safety. The problem is an important one and there is a large literature on the subject (e.g. National Academy of Engineering, 1972).

Some of the methods that can be used to estimate the value of a life have been reviewed by Melinek (1974 BRE CP88/74) and Kletz (1976d). The following account is based on their work and the figures quoted from it are taken unchanged and reflect the value of money at that time. The methods that they describe may be summarized as (1) future production, (2) administrative decisions, (3) consumer preference, (4) court awards and (5) life assurance.

Thus one method of assessing the value of a life is to calculate the future production or services which an individual may be expected to give to the community. A variant of this is to estimate future earnings, although these are not synonymous with the value of the work done. Most estimates of the value of future production lie in the range £10,000–£100,000. The Road Research Laboratory has given an estimate of £15,000 (R.F.F. Dawson, 1967).

There are many administrative decisions made by government that effectively set a particular value on life. Mellinek quotes:

Worker safety	£15,000–£20 million
Consumer safety	£0–£20 million
Medical care	up to £20,000

Similarly Kletz quotes:

Agriculture	£2000
Steel handling	£200,000
Pharmaceuticals	£5 million

The value set in medical work seems to be particularly low. Leach (1972) has shown that lives can be saved for very small expenditures:

Lung X-ray machines for older smokers	£400
Cervical cancer screening	£1400
Artificial kidney	£9500

Another approach is based on consideration of consumer preference. The following illustration is given by Melinek for the implicit valuation put on his own life by a pedestrian who crosses the road on the surface instead of using the safer subway:

Probability of being killed crossing a road	$\approx 10^{-8}$
Extra time taken by using subway	$\approx 15\ \text{s} = 0.004\ \text{h}$
Value which people put on own time	$\approx$ £0.25/h
Value of a life	$\approx \dfrac{0.25 \times 0.004}{10^{-8}} = £100{,}000$

The value that people put on their own time is taken from transport studies. The value of a life as obtained from more extensive studies by the FRS is, as described by Melinek, about £50,000.

The damages which courts award for death or injury often include a sum for the reduction of life expectancy and are thus another means of estimating the value of a life. It has also been suggested that the value of a life may be determined from the sums covered by life assurance.

There are quite serious objections to some of these approaches. In the case of the valuation of life in terms of the value of the person's future production, the *reductio ad absurdam* is that this criterion puts a zero value on the life of a retired person. Society, however, is prepared to pay to preserve that life. Consumer preference seeks an objective basis in what people actually do, but hardly appears to reflect the way they actually think. Court awards set a notoriously low value on life expectancy and are thus a poor guide. Life assurance is taken out to protect dependants or as an investment and is not intended to compensate for death. The values implied in administrative decisions show a very wide spread and again are far from satisfactory as a guide.

A rather different, and more relevant, approach is described by Kletz (1976d). This is to consider the cost of achieving the risk target that he uses for process plants. He estimates this cost as equivalent to about £1 million per life and suggests that in general this is a reasonable figure to take as the value of a life. A valuation less than £100,000 would hardly be acceptable, while one more than £10 million would seem extravagant.

The value of a life criterion is applied as follows:

$$v = \frac{c}{h} \qquad [9.21.1]$$

where c is the annual cost of eliminating the hazard (£/year), h is the hazard rate (deaths/year) and v is the value of a life (£/death avoided). Thus, for example, if in a given case a particular hazard is assessed as presenting a hazard rate of 10^{-4} deaths/year, if the value of a life is taken as £1 million and if £1 million capital expenditure is equivalent to £200,000/year recurrent expenditure, then the application of the criterion indicates that it is appropriate to spend up to £20/year to eliminate the hazard.

9.21.21 Comparisons of process and other risks

Whereas the risk to which a member of the public is exposed from a hazardous installation is an involuntary one, it is generally considered that to some degree at least, an employee accepts voluntarily the risk associated with work on the plant.

Writers on hazard analysis such as Kletz (1971) and S.B. Gibson (1976a) have compared the risks to employees on process plant with other risks accepted voluntarily or borne involuntarily. Following Kletz (1976d) some data on voluntary and involuntary risk are

	Fatality rate (deaths/person-year)
Voluntary risk	
Taking a contraceptive pill[a]	2×10^{-5}
Playing football[b]	4×10^{-5}
Rock climbing[b]	4×10^{-5}
Car driving[c]	17×10^{-5}
Smoking (20 cigarettes/day)[b]	500×10^{-5}
Involuntary risk	
Meteorite[d]	6×10^{-11}
Transport of petrol and chemicals (UK)	0.2×10^{-7}
Aircraft crash (UK)[a]	0.2×10^{-7}
Explosion of pressure vessel (USA)[d]	0.5×10^{-7}
Lightning (UK)[e]	1×10^{-7}
Flooding of dikes (The Netherlands)[f]	1×10^{-7}
Release from nuclear power station (at 1 km) (UK)	1×10^{-7}
Fire[g]	150×10^{-7}
Run over by vehicle (UK)	600×10^{-7}
Leukaemia[a]	800×10^{-7}

[a] S.B. Gibson (1976c); [b] Pochin (1975); [c] Roach (1970); [d] Wall (1976); [e] Bulloch (1974); [f] Turkenburg (1974); [g] Melinek (1974 BRE CP 88/74).

The validity of such comparisons has been discussed in Chapter 4.

9.21.22 Computation of risk

The risk of an individual may be formulated in simple terms as:

$$r = \frac{1}{N}\sum_{i=1}^{n} x_i f_i \qquad [9.21.2]$$

where f_i is the frequency of accident type i, r is the individual risk of death, x_i, is the number of deaths for accident type i, n is the number of types of accidents and N the total number of persons at risk.

The calculation is concerned with the risk to the individual. All accidents that might have a significant effect on this individual risk should be taken into account. The estimate should not be distorted by inclusion of numbers of people who have a significantly lower exposure.

Often the relationship for individual risk is more complex than Equation 9.21.2. The ACDS *Transport Hazards Report* (1991) contains a number of examples of the more complex formulations necessary in certain cases.

9.21.23 Application of risk criteria

The foregoing treatment has outlined some approaches to the setting of individual and societal risk criteria. An account is now given of some of the practicalities of engineering design utilizing these and other criteria.

The treatment for risk to employees essentially follows the systems developed by Kletz (1971) and S.B. Gibson (1976a). Their approach is based on the use of hazard analysis and of the FAR criterion, as described in Section 9.2. For, say, an overall FAR of 3.5 the target value for a given plant hazard is 0.35, or one-tenth of the overall value. If some particular jobs on a process are more subject to this hazard than others, then the FAR is applied to the more hazardous ones; it is not averaged over all the jobs. Thus no one is exposed to a risk higher than the target value.

This *primary criterion* of maximum risk must normally be met and any expenditure required to meet it must be incurred.

It is not necessarily enough, however, to meet the FAR criterion. It still remains to determine whether all that is 'reasonably practicable' has been done to ensure safety. For this, use is made as a *secondary criterion* of the concept of the value of a life. The value of a life criterion is applied to evaluate additional expenditure aimed at eliminating hazards and reducing risk.

Various figures have been given for the value of a life for use in this context. As described in Section 9.21.20, the value suggested for the chemical industry by Kletz when he wrote in the mid-1970s was £1 million. Publications in the recent past, say 1990, have quoted for a wider range of activities a value of about £3 million.

This approach represents the practical application of the ALARP principle.

9.21.24 Safety improvement

It is often suggested that it would be unfortunate if the adoption of particular risk criteria was to lead to the situation where there ceased to be any improvement in safety standards. In fact the system described, based on the FAR, does tend towards a continuous improvement in safety standards provided the system is universally applied, that factors other than the plant design, particularly the standard of management, do not deteriorate and that the target FAR used is the moving average for the industry. For, while it is then not accepted that any plant have an FAR worse than the current average, some will have one which is better, so that the average will gradually improve. Moreover, the use of the value of a life as a secondary criterion injects a further degree of improvement. There is therefore a ratchet effect that tends to raise standards.

9.21.25 Allocation of resources

The problem of expenditure on safety measures is one of allocation of resources and of cost-effectiveness. As already indicated, the administrative decisions made by government and industry imply a wide range of valuations of human life.

Some of the examples quoted do at least prompt the question whether the chemical industry perhaps spends too much on safety. This may be so, but the hazards of the chemical industry tend to provoke a strong reaction and it is doubtful if much relaxation would be tolerated. This is doubly so following disasters such as that at Bhopal.

Moreover, it is probably of value to the community as a whole to have an industry that despite the high intrinsic hazards of its materials and processes is able to pioneer methods of improving control of hazards and to achieve high levels of safety.

Nevertheless, the allocation of resources to safety is a legitimate subject for public debate. The chemical industry can only try to respond responsibly to this.

9.22 Guide Assessments

The arrangements for the control of major hazards in the United Kingdom were described in Chapter 4. It was mentioned there that in order to give advice to local planning authorities the HSE has developed assessment methods for LPG and for chlorine installations.

An outline approach to assessment for emergency planning for a chlorine release has been given by the UK Chlorine Producers under the auspices of the CIA. The CIA has also issued a Control of Industrial Major Accident Hazards (CIMAH) guide for ammonia. Other CIMAH guides include those on LPG by the Liquefied Petroleum Gas Industry Technical Association (LPGITA), on liquid oxygen by the British Compressed Gases Association (BCGA) and on ammonium nitrate by the Fertilizer Manufacturers Association (FMA). These guide assessments are now described in turn. Some of the features mentioned draw on material described in Chapters 15–18.

9.22.1 HSE LPG methodology

The HSE methodology for the hazard assessment of LPG has been described by Crossthwaite (1984, 1986) and its further development has been described by Clay *et al.* (1988). It is embodied in the program RISKAT. The assessment has been carried out as part of the work done by HSE on their advice to local planning authorities on consultation distances. The overall approach taken is that described in the *Third Report* of the ACMH that states:

> It seems reasonable to aim for a separation which gives almost complete protection for lesser but more probable accidents and worthwhile protection for major but less probable accidents.

In applying this principle the HSE has judged that releases due to pipework failure fall in the first category and fireballs and vapour cloud explosions (VCEs) fall in the second.

The events considered by Crossthwaite (1984) are shown in Table 9.37. For thermal radiation from a fireball, the effects of different levels of received radiation are taken to be:

	kJ/m^2
50% fatalities	700
Blistering of exposed skin	200
Blistering of skin (threshold)	100

and of explosion overpressure:

	psi
5% fatalities	5
Injury due to flying glass	1
Injury but very unlikely to be serious	0.7

The distances at which and the areas over which these levels of effect are estimated to occur for the more serious accidents such as a release of 100 te of LPG are shown in Table 9.38.

The guidelines on consultation distances issued by the HSE on the basis of such assessments are described in Chapter 4.

9.22.2 HSE chlorine methodology

The HSE methodology for the hazard assessment of chlorine has been described by Pape and Nussey (1985). It is embodied in the program Risk Assessment Tool (RAT), now RISKAT. The type of installation considered is shown in Figure 9.40. The listing of hazard scenarios given is shown in Table 9.39. These releases were developed as shown in Figure 9.41 and the consequences analysed as

Table 9.37 *HSE guide assessment on LPG installations: hazardous events (after Crossthwaite, 1984)*

Event	*Consequences*	*Likelihood*
Small flange leak	Local effects only. No off-site hazard	Considerable number each year
Severe pipe leak (guillotine rupture)	If ignition occurs on site, then off-site consequences unlikely to be serious. If ignition occurs off site, a flash fire would injure persons in and near the cloud	Average of about 1/year in UK
BLEVE	High levels of thermal radiation at substantial distances from point of release	Two incidents known to have occurred in UK
Vessel rupture	Flash fire: persons within the (quasi-instantaneous) cloud likely to be killed. Explosion: this will have serious effects at substantial distances from release	No history in UK

Table 9.38 *HSE guide assessment on LPG installations: physical effects from a 100 te release of propane (after Crossthwaite, 1984)*

A Fireball from a BLEVE

Thermal radiation (kJ/m^2)	*Distance from installation* (m)	*Area of land* (hectares)
(Fireball radius)	107	3.6
700	200	12.6
200	380	45
100	530	88

B Explosion of a vapour cloud

Overpressure (psi)	*Distance from installation* (m)	*Area of land* (hectares)
5	176	9.7
1	513	83
0.7	675	143

shown in Figure 9.42. Some of the principal assumptions used in the analysis are given in Table 9.40.

The hazard scenarios to be considered were simplified by reducing the pipe failures to two cases: guillotine fracture with both ends open, and a split equivalent to a hole of half the pipe size. Each release was expressed as a vapour flow rate. It was assumed that small releases from pipes would vaporize completely. The justification for this was that for unbunded releases the SPILL computer code for vaporization predicts that the vaporization rate quickly reaches the release rate.

For convenience, large instantaneous releases were treated as pseudo-continuous. A rule of thumb was used that a release over 10 te is equivalent to a continuous release of 1.5 times the actual release with a duration of 10 min, and that smaller releases have an effective duration of 5 min. The heavy gas dispersion was modelled using the CRUNCH computer code for dispersion of a continuous release of heavy gas.

The results for the base case studied are shown in Table 9.41. They show that very close to the plant the principal risks are from gasket failures, pipe splits, coupling/hose failures and releases from the vaporizer unit. At 200 m, it is the last three that are the main risks, while at 300 m and beyond the risk of major vessel failures becomes dominant, with a contribution from uncontrolled gasket failures and pipe splits. A large proportion of the risk beyond 200 m occurs with Pasquill category F weather.

The assessment includes a sensitivity analysis on the following features:

(1) plant size;
(2) vessel failure rate;
(3) gasket size;
(4) proportion of time outdoors;
(5) ventilation rate;
(6) evacuation time;
(7) gas toxicity.

A plant larger than the base case was studied. The increase in risk was roughly proportional to the change in the numbers of components. A 10-fold increase in the vessel failure rate had a strong effect on the risks in the far field, doubling the range of the 10^{-7}/year risk. The effect of reducing gasket thickness was to cut release rates by a factor of 4 and to reduce risks at short ranges. The proportion of time spent outdoors was varied from 0 to 100%. Zero time outdoors gave results little different from the base case, while 100% time outdoors increased the risk by a factor of 2 at intermediate distances. Ventilation rate increases by factors of 4 in weather category D and 2 in category *F* resulted in risks at intermediate distances which were 2 or 3 times the base case, while decreases of the rate to 0.5 in D/2.4 weather and a halving of the rate in *F* weather gave reductions in the risk of up to 4 at intermediate distances. The effect of increasing to 60 min the time taken to evacuate the building after passage of the cloud was to increase the risk at intermediate distances by a factor of about 2.5. For gas toxicity several relations were investigated. The use of a toxicity estimate by ten Berge and van Heemst instead of the Dicken value had a dramatic effect on risks, reducing the range of the 10^{-7}/year risk from 750 to 300 m. In addition to the results given in Table 9.41 the results were also presented in the form of risk contours on a typical site plan and of a FN curve.

9.22.3 UKCP chlorine emergency planning guidelines

Guidelines for chlorine emergency planning are given in *General Guidance on Emergency Planning with the CIMAH Regulations for Chlorine Installations* by the UK Chlorine Producers (UKCP) (CIA, 1986) (the UKCP *Chlorine Guide*);

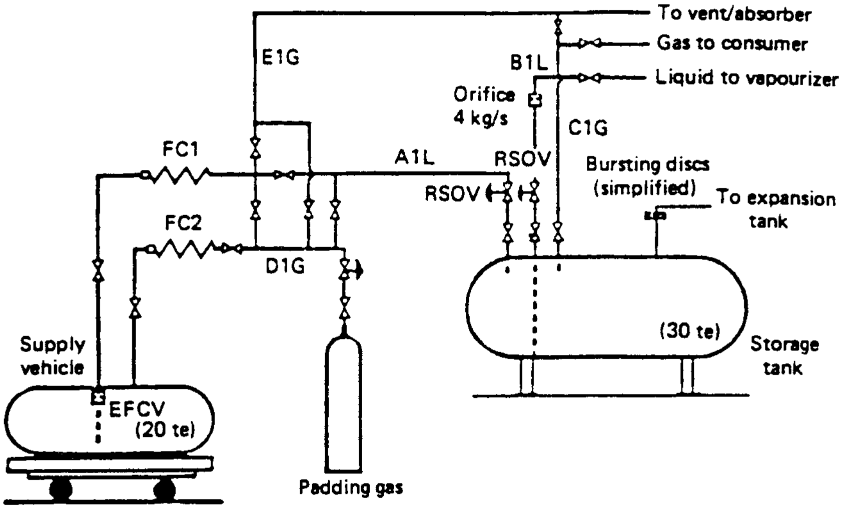

Figure 9.40 HSE guide assessment on chlorine installations: typical installation (after Pape and Nussey, 1985) (Courtesy of the Institution of Chemical Engineers)

an extract (CIA, 1989) is given in Lees and Ang (1989b). Although the guidelines are intended primarily for emergency planning, it is explicitly stated that the methods given may also be helpful in producing a safety case.

The type of installation considered is shown in Figure 9.43. Typical equipment and inventories at the installation and the process activities are shown in Table 9.42, Sections A and B, respectively. The steps in the hazard assessment are given in Section C of the table. A list of typical incidents to assist in hazard identification is given in Section D. The summary of possible incidents given in the guide and the interpretation of the terminology are given in Table 9.43, Sections A and B, respectively.

The guide gives, in addition, methods of estimating the emission rate and gas dispersion, using for the latter overlays that can be placed on a map of the site, and data on gas toxicity.

9.22.4 CIA ammonia CIMAH guidelines

The CIMAH Safety Case: Ammonia by the CIA (1988 PA9) (the CIA *Ammonia Guide*) gives guidance for that substance. The main body of the CIA *Ammonia Guide* is largely concerned with the safety report itself. It says relatively little about the frequency of events, but it gives in Chapter 5 a set of release scenarios for different storage conditions and some guide to toxic concentration estimates.

The guide contains a detailed table (15 pages) of causes of release. It gives five main release scenarios as follows: Scenario 1, release of liquid from a hole in pressurized storage; Scenario 2, release of liquid from a hole in refrigerated storage; Scenario 3, release of vapour from a relief valve; Scenario 4, failure of a refrigerated bunded storage tank; and Scenario 5, a spill of refrigerated liquid ammonia onto water. For the first two continuous releases, two flows (10 and 40 kg/s) are considered, and for the relief valve a flow of 6 kg/s is considered. In the fourth scenario, two subscenarios are considered: (1) a failure near the top of the tank and (2) a failure near the bottom; in the latter case a flash evaporation of 5 te is estimated. In the fifth scenario the evaporation rate is taken as 50 kg/s during the 2 min of the spill. Results are given without and with allowance for plume rise. The guide gives estimates of the ground level concentration of ammonia for the five scenarios, including the results given here in Table 9.44.

9.22.5 LPGITA LPG CIMAH guidelines

Guidance for LPG is given in *A guide to the writing of LPG safety reports* by the LPGITA (1988 GN1) (the LPGITA *LPG Guide*).

The LPGITA LPG *Guide* deals in the main body largely with the safety report. It has relatively little on the frequency of events, but it gives in Appendix 2, a set of graphs based on simplified hazard models for propane, butane and LPG.

These models appear broadly similar to those given in the Second *Canvey Report* and by Considine and Grint (1985) and the graphs are similar in form to those given by Grint (1989). The graphical correlations cover gas flow and two-phase flow from holes, distance to the LFL, mass of gas in cloud formed, distance to given levels of thermal radiation from a fireball, length of a jet flame and distance to given levels of thermal radiation from such a flame and distance to given overpressures from a vapour cloud explosion. There are also tables listing the injury effects at these levels of thermal radiation and overpressure.

9.22.6 BCGA liquid oxygen CIMAH guidelines

A method for estimating the Off-site Risks from Bulk Storage of Liquid Oxygen (*LOX*), by the British Compressed Gases Association (BCGA, 1984) (the BCGA *Guide*), gives guidance for that substance. The hazard of liquid oxygen is quite different from that for conventional flammables or toxics. Essentially it is the hazard due to enhancement of flammability in an oxygen-enriched atmosphere. This effect is discussed in Chapter 16.

The BGCA *Guide* deals with (1) the consequences of oxygen enrichment, (2) the chance of being injured, (3) the

***Table 9.39** HSE guide assessment on chlorine installations: hazard scenarios[a] (after Pape and Nussey, 1985) (Courtesy of the Institution of Chemical Engineers)*

Item	*Event*[b]	*Release* (kg/s)	*Duration*[d] (min)	*Frequency* (failures $\times 10^6$/year)	*Comments*
Storage vessels; only 1 live at once; typical stock 20 te	Burst	50[c]	10	1	Over bund, pseudo-plume
	Burst	25[c]	10	1	Into bund, pseudo-plume
	50 mm hole, L	25[c]	10	1.6	Pseudo-plume
	50 mm hole, G	6.4	20	2.4	2 × flash
	25 mm hole, L	19	8.8	3.2	
	25 mm hole, G	1.6	30	4.8	2 × flash
	13 mm hole, L	5	30	4	
	13 mm hole, G	0.25	30	6	
	6 mm hole, L	1.3	30	16	
	6 mm hole, G	0.06	30	24	
Tanker vessels	*Neglect*: only on site 2% of time, so probability of failure on site much less than for static tanks				
Other vessels					None on site
Pipelines, guillotine fractures	A1L (10 m)	1	5(C)	0.6	Tanker EFVC[h] works, live 2% of time
		9	20	0.006	Tanker EFVC fails, failure 10 × B1L/m[e]
	B1L (40 m)	4	5(C)	12	Normally live, limited to 4 kg/s by orifice plate
		4	20	0.12	
	C1G (20 m)	1	20	6	Normally live
	D1G (20 m)	1.25	20	0.3	Live as A1L[f]
	E1G	1.25	20	0.15	Live 0.1%; 10 × failure rate
Pipe splits	A1L	5	20	6	EFVC on tanker not actuated
	B1L	4	5(C)	120	
	C1G	0.25	20	60	
	D1G	0.25	20	3	
	E1G	0.25	20	1.5	
Gaskets, equivalent 9 mm diameter holes, 3 mm thick, $\frac{1}{4}$ of circumference	A1L	2.4	20	17	17 joints, live 2% of time, failure 10 × normal rate
	B1L	2	5(C)	220	47 joints (3 below RSOV so 'uncontrollable')
		2	20(U)	15	
	C1G	0.13	20	60	12 joints
	D1G	0.13	20	9	9 joints, live as A1L
	E1G	0.13	20	1.3	26 joints
Transfer coupling/ hose	FC1	1	5(C)	150	50 operations[g]
		9	20	1.5	EFVC fails
	FC2	1.25	20	150	50 operations[g]
Other vaporizer	Failure leads to liquid from	4	5(C)	100	
	B1L	4	20(U)	1	

[a] In deducing source terms, due account is taken of the possibilities for forward and back flow, and the differences between normally live and intermittent use items.

[b] L, liquid; G, gas.

[c] Equivalent continuous release.

[d] C, controlled by remotely operated shut-off valve (RSOV); U, RSOV fails or absent.

[e] Pipe used intermittently. Failure rate assumed to be 10× that of normal pipeline, then multiplied by fractional use.

[f] Pipe live when AIL is live.

[g] 50 operations per annum.

[h] EFVC, excess flow valve cut off.

dispersion of oxygen vapour and (4) the probability of the failure event and gives (5) examples of release and their range of hazard. It contains appendices on (1) the effect of oxygen enrichment on the burning characteristics of cloth materials, (2) the potential for low temperature and wind chill to cause injury, (3) the factors affecting the number of casualties, (4) the principles for validation of storage tank design and (5) release rate calculations and dispersion estimates.

The *Guide* treats three representative scenarios: (1) release of liquid from a hole in a 2 in. pipe, (2) release of liquid

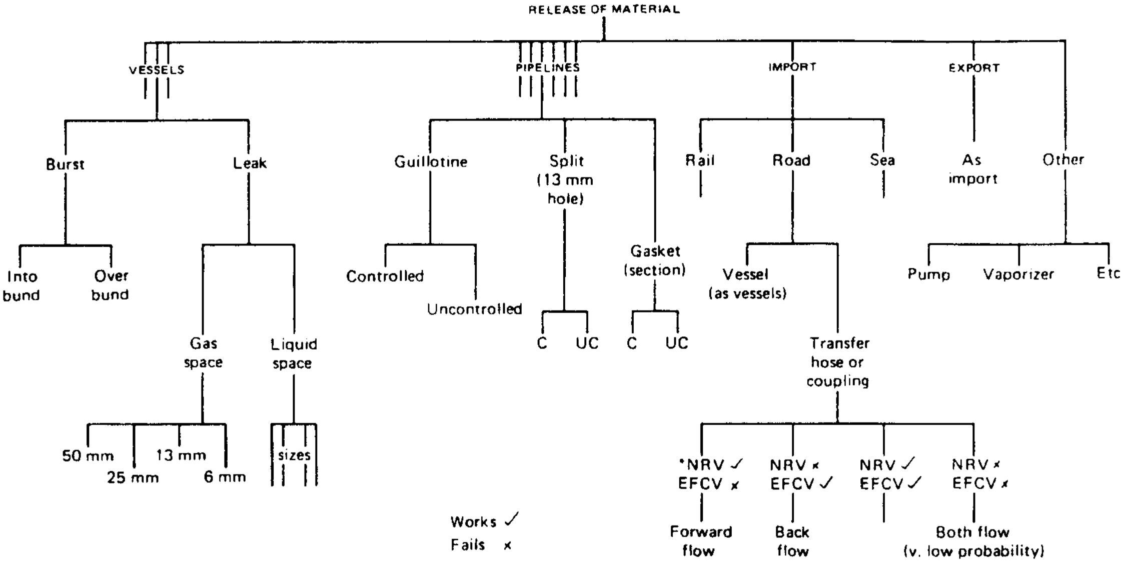

Figure 9.41 *HSE guide assessment on chlorine installations: releases (after Pape and Nussey, 1985) (Courtesy of the Institution of Chemical Engineers)*

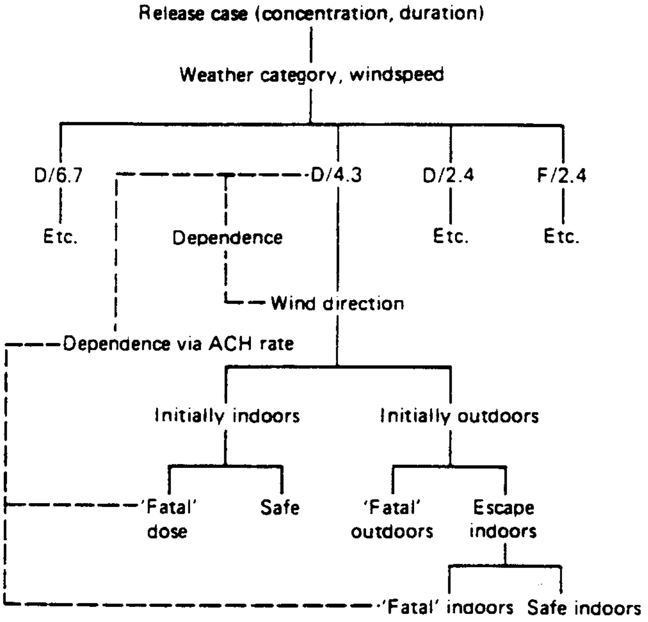

Figure 9.42 *HSE guide assessment on chlorine installations: consequences of release (after Pape and Nussey, 1985) (Courtesy of the Institution of Chemical Engineers)*

Table 9.40 HSE guide assessment on chlorine installations: key assumptions (after Pape and Nussey, 1985) (Courtesy of the Institution of Chemical Engineers)

A Failure frequency[a]

Vessels[b]
Frequency of near instantaneous release of whole contents = 2×10^{-6}/year

Frequency lesser releases = 6×10^{-5}/year partitioned as follows:

Equivalent hole diameter (mm)	*Frequency*
50	4×10^{-6}/year
25	8
13	10
6	40

and

Gas space 60%, liquid space 40%

Pipework
Frequency of guillotine fracture on 25 mm pipework = 0.3×10^{-6} years
Frequency of lesser releases (equivalent to 13 mm hole) = 0.3×10^{-5} years

Gaskets[c]
Frequency of failure for 0.6 mm thick gaskets = 3×10^{-6}/year
Frequency of failure for 3 mm thick gaskets = 5×10^{-6}/year

Tankers
Probability of failure of coupling/hose = 3×10^{-6}/operation
Probability of failure of excess flow valve = 0.01/demand
Frequency of failure of tanker vessels same as vessels given above, but with allowance made for time on site

B Release duration

Vessels
For lesser releases duration is 30 min or time taken to release all the contents, whichever is less[d]

Pipework
For automatic shut-off duration[e] = 1 min
For remote manual shut-off duration[e] = 5 min
For local manual shut-off duration = 20 min

C Release rate

Vessels
For vessel bursts over bund, 100% of release vaporizes
For vessel bursts directed into bund, 50% vaporizes

Pipeline
For pipeline release, 100% vaporizes
For two-phase flashing flow from pipeline guillotine fracture in a 25 mm internal diameter pipe with flow driven by chlorine vapour pressure, flow rate = 4 kg/s
For single-phase liquid flow from tanker coupling failure in 25 mm pipe driven by padding pressure, flow rate = 9 kg/s
For single-phase liquid flow from pipework in 13 mm hole in pipe, flow rate = 4 kg/s

D Release dilution

For releases from pressurized containment initial release is diluted by a factor of 10

E Weather conditions

Pasquill category/ wind speed (m/s)	*Probability*
D/2.4	0.30
D/4.3	0.24
D/6.7	0.29
F/2.4	0.17

F Gas dispersion

Gas dispersion calculated using CRUNCH heavy gas dispersion model. Concentrations within the plume predicted by this model are assumed to be Gaussian, concentrations outside the plume are not considered. During the time of passage of the plume, the concentration at a particular location is assumed to be uniform for the duration of the release

G Modification of exposure

Probability of being initially outdoors = 0.1 Pasquill D
= 0.01 F

For person initially outdoors, probability of escape indoors after receiving significant dose:

Concentration outdoors (ppm)	*Probability of escape indoors*
>1000	0
570–1000	0.2
140–570	0.8
<140	1

Evacuation occurs 30 min after arrival of cloud, or later if cloud persists more than 30 min

H Effect of shelter

Concentrations indoors calculated using a single exponential stage model with following values for the product of the ventilation rate constant λ and the mixing efficiency factor k[f]:

Pasquill category/wind speed (m/s)	$k\lambda$(h^{-1})
D/2.4	0.7
D/4.3	1.0
D/6.7	1.5
F/2.4	0.5

I Gas toxicity

Significant exposure is $C^{1.67}t \geq 20{,}000$, equivalent to the Dicken 'fatal' dose

Threshold of significant dose is 140 ppm for 5 min

---

[a] Failure rates are based on aggregated data from various sources modified by judgement. Rates used are for sudden failures, that is leaks which can develop into major failures before preventive action can be taken.

[b] Vessel failure includes events up to and including the first flange on any nozzle or penetration.

[c] Gasket failure means loss of one section between two adjacent bolts. It should be checked whether the gasket internal diameter equals that of the pipeline. Actual frequency may depend on inspection and replacement practices.

[d] For leaks in gas space, the available contents for 50 and 25 mm holes are 2× the flash fraction and, for smaller holes, the flash fraction.

[e] Fractional dead time of automatic or remote shut-off is 0.01. Such a failure places a demand on the manual shut-off leading to a release duration of 20 min.

[f] These values are based on data modified by judgement and make some allowance for the possibility of a few windows being open.

***Table 9.41** HSE guide assessment on chlorine installations: risks (after Pape and Nussey, 1985) (Courtery of the Institution of Chemical Engineers)*

Rate (kg/s)	*Duration* (min)	*Frequency* ($\times 10^6$/year)	*Distance* (m)			*Risks* ($\times 10^6$/year)				
			50	100	200	300	500	750	1000	1500
50	10	1	0.29 (23)	0.23 (24)	0.17 (26)	0.13 (29)	0.08 (39)	0.04 (57)	0.01 (94)	0

1	5	150	13.64 (49)	1.36 (82)	0.03 (20)	0	0	0	0	0
9	20	1	0.33 (26)	0.24 (29)	0.14 (36)	0.07 (48)	0.01 (94)	0	0	0
1.4	30	20	3.38 (33)	1.55 (46)	0.26 (94)	0.08 (92)	0	0	0	0
2	20	15	2.63 (31)	1.37 (43)	0.23 (94)	0.09 (93)	0	0	0	0
Total			131.5 (35)	48.1 (51)	8.8 (76)	1.6 (53)	0.4 (66)	0.1 (80)	0	0

Note: The values in parentheses show the percentage contributions to risk levels due to accidents in stable weather conditions.

from a hole in a 6 in. pipe into a bund and (3) failure of a 135 te storage vessel. It gives for different air entrainment factors estimates of the distances to specified oxygen concentrations.

In determining the effect of enhanced oxygen concentration, the BCGA *Guide* assumes that clothing fires are the only type of fire that would increase casualties. It concentrates largely on the potential for persons who are smoking or using matches to ignite their clothing, the source of fuel closest to them.

9.22.7 FMA ammonium nitrate CIMAH guidelines

Guidance for ammonium nitrate is given in *Safety Case for Ammonium Nitrate Required by Regulation 7 of CIMAH* by the Fertilizer Manufacturers Association (the *FMA Ammonium Nitrate Guide*) (1989); an extract (FMA, 1989) is given in Lees and Ang (1989b). The FMA *Ammonium Nitrate Guide* is mainly concerned with the safety report and, in particular, with the properties of ammonium nitrate.

The *Guide* discusses the hazard of explosion of ammonium nitrate and considers the consequences of deflagration of a stack of 300 te of ammonium nitrate. It obtains for such an explosion a trinitrotoluene (TNT) equivalent of 41 te, based on an ammonium nitrate TNT equivalent of 55% and a maximum explosion efficiency of 25%, and hence at 600 m a scaled distance of 175 m. It reproduces the ACMH correlation for the overpressure from a TNT explosion (Harvey, 1979b) and utilizes this correlation to determine that for this explosion an overpressure of 1 psi occurs at 600 m.

9.23 Hazard Impact Model

The impact of a hazard on the surrounding area may be modelled analytically by making certain simplifying assumptions. The hazard impact model so derived may be

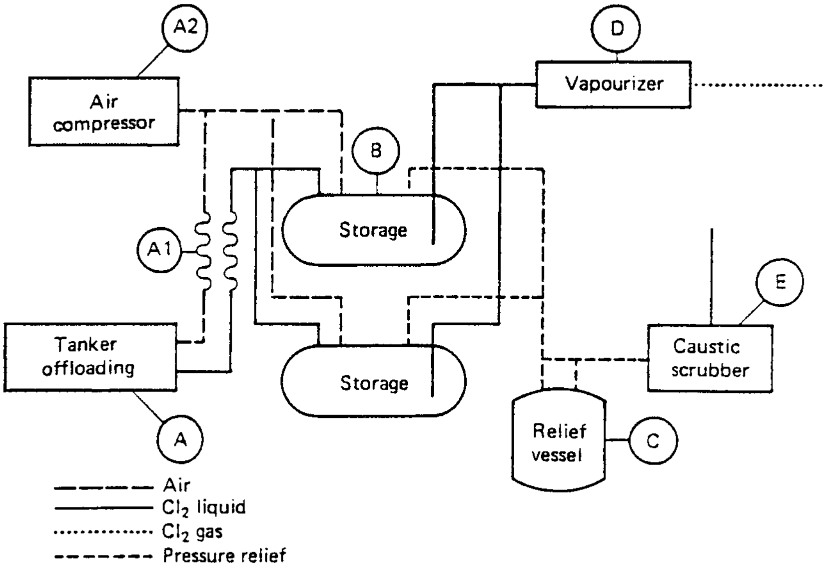

Figure 9.43 *UKCP guide on emergency planning for chlorine installations: typical installation (after Chemical Industries Association, Chlorine Sector Group, 1989)*

Table 9.42 *UKCP guidance on emergency planning for chlorine installations: typical installation (after Chemical Industries Association, Chlorine Sector Group, 1989)*

A Typical equipment and inventories

Equipment	*Pressure* (bar g)		*Size*	*Quantity*
	Normal	*Design*		
Stock tanks	7	13	20–200 te	2 × 35 te, typically
Expanse tanks	0	13	10% of stock tank	1 × 5 te, typically
Vaporizers	3	14	0.2–2 te/h	1, typically
Scrubbers	Pressurized			1
Air compressors	9	11	–	1
Piping:				
Gas	2–9			<20 m
Liquid	9 ASA 150 1 in. diam			<20 m
Vent	13			<20 m
Valves	Primary – globe		1 in. Table D	<20
	Isolation – ball		1 in. ASA 150	<20
'Flexibles' (liquid/vent)	2–9	25	1 in. ASA 150	<10 m

B Process activities

Air compression
Pressurization of tanker for offloading
Pressurization of storage tanks for chlorine transfer
Vaporization of chlorine
Controlled venting of tanker and storage tanks after transfer or for maintenance
Pressure relief
Possible interaction between the chlorine and its point of application

C Steps in hazard assessment

Examination of piping and instrument diagram
Systematic identification and listing of hazards
Assessment of credible size of leak
Definition of operating pressure

Table 9.42 *(continued)*

Assessment of extent of vaporization
Estimation of extent of gas concentrations at different locations
Estimation of potential duration of leak

D List of typical incidents[a]

1. Loss of containment of chlorine from pipework
   (a) Corrosion due to freeze/thaw conditions (particularly under lagging)
   (b) Pipe flange leaks (e.g. expansion of trapped liquid)
   (c) Flange gasket failure (due to incorrect gasket material)
   (d) Leak from pipework (e.g. spool fabricated/fitted to wrong specification, section of pipework not subject to routine inspection)
2. Loss of containment from the offloading installation
   (a) Leaks from flexibles (e.g. pinhole on weld)
   (b) Damage to filling/discharge connection due to transport container movement (e.g. collision)
   (c) Liquid chlorine ingress into vent/compressed air systems/absorption systems overloaded
3. Incidents involving bulk storage and relief systems
   (a) Contamination of stock tank contents (e.g. water ingress/incomplete drying out procedure)
   (b) Leaks from valves (incorrect valve specification)
   (c) Leaks from relief system/expanse vessel (valve maloperation, water ingress, etc.)
   (d) Total loss of containment from bulk storage needs to be considered in each case to estimate the likelihood of this event. In particular, the systems and procedures used in the operation and maintenance of the plant must be carefully reviewed
4. Loss of containment from the system supplying chlorine to the point of application
   (a) Internal chlorine iron fires (e.g. vaporizers)
   (b) Nitrogen trichloride explosion (e.g. drains from vaporizer)
   (c) Interaction in the chlorine delivery pipework, backflow of water/reagents

[a] These examples are of typical incidents but do not cover all possibilities, particularly those associated with site specific features.

used for various purposes, including estimating the number of injured and assessing the error in the estimates.

9.23.1 Approximate model

An approximate model that may be used to estimate the number of people who suffer injury is

$$N_{\mathrm{i}} = \pi r_{50}^2 d_{\mathrm{p}} \qquad [9.23.1]$$

where d_{p} is the population density (persons/m^2), N_{i} is the total number of injured and r_{50} is the radius (metres) at which the probability of injury is 50%.

In this model, the assumption is made that the number of people inside the circle of radius r_{50} who escape injury is equal to the number outside the circle who suffer injury. It is also assumed that the population density is uniform. The use of the radius r_{50} has some justification apart from computational convenience in that, although injury relations are usually subject to much uncertainty, the uncertainty tends to be least at the 50% injury level.

It can readily be appreciated that the degree of error in this approximate model depends on the relation between the distance and the probability of injury. Three possible cases are illustrated in Figure 9.44. In case (a), the transition from a probability of injury of unity to one of zero is very gradual, in case (b) more sharp, and in case (c) immediate. The error in the estimate reduces to zero for this latter case.

If the population density is not uniform, the approximate model given by Equation 9.23.1 cannot itself be used, but use may still be made of the radius r_{50} in conjunction with the site population density to obtain an approximate estimate of the number of injured, although in this case the number of injured inside the circle who escape injury and the numbers outside who suffer injury may not balance. As before the error in the estimate reduces to zero for case (c).

It has been shown, however, by Poblete, Lees and Simpson (1984) and Lees, Poblete and Simpson (1986) that it is possible to derive an alternative, more accurate model.

9.23.2 Intensity of physical effect

Some principal physical effects are:

Fire	
Thermal radiation	I
Thermal radiation dose	It
Thermal radiation-time function	$f(I, t)$
Explosion	
Overpressure	p^{o}
Impulse	I_p
Toxic release	
Concentration	C
Dose	Ct
Concentration–time function	$f(C, t)$

It is assumed in the model that the intensity of the physical effect decays with distance according to an inverse power law. Hence:

$$w = k_w / r^{n_w} \qquad [9.23.2]$$

where k_w is the intensity constant, n_w the intensity index and w the intensity.

The normalized intensity i is obtained by dividing the actual intensity w by the value w_0 of the intensity at the

Table 9.43 *UCKP guidance on emergency planning for chlorine installations: hazard scenarios*[a] *(after Chemical Industries Association, Chlorine Sector Group, 1989)*

Event	*Event likelihood*	*Pressure* (bar g)	*Hole size* (diameter) (mm)	*Leak rate* (kg/s)		*Consequence Downwind Distance affected* (m)

4(b)	300–500	200–400	100–200	200–300	400–600	600–800 (no plume rise)
	50–100	60–120	30–60	0	0	10–20 (plume rise)
	Same order of magnitude as Scenario 1					

distance r_0, which is termed the 'radius of the physical effect', and which is discussed further below. Hence:

$$i = w/w_0 \qquad r = r \qquad [9.23.3a]$$

$$i = 1 \qquad r = r_0 \qquad [9.23.3b]$$

9.23.3 Injury factor

Some principal injury factors are

Fire	$I^{4/3}\,t$
Explosion	p°
	I_p
Toxic release	C
	Ct
	C^2t

It is assumed in the model that the injury factor is a power function of the intensity.

Hence:

$$v = k_{vw} w^{n_{vw}} \qquad [9.23.4]$$

where k_{vw} is the first injury factor constant, n_{vw} is the injury factor power index and v the injury factor.

Combining Equations 9.23.2 and 9.23.4 gives

$$v = k_v / r^n \qquad [9.23.5]$$

with

$$k_v = k_{vw} k_w^{n_{vw}} \qquad [9.23.6]$$

$$n = n_w n_{vw} \qquad [9.23.7]$$

where k_v is the second injury factor constant and n is the injury factor decay index.

The normalized injury factor x is obtained by dividing the actual injury factor v by the value v_O of the injury factor at the distance r_0:

$$x = v/v_0 \qquad r = r \qquad [9.23.8a]$$

$$x = 1 \qquad r = r_0 \qquad [9.23.8b]$$

9.23.4 Probability of injury

The relationship between the injury factor and the probability of injury is assumed to be the log–normal distribution:

$$P = \frac{1}{(2\pi)^{1/2}\sigma} \int_0^x \frac{1}{x} \exp\left[-\frac{\ln(x - m_n^*)^2}{2\sigma^2}\right] \mathrm{d}x \qquad [9.23.9]$$

where P is the probability of injury, m_n^* is the normalized location parameter of the distribution, and σ is the spread parameter of the distribution.

An alternative way of expressing this relation is in the form of a probit equation:

$$Y = k_{n1} + k_{n2} \ln x \qquad [9.23.10]$$

with

$$k_{n1} = 5 - m_n^*/\sigma \qquad [9.23.11a]$$

$$k_{n2} = 1/\sigma \qquad [9.23.11b]$$

The relation between the probability and the probit is given by Equation 9.18.1.

The probit equation given by Equation 9.23.10 is in normalized form. The unnormalized equation is

$$Y = k_1 + k_2 \ln v \qquad [9.23.12]$$

with

$$k_1 = 5 - m_{\mathrm{u}}^* \sigma \qquad [9.23.13a]$$

$$k_2 = 1/\sigma \qquad [9.23.13b]$$

The two forms are related through two location parameters

$$m_n^* = m_{\mathrm{u}}^* - n \ln v \qquad [9.23.14a]$$

$$v = \exp(m_{\mathrm{u}}^* - m_n^*) \qquad [9.23.14b]$$

9.23.5 Distances r_0 and r_{50}

The intensity of the physical effect and the injury factor are scaled in relation to the distance r_0. In principle, r_0 is intended to represent the radius of the physical effect, where this is a meaningful concept as with, say, a fireball, and hence the radius at which the probability of injury is unity. The choice of r_0 is, however, unrestricted. It is recommended that it be chosen so as to give a probability of injury close to unity.

Then the normalized injury factor decays with distance according to the relation

$$x = (r_0/r)^n \qquad r = r \qquad [9.23.15a]$$

$$x = x_0 = 1 \qquad r = r_0 \qquad [9.23.15b]$$

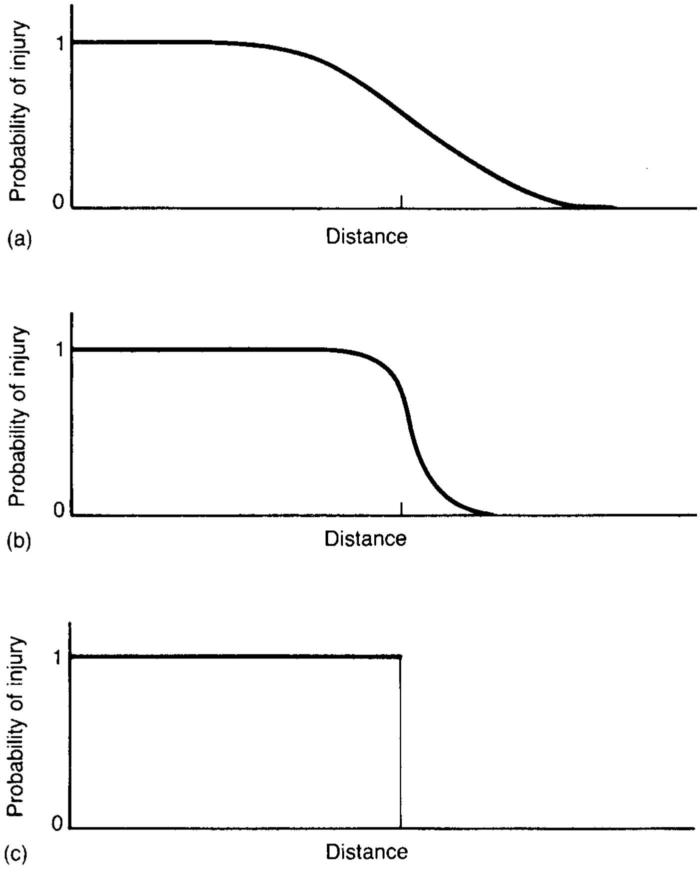

Figure 9.44 *Some hypothetical relations between distance and probability of injury*

The distance r_{50} has been defined as the radius at which the probability of injury is 50% ($P = 0.5$). The normalized injury factor x_{50} at this distance is then:

$$x_{50} = (r_0/r_{50})^n \qquad [9.23.16]$$

Also, putting $x = x_{50}$ and $Y = 5$ ($P = 0.5$) in Equation 9.23.10, gives

$$x_{50} = \exp(m_n^*) \qquad [9.23.17]$$

Hence from Equations 9.23.16 and 9.23.17

$$\begin{aligned} r_{50} &= r_0/x_{50}^{1/2} && [9.23.18a] \\ &= r_0/\exp(m_n^*/n) && [9.23.18b] \end{aligned}$$

9.23.6 Number of injured

It is assumed that the density d_p of the population around the hazard source is uniform. This assumption can be relaxed in certain specific ways as described below. The number N_i of people injured is:

$$N_i = \int_0^\infty 2\pi d_p P(r) r \, dr \qquad [9.23.19]$$

It can be shown that the solution of Equation 9.23.19 is

$$N_i = \pi r_{50}^2 d_p \phi \qquad [9.23.20]$$

With

$$\phi = \exp(2\sigma^2/n^2) \qquad [9.23.21]$$

where ϕ is the correction factor for variance and decay. Equation 9.23.20 together with Equation 9.23.21 constitutes the hazard impact model derived by Lees, Poblete and Simpson.

9.23.7 Practical decay relations

An important feature of the model is the assumption that the intensity of the physical effect decays according to an inverse power law. It has been shown by Poblete, Lees and Simpson (1984) and Lees, Poblete and Simpson (1986) that a number of the simpler hazard models give such a decay relation. There are others, however, particularly some gas cloud models, which do not.

The question of the decay of the physical effect is considered in more detail in Section 9.25.

Table 9.45 Hazard impact model sensitivity coefficients (after Lees, 1987) (Courtesy of Elsevier Science Publishers)

$$(\partial N_i/N_i)/(\partial d_\mathrm{p}/d_\mathrm{p}) = 1$$
$$(\partial N_i/N_i)/(\partial k_w/k_w) = 2/n_w$$
$$(\partial N_i/N_i)/(\partial n_w/n_w) = -(2/n)\ln k_v + (2/n)m_u^* - 4\sigma^2/n^2$$
$$(\partial N_i/N_i)/(\partial k_{vw}/k_{vw}) = 2/n$$
$$(\partial N_i/N_i)/(\partial n_{vw}/n_{vw}) = -(2/n)\ln k_{vw} + (2/n)m_u^* - 4\sigma^2/n^2$$
$$(\partial N_i/N_i)/(\partial m_u^*/m_u^*) = -2m_u^*/n$$
$$(\partial N_i/N_i)/(\partial\sigma/\sigma) = 4\sigma^2/n^2$$

9.23.8 Sensitivity estimates

It has been shown by Lees (1987) that there can be derived from Equation 9.23.20 a set of sensitivity coefficients which can be used to determine the effect of errors in the various physical models and injury relations utilized on the estimate of the number of injured given by that model. The parameters of interest are: d_p, k_w, n_w, k_{vw}, n_{vw}, m_u^* and σ. The normalized partial derivatives, or sensitivity coefficients, of N_i with respect to these parameters are given in Table 9.45.

9.23.9 Applications of model

The hazard impact model presented in Equation 9.23.20 is more accurate than that given in Equation 9.23.1 and, if the assumptions hold exactly, the results given by the model are exact, but in most practical cases there is likely to be a degree of approximation in the assumptions and hence in the results.

One application of the model is to make a rapid estimate of the number of injured. The model may be used to make a quick, ranging estimate, usually prior to a more detailed assessment. The use of the model is straightforward, but there are two common situations where some modification is necessary. These are for population density and directional effects.

In many cases the population density is not uniform. Two specific deviations can readily be taken into account. One is the case where there is a different population density, perhaps zero, up to some distance r_w from the hazard source. If this is such that the probability of injury up to this point is virtually unity, it is straightforward to calculate the number of injured inside the circle radius r_w and to adjust the value of N_i accordingly. The other case is where there are different population densities in different sectors around the hazard source. Again it is straightforward to adjust the value of N_i. Combination of these two cases can also be handled and, taken together, these adjustments extend appreciably the scope of the model.

Some physical phenomena are directional and affect not a circular area around the hazard source but an area that is a sector with its apex at the source. The most important case here is a gas cloud.

Directional effects can be handled by the model by considering only the sector affected and, where necessary, dividing it into a sufficient number of subsectors such that the conditions along any arc in a subsector are essentially uniform.

Another, and perhaps more significant, application of the model is to determine the effect of errors in the physical models and injury relations on the estimate of the number of injured. This may be of value not only in the conduct of hazard assessments but also in the identification for research purposes of areas where improved models and correlations would, or would not, give significant improvements in the accuracy of the assessment.

9.24 Simplified assessment methods

A full hazard assessment is a major exercise. It is useful, therefore, to have short-cut methods. The short-cut methods described may be used to obtain an approximate estimate with economy of effort. The use of such a method may improve understanding of the hazards and may highlight unexpected features. But short-cut methods have their limitations. By definition they tend to be based on generalized relations and thus are much less effective in revealing critical features and assumptions in a specific design.

A study of simplified methods of hazard assessment has been described by R.A. Cox and Comer (1982). The study was commissioned following the *Rijnmond Report*. The aim of the work was to devise a method of hazard assessment that would yield risk contours, FN curves and individual and group risks. It was accepted that such a method would not be able to give individual risk for employees, since the degree of detail required to do this was not consistent with the simplicity sought. The method was required to yield intermediate as well as final results to permit checking and to improve confidence in the latter. Two methods were devised and compared:

(1) Simplified classical method.
(2) Parametric correlation method.

These are now described in turn.

9.24.1 Short-cut classical method

The short-cut classical method (SCM) is a simplified form of the full classical method in which individual failure scenarios are defined and estimates are made of their frequency and consequences.

The SCM approach involves three stages: failure case selection and frequency estimation; application of consequence submodels; and summarization of risks.

Crucial to the method is the selection of the failure cases. The original intent was to pick a set of representative cases. But it was concluded that it is necessary to start from the full set of failure cases. These cases are then reduced to a more limited set of equivalent discrete failures (EDFs). One method is to cluster together 'similar' failures, another is to compare each case with a standard EDF (SEDF). It was the latter approach that was adopted.

A standard EDF (SEDF) is defined by standard physical consequences such as the distance travelled by a vapour cloud in standard weather conditions. An SEDF list was created, giving for each EDF the distances for defined intensities of the relevant physical effects such as toxic concentration. For each EDF the consequences are determined by a once-and-for-all assessment. Then, in applying the method to a particular plant the actual EDF for a particular failure case is equated to one of the standard EDFs using consequence submodels. This is the only use of these submodels in the method.

Some of the principal elements in the method are shown in Table 9.46. Section A of the table lists the data schedules required to define the failure cases. They are schedules of the plant units, of the items on the plant and of the connections between items. Section B shows the six main categories of release considered, and section C gives the consequence submodels used. Figure 9.45 is a flow diagram

Table 9.46 Some elements of the short-cut classical methods (SCM) of hazard assessment (after R.A. Cox and Comer, 1982) (Courtesy of the Institution of Chemical Engineers)

A Schedule of item interconnections
Each item to item connection defined by: Identification of items of either end of pipe Pipe diameter Location of connection at either end of pipe – in vapour Space or below liquid level Presence of particular types of valving along pipe (excess flow, non-return and shut-off valves)
B Schedule of items
For each plant item: Item identification Materials and inventory contained Temperature and pressure The item location is specific by the item identification that identifies the plant unit on which the item is located
C Schedule of plant units
For each plant unit: Set of parameters to define failure frequencies Location coordinates

of the algorithm for pipe failure and Figure 9.46 one for application of the method to an actual plant.

Up to this point the analysis is independent of the environment. Factors defining this environment, such as the weather, ignition sources, etc., are now brought in. The effect of introducing these factors is to alter not consequences, but the frequencies for each standard. From this information on the frequency and consequences of each standard EDF at the particular plant it is possible to obtain estimates of risk. The frequencies of the various physical outcomes, the areas affected and the number of casualties are determined, and risk estimates made in the usual way.

9.24.2 Parametric correlation method

The alternative method considered was the parametric correlation method (PCM). With this method there are two principal features that must be specified: the form of the correlation function and the method of determining its parameters.

One approach to selecting the form of the correlation function is to run a large number of full hazard assessments and derive a correlation function from these. Another is to use expert judgement to select suitable functional forms. The correlation function should be carefully chosen to give an appropriate number of parameters. There is a potential problem of escalation of the number of parameters required.

A possible form of correlation function might be:

$$R(d) = \frac{R(0)}{2}[1 + \cos(\pi d/d_{\max})] \qquad [9.24.1]$$

where d is the distance from the unit, R is the risk and the subscript max indicates the maximum at which any risk exists.

The correlation function given in Equation 9.24.1 has two parameters, $R(0)$ and $d_{\max}$. Its characteristics are shown in Figure 9.47. Since $R(0)$ is the risk at the unit itself, it is in effect a measure of frequency, while $d_{\max}$ is a measure of consequences. Thus the two parameters are independent. This correlation function therefore has the attraction of simplicity.

9.24.3 Comparison of methods

The two candidate methods were then compared both with the full classical method and with each other. The full method used in the Rijnmond study was considered to be accurate in most cases to within one order of magnitude in each direction, but in some cases only to within two orders of magnitude. The SCM approach was not expected to be appreciably less accurate. Insofar as a multiparameter PCM approach would be derived from full analyses, it too should have a similar accuracy, but it would have less transparency than the SCM. A two-parameter PCM would probably be appreciably less accurate.

With regard to cost, the capital cost of the SCM and two-parameter PCM were assessed as comparable and that of a multiparameter PCM as about double. On the other hand, the operating costs of the two-parameter PCM were estimated as half those of the SCM, with the multiparameter PCM costs lying in between.

9.24.4 Hazard impact model

The hazard impact model may be used as a short-cut method for hazard assessment. The method depends on the availability of decay and injury relations and on certain simplifying assumptions. The use of the model for this application is described in Section 9.23.

9.25 Decay Relations

Several of the methods described make use of decay relations. These may be generic relations intended to be applicable to any hazard with suitable choice of parameters or they may be specific to a particular hazard.

For the simpler hazard models decay may often be derived analytically, while for the more complex models embodied in computer codes it is necessary to obtain and then correlate numerical results. Similarly, correlations may be derived from experimental data.

9.25.1 Generic decay relations

Several decay relations have been given in the literature. They include: Equation 9.24.1, used by R.A. Cox and Comer (1982) for the parametric correlation model; Equation 9.23.20 used by Lees, Poblete and Simpson (1986) for the hazard impact model; and Equation 9.14.1, used by Bagster and Pitblado (1991) for the domino effect model.

9.25.2 Decay relations for specific hazards

Decay relations can be obtained from the simpler hazard models for fire, explosion and toxic release, as described by Poblete, Lees and Simpson (1984) and Lees, Poblete and Simpson (1986).

The intensity of heat radiation from a fireball is:

$$F = E/4\pi r^2 \qquad [9.25.1]$$

where E is the heat radiated (kW), F is the heat radiated on the target (kW/m^2), and r is the distance (m) from the centre of the fireball to the target. Similar equations apply to other types of fire, such as pool fires and flares.

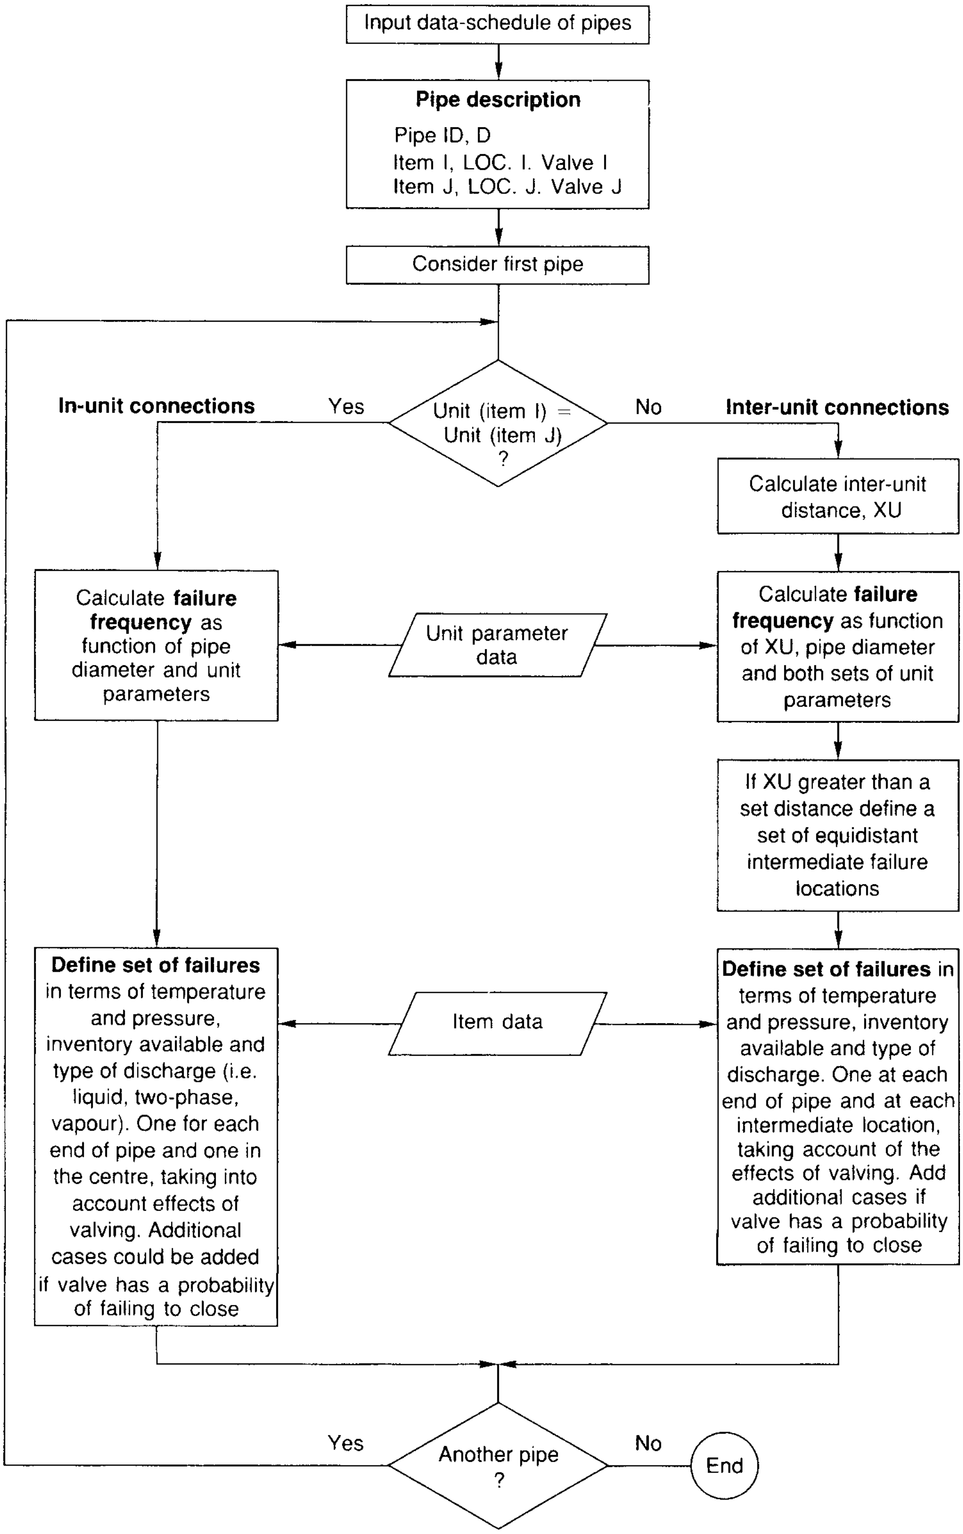

Figure 9.45 *Flow diagram of algorithm for pipe failure in short-cut classical method (SCM) (R.A. Cox and Comer, 1982) (Courtesy of the Institution of Chemical Engineers)*

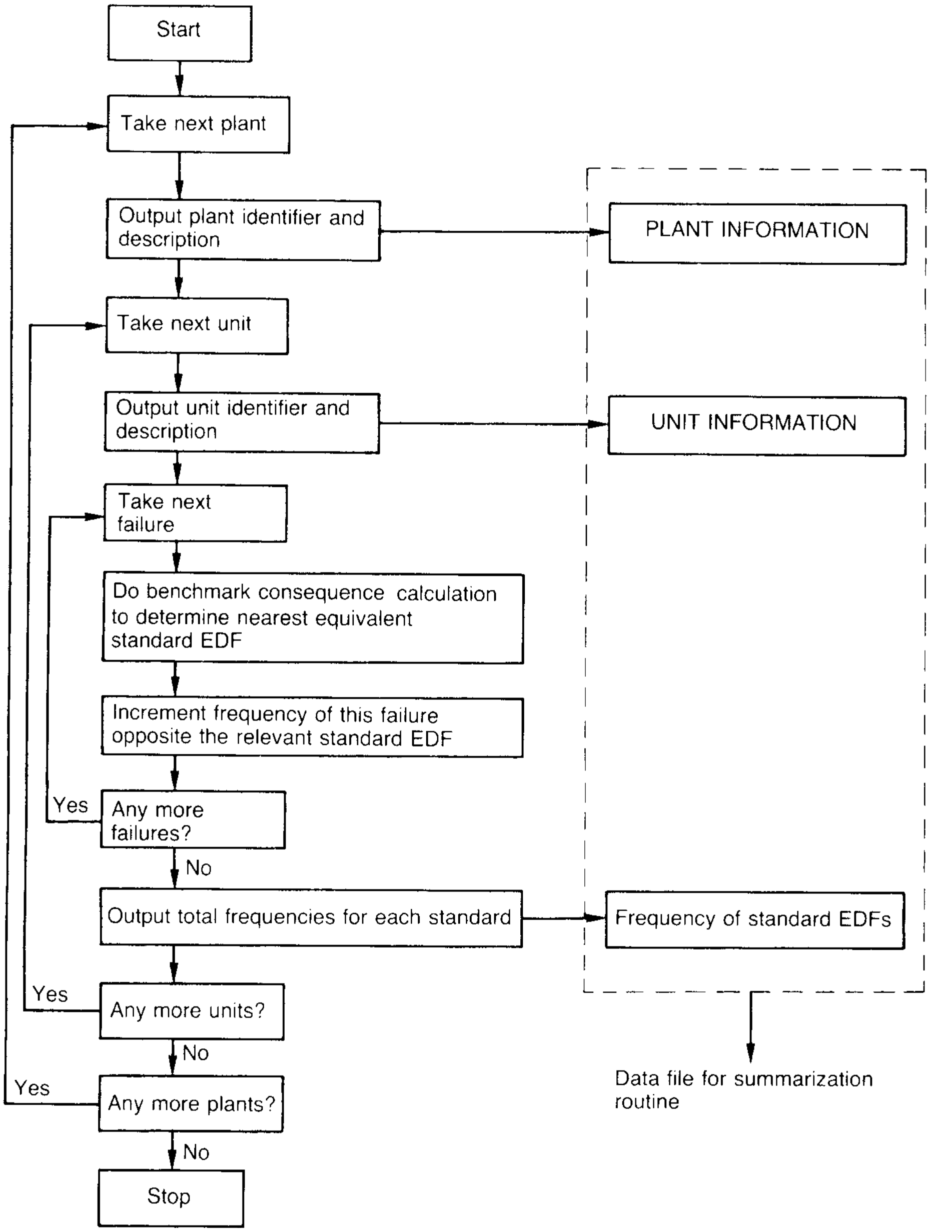

Figure 9.46 *Flow diagram of algorithm for analysis of an installation in short-cut classical method (SCM) (R.A. Cox and Comer, 1982) (Courtesy of the Institution of Chemical Engineers)*

The peak overpressure and impulse from the explosion of a high explosive are functions of scaled distance:

$$p^0 = f(z) \qquad [9.25.2]$$

$$I_p = f(z) \qquad [9.25.3]$$

with

$$z = r/W^{1/3} \qquad [9.25.4]$$

where I_p is the impulse (N s/m), p^o is the peak incident overpressure (N/m^2), W is the mass of explosive (kg) and z is the scaled distance (m/kg$^{1/3}$). The function in Equation 9.25.2 is usually provided in graphical form, such as the curves given by W.E. Baker *et al.* (1983). However, over a limited overpressure range it can be represented by the relation

$$p^0 = 1/r^{n_1} \qquad [9.25.5]$$

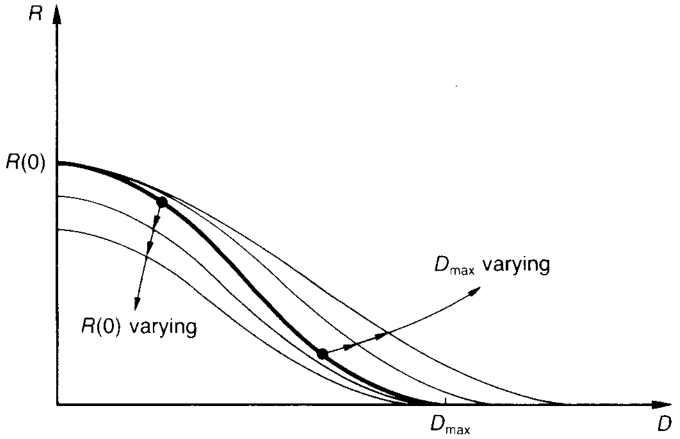

Figure 9.47 Characteristics of the decay function R(d) used in the parametric correlation method (R.A. Cox and Comer, 1982) (Courtesy of the Institution of Chemical Engineers

where n_1 is an index. The Baker curves correspond over the overpressure range 1.0–0.1 bar to decay indices of 1.7 and 0.9 for peak overpressure and impulse, respectively.

For VCEs there is no established model. Some theoretical models give a decay index of approximately unity. On the other hand, the decay curve established for the Flixborough explosion gives over the overpressure range 1.0–0.1 a decay index of 1.7.

Decay indices for dispersion of neutral density gas may be derived from the Sutton equations. For an instantaneous release the concentration at ground level on the centre line of the cloud and at cloud centre is

$$\chi = \frac{2Q^*}{\pi^{3/2}C^3(ut)^{3/2(2-n)}} \qquad [9.25.6a]$$

where C is the diffusion parameter ($m^{n/2}$), n is the diffusion index, Q^* is the mass released (kg), t is the time (s), u is the wind velocity (m/s) and χ is the concentration (kg/m^3). For neutral conditions, $n = 0.25$:

$$\chi \propto 1/x^{2.6} \qquad [9.25.6b]$$

where χ is the distance (m). The total integrated dosage D_{tid} ((kg/m^3) s) is

$$D_{tid} = \frac{2Q^*}{\pi C^2 u(ut)^{2-n}} \qquad [9.25.7a]$$

Setting $n = 0.25$:

$$D_{tid} \propto 1/x^{1.75} \qquad [9.25.7b]$$

For a continuous release the concentration at ground level on the centre line of the cloud is

$$\chi = \frac{2Q}{\pi C^2 u x^{2-n}} \qquad [9.25.8a]$$

where Q is the mass rate of release (kg/s) setting $n = 0.25$:

$$\chi \propto 1/x^{1.75} \qquad [9.25.8b]$$

The total integrated dosage is obtained by assuming that the continuous release lasts for some finite time. Then the total integrated dosage is:

$$D_{tid} \propto 1/x^{1.75} \qquad [9.25.9]$$

Models of heavy gas dispersion tend to be too complex to permit the analytical derivation of general decay indices, although an index may sometimes be derived for particular cases. Some decay indices for some principal hazards are given in Table 9.47.

The decay index for the physical effect can be combined with the power index for the injury factor to give an overall decay index for injury, as described the discussion of the hazard impact model in Section 9.23.

Another decay relation used is:

$$r = kM^{n_2} \qquad [9.25.10]$$

where M is mass released (kg), n_2 is a decay index, r is the distance for some physical effect (m) and k is a constant.

Equation 9.25.10 has been used to correlate results from numerical computations or empirical data. In particular, it has been used to give a correlation for the decay of the concentration of a flammable gas cloud to its lower flammability limit (LFL) or some fraction of this. For example, it was used in the Second *Canvey Report* to correlate distance to 0.5 LFL.

9.26 Hazard Warning

The use of hazard assessment of the kind so far described to provide assurance that a hazard is under control has certain weaknesses. One is the problem of credibility. The most difficult situation arises where there is a major hazard. Industry may attempt to argue qualitatively and then to demonstrate quantitatively that although in the most unfavourable circumstances the hazard has the

Table 9.47 *Decay indices for some principal hazards*

Hazard	*Model*	*Physical effect*	*Intensity*	*Decay index*
Fire	Fireball, pool fire	Thermal radiation	I	2
Explosion	TNT	Peak overpressure	p^o	1.7[a]
		Impulse	I_p	0.9[a]
	VCE (Flixborough)	Peak overpressure	p^o	1.7[b]
	VCE (models)	Peak overpressure	p^o	1.0[c] 1.1[d]
Toxic release	Neutral density gas: instantaneous release	Concentration Dosage	C Ct	2.6 1.75
	Neutral density gas: continuous release	Concentration Dosage	C Ct	1.75 1.75

potential to kill a large number of people, the probability that the hazard will be realized during the lifetime of the plant is very low. Frequently such arguments do not satisfy the objectors, who tend to concentrate exclusively on the hazard potential and to emphasize that the major accident could occur out of the blue at any time.

Another weakness is that when the plant comes to be operated, usually relatively little use is made of the information generated during the design, particularly the fault trees, for the control of hazards and the analysis of accidents and failures. These problems may be tackled using the concept of hazard warning structure described by Lees (1982b, 1983b, 1985). This is now outlined.

9.26.1 Hazard warning structure

If the structure of a major accident is analysed by constructing a fault tree, it is generally found that this event occurs as a result of a minor accident and of failure of a mitigating feature that is normally effective in preventing such escalation. In turn the minor accident may occur only if there is a lesser accident and failure of a second mitigating feature. Typically, there is a series of events that result in a major accident only if all the mitigating features fail. Generally, therefore, there are many more lesser accidents than major accidents. This high ratio of lesser to major accidents is the concept underlying the accident pyramid discussed in Chapter 1 and shown in Figure 1.4.

The major accident is likely therefore to be preceded by a number of lesser events, some of which may be regarded as 'near misses'. Thus the time order of the events is also important. The exploitation of the time order of major and lesser accidents underlies the concept of learning from near misses.

These ideas are well understood. What does not appear to have been sufficiently appreciated and exploited is the potential for using these concepts in conjunction with a formal analysis of accident structure such as the fault tree. A hazard possesses a characteristic warning structure. The hazard warning structure may be laid bare by casting the fault tree for the hazard in a particular way.

9.26.2 Hazard warning tree

A typical hazard warning tree is shown in Figure 9.48. An event at level 1, which has a frequency λ_1, escalates into a level 2 event only if there is failure of a level 1 mitigating feature, which has a probability p_1. Similarly, the level 2 event with frequency λ_2 escalates into a level 3 event with frequency λ_3 only if there is failure of the level 2 mitigating feature with probability p_2. The probabilities p_1 and p_2 are attentuation fractions associated with the mitigating features.

A simple illustration is a release from a large refrigerated atmospheric storage tank holding toxic liquefied gas towards a housing estate as shown in Figure 9.49. In this case, the first level event might be defined as a release of unspecified size that might have a number of possible causes. The first level feature might then be the size of release, since only a proportion of such releases would be large ones. Further mitigating features at higher levels in the tree would be the wind direction, the stability condition, the population exposure and the injury relations.

9.26.3 Events before and after release

For a major hazard the critical event is usually loss of containment, and consideration here is directed mainly to this.

Generally in hazard assessment the frequency of the critical event is estimated either directly from failure data or else the structure of the events leading up to the release is analysed and the frequency obtained indirectly using a fault tree, while the structure of the events following the release and the frequency of particular outcomes is determined using an event tree. For a particular outcome the event tree can then be recast in the form of a fault tree. In some cases, therefore, there are available, in principle, both pre-release and post-release fault trees, whilst in other cases only the latter are available.

Even where it is not normally considered necessary to construct a pre-release fault tree in order to estimate release

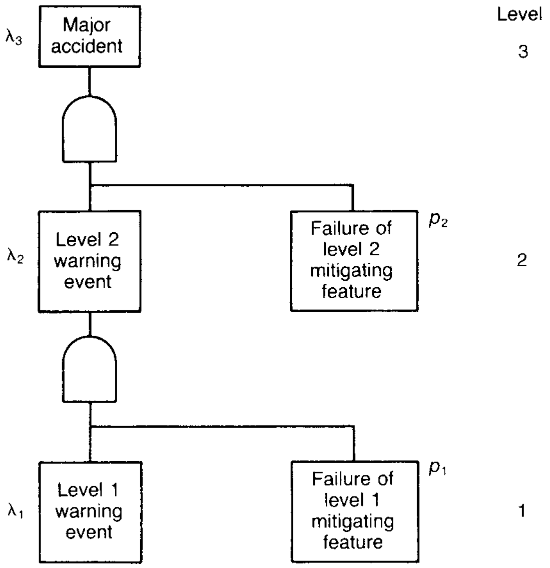

Figure 9.48 *A hazard warning tree (Lees, 1983b) (Courtesy of the Institution of Chemical Engineers)*

frequency, it may nevertheless by worth doing so for the purpose of analysing hazard warning structure. If both pre- and post-release fault trees are available, the two trees may be consolidated to form a single fault tree.

The concept of hazard warning was originally described primarily in terms of the critical event and the post-release tree, using the illustrative example of the release of refrigerated toxic liquefied gas as just described. The reason for this was simple. After the release the event/mitigating feature pairs are readily defined. They are features such as leak size, wind direction, stability condition, and so on. The hazard warning analysis is therefore relatively straightforward.

However, the application of hazard warning analysis to the situation prior to release is equally valid and may actually be of more value, since it deals with the features over which management has some control. Management can do little about the weather, but it can do something about plant design and operation. Pre-release analysis may therefore be more valuable, but it is usually more difficult.

9.26.4 Events, mitigating features and attenuation factors

The essential feature of a hazard warning analysis is that an event above the lowest level is defined as the outcome of a lower level event and of failure of a mitigating feature. The quality of the analysis depends largely on this first stage in which events, or in effect event/mitigating feature pairs, are defined.

In defining an event the object should be to give a definition that corresponds to an observable, and recordable, event. This is an essential condition both for the use of historical event data in conventional hazard assessment and for the use of event data from the operating plant. The definition of an event implies that of the associated mitigating feature. The term 'mitigating feature' is interpreted very broadly. For example, hole size for a noxious release is a mitigating feature on the basis that only a proportion of holes are large ones.

As in constructing a fault tree, with a hazard warning tree it is important that events be defined in such a way as to make the tree comprehensive and to guard against omissions. Such robustness of event definition may be achieved by working, at least in the first instance and at higher levels of the tree, in terms of generic failure modes rather than specific causes. For example, blockage may represent a generic mode of which solids deposition, freezing, crystallization and polymerization are specific causes. This approach is a safeguard against omissions insofar as it is much less probable that a generic mode will be overlooked than a specific, and perhaps low probability, cause.

Some events and mitigating features are under the influence of management, while others are not. Broadly speaking, management has relatively good control up to the point where loss of containment occurs, but much less thereafter. Management decides the hardware and software protection that is to be provided. The former includes both passive protection such as plant layout and active protection such as trip systems, while the latter covers a range of measures such as formal systems and procedures and training. Management is also able to influence the occurrence of initiating events. Once emission has occurred, the features that come into play are those such as weather conditions and exposure of people, factors over which management has little or no control.

Another important distinction is between predictable and unpredictable event rates and attenuation factors. It is much more difficult to make quantitative estimates for some event/mitigating feature pairs than for others.

Since there is a potential ambiguity it is necessary to define the sense in which 'attenuation' and associated terms are used here. The frequency of a lower level event is divided by the attenuation, or attenuation factor, associated with the mitigating feature in order to obtain the frequency of the higher level event. The attenuation is therefore greater than unity. The attenuation fraction, which is the probability of failure of the mitigating feature, is the reciprocal of the attenuation factor and is less than unity.

A hazard has a high or low warning structure depending on the total attenuation between the major accident and the lowest level of event that can serve as a warning. For a hazard to be classed as 'high warning', which is the desirable case, the total attenuation should ideally be several orders of magnitude. Generally, this means that the attenuation attributable to a single feature should be an order or magnitude or more. Attentuations of 2 or 3 are of limited value, although not completely worthless. Fortunately, for many hazards there are mitigating features that do tend to be associated with quite large attenuations. For example, the proportion of large leaks to total leaks, the probability of explosion rather than fire, the probability of particular meteorological conditions may each be quite low. If a mitigating feature represents a significant barrier to escalation and if it is one over which management has some control, it is important that it be identified

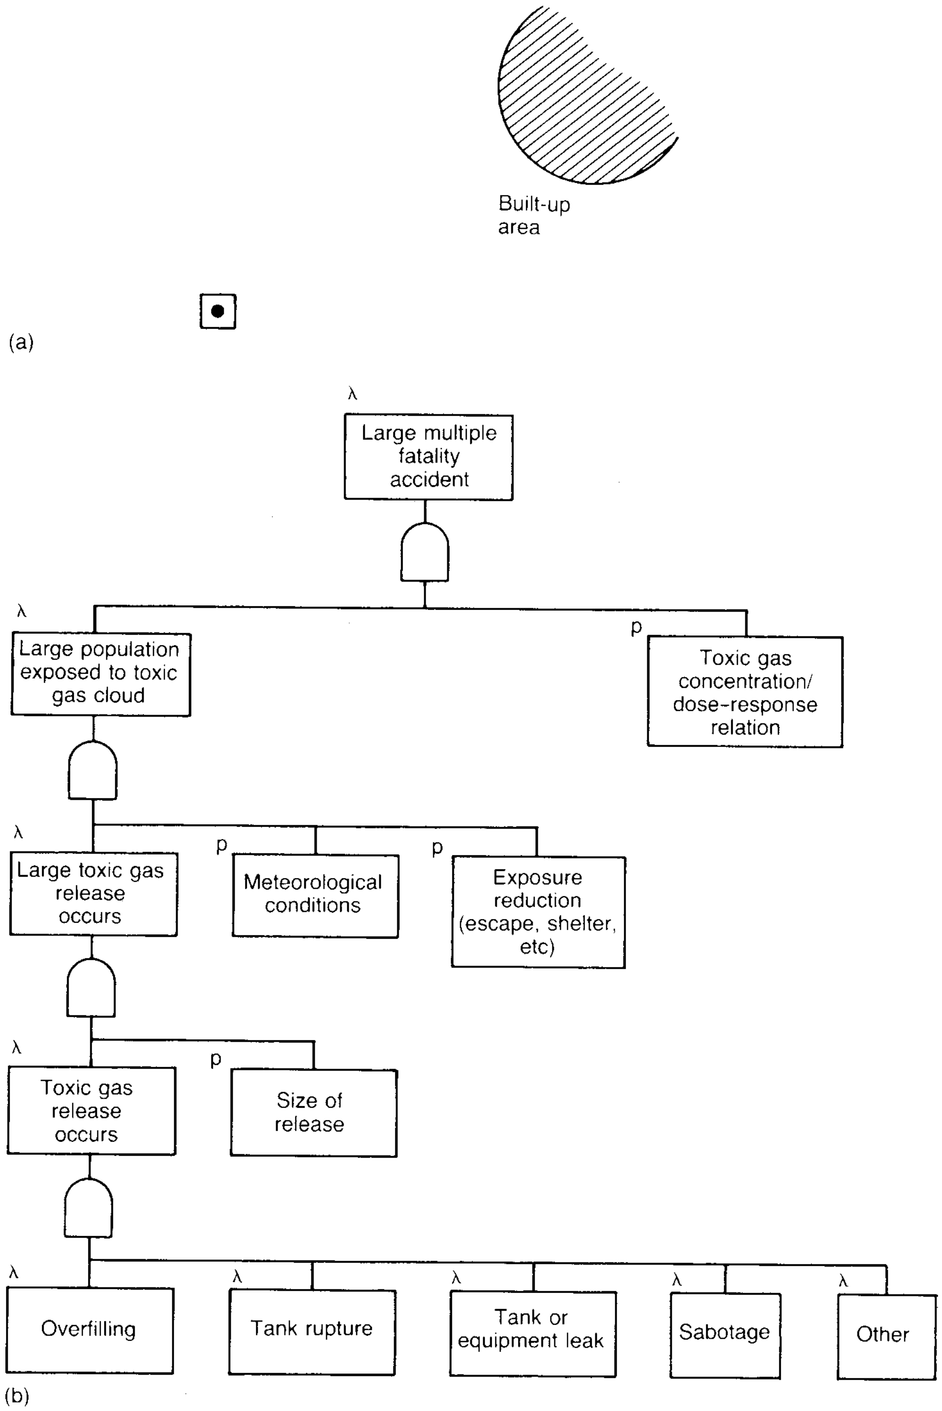

Figure 9.49 *Hazard warning tree for large multiple fatality accident due to large release of toxic liquefied gas: (a) storage tank with built-up area distant and in one sector only; (b) hazard warning tree (Lees, 1982b) (Courtesy of the Institution of Chemical Engineers)*

and that measures be taken to maintain or even improve its effectiveness.

Hazard warning is best viewed not so much as a property inherent in an installation but rather as one conferred on it by the observer. The property of hazard warning is conferred partly by recognition of features capable of giving warning and partly by the creation of such features. The principal means of creating a warning feature are, in the pre-release phase, the use of monitoring and inspection in some form and, in the post-release phase, the use of separation distances.

9.26.5 Post-release analysis

The starting point for the post-release analysis is the critical event, which is here taken as a loss of containment. In constructing the post-release tree, it is generally convenient to include as a mitigating feature the size of release, even though this could be regarded strictly as part of the pre-release tree, provided that double counting is avoided in the final assessment. The justification for this practice is that leak size is nearly always an important mitigating feature with a high attenuation factor, and that inclusion in the post-release tree ensures that it is taken into account even if no pre-release tree is developed.

Some principal mitigating features in a post-release tree are given in Table 9.48. The list is illustrative rather than exhaustive, and is self-explanatory. A post-release hazard warning analysis of the St Fergus to Moss Morran pipeline has been given by Lees (1985). A hazard assessment for this pipeline has been made by the HSE, as described in Chapter 23.

The hazard considered in the HSE report is a release of NGL from the pipeline, resulting in interactions with housing and hospitals. For this hazard there is a single base event that has 11 potential bad outcomes. The base event is a release of NGL from the pipeline. The pipeline is 220 km long. The frequency of the base event is:

Frequency of release of NGL $= 2.32 \times 10^{-4}$/km-year
$= 220 \times 2.32 \times 10^{-4} = 5.1 \times 10^{-2}$/years

The bad outcomes are interactions with housing at eight locations and with hospitals at three locations. The frequencies of these bad outcomes are:

Location	*Frequency* (10^{-6} interactions/year)	*Location*	*Frequency* (10^{-6} interactions/year)
1	2.5	7	1.0
2	2.0	8	1.2
3	3.3	9	1.0
4	4.0	10	1.3
5	1.5	11	1.4
6	2.8		
Total			22.0

The frequency of all bad outcomes is 22×10^{-6}/year. The overall attenuation factor for all bad outcomes is:

Overall attenuation factor $= (5.1 \times 10^{-2})/(22 \times 10^{-6}) = 2300$

The individual attenuation factors that make up this overall attenuation factor may be derived from the report as follows. For each location there is an estimated length of pipeline that is capable of giving rise to an interaction. The total length for all locations is 32.5 km. Hence:

Attenuation factor for location $= 220/32.5 = 6.8$

There is no interaction for ruptures with hole sizes up to 20 mm, but there can be interactions for ruptures with hole sizes in the range 20–80 mm. The estimated frequencies for these two cases are:

Frequency of rupture with hole size up to 20 mm
$= 2.0 \times 10^{-4}$/km-year
Frequency of rupture with hole size 20–80 mm
$= 2.2 \times 10^{-5}$/km-year

and hence

Attenuation factor for leak size $= (2.0 \times 10^{-4} + 2.2 \times 10^{-5})/(2.2 \times 10^{-5}) = 10.1$

Interaction can occur only if the wind direction allows. The probability of such wind direction, weighted in accordance with the interaction frequencies, is 0.240. Hence:

Attenuation factor for wind direction $= 1/0.240 = 4.2$

Also, interaction can occur only if the stability condition allows. Interactions are possible at all locations for Pasquill

stability category F and at eight locations for category E, giving for the latter a weighting factor of 0.72 based on the length of line at each location over which interaction can occur. The probabilities of categories E and F are 0.06 and 0.08, respectively. Hence:

$$\text{Attenuation factor for stability conditions} = 1/[(0.06 \times 0.72) + 0.08] = 8.1$$

The overall attenuation factor from these four separate attenuation factors is 2300, which agrees with the figure derived earlier. In this case, therefore the overall attenuation factor is a very large one.

9.26.6 Pre-release analysis

It is generally much more difficult to carry out a pre-release analysis and the methods for doing this are not well developed. As before, the approach involves the definition of mitigating features. Some principal mitigating features are shown in Table 9.49. These features are rather less straightforward and require some explanation. The pre-release tree may be envisaged as consisting of the main potential hazard tree which has as its top event the hazard, namely a leak, which will be realized unless protection acts to prevent it, and as having grafted onto it two branches, one of hardware protection and one of software protection. These two latter modes of protection are effected by protective devices such as pressure relief valves, trips and interlocks and by the process operator, respectively. Within the potential hazard tree there are two main mitigating features. These are inspection and procedures. Inspection is the means of detecting and correcting mechanical failures. Procedures are the means of preventing human error. Both types of failure can constitute initiating events. The construction of a pre-release tree requires a degree of inventiveness. There is wide scope for creative definition of mitigating features. A pre-release hazard warning analysis of a hydrocarbon sweetening plant has been described by Lees (1985). The analysis is based on an account given by Kletz (1972a) of the use in the design of the plant of several trip systems to protect against the hazard of explosion.

The plant consists of a reactor that is fed with both hydrocarbon and air. The air is supplied from an air receiver, which is fed by an air compressor. There is a pressure relief valve on the air receiver and a non-return valve between the air receiver and the reactor. An explosion is assumed to occur if an explosive mixture develops, since an ignition source is assumed always to be present. An explosive mixture can occur if an air pocket develops and the feed is above its flashpoint or if backflow occurs from the reactor into the air receiver, which is at a temperature above the flashpoint. The combination of an air pocket and of a feed above its flashpoint can result from a high feed temperature, which is a common cause for both these conditions, or from other causes. The fault tree for the system is given by Kletz in his paper.

Table 9.49 Some release modes and mitigating features for pre-release hazard warning

A Release modes
Pressure envelope failure:
Equipment defect
External threat
Maintenance/modification activity
Process parameter deviation
B Mitigating features
Leak size
Protective devices
Operator action
Inspection procedures

The hazard warning tree derived by Lees from this fault tree is shown in Figure 9.50. The release mode in this case is a process parameter deviation. The initiating and enabling events are:

(1) relief valves fails open;
(2) compressor fault;
(3) mixer fault;
(4) supply fault;
(5) instrument fault;
(6) operator error.

The protective device failures are:

(1) non-return valve fails;
(2) high temperature trip fails;
(3) air pocket trip fails.

The procedure failures are

(1) purging procedure fails;
(2) flash point control procedure fails.

The mitigating features of protective devices and of procedures are underlined in Figure 9.50. Events that might be reduced in frequency by mitigating features such as inspection (equipment failures) and procedures (operator errors) are shown with broken underlining. This indicates points at which additional mitigating features might in some cases be created to give reduced frequency of occurrence and increased warning if these are judged desirable.

This hazard warning tree shows that there is one mitigating feature, the non-return valve and the high temperature trip, on the first and second branches, respectively, but two mitigating features, the air pocket trip and the flashpoint control procedure, on the third branch. In the event, it was decided to accept low flashpoint feeds as well, so that with this policy there was then one mitigating feature on the third branch also.

In general, the process operator appears both as a source of initiating events and as a form of protection. In the tree considered the protection afforded by the operator is limited to formal checking procedures. In principle, the operator might also intervene to effect protection at other points. For example, he may act as a further layer of protection against high feed temperature. However, for the operator to be able to give protection against a condition he must be able to observe or at least infer it. Observability is one of the principal aspects of operability, which in turn is one of the two main concerns of hazard and operability (hazop) studies.

Another illustrative example of pre-release analysis is shown in Figure 9.51 for the hazard of rupture of a batch reactor due to reaction runaway. Figure 9.51 (a) gives the master tree and Figures 9.51(b) and 9.51(c) show the subsidiary trees. The reactor is one for which only a proportion

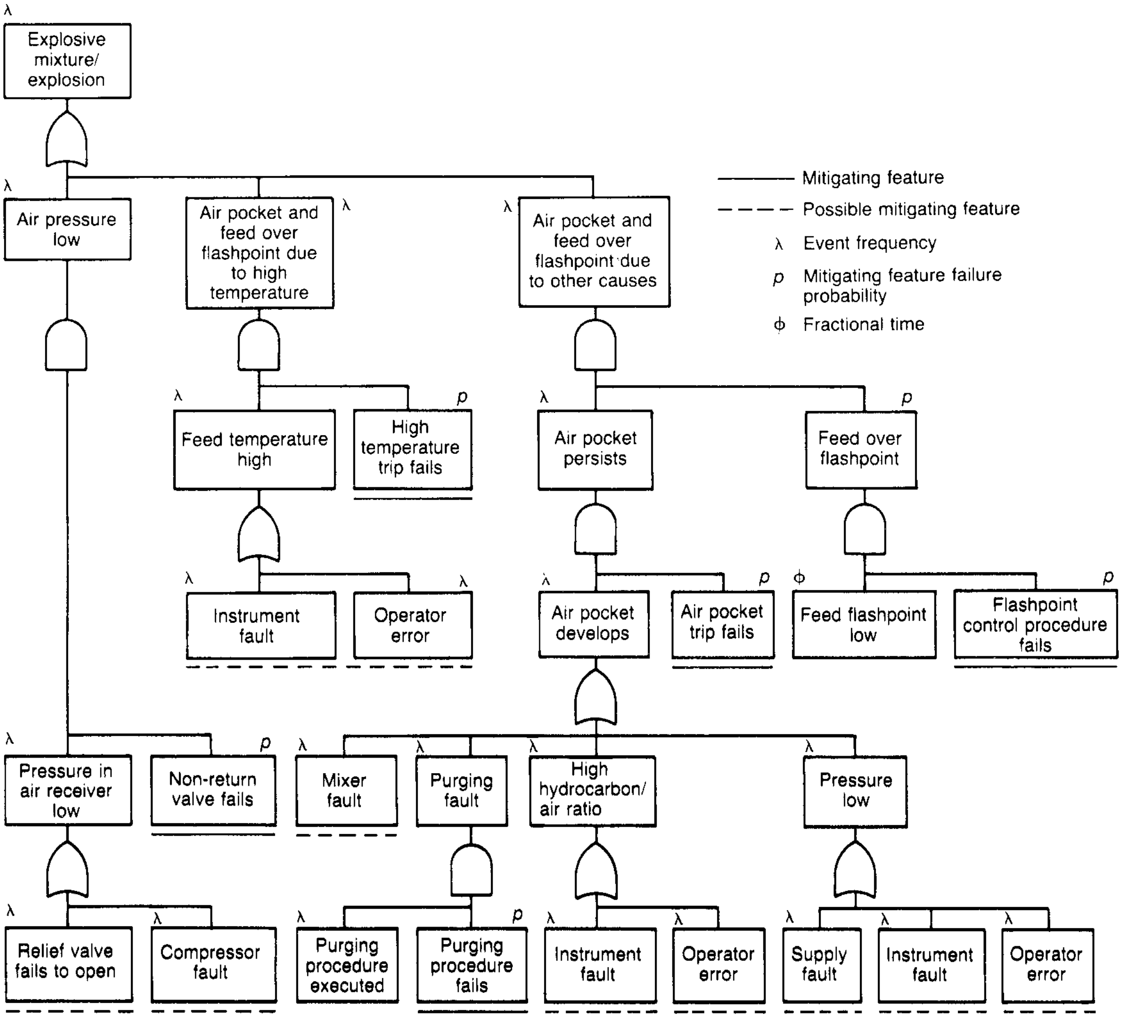

Figure 9.50 *Hazard warning tree for explosion in hydrocarbon sweetening plant (Lees, 1985) (Courtesy of the Institution of Chemical Engineers)*

of batches are prone to reaction runaway, which gives an additional mitigating feature.

Of particular interest in this tree is the fact that two of the initiating events may also cause failure of a mitigating feature. Thus loss of agitation is not only an initiating event but also prevents the use of shortstop, since without agitation distribution of the shortstop is poor. Similarly, if there is a single temperature measuring instrument both for the control loop and for display to the operator, failure of this instrument is not only an initiating event but may also cause a failure of operator intervention.

In the first example of pre-release analysis given above, the problem was of the type to which fault tree analysis is typically applied. There is a basic hazard and trip, and other protective systems are used to guard against it. The problem in the second example possesses a somewhat similar structure. It is also possible to apply hazard warning analysis to less explicitly structured problems, but the investigator must then impart much of the structure himself.

Of particular importance is loss of containment from the plant. Figure 9.52 gives an outline hazard warning tree for a major release of flammables from a plant, referred to as Plant EB. Figure 9.52(a) gives the master tree and Figures 9.52(b)–9.52(g) show the subsidiary trees. For example, for vessel corrosion (Figure 9.52(b)), the initiating event is vessel deterioration. Only if the mitigating feature of inspection fails does this escalate into a vessel leak. In turn, only in a proportion of cases will the leak be a major one, so that hole size is another mitigating feature.

For pipework rupture by maintenance or modification (Figure 9.52(c)), the initiating event is non-adherence to procedures anywhere in the works. Only in a proportion of cases will this lead to a leak, which gives a mitigating feature. Furthermore, only in a proportion of cases will

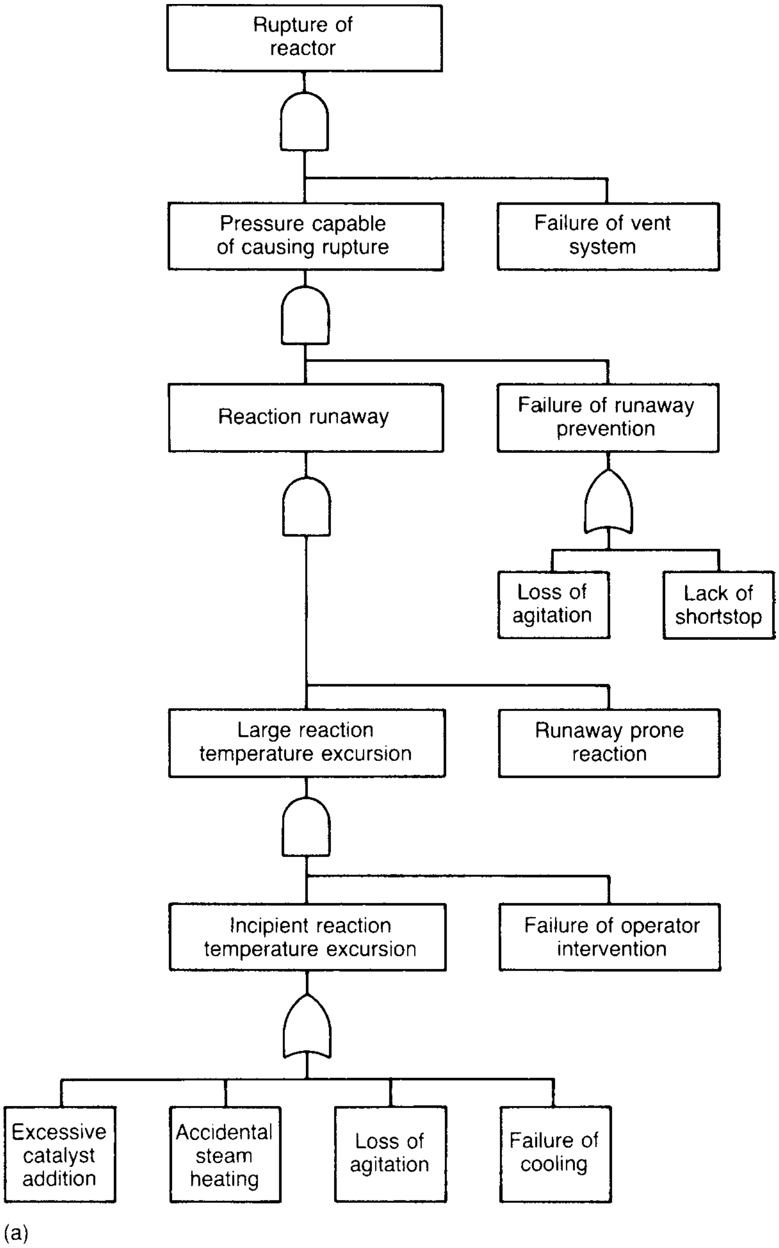

Figure 9.51 *Hazard warning tree for reaction runaway in a batch reactor, (a) Master tree, and subsidiary trees for (b) failure of operator intervention; (c) failure of cooling*

such a leak occur on Plant X, as opposed to elsewhere in the works, which gives a further mitigating feature. Finally, only in a proportion of cases will the leak be a major one, so that again hole size is another mitigating feature.

The other subsidiary trees for vehicle impact, missile impact and fire on the same plant and on another plant shown (Figures 9.52(d)–9.52(g)) follow the same principles. In some of the trees not all the branches are fully developed. In this example, therefore, the lowest level warnings even

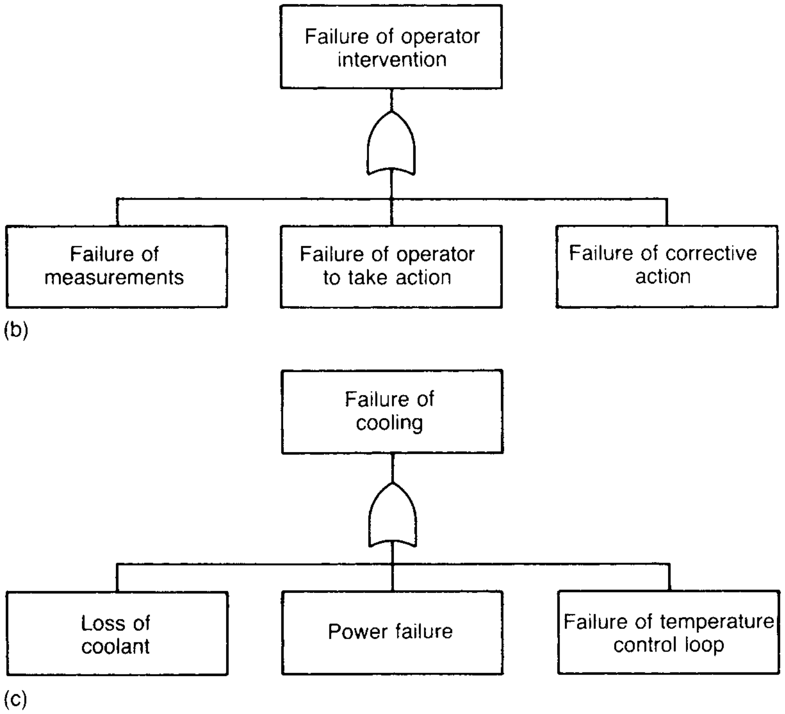

Figure 9.51 *continued*

include events that occur elsewhere on the works. It is quite legitimate to include these as warnings if they are indicators, for example, of non-adherence to procedures. The example illustrates the fact that it is up to the analyst to impose the hazard warning structure on the problem.

Another illustrative example of a similar type is that shown in Figure 9.53 for the hazard of failure of a materials testing system. Such failure may lead to a major leak from a pipework component. The initiating event is receipt of an unsuitable component. The materials testing system allows through only a proportion of defective components and acts as a mitigating feature. Only in a proportion of cases will the leak be a major one, which is a further mitigating feature. The failure of the mitigating feature of detection can occur as a result of failure of the detection procedure, but less obviously it can also be a result of failure to select the component for inspection in the first place.

9.26.7 Failure of warning

It is of interest to be able to estimate the probability that there may be a failure of hazard warning.

For a top event T of frequency λ_1 which is caused on a proportion p of occasions by a base event B of frequency λ_2:

$$\lambda_1 = p_1\lambda_2 \qquad [9.26.1]$$

Over a given time interval t the probability $P_T(t)$ that the top event will occur is:

$$P_T(t) = 1 - \exp(-\lambda_1 t) \qquad [9.26.2]$$

The probability $\bar{P}_T(t)$ that the top event will not occur is:

$$\bar{P}_T(t) = \exp(-\lambda_1 \mathrm{t}) \qquad [9.26.3]$$

The probability $P_B(t,k)$ that the base event will occur exactly k times is:

$$P_B(t,k) = \exp(-\lambda_2 t)\frac{(\lambda_2 t)^k}{k!} \qquad [9.26.4]$$

The probability $P_\mathrm{B}(t,\, k \leq n)$ that the base event will occur no more than n times is:

$$P_B(t, k \leq n) = \exp(-\lambda_2 t)\sum_{k=0}^{n}(\lambda_2 t)^k/k! \qquad [9.26.5]$$

The probability $P_B(t, k \leq n)$ that the top event will occur given that the base event occurs no more than n times is:

$$P_T(t, k \leq n) = \exp(-\lambda_2 t)\sum_{k=1}^{n} p(k)(\lambda_2 t)^k/k! \qquad [9.26.6]$$

where

$$p(k) = \sum_{j=1}^{k}(-1)^{j-1}\binom{k}{j}p^j \qquad [9.26.7]$$

Then the probability $W(t,\, k \geq n)$ that there will be a failure of hazard warning, in other words that the top event will occur and that the number of base events will be no more than n when the top event occurs so that there will not be n clear warnings, is:

$$W(t, k \geq n) = P_T(k \leq n) \qquad [9.26.8]$$

The ratio of the probability P_T of the top event to the hazard warning index W is the hazard warning ratio and it gives a measure of the degree of warning available.

As an illustrative example, Lees considers the case shown in Figure 9.54(a), for which:

$$\lambda_1 = 0.001/\text{year}$$

$$\lambda_2 = 0.5/\text{year}$$

$$p = 0.002$$

Then for a time period $t = 10$ years and $n = 2$

$$P_T(t) = 0.01$$

$$W(t, k \geq n) = 0.0004$$

Pitblado and Lake (1987) have derived an expression equivalent to Equation 9.26.8 and have explored the numerical implications using Lees' example. Their results are plotted in Figure 9.54 (b). They show that the value of the hazard warning ratio is lower in the early years and that it is reduced if the number of warnings specified is excessive, but that otherwise a worthwhile degree of warning is obtained.

9.26.8 High and low warning hazards

For many hazards the expected number of warnings is large, but for some it is not. The intention behind hazard warning analysis is to exploit the warnings, but analysis is not wasted if it reveals a low warning hazard. It is important to be aware of such a hazard, because it is unforgiving and needs special care.

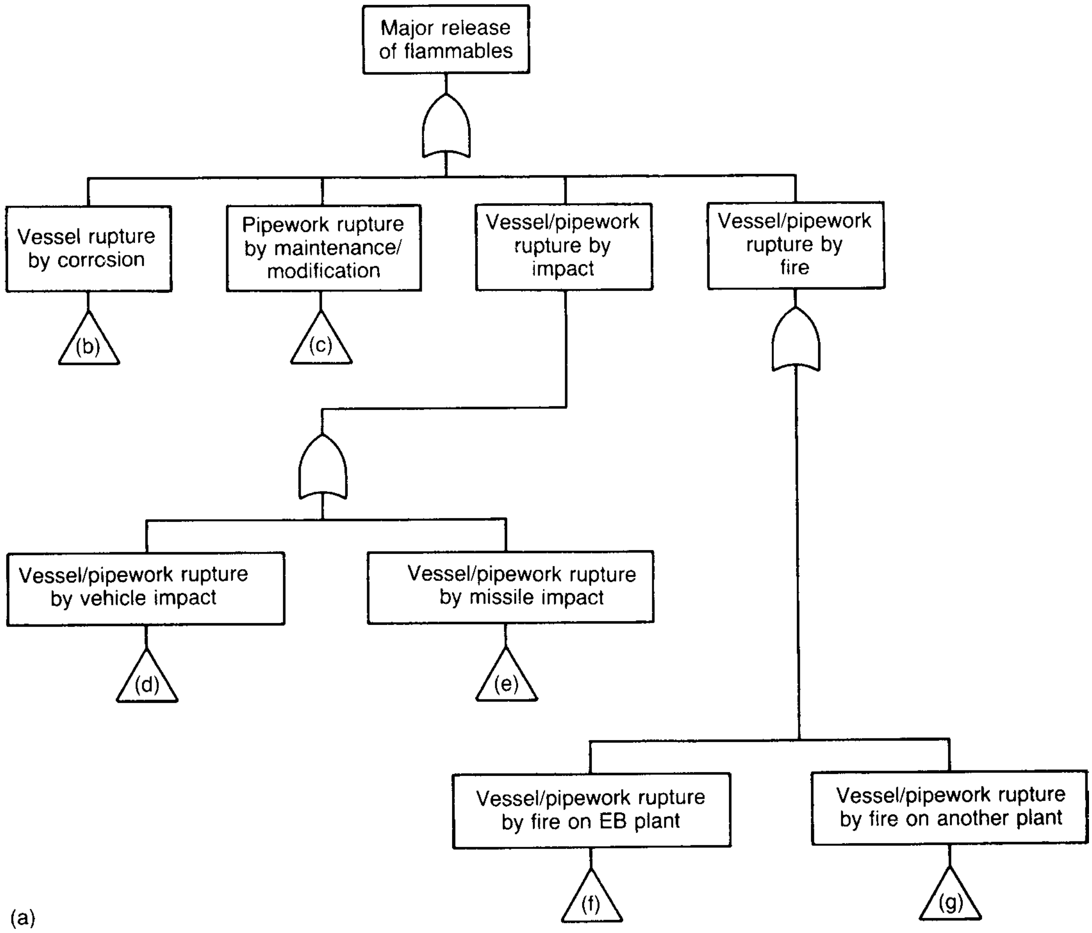

Figure 9.52 *continued*

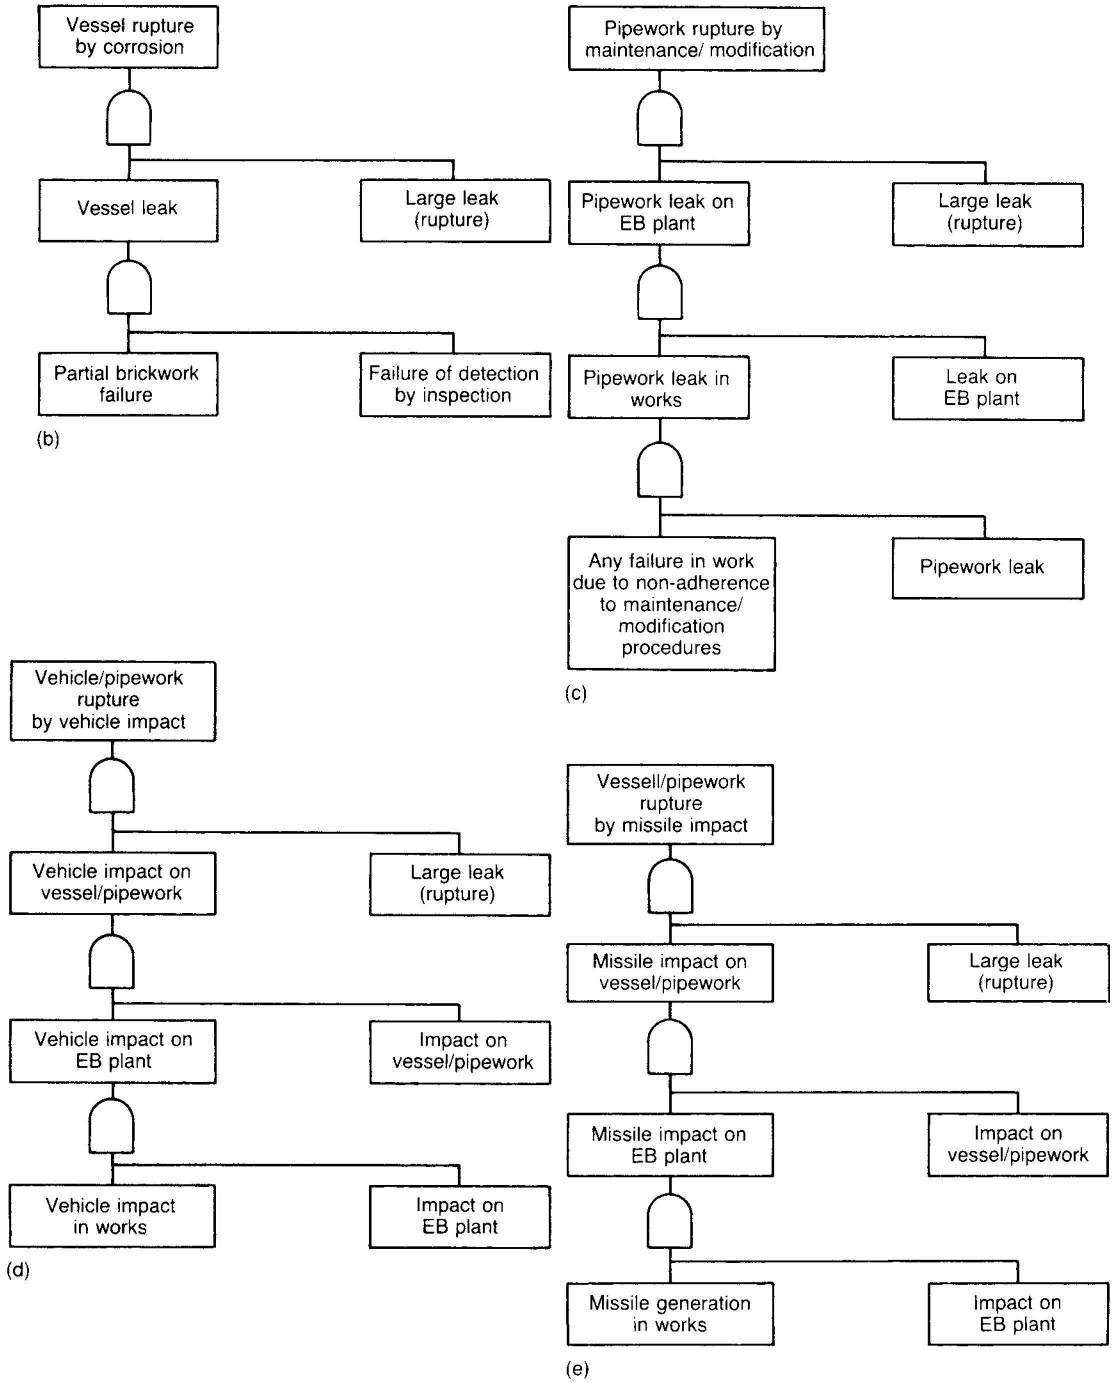

Figure 9.52 *continued*

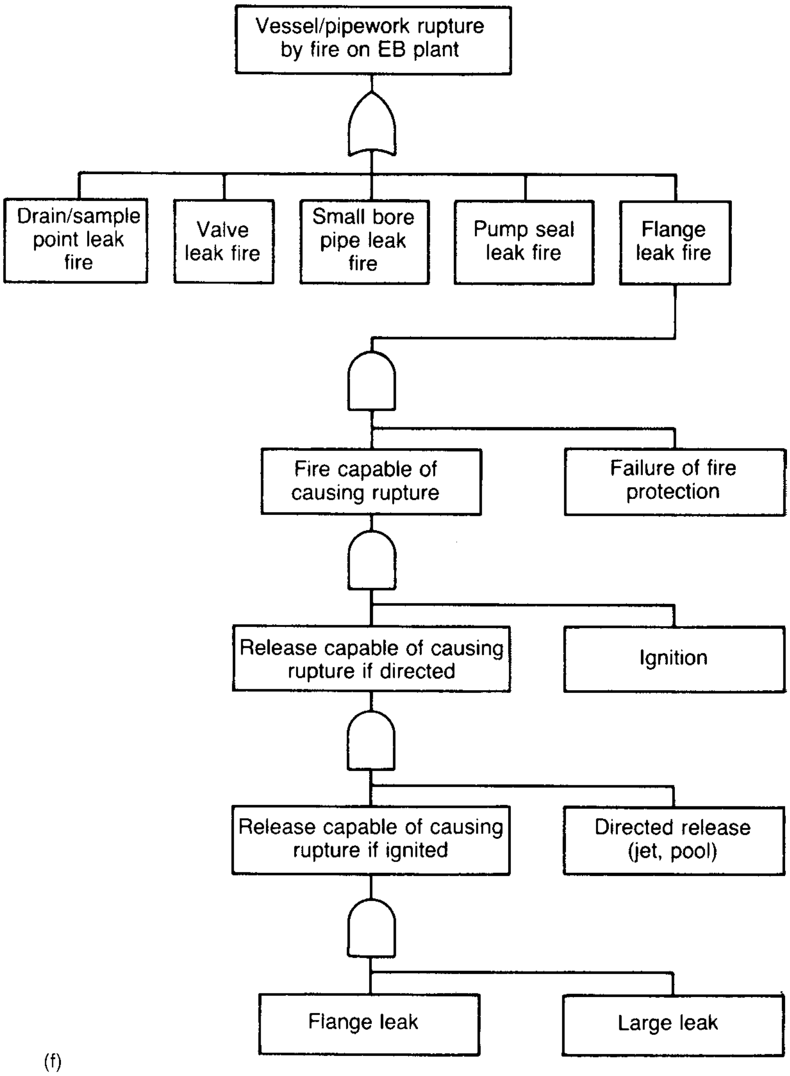

(f)

Figure 9.52 *continued*

The degree of warning may be defined as follows (Lees, 1983b):

Degree of warning	*Attenuation factor*
Zero	1
Low	10
Medium	100
High	1000

An example of a low warning hazard was given in the First *Canvey Report*, where an ammonium nitrate explosion was identified as a hazard which, if it occurred at all, would cause casualties.

9.27 Computer Aids

Hazard assessment is an active field for the development of computer aids. Computer aiding has been applied to the following:

(1) fault tree analysis;
(2) fault tree synthesis;
(3) hazard models;
(4) hazard model systems;
(5) risk assessment.

These developments are described in Chapter 29. Also important in hazard assessment are computer data banks, which are described in Appendix 14.

9.28 Risk Assessment Debate

Almost from their inception, both the philosophy and methodologies of risk assessment have attracted criticism. The whole status of risk assessment as a scientific activity has been questioned by Weinberg (1972a,b). He argues that the assessed risks for very rare events are likely always to be derived by a process involving much subjective judgement and intractable for peer review and, therefore, to be subject to much uncertainty. In effect, it is possible to pose the problem in scientific terms, but the answer that can be given is not based on science but 'trans-science'. He quotes a major nuclear reactor accident as an example of this type of problem. He argues further that, insofar as in this area truth may be unattainable, the search should be rather for wisdom and that laymen have a correspondingly larger part to play in making the decision. Other critiques of risk assessment as applied to nuclear hazards include those by Hanauer and Morris (1971) and Critchley (1976).

Criticisms of specific techniques were also not slow to appear. Much of the initial work on the use of fault trees was done in the aerospace industry. The effectiveness of fault tree estimates in this work has been criticized by Bryan (1976), who was in charge of reliability assessment during testing of the Apollo Service Propulsion System (or SPS engine). He states:

> This optimism was soon dispelled by hundreds of cases of unexpected test and operational failures and thousands of system malfunctions. Many of the failures and malfunctions modes had either been previously analysed and seemed to be noncredible events or had come as a complete surprise which previous analyses had not identified at all. By the early 1960s, it had become apparent that the traditional method of identifying potential failure events and assigning historical probabilities of occurrence to these events . . . had consistently led to overly optimistic conclusions. Consequently, the failure rates were consistently underestimated.

Further discussion of experience in reliability assessment of the SPS engine is given by the Union of Concerned Scientists (1977).

The debate on the *Rasmussen Report*, described in Appendix 23, was in large part concerned with the validity of risk assessment. The use of risk assessment in the process industries has also had its critics, including Bjordal (1980), Pilz (1980a,b), Joschek (1983) and Lowe (1984). This criticism comes from experienced practitioners and is directed not at the use of quantitative methods but rather at what is considered to be their misuse.

It is argued by Lowe that hazard analysis and risk analysis are quite different activities. Whereas the former is action oriented, being undertaken to assist in making engineering decisions, the latter is information oriented, yielding little except very uncertain risk estimates. At first sight it appears that risk estimates, even if approximate, should be of value in assisting decisions in the public domain. Where most of the other factors, however, are unquantifiable, quantification of a single factor may actually be a hindrance by putting undue weight on and creat-

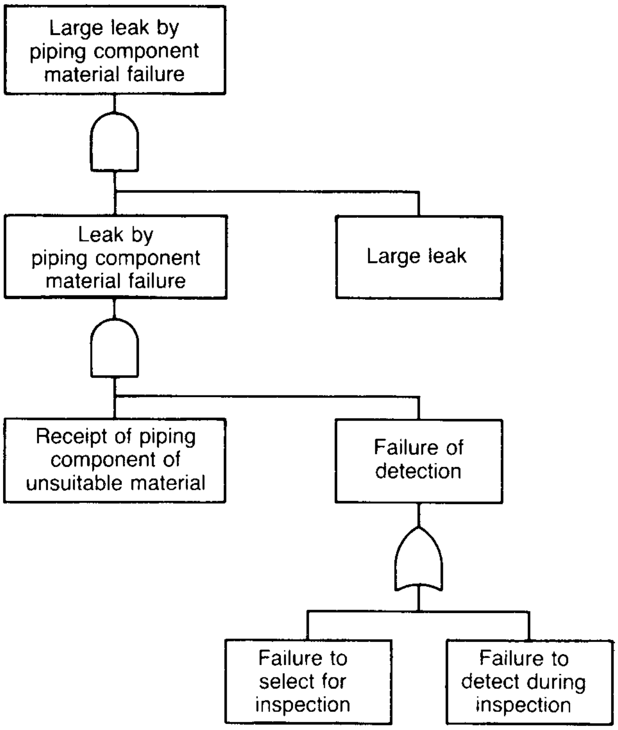

Figure 9.53 *Hazard warning tree for major leak by piping component due to failure of materials inspection*

ing excessive debate about that factor. He concludes:

> In my view risk analysis of the type considered here is to safety what the merry-go-round is to transport. We can spend a lot of time and money on it, only to go round in circles without really getting anywhere.

Bjordal's criticism is directed particularly to risk assessments that concentrate exclusively on fatalities. He draws attention to the wide variety of other factors that may concern the public, ranging from pollution to anxiety. He emphasizes the importance of defining beforehand the use to which the results are to be put, and cites one case where the point which the public were most anxious to have answered was not the risks as usually assessed, but the question: 'Is it more dangerous to live along the fjord than before?'

Pilz describes the many difficulties in the way of obtaining a meaningful risk assessment for a process plant. The value of the assessment is crucially dependent on the insight the analyst has regarding the system. Failure rates are usually assumed to be constant over time, but may well not be so. Failure data are often lacking and are strongly affected by the differences in aggressiveness of the chemicals handled and in operating and maintenance practices. Fault tree methods are based on classifying states that are essentially a continuum as discrete states of failure or success. Human error plays a critical role. It is necessary to consider not simply the steady-state operating condition but also other conditions such as start-up, shut-down, etc. He concludes that it is a virtually hopeless task to obtain a risk assessment that is meaningful in terms of the uses for which it is usually advocated and quotes the wide confidence bounds given by the authors of the *Nuclear Reactor Risk Study* in Germany.

In Pilz's view, fault tree analysis can nevertheless play a useful role. It is a valid technique for comparing different protective systems. It should be used to check different safety concepts and to discover weak points, but it should not be made to bear the burden of risk assessment. He points out that in Germany a risk assessment is not done for every nuclear reactor, and that indeed the *Reactor Risk Study* dismisses this as impossible. What is done is to study a number of typical plants and to determine the average risk from these.

The debate on risk assessment is reflected in the two guides *Methodologies for Hazard Analysis and Risk Assessment in the Petroleum Refining and Storage Industry* (CONCAWE, 1982 10/82) and *Risk Analysis in the Process Industries* by the International Study Group on Risk Assessment (ISGRA, 1985; Pitblado, 1994b). Both publications give guidance on the methodologies of hazard analysis and risk assessment. Neither recommend the universal use of risk assessment. The CONCAWE guide emphasizes the uncertainties inherent in risk assessment. The ISGRA guide explicitly states: 'Whilst a large number of companies have found benefit from the use of quantified risk analysis, it must be recognised that others in the process industries have not found it necessary'.

One aspect of quantification which has attracted less criticism is the modelling of consequences. Certainly there are many comments on the wide disparities in the results from different models of particular physical phenomena,

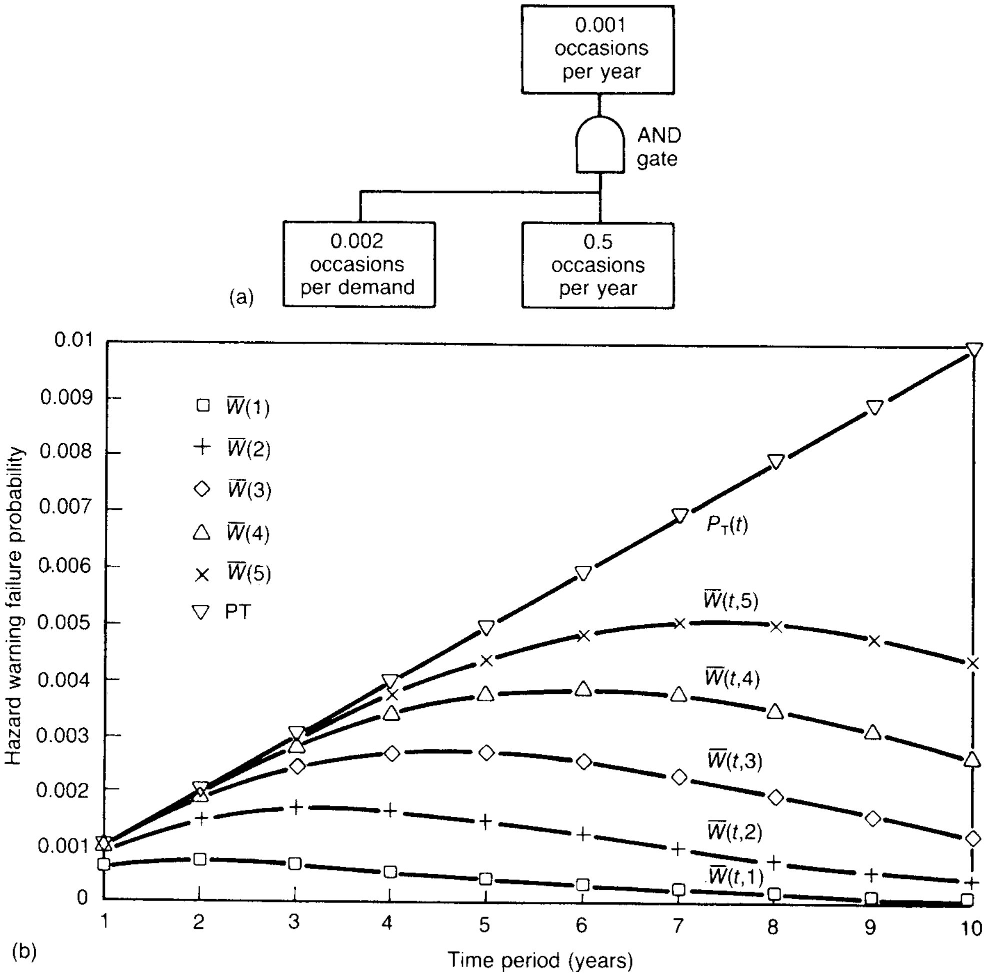

Figure 9.54 *Effectiveness of hazard warning (after Pitblado and Lake, 1987); (a) simple hazard warning tree; (b) probability of failure of warning (Courtesy of the Institution of Chemical Engineers), Note: In these authors' notation P_T is the probability of the top event, or hazard realization; W is the probability of failure of hazard warning and is thus equivalent to Lees' W*

but there is also perhaps a feeling that there is good prospect of resolving these differences in due course and that the models are already becoming sufficiently accurate to give useful results.

9.29 Overview

There are three principal reasons why hazard assessment may be undertaken:

(1) engineering decisions;
(2) public acceptance;
(3) regulatory requirements.

There are important differences between these three situations. The first two are voluntary, while the third is imposed. The first is in-company, while the last two are in the public domain.

Hazard assessment is undertaken by industry as an aid to decision-making. It assists in identifying the significant hazard, in choosing cost-effective countermeasures, and in bringing out the underlying assumptions and the conditions that must be met if the hazard is to be controlled. There is little dispute over its value for these purposes. Applied in this way hazard assessment has the aspect of hazard analysis (HAZAN).

Debate centres on the value of hazard assessment in the form of probabilistic risk assessment. Here the common features of risk assessments in respect of consequence modelling appear to have obscured the fact that there are major differences between assessments in the treatment of frequency estimation.

Assessments tend to vary in nature according to the system studied. As already pointed out, the *Canvey Reports* contain little in the way of fault trees, whereas the *Rasmussen Report* contains large numbers.

For a process plant it is possible to conduct a risk assessment that is based on a release source review and uses generic failure data. This overcomes many of the problems associated with completeness of hazard identification and with hazard assessment using fault tree methods. On the other hand, the information obtained from such a study is of limited use. Essentially what it reveals is the risks to be expected if the plant is designed and operated to some average standard. A study of this kind appears relevant primarily to decisions about the siting of and development around a major hazard.

A risk assessment for a process plant which starts from a release source review but also includes extensive hazard identification and assessment studies on the particular plant using methods such as hazop and fault trees and utilizing, as far as possible, plant specific data is another matter. Such a study involves much more work, but it also yields much more information and is of much greater assistance in engineering decision-making. It is convenient to refer to these two types of risk assessment as 'generic' and 'specific' assessments, respectively.

The use of risk assessments in the public domain arises from the demand that the operator of a major hazard plant should demonstrate that the hazards on its plant are under control. In making this demand, it seems probable that the public is seeking assurance in respect both of the magnitude of the hazard and of the risk of its realization. What the public gains from a generic assessment is a general picture of the hazard and the associated risks, the latter based on the assumption that the plant standards are average.

The value to the public of a specific risk assessment is rather different. In this case what the public gains is the assurance that the company has made a detailed study of the hazards of its plant and that, as a result, the standards should not be below average. The difference between generic and specific risk assessments, therefore, lies less in the assessment of the consequences than in that of the frequency.

A full risk assessment of a major hazard plant is a substantial undertaking. Much of the effort, however, lies in the assembly of data and models and is in some degree transferable to other assessments. Moreover, computer aids are now available which besides carrying out the actual calculations, also provide a framework and set of default data and models.

Some aspects of risk assessment, therefore, may become virtually routine, but care is needed in identifying those features for which in a given case a relatively routine treatment may be appropriate and those that require detailed study. The aim should be to free the engineer to concentrate on the latter. It is such detailed studies that are most likely to yield useful results.

A risk assessment should be realistic rather than conservative. In engineering design, it is not uncommon for a number of safety factors to be introduced at the various stages. This approach is not suitable in risk assessment. The use of excessively conservative assumptions leads to overly pessimistic and unrealistic risk estimates that are of little value for decision-making. The assessed risks should be 'best estimates'. The decision-makers can then treat these results with whatever degree of conservatism they think appropriate.

Risk assessment has undergone substantial development in recent years and the pace of change is still rapid. The methodology is still only barely adequate for the tasks often required of it. This should be borne in mind when evaluating the assessed risks.

The numerical risk results are only one of the outputs from a risk assessment. Equally important, and perhaps more so, are the other findings such as the identification and ranking of hazards, the identification and assessment of engineering measures to avoid, protect against and mitigate hazards, and an appreciation of the conditions necessary to keep hazards well controlled.

10

Plant Siting and Layout

Contents

10.1 Plant Siting

Safety is a prime consideration in plant siting. Other important factors include: access to raw materials and to markets; availability of land, labour and cooling water; means of effluent disposal; interlinking with other plants; and government policies, including planning permission and investment incentives. It is only safety aspects which are considered here.

As far as safety of the public is concerned, the most important feature of siting is the distance between the site and built-up areas. Sites range from rural to urban, with population densities varying from virtually zero to high. Separation between a hazard and the public is beneficial in mitigating the effects of a major accident. An area of low population density around the site will help to reduce casualties. In the ideal case, the works is surrounded by fields or waste land forming a complete cordon sanitaire. In many situations, however, it is unattractive to 'sterilize' a large amount of land in this way, particularly in an urban area, where land is generally at a premium.

The physical effects of a major accident tend to decay quite rapidly with distance. Models for fire give an inverse square law decay, as do many of the simpler models for explosion and toxic release, though other explosion and toxic release models give different decay relations, some with less rapid decay. Decay laws were discussed in Chapter 9 and further treatments are given in Chapters 15–17.

Information on the potential effects of a major accident on the surrounding area is one of the main results obtained from a hazard assessment and such an assessment is of assistance in making decisions on plant siting.

Siting is not a substitute for high standards of design and operation of the plant. It should never be forgotten that the people most at risk are the people on site, and standards should be such as to safeguard this workforce. It is sometimes argued in fact that standards should be sufficiently high so that separation between site and public is not necessary. Such standards, however, are essentially a form of active protection, which depends crucially on the quality of management. In most countries, including the United Kingdom, the view is taken that it is prudent nevertheless to have a degree of separation. The provision of a separation distance is a form of passive protection which provides a further mitigating factor and which is relatively robust in the event of deterioration in the plant management.

In terms of hazard warning, separation tends to create a hazard, which will give more warnings and which is therefore less unforgiving.

Topography is another relevant feature. It is desirable to avoid terrain where hazardous fluids, whether liquids or dense gases, can flow down into populated areas. Another consideration to be taken into account is contamination of water courses by liquid spills.

In selecting a site, allowance should be made for site emergencies. One factor is the availability of emergency utilities such as electrical power and water. Another is the availability and experience of outside emergency services, particularly the fire service. A third is access for these services.

A discussion of siting for high toxic hazard materials (HTHMs) is given in the CCPS HTHM *Storage Guidelines* (1988/2). Siting policy for major hazard plants in the United Kingdom was discussed in Chapter 4. Selected references on plant siting are given in Table 10.1.

10.2 Plant Layout

Plant layout is a crucial factor in the economics and safety of process plant. Some of the ways in which plant layout contributes to safety and loss prevention (SLP) are:

(1) segregation of different risks;
(2) minimization of vulnerable pipework;
(3) containment of accidents;
(4) limitation of exposure;
(5) efficient and safe construction;
(6) efficient and safe operation;
(7) efficient and safe maintenance;
(8) safe control room design;
(9) emergency control facilities;
(10) fire fighting facilities;
(11) access for emergency services;
(12) security.

Plant layout can have a large impact on plant economics. Additional space tends to increase safety, but is expensive in terms of land and also in additional pipework and operating costs. Space needs to be provided where it is necessary for safety, but not wasted.

The topics considered under the heading of 'plant layout' are traditionally rather wide ranging. Many of these subjects are treated here in separate chapters and only a brief treatment is given in this one. This applies in particular to such topics as hazard assessment, emission and dispersion, fire and fire protection, explosion and explosion protection, storage and emergency planning.

A general guide to the subject is given in *Process Plant Layout* (Mecklenburgh, 1985). This is based on the work of an Institution of Chemical Engineers (IChemE) working party and expands an earlier guide *Plant Layout* (Mecklenburgh, 1973). The treatment of hazard assessment in particular is much expanded in this later volume. The loss prevention aspects of plant layout have also been considered specifically by Mecklenburgh (1976).

Other work on plant layout, and in particular SLP, includes that of: Armistead (1959), R. Kern (1977a–f, 1978a–f) and Brausbacher and Hunt (1993), on general aspects and spacing recommendations; Simpson (1971) and R.B. Robertson (1974a, 1976b), on fire protection; Fowler and Spiegelman (1968), the Manufacturing Chemists Association (MCA, 1970/18); Balemans *et al.* (1974) and Drewitt

(1975), on checklists; and Madden (1993), on synthesis techniques.

Plant layout is one of the principal aspects treated in various versions of the Dow *Guide* by the Dow Chemical Company (1994b). It is also dealt with in the *Engineering Design Guidelines* of the Center for Chemical Process Safety (CCPS, 1993/13). There are also a large number of codes relevant to plant layout, and particularly separation distances and area classification. These are described below.

The treatment given here for the most part follows that of Mecklenburgh, except where otherwise indicated. It is appropriate to repeat here, his caution that the practice described should be regarded only as typical and that it may need to be modified in the light of local conditions, legislation and established safe practices. In particular, the account given generally assumes a 'green-field' site, and some compromise is normally necessary for an existing site.

Selected references on plant layout are given in Table 10.2.

10.3 Layout Generation

10.3.1 Factory layout

For factories generally there are a number of different principles on which plant layout may be based (Muther, 1961).

Hazard assessment
Mecklenburgh (1982, 1985)

Thus, in light engineering, use is made of layouts in which the material fabricated remains in a fixed position and others in which a particular process or function is performed at a fixed point.

10.3.2 Flow principle

For process plants, however, the most appropriate method is generally to lay the plant out so that the material flow follows the process flow diagram. This is the process flow principle. This arrangement minimizes the transfer of materials, which is desirable both for economics and safety. It is difficult to overemphasize the importance of efficient materials handling. It has been estimated by the Department of Trade and Industry (DTI, 1974) that about a quarter of the production costs of manufacturing industry generally are for materials handling – an activity which in itself is totally unproductive.

Likewise, long runs of pipework with vulnerable features are an undesirable addition to the hazards of the plant. There are features which can lead to the layout sequence diverging from the process sequence. They relate particularly to: requirements for gravity flow; equipment needing specially strong foundations; access for construction, commissioning, operation and maintenance; future extension; operator protection; escape and fire fighting; containment of accidents; and environmental impact.

10.3.3 Correlation and compatibility

There are certain other layout approaches which are used for factory layouts generally and which merit mention. Correlation and compatibility techniques are used for the elimination of layout arrangements which are incompatible or impossible, and also for the preliminary formulation of compatible arrangements.

In the correlation chart method, for example, the procedure is as follows. The constraints and objectives are listed. The floor space is subdivided into a grid and for each item the grid divisions which violate the constraints are deleted. The permissible layouts are then determined. There is a corresponding algebraic method.

Proximity and sequencing techniques are available for the determination of the costs of material transfer with different layouts.

These general factory layout techniques are described in more detail by Mecklenburgh (1973), but he states that they appear to have found little application in process plant layout.

10.3.4 Process plant layout

As with design generally, the design of a process plant layout involves first synthesis and then analysis. Despite its importance, there is relatively little written on the generation of the layout. An indication of some of the principles which guide the designer has been given by Madden (1993). He describes a structured approach to the generation of the layout which has four stages: (1) three-dimensional (3D) model, (2) flow, (3) relationships and (4) groups.

10.3.5 Three-dimensional model

The first step is to produce a 3D model of the space occupied by each item of equipment. This 3D envelope should include space for (1) operations access, (2) maintenance access and (3) piping connections. The effect of allowing for these aspects is generally to increase several-fold the volume of the envelope.

10.3.6 Flow

The concept of 'flow' as used by Madden has two meanings: (1) progression of materials towards a higher degree of completion, and (2) mass flows of process or utility materials. Often the two coincide, but where there is a feature such as a recycle the relationship is less straightforward.

10.3.7 Relationships

A relationship exists between two items when they share some common factor. Relationships may be identified by considering the plant from the viewpoint of each discipline in turn. Broad classes of relationship are (1) process, (2) operations, (3) mechanical, (4) electrical, (5) structural and (6) safety.

Process relationships are exemplified by: direct flow diagram connectivity between items; gravity flow; hydraulics and net positive suction head (NPSH) requirements; and heat interchange and conservation. Operations relationships include multiple items with similar features, for example batch reactors and centrifuges. Examples of mechanical relationships are the space needed between items for piping and transmission or isolation of vibrations. Electrical relationships may be associated with electrical area classification and with high voltage or power features. Structural features include the grouping together of heavy items and the location of heavy items on good ground. Some safety features are separation between potential leak sources and ignition sources and the provision of a sterile area such as that around a flare.

10.3.8 Groups

From the relationships identified it is then necessary to select those which are to be given priority. It is then possible to arrange the items into groups. It is found by experience that a group size of about seven items is the largest which a layout designer can readily handle; above this number the arrangement of items within the group becomes excessively complex. A typical group is a distillation column group consisting of the column itself and its associated heat exchangers, etc.

10.3.9 Segregation

A relationship of particular importance in plant layout is that between a hazard and a potential target of that hazard. The minimization of the risk to the target is effected by segregating the hazard from the target. The requirement for segregation therefore places constraints on the layout.

10.4 Layout Techniques and Aids

There are a number of methods available for layout design. These are generally more applicable to the analysis rather than the synthesis of layouts, but some have elements of both. They include:

(1) classification, rating and ranking;
(2) critical examination;
(3) hazard assessment;
(4) economic optimization.

There are also various aids, including:

(5) visualization aids;
(6) computer aids.

10.4.1 Classification, rating and ranking

There are several methods of classification, rating and ranking which are used in layout design. The main techniques are those used for the classification of (1) hazardous areas, (2) storage, (3) fire fighting facilities and (4) access zones, together with methods based on hazard indices.

Hazardous area classification is aimed at the exclusion of ignition sources from the vicinity of potential leak sources and involves the definition of zones in which control of ignition sources is exercised to differing degrees. It is described in Section 10.12 and Chapter 16.

Storage classification is based on the classification of the liquids stored. Accounts are given in Section 10.10 and Chapter 22.

Closely related is classification based on fire fighting requirements, since this is applicable particularly to storage.

Restriction of access may be required near major hazard plants or commercially sensitive processes. Areas are therefore classified by the need to control access.

10.4.2 Critical examination

Critical examination, which is part of the technique of method study (Currie, 1960), may be applied to plant layout. This application has been described by Elliott and Owen (1968). In critical examination of plant layout, typical questions asked are: Where is the plant equipment placed? Why is it placed there? Where else could it go?

The technique therefore starts with and involves analysis of a proposed layout, but insofar as other possible solutions are suggested, it may be regarded also as a method for the generation of alternatives which can then be evaluated.

As already mentioned in Chapter 8, the working document in an early hazard study is a plant layout diagram, and to this extent such a hazard study may be regarded as a form of critical examination of layout.

10.4.3 Hazard assessment

Hazard assessment of plant layout is practised both in respect of major hazards which affect the whole site, and of lesser hazards, notably leaks and their escalation. The traditional method of dealing with the latter has been the use of minimum safe separation distances, but there has been an increasing trend to supplement the latter with hazard assessment. An account of hazard assessment is given in Chapter 9 and its role in plant layout is discussed in Sections 10.5 and 10.13.

10.4.4 Economic optimization

The process of layout development generates alternative candidate layouts and economic optimization is a principal method of selection from among these. The points at which such economic optimization is performed are described in Section 10.5. Some factors which are of importance for the cost of a plant layout include foundations, structures, piping and pipetracks, and pumps and power consumption.

10.4.5 Visualization aids

There are various methods of representing the plant to assist in layout design. These include drawings, cutouts, block models and piping models. Cutouts are a two-dimensional (2D) layout aid consisting of sheets of paper, cardboard or plastic which represent items in plan, whether whole plots or items of equipment, and are overlaid on the site or plot plan, as the case may be. The other main physical aids are 3D. Block models are very simple models made from wood blocks or the like which show the main items of equipment and are used to develop plot and floor plans and elevations. Piping models include the pipework, are more elaborate, and can constitute up to 0.5% of the total installed plant cost. They are useful as an aid to: doing layout drawings; determining piping layout and avoiding pipe fouls; positioning valves, instruments, etc.; checking access for operation and maintenance; planning construction and executing it; and operator training.

10.4.6 Computer aids

Plant layout is one of the areas in which computer aided design (CAD) methods are now widely used. One type of code gives visualization of the layout. This may take a number of forms. One is a 2D layout visualization equivalent to cutouts. Another is a 3D visualization equivalent to either a block model or a piping model, but much more powerful. The visualization packages available have become very sophisticated and it is possible in effect for the user to sit at the display and take a 'walk' through the plant. A recent development is enhancement by the use of the techniques of virtual reality. Typically, such CAD packages not only give 3D display but hold a large amount of information about the plant such as the coordinates of the main items and branches, the piping routes, the materials list, etc.

A particular application of 3D visualization codes is as input to other computer programs such as computational fluid dynamics codes for explosion simulation. The 3D layout required for the latter is provided by the 3D visualization code, which then forms the front end of the total package.

Another type of code tackles the synthesis of layouts. The general approach is to define a priority sequence for locating items of equipment inside a block and then for the location of the block. The pipework is then added and costed. Such a method has been described by Shocair (1978).

A third type of code deals with the analysis of layouts to obtain an economic optimum. Typical factors taken into account in such programs include the costs of piping, space and buildings. A program of this type has been described by Gunn (1970).

The extent to which computer aids are used in the design of plant layout is not great, but some visualization packages are very powerful and are likely to find increasing application. Computer techniques for plant layout are described in more detail in Chapter 29.

10.5 Layout Planning and Development

10.5.1 Layout activities and stages

Plant layout is usually divided into the following activities:

(1) site layout;
(2) plot layout;
(3) equipment layout.

The layout developed typically goes through three stages:

(1) Stage One layout;
(2) Stage Two layout;
(3) Final layout.

The sequence of layout development described by Mecklenburgh is:

(1) Stage One plot layout;
(2) Stage One site layout;
(3) Stage Two site layout;
(4) Stage Two plot layout.

Typical stages in the development of a plant layout are given in Table 10.3. The Stage Two and Final Stage design network is shown in simplified form in Figure 10.1. The process of layout development makes considerable use of guidelines for separation distances. These are described in Section 10.11

Table 10.3 Typical stages in the development of a plant layout (after Mecklenburgh, 1985) (Courtesy of the Institution of Chemical Engineers)

C	**Stage Two site layout**
16	Stage Two site data
17	Stage Two site layout
D	**Stage Two plot layout**
18	Stage Two plot layout data
19	Stage Two plot layout

Stage One is the preliminary layout, also known as the conceptual, definition, proposal or front end layout. In this stage consideration is given to the various factors which are important in the layout, which may threaten the viability of the project if they are not satisfactorily resolved and which are relevant to site selection.

10.5.2 Stage One plot layout

In the Stage One plot layout, the information available should include preliminary flow sheets showing the major items of equipment and major pipework, with an indication of equipment elevations, and process engineering designs for the equipment. The plot layouts are then developed following the process flow principle and using guidance on preliminary separation distances. The plot size generally recommended is 100 m × 200 m with plots separated from each other by roads 15 m wide.

For each plot layout the elevation and plan are further developed. The proposed elevation layouts are subjected to a review such as critical examination which generates alternatives, and these alternatives are costed. Similarly, alternative plan layouts are generated accommodating the main items of equipment, pipework, buildings and cable runs, and are reviewed to ensure that they meet the principal constraints. These include construction, operation, maintenance, safety, environment and effluents. The plan layouts are then costed. The justification for the use of buildings is examined. The civil engineering aspects are then considered, including foundations and support and access structures.

The outcome of this process for each plot is a set of candidate layouts. These are then presented for view as layout models in block model or computer graphics form. The different disciplines can then be invited to comment. These plot layouts are then costed again and a short list is selected, preferably of one.

The plot layouts are then subjected to hazard assessment. This assessment is concerned largely with the smaller, more frequent leaks which may occur and with sources of ignition for such leaks. The process of hazardous area classification is also performed. Hazard assessment and hazardous area classification are described in Sections 10.12 and 10.13.

Studies are carried out to firm up on piping and piping routes and on electrical mains routes. Finally, each plot layout is subjected to a critical examination, typically using a model and following a checklist.

10.5.3 Stage One site layout

The Stage One plot layouts provide the information necessary for the Stage One site layout. These include the size and shape of each plot, the desirable separation distances, the access requirements and traffic characteristics. The flow of materials and utilities on the site are represented in the form of site flowsheets.

The site layout is now developed to accommodate not only the process plots but also storage and terminals, utilities, process and control buildings, non-process buildings and car parks, and the road and rail systems. The flow principle is again followed in laying out the plots, but may need to be modified to meet constraints. Guidance is available on separation distances for this preliminary site layout.

Hazard assessment is then performed on the site layout with particular reference to escalation of incidents and to

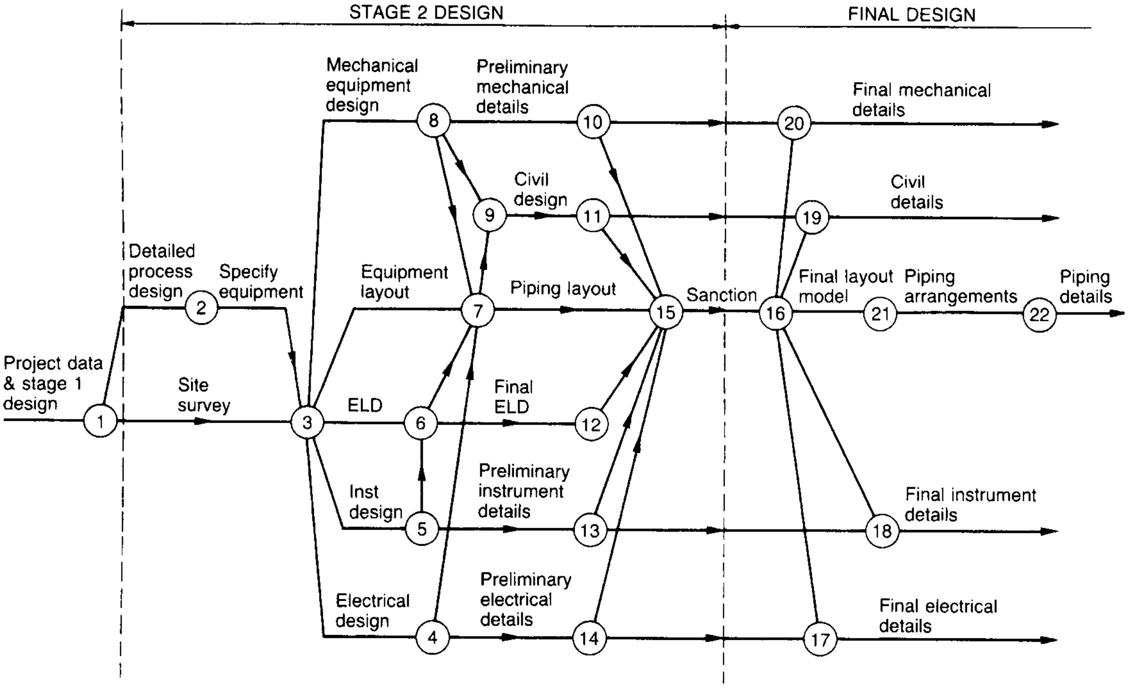

Figure 10.1 *Simplified Stage Two and Final Stage design network (Mecklenburgh, 1985). ELD (Courtesy of the Institution of Chemical Engineers) engineering line diagram*

vulnerable features such as service buildings and buildings just over the site boundary.

If alternative site layouts have been generated, they are then costed and the most economic identified. The site layout is then subjected to a critical examination. If there is a choice of site, the selection is made at this point.

10.5.4 Stage Two site layout

Stage Two layout is the secondary, intermediate or sanction layout. As the latter term implies, it is carried out to provide a layout which is sufficiently detailed for sanction purposes. It starts with the site layout and then proceeds to the layout.

At this stage information on the specific characteristics of the site is brought to bear, such as the legal requirements, the soil and drainage, the meteorological conditions, the environs, the environmental aspects and the services. Site standards are set for building lines and finishes, service corridors, pipetracks and roads.

Stage Two layout involves reworking the Stage One site layout in more detail and for the specific site, and repeating the hazard assessment, economic optimization and critical examination.

Features of the specific site which may well influence this stage are: planning matters; environmental aspects; neighbouring plants, which may constitute hazards and/or targets; other targets such as public buildings; and road, rail and service access points.

At this stage, there should be full consultation with the various regulatory authorities, insurers and emergency services, including the police and fire services.

A final site plan is drawn up in the form of drawings and models, both physical and computer-based ones, showing in particular the layout of the plots within the site, the main buildings and roads, railways, service corridors, pipetracks and drainage.

10.5.5 Stage Two plot layout

There then follows the Stage Two plot layout. The information available for this phase includes (1) standards, (2) site data, (3) Stage Two site layout, (4) process engineering design and (5) Stage One plot layout. The standards include international and national standards and codes of practice, company standards and contractor standards. The process engineering design data include the flowsheets, flow diagrams, equipment lists and drawings, process design data sheets and pipework line lists.

The Stage Two plot layout involves reworking in more detail and subject to the site constraints the plot plans and layouts and repeating the hazard assessment, piping layout and critical examination. The reworking of the plot layout, which occurs at node 7 in Figure 10.1, is a critical phase, requiring good coordination between the various disciplines.

10.6 Site Layout Features

10.6.1 Site constraints and standards

Once a site has been selected the next step is to establish the site constraints and standards. The constraints include:

(1) topography and geology;
(2) weather;
(3) environment;
(4) transport;
(5) services;
(6) legal constraints.

Topographical and geological features are those such as the lie of the land and its load-bearing capabilities. Weather includes temperatures, wind conditions, solar radiation, and thunderstorms. Environment covers people, activities and buildings in the vicinity. Services are power, water and effluents. Legal constraints include planning and building, effluent and pollution, traffic, fire and other safety laws, bylaws and regulations.

Site standards should also be established covering such matters as:

(1) separation distances;
(2) building lines;
(3) building construction, finish;
(4) road dimensions;
(5) service corridors;
(6) pipebridges.

Road dimensions include width, radius and gradient.

10.6.2 Site services

The site central services such as the boiler house, power station, switch station, pumping stations, etc., should be placed in suitable locations. This means that they should not be put out of action by such events as fire or flood and, if possible, not by other accidents such as explosion, and that they should not constitute sources of ignition for flammables.

Electrical substations, pumping stations, etc., should be located in areas where non-flameproof equipment can be used, except where they are an integral part of the plant.

Factors in siting the boiler house are that it should not constitute a source of ignition, that emissions from the stack should not give rise to nuisance and that there should be ready access for fuel supplies.

10.6.3 Use of buildings

Some or part of the plants may need to be located inside a building, but the use of a building is always expensive and it can create hazards and needs to be justified. Typically, a building is used where the process, the plant, the materials processed and/or the associated activities are sensitive to exposure. Thus the process may need a stable environment not subject to extremes of heat or cold or it may need to be sterile. The plant may contain vulnerable items such as high-speed or precision machinery. The process material may need to be protected against contamination or damage, including rain. The activities which the operators have to undertake may be delicate or skilled, or simply very frequent. Thus, a building may be used to encourage more frequent inspection of the plant. Similarly, there may be maintenance activities which are delicate or skilled or simply frequent. In some cases where there are high elevations, an indoor structure may be, or may feel, safer. The need to satisfy customers of the product and to keep unsightly plant out of view are other reasons. Examples of the use of buildings are the housing of batch reactors, centrifuges and analysis instruments.

Since ventilation in a building is generally less than that outdoors, a leak of flammable or toxic material tends to disperse more slowly and a hazardous concentration is more likely to build up. Moreover, if an explosion of a flammable gas or dust occurs the overpressure generated tends to be much higher. These are major disadvantages of the use of a building.

10.6.4 Location of buildings

Buildings which are the work base for a number of people should be located so as to limit their exposure to hazards.

Analytical laboratories should be in a safe area, but otherwise as close as possible to the plants served. So should workshops and general stores. The latter also require ready access for stores materials.

Administration buildings should be situated in a safe area on the public side of the security point. The main office block should always be near the main entrance and other administration buildings should be near this entrance if possible. Other buildings, such as medical centres, canteens, etc., should also be in a safe area and the latter should have ready access for food supplies.

All buildings should be upwind of plants which may give rise to objectionable features.

Water drift from cooling towers can restrict visibility and cause corrosion or ice formation on plants or transport routes, and towers should be sited to minimize this. Another problem is recycling of air from the discharge of one tower to the suction of another, which is countered by placing towers cross-wise to the prevailing wind. The entrainment of effluents from stacks and of corrosive vapours from plants into the cooling towers should be avoided, as should the siting of buildings near the tower intakes. The positioning of natural draught cooling towers should also take into account resonance caused by wind between the towers. The problem of air recirculation should also be borne in mind in siting air-cooled heat exchangers.

10.6.5 Limitation of exposure

An aspect of segregation which is of particular importance is the limitation of exposure of people to the hazards. The measures required to effect such limitation are location of the workbase outside, and control of entry to the high hazard zone. The contribution of plant layout to limitation of exposure, therefore, lies largely in work-base location. Limitation of exposure is considered more fully in Chapter 20.

10.6.6 Segregation

Although a layout which is economical in respect of land, piping and transport is in general desirable, in process plants it is usually necessary to provide some additional space and to practise a degree of segregation. The site layout should aim to contain an accident at source, to prevent escalation and avoid hazarding vulnerable targets. A block layout is appropriate with each plot containing similar and compatible types of hazard and with different types segregated in separate plots.

10.6.7 Fire containment

The site layout should contribute to the containment of any fire which may occur and to combating the fire.

Features of the site layout relevant to fire hazard are illustrated in Figures 10.2 and 10.3 (Simpson, 1971). Figure 10.2 shows a compact layout, which minimizes land usage and pipework, for a petrochemical plant consisting of a major process with several stages and a number of subsidiary processes. There are two main process areas and at right angles to these is an area with a row of fired heaters, and associated reactors, steam boilers and a stack.

This layout has several weaknesses. The lack of firebreaks in the main process blocks would allow a fire to propagate right along these, particularly if the wind is

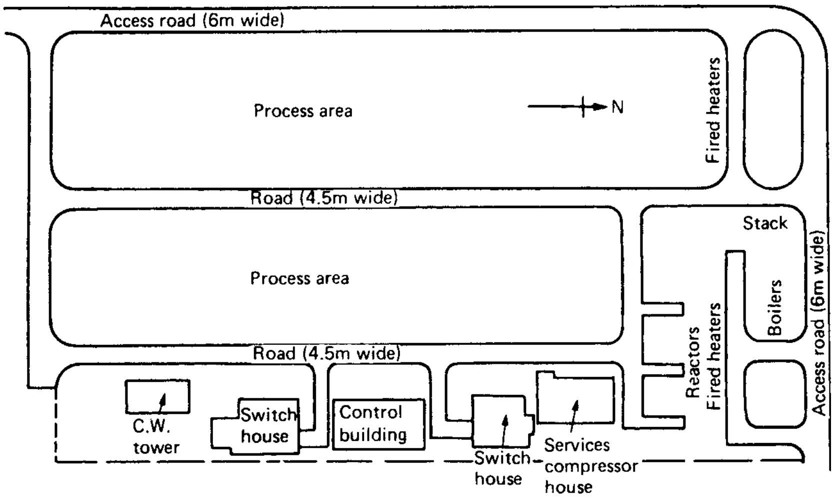

Figure 10.2 *Compact block layout system in the process area of a petrochemical plant with 4.5 m roads (Simpson, 1971) (Courtesy of the Institution of Chemical Engineers)*

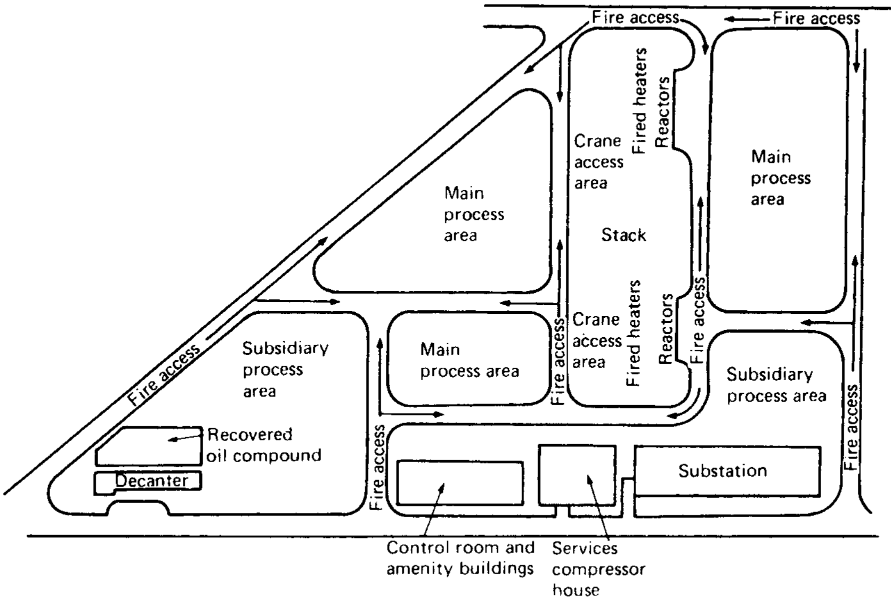

Figure 10.3 *Block layout system in the process area of a petrochemical plant with 6 m roads (Simpson, 1971) (Courtesy of the Institution of Chemical Engineers)*

blowing along them, which, on the site considered it does for 13% of the year. There is entry to the plant area from the 6 m roads from opposite corners, which allows for all wind directions. But the only access for vehicles to the process plots is the 4.5 m roads. In the case of a major fire, appliances might well get trapped by an escalation of the fire. The 4.5 m roads give a total clearance of about 10 m after allowance for equipment being set back from the road, but this is barely adequate as a firebreak. The layout is also likely to cause difficulties in maintenance work.

The alternative layout shown in Figure 10.3 avoids these problems. The process areas are divided by firebreaks. There are more entry points on the site and dead ends are eliminated. The roads are 6 m wide with an effective clearance of 15 m. The crane access areas provide additional clearances for the fired heaters.

Other aspects of fire protection are described in Section 10.15 and Chapter 16.

10.6.8 Effluents

The site layout must accommodate the systems for handling the effluents – gaseous, liquid and solid – and storm water and fire water. The effluent systems are considered in Section 10.16 and the drain system in Section 10.17.

10.6.9 Transport

It is a prime aim of plant layout to minimize the distances travelled by materials. This is generally achieved by following the flow principle, modified as necessary to minimize hazards.

Access is required to plots for transport of materials and equipment, maintenance operations and emergencies. Works roads should be laid out to provide this to plant plots, ideally on all four sides. Roads should be suitable for the largest vehicles which may have to use them in respect of width, radius, gradient, bridges and pipe-bridges. Recommended dimensions for works roads are given by Mecklenburgh (1973). Road widths of 10 m and 7.5 m are suggested for works' main and side roads, respectively. Standard road signs should be used. A road width of 7.5 m with the addition of free space and/or a pipe trench on the verges may be used to give a separation distance of 15 m between units.

There are various types of traffic in a works, including materials, fuel, wastes, stores, food and personnel. These traffic flows should be estimated and their routes planned. Incompatible types of traffic should be segregated as far as possible.

Road and rail traffic should not go through process areas except to its destination and even then should not violate hazardous area classifications. In this connection, it should be borne in mind that some countries still use open firebox engines. Railway lines should not cross the main entrance and should not box plants in. There should be as few railway crossings, crossroads, right angle bends, dead ends, etc., as possible.

There should be adequate road tanker parking and rail tanker sidings at the unloading and loading terminals, so that vehicles can wait their turn at the loading gantry or weighbridge without causing congestion at entrances, or on works or public roads.

Pedestrian pathways should be provided alongside roads where there are many people and much traffic. Bridges may need to be provided at busy intersections. Car and bus parks and access roads to these should be situated in a safe area and outside security points. The park for nightshift workers should be observable by the gatekeeper. There should be gates sited so that the effect of shift change on outside traffic is minimized.

10.6.10 Emergencies

There should be an emergency plan for the site. This is discussed in detail in Chapter 24. Here consideration is limited to aspects of layout relevant to emergencies.

The first step in emergency planning is to study the scenarios of the potential hazards and of their development. Plant layout diagrams are essential for such studies. Emergency arrangements should include an emergency control centre. This should be a specially designated and signed room in a safe area, accessible from the public roads and with space around it for emergency service vehicles.

Assembly points should also be designated and signed in safe areas at least 100 m from the plants. In some cases, it may be appropriate to build refuge rooms as assembly points. A control room should not be used either as the emergency control centre or as a refuge room.

The maintenance of road access to all points in the site is important in an emergency. The site should have a road round the periphery with access to the public roads at least at two points. The vulnerability of the works road system to blockage should be as low as possible. Data on typical fire services appliance dimensions and weights are given by Mecklenburgh (1985). For several of these the turning circle exceeds 15 m.

Arrangements should be made to safeguard supplies of services such as electricity, water and steam to plants in an emergency. Power cables are particularly vulnerable to fire and, if possible, important equipment should be provided with alternative supplies run through the plant by separate routes.

10.6.11 Security

The site should be provided with a boundary fence and all entrances should have a gatehouse. The number of entrances should be kept to a minimum. If construction work is going on in part of the works, this building site should have its own boundary fence and a separate entrance and gatehouse. If the works boundary fence is used as part of this enclosure, movement between the building site and the works should be through an entrance with its own gatehouse.

10.7 Plot Layout Considerations

Some considerations which bear upon plot layout are:

(1) process considerations;
(2) economic considerations;
(3) construction;
(4) operations;
(5) maintenance;
(6) hazards;
(7) fire fighting;
(8) escape.

10.7.1 Process considerations

Process considerations include some of the relationships already mentioned, such as gravity flow and availability of head for pump suctions, control valves and reflux returns. Under this heading come also limitations of pressure drop in pipes and heat exchangers and across control valves and of temperature drop in pipes, the provision of straight runs for orifice meters, the length of instrument transmission lines and arrangements for manual operations such as dosing with additives, sampling, etc.

10.7.2 Economic considerations

As already mentioned, some features which have a particularly strong influence on costs are foundations, structures, piping and electrical cabling. This creates the incentive to locate items on the ground, to group items so that they can share a foundation or a structure, and to keep pipe and cable runs to a minimum.

10.7.3 Construction

Additional requirements are imposed by the needs of construction and maintenance. The installation of large and heavy plant items requires space and perhaps access for cranes. Such items tend to have long delivery times and may arrive late; the layout may need to take this into account.

Construction work may require an area in which the construction materials and items can be laid out. On large, single-stream plants major items can often be fabricated only on site. There needs to be access to move large items into place on the plant. If the plot is close to the site boundary, it should be checked that there will be space available for cranes and other lifting gear.

10.7.4 Operation

Access and operability are important to plant operation. Mention has already been made of the development of the 3D envelope of the main items of equipment to allow for operation. Hazop studies, described in Chapter 8, may be used to highlight operating difficulties in the layout.

The routine activities performed by the operator should be studied with a view to providing the shortest and most direct routes from the control room to items requiring most frequent attention. Clear routes should be allowed for the operator, avoiding kerbs and other awkward level changes.

General access ways should be 0.7 m and 1.2 m wide for one and two persons, respectively. Routes should be able to carry the maximum load, which often occurs during maintenance.

Stairways rather than ladders should be provided for main access, the latter being reserved for escape routes on outside structures and access to isolated points which are only visited infrequently. Recommended dimensions for stairways are an angle of 35–40° and overall width of 1 m with railings 0.85 m high and clearances 2.1 m. The height of single flights without a landing should not exceed 4.5 m. No workplace should be more than 45 m from an exit.

Ladders should be positioned so that the person using it faces the structure and does not look into space. A ladder should not be attached to supports for hot pipes, since forces can be transmitted which can distort the ladder. Recommended dimensions for ladders are given by appropriate codes.

If plant items require operation or maintenance at elevated levels, platforms should be provided. The levels are defined as 3.5 m above grade for vessels, 2 m above grade for instruments or 2 m above another platform. Platform floors are normally not less than 3 m apart. Headroom under vessels, pipes, cable racks, etc., should be 2.25 m minimum, reducing to 2.1 m vertically over stairways.

Good lighting on the plant is important, particularly on access routes, near hazards and for instrument reading.

Operations involving manipulation of an equipment while observing an indicator should be considered so that the layout permits this. Similarly, it is helpful when operating controls to start or stop equipment to be able to see or hear that the equipment has responded to the signal.

Hand valves need good access, particularly large valves which may require considerable physical effort to turn. Valves which have to be operated in an emergency should be situated so that access is not prevented by the accident through fire or other occurrences. For emergency isolation, however, it may be preferable to install remotely operated isolation valves, as described in Chapter 12.

Batch equipment such as batch reactors, centrifuges, filters and driers, tends to require more manual operation, so that particular attention should be paid to layout for such items.

Insulation is sometimes required on pipework to protect operating and maintenance personnel rather than for process reasons.

10.7.5 Maintenance

Plant items from which the internals need to be removed for maintenance should have the necessary space and lifting arrangements. Examples are tube bundles from heat exchangers, agitators from stirred vessels and spent catalyst from reactors.

10.7.6 Hazards

The hazards on the plant should be identified and allowed for in the plot layout. This is discussed in other sections, but some general comments may be made at this stage.

Plot layout can make a large contribution to safety. It should be designed and checked with an intent to reducing the magnitude and frequency of the hazards and assisting preventive measures. The principle of segregation of hazards applies also to plot layout.

Hazardous areas should be defined. They should not extend beyond the plot boundaries or to railway lines. It is economic to minimize the extent of hazardous areas and to group together in them items which give the same hazard classification.

Plants which may leak flammables should generally be built in the open or, if necessary, in a structure with a roof but no walls. If a closed building cannot be avoided, it should have explosion relief panels in the walls or roof with relief venting to a safe area. Open air construction ventilates plants and disperses flammables but, as already indicated, scenarios of leakage and dispersion should be investigated for the plant concerned.

Fire spread in buildings should be limited by design, as should fire spread on open structures. Sprinklers and other protective systems should be provided as appropriate. A more detailed consideration of fire hazards and precautions is given in Chapter 16.

Plants which may leak toxics should also generally be built in the open air. The hazardous concentrations for toxics are much lower than those for flammables, however, and it cannot be assumed that an open structure is always sufficiently ventilated. A wind of at least 8 km/h is needed to disperse most toxic vapours safely before they reach the next plant. Some toxic plants, however, require a building and in some cases there has to be isolation of the toxic area through the use of connecting rooms in which clothing is changed.

Ventilation is necessary for buildings housing plants processing flammables or toxics. Air inlets should be sited so that they do not draw in contaminated air. The relative position of air inlets and outlets should be such that short circuiting does not occur. Exhaust air may need to be treated before discharge by scrubbing or filtering.

Plants which are liable to leak liquids should stand on impervious ground with suitable slopes to drain spillages away. The equipment should be on raised areas which slope down to valleys and to an appropriate collecting point. Suitable slopes are about 1 in 40 to 1 in 60. Valleys should not coincide with walkways, and kerbs may be needed to keep liquid off these. The collecting points should be away from equipment so that this is less exposed to any fire in the liquid collected. The amount of liquid which may collect should be estimated and the collecting point should be designed to take away this amount. The heat generated if the liquid catches fire should be determined and vulnerable items relocated if necessary.

The use of pervious ground, such as pebbles, to absorb leaks of flammable liquids should be avoided. Such liquid may remain on the water table and may be brought up again by water from fire fighting. Other hazards which are prevalent mainly outside the United Kingdom include earthquakes and severe thunderstorms. These require special measures.

Personal safety should not be overlooked in the plot layout. Measures should be taken to minimize injury due to trips and falls, bumping of the head, exposure to drips of noxious substances and contact with very hot or cold surfaces. Where such hazards exist, they generally present a threat not just on occasion but for the whole time.

10.7.7 Fire fighting

Access is essential for fire fighting. This is provided by the suggested plot size of 100 m × 200 m with approaches preferably on all four sides and by spacing between plots and buildings of 15 m.

Fire water should be available from hydrants on a main between the road and the plant. Hydrant points should be positioned so that any fire on the plot can be reached by the hoses. Hydrant spacings of 48, 65 and 95 m are suitable for high, medium and low risk plots, respectively. Plants over 18 m high should be provided with dry riser mains and those over 60 m high or of high risk should be equipped with wet riser mains. The inlets on the ground floor to dry riser mains and the outlets on all floors to both types of main should be accessible.

Pipes for fire water supply should be protected against explosion damage. Isolation valves should be provided to prevent loss of fire water from damaged lines and, if these valves are above ground level, they should be protected by concrete blast barriers.

Fire extinguishers of the appropriate type and fire blankets should be placed at strategic points. There should be at least two extinguishers at each point. Some extinguishers should be located on escape or access routes, so that a person who decides to fight the fire using the extinguisher has a route behind him for escape. The location of other fire fighting equipment such as sprinklers and foam sprays is a matter for experts.

Fire equipment should be located so that it is not likely to be disabled by the accident itself. It should be accessible and should be conspicuously marked. The main switchgear and emergency controls should have good access, preferably on an escape route, so that the operator does not have to risk his life to effect shut-down.

There are numerous legal requirements concerning fire, fire construction and fire fighting. There should be full consultation on this at an early stage with the works safety officer and with other parties, such as the local authority services, the Factory Inspectorate and the insurers.

10.7.8 Escape

A minimum of two escape routes should be provided for any workspace, except where the fire risk is very small, and the two routes should be genuine alternatives. No workplace should be more than 12–45 m, depending on the degree of risk, from an exit, and a dead end should not exceed 8 m.

Escape routes across open mesh areas should have solid flooring. Escape stairways should be in straight flights. They should preferably be put on the outside of buildings. Fixed ladders may be used for escape from structures if the number of people does not exceed 10. Doors on escape routes should be limited to hinged or sliding types and hinged doors should open in the direction of escape. Handrails should be provided on escape routes across flat roofs. Escape routes should be signposted, if there is any danger of confusion, as in large buildings. They should be at least 0.7 m and preferably 1.2 m wide to allow the passage of 40 persons per minute on the flat and 20 persons per minute down stairways. Good lighting should be provided on escape routes and arrangements made to ensure a power supply in an emergency. The escape times of personnel should be estimated, paying particular attention to people on tall items such as distillation columns or cranes. Bridges between columns may be used.

10.8 Equipment Layout

10.8.1 General considerations

Furnaces and fired heaters are very important. Furnace location is governed by a number of factors, including the location of other furnaces, the use of common facilities such as stacks, the minimization of the length of transfer lines, the disposal of the gaseous and liquid effluents, the potential of the furnace as an ignition source and the fire fighting arrangements. Furnaces should be sited at least 15 m away from plant which could leak flammables.

No trenches or pits which might hold flammables should extend under a furnace, and connections with underground drains should be sealed over an area 12 m from the furnace wall. The working area of the furnace should be provided with ventilation, particularly where high temperatures and high sulfur fuels are involved.

On wall-fired furnaces there should be an escape route at least 1 m wide at each end and on top-fired furnaces there should also be an escape route at each end, one of which should be a stairway. The provision of peepholes and observation doors should be kept to a minimum. Access to these may be by fixed ladder for heights less than 4 m above ground, but platforms should be provided for greater heights.

Incinerators and burning areas for waste disposal should be treated as fired equipment. Waste in burning areas should be lit by remote ignition and, if it is an explosion hazard, blast walls should be provided.

Chemical reactors in which a violent reaction can occur, may need to be segregated by firebreaks or even enclosed behind blast walls.

Heat exchangers should have connecting pipework kept to a minimum, consistent with provision of pipe lengths and bends to allow for pipe stresses and with access for maintenance.

Equipments which have to be opened for cleaning, emptying, charging, etc., may need ventilation.

Driers in which volatile materials are driven off solids will generally need ventilation of the drying area and probably of the drier itself. If the materials are noxious, defraying booths may be necessary.

Dust-handling equipment such as driers, cyclones and ducts may constitute an explosion hazard, but tends to be rather weak. It should be separated from other plant by a wall and vented. Vents should be short and should go through the roof. Some equipment such as cyclones are often placed outside the building and this is preferable to ducting a vent to the outside. Vents should pass to a safe area. Mills are relatively strong and are not usually provided with explosion relief. Dust should be transferred through chokes to prevent the transmission of fire or explosion. Surfaces which might collect dust should be kept to a minimum. Dust hazards are considered further in Chapter 17.

Pumps handling liquids which are hot ($> 60°C$) should be separated from those handling liquids which are flammable and volatile (boiling point $< 40°C$) or from compressors handling flammable gases. In the open, separation may be effected by a spacing of at least 7.5 m and in a pump room by a vapour-tight wall.

Hazards associated with particular plant equipment are also considered in Chapter 11.

10.8.2 Corrosive materials

If the process materials are corrosive, this aspect should be taken into account in the plant layout. The layout of plants for corrosive materials is discussed in Safety and Management by the Association of British Chemical Manufacturers (ABCM, 1964/3).

Corrosive materials are responsible for an appreciable proportion of accidents on chemical plants and of damage done to the plant. The presence of corrosive materials creates two particular hazards: (1) corrosion of materials of construction, and (2) contact of persons with corrosive materials. On a plant handling corrosive chemicals, the materials of construction should be chosen with particular care, should be protected by regular painting and should be checked by regular inspection.

Some features of plant layout which are particularly important in relation to corrosive chemicals are foundations, floors, walkways, staging, stairs, handrails, drains, ventilation.

Foundations of both buildings and machines, especially those constructed in concrete, may be attacked by leakage of corrosive materials, including leakage from drains. If the corrosion is expected to be mild, it may be allowed for by the use of additional thickness of concrete, but if it may be more severe, other measures are necessary. These include the use of corrosion resistant asphalt, bricks and plastics.

Floors should be sloped so that spillages are drained away from vulnerable equipment and from walkways and traffic lanes. The latter should generally be laid across the direction of fall and should, as far as possible, be at the high points of the slopes.

Severe corrosion of steel stanchions can occur between a concrete subfloor and a brick floor surface, and this possibility should be considered.

Pipe flanges which may drip corrosive substances should not be located over walkways. There should be guardrails around vessels or pits containing corrosive liquids. The floors and walkways should be of the 'non-skid' type.

Staging should not be located over an open vessel which may emit corrosive vapours.

Staircases and handrails should be designed to minimize corrosion. Stairheads should be located at the high points of sloping floors. Handrails tend to corrode internally and may collapse suddenly. They should be made of a suitable material. Aluminium is suitable, if it is not corroded by the atmosphere of the plant. Metal protectors of the vapour type are also available. These are put inside the pipe and the ends sealed. Alternatively, solid rails can be used. The rails should be protected against external corrosion by regular painting or other means. Regular inspection and maintenance is particularly important for staging, staircases and handrails on plants containing corrosive materials.

Drains should be designed to handle the corrosive materials, and mixtures of materials, which may be discharged into them.

Ventilation should be provided and maintained as appropriate. This requires as a minimum the circulation of fresh air. It may also involve local exhaust ventilation.

10.9 Pipework Layout

In general, it is desirable both for economic and safety reasons to keep the pipe runs to a minimum. Additional pipework costs more both in capital and operation, the latter through factors such as heat loss/gain and pumping costs. It is also an extra hazard not only from the pipe itself but more particularly from the joints and fittings.

The application of the flow principle is effective in minimizing pipe runs, but it is also necessary to practise segregation and this will sometimes lead to an unavoidable increase in the length of pipe runs. The design, therefore, involves a compromise between these two factors.

Piping for fluids servicing a number of points may be in the form of a ring main, which permits supply to most points, even if part of the main is disabled. Ring mains are used for steam, cooling water, process water, fire water, process air, instrument air, nitrogen and even chlorine.

Services such as steam and water mains and electricity and telephone cables should generally be run alongside the road and should not pass through plant or service areas.

Pipes may be buried, run at ground level, run on supports or laid in an open pipe trench. Open pipe trenches may be used where there is no risk of accumulation of flammable vapours, of the material freezing or of flooding.

Water mains should be buried below the frost line or to a minimum depth of 0.75 m to avoid freezing. If they run under roads or concreted areas, they should be laid in ducts or solidly encased in concrete.

Steam mains may be laid on the surface on sleepers. They should be run on the outside edge of the pipeway to allow the expansion loops to have the greatest width and to facilitate nesting of the loops. Steam mains may also be run in open pipe trenches.

Electrical power and telephone cables should be run in sand-filled trenches covered by concrete tiles or a coloured concrete mix. If possible, the cables should be run at the high point of paving leaving room for draw boxes. If use is made of underground piping and cabling, it should be put in position at the same time as the foundation work is being done. Alternatively, cables can be run overhead. Overhead cables are less affected by spillages and are easier to extend, but may require fire protection.

Electrical lines can give rise to fields of sufficient intensity to cause local overheating of adjacent metalwork or to induce static electricity in plant nearby, and this should be taken into account in positioning them. Pipes which are hot or carry solvents should be laid as far as possible from electrical cables.

Piping may be run as a double layer, but triple layers should be avoided. Double layer piping should be run with service lines on the upper and process lines on the lower deck.

Piping may require a continuous slope to permit complete drainage for process, corrosion or safety reasons;

other pipes should not be sloped. Sloped lines should be supported on extensions of the steel structure. The slope arrangement should not create a low point from which liquid cannot be drained.

Overhead clearances below the underside of the pipe, flange, lagging or support should have the following minimum values:

Above roads and areas with access for crane	7 m
Plant areas where truck access is required	4 m
Plant areas in general	3 m
Above access floors and walkways within buildings	2.25 m
Above railway lines (from top of rail)	4.6 m

Pipe flanges should be positioned so as to minimize the hazards from small leaks and drips. Flanges on pipework crossing roads on pipebridges should be avoided. Pipebridges over roads should be as few as possible. Every precaution should be taken to prevent damage from vehicles, particularly cranes and forklift trucks.

Attention should be paid to the compatibility of adjacent pipework, the cardinal principle being to avoid loss of containment of hazardous materials. Thus, it is undesirable, for example, to put a pipe carrying corrosive material above one carrying flammables or toxics at high pressure.

Emergency isolation valves should be used to allow flows of flammable materials to be shut off. Valves may be manually or power operated and controls for the latter may be sited locally or remotely. The use of such valves is described in more detail in Chapter 12.

If a manual valve is used for isolation, it should be mounted in an accessible position. Emergency operation of valves from ladders should be avoided. If the valve is horizontally mounted and its spindle is more than 2.1 m above the operating level, a chain wheel should be provided. A valve should not be mounted in the inverted position, since solids may deposit in the gland and cause seizure.

Discharges from pressure relief valves and bursting discs are normally piped away in a closed system. In particular, a closed system is necessary for hydrocarbon vapours with a molecular weight greater than 60, flammable liquids and toxic vapours and liquids. Pressure relief and flare systems are considered more fully in Chapter 12.

Liquid drains from drainage should also be taken to a safe point. Liquids which are not flammable or toxic may be discharged to grade.

Sample points should be 1 m above the floor and not at eye level.

Flexible piping should be kept to a minimum. Where such piping is used on vehicles, use may be made of devices which shut off flow if the vehicle moves away.

Instruments incorporating glass tubing, such as sight glasses and rotameters, are a source of weakness. In some cases the policy is adopted of avoiding the use of such devices altogether. If this type of instrument is used, however, it should be enclosed in a transparent protective case.

The layout for piping and cabling should allow for future plant expansion. An allowance for 30% additional pipework is typical. Full documentation should be kept on all piping and cabling.

10.10 Storage Layout

Treatments of plant layout frequently cover all aspects of storage, including bunding, venting, etc. In this book, storage is dealt with separately in Chapter 22, and only those features which are directly relevant to the layout of the plant as a whole are dealt with at this point.

The principal kinds of storage are bulk storage of fluids, bulk storage of solids and warehouse storage. The storage of main interest in the present context is storage of fluids, particularly flammable fluids. The types of storage include:

(1) liquid at atmospheric pressure and temperature;
(2) liquefied gas under pressure and at atmospheric temperature (pressure storage);
(3) liquefied gas at atmospheric pressure and at low temperature (refrigerated storage);
(4) gas under pressure.

There are also intermediate types such as semi-refrigerated storage.

For liquid storage it is common to segregate the liquids stored according to their class. The current classification, given in the *Refining Safety Code* of the Institute of Petroleum (IP, 1981 MCSP Part 3) and used in BS 5908 : 1990, is

Class I	Liquids with flashpoint below 21°C
Class II (1)	Liquids with flashpoint from 21°C up to and including 55°C, handled below flashpoint
Class II (2)	Liquids with flashpoint from 21°C up to and including 55°C, handled at or above flashpoint
Class III (1)	Liquids with flashpoint above 55°C up to and including 100°C, handled below flashpoint
Class III (2)	Liquids with flashpoint above 55°C up to and including 100°C, handled at or above flashpoint

An earlier classification, given in the former BS CP 3013: 1974, was as follows:

Class A	Liquids with flashpoint below 22.8°C (73°F)
Class B	Liquids with flashpoint between 22.8 and 66°C (73 and 150°F)
Class C	Liquid with flashpoint above 66°C (150°F)

The classification given in the National Fire Protection Association's (NFPA 321: 1987) *Basic Classification of Flammable and Combustible Liquids* is:

Class I	Liquids with flashpoint below 37.8°C (100°F)
Class IA	Liquids with flashpoint below 22.8°C (73°F) and boiling point below 37.8°C (100°F)
Class IB	Liquids with flashpoint below 22.8°C (73°F) and boiling point at or above 37.8°C (100°F)
Class 1C	Liquids with flashpoint at or above 22.8°C (73°F) and below 37.8°C (100°F)
Class II	Liquids with flashpoint at or above 37.8°C (100°F) and below 60°C (140°F)
Class III	Liquids with flashpoint at or above 60°C (140°F)
Class IIIA	Liquids with flashpoint at or above 60°C (140°F) and below 93.4°C (200°F)
Class IIIB	Liquids with flashpoint at or above 93.4°C (200°F)

NFPA 321 distinguishes between flammable and combustible liquids. It defines a flammable liquid as one having a flashpoint below 37.8°C (100°F) and having a vapour pressure not exceeding 40 psia at 37.8°C (100°F), and a combustible liquid as one having a flashpoint at/or above 37.8°C (100°F).

Quantities in storage are almost invariably much greater than those in process. Typical orders of magnitude for a large plant are several hundred tonnes in process and ten thousand tonnes in storage.

Storage is usually built in the open, since this is cheaper and allows dispersion of leaks. The site chosen should have good load-bearing characteristics, since tanks or vessels full of liquid represent a very heavy load. The design of foundations for storage tanks is a specialist matter.

The storage site should be such that the contour of the ground does not allow flammable liquid or heavy vapour to collect in a depression or to flow down to an area where it may find an ignition source. The prevailing wind should be considered in relation to the spread of flammables to ignition sources or of toxics to the site boundary.

Storage should be segregated from process. A fire or explosion in the latter may put at risk the very large inventory in storage, and a small fire in storage, which is otherwise easily dealt with, may jeopardize the process. The storage area should be placed on one or at most on two sides of the process and well away from it. This gives segregation and allows room for expansion of the process and/or the storage. The separation distance between process and storage has been discussed above. It should not be less than 15 m.

It is also necessary to keep terminals away from the process, since they are sources of accidents. A suitable layout is therefore to interpose the storage between the process and the terminals. The separation distance between storage and terminals should be not less than 15 m.

The storage tanks should be arranged in groups. The grouping should be such as to allow common bunding, if bunds are appropriate, and common fire fighting equipment for each group. There should be access on all four sides of each bund area and roads should be linked to minimize the effect if one road is cut off during a fire.

It is not essential that there be only one storage area, one unloading terminal or one loading terminal. There may well be several, depending on the materials and process, and the principle of segregation. The raw material unloading and the product loading terminals should be separate. Normally, both should be at the site boundary near the entrance. If the materials are hazardous or noxious, however, the terminal should not be near the entrance, although it may be near the site boundary, provided it does not affect a neighbour's installation.

10.11 Separation Distances

Plant layout is largely constrained by the need to observe minimum separation distances. For hazards, there are basically three approaches to determining a suitable separation distance. The first and most traditional one is to use standard distances developed by the industry. The second is to apply a ranking method to decide the separation required. The third is to estimate a suitable separation based on an engineering calculation for the particular case. Not all separation distances relate to hazards. Construction, access and maintenance are other relevant factors. The first two methods of determining separation distances are considered in this section, and the third is considered in Section 10.14.

10.11.1 Types of separation

The types of separation which need to be taken into consideration are illustrated by the set of tables of separation distances given by Mecklenburgh (1985) and include:

(1) site areas and sizes;
(2) preliminary spacing for equipment
    (a) spacing between equipment,
    (b) access requirements at equipment,
    (c) minimum clearances at equipment;
(3) preliminary spacings for storage layout
    (a) tank farms,
    (b) petroleum products,
    (c) liquefied flammable gas,
    (d) liquid oxygen;
(4) preliminary distances for electrical area classification;
(5) size of storage piles.

Further types of separation used by D.J. Lewis (1980b) are given in Section 10.11.4.

10.11.2 Standard distances

There are a large number of standards, codes of practice and other publications which give minimum safe separation distances. The guidance available relates mainly to separation distances for storage, either of petroleum products, of flammable liquids, of liquefied petroleum gas (LPG) or of liquefied flammable gas (LFG).

Recommendations for separation distances are given in: for petroleum products, *The Storage of Flammable Liquids in Fixed Tanks Exceeding 10,000 m^3 Total Capacity* (HSE, 1991 HS(G) 52), the *Refining Safety Code* (IP, 1981 MCSP Pt 3), the American Petroleum Institute (API) standards API Std 620: 1990 and API Std 650: 1988 and NFPA 30: 1990 *Flammable and Combustible Liquids Code*; for LPG, in *The Storage of LPG at Fixed Installations* by the HSE (1987 HS(G) 34), *Liquefied Petroleum Gas* by the IP (1987 MCSP Pt 9), the *Code of Practice, Part 1, Installation and Maintenance of Fixed Bulk LPG Storage at Consumers' Premises* by the Liquefied Petroleum Gas Industry Technical Association (LPGITA) (1991 LPG Code 1 Pt 1), API Std 2510: 1989 and 2510A: 1989 and NFPA 58: 1989 *Storage and Handling of Liquefied Petroleum Gases*; and for LFG, the ICI *Liquefied Flammable Gases, Storage and Handling Code* (the ICI LFG Code) (ICI/RoSPA 1970 IS/74). Another relevant code is BS 5908: 1990 *Fire Precautions in the Chemical and Allied Industries*. Separation distances are also given in many of the NFPA codes.

Further guidance on separation distances and clearances is given by Armistead (1959), House (1969), the Oil Insurance Association (OIA) (1972/6), Backhurst and Harker (1973), Mecklenburgh (1973, 1985), Kaura (1980b), F.V. Anderson (1982) and Industrial Risk Insurers (IRI) (1991, 1992).

Separation distances are specified in the *Fire and Explosion Index. Hazard Classification Guide* (*the Dow Guide*) (Dow Chemical Company, 1976) as a function of the Fire and Explosion Index (F&EI) and the maximum probable property damage (MPPD). These do not appear as such in the current edition of the *Guide* (Dow Chemical Company, 1994b), which is described in Chapter 8. Some tables of separation distances for storage of flammable liquids, for LPG and for LFG are reproduced in Chapter 22.

Separation distances for process units are usually given as the distances between two units or as the distance between a single unit and an ignition source. It is normal to quote distances between the edges of units and not centre to centre. There is generally little explanation given of the basis of the separation distances recommended.

The separation distances for liquids which have a lower vapour pressure, including the bulk of petroleum products and flammable liquids, tend to be less than those for liquids which have a high vapour pressure and so flash off readily, such as LPG and LFG. It is frequently stated that for LPG a smaller separation distance may be allowed if there is provision of adequate radiation walls and/or water drench systems.

There is naturally some tendency for separation distances to be reproduced from one publication to another. In general, however, there are differences between the various codes and guidelines, so that the overall situation is rather confused. This problem has been discussed by Simpson (1971).

Typical separation distances for preliminary site layouts are given by Mecklenburgh (1985). The table of spacings which he gives is shown in Table 10.4. Some interunit and interequipment separation distances given by IRI (1991, 1992) are shown in Table 10.5.

10.11.3 Rating and ranking methods

An alternative to the use of standard separation distances is the utilization of some form of rating or ranking method. The most widely applied method of this kind is that used in hazardous area classification. This method ranks items by their leak potential. An outline of the method is given in Section 10.12. Another such method is the Mond Index, which is now described.

10.11.4 Mond Index

The Mond Index is one of the hazard indices described in Chapter 8. A particular application of this index is the determination of separation distances as described by D.J. Lewis (1980b, 1989b). In the Mond Index method two values are calculated for the overall risk rating (ORR), those before and after allowance is made for offsetting factors. It is the latter rating R_2 which is used in applying the technique to plant layout. The ORR assigns categories ranging from mild to very extreme.

(1) Flare spacing should be based on heat intensity with a minimum space of 60 m from equipment containing hydrocarbons.
(2) The minimum spacings can be down to one-quarter these typical spacings when properly assessed.

The objectives of layout are: to minimize risk to personnel; to minimize escalation, both within the plant and to adjacent plants; to ensure adequate access for fire fighting and rescue; and to allow flexibility in combining together units of similar hazard potential.

Lewis enumerates the basic concepts underlying the initial layout. In addition to general layout principles, he includes several applications of the ORR. Control and other occupied buildings should be adjacent to low or medium risk units, the latter being acceptable only if a low risk unit is not available and if the R_2 value is just inside the medium risk band. Units with the highest value of the aerial explosion index A_2 should not be located near to the plant boundary but should be separated by areas occupied by low risk activities and with low population densities (up to 25 person/acre). Major pipebridges with medium to high R_2 should be located to reduce their vulnerability to incidents from tall process units and from transport accidents arising from normal vehicle traffic.

Units separately assessed can be combined into a single unit, providing that the hazards are compatible and the risks similar, the potential direct and consequential losses do not become excessive and the reassessed R_2 value is acceptable.

The initial layout is based on a nominal interunit spacing of 10 m. It includes pipebridges and vehicle routes. The nominal interunit distances are then replaced by those established by engineering considerations, including the use of guidance on minimum separation distances and of the ORR.

Lewis states that the minimum separation distances given in the relevant codes are absolute minimum distances and are not necessarily good practice for new installations. Some situations for which separation distances are required are given by Lewis as follows:

(1) distances between a unit of a particular degree of hazard and
    (a) another unit of the same degree,
    (b) another unit of lower or higher degree;
(2) distances between a process unit and
    (a) a storage unit,
    (b) the bund of a storage unit;
(3) distances between adjacent storage units containing materials of different flammability;
(4) distances between a unit and
    (a) occupied buildings,
    (b) potential ignition sources,
    (c) a plant boundary,
    (d) the works boundary.

For units, the relevant distance for the determination of separation is taken as that between the nearest wall, structural frame or free-standing equipment of the two units.

Separation distances for pipebridges receive particular attention. For a pipebridge between two units, the separation distance is between one side of the pipebridge and the adjacent unit. The distance should not include the plan area occupied by the pipebridge itself, but it is not normally necessary to provide two separation distances, one on each side of the pipebridge. A pipebridge which itself has significant potential for a hazardous release should not be located alongside a unit without a separation distance unless assessment shows that the hazard level of the combination of unit and pipebridge is acceptable. If it is not, there should be a separation between the pipebridge and all units, using the pipebridge separation distances given.

The spacings for storage units given in the initial treatment (D.J. Lewis, 1980b) were subsequently revised (D.J. Lewis, 1989b). The principal changes are considerable increases in separation distances for the extreme and very extreme values of R_2, exclusion of units which have potential for 'frothover' or for 'boilover' in a fire, and restriction to units which are on level ground.

The recommendations for separation distances for process units are shown in Table 10.6 and those for storage units in Tables 10.7 and 10.8. D.J. Lewis (1989b) gives further

Table 10.4 *Preliminary areas and spacings for site layout (Mecklenburgh, 1985) (Courtesy of the Institution of Chemical Engineers)*

Administration	10 m^2	per administration employee
Workshop	20 m^2	per workshop employee
Laboratory	20 m^2	per laboratory employee

recommendations for dealing with storage units with frothover or boilover potential and with units located on sloping ground.

10.11.5 Hazard models

Another approach to the determination of separation distances is to use hazard models to determine the separation distance at which the concentration from a vapour escape or the thermal radiation from a fire fall to an acceptable level. This is the other side of the coin to hazard assessment of a proposed layout. Early accounts of the use of hazard models to determine separation distances include those of Hearfleld (1970) and Simpson (1971).

Two principal factors considered as determining separation are (1) heat from burning liquid and (2) ignition of a vapour escape.

Table 10.6 *Separation distances for process units: spacings between process units and other features obtained using the Mond Index (D.J. Lewis, 1980b) (Courtesy of the American Institute of Chemical Engineers)*

Permissible heat fluxes are discussed by Simpson, who distinguishes three levels of heat flux: 12.5 kW/m^2 (4000 BHU/ft^2h), 4.7 kW/m^2 (1500 BTU/ft^2h) and 1.6 kW/m^2 (500 BTU/ft^2h). The first value is the limit given in the Building Regulations 1965 and is suggested as a suitable limit for buildings such as control rooms or workshops; the second is the threshold of pain after a short time and is suggested as the limit for workers out on the plant who must continue doing essential tasks; and the third is the level of minor discomfort and is suggested as the limit for people in adjoining areas. A more detailed discussion of thermal radiation criteria is given in Chapter 16.

Simpson also considers separation distances based on the dilution of a vapour leak to a concentration below the lower flammability limit. The estimates are based on calculations of leak emission flows, pool vaporization rate and vapour cloud dispersion, as described in Chapter 15. One problem which he discusses is the separation between storage and an ignition source for petroleum spirit and other flammable liquids of similar volatility. For this case, he concludes that in most instances a separation distance of 15 m is adequate.

Another problem is the separation distance between a petrochemical unit and an ignition source. The typical scenarios which he discusses give separation distances as high as 88 m, this being for a necked-off branch on a C_2 fractionator.

A further discussion of the basis for separation distances has been given by R.B. Robertson (1976b).

The principle of the use of hazard models to set separation distances is now recognized in codes. *Liquefied Petroleum Gas* (IP, 1987 MCSP Part 9) gives separation distances for liquid storage units based on hazard models, as described in Section 10.14.

10.11.6 Liquefied flammable gas

A separation distance of 15 m frequently occurs in codes for the storage of petroleum products, excluding LPG. For LPG and LFG, the separation distances are generally greater. Thus in the ICI *LFG Code* the separation distances recommended between a storage and an ignition source are, for ethylene, 60 m for pressure storage and 90 m for refrigerated storage, and for C_3 compounds, 45 m for both types of storage. The general approach there taken is that there is significant risk of failure for a refrigerated storage but negligible risk for a pressure storage vessel.

Separation distances are also implied in the ICI *Electrical Installations in Flammable Atmospheres Code* (the *ICI Electrical Installations Code*) (ICI/RoSPA 1972 IS/91) in that the code gives guidance on the radius of the electrical area classification zone from potential leak points. For a pump with a mechanical seal containing a flammable liquid with

≤100	6
100–200	20
>200	30

10.12 Hazardous Area Classification

Plant layout has a major role to play in preventing the ignition of any flammable release which may occur. This aspect of layout is known as 'area classification'. One principal type of ignition source is electric motors, and area classification has its origins in the need to specify motors with different degrees of safeguard against ignition. As such, the practice was known as 'electrical area classification' and was usually performed by electrical engineers. The extension of this practice to cover the exclusion of all sources of ignitions is known as 'hazardous area classification' and is generally performed by chemical engineers.

Hazardous area classification is dealt with in BS 5345: 1977 *Code of Practice for the Selection, Installation and Maintenance of Electrical Apparatus for Use in Potentially Explosive Atmospheres (Other than Mining Applications or Explosive Processing and Manufacture)*, and in a number of industry codes, including the *Area Classification Code for Petroleum Installations* (IP, 1990 MCSP Pt 15).

The process of hazardous area classification involves assigning areas of the site to one of four categories. The international definition of these by the International Electrotechnical Commission (IEC), given in BS 5345: 1977, is:

Zone 0 A zone in which a flammable atmosphere is continuously present or present for long periods.

Table 10.8 *Separation distances for process units: spacings between storage units and other features obtained using the Mond Index (D.J. Lewis, 1989b) (Courtesy of the Norwegian Society of Chartered Engineers)*

Very extreme	65	45	20	40	32	$H + 28$

[a] In the case of a buried tank, the tank wall distance is measured to the position on the plan of the tank wall or other items not more than 10 m below ground level.

[b] In the case of a flare stack, the distances is a function of the flare stack tip height *H*, as shown in the last column.

Zone 1 A zone in which a flammable atmosphere is likely to occur for short period in normal operation.
Zone 2 A zone in which a flammable atmosphere is not likely to occur in normal operation and if it occurs only exist for a short time.

A non-hazardous area is an area not classified as Zone 0, 1 or 2. In the United Kingdom, this classification system replaces an earlier system based on three Divisions: 0, 1 and 2.

In the United States of America, hazardous area classification is covered in Article 500 of NPFA 70: 1993 *National Electrical Code* and in API RP 500: 1991 *Recommended Practice for Classification of Locations for Electrical Installations at Petroleum Facilities*.

The purpose of hazardous area classification is to minimize the probability of ignition of small leaks. It is not concerned with massive releases, which are very rare. This distinction is a necessary one, but the difference can sometimes be blurred. Mecklenburgh instances a pump seal which, if it leaks, will generally give a rather small release, but which may on occasion give a leak greater than that from the rupture of a small pipe. Because the leaks considered are small and because small flammable releases burn rather than explode, it is fire rather than explosion with which hazardous area classification is concerned.

Since it is difficult to specify leaks fully in terms of size, frequency and duration, the following grades of leak are defined:

(1) Continuous grade: release is continuous or nearly so.
(2) Primary grade: release is likely to happen regularly or at random times during normal operation.
(3) Secondary grade: release is unlikely to happen in normal operation and in any event will be of limited duration.

Broadly speaking, continuous, primary and secondary grade releases equate to Zones 0, 1 and 2, respectively.

Hazardous area classification proceeds by identifying the sources of hazard, or potential leak points, and the sources of ignition. Typical leak points include flanges, seals, sample points and temporary connections; typical ignition sources include electric motors, burners and furnaces, engines and vehicles.

There are three main strategies available for the control of ignition sources: prevention, separation and protection. The approach to hazardous area classification based on these strategies is broadly as follows. First, the potential leak sources are identified. The characteristics of the leak are defined, for start-up, shut-down and emergency conditions as well as normal operation, and the grade of leak assigned. For each leak point, consideration is given to reducing or eliminating any leak. Guidance on separation distances is then used to determine the area around the leak source from which ignition sources should be excluded. Next the ignition sources near the leak point are identified. For each ignition source in turn, consideration is given to the possibility that it can be eliminated or moved. Where this is not applicable, the zone is specified and appropriate protection of the ignition source is determined. For electrical equipment this means specifying the type of safeguarding appropriate to the zone.

A check may be made on the separation distances used and on the degree of protection required by modelling the dispersion of the leak. Consideration should also be given to the effect of any pool fire arising from flammable liquid released at the leak point. In some instances this may require an increase in the separation distance or the use of protection measures such as insulation or water sprays.

The control of ignition sources reduces the risk of injury to personnel and the risk of property damage. The extent to which the plant design is modified for reasons of hazardous area classification is governed for personal injury by the usual risk criteria and considerations of what is reasonably practicable, and for property damage by economic considerations. In cases where property damage is the issue, it may be preferable to accept a certain risk rather than to undertake unduly expensive countermeasures.

The outcome of this exercise for all the ignition sources identified is the definition of the zones in three dimensions for the whole plant. Drawings are produced showing these zones in plan and elevation, both for individual items of equipment and for the plant as a whole. A typical plan drawing is illustrated in Figure 10.4.

Hazardous area classification provides the basis for the control of ignition sources both in design and in operation. A further discussion of hazardous area classification is given in Chapter 16.

10.13 Hazard Assessment

In the methodology for plant layout described by Mecklenburgh (1985), hazard assessment is used at several points in the development of the layout. In each case, the procedure is essentially an iterative one in which hazards are identified and assessed, modifications are made to the design and the hazards are reassessed. The nature of the hazard assessment will vary depending on whether it is done in support of site location, site layout, Stage One plot layout or Stage Two plot layout.

Hazard assessment in support of site location is essentially some form of quantitative risk assessment.

Hazard assessment for site layout concentrates on major events. It provides guidance on the separation distances required to minimize fire, explosion and toxic effects and on the location of features such as utilities and office buildings.

Hazard assessment for plot layout deals with lesser events and with avoidance of the escalation of such events. It is used as part of the hazardous area classification process and it provides guidance on separation distances to prevent fire spread and for control building location.

At the plot layout level, hazard assessment is concerned mainly with flammable releases. It is not usually possible at this level to do much about explosions and toxic releases.

10.14 Hazard Models

10.14.1 Early models

An account has already been given of the early work of Simpson (1971) on the use of models for plant layout purposes. The hazard models described by him include models for two-phase flow and for vapour dispersion and criteria for thermal radiation, as described in Section 10.11.

10.14.2 Mecklenburgh system

A set of hazard models specifically for use in plant layout has been given by Mecklenburgh (1985). A summary of the models in this hazard model system is given in Table 10.9. Some of the individual models are described in Chapters 15, 16 and 17. Although the modelling of some of the phenomena has undergone further development, this hazard model system remains one of the most comprehensive available for its purpose.

10.14.3 IP system

Another, more limited, set of hazard models for plant layout is that given in *Liquefied Petroleum Gas* (IP, 1987 MCSP Pt 9). The models cover:

(1) emission;
  (a) pressurized liquid,
  (b) refrigerated liquid,
(2) pool fire;
(3) jet flame.

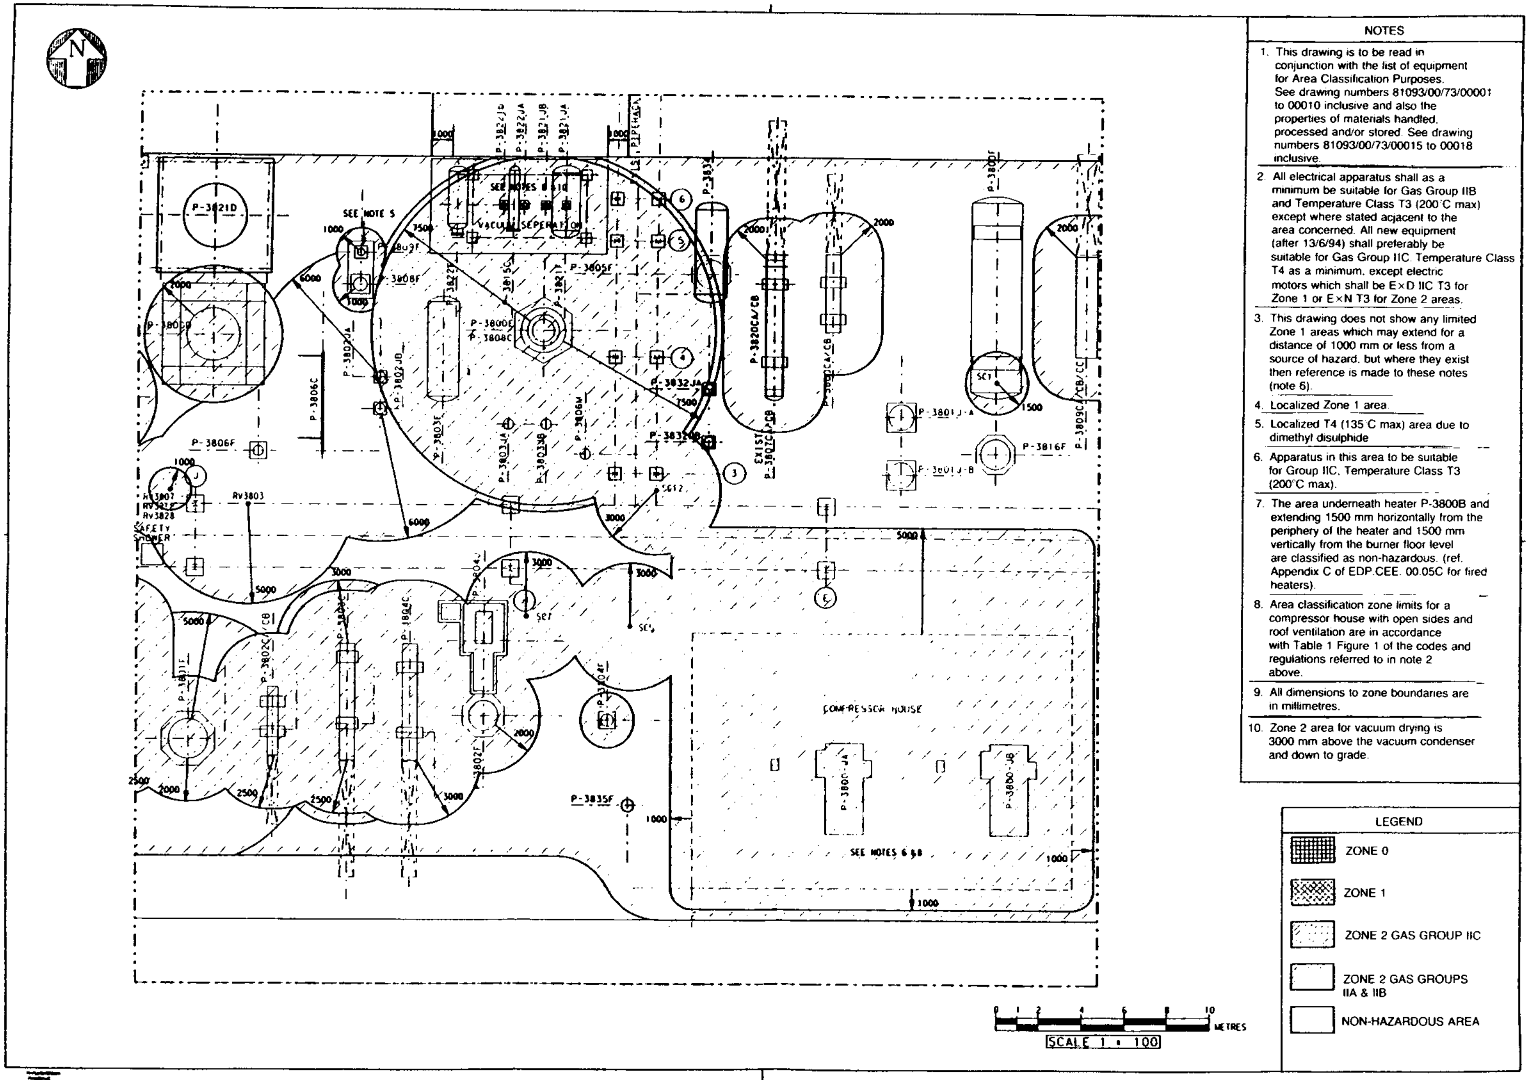
The models include view factors for thermal radiation from cylinders at a range of angles to the vertical and of positions of the target. The requirements for separation distances between storage units are based on thermal radiation flux criteria. These are given in Chapter 22. The code gives worked examples.

10.14.4 Injury and damage criteria

Criteria for injury and damage, principally the latter, are given by Mecklenburgh as part of his hazard model system.

For the heat flux from a flame or fire the tolerable intensities are given as follows:

	Heat flux (kW/m^2)
Drenched storage tanks	38
Special buildings	25
Normal buildings	14
Vegetation	12
Escape routes	6
Personnel in emergencies	3
Plastic cables	2
Stationary personnel	1.5



NOTES

1. This drawing is to be read in conjunction with the list of equipment for Area Classification Purposes. See drawing numbers 81093/00/73/00001 to 00010 inclusive and also the properties of materials handled, processed and/or stored. See drawing numbers 81093/00/73/00015 to 00018 inclusive.
2. All electrical apparatus shall as a minimum be suitable for Gas Group IIB and Temperature Class T3 (200°C max) except where stated acjacent to the area concerned. All new equipment (after 13/6/94) shall preferably be suitable for Gas Group IIC. Temperature Class T4 as a minimum, except electric motors which shall be E×D IIC T3 for Zone 1 or E×N T3 for Zone 2 areas.
3. This drawing does not show any limited Zone 1 areas which may extend for a distance of 1000 mm or less from a source of hazard, but where they exist then reference is made to these notes (note 6).
4. Localized Zone 1 area.
5. Localized T4 (135°C max) area due to dimethyl disulphide
6. Apparatus in this area to be suitable for Group IIC, Temperature Class T3 (200°C max).
7. The area underneath heater P-3800B and extending 1500 mm horizontally from the periphery of the heater and 1500 mm vertically from the burner floor level are classified as non-hazardous. (ref. Appendix C of EDP.CEE. 00.05C for fired heaters).
8. Area classification zone limits for a compressor house with open sides and roof ventilation are in accordance with Table 1 Figure 1 of the codes and regulations referred to in note 2 above.
9. All dimensions to zone boundaries are in millimetres.
10. Zone 2 area for vacuum drying is 3000 mm above the vacuum condenser and down to grade.

B16	Evaporation and dispersion from small liquid pool Distance to given concentration
B17	Dispersion of flammable vapour from small continuous release in a building Jet dispersion: distance to given concentration Passive dispersion: distance to given concentration Jet flame: distance to given heat flux (*see* B8)
B18	Evaporation and dispersion from small liquid pool in a building Evaporation rate Mean space concentration Other parameters for (a) horizontal air flow and (b) vertical air flow

[a] In Mecklenburgh (1985).

For a fireball, the safe dose is given as $It_B^{2/3} < 47$, where I is the heat flux (kW/m^2) and t_B is the duration of the fireball (s).

For the peak incident overpressure from an explosion the limits which should not be exceeded are given as follows:

	Peak incident overpressure (bar)
Schools	0.02
Housing	0.04
Public roads	0.05
Offices	0.07
Shatter-resistant windows	0.10
Site roads, utilities	0.20
Hazardous plants	0.30–0.40
Protected control room	0.7

10.14.5 Illustrative example

Mecklenburgh illustrates the application of his hazard models by giving for each a scenario and worked example, and for some of the outdoor cases he combines these into an assessment of the effects on-site and off-site. For this latter assessment he considers a set of scenarios which may be summarized as follows:

(1) instantaneous release of flashing liquid from storage tank:
  (a) flammable liquid giving rise to unignited vapour cloud, or fireball or vapour cloud explosion,
  (b) toxic liquid giving rise to toxic gas cloud, in open and around building;
(2) residual liquid in tank:
  (a) flammable liquid giving rise to unignited vapour cloud, pool fire,
  (b) toxic liquid giving rise to toxic gas cloud;
(3) liquid pool from 10 cm leak in tank base following instantaneous release:
  (a) flammable liquid giving rise to unignited vapour cloud, or pool fire,
  (b) toxic liquid giving rise to toxic gas cloud;
(4) Continuous release of pressurized liquid from 2.5 cm hole:
  (a) flammable fluid giving rise to passively dispersing unignited vapour cloud, or jet fire,
  (b) toxic fluid giving rise to passively dispersing toxic gas cloud;
(5) continuous release of pressurized liquid from 10 cm hole:
  (a) flammable fluid giving rise to passively dispersing unignited vapour cloud, or jet fire,
  (b) toxic fluid giving rise to passively dispersing toxic gas cloud.

The overall results are summarized in Table 10.10. These results are discussed by Mecklenburgh in relation to both on-site and off-site effects and to the countermeasures which might be taken.

10.15 Fire Protection

Plant layout can make a major contribution to the fire protection of the plant. This has a number of aspects.

Plant layout for fire protection is covered in BS 5908: 1990 *Fire Precautions in the Chemical and Allied Industries*. Also relevant are BS 5306: 1976 *Fire Extinguishing Installations and Equipment on Premises*, particularly Part 1 on fire hydrants, and BS 5041: 1987 *Fire Hydrant Systems Equipment*. An important earlier code, BS CP 3013: 1974 *Fire Precautions in Chemical Plant*, is now withdrawn. The coverage of BS 5908: 1990 is indicated by the list of contents given in Table 10.11. Accounts of the fire protection aspects of plant layout include those by Simpson (1971), Hearfleld (1970) and Kaura (1980a).

Some aspects of plant layout for fire protection may be classed as passive and others as active measures. The former include (1) separation of hazards and targets, (2) measures to prevent fire spread and (3) provision of access for fire fighting; the latter include provision of (4) fire water and (5) fire protection systems. The segregation of hazards and targets and the containment of fire are important aspects of site layout and are considered in Section 10.6. The provision and location of fire water hydrants and fire protection equipment are prominent features of plot layout and are discussed in Section 10.7. This section deals primarily with access, fire water and fire protection equipment. Fire protection is discussed further in Chapter 16.

Table 10.10 *Hazard assessment in support of plant layout: illustrative example (after Mecklenburgh, 1985) (Courtesy of the Institution of Chemical Engineers)*

A Off-site effects – summary of distances (m)

	All built-up area	*100m built-up, then country*	*All country*
1(a) Instantaneous release

13. Classification of fires and selection of extinguishing media
14. Fixed fire extinguishing systems
15. Portable and transportable appliances
16. Organization of emergency procedures

There are numerous legal requirements concerning fire, fire construction and fire fighting. There should be full consultation at an early stage with the works safety officer and with other parties such as the local authority services, the Health and Safety Executive (HSE) and the insurers.

10.15.1 Fire fighting access

Access is essential for fire fighting. Some basic principles are that it should be possible to get fire fighting equipment sufficiently close to the site of the fire and that there should be access from more than one side. Access should be provided within 18 to 45 m of a hazard and there should be water supplies and hard standing at these access points.

The site should have a peripheral road connected at not less than two points with the public road system. It may be necessary to provide a waiting area for fire fighting vehicles near each main gate. Site roads should be arranged to allow approach to a major fire from two directions. Major process or storage units should be accessible from at least two sides. Access is assisted by a plot size of 100 m×200 m with approaches preferably on all four sides and by spacing between plots and buildings of 15 m.

Access for fire fighting vehicles should be over firm ground, should have sufficient road and gate widths, should give adequate clearance heights and should allow for the necessary turning and manoeuvring. The vehicles requiring access may include heavy bulk foam or carbon dioxide carriers.

10.15.2 Fire water

In a fire, water is required for extinguishing the fire, for cooling tanks and vessels and for foam blanketing systems.

The quantities of water required can be large, both in terms of the instantaneous values involved and of the duration for which they may be needed. In some fires water sprinkler systems have been required to operate for several days.

The design of a fire water system requires the determination of the maximum fire water flow which the system should deliver. Some order of magnitude figures are given in the *Refining Safety Code* (IP, 1981 MCSP Pt 3). This states that for a major process fire the fire water flows required might be of the order of 750–1500 m^3/h. The code also quotes for a major fire on a 50 m diameter storage tank a fire water flow of 830 m^3/h for the application of foam to the burning tank and for the cooling of the adjacent tanks. R.B. Robertson (1974a) refers to investigation of the fire water actually used in major process plant fires and quotes water flows in the range of 900–2700 m^3/h.

It is also necessary to specify the length of time for which such fire water flows should be sustained. This specification also may be obtained using the design basis fire approach. Typically this length of time is recommended to be 2–3 hours. Robertson states that study of time taken to control fires points to a duration of 2 hours.

The fire water requirement may be based on the specification of a design basis fire. Kaura (1980a) suggests that this might be two simultaneous fires, one on a major process unit and the other at the storage tanks. The IP *Refining Safety Code* states, on the other hand, that it is usual to assume that there will be only one major fire at a time. The practical difference between these approaches depends on how generous an allowance is made for the single fire.

The fire water main may be fed from the public water supply, but for large works the public supply may well not be adequate to provide the quantities of water required. Additional water supplies may be drawn be the fire brigades from rivers, canals, reservoirs or static tanks, but such sources should be near enough to allow suction to be obtained directly, since reliance on relays is likely to involve undue delay. Cooling water should not be used, because loss of cooling on other plants is itself a hazard. Where the public supply is to be used, this should be done in accordance with BS 6700: 1987. The water and fire authorities should be consulted about fire water supplies.

Water supplies for water sprays and sprinklers may be provided in the form of elevated static water tanks. A typical capacity might be such as to supply water for 1 hour. Pumps should be provided to replenish the supplies.

Fire water should be available from hydrants adjacent to the fire hazards on a ring main running alongside the road and located between the road and the plant. The main should preferably be buried under ground. The installation should be generally in accordance with BS 5306: 1976–and fire water hydrants with BS 750: 1984 and BS 5306: Part 1: 1976. The main should take the form of a ring main encircling the plant, with cross-connections and with isolation valves to allow shut-off if a section of the main is damaged.

Hydrant intervals should be 45 m for high risk areas but may be up to 100 m for low risk ones. The distance between the hydrant, the plant structure or storage area should be not less than 18 m and may be up to 45 m. The hydrants should be provided with a hard standing and with signs in accordance with BS 5499: Part 1: 1990. The signs should indicate the quantity of water available.

Rising mains should be installed in a building or structure on any floor exceeding 18 m above ground level. Dry rising mains are suitable for heights up to 60 m, but above this height a wet main may be preferable. The inlets on the ground floor to dry riser mains and the outlets on all floors to both types of main should be accessible.

Fire water for sprinkler and water spray systems should be in accordance with BS 5908.

Pipes for fire water supply should be protected against explosion damage. Isolation valves should be provided to prevent loss of fire water from damaged lines and, if these valves are above ground level, they should be protected by concrete blast barriers. The fire water is normally pumped through the main by fixed fire pumps. There should be at least two full capacity pumps with separate power supplies. Cabling for electric pumps should not run through high risk areas or, if this is unavoidable, it should be protected. The location of the pumps is usually determined by that of the source of supply, but they should not be in a high risk area. The fire pumps should be housed to protect them from the weather. In a fire, mobile pumps may sometimes be used to boost the fire main pressure, though their principal use is to supply fire hoses from the main or other sources.

10.15.3 Fire protection equipment

The other aspects of fire protection of plant, including fire containment by layout, gas, smoke and fire detection, passive fire protection such as fire insulation, and active fire protection such as the use of fixed, mobile and portable fire fighting equipment, are considered in Chapter 16.

It is appropriate to mention here, however, the provision of certain minimal equipment which is generally treated as an aspect of plant layout. Fire extinguishers of the appropriate type and fire blankets should be placed at strategic points on the plant. There should be at least two extinguishers at each point. Some extinguishers should be located on escape or access routes, so that a person who decides to fight the fire using the extinguisher has a route behind him for escape.

Fire equipment should be located so that it is not likely to be disabled by the accident itself, should be accessible and should be conspicuously marked. The main switchgear and emergency controls should have good access, preferably on an escape route, so that the operator does not have to risk his life to effect shut-down.

10.16 Effluents

General arrangements for dealing with effluents are discussed by Mecklenburgh (1973, 1985). Pollution of any kind is a sensitive issue and attracts a growing degree of public control. There should be the fullest consultation with the local and water authorities and the Inspectorate of Pollution in all matters concerned with effluents.

Hazard identification methods should be used to identify situations which may give rise to acute pollution incidents and measures similar to those used to control other hazards should be used to ensure that this type of hazard also is under control.

10.16.1 Liquid effluents

Liquid effluents include soil, domestic and process effluents, and cooling, storm and fire water. Harmless aqueous effluents and clean stormwater may be run away in open sewers, but obnoxious effluents require a closed sewer. One arrangement is to have three separate systems: an open sewer system for clean stormwater and two closed sewer systems, one for domestic sewage and one for aqueous effluent from the plant and for contaminated stormwater.

There are a number of hazards associated with liquid effluent disposal systems such as drains and sewers. One is the generation of a noxious gas by the mixing of incompatible chemicals. Another hazard is that a flammable gas may flow through the drains, become distributed around the plant and then find a source of ignition. This can give rise to a quite violent explosion, or even detonation. A flammable liquid which is immiscible with water flowing through the drains constitutes another hazard. Again it may become distributed around the plant and find an ignition source. If the liquid is already on fire, its entry into the drains may cause the fire to be distributed around the plant.

Other problems with sewers include overloading, blockage and back flow, each of which can be hazardous. Overloading or blockage can result in a liquid fire being floated across to other parts of the site. Some case histories of problems in sewers are given by Anon. (1978 LPB 19, p. 10).

There are also environmental factors to consider. It is necessary to avoid the discharge of untreated contaminated liquid.

As stated above, process effluents, essentially aqueous, and contaminated stormwater are collected in a common sewer. The liquids discharged to this sewer should be closely controlled. If different effluents are to be mixed together, it should be checked that this can be done safely. Chemical works effluents are quite prone, for example, to generate obnoxious gases.

Water-immiscible flammable liquids should not be allowed to enter the sewers, where they create the hazard of fire or explosion. In particular, open sewers with solvent floating on the water may transmit fires over long distances. There should be arrangements to prevent the entry of such liquids into the sewers. Runoff from the plant area should be routed to interceptors located at the edge of the fire risk area. In order to avoid overloading, use is made of primary interceptors to effect a preliminary separation. Measures may need to be taken to prevent sedimentation in, and freezing of, the interceptors.

It may be necessary to take measures to avoid flooding on process and storage plots. There is need for care to avoid the flooding by effluents of vulnerable points such as pump pits. Flooding of bunds can cause the tanks inside to float. Effluents should not be permitted to run off plant areas onto adjacent sites, or vice versa. If the site slopes or contains a natural water course, additional precautions are needed.

The traditional sewer is the gravity flow type. This should have a gradient and be self-cleaning. Sewer boxes should be used as interconnections with a liquid seal to prevent the transmission of gases and vapours and reduce the hazard of fire/explosion. Where noxious vapours might collect, the sewer box lids should be closed, sealed and vented to a safe place. A suitable point is above grade 3 m, horizontally 4.5 m from platforms and 12 m from furnaces walls. The routing of sewers should be parallel to the road system. They can go under the road, but for preference should be alongside it.

Sewers are considered in more detail in Section 10.17. The sewer system should be settled at an early stage. It is usually not practical to increase the capacity once the plant is built.

10.16.2 Gaseous effluents

Gaseous effluents should be burned or discharged from a tall stack so that the fumes are not obnoxious to the site or the public. The local Industrial Pollution Inspector is able to advise on suitable stack heights and should be consulted. It is also necessary to check whether a high stack constitutes an aerial hazard and needs to be fitted with warning lights.

Flare stacks are a particular problem, because they radiate intense heat and can be very noisy. Quite a large area of ground beneath a flare stack is unusable and is effectively 'sterilized'. A flare stack may have to be relegated to a distant site. A further discussion of flare stacks is given in Chapter 12.

The behaviour of airborne emissions of all types should be carefully considered. Although the prevailing wind is the main factor, other possible troublesome wind conditions should be taken into account. The effect of other weather conditions, such as inversions should also be considered.

10.16.3 Solid wastes

Solid waste should preferably be transferred directly from the process to transport. If intermediate storage is unavoidable, care should be taken that it does not constitute a hazard or a nuisance. If combustible solid and solvent wastes are burnt, the incinerator should be convenient to the process.

10.17 Drain Systems

The main plant sewers are of particular importance and merit further description. As already stated, it is common to have an open clean stormwater sewer and a closed contaminated stormwater sewer. These sewers also carry fire water runoff during fire fighting.

Accounts of sewer systems include those by J.D. Brown and Shannon (1963a,b), Seppa (1964), D'Alessandro and Cobb (1976a) and Anon. (1978 LPB 19, p. 10). These systems are also considered by Mecklenburgh (1973, 1985). Stormwater systems are discussed by Elton (1980), W.E. Gallagher (1980) and G.S. Mason and Arnold (1984).

10.17.1 Clean stormwater system

Clean stormwater is usually collected in an open sewer. The discharge may be to water courses or the sea, or to a holding pond. On large sites it is generally not practical to discharge it to the public system, due to overload of the latter.

10.17.2 Contaminated stormwater system

The contaminated stormwater system consists of the contaminated stormwater sewers together with an impounding basin to hold the contaminated water prior to treatment and discharge. The design of the impounding basin is discussed by Elton (1980) and W.E. Gallagher (1980) and that of the contaminated stormwater sewers themselves by G.S. Mason and Arnold (1984).

First it is necessary to determine the catchment area, or watershed, from which the stormwater will flow onto the plant site. The next step is to characterize the rainfall. A suitable starting point is a rainfall atlas such as the *Rainfall Frequency Atlas* in the United States of America. The available data may be used to make an estimate of the maximum 24 hour rainfall. For some locations information is available from which the recurrence interval of particular levels of 24 hour rainfall may be determined.

A gravity flow stormwater system allows nearly immiscible liquids such as chlorinated hydrocarbons to accumulate and to contaminate water passing through until they are gradually dissolved. It may also allow a light, nearly immiscible flammable liquid to float on the top of the water and pass through unless liquid seals are installed to prevent this.

The alternative type of system is the fully flooded system. The system is flooded by a dam at the entrance to the collection sump. As water enters, the sewer becomes fully flooded. The catchbasins and manholes used in this case are of the dry-box type. A fully flooded system prevents the passage of flammable vapours and of burning liquids. There is no accumulation of nearly immiscible liquids and thus no contamination of the stormwater by such liquids.

A flooded stormwater system may not be justified if the liquids handled on the plant are not flammable. Such a system may be impractical in a location sufficiently dusty to cause clogging.

The selection of the materials of construction for a fully flooded system is important and is considered by the authors. These need to withstand both corrosion and thermal shock. They also discuss the conversion of a gravity flow system to fully flooded system and give cost comparisons.

10.17.3 Firewater disposal

There should be arrangements for the disposal of fire water, but it is expensive to provide sewers for the very large quantities of water involved, and different views have been expressed on the necessity for this (e.g. Simpson, 1971; Mecklenburgh, 1976). A practical compromise is to design the sewers to take at any rate the initial 'first aid' fire fighting water (R.B. Robertson, 1974a).

There are also different estimates given of the quantities of fire water likely to be involved. Mecklenburgh (1985) states that the allowance for fire water is about five times the volume allowed for the stormwater. Presumably this refers to UK conditions. A different ratio may well apply in other parts of the world.

Consideration should be given to the fire water flow in all sections of the sewer system. The main trunk sewer usually receives water from a relatively large watershed, but branch sewers may well be prone to overloading from large fire water usage on particular parts of the site.

In view of the large quantities of fire water which can be generated, it may well not be practical to design the sewers for these flows, and other methods of disposal may be needed. These include measures to pump it away or to run it off onto other land.

10.18 Blast-Resistant Structures

It is sometimes necessary in the design of structures such as plant and buildings to allow for the effect of shocks from explosions and/or earthquakes. In both these cases, there is a strong probabilistic element in the design in that it is not possible to define the precise load to which the plant structure may be subjected. The starting point is therefore the definition of the design load in terms of the relation between the magnitude of the load and the frequency of occurrence.

The full design of shock-resistant structures is beyond the scope of this book, but some limited comments are made here. Further accounts of explosion-resistant structures are given in Chapter 17 and of earthquake-resistant structures in Appendix 15.

10.19 Control Buildings

Until the mid-1970s, there were few generally accepted principles, and many variations in practice, in the design of control buildings. Frequently the control buildings constructed were rather vulnerable, being in or close to the plant and built of brick with large picture windows.

10.19.1 Flixborough

The Flixborough disaster, in which 18 of the 28 deaths occurred in the control building, caused the Court of Inquiry to call for a fundamental reassessment of practice in this area.

The control building at Flixborough has been described by V.C. Marshall (1976a). It was constructed with a reinforced concrete frame, brick panels and considerable window area. It was 2½ storeys high in its middle section, the 1½ storeys over the control room consisting of a half-storey cable duct and a full-storey electrical switchgear room. The control room was part of a complex of buildings some 160 m long, which also housed managers' offices, a model room, the control laboratory, an amenities building and a production block.

This building complex was 100 m from the assumed epicentre of the explosion and was subjected to an estimated overpressure of 0.7 bar. The complex lay with its long axis at right angles to the direction of the blast. It was completely demolished by the blast and at the control room the roof fell in. The occupants of the control room were presumably killed mainly by the collapse of the roof, but some had been severely injured by window glass or wired glass from the internal doors. It took mine rescue teams 19 days to complete the recovery of the bodies.

The main office block, which was a 3-storey building, again constructed with a reinforced concrete frame, brick panels and windows, was only 40 m from the assumed epicentre and was also totally demolished.

The implications of the Flixborough disaster for control building location and design have been discussed by V.C. Marshall (1974, 1976a,c,d) and by Kletz (1975e).

10.19.2 Building function

The control building should protect its occupants against the hazards of fire, explosion and toxic release. Much the most common hazard is fire, and this should receive particular attention.

There are several reasons for seeking to make control buildings safer. One is to reduce to a minimum level the risk to which operators and other personnel are exposed. Another is to allow control to be maintained in the early stages of an incident and so reduce the probability of escalation into a disaster. A third is to protect plant records, including those of the period immediately before an accident.

It is sometimes suggested that another aim should be to equalize the risks to those inside and outside. Since those outside tend to be less at risk in an explosion, this means in effect reducing the risk to those inside. This objective is not self-evident, however. The philosophy of risk described earlier is that no one should be subjected to more than a specified risk, not that the risk should be equal for all. In any event, before designing a control room, it is necessary to be clear as to what the objectives are.

10.19.3 ACMH recommendations

Control building location and design is one of the topics raised by the Court of Inquiry on the Flixborough disaster and considered in the First and Second *Reports* of the Advisory Committee on Major Hazards (ACMH) (Harvey 1976, 1979b). The recommendations of the committee are that control rooms which may be subject to explosion should not be built in brick with large picture windows, but in reinforced concrete with small, protected windows.

10.19.4 Control facilities

There is a tendency for control rooms to become part of a complex of facilities, as the buildings at Flixborough illustrate. As a result, more people are exposed to hazard than is necessary and/or the buildings must be of more elaborate and expensive construction. Some of the additional rooms often associated with the control room include computer room, locker room, mess room, toilets, supervisors' offices, analytical laboratories, test rooms, instrument workshops, electrical relay and switchgear rooms.

The proper policy is to build a secure control room in which the functions performed are limited to those essential for the control of the plant and to remove all other functions to a distance where a less elaborate construction is permissible. The essential functions which are required in the control room are those of process control. There are other types of control which are required for the operation of the plant, such as analytical control and management control, but they need not be exercised from the control room. Thus other facilities such as analytical laboratories, amenities rooms, etc., should be located separately from the control room.

The control room should not be used as a centre to control emergencies. There should be a separate emergency control centre, as described in Chapter 24. The control room should also not be used as an emergency assembly point or refuge room.

10.19.5 Location

The ability of a control building to give protection against a hazard such as an explosion depends not only on its design but also on its location. The siting of a control building can, therefore, be as important as its construction.

It is good practice to lay plant out in blocks with a standard separation distance. The control building should be situated on the edge of the plant to allow an escape route. Recommended minimum distances between the plant and the control building tend to lie in the range 20–30 m. If hazard studies indicate, however, that the standard separation distance may not be adequate, the distance between the control building and the plant should, of course, be increased.

The control building should not be so near the plant that its occupants are at once put at risk by a serious leak of flammable, toxic or corrosive materials. On the other hand, increasing the distance from the process may make the operators less willing to get out on the plant. Managers are generally opposed to control rooms which are too remote. This is important, because active patrolling by the operator is one of the main safeguards against plant failures.

A control building should not be sited in a hazardous area as defined in BS 5345: 1977–. Further guidance on location of the control building is given below.

10.19.6 Basic principles

Arising from the experience of Flixborough, V.C. Marshall (1976a) has suggested certain principles for control building design which may be summarized as follows:

(1) The control room should contain only the essential process control functions.
(2) There should be only one storey above ground.
(3) There should be only the roof above the operator's head. The roof should not carry machinery or cabling.
(4) The building should have cellars built to withstand earthshock and to exclude process leaks and should have ventilation from an uncontaminated intake.
(5) The building should be oriented to present minimum area to probable centres of explosion.
(6) There should be no structures which can fall on the building.
(7) Windows should be minimal or non-existent and glass in internal doors should be avoided.
(8) Construction should be strong enough to avoid spalling of the concrete, but it is acceptable that, if necessary, the building be written off after a major explosion.

10.20 Toxics Protection

Another hazard against which protection may be required is that posed by a release of toxic gas. In general, ordinary buildings off site and even on site can afford an appreciable degree of protection against a transient toxic gas release, but for certain functions enhanced protection is required. It is also necessary to ensure that the protection potentially available is not defeated. Buildings of particular interest here are (1) the control building, (2) the emergency control centre and (3) any temporary refuges.

10.20.1 Control room

The design of a control room for protection against toxic release is discussed in the CIA *Control Building Guide* (CIA, 1979). The design should start by identifying the release scenarios against which protection is required and by making some quantitative assessment of the dispersion of the gas. If persons outside exposed to the gas release would be incapacitated or unable to escape, protection is needed. The time for which protection is needed should also be defined. This will normally be governed by the time required to shut the plant down or the time needed to control the emergency.

The control building should be located at the edge of the plant, and its siting should take into account both fire/explosion and toxic gas hazards. There should be at least two escape routes, which should be chosen bearing in mind that they may need to be used by partially incapacitated people and by rescue teams wearing heavy breathing apparatus. They should be free from obstructions and well lit.

The construction of the building should be gas-tight. This means, among other things, that windows should be non-opening and that door and window frames should be designed and maintained to minimize entry of gas. There should be no more than two doors, each with an air lock and each gas-tight. The wedging open of these doors should not be tolerated.

The occupants of the control building should be provided with a supply of air sufficient for the time for which protection is required. Generally, it will be necessary to shut off the normal ventilation and the control building will then lose any overpressure and may become contaminated. Self-contained breathing apparatus should be provided for each occupant.

In some cases, it may be possible to supply air from a source sufficiently far from the control building that the air from it is clean. The air supply should maintain within the building a positive pressure of 0.5–1.0 in. water gauge, which requires 2 to 15 air changes per hour, depending on building size, construction and gas-tightness.

There are various ways in which toxic gas may enter such a building. One is via service trenches and cellars. These should be avoided, but if used should incorporate sealed barriers and should be subject to a permit-to-work system. Another mode of entry is via instrument air lines and appropriate precautions should be taken. Instrument sample lines should not bring toxic process fluids into the control building.

Where available, gas detectors should be used to give warning of a toxic gas escape by activating an alarm in the control room, where there should be means of activating the toxic gas alarm. There should be in the control room an indication of wind direction.

It may be possible to provide protection to the control building using a water spray system. The gas detector signal may be used to activate such a water spray and to shut off the normal ventilation air.

The control building should have a priority communication link, other than the normal telephone system, to the emergency control centre.

Appropriate breathing apparatus or respirators should be provided in the control building to assist the escape of any persons who have to be evacuated in the emergency.

10.20.2 Emergency control centre

Protection of the emergency control centre from a toxic release will normally be in large part by location. It is necessary for the emergency controllers to gain access to the centre at the start of the emergency and it is undesirable that they should have to pass through a toxic gas cloud. Nevertheless, it may need to be designed to afford protection against toxic gas, in which case the points just made in relation to the control building are pertinent.

10.20.3 Refuges

A temporary refuge, or haven, has the quite different function of providing temporary shelter for personnel. The design of such havens is described in the *Vapor Release Mitigation Guidelines* (CCPS, 1988/3). The *Guidelines* distinguish between temporary and permanent havens, or more effective temporary havens. Virtually any weather-tight building should suffice as a temporary haven. Personnel in such a haven should be notified to leave the building when the toxic gas cloud has passed. There should be arrangements for them to be rescued, if necessary, by well-equipped teams. It would also seem necessary that there be means whereby the emergency controllers know the location of personnel needing rescue.

For permanent havens, the CCPS *Guidelines* refer to the arrangements for control buildings as described in the CIA *Control Building Guide*. They also give a method of estimating the capacity of a haven. The conditions in the haven should not exceed the following limits: minimum oxygen concentration 18%; maximum carbon dioxide concentration 3%; maximum temperature 33°C; and maximum 100% relative humidity (RH).

10.21 Modular Plants

During the late 1950s and early 1960s, there was introduced a type of plant consisting of a number of modules and mounted on skids which could be transported by road from the fabrication to the operating site. The processes were straightforward and the plants were simple and cheap. From these early skid-mounted plants, there has developed a whole range of modular and barge-mounted plants, some of which are large and complex.

Accounts of modular plants have been given by Glaser, Kramer and Causey (1979), Zambon and Hull (1982), Glaser and Kramer (1983), Hulme and La Trobe-Bateman (1983), Kliewer (1983), Clement (1989), Hesler (1990) and Shelley (1990), and accounts of barge-mounted plants have been given by Birkeland *et al.* (1979), Charpentier (1979), J.L. Howard and Andersen (1979), R.G. Jackson (1979), Jansson *et al.* (1979), Shimpo (1979), Ricci (1981), Bolt and Arzymanow (1982), de Vilder (1982) and Glaser and Kramer (1983). Both types of plant are treated by Mecklenburgh (1985).

10.21.1 Skid-mounted plants

The early skid-mounted plants were typically natural gas processing plants and pipeline compressor stations mounted on skids. The plants had a quite small number of modules of limited dimensions. They were transported by truck from the fabrication works to the operating site. The plants were simple and were equipped to shut-down if an operating problem arose. The plant operator typically lived in a house close by. These plants were designed for a relatively short life and had low capital and running costs. A description of such skid-mounted plants is given by Kliewer (1983).

10.21.2 Modular plants

The late 1970s saw a significant extension of the scale and complexity of modular plants. Such plants were seen as offering benefits where site construction was unusually difficult, particularly on remote sites. Factors favouring modular plants include problems associated with (1) access difficulties, (2) severe weather and (3) the labour force.

Advantages of modular construction are those associated with (1) access for equipment suppliers, (2) work in sheltered conditions and (3) availability of a skilled workforce. Arising from these are (4) easier construction and testing, (5) improved quality assurance and (6) shorter project timescale. Construction of the plant at a dedicated fabrication site minimizes access difficulties for equipment suppliers, and allows the work to be done under cover and by a skilled workforce. Main items of equipment, pipework, supports, instrumentation and cabling can be installed and tested under essentially factory conditions. The project timetable can be shorter, both because work on foundations and on plant construction can proceed in parallel and because construction can be done in more favourable conditions.

Disadvantages of modular construction include those associated with (1) engineering design, (2) modifications, (3) steelwork and (4) transport. Modular construction necessitates high quality and more expensive engineering design. It is relatively unforgiving of modifications, which can therefore be disruptive and expensive. There are additional costs for steelwork but, because steel is relatively cheap, these may be modest. There are additional transport costs which vary depending on the site and the plant, and which can be considerable.

Modular construction requires its own design approach. It is not effective to design a plant by conventional methods and then divide it into modules. It is necessary to design for a modular layout from the start. It is also necessary to accept that the main features affecting layout have to be frozen earlier than is often the case is normal design.

Plants have been constructed with some 200 modules and with modules stacked as high as 50 m. With regard to module dimensions and weight, in one project described by Kliewer (1983) the maximum module dimensions were set at 6.7 m wide × 4.0 m high × 30.5 m long. The weight limit was 125 ton, though most modules did not exceed 50 ton. Shelley (1990) describes rubber-track crawlers and trailers with up to 360 wheels capable of transporting 3000–4000 ton and cranes with lifting capacity of 5000 ton.

Advocates of modular design typically claim savings on project cost and time. Accounts of cost benefits include those of Kliewer (1983) and Shelley (1990). Broadly, capital costs are less, but design, steelwork and transportation cost more. Shelley quotes construction times shortened by up to 50% and capital cost savings of up to 20%.

Progress in modular construction has been reviewed by Shelley (1990). The image of modular plants has tended to be that of skid-mounted plants and plants shipped to remote locations. Modularization has generally been considered only for remote locations where the weather is hostile or skilled labour unavailable. The author discerns a trend towards increasing use of modular construction for regular projects, arising from its advantages of cutting capital costs and shortening construction times. Another stereotype which is somewhat outdated is that modular plants necessarily involve a cramped layout.

10.21.3 Barge-mounted plants

A particular type of modular plant is that mounted on a barge or other vessel. The development of such plants has received impetus from the need for shipyards to diversify. Features of the operating site which favour the use of a barge-mounted plant include: a seaboard inaccessible from the hinterland; a navigable, if shallow, river; or a delta unsuitable for land traffic.

A plant transported by sea may, in fact, be truly barge mounted or it may be self-floating. In the latter case it is effectively a sea-going object in its own right, must be fully seaworthy and must meet the requirements of the classification societies. The direct costs of transport of a barge-mounted plant may well be modest, but those of providing the stiff framing for, and the measures to counter stresses developed in, a sea voyage can be appreciable. A barge-mounted plant is a sea-going object so that it must be seaworthy and must meet the classification society specifications, which can be expensive.

One solution is to use a vessel designed specifically for the transport of modular plants. The Wijsmuller semi-submersible heavy lift vessel Super Servant, described by de Vilder (1982) is of this type. This is a development from the semi-submersible barges which have been in use for some decades, either unpowered or with auxiliary propulsion only.

The options for installation at the operating site have been discussed by Charpentier (1979), who lists four. One is a barge floating at sea or anchored. This means, in effect, a factory ship with its own propulsion and mooring systems. Another is a barge which floats but is moored along a quay, accessible from the sea on one side and from the land on the other. A third is a barge grounded on a dredged bed in a shelter site, possessing connections similar to those in the previous case but not subject to water movement. The fourth option is a barge grounded on a foundation sill and protected by some form of dike or dam.

The use of prestressed concrete hulls for barge-mounted plants has been described by Birkeland *et al.* (1979). They outline three options for installation at the operating site: a self-floating plant may be permanently floating or permanently grounded; a plant delivered by a barge is off-loaded and floated into position and then permanently grounded.

Reviews of projects on barge-mounted plants include those by Charpentier (1979) and Ricci (1981). Birkeland *et al.* (1979) describe several barge-mounted projects. They include a self-floating LPG refrigeration and storage barge, the *Ardjuna Sakti*, sited near Jakarta and permanently floating. Charpentier (1979) describes a number of projects involving barge-mounted plants. They include a refinery, a natural gas liquefaction plant, an ammonia plant and a methanol plant.

The design of a barge-mounted liquefied natural gas (LNG) liquefaction and storage plant, the marine LNG system (MLS), has been described by J.L. Howard and Andersen (1979); the project was intended for the Pars gas field off Kangan, Iran, but was interrupted by political factors. The authors give details of the process flow diagram, the LNG storage spheres and the fire protection and emergency shut-down systems. The design was done according to the requirements of the International Maritime Consultative Organization (IMCO) gas carrier codes. The installation was of the dredged basin type.

In the 1970s, the conversion of LNG to methanol prior to transport appeared to be a potentially attractive way of transporting energy on long hauls, and studies of barge-mounted plants for such conversion were carried out (R.G. Jackson, 1979). One application envisaged for such units was the exploitation for smaller, shorter life fields.

A somewhat similar motivation underlies the use of barge-mounted plants to process gas from fields for which a pipeline would be uneconomic and at which the gas would therefore be flared (Jansson *et al.*, 1979). These fields may include subsea completions where there is no production platform. The main design described is for an ammonia plant with the platform—a flat, broad barge moored at a single point mooring, but variations include barge-mounted urea, methanol, natural gas liquids (NGL) and LNG plants and beaching of the plant.

Ricci (1981) gives an account of a barge-mounted low density polyethylene (LDPE) plant for Bahia Blanca, Argentina. This plant was transported by the heavy lift semi-submersible described by de Vilder (1982) and referred to above. This author describes in detail the planning of the voyage in respect of the wind and acceleration forces and of the mechanical stresses to which the load would be subjected.

An account of a barge-mounted pulp plant installed in the upper reaches of the Amazon in Brazil using the industrial platform system has been given by Shimpo (1979). The site was one with no roads and accessible only by plane. There were two platforms, one for the pulp plant and one for the power plant. The platforms had to be designed for structural strength whilst being towed and during operation. Platform construction posed various difficulties. It proved impossible to set up a longitudinal

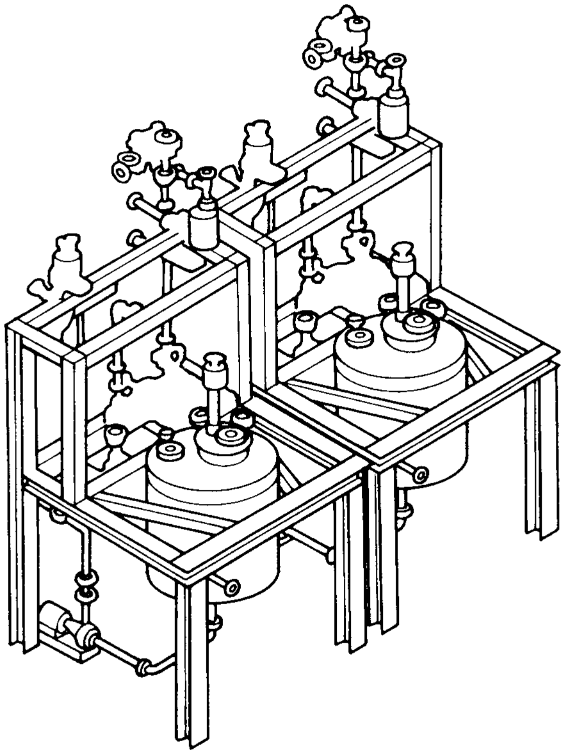

Figure 10.5 *Modular two-unit reactor train (Hester, 1990) (Courtesy of the American Institute of Chemical Engineers*

bulkhead and there were few straight transverse bulkheads. There were many large irregular openings in the main deck, especially close to the side. At the site the design was for the platform to be set on piles. There were problems arising from unbalanced soil strength and uneven live load on the platform. The project yielded much information on motions and stresses during the voyage and at the site.

10.21.4 Modular design

It is possible to adopt a modular approach to the design of plant, even if modular construction is not intended. An account of such modular design is given by Hesler (1990). A modular approach not only saves on design costs but also allows the design to be optimized and defects eliminated and, by offering equipment suppliers repeat runs, reduces equipment costs and procurement times. For some types of plant the normal design consists of replicated modules.

One type of plant for which modular design is often appropriate is a batch reactor system. Such plant generally consists of a number of similar reactor trains. Furthermore, these trains are frequently required to have the flexibility to permit changes in the raw materials used and products made and a modular design is able to accommodate such modifications. Typical units in such plant are reactors, columns, quench tanks, crystallizers, liquid-solid separators, and driers. Figure 10.5 illustrates the two-unit reactor train described by Hesler. Another example given by this author is the ICI FM-21 membrane chlorine cell.

10.21.5 Offshore modules

Another application of modular construction is on offshore oil and gas production platforms. The production deck of such a platform will typically consist of some four modules which are lifted whole onto the platform. The lifting capacity of the floating cranes used is now in fact such that a whole deck can be installed in one lift.

Process Design

Contents

11.1 The Design Process

Process design designates the Chemical Engineering development aspects of a process plant. This is augmented by the classical related engineering disciplines: Mechanical, Electrical, Civil along with others, which provide constraints as to the availability and feasibility of industrial equipment, electrical hazards and siting issues covered in Chapter 10. Clearly, issues such as single or multiple trains; equipment topological aspects (layout); industrial availability of machinery; heat exchangers and process towers and reactors; influence and interact with the process design.

The design of a large process plant, or plant modification or extension is a complex activity involving engineers of many disciplines. The design process normally involves engineering organizations and expertise other than the operating company. This aspect is considered in Section 11.2, Conceptual Design, or in the current parlance of the industry front-end engineering.

The project evolves under the influence of: research and development, which define the technical possibilities and constraints; safety, health and environmental studies, which lead to further constraints; economic studies, which indicate the productions costs and sales returns together with their sensitivity to the various factors; and the financial approvals, which allow the project to proceed. The political, social and environmental issues at the location must be recognized. An overall risk of the plant to the community must be developed and agreed with the appropriate local, state and federal authorities before further process design can proceed. This will largely comply with regulations and avoid a Bhopal-type catastrophe. The infrastructure available will dictate whether the design is a self-supporting grassroots or an integrated facility. Of course, the additional constraint of the limited space and congestion affect the design of offshore facilities.

The decisions made in the early stages, particularly concerning the process route, the plant capacity and their locations, are crucial. Thereafter, many options are foreclosed such that further fundamental changes are difficult, if not simply impractical.

From the safety and loss prevention (SLP) viewpoint it is essential to get the process fundamentally right from the start, as illustrated above. The design should be to eliminate hazard rather than devise measures to control it. This aspect is discussed in Section 11.3, Detailed Design, and also in Section 11.6, Inherently Safer Design.

The safety of the plant is determined primarily by the quality of the basic design rather than by the addition of special safety features. It is necessary, however, to incorporate specific systematic safety checks throughout the design process at each level, generally termed hazard identification and assessment studies.

11.1.1 Process risk management strategies

Risk has been defined as a measure of economic loss or human injury in terms of both the incident likelihood and the magnitude of the loss or injury (CCPS, 1989). Thus, any effort to reduce the risk arising from the operation of a chemical processing facility can be directed toward reducing the likelihood of incidents (incident frequency), reducing the magnitude of the loss or injury should an incident occur (incident consequences), or some combination of both. In general, the strategy for reducing risk,

Table 11.1 *Examples of process risk management strategies*

Risk management strategy category	*Example*	*Comments*
1. Inherent	An atmospheric pressure reaction using non-volatile solvents which is incapable of generating any pressure in the event of a runaway reaction	There is no potential for overpressure of the reactor because of the chemistry and physical properties of the materials
2. Passive	A reaction capable of generating 150 psig pressure in case of a runaway, done in a 250 psig reaction	The reactor can contain the runaway reaction. However, 150 psig pressure is generated and the reactor could fail due to a defect, corrosion, physical damage or other cause
3. Active	A reaction capable of generating 150 psig reactor with a 5 psig high pressure interlock to stop reactant feeds and a properly sized 15 psig rupture disc discharging to an effluent treatment system	The interlock could fail to stop the reaction in time, and the rupture disk could be plugged or improperly installed, resulting in reactor failure in case of a runaway reaction. The effluent treatment system could fail to prevent a hazardous release
4. Procedural	The same reactor described in example 3 above, but without the 5 psig high pressure interlock. Instead, the operator is instructed to monitor the reactor pressure and stop the reactant feeds if the pressure exceeds 5 psig	There is a potential for human error, the operator failing to monitor the reactor pressure, or failing to stop the reactant feeds to stop the reactant feeds in time to prevent a runaway reaction

Note: These examples refer only to the categorization of the risk management strategy with respect to the hazard of high pressure due to a runaway reaction. The processes described may involve trade-offs with other risks arising from other hazards. For example, the non-volatile solvent in the first example may be extremely toxic, and the solvent in the remaining examples may be water. Decisions on process design must be based on a thorough evaluation of all the hazards involved.

whether directed toward reducing frequency or consequence of potential accidents, falls into one of the following categories (Table 11.1):

(1) Inherent, or Intrinsic – Eliminating the hazard by using materials and process conditions that are nonhazardous (e.g. substituting water for a flammable solvent).
(2) Passive – Eliminating or minimizing the hazard by process and equipment design features that do not eliminate the hazard, but do reduce either the frequency or consequence of realization of the hazard without the need for any device to function actively (e.g. the use of higher pressure-rated equipment).
(3) Active – Using controls, safety interlocks and emergency shut-down systems to detect potentially hazardous process deviations and take corrective action. These are commonly referred to as engineering controls.
(4) Procedural – Using operating procedures, administrative checks, emergency response and other management approaches to prevent incidents, or to minimize the effects of an incident. These are commonly referred to as administrative controls.

Risk control strategies in the first two categories, inherent and passive, are more reliable and robust because they depend on the physical and chemical properties of the system rather than the successful operation of instrument, devices and procedures. Inherent and passive strategies are not the same and are often confused. A truly inherently safer process will completely eliminate the hazard (Kletz, 1991a).

The design experience and know-how of the organization may be generalized in terms of its knowledge of the characteristics of particular chemicals,unit operations and unit processes and so on. Full use should be made of this information both for process design and for hazard identification.

Accounts of process design are given in *Applied Process Design for Chemical and Petrochemical Plants* (Ludwig, 1964–), *Equipment Design Handbook for Refineries and Chemical Plants* (Evans, 1971), *Applied Chemical Process Design* (Aerstin and Street, 1978), *Introduction to Chemical Process Technology* (van den Berg and Dejong, 1980), *Chemical Process Synthesis and Engineering Design* (Kumar, 1981), *Process Analysis and Design for Chemical Engineers* (Resnick, 1981) *Process Design for Reliable Operation* (Lieberman, 1983), *Introduction to Material and Energy Balances* (Reklaitis, 1983), *Scaleup of Chemical Processes* (Bisio and Kabel, 1985) *Chemical process Computations* (Raman, 1985), *The Art of Chemical Process Design* (Wells and Rose, 1986), *Process Modelling* (Dean, 1987), *Conceptual Design of Chemical Processes* (Douglas, 1988), *Foundations of Computer Aided Process Operations* (Reklaitis and Spriggs, 1988), *Chemical Process Equipment* (Walas, 1990) and *Dimensional Analysis and Scaleup in Chemical Engineering* (Zlokarnik, 1991).

Economic aspects of process design are treated in *A Guide to Chemical Engineering Process Design and Economics* (Ulrich, 1984), *Economic Evaluation of Projects* (D.H. Allen, 1988) and *A Guide to Capital Cost Estimating* (IChemE, 1982a,b).

Case studies of process design include *Process Design Case Studies* (R.Scott and McLeod, 1991) and the Institution of Chemical Engineers (IChemE) model design projects described by Jeffreys (1961), Austin and Jeffreys (1979) and Ray and Johnston (1990).

Treatment of the SLP aspects of process design is given in *Hazard Survey of the Chemical and Allied Industries* (Fowler and Spiegelman, 1968), *Flowsheeting for Safety* (Wells, Seagrave and Whiteway, 1976), *Industrial Hazard and Safety Handbook* (R. King and Magid, 1979), *Safety in Process Plant Design* (Wells, 1980), *Chemical Process Safety* (Crowl and Louvar, 1990), *Safety in the Process Industries* (R. King, 1990), *Safety at Work* (Ridley, 1994) and Austin (1965a, 1982a), Hudson (1965) and Fitt (1976a).

Selected references on chemical reactors, unit processes, unit operations and equipments, extreme operating conditions, utilities, particular chemicals, particular processes and plants, ammonia, urea and ammonium nitrate plants, and liquefied petroleum and natural gases (LPG and LNG) are given in further tables in this chapter.

11.1.2 Design stages

Some important stages of the design of a process plant are:

(1) research and development – pilot plant;
(2) process design;
    (a) selected process flowsheet,
    (b) detailed process design-simulation,
(3) front-end conceptual engineering;
    (a) Process development unit (new design),
(4) Engineering design and equipment specification – selection.

The current execution technique in virtually all organizations is not to have the discrete stages indicated which are designated silos, but to have engineering interaction at the earliest process stages to avoid subsequent pitfalls.

The design of a plant is an interactive and iterative process. Modifications are made as more information becomes available, as constraints or opportunities are recognized, and as the situation changes.

It is necessary to pay close attention to the scheduling and co-ordination of the project, which is a project management function to provide the guidelines required.

11.1.3 Design information

Process design can be properly done and executed only with adequate and correct design data. This should include as a minimum:

(1) the physical and chemical properties of the chemicals;
(2) the reaction characteristics, including mechanism, kinetics and thermal data for all likely reactions;
(3) fire, explosion and toxic hazards;
(4) the effect of trace impurities which may have a major impact on metallurgy.

Particularly relevant for safety and loss prevention are material safety data sheets (MSDSs). These data are legally required and must be available for operating plants.

The data used in the design must be consistent throughout the design team. It is necessary, therefore, to devote some effort to the provision and documentation of these data.

Beside special proprietary data, processes data are available on line from suppliers such as ASPEN.

11.1.4 Design standards and codes

The standards and codes which are to be used in the design should be specified from the start. Standards and codes give design requirements and guidance. They constitute both an aid to the designer and a means of communicating design requirements to other parties, with certain contractual implications. They embody the lessons which industry has learned from past incidents and are therefore a store of experience which the designer should draw on.

Consistency should be maintained both in the initial choice of standards and codes and in their subsequent use. A particular code or set of codes embodies a particular design philosophy. It is not good practice to use an indiscriminate mix of codes or to use a different code for a particular problem simply because its requirements are less onerous. This can cause difficulties not only at the design stage but also later in plant operation and maintenance when confusion may arise as to the design philosophy.

There is often some degree of overlap in the topics covered by different codes. Consideration should be given to areas where codes may conflict or where there may be gaps which are not covered.

An account of standards and codes is given in Appendix 27.

11.1.5 Design experience

It is useful to consider the forms in which process design experience and know-how are available. The information may relate to:

(1) chemical reactors;
(2) unit processes;
(3) unit operations and equipment;
(4) operating conditions;
(5) utilities;
(6) particular chemicals;
(7) particular processes and plants.

Thus, much information is available on: the characteristics of chemical reactors, including reactor protection; unit processes, such as oxidation; unit operations, such as distillation; operating conditions, such as high pressures and low temperature; utilities, such as electricity, steam and nitrogen; on particular chemicals such as ethylene or chlorine; and particular processes and plants, such as air and ammonia plants.

In particular, information is available in the form of national standards and codes of practice, in-house standards, procedures and reports and checklists. This documentation is the principal means whereby experience won at considerable expense of money, effort and sometimes life is made available for design of new plants. This information should be used in design, and in the reviews of the design.

11.1.6 Design communication and documentation

It is essential in the design process that there be effective communication. Much of this communication is done on an individual basis or in design committees. The most important channel of communication, however, is the documentation. Details of this have been given in Chapter 6 and are not repeated here. Of particular importance are the process flow sheet, the process flow diagram and the engineering line diagram. Examples of the two latter are shown in Figures 11.1 and 11.2.

One item of information which is often required for SLP work and which has frequently not been shown on flow diagrams is the inventory of the principal vessels. It is desirable that flow diagrams show the normal and maximum design inventories.

Of particular importance are the process flow diagram, process heat and mass balances, and the engineering flow sheets (piping and instrument diagram, P&ID). Typical examples are shown in Figure 11.1 process flow diagram and Figure 11.2 P&ID.

11.1.7 Design changes

At a critical point in the design, a freeze is instituted to complete the design effectively. Inevitably, changes occur subsequently, usually due to external factors which must be accommodated. A management of change (MOC) procedure is instituted to ensure all aspects of the change are properly reviewed, accredited and authorized, and communicated to all parties involved. This is also required for construction and commissioning activities. The control of plant changes or modifications is considered in Chapter 21.

11.1.8 Overdesign

Overdesign in engineering is often equivalent to the incorporation of an extra factor of safety, but this is by no means always so. In some cases such overdesign can reduce safety. There is an inherent tendency to overdesign in a project as the various individuals in the chain introduce factors of safety. In this context overdesign is taken to cover the purchasing as well as the design decisions. What matters is the item which is finally installed.

This is illustrated by two common items of process equipment, pumps and control valves. If a pump is required which has a certain characteristics relating to flow and pressure and if the pump installed is capable of a higher flow or pressure, this may introduce a hazard insofar as the rest of the plant is not designed for these conditions. Similarly, control valves are almost always oversized. If reliance has been placed on a valve of a certain size to limit flow to a maximum value and a larger valve is provided, a hazardous situation may result.

11.1.9 Design error propagation

It is sometimes appropriate to check the error associated with a design calculation, particularly if this has important safety aspects. If a calculated variable z is a function of two other variables x and y,

$$z = f(x, y) \tag{11.1.1}$$

then the calculated value of z will have an error S_z which results from the errors δx and δy in x and y, respectively. There are two errors which are of interest. The maximum error is

$$\delta z = \left|\frac{\partial f}{\partial x}\right|\delta x + \left|\frac{\partial f}{\partial y}\right|\delta y \tag{11.1.2}$$

A more realistic estimate is the probable error

$$\delta z = \left[\left(\frac{\partial f}{\partial x}\right)^2 \delta x^2 + \left(\frac{\partial f}{\partial y}\right)^2 \delta y^2\right]^{1/2} \tag{11.1.3}$$

Further information is given in standard texts (e.g. Jenson and Jeffreys, 1963). A discussion of error propagation is given by Park and Himmelblau (1980).

11.1.10 Computer-aided design

Modern process design involves considerable use of computer-aided design (CAD) techniques, particularly for flowsheeting, equipment design, plant layout, piping and instrument diagrams. Other applications continue to be developed. In particular, extensions of computer design are developing in the area of information flow in plants, leading to automatic hazard identification, fault tree analysis and reliability assessment.

In the design context, computer systems constitute a powerful tool not only for design but also for information storage and retrieval, and thus for communication. Here their effectiveness depends on the database. The design of databases which can be used by all members of the team and which can be quickly but securely updated is another area of development.

A fuller treatment of CAD is given in Chapter 29 and treatment of more advanced CAD developments is given in Chapter 30.

11.2 Conceptual – Front End Design

At the conceptual design stage the process concept is developed, its implications are explored and potential problems are identified. Design in general and conceptual design in particular is generally regarded as an art. Much work is going on, however, to put it on a more systematic basis. Early work is described in *Strategy of Process Design* (Rudd and Watson, 1968). A systematic approach is stated in *The Conceptual Design of Chemical Processes* (J.M. Douglas, 1988). A further discussion of fundamental developments is given in Chapter 30.

In most cases, the process is an established one, so that the conceptual design stage may be quite short. The nature of this stage is best appreciated, however, by considering the conceptual design of a new process. Elements of the process and plant considered in conceptual design are:

(1) process materials;
(2) chemical reaction;
(3) overall process;
(4) effluents;
(5) storage;
(6) transport;
(7) utilities;
(8) siting and layout.

The topics addressed in the conceptual design are principally:

(9) process design;
(10) mechanical design;
(11) pressure relief, blow down, venting, disposal and drains;
(12) control and instrumentation;
(13) plant construction and commissioning;
(14) plant operation;
(15) plant maintenance;
(16) health and safety;
(17) environment;
(18) costing.

The plant turn-down capability must be defined and the potential problems for each piece of equipment identified.

The philosophy underlying the conceptual design should be that of inherently safer design, which is applicable to virtually all aspects. Likewise, in regard to the environment, there should be a philosophy of inherently cleaner design.

The process materials include the raw materials, or feedstocks, the intermediates, and the products and also catalysts, additives and so on. Data are assembled on the physical and chemical properties, on the flammability and the health and toxicity, including material safety data sheets, and any special hazards of, or processing problems associated with, the materials. The composition of the raw materials is considered, including impurities which they may contain. The main chemical reaction of the process is reviewed with several aims in view. These are to ensure that the information available is adequate and that the reaction is sufficiently well understood; to identify the problems and hazards associated with the reaction; to define the reaction sequence and conditions; to examine the effect of the reaction stage on the later processing stages; to explore the possibility of alternatives and to determine the basis of safety of the reaction.

Processes which are likely to be particularly hazardous with respect to the reaction include those involving: highly reactive substances, such as those with a triple carbon bond; a high exotherm; unstable substances; thermally sensitive substances; substances sensitive to impurities, such as air, water, rust or oil and high pressure and/or high temperature.

The other stages of the process are reviewed in a similar way. Here the aims are: to ensure that there is sufficient design information available; to identify the problems and hazards associated with particular process conditions, unit operations and equipments; to define the operating conditions of the equipment; to explore alternatives and to determine the basis of safety of the equipment.

Some features of process conditions which may point to problems or hazards include: operation close to a phase change (boiling, condensation, freezing); operating conditions which give on release a flashing liquid and extreme requirements for exclusion of air or water, for leak tightness or for cleanliness. Corresponding features for equipment include: use of novel equipment; requirement for special materials of construction; pumping of difficult fluids; and unusual pressure relief requirements.

The gaseous and liquid effluents and solid wastes generated by the process are reviewed with a view to: reducing or eliminating them; rendering them less noxious and more easy to dispose of; to explore process alternatives which may be beneficial in this regard; and to decide on their handling and disposal.

A review is made of the requirements for storage of raw materials, intermediates and products. Storage is always a large contributor to costs and often to the hazards of the installation. Here the aims are: to define an operating philosophy for the plant in respect of storage and to match the storage provided to this; to determine the type of storage to be used for each material and the conditions under which it is to be stored and to decide in outline the siting and layout of the storage. The thrust should be to eliminate storage by the use of a 'just-in-time' approach.

The methods of transport of the raw materials and products are reviewed in order: to define material flows for delivery and shipping which match the process and storage requirements; to explore the implications of the different modes of transport available; to select the mix of transport modes which best meets the governing factors; and to decide in outline the siting and layout of terminals and pipelines. Factors which need to be taken into account include the volume of materials transported, the hazards of these materials and of the modes of transport, the probable life and growth of the transport requirement, the effects of traffic on the environment outside the site, and the traffic flows and handling within the site. The review of storage and transport generally involves interactions particularly between these two but also with the process.

The utilities for the process are reviewed in order: to define the requirements not simply in terms of the nominal quantities but also of the quality and dependability of the supply; to identify any problems and hazards, including implications for existing plants; to explore alternatives; to determine the method of supply for each utility and to decide in outline on siting and layout. On the basis of the foregoing information, decisions may then be made concerning the siting and layout. An account has been given in Chapter 10 of the principles applicable at the conceptual design stage.

In the foregoing the conceptual design has been treated in terms of the process and the plant. In the following it is considered essentially in relation to the design disciplines. The first of these is process design. Some account of this has already been given above. In essence, process design at this stage involves consideration of the process and plant from a number of different viewpoints: the process flow sheet and process conditions; the unit processes and the unit operations and equipments. Two of the principal aims at this stage should be the minimization of hazards by inherently safer design and the minimization of effluents by inherently cleaner design. Regard should also be given to the location where the plant is to be built. Features such as the nature of the available workforce or the access for transport of plant equipment may be relevant. In some cases such factors may point to a more robust design.

The reliability and availability aspects of the plant need to be given some thought at this stage. Different philosophies may be adopted. Options are to accept loss of a function for a period or to minimize its downtime by use of a single high reliability unit or to use several units, with parallel redundancy or stand-by configurations. For some types of plant a single-stream philosophy is the norm. Even with such plants, however, there are certain types of units, such as furnaces, which are commonly multiple and others for which stand-by configurations are widely used.

The process designer is rarely a completely free agent. In most cases, the process in view is an established one, but even where this is not the case there tend to be numerous constraints. There is commonly within the company itself a preference for established technology and an aversion to innovation and the risk perceived to be associated with it. Generally, there are requirements imposed by outside parties. A licensor of a process usually imposes certain requirements which are a condition of the guarantees provided. Likewise, an equipment vendor generally makes his guarantees conditional on requirements such as use of certain ancillary equipment or of alarm and trip instrumentation. An insurer often has preferred arrangements for fire protection. Acceptance of various constraints may be a condition for raising the necessary finance.

Mechanical design at this stage is fairly limited, but consideration is given to materials of construction and to the principal vessels and other items of equipment.

The arrangements for pressure relief, blowdown and venting, for relief and vent disposal, and for drains are also addressed at this stage. These generally have a number of significant implications which it pays to explore at the conceptual stage, because changes later in the design tend to be either disruptive and costly or simply not possible. Thus, a decision to contain rather than to relieve a high pressure may entail a stronger vessel, but such vessels have to be ordered early. A decision to dispose of a relief flow by venting or flaring may require a sterile area which needs to be incorporated early in the layout.

Control and instrument system design is concerned at this stage with the philosophy in respect of allocation of function between the human operator and automatic systems and of the means of providing the latter. The process may be reviewed to assess unsteady-state features, including the dynamics of continuous processes, the sequential operation of batch processes, and start-up and shut-down, and to identify any particular control and instrument problems, including difficult measurements.

The conceptual design stage also covers consideration of the construction and commissioning, operation and maintenance of the plant. Construction creates requirements for space on site, for additional traffic and for lifting equipment, and may affect existing plants. Commissioning also may effect existing plants as the new plant is tied in and manned. The operation of the plant too has implications for other linked plants and for storage requirements.

The start-up and shut-down of the plant are considered at the conceptual design stage. Start-up involves taking the plant through a series of discrete stages. In general, some of these stages can be held indefinitely, whilst others are essentially transient, with no choice but to proceed to the next stage or revert to an earlier one. These stages need to be defined and holding states identified. Likewise, normal shut-down may be effected in a series of discrete stages and these need to be defined. It is also prudent to identify holding states, or fall-back positions, short of shut-down, to which the operator can move if abnormal conditions develop, thus taking pressure off him and making the plant more friendly. Definition of emergency shut-down is necessary since it is liable to involve abnormally high flows which have to be catered for.

The plant needs to be reviewed in respect of health, safety and environmental factors. Each of these aspects needs to be assessed using a formal method to identify the problems. Health factors may affect features such as the degree of leak-tightness required, the use of buildings and the need for particular operating practices.

The factors related to safety are discussed throughout this text and are not rehearsed here, but one particular aspect merits mention at this point. This is the major hazard potential of the plant, which needs to be addressed at the conceptual design stage. This evaluation is necessary because the information gained has a bearing on many fundamental aspects of the design. Methods of hazard identification and assessment appropriate to the conceptual design stage have been described in Chapters 8 and 9. Relevant techniques include the various preliminary hazard study and hazard ranking methods. The formal requirement for the use of such methods as part of the management system has been discussed in Chapter 6.

The approach to environmental aspects is essentially similar, with a formal requirement for the assessment of the major environmental impact potential using specified methods. There are now regulatory requirements for a safety case for major hazard installations and for an environmental impact statement for certain developments, as described in Chapters 3 and 4.

The conceptual design includes, as part of an overall economic assessment, an estimate of the costs of the various elements described.

11.3 Detailed Engineering

The detailed design stage involves the detailed process and mechanical design together with detailed design from a large number of supporting disciplines. The treatment given here is confined to a broad outline, with particular reference to features bearing on SLP.

Elements of the detailed design of the process and plant include:

(1) process design;
(2) mechanical design;
(3) storage;
(4) transport;
(5) utilities;
(6) layout;
(7) pressure relief, venting and disposal;
(8) control and instrumentation;
(9) fire protection;
(10) explosion protection;
(11) toxic emission protection;
(12) personnel protection;
(13) plant failures;
(14) plant operation;
(15) plant maintenance;
(16) plant reliability, availability and maintainability;
(17) equipment specification, selection and procurement;
(18) health and safety;
(19) environment.

Central to the process design is the chemical reactor. The design should minimize the probability of a hazardous excursion and provide means for dealing with one should it occur.

The process design should take full account of the experience available, both within the company and elsewhere, in respect of the unit processes, the unit operations and equipments, the operating conditions, the utilities, the particular chemicals and the particular processes and plants, as described in Sections 11.7–11.12, respectively.

The process design sets the operating conditions throughout the process for normal operation and defines the envelope of conditions within which the process can operate safely. This information governs the mechanical design. Consideration should be given in the process design to the various operational deviations which may occur and to the impurities which may be present, as described in Sections 11.13 and 11.14, respectively.

In the mechanical design, the materials of construction need to be compatible with the process materials not only at flow sheet conditions, but within the whole envelope of operating conditions, and compatible also with each other. Attention needs to be paid to impurities which may cause greatly increased corrosion. Consideration has to be given also to erosion. Major piping vessel codes have been rewritten and emphasis placed on low temperature design to avoid catastrophic low temperature material failure.

The design should ensure effective containment of the process fluids within the pressure system of vessels, pipework and rotating machinery. Piping design accounts for 50% of the reported loss of containment incidents. Detailed attention needs to be given to pipework, pipework joints and pipework supports, and to the numerous features which can cause damage, including vibration, thermal expansion and contraction, shut-in fluids, water hammer and external events. Likewise, weak points on rotating machinery such as pump seals require consideration.

In addition to avoidance of loss of containment, it is also necessary to design to minimize much smaller but continuous leaks, known as fugitive emissions. These are considered in Chapter 15.

There often arise situations where there is a trade-off to be made between flexibility and complexity. It may be possible to design manifolds which allow a more flexible use of certain items of equipment but at the price of a considerable increase in complexity of the pipework. Often complexity may be too high a price to pay for the additional flexibility. The mechanical design of the plant is dealt with in Chapter 12.

Features of the design of storage are the choice between pressure and refrigerated storage for liquefied gases, the specification of the design pressure and temperature, the venting and the operating and fire relief arrangements, the fire protection, the bunding or drain-off arrangements, and other aspects of storage layout.

For the loading and unloading terminals for the transport of raw materials and products, features are the fluid transfer arrangements, the fire protection, the emergency isolation, the control of ignition sources, including precautions against static electricity and hazardous area classification, and other aspects of terminal layout. Non-return or check valves must always be used at any connection between a utility and the process, often removable isolation spools are also provided.

Location of vent stacks, furnaces and boilers should take into account the prevailing wind. Seismic design is particularly relevant in storage tank areas.

Plant layout is considered in Chapter 10. Features which merit mention here are: the provision of separation to minimize both ignition of flammable leaks and the effects of fire and explosion, and hence domino effects; the control of ignition sources through hazardous area classification; the provision of a suitable drainage system; and the labelling of equipment to ensure positive identification in plant operation and maintenance; as well as the aspects of the layout of storage and terminals already mentioned.

The arrangements for venting, pressure relief and blowdown are a significant feature and have a pervasive influence on the overall design. It is normally necessary to cater: for venting from the process, either continuously or periodically; for pressure relief for operational conditions; and for pressure relief for fire conditions. Features are: the relief scenarios; the location, setting and capacity of relief devices; the selection of these devices; the relief collection system; the choice between relief to atmosphere or to a disposal system; and the selection of the disposal system.

It is also necessary to cater for the relief and blowdown which occurs during emergency shut-down. Venting and pressure relief are treated in Chapters 12 and 15.

Aspects of the control and instrumentation system which are particularly relevant here are the provision of: protective systems in the form of trips and interlocks; a fire and gas detection system; and an emergency shut-down system. Control and instrumentation are considered in Chapter 13.

The fire protection system will generally rely on a combination of passive features such as layout and fire insulation and active ones such as fire and gas detection, emergency blowdown, and fire fighting and equipment cooling systems using water spray, foam and other measures. Fire and fire protection are discussed in Chapter 16; layout aspects are treated in Chapter 10.

Protection may also be required against explosion of flammable vapours or dusts within the plant or inside buildings. Explosions and explosion protection are considered in Chapter 17; layout aspects are treated in Chapter 10.

If the substances handled are particularly toxic, it may well be necessary to design for an enhanced degree of protection against them. The first line of defence is a more leak-tight plant. Dilution and removal of any leaks which occur is assisted if the plant is located in the open, but if it is in a building ventilation may be necessary. Toxic releases and occupational health are dealt with in Chapters 18 and 25; fugitive emissions are considered in Chapter 15.

Personnel protection should not be neglected. Aspects include: access to equipment, particularly hand valves; layout to minimize contact with corrosive substances; guarding of moving machinery; insulation and other measures to prevent contact with hot surfaces; and safeguards to prevent injury due to the operation of fire extinguishing systems. Chapters 10, 16 and 25 in particular deal with such topics.

The design should cater for the requirements of plant operation, discussed in Chapter 20. The requirement to isolate items of equipment or sections of the plant should be studied and features such as high frequency of isolation or need for positive isolation identified and, where appropriate, measures taken or facilities provided. Thus flexibility may be built into the pipework to assist the insertion of slip plates, or isolation facilities, such as a spectacle plate or double block and bleed valves, may be provided.

The requirements for plant start-up, normal shut-down and emergency shut-down should be studied and facilities provided as necessary.

Facilities need to be available to dispose of any material which is off specification, contaminated, or otherwise unsatisfactory, which may be produced in the course of plant operation, whether in the plant itself or in storage. Inspection is practised on a range of plant equipment and using a variety of techniques, and for some of these it may be necessary to provide facilities, even if this amounts to no more than suitable access. Likewise, facilities may be required for various types of test on equipment. Plant inspection and testing are considered in Chapter 19.

For plant maintenance reference has already been made to isolation arrangements. Maintenance often involves emptying the plant of fluids and suitable vents and drains need to be provided for this purpose. It may also be necessary to clean the inside of the plant, and this too may require particular facilities. Plant maintenance is discussed in Chapter 21. Plant lock-out tag procedures must be in place to meet legislative requirements for the Occupational Safety and Health Laws.

The failures that may occur on the plant should be considered. The items of plant equipment should be identified which are particularly vulnerable to frequent failure and/or failure of which could have serious consequences. For plant systems failures, 'Hazop', 'what if', or check list techniques should be used. A technique particularly suitable for investigation of potential equipment failures is failure modes and effects analysis (FMEA).

Consideration should be given to hazardous passages of fluid through isolation, which include leaks through valves which are not leak-tight and opening of bypasses around equipment.

The effect on the plant of failure of utilities such as electrical power or cooling water should be reviewed. The need for emergency back-up supplies should be considered, as described earlier.

The effect of abnormal conditions and of start-up, normal shut-down and emergency shut-down on plant under design on other linked plants should receive attention. Links exist by virtue of the transfer of materials between the plants or common use of a utility. Likewise, the effect on the plant in question of such conditions on other plants should be considered.

For critical functions the reliability and availability required should be specified. Steps can then be taken to ensure that the specification is met by the elimination of causes of failure, the use of single, high reliability items, or the use of suitable configurations of multiple items, such as installed spares. This approach should also be applied to the utilities, including the emergency back-up supplies.

The specification, selection and procurement of equipment should receive its share of attention. The equipment specification should match the design of the plant into which it is to be incorporated. The initial specification may be defective in neglecting some important aspect. Alternatively, it may be unnecessarily restrictive. It may well pay to discuss the specification with other parties to the design and with the prospective manufacturer. In selecting the equipment, the experience of the manufacturer in supplying equipment for similar duties should be taken into account. It should be borne in mind, however, that whilst a manufacturer supplies a range of equipments which are suitable for a generic duty, he cannot be expected to know about special features or requirements which may exist on the plant in question.

The detailed design needs to be subjected to review in respect of health, safety and environment. The design assessments made of these and other aspects are now considered.

11.4 Design Assessments

As the design progresses, it is subject to various assessments, which draw on a number of specific techniques. Those considered here are: (1) critical examination, (2) value engineering assessment, (3) energy efficiency assessment, (4) reliability and availability assessment, (5) hazard identification and assessment, (6) occupational health assessment and (7) environmental assessment.

11.4.1 Critical examination

Critical examination, which is a structured method for asking basic questions about the plant, is an effective method for fundamental review, exposing assumptions and generating alternative options. There are in effect a family of techniques which have grown out of critical examination. One is hazop, which is directed to hazard identification, as described in Chapter 8. Another is value engineering, which is now considered; construction management; inspection and documentation.

Value engineering utilizes the techniques of reliability engineering and hazard identification such as Pareto analysis and FMEA. A large value engineering study may take approximately 300–400 h, a medium one 100–300 h and a small one 20–100 h. Others include value improving practices (VIPs), which are now considered.

11.4.2 Value improving practices

VIPs are formal structured practices applied to the front-end stages of any project to improve profitability above that attained through good engineering and project management practices. VIPs are also intended to challenge existing project and design premises to ensure the most robust and profitable facility results. Often, design deficiencies are revealed in these workshops and better alternates identified. Well-recognized VIPs include:

(1) classes of facility quality;
(2) technology selection;
(3) process simplification;
(4) constructability;
(5) customization of standards and specifications;
(6) predictive maintenance;
(7) process reliability simulation;
(8) value engineering;
(9) design to capacity;
(10) energy optimization;
(11) waste minimization;
(12) Three-dimensioanl-CAD.

All VIPs include key components that ensure that the design will result in a safe and predictably operable facility. Moreover, the practices all focus on identifying safe, technically viable and economically attractive improvements. To accomplish this, improvements are identified, analysed and recommended by multidiscipline expert teams composed project team members and experts from outside the project team. Experience has proven that including subject matter experts from the operating company involved, the engineering contractor and key technology licensors produce the best overall results. Experince has also shown that three of the VIPs are the most rigorous and consistently produce greater value improvements. They are the process simplification VIP, the constructability VIP, and the value engineering VIP.

11.4.3 The value methodology

The process simplification VIP and the value engineering VIP require the use of the value methodology. This methodology has been used extensively throughout industry since the 1940s and is supported by the Society of American Value Engineers (SAVE) International (see SAVE at http://www.value-eng.org). This methodology is now used worldwide and is an integral part of many major project plans in industry and government today.

The value methodology follows an established set of procedures that include: (1) pre-study planning and information gathering, (2) information analysis, (3) function identification and analysis, (4) identification of creative alternatives for key functions via brainstorming, (5) evaluation of selected alternatives, (6) development of selected alternatives to estimate costs, benefits, risks and other impacts to the project, (7) recommendation of the best alternatives, (8) implementation or approved recommendations by the project team and (9) post-study follow-up.

The value methodology differs from simple brainstorming session and simple cost-cutting exercises by emphasizing function analysis based on health, safety and environmental (HSE) requirements, required construction, operations and maintenance needs, project and market schedule constraints, all expected facility uses and operating conditions, and consideration of life-cycle costs and not just installed costs.

11.4.4 Function analysis

A function is the intent or purpose that the equipment, product or process is expected to perform best described using an active verb and a measurable noun. In the function analysis phase, each function is depicted in graphical intuitive-logic format known as a function analysis system technique (FAST) diagram. For example, one of a distillation column's functions could be to 'separate volatile compounds'. Another function might be 'separate final product.' Functions are obtained by confirming what the process system or equipment component must do or how it must perform under steady-state and non-steady-state conditions.

Once the functions of the design and project are identified in a collaborative team environment, alternatives for each function are sought in an open creative environment via various brainstorming techniques. These alternatives are then evaluated by the team. If they are found to offer higher overall value than the current design, they are recommended for further engineering analysis. If the analysis confirms that the life-cycle benefits outweigh the risks, then the change becomes a permanent part of the design or facility.

11.4.5 The process simplification VIP

The process simplification VIP consistently yields the greatest value improvements of the VIPs. It is a formal, rigorous process to search for opportunities to eliminate or combine process and utility system steps or equipment ultimately resulting in the reduction of investment and operating costs. The focus is the reduction of installed costs and critical path schedule while balancing these value improvements with expected facility operability, flexibility and overall life-cycle costs. The so-called value improvements that compromise safe operations or required environmental performance are not accepted or recommended from these formal studies. Critical analysis of each recommended improvement is required by the project team to verify that the risks associated with the recommended change are well understood and manageable.

Process simplification is executed in a formal workshop with an experienced facilitator. It insures that low- or zero-value functions or equipment included in the project scope are challenged to be the highest value possible for the project. Removal of these low- or zero-value functions from the project scope, if possible, will most likely yield significant economic improvements to the overall project.

Process simplification results in reduced capital costs (CAPEX), improved critical-path schedule, reduced process inventory, increased yields, reduced operating and maintenance costs (OPEX), increased productivity, incremental capacity gains, reduced utility and support systems requirements and reduced waste generations. It also provides a means for integrating overall plant wide systems when applied at the block level in addition to the unit level.

11.4.6 The constructability VIP

The constructability VIP is the facilitated systematic implementation of the latest engineering, procurement and construction concepts and lessons learned consistent with the facility's operations and maintenance requirements to enhance construction safety, scope, cost, schedule and quality. This VIP involves planning, design, procurement, fabrication and installation to achieve the best overall project safety record, lowest installed costs and the shortest reasonable schedule. Constructability helps account for construction options and requirements during design, thus reducing re-work and delay in the construction and start-up schedules.

11.5 Licensors, Vendors and Contractors

The description of the design process which has just been given is based essentially on that which takes place in an operating company which is designing its own plant. The ultimate responsibility for the safe design and operation of plant lies with the operating company and the owner. It should take the appropriate steps to ensure that the processes designed and the equipment supplied by the other parties are safe.

Some design responsibility resides, however, with other parties. These may be (1) licensor, (2) vendor and (3) contractor. A treatment of licensing is given in *Licensing Technology and Patents* (V. Parker, 1991). Contractual arrangements are the subject of the series *Model Form of Conditions of Contract for Process Plants* in three volumes – (1) subcontracts, (2) lump sum contract and (3) reimbursable contracts – by the IChemE (1992a–c) (the 'Yellow Book', 'Red Book' and 'Green Book', respectively) with a guide by D. Wright (1993) (the 'Purple Book').

If the process has been bought under licence, then the licensor has some design responsibility. The extent of this depends on how much information the licensor releases as a result of the licence agreement. Normally the licensor is responsible for the basic process flowsheet, but he may also specify some detailed process design and safety features. It is important to ensure that the division of responsibilities is specified in the licence and that adequate information and documentation are made available.

There is a responsibility on the vendor to supply equipment which is safe. The equipment should conform to specified standards and codes and it should have adequate documentation such as fabrication records or operating instructions. The purchaser is responsible for specifying standards and codes to be used, for ensuring that the equipment delivered is that specified and for seeing that it is used as intended. If changes are required to a licensed process or to equipment, consideration should be given as to whether these constitute modifications on which consultation is required.

The responsibilities of the contractor depend on whether he is responsible for the whole process and engineering design on a turnkey basis or whether he is acting as an extension of the client's own organization and is thus undertaking detailed engineering only. In the first case the responsibility of the contractor is obvious, but even in the second he retains a residual responsibility. Again it is important for the contract to state clearly the division of responsibility. If the design responsibility lies primarily with the contractor, he should subject the design to safety checks using methods of hazard identification and assessment, as already described.

It may happen in some cases that the client proposes a feature which the contractor considers unsafe. If agreement cannot be reached, the contractor should not undertake this feature. Another point of difficulty can arise if the client wishes to make a modification. The contractor should make all reasonable checks that the modification does not introduce a hazard.

11.6 Inherently Safer Design

The best way of dealing with a hazard is to remove it completely. The provision of means to control a hazard is very much the second best solution. This has been succinctly stated by Trevor Kletz as 'What you don't have, can't leak'. This, of course, immediately eliminates fire and explosive hazards. A corollary to this is the importance of limiting inventory of hazardous materials, which is one of the lessons learned in the Flixborough disaster. This principle has been incorporated in the systematic application of inherent safety.

The terminology 'inherently safer design' is 'intrinsically safer design' which is associated with electrical power and control issues. The comparative term safer is used since no operating plant is absolutely or totally 'safe'.

11.6.1 Limitation of inventory

One of the principal ways in which a process may be made inherently safer is to limit the inventory of hazardous material. The scale of the Flixborough disaster was due to the fact that the holdup of flammable liquid at high pressure and temperature in the reactors was large. The inventory in the five reactors and one after-reactor operating at the time of the explosions was about 120 te. The *Flixborough Report* recommended that consideration be given to reducing the inventories on process plants.

It is a normal objective in design to minimize the volume of process vessels, as this saves on the cost both of the vessels themselves and of the supporting structures. But the reduction of holdup, though recognized as a generally desirable aim from the safety viewpoint, had not been particularly emphasized as an explicit aim in safe design.

This situation has been changing, largely as a result of Flixborough. The *Second Report of the ACMH* (Harvey, 1979b) states that limitation of inventory should be a specific design objective. The philosophy of limitation of inventory has been memorably captured by the motto of Kletz (1978c): 'What you don't have, can't leak'. It is better to have only a small inventory of hazardous material than a large one which can be rendered relatively safe only by highly engineered safety systems. In other words, it is better to keep a lamb than a caged lion.

Process inventories have been increasing proportionally to plant capacities based on fixed holdup time rules.

This has usually been based on pneumatic and direct controlled instrumentation with limited response times. Currently with electronic instrumentation, smart control valves and transmitters, DCS- and PC-integrated systems these rules no longer apply. This results in adequate controllability with much smaller inventories.

The advent of very large process plants has resulted in massive overhead distillation accumulators which require isolation safety systems as well. In many cases, the accumulators can be eliminated by providing judiciously reduced inventory in the wells of the overhead condensers. This principle has been utilized on a number of recent plant designs.

11.6.2 Some basic principles

Some basic principles of inherently safer design Kletz (1984a–m, 1991b) are:

(1) intensification;
(2) substitution;
(3) attenuation;
(4) simplicity;
(5) operability;
(6) fail-safe design;
(7) second chance design.

A plant which embodies these principles is described by Kletz (1989c, 1990f) as a ‘friendly plant’. Some features of friendly plants are given in Table 11.2.

These basic principles have been distilled down to the following systemized approaches (CCPS, 1996 ‘Gold Book’):

(1) minimize;
(2) substitute;
(3) moderate;
(4) simplify.

Approaches to the design of inherently safer processes and plants have been grouped into four major strategies by IChemE and IPSG (1995) and Kletz (1984a–m, 1991b); and CCPS (1996 ‘Gold Book’ 1993a).

11.6.3 Intensification

A principal route to limitation of inventory is intensification of the process. This means carrying out the reaction or unit operation in question in a smaller volume. Process intensification is applicable to a wide range of chemical engineering operations, including reactors, mass transfer operations such as distillation and gas absorption, and to heat exchange, as described below.

11.6.4 Substitution

Another principle of wide applicability is that of substitution, in which a hazardous feature is replaced by a less hazardous one. Applications described below include substitution in the main process reaction and in heat transfer media.

11.6.5 Attenuation

A third principle, that of attenuation, involves the use of less hazardous process conditions. Examples of its application are given below. What constitutes a less hazardous process condition, however, is not always obvious. The problem is a multidimensional one. This aspect is described below in the context of the hazards of compromise.

11.6.6 Selection of process

The starting point for inherently safer design is the selection of the process with a view to eliminating particularly hazardous chemicals and/or to operating under less hazardous conditions. Some examples of selection of inherently safer processes are given by Kletz. In dyestuffs production use is no longer made of benzidene and certain other intermediates because they are carcinogenic.

In the production of KA, a mixture of cyclohexanone and cyclohexanol, used in the manufacture of nylon, two routes are available. One is by air oxidation of cyclohexane, the process used at Flixborough. The other involves the hydrogenation of phenol, which occurs in the vapour phase and is less hazardous. That the choice of route cannot be considered in isolation, however, is illustrated by the fact that the usual process for the production of phenol involves oxidation of cumene, a process generally regarded as at least as hazardous as cyclohexane oxidation.

The compounds 4,4-diphenylmethane diisocyanate (MDI) and toluene diisocyanate (TDI) are made using phosgene as an intermediate, which is highly toxic. Efforts have been made to devise an alternative, but these have not been entirely successful. However, manufacturers using the original route have been able to reduce drastically the amount of phosgene stored, or even to eliminate phosgene storage completely by passing the gas direct from the production to the consumer unit.

Generation and immediate consumption, rather than storage, of the intermediate methylisocyanate (MIC) is one of the proposals made for inherently safer design of the process used at Bhopal. Other manufacturers are known to make use of much smaller storages of the intermediate.

11.6.7 Hazards of compromise

It is as well at this point to draw attention to the fact that, as far as operating conditions are concerned, a compromise solution may turn out to be the most hazardous. The hazard may be relatively low for a process with a large inventory but operating at low pressure and temperature such that if an escape occurs only a small amount of material will flash off. At the other extreme a process operating at high temperature and pressure may present only a low hazard, because the use of these operating conditions allows the inventory to be kept low. The compromise solution of moderate inventory at moderate pressure and temperature may actually be the most hazardous, if the conditions are such that on release a large fraction of the material will flash off and the inventory is such that the quantity escaping is likely to be large. In cyclohexane reactors, the reaction product still contained approximately 94% of unreacted cyclohexane. The holdup in the reactors and the circulation of unreacted material were both large.

Limitation of inventory in the reactor is illustrated by the evolution of the processes for the manufacture of nitroglycerine, which has been described by N.A.R. Bell (1971). The first stage of development was a batch process with a holdup of about 1000 kg. The second was a continuous process with a 200–300 kg inventory. The third, the NAB process, is again continuous, with reaction taking place in a nozzle and with a holdup of only about 5 kg.

Another example of inherently safer design of a reactor is the development of an alternative design of adipic acid reactor as described by Hearfield (1980a). The original

***Table 11.2** Some features of friendly plants (Kletz, 1990f) (Courtesy of Elsevier Publishing Company)*

Characteristic		*Friendliness*	*Hostility*
1. Intensification	Distillation	Higee	Conventional
	Heat transfer	Miniaturize	Conventional
	Nitroglycerine manufacture	NAB process	Batch process
	Intermediate storage	Small or nil	Large
	Reaction	Vapour phase	Liquid phase
		Tubular reactor	Pot reactor
2. Substitution	Heat transfer media	Non-flammable	Flammable
	Solvents	Non-flammable	Flammable
	Chlorine manufacture	Membrane cells	Mercury and asbestos cells
	Carbaryl production	Israeli process	Bhopal process
3. Attenuation	Liquefied gases	Refrigerated	Under Pressure
	Explosive powders	Slurried	Dry
	Runaway reactants	Diluted	Neat
	Any material	Vapour	Liquid
4. Simpler design with fewer leakage points or opportunities for error		Hazards avoided	Hazards controlled by added equipment
		Single stream	Multi-stream with many cross-overs
		Dedicated plant	Multi-purpose plant
		One big plant	Many small plants
	Spares	Uninstalled	Installed
5. No knock-on effects		Open construction	Closed buildings
		Firebreaks	No firebreaks
	Tank roof	Weak seam	Strong seam
	Horizontal cylinder	Pointing away from other equipment	Pointing at other equipment
6. Incorrect assembly impossible	Compressor valves	Non-interchangeable	Interchangeable
	Device for adding water to oil	Cannot point upstream	Can point upstream
7. Status clear		Rising spindle valve or ball valve with fixed handle	Non-rising spindle valve
		Spectacle plate[a]	Slip plate
8. Tolerant of maloperation or poor maintenance		Continuous plant	Batch plant
		Spiral wound gasket	CAF gasket
		Expansion loop	Bellows
		Fixed pipe	Hose
		Articulated arm	Hose
9. Low leak rate		Spiral wound gasket	CAF gasket
		Tubular reactor	Pot reactor
		Vapour phase reactor	Liquid phase reactor
10. Easier to control	Response to change	Flat	Steep
	Negative temperature coefficient	Processes in which rise in T produces reaction stopper	Most processes
		Most nuclear reactors	Chernobyl reactor
	Slow response	AGR	PWR
	Less dependent on added-on	AGR, FBR, HTGR	PWR
	Safety systems	PIUS	

Table 11.2 *continued*

Characteristic		*Friendliness*	*Hostility*
11. Software	Errors easy to detect and correct	Some PES	Some PES
	Training and instructions	Some	Most
	Gaskets, nuts, bolts, etc.	Few types stocked	Many types stocked
12. Other industries	Continuous movement[b]	Rotating engine	Reciprocating engine
	Helicopters with two rotors	Cannot touch	Can touch
	Chloroform dispenser	Reverse connection possible	Reverse connection impossible
13. Analogies		Lamb	Lion
		Bungalow	Staircase
		Tricycle	Bicycle
	Marble on saucer	Concave up	Convex up
	Boiled egg	Pointed end up, hard-boiled, medieval egg-cup	Blunt end up, soft-boiled, standard egg-cup

[a] A spectacle plate is easier to fit (in rigid piping) and easier to find.

[b] In practice reciprocating internal combustion engines are not less friendly than rotating engines, though one might expect that equipment which continually starts and stops would be less reliable.

AGR, advanced gas-cooled reactor; CAF, compressed asbestos fibre; HTGR, high temperature gas reactor; FBR, fast breeder reactor; PES, programmable electronic system; PIUS, process inherent ultimate safety reactor; PWR, pressurized water reactor.

design and the design finally adopted in 1980 are shown in Figure 11.3. In the latter the inventory is reduced and many of the sources of leaks – the agitator, pump, external cooler and connecting pipework – are eliminated.

11.6.8 Plate heat exchangers

Another application of process intensification is the use of plate heat exchangers, as described by C. Butcher (1992c). Plate heat exchanger technology is developing rapidly and exchangers are available for a much wider range of applications than previously. For example, the pressure range has been extended from about 80 to 100 bar.

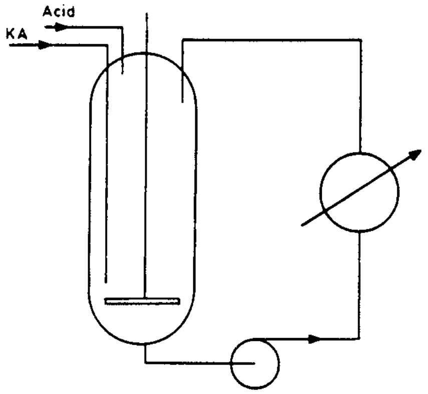
The potential of plate heat exchangers goes beyond conventional heat transfer applications. One concept is the use of plate heat exchangers coated with catalyst as methane reformers. It is estimated that a plate heat exchanger reformer with capacity sufficient for a 1000 te/day methanol plant would be about 4 m^3; this contrasts with conventional reformers which are about 20 m high.

11.6.9 Combination of unit operations

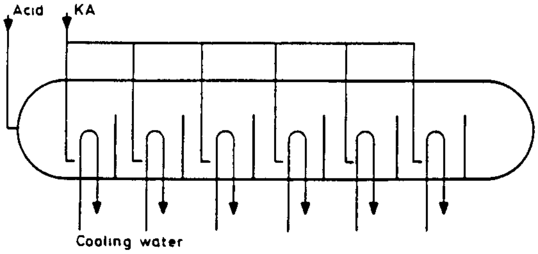
Another form of intensification is the conduct of several unit operations in one equipment. Kletz (1992c) cites the example of a design in which the operations of drying, heat exchange and granulation are combined.

11.6.10 Applications of substitution

Some applications of substitution in the main reaction of the process have been described by S.E. Dale (1987). One is the process for acrylonitrile, which was originally manufactured from acetylene and hydrogen cyanide, both hazardous chemicals, but is now made from propylene, ammonia and air, all less hazardous. Another example is the production of ethylene glycol from ethylene rather than from ethylene oxide, another hazardous material. These are good examples of inherently safer design, even though they have been made for essentially economic reasons. Further



(a) Externally cooled



(b) Internally cooled

Figure 11.3 Alternative designs of adipic acid reactors (Hearfield, 1980a): (a) original design with external cooling; (b) evolved design with internal cooling (Courtesy of the Institution of Chemical Engineers) illustrations of the substitution of less hazardous reactions have been given by R.L. Rogers and Hallam (1991). One case quoted is the manufacture of the synthetic nitrocarbamate shown in Figure 11.4(a). One of the routes considered involved the preparation and isolation of the nitrobenzoyl chloride intermediate shown in Figure 11.4(b). Experience indicated that this was likely to be thermally unstable. Further work identified a route in which the nitration is effected at a later stage. Another example involves the oxidation of a substituted acetophenone to a carboxylic acid. The reaction shown in Figure 11.4(c) involves hydrogen peroxide. This was replaced by that shown in Figure 11.4(d) with air and a catalyst.

11.6.11 Applications of attenuation

S.E. Dale (1987) has also described some applications of attenuation. He cites a number of processes which now operate at lower pressures, often due to improvements in the catalysts. Processes which he mentions include methanol synthesis, polyethylene and polypropylene processes, and the Oxo process.

Another process which he quotes is the production of butyl lithium, which is pyrophoric and thus liable to ignite when exposed to air. This hazard is minimized by producing the butyl lithium in dilute solution.

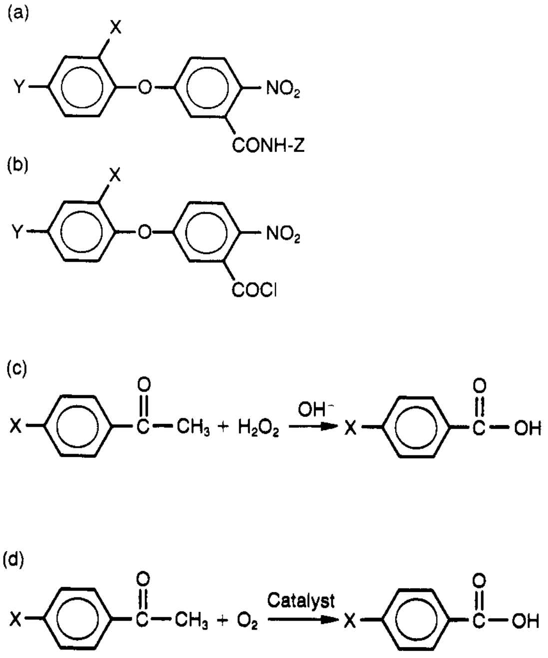


Figure 11.4 *Some reaction routes of varying degree of hazard (R.L. Rogers and Hallam, 1991): (a) substituted nitrocarbamide; (b) nitrobenzoyl chloride intermediate; (c) oxidation of a substituted acetophenone to a carboxylic acid using hydrogen peroxide; and (d) oxidation of the substituted acetophenone to the carboxylic acid using air and catalyst (Courtesy of the Institution of Chemical Engineers)*

11.6.12 Design of unit operations

Distillation units may contain appreciable inventories of hazardous materials. The quantities held up in a large modern unit are of the same order as those previously held in storage on smaller plants. Substantial reductions in the inventory in distillation units by better design have been demonstrated.

Column inventory may be reduced by the use of low holdup internals. The estimate given by Kletz (1975c) of the holdup per theoretical plate is:

Conventional trays (sieve, valve, etc.)	40–100 mm liquid
Packing	30–70 mm liquid
Film trays	10–20 mm liquid

Holdup in the column base may be reduced by the use of a narrow bottom section. Thermosiphon reboilers have a lower inventory than kettle reboilers. It may be possible to eliminate intermediate storages.

Original and revised designs of a distillation unit for separation of LPG described by Kletz are shown in Figure 11.5. The inventories in the two designs are:

	Original inventory (te)		*Revised inventory* (te)	
	Working	*Maximum*	*Working*	*Maximum*
Plant	85	150	50	80
Storage	425	850	–	–

In addition to reductions of inventory due to the use of low holdup packing and of a narrow column base, the revised design achieves even larger reductions by the eliminating intermediate storages. The reflux pump suction is taken from the condenser and the reflux drum is omitted. So also are the raw materials and product buffer storage.

Heat exchangers also offer scope for reduction of inventory. In the revised distillation unit design just described the fluids in the condenser were reversed so that the LPG and refrigerant are on the shell and tube sides, respectively. This has the effect of reducing the inventory of coolant and the total flammable inventory. A table of surface compactness of heat exchangers as a guide to inventories is given by Kletz.

11.6.13 Selection of heat transfer media

The refrigeration systems on olefins plants contain large inventories of flammables such as ethylene and propylene. Ammonia is a possible substitute, but in view of the toxic risk seems no safer. A viable alternative refrigerant, however, would make a real contribution to inventory reduction. Some alternative refrigerants have been discussed by Jacob (1991a).

Large inventories of flammables occur in heat transfer systems. For example, in an ethylene oxide plant using kerosene boiling under pressure as the heat transfer medium this may well constitute a greater hazard than the ethylene oxide mixture, which is very closely controlled. Use has been made of steam as an alternative, inherently safer heat transfer fluid.

Many alternative heat transfer fluid have been designed for specific temperature ranges and a high degree of safety in flammability or in some cases completely non-flammable (see Chapter 7 (CCPS, 1993b)).

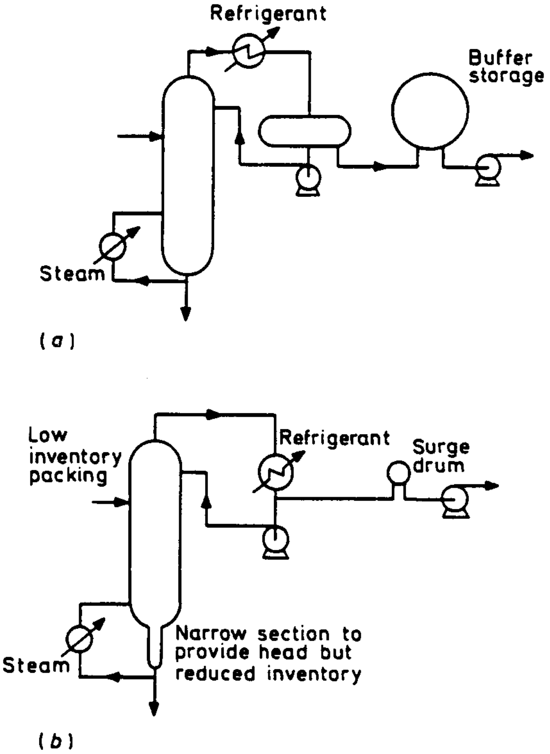

Figure 11.5 *Alternative designs of LPG distillation unit (Kletz, 1984d): (a) original design with high inventory; (b) revised design with low inventory (Courtesy of the Institution of Chemical Engineers)*

11.6.14 Design of storage

In general, storage capacity is of great assistance to plant management in the operation of the plant, but this has to be balanced against the cost and the hazard of storage. Application of inherently safer design to storage may involve:

(1) elimination of intermediate storage;
(2) reduction in storage inventory;
(3) storage under less hazardous conditions.

If the plant producing an intermediate can be located near the consumer plant, it may be possible to eliminate intermediate storage altogether. Mention has already been made of the elimination of intermediate storage of phosgene in the manufacture of MDI and TDI.

Even if it is not practical to eliminate storage it may be possible to reduce it. Kletz quotes the case of a company which used to hold several thousand tonnes of chlorine, but found it was in fact able to operate with only a few hundred tonnes.

A third approach is to store the material in a safer form. Examples given by Kletz include the storage and transport of acetylene in acetone, of organic peroxides as solutions and of hydrogen in the form of ammonia which is 'cracked' when the hydrogen is required.

The issue of inherently safer storage conditions arises most often, however, in relation to pressure and refrigerated storage. Considering the storage alone, for a liquefied gas refrigerated storage is safer than pressure storage. Large storages of such gases tend to be refrigerated. On the other hand, if the fluid is required as a gas and it is necessary to provide vaporizers and other equipment, it is the whole system which then needs to be considered and in this case refrigerated storage may be assessed as no safer. Pressure and refrigerated storage are considered further in Chapter 22.

The issue of centralized vs distributed smaller storage systems, such as chlorine, is highly controversial, dependent on a number of factors in the plant environment, engineering judgement, etc. and cannot be pontificated.

11.6.15 Major hazard storages

An account of the reductions in hazardous storage inventories at one's works in the context of the CIMAH Regulations has been given by Orrell and Cryan (1987). The principal hazardous chemicals involved were ethylene oxide, propylene oxide and sulfur trioxide. Disregarding the former, the use of which was discontinued on that site, the reductions achieved between 1980 and 1987 were as follows:

	Inventory (te)				
	1980		*1987*		*1987*
	Process	*Storage*	*Process*	*Storage*	*CIMAH level*
Propylene oxide	51	246	<0.2	<50	50
Sulfur trioxide	<0.5	75	<0.2	<50	75

11.6.16 Toxic storages

Following the Bhopal incident, many companies reviewed their inventories of toxic chemicals and achieved appreciable reductions. An account of one such exercise has been given by Wade (1987), who cites five examples of major reductions of inventory.

In one case, a large acrylonitrile plant, the purification section had a shorter time interval between scheduled shutdowns than the reaction section, and intermediate storage was used to allow the reaction section to continue running whilst the purification section was shut down. Practice was changed so that the reaction section ran at a lower, but safe, throughput whilst the purification section was down and until the latter had run the storage down again, thus effecting a large reduction in the average intermediate storage inventory.

In the second case, by-product hydrogen cyanide from a large acrylonitrile plant was sent to storage before being distributed to satellite plants. The intermediate storage was eliminated, the hydrogen cyanide being passed direct to the user plants. Elimination of the storage created some problems of composition control and of flow smoothing as user plants started up and shut-down, but these were met.

A third case involved the elimination of chlorine horizontal storage bullets and their replacement with smaller storage containers. In the fourth case, changes were made to the practice of using as storage rail tank cars hooked up to the plant. One approach was to work more closely with the supplier to ensure that deliveries were made when needed. The other was to work with the railway company to locate areas where such tank cars could be held with minimal public exposure.

The fifth case, described earlier, involved the transfer of the first stage of a multi-step reaction process to the reactant supplier, thus giving more benign reactants for the remainder of the reaction sequence.

11.6.17 On-site production

Another way of eliminating a storage inventory is on-site production of the chemical. There are now available skid-mounted phosgene plants with a capacity of 2–15 te/day which can be installed at the user's work and obviate the need for phosgene storage. On-site production has the further advantage of eliminating the need to transport the chemical produced, although it does of course involve transport of the raw materials. On-site production of hydrogen is commonly employed.

11.6.18 Design against overpressure

Virtually all pumps installed in process plants are specified such that a future full-sized impeller can be installed in the future. In the majority of cases with centrifugal pumps this has no or a minor safety implication.

Control valve sizing is an industry-wide problem due to the cumulative effects of each discipline safety factor which result in a valve two to three times oversize. The valve exhibits poor controllability due to the low valve lift and the bath-tub stopper effect. The valve suppliers exacerbate the problem by providing the next size larger valve. Only careful surveillance of each process step will eliminate the problem. Oversize pressure relief valves are the safety implication.

11.6.19 Design for containment

Another aspect of inherently safer design is the prevention and reduction of loss of containment of the more hazardous materials. Three typical leak situations are illustrated in Figure 11.6. Figure 11.6(a) shows a leak of liquid petrol at high pressure but atmospheric temperature. For this case the fraction flashing off and the amount of vapour formed are small. Figure 11.6(b) shows a leak of propane gas at high pressure and temperature. The mass flow is much smaller but all the material is in gaseous form. The release may well be rapidly dispersed below its lower flammability limit by the momentum of the escaping jet. Figure 11.6(c) shows a leak of liquid petrol at high pressure and temperature. This is the most hazardous of the three cases. The fluid is a superheated liquid so that the mass flow is high and the flash fraction, and thus the vapour cloud formed, are large. It is therefore this third case which should receive particular attention. Utilizing excess flow valves can limit the risk.

Each leak situation must be analysed for its characterization for forming a flammable liquid pool or a potential vapour cloud explosion. The size of the leaks must be empirically assessed. It should be noted that leakage of an LPG, LNG or intermediate material can result in refrigeratioin of the metal to a low temperature resulting in a brittle fracture.

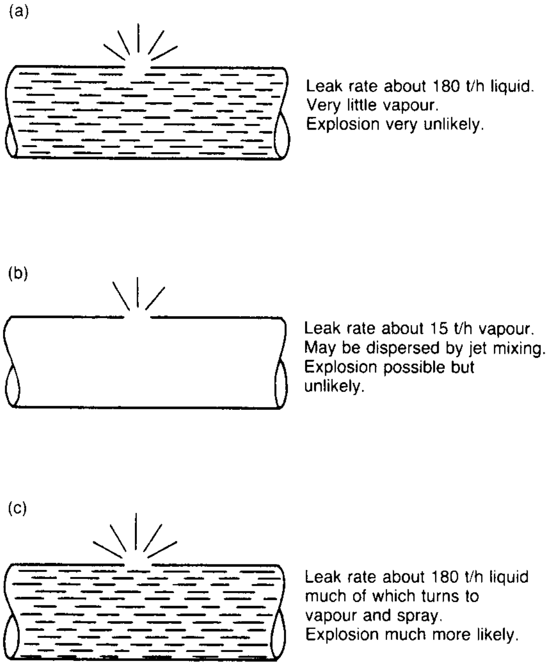

Figure 11.6 *Some typical leak situations (Kletz, 1984d): (a) petrol at 7 bar and 10° C; (b) propane gas at 7 bar and 100° C; (c) petrol at 7 bar and 100° C (Courtesy of the Institution of Chemical Engineers)*

11.6.20 Simplicity in design

A fundamental principle of inherently safer design is simplicity. Many actual plant designs are extremely complex. That shown in Figure 11.7 is used by Kletz (1984d) to illustrate the problem of complexity. Aspects of simpler design instanced by Kletz include:

(1) design for full overpressure;
(2) design modification to avoid instrumentation;
(3) use of resistant materials of construction;
(4) use of simple alternatives to instrumentation.

Where a vessel may be subject to overpressure, the simplest solution may be to design it to withstand this overpressure. Most commonly, a pressure relief system is employed. The environmental and regulation issues must be addressed as well as the design.

Sometimes instrumentation is provided to overcome a problem for which the alternative solution is a design change. Kletz gives as an example a liquid phase oxidation plant. The oxidizing air was fed to the plant mixed with the hydrocarbon recycle and instrumentation was provided to keep the mixture outside the flammable range. An alternative design was to add the air directly to the liquid so that a flammable mixture could not form.

Another reason for installing instrumentation may be to prevent attack on materials of construction. Use of more resistant materials may avoid the need for the instruments. Whether this is the best solution depends on the particular case. A contrary example is given in Chapter 9, where hazard assessment showed that use of a trip was preferable to constructing a pipe in special steel.

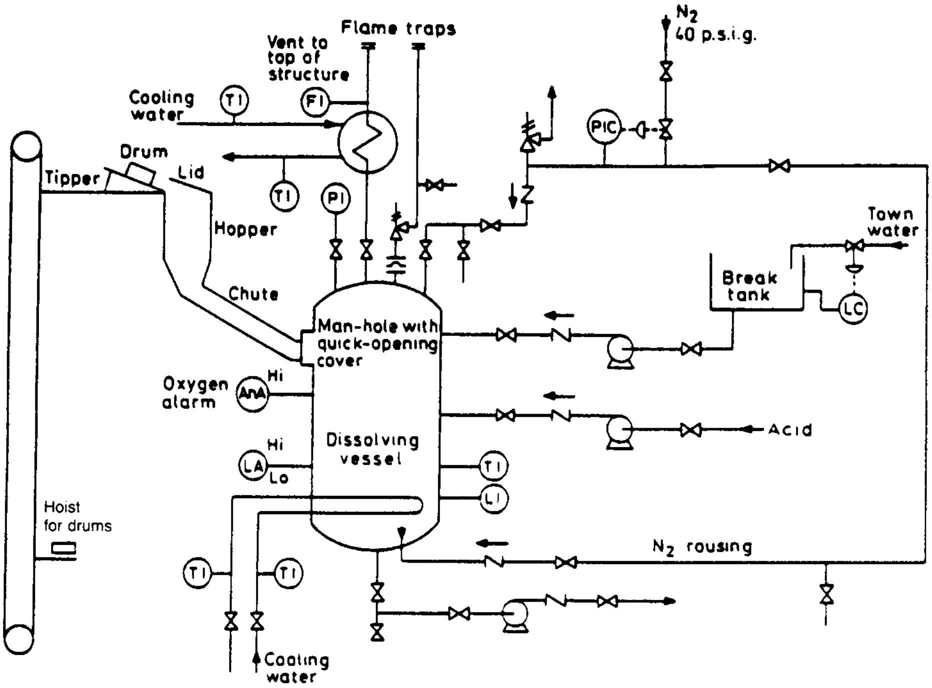

Figure 11.7 *A complex plant design involving instrumentation (Kletz, 1984d) (Courtesy of the Institution of Chemical Engineers)*

High integrity protective systems (HIPSs) are widely used to improve the safety (by orders of magnitude) and increasing the plant reliability (see Chapter 13).

11.6.21 Flexibility of plant

Flexibility is a valuable feature on a plant, but it can be taken too far. Not only can the interconnections needed to give such flexibility become very complex and costly but also they introduce further potential sources of leaks and human errors. General multiple single trains are employed rather than complex crossovers.

11.6.22 Modification chains

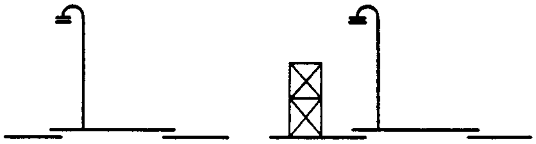
Another source of complexity is the modification chain: an initial modification is made which leads to others. This is a problem not only in design, but perhaps even more on existing plant, where a single *ad hoc* modification can lead to a whole series.

A simple modification chain is shown in Figure 11.8. The manhole cover in Figure 11.8(a) is not leak-tight and traces of flammable vapour escape into the plant. In order to reduce the probability that they will ignite or be inhaled, a vent 4 m high is fitted to the cover, as shown in Figure 11.8(b). In turn, as shown in Figures 11.8(c–e), a flame trap is fitted because the gas leaving the vent might be ignited by lightning, an access platform is provided to allow regular cleaning of the flame trap, and handrails and toe boards are fitted because it is realized that the platform is now a ‘place of work’.

A more complex example is the system for transfer of slurry under pressure between the two vessels shown in

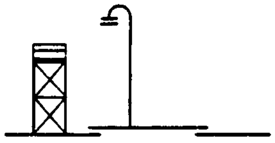
(a) Leaking manhole on drain

(b) Vent added



(c) Flame trap added

(d) Access platform added



(e) Handrails and toe-boards added

Figure 11.8 *A modification chain for a manhole cover (Kletz, 1984d): (a) manhole cover; (b) addition of vent; (c) addition of flame trap; (d) addition of platform; (e) addition of handrail and toe boards (Courtesy of the Institution of Chemical Engineers)*

Figure 11.9. Figure 11.9(a) shows the original design with a single transfer line and arrangements to blow the line with steam to clear the line of chokes and to clean it. The plant was the first version to be continuous, earlier plants being batch. In order to avoid downtime due to blockages in the transfer line, a second transfer line, Figure 11.9(b), was added. The relief and blow-down review revealed that the two transfer lines could be operated simultaneously and that in this situation the downstream vessels would require twice the relief capacity. In order to avoid this, the valves on the two lines were interlocked, Figure 11.9(c). This created two more dead legs in each line so it was necessary to add four more steam connections to allow steam flushing, Figure 11.9(d). It was then realized that in order to be sure that the stand-by line was ready for use it was necessary to keep steam flowing through it. The transfer line was protected against the pressure of the process but not against that of the steam. Whereas it was considered acceptable not to provide relief for occasional use of steam, it was necessary to do so for steam continuously in the line, and so a pressure relief valve was fitted to the steam line, Figure 11.9(e).

11.6.23 Process operability

Some processes are inherently more operable than others. This aspect should be borne in mind in the selection of the process. In particular, a process which has no ‘fallback’ positions and which in the extreme case presents the operator with a stark choice of continuing to run at a given set of conditions or of shutting down completely is not easy to operate. The operability of process and plant is one of the two main aspects which are examined in hazop studies.

11.6.24 Fail-safe design

The concept of fail-safe design is well established in the process industries. It refers to the design of equipment such as control and solenoid valves so that in the event of failure of a utility such as electricity or instrument air the plant moves to a safe state.

The decision of whether a valve should be open or closed on utility failure is made in the light of the consequences for the process. The fail-safe position, assuming there is one, is then determined. Thus pneumatic control valves, for example, are available as ‘air-to-open’ or ‘air-to-close’; the former close and the latter open on air failure.

Current electronic components do not have identified fail-safe positions. See HSE 1987a–d *Programmable Electronic Systems* for random and systemic failures which are not fail-safe.

The principle of fail-safe design may be extended to include the action of whole control loops. This aspect is considered in Chapter 13.

11.6.25 Second chance design

Another relevant concept is that of ‘second chance design’. This means the provision of a second line of defence to guard against an initial hazard or failure. Some features which are prominent in second chance design are:

(1) plant layout;
(2) pressure system design;
(3) materials of construction;
(4) isolation arrangements;
(5) alarms and trips;
(6) operating and maintenance procedures.

Second chance design is illustrated by: many of the normal features of plant layout such as bunding and drainaway arrangements; many normal features of pressure systems such as the installation on pressure vessels of pressure relief and blow-down systems and on pumps of double mechanical seals with monitoring of the pressure sealing system; the use of materials of construction which can withstand deviations from normal operating conditions such as a slug of low temperature liquid; the provision of arrangements for isolation if there is loss of containment; the use of alarms which warn of, and trips which take action against, hazardous conditions; and adherence to operating and maintenance procedures which reduce the probability of the hazard, such as purging again after a delay in lighting a furnace.

It will be apparent from these examples that second chance design is a rather general concept, embracing both preventive and mitigating features, but is a very valuable one.

11.6.26 Layers of protection

A newer concept, analogous to the previous paragraph on second change design, is layers of protection. This technique was introduced by Drake and Thurston in 1992 and is now widely adopted and included in safety codes such as ISA 84.01. The basic idea is illustrated plainly in the onion skin Figure 11.10 which is self-explanatory. This inner most layer is the process design, basic control systems (BPCS), critical alarms, automatic actions such as the safety interlock systems (SIS), emergency shut-down (ESD); physical protection, dikes, and emergency responses, both plant- and community-wide. This provides the multiple safety layers present to provide protection from a hazardous incident. Each safety layer must be independent, specific, dependable and auditable, providing an order of magnitude protection over the previous layer. Further detailed information is available in CCPS *Guidelines for Safe Automation of Chemical Processes*. This approach has been touted to be highly effective and has resulted in a significant reduction of incidents.

11.6.27 Single large vs multiple small systems

A question which occurs in the context of inherently safer design is whether it is preferable from this aspect to have a single large unit, plant or storage, or several smaller ones. Generally it is economically attractive to choose the single large unit. Many consider that this is usually the best choice for safety also. If several small units are built, the number of weak points such as pumps, flanges, etc., increases roughly in proportion to the number of units, and the management effort is more thinly spread. If a single large unit is built, the number of weak points is much reduced and the management can concentrate on this unit. For both these reasons the frequency of incidents with a single large unit should be less than with several smaller ones. The argument for the single large unit is thus, in part, that if one puts all one’s eggs in one basket, one can afford a good basket. The drawback is that the scale of any incident which does occur is likely to be larger with the single unit. There is probably no general solution to this problem. Each case should be considered on its merits.

11.6.28 Limitation of exposure

A rather different aspect of inherently safer design is the limitation of exposure of personnel. This is another concept

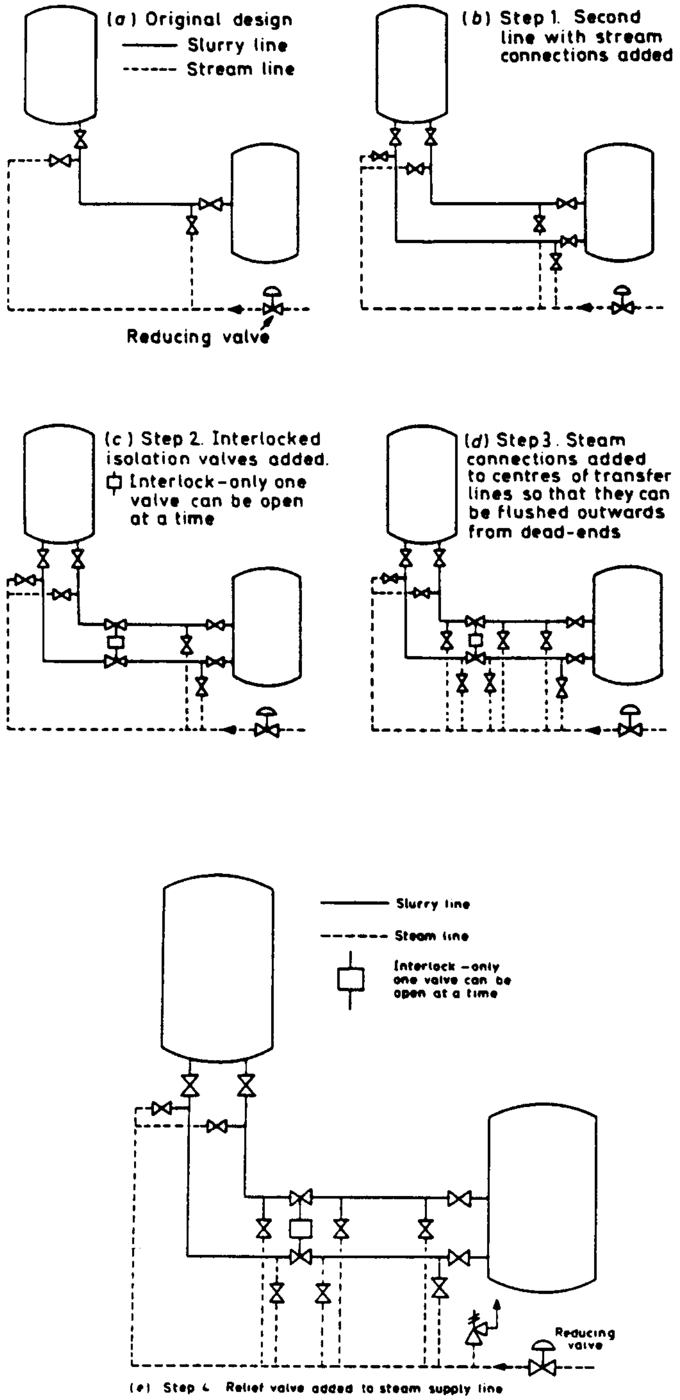


Figure 11.9 A modification chain for a slurry transfer system (Kletz, 1984d): (a) slurry transfer system; (b) addition of second transfer line; (c) addition of interlock between values on two transfer lines; (d) addition of extra steam connections; (e) addition of pressure relief value on stream line (Courtesy of the Institution of Chemical Engineers)

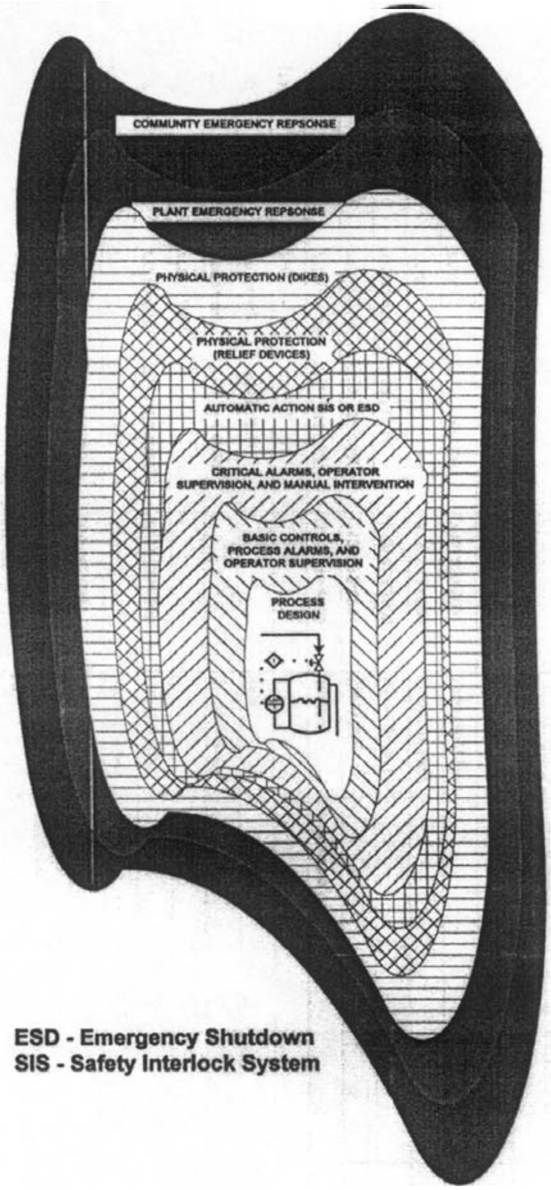

Figure 11.10 *Typical layers of protection in modern chemical plant (CCPS, 1993)*

which received impetus from the Flixborough incident, in which 18 of the 28 deaths occurred in the control room. The question was asked whether so many people really needed to be exposed to the hazard in this way. Limitation of exposure of personnel may be achieved by location of the workbase and by control of access to the high hazard zones. These aspects are considered in Chapters 10 and 20. This subject is covered in detail with a quantitative analysis in the CCPS *Guidelines for Evaluating Process Plant Buildings for External Explosion and Fires* (CCPS, 1996).

11.6.29 Inhibiting factors

Progress in the realization of inherently safer designs has not been as rapid as its advocates would wish. Some reasons for this have been examined by Kletz (1991h, 1992c) and Mansfield and Cassidy (1994).

The arguments advanced by Kletz have application particularly where an inherently safer alternative design involves a significant degree of innovation, which affects only a part of the whole plant and where the scale of production is large. Since, in general, technical and economic risk is increased by novel features, opponents will argue that a large project is being put at risk for relatively small gain.

Essentially, part of the problem is that a single project is being made to bear the 'cost' of an innovation which has the potential eventually to make a significant contribution to the reduction of costs and enhancement of safety over a range of processes operated by the company.

Another feature of the problem is that once plant design is under way, there is often not sufficient time to accommodate such innovation, and there is pressure to follow the previous design. This aspect has been addressed by Malpas (1983), who argues that whilst the design of the next plant is in progress thought should be given to the improvements which have been identified, which it is not practical to incorporate in the design but which, with forethought, could be implemented in 'the plant after next'.

The problem of furthering innovation is exacerbated, moreover, by the move towards business-centred rather than functional organization of companies. However, as Mansfield and Cassidy (1994) point out, inherently safer design is not necessarily radical but may involve incremental change. Among the reasons which they give for lack of progress are lack of awareness, lack of a recognized tool and failure to build the practice into company procedures. Moreover, even where what is in question is a radical change, the proposed process may be such as to constitute a minimal risk.

11.6.30 HSE initiatives

The Health and Safety Executive (HSE) now has an explicit policy of encouraging the application of inherently safer design concepts. Its philosophy and activity in this area have been described by Barrell (1988a) and P. Jones (1992). The work described by Mansfield and Cassidy (1994) is one aspect of this programme.

11.6.31 Inherently safer design methodology

The work of Mansfield and Cassidy is aimed at furthering the practice of inherently safer design by the development of suitable tools. The authors argue that there is need for a technique which will do for inherently safer design what hazop has done for hazard identification. Such a tool needs to address particularly the conceptual design stage. Concept design is generally done quite rapidly. The tendency is that thereafter the basic concept does not undergo any great change.

These authors suggest four broad categories of tool for inherently safer design: (1) brainstorming with a degree of structure, (2) a more highly structured hazop-style examination of flow sheets and process diagrams, (3) examination, using checklists, of the plant layout and (4) indices of inherent safety.

11.6.32 Inherently safer design index

The development of an index for inherently safer design has been described by D.W. Edwards and Lawrence (1993).

This index is intended for use early in the design, at the stage of process selection. The authors list a number of variables relevant to inherent safety, including: properties of the chemicals such as corrosiveness, flammability, explosibility and toxicity; operating conditions such as pressure and temperature; reaction conditions such as phase, rate, heat release, yield and side reactions; and effluents and wastes. At this early stage information on inventory, for example, is lacking and has to be represented by surrogates such as yield. The method involves assigning scores to the individual parameters. These are then used to compute a chemical score, a process score and an overall inherent safety index. A low value of this index means a high degree of inherent safety. The inherent safety index is obtained from the sum of the scores of the individual process stages. Hence the index penalizes processes with a large number of stages.

Edwards and Lawrence state that one of their aims is to test the hypothesis that inherently safer design means cheaper plants, and give as an illustrative example of a comparison of six routes to methylmethacrylate in respect of: (1) the estimated costs and (2) the inherent safety index. Perhaps the most salient point from this single example is the benefit of a smaller number of stages. They also refer to work on comparison of the index with expert rankings.

The *Dow Fire and Explosion Index – Hazard Classification Guide* which has been available for over 20 years, now in the eighth edition, provides also quantitative results based on the same issues previously described.

11.6.33 Miniaturized and distributed plants

In a speculative treatment, Benson and Ponton (1993) suggest that one future trend may well be towards distributed manufacture of chemicals using miniaturized plants at the users' sites. Such an approach chimes with demands for plants which are environmental friendly and deliver their products on a 'just-in-time' basis.

Development on these lines requires that the plants be fully automated and highly reliable. The authors envisage plants that operate at moderate pressure and temperature, are self-cleaning and are sealed for life. There is also an implication that there is no insuperable effluent problem.

Benson and Ponton list a number of types of equipment which have been the subject of much development in recent years but which have not realized their full potential because they come into their own in small scale rather than large scale production. Table 11.3 contrasts some of the characteristics of distributed plants and large scale plants.

11.7 Unit Processes

11.7.1 Chemical industry

The chemical and petrochemical industries are described in *The Petroleum Chemicals Industry* (Goldstein and Waddams, 1967), *The Petrochemical Industry* (Hahn and Williams, 1970), *Structure of the Chemical Processing Industries* (Wei, Fraser and Swartzlander, 1978), *The Chemical Industry* (Sharp and West, 1982), *Shreve's Chemical Process Industries* (G.T. Austin, 1984), *The Chemical*

Table 11.3 *Some characteristics of miniaturized and of large scale plants (Benson and Ponton, 1993) (Courtesy of the Institution of Chemical Engineers)*

Distributed plants	*Large site plants*
Feedstocks:	
Readily available at the customer's site (e.g. air, methane, water, electricity)	Available from other processes on the site (e.g. chlorine)
Safe to transport (e.g. CO_2, salt, lime, most solids)	Dangerous to transport (e.g. ethylene oxide)
Processes:	
That build new molecules from simple feedstocks (e.g. phosgene)	That involve cracking complex molecules to low molecular weight products (e.g. oil refining, olefins from naphtha)
Catalytic processes (e.g. ammonia from methane)	Low specificity, multi-product processes
Low pressure and temperature (e.g. bioprocesses)	High temperature or pressure (e.g. polyethylene)
Stand-alone processes (e.g. air liquefaction)	Highly integrated processes
Physical change processes (e.g. formulation, shredding)	
Customer products:	
Considered to be dangerous to transport (e.g. phosgene, bromine)	Involving a hazardous processing step (e.g. highly exothermic reaction)
Production state matches customer requirement, but would require change for transport (e.g. molten polymer, liquefied gases, many powders)	
Produced and required in dilute state, but normally concentrated for transport (e.g. aqueous HF)	
Waste products:	
Suitable, after treatment, for returning to the immediate environment (e.g. oxygen, water)	Requiring controlled thermal oxidation (e.g. tars, chlorinated wastes)
May be reacted with other customer waste to produce benign products (e.g. chlorine, caustic)	Treatment requires other plants on the site
Biodegradable waste (e.g. from biological processes)	

Industry (Heaton, 1985–), *Handbook of Chemicals Production Processes* (Meyers, 1986a) and *Petrochemicals* (Spitz, 1988). Further references are given in Section 11.11.

Accounts of the European chemical industry are given in the following: France, E. Johnson (1989c) and Redman *et al.* (1991); Germany, E. Johnson *et al.* (1990); Italy, Redman *et al.* (1990) and the Netherlands, Redman and Smith (1991).

11.7.2 Principal processes

Descriptions of unit processes and of their thermodynamics and kinetics are given in *Unit Processes in Organic Synthesis* (Groggins, 1952), *Industrial Chemicals* (Faith, Keyes and Clark, 1965), *Chemical Process Industries* (Shreve, 1967), *Organic Chemicals Manufacturing Hazards* (Goldfarb *et al.*, 1981), *Shreve's Chemical Process Industries* (G.T. Austin, 1984), *Survey of Industrial Chemistry* (Chenier, 1986) and *Introduction to Industrial Chemistry* (H.L. White, 1986). Further information is given in other standard texts, including encyclopaedias such as those by Kirk and Othmer (1963–, 1978–, 1991–) and Ullman (1969–, 1985–). Selected references on unit processes and their hazards are given in Table 11.4.

Unit processes are listed by Fowler and Spiegelman (1968) as follows: acylation, alkaline fusion, alkylation, animation, aromatization, calcination, carboxylation, causticization, combustion, condensation, coupling, cracking, diazotization, double decomposition, electrolysis, esterification, fermentation, halogenation, hydration, hydroforming, hydrogenation, hydrolysis, ion exchange, isomerization, neutralization, nitration, oxidation/reduction, polymerization, pyrolysis and sulfonation. The unit processes which are generally more hazardous are given by Fowler and Spiegelman as alkylation, animation, aromatization, combustion, condensation, diazotization, halogenation, hydrogenation, nitration, oxidation and polymerization. The unit processes considered here by way of illustration are (1) oxidation, (2) hydrogenation, (3) chlorination and (4) nitration.

A particular unit process tends to have certain characteristic features. These often relate to:

(1) reactant and product;
(2) reactor phase;
(3) main reaction
    (a) thermodynamic equilibrium,
    (b) heat of reaction,
    (c) velocity constant,
    (d) activation energy;
(4) side reactions;
(5) materials of construction.

11.7.3 Oxidation

The oxidation reactions considered here are those of an organic compound with molecular oxygen. Some principal industrial oxidation reactions include:

Vapour phase

- Ethylene → ethylene oxide
- Propylene → acrylic acid
- Methanol → formaldehyde
- Naphthalene → phthalic anhydride
- Benzene, butenes → maleic anhydride

Liquid phase

- Acetaldehyde → acetic acid
- Butane → acetic acid and related products
- *i*-Butane → *t*-butyl hydroperoxide
  (and hence propylene oxide)
- Cumene → cumene hydroperoxide
  (and hence phenol, acetone)
- Cyclohexane → cyclohexanone and cyclohexanol
  (and hence adipic acid and caprolactam)
- Ethylbenzene → ethylbenzene hydroperoxide
  (and hence propylene oxide)
- Naphtha → acetic acid
- Toluene → benzoic acid (and hence phenol)
- *p*-Xylene → terephthalic acid
- *p*-Xylene → monomethylterephthalate
- Higher hydrocarbons → primary hydroperoxides
  (and hence primary alcohols, aldehydes and acids)
- Higher hydrocarbons → secondary hydroperoxides
  (and hence secondary alcohols and ketones)

The reactions are generally exothermic and sometimes highly so. There is frequently, therefore, a problem of heat removal and of temperature control.

Oxidation reactions tend not to be limited by thermodynamic equilibrium. There can be problems, however, of the reaction of complete combustion and of side reactions to unwanted by-products. Frequently, it is necessary to employ catalysts and to use only moderate temperatures in order to avoid these undesired reactions.

The heat generated in such oxidation processes may considerably exceed the theoretical heat of reaction. Thus the heat of oxidation of napthalene to phthalic anhydride is about 5460 BTU/lb of naphthalene, but for some reactor conditions it is reckoned that the occurrence of the complete combustion reaction can raise the effective heat of reaction to 10,000 BTU/lb of naphthalene-fed.

Vapour phase oxidations are carried out in various types of reactor, such as a reactor vessel with catalyst on a tray, a tubular packed bed reactor or a fluidized bed reactor. Tubular and fluidized bed reactors are suitable if the heat release is large. Thus, the oxidation of napthalene to phthalic anhydride is highly exothermic. Initially, this reaction was carried out in a tubular reactor, but is now usually done in a fluidized bed.

In vapour phase oxidation the reactor feed is generally kept outside the flammable range. This requires the use of well designed and highly reliable trip systems. The use of a high integrity protective system to maintain the ethylene and oxygen feeds in the ethylene oxide process on the ethylene-rich side has been described by R.M. Stewart (1971) and is considered in more detail in Chapter 13.

Another approach to the control of the feed composition has been outlined by Pickles (1971), who describes a method used in the production of formaldehyde by oxidation of methanol. The methanol–air feed is obtained by bubbling air through the methanol vaporizer. The feed is maintained on the methanol-rich side, mainly by ensuring that the temperature of the methanol in the vaporizer is sufficiently high.

The hazard of a flammable mixture is much less if the burning velocity is low, which it is near the flammability limits. In the methanol–air system the burning velocity is low not only at the upper flammability limit but also some way inside it. In the system described by Pickles this fact is exploited.

If the risk of ignition is judged sufficiently low, the reaction may be carried out within the flammable limits. R. Davies (1979) cites benzene and propylene oxidation as two processes which have been operated in this way.

Liquid phase oxidations are typically carried out in tank reactors at a pressure in the range 10–50 bar and a temperature in the range 100–200°C. Air is bubbled into the reactor by a sparge pipe.

One of the main liquid phase processes is the oxidation of cyclohexane to cyclohexanone and cylcohexanol. This was the process at Flixborough. It has been described in *The Oxidation of Cyclohexane* (Berezin, Denison and Emmanuel, 1966) and by Haberle (1971). In this process, which is carried out industrially at pressures in the range 10–25 bar and temperatures in the range 140–170°C, the conversion per pass has to be kept to a few per cent in order to minimize undesirable side reactions. Therefore, heat removal is fairly simple. The principal hazard is the large amount of cyclohexane liquid which is held in and circulated around the reactors.

The air inlet line can be a hazard in a liquid phase oxidation process. It is known that in the manufacture of KA, a mixture of cyclohexanone and cyclohexanol, by air oxidation of cyclohexane a blackened product is occasionally made. The conditions under which this 'black KA' is produced are always those of start-up. The cause is that liquid from the reactor flows back up the line, stays there until the plant is started up and then catches fire when the air flow resumes. The temperatures reached are sufficient to melt through the air pipe. There is a hazard, therefore, that the reactor contents may escape through this line. The phenomenon has been discussed by Alexander (1974).

The hazards of oxidation processes have been reviewed by R. Davies (1979). He describes the transition in liquid phase oxidations from batch reactors to large-scale continuous reactors. This growth was accompanied by an increasing number of incidents.

Davies identifies three principal hazards of oxidation processes, in the liquid or vapour phase: flammable release, internal ignition and unstable or reactive substances. The majority of liquid phase oxidation processes require a large inventory held at a temperature above the boiling point. This creates the potential for a large release of flashing flammable liquid. Moreover, the operating conditions are quite difficult, which increases the risk that such a release will occur.

A second hazard of liquid phase oxidations is internal ignition. This can occur if for any reason the concentration of oxygen builds up in the vapour space. Such build-up may happen if the dispersion of the air in the liquid is poor or if the oxygen is not immediately absorbed and reacted. In some processes a flammable mixture can occur where recycle offgas is mixed with the air prior to injection into the liquid.

Vapour phase oxidation processes have a low inventory of process fluids, but a flammable release hazard may still exist where there is a large inventory of flammable heat transfer fluid. Single-pass, atmospheric processes may be protected against internal ignition by explosion venting, but this is more difficult to do where the process is at higher pressure or involves recycle.

The products of oxidation processes tend to contain unstable substances, which in some cases can constitute a severe hazard. These include cumene hydroperoxide and ethylene oxide. Another is acetaldehyde, though this is more readily controlled. Davies gives a detailed account of the characteristics of, and precautions against, these substances.

Davies identifies four oxidation processes which have been responsible for a relatively large number of incidents. They are the liquid phase oxidations of cyclohexane and cumene, the vapour phase oxidations of ethylene and naphthalene or *o*-xylene. He gives a list of incidents and identifies several factors which have contributed to such incidents. One is the use of a series of liquid phase reactors in cascade with insufficient attention paid to the interconnecting pipework. Another is modifications which are intended to increase yield or to improve thermal economy but which also increase inventory and complexity. A third is deficiencies of various kinds in the trip systems.

An account of the continuing problem of liquid phase oxidation processes has been given by Alexander (1990b,c). The loss potential in an oxidation process can be large and the margin between a minor and a major incident small. He deals in particular with internal ignition. Such incidents are relatively frequent, but tend not to be reported.

The author suggests that most internal ignitions are due to a common cause and puts forward the following hypothesis. Oxidizable material is exposed to air at a temperature high enough to initiate liquid phase oxidation. Poor dispersion of the air allows a high concentration of oxygen to build up close to the liquid–air interface and a flammable mixture forms. Free radicals from the oxidation reaction in the liquid phase evaporate into the flammable mixture near the interface and ignite it. He cites the work of Sokolik (1960) in support of the ability of free radicals to ignite a flammable mixture well below the autoignition temperature. Alexander argues that this proposed mechanism is consistent with the wide variety of conditions in which ignitions occur. He refers also to other proposed mechanisms of ignition, including deposits of peroxides, of pyrophoric materials, and of catalyst, and friction between metal surfaces. Alexander describes some of the situations in which internal ignitions occur, and gives explanations based on his hypothesis. These situations involve the formation of a flammable mixture, followed by ignition by free radicals from the liquid, present as bulk liquid or as liquid droplets. One is backflow of liquid into the air feed line. This can occur if the air flow is shut off but the isolation is not good enough to prevent the pressure of the air in the pipe in the reactor falling below that of the liquid. It can occur if the air flow is interrupted momentarily. If the air temperature is above the critical value, burning will occur. This may result only in a very hot pipe, but can cause pipe failure followed by release of the reactor contents. If under very unfavourable circumstances a flammable mixture occurs along a sufficient length of the air pipe, there is potential for detonation.

Another situation with potential for internal ignition occurs where there is a recycle of fuel-rich offgas back into the air pipe, designed so that under normal operation the gas mixture downstream of the mixing point is also fuel-rich. If there is an upset, the mixture may enter the flammable range. Another such situation is where a temporary liquid diversion is made to flush out blockages in the air line.

Alexander also describes precautions which can be taken. One is the design of the air line, which should be such that liquid is not likely to be held up if there is an interruption of the air flow. The line should not rise up through the bottom of the vessel. Nor should it enter through the top, since a leak from the pipe in the vapour space could give a flammable mixture there. The preferred configuration is for the air line to come down from a height, slope gently down to the vessel and then enter its side. Another precaution is positive isolation of the air line by a double block and bleed valve arrangement. Another is the use of cool air. Other precautions relate to recycle gas, liquid diversion, offgas analysis and explosion containment.

11.7.4 Hydrogenation

The hydrogenation reactions considered here are those of an organic compound with molecular hydrogen in the presence of a catalyst. Some principal hydrogenation reactions include:

Vapour phase
Carbon monoxide → methanol
Olefins → paraffins

Liquid phase
Coal → oil

The thermodynamic equilibrium in hydrogenation reactions is almost invariably such that the yield falls as temperature rises and therefore the reaction temperature is a compromise between high reaction yield and high reaction rate.

Hydrogenation reactions are generally exothermic. The reaction usually occurs only on the catalyst, so that the local surface temperature can be very high. This may result in undesirable side reactions and catalyst deterioration, and may have implications for reactor materials of construction and for control.

The activation energy of hydrogenation reactions is normally low. For most hydrogenation reactions an increase in temperature of 50°C or more is required to double the reaction rate. There are few for which an increase of 10°C is sufficient to do this.

Vapour phase hydrogenations are carried out typically in the pressure range from atmospheric to several hundred bar and in the temperature range 100–400°C. Most catalysts used in hydrogenations are also capable of promoting oxidation. Also catalysts can be rendered more pyrophoric by the adsorption of hydrogen. Hydrogenation involves the hazards of the use of hydrogen under pressure. These are considered elsewhere, but particularly in Section 11.9.

11.7.5 Chlorination

The chlorination reactions considered here are those of an organic compound with molecular chlorine. Some principal industrial chlorination reactions include:

Vapour phase
Methanol → chloromethanes

Liquid phase
Ethylene → ethylene dichloride

Chlorination reactions have many similarities with oxidation reactions. They tend not to be limited by thermodynamic equilibrium, but there can be problems of the reaction of complete chlorination and of side reactions to unwanted by-products.

Again the reactions are generally exothermic and often highly so, with the result that there tends to be a problem of heat removal and temperature control. For the substitution reaction

$$RH + Cl_2 \rightarrow RCl + HCl$$

the heat of reaction is about 24,000 kcal/kmol of chlorine.

The vapour phase reaction of chlorine with paraffinic hydrocarbons is apt to become too violent and it may be necessary to take measures to prevent this. These include limiting the proportion of chlorine or admitting it in stages and using diluents such as nitrogen or recycle gases.

Vapour phase reactors are typically empty vessels or packed beds. Chlorine, like oxygen, forms flammable mixtures with organic compounds. Thus, for example, the following flammability limits have been quoted for methane:

	Oxygen	*Chlorine*
Lower flammability limit (%)	5.2	5.6
Upper flammability limit (%)	60.5	70.0

Further details are given by Daniel (1973).

The reactor feed in vapour phase chlorinations is kept outside the flammable range. Liquid phase reactions are frequently carried out by blowing the chlorine and organic reactants into liquid product in a tank reactor.

11.7.6 Nitration

The nitration reactions considered here are those of an organic compound with a nitrating agent such as nitric acid or mixed acid. Mixed acid is nitric acid admixed with a dehydrating acid such as sulfuric acid. Nitration accidents are among not only the most frequent but also the most destructive in the chemical industry. The processes for the manufacture of nitroglycerine (NG) and trinitrotoluene (TNT) are particularly sensitive.

The typical nitration is a batch process carried out in the liquid phase and it is this which is discussed first. Nitric acid is not only a nitrating agent but also an oxidizing agent. The nitration and the oxidation reactions both constitute a hazard. Nitric acid is itself a hazardous chemical, since it is not only a corrosive substance but also a strong oxidant. As indicated, it may react explosively with some organic liquids.

Both the nitration reaction itself and the oxidation reaction are strongly exothermic. Since nitration mixtures are often very sensitive and liable to explode, unless conditions are closely controlled, this strong heat generation is a problem. The heat evolved in a nitration reaction includes not only the heat of nitration but also the heat of dilution. Thus the heat of nitration of benzene is 761 BTU/lb, but under certain conditions the heat released by reaction and dilution is 895 BTU/lb.

Nitration reactions may constitute a hazard due to a reaction exotherm or a sensitive product. In some incidents the phenomena appear not to have been recorded previously, but in others the hazard was known in general terms, but its full implications have not been appreciated. There have been a number of explosions in nitration reactors which have subsequently been shown to have been due to the fact that the temperature of the reaction was too close to that at which a runaway reaction could start. The temperature differences between the main reaction and the runaway reactions have been typically of the order of 10−50°C. Similarly, explosions have occurred due to the sensitivity of the product of the nitration. Some nitro compounds have a quite low decomposition temperature, in the range 100−150°C, and are thus relatively hazardous. Information is available on this aspect (e.g. T.L. Davis, 1943; Kirk and Othmer, 1963−, 1978−, 1991−).

Rapid autocatalytic decompositions or 'fume-offs' of nitration products sometimes occur. Often they do not involve an explosion, but are nevertheless quite violent. Factors which have contributed to explosions due to runaway reactions or sensitive materials have included lack of knowledge and lack of appreciation of the need for particular precautions and for a wide margin of safety.

Nitrations are frequently carried out in stirred batch reactors. This type of reactor has certain characteristic hazards. These include the charging of reactants in incorrect quantities or sequence and the accumulation of unmixed reactants which react violently when the agitator is switched on.

Another hazard in nitration reactions is the ingress of water. The addition of water to the nitration mixture may result in a large release of heat which causes an explosion either directly or by initiating some other effect.

Whereas the other unit processes considered above are carried out in plants dedicated to that single process, nitrations are frequently performed in plants which make a number of products on a campaign basis. This method of manufacture introduces some additional opportunities for error.

Since nitration often presents problems both in respect of runaway exotherms and heat-sensitive products, it is especially important to have full information about the reaction and the products, particularly for a new reaction. Many of the problems of nitration are alleviated by the use of a continuous nitration process. The nitration is carried out in several vessels, each of which has a smaller holdup and time-invariant operating conditions. Many stages such as charging and discharging, precooling and preheating are eliminated, as are some items of equipment such as pumps. The process is more readily adaptable to automatic control. There is less human intervention and thus both less human error and less exposure of personnel. The evolution of nitroglycerine manufacture from a process using a batch reactor to a continuous process carried out in a nozzle has already been described.

Nitration is also carried out in the vapour phase. A further discussion of safety in nitration processes is given by Biasutti and Camera (1974). An accident in a nitration process is described in *Case History B22.*

11.8 Unit Operations and Equipments

Unit operations include: mixing, dispersion; distillation, gas absorption, liquid−liquid extraction; leaching, ion exchange; precipitation, crystallization; centrifugation, filtration, sedimentation; classification, screening, sieving; crushing, grinding; compacting, granulation, pelletizing; gas cleaning; heat transfer; and drying and dehydration. A further listing is given by Fowler and Spiegelman (1968).

Characteristic types of equipment are associated with these different operations. Accounts of unit operations are given in *Chemical Engineering* (Coulson and Richardson, 1955–, 1977–), *Unit Operations of Chemical Engineering* (McCabe and Smith, 1967), *Handbook of Separation Techniques for Chemical Engineers* (Schweitzer, 1979), *Principles of Unit Operations* (Foust *et al.*, 1980), *Chemical Engineers Handbook* (Perry and Green, 1984) and *Handbook of Separation Processes* (Rousseau, 1987) and by McCabe, Smith and Harriott (1985).

The unit operations and equipments considered here by way of illustration are: (1) mixers, (2) centrifuges, (3) driers, (4) distillation columns and (5) activated carbon adsorbers. All five feature in the CCPS *Engineering Design Guidelines* (1993/13) and the first three are the subject of IChemE guides.

There is a large group of unit operations in which dusts are handled with the associated hazard of dust explosion. This includes driers, as described below. Further treatment of this and other operations involving dusts is given in Chapter 17.

Other equipments such as fired heaters, heat exchangers, pumps and compressors are treated in Chapter 12 as parts of the pressure system. Selected references on unit operations and equipments and their hazards are given in Table 11.5.

11.8.1 Mixers

Mixers present a variety of hazards. An account of hazards of, and precautions for, mixers is given in the *Guide to Safety in Mixing* (Schofield, 1982) (the IChemE *Mixer Guide*). The body of the *Mixer Guide* is in the form of a checklist of hazards and precautions under the headings: (1) equipment, (2) operations, (3) substances and (4) plant.

The equipment should be suitable for its purpose. Dead spaces where reactions may occur or material may solidify should be avoided. The mixer body may be subjected to pressure or vacuum and to fatigue due to any vibration. It may experience out-of-balance loads such as the dropping in or the shifting of the charge. It should be capable of withstanding these different effects.

The rotating parts may experience inertia loads on start-up and out-of-balance loads during operation. Loads may be imposed due to high liquid viscosity or high powder shear resistance. Other hazards include entry of foreign material such as tramp metal and contact between the impeller and the body of the vessel due to bending of the shaft. There is a critical speed for an impeller. It should normally not be run between 70 and 100% of this critical speed.

There are various features that may constitute weak points on a mixer. They include closures, sight glasses, instruments, sample points on the body, and bearings and seals on the agitator. The moving parts and the charge may present a hazard to personnel. The moving parts may include the mixer body or other features such as counterbalanced closures. Other hazards include unguarded impellers, splashing or even ejected material, or ejected objects.

Failure of utilities can cause problems for mixers. Some failures include loss of electrical power to the agitator, loss of cooling, loss of inerting and loss of exhaust ventilation. If there is loss of agitation, reactions may occur or material may solidify. Another hazard of failure of electrical power is unexpected restart of the mixer. It should be arranged that the mixer does not restart automatically following restitution of power after a power failure. Measures should also be taken to prevent other inadvertent start-up of the mixer.

Mixers sometimes handle flammable materials. Sources of ignition characteristic of mixers are hot surfaces, friction and impact, and static electricity. Hot surfaces include electric motor casings, drive components, bearings and lamps. Friction and impact can occur due to breakage of rotating parts, entry of foreign material or contact between the impeller and the vessel. Friction may also occur due to bearings or seals running dry. Static electricity may be generated during the loading or during mixing of liquids or powders. A principal precaution against ignition is inerting.

The plant layout should provide good access to the mixer for operation and maintenance and should cater for foreseeable leaks and spillages. Operational hazards include: overfilling, leading to overpressure or spillage; underfilling, leading to splashing or, if the mixer is nearly empty, mechanical damage; and overmixing, leading to thickening, overheating or overreaction of the mixture.

The *Mixer Guide* describes some of the principal types of mixer such as the rotating shape (double cone), orbiting screw, 'U' trough, high speed rotor, Muller, top entry agitator (stirred tank), agitated bead mill (attrition), change can, planetary, heavy paste (Z-blade), internal (Banbury), roll mills and mixer/extruder types, and gives a matrix of mixer types vs relevant hazards.

Two precautions which find widespread use on mixers are fixed guards and interlocks. Fixed guards include annular covers around agitators and bars to prevent entry of a limb into a running nip. These are complemented by non-manual methods of loading and discharging such as chutes and feed belts.

Interlocks are used to prevent a mixer from being started up or approached unless it is in a safe condition. One application is to ensure that the cover is closed, another to ensure that the agitator is properly centred in the body and another to prevent access either to the agitator shaft or to the mixer body while it is moving. The *Mixer Guide* gives a number of examples.

A further treatment of mixers is given in the CCPS *Engineering Design Guidelines*.

11.8.2 Centrifuges

Centrifuges likewise present a variety of hazards. The hazards of, and the precautions for, centrifuges are considered in the *User Guide for the Safe Operation of Centrifuges with Particular Reference to Hazardous Atmospheres* (Butterwick, 1976) and the later publication *User Guide for the Safe Operation of Centrifuges* (Lindley, 1987) (the IChemE *Centrifuge Guide*).

Centrifuges often handle volatile flammable liquids and, unless special precautions are taken, are almost certain to contain a flammable mixture at some stage in the operational cycle. The probability of ignition of the flammable mixture is quite high. Main sources of ignition are mechanical friction, hot surfaces and static electricity. A centrifuge rotates at high speed and a mechanical fault, leading to a spark, or a hot surface, can cause ignition.

The movement of the slurry in an operating centrifuge favours the generation of static electricity, particularly if the liquid has a high resistivity. Alternatively, if the centrifuge is stopped and open, a static electricity hazard may occur from an operator who has too high an insulation path to earth.

There is also a mechanical hazard from the high kinetic energy of the rotating centrifuge bowl. The main causes of mechanical failure are basket imbalance, incorrect assembly, corrosion and bearing failure.

Since centrifuge operations involve frequent opening of the centrifuge, there is with some substances a toxic hazard. This may be an immediate, acute hazard or a long-term cumulative one.

If there is an explosion hazard in a centrifuge, it should be blanketed with inert gas, usually nitrogen. The maintenance of an inert atmosphere should be monitored. The three monitoring systems commonly used are based on measurement of: (1) flow of inert gas into centrifuge, (2) pressure of gas in centrifuge and (3) oxygen concentration of gas in centrifuge. The most suitable system depends on the degree of hazard. But the system based on the measurement of oxygen concentration, which is the variable of direct interest, is the most positive and should be used for high risk situations.

If there is a toxic hazard, the centrifuge system should be enclosed as far as practicable. Local exhaust ventilation should be provided. Alternatively, it is possible to extract from the casing and operate under a negative pressure, provided that the liquid is not flammable. Other measures which may be required include provision of a forced air supply or of breathing equipment for the operator.

Centrifuges are treated further in the CCPS *Engineering Design Guidelines*.

11.8.3 Driers

The principal hazards presented by driers are those of fire and explosion. These hazards and the corresponding precautions are discussed in *Prevention of Fires and Explosions in Dryers* (Abbott, 1990) (the IChemE *Drier Guide*). This is the second edition of, and thus supersedes, the *User Guide to Fire and Explosion Hazards in the Drying of Particulate Materials* (Reay, 1977).

The *Drier Guide* states that each year in the United Kingdom driers are responsible for 30 fires and one explosion serious enough to be attended by the local fire brigade. A detailed account of the self-heating of combustible materials is given in Chapter 16 and of combustibility and explosibility of dusts and of dust fires and explosions and dust explosion venting in Chapter 17, and the treatment given here is correspondingly limited.

Differences between the first and second editions of the *Drier Guide* are in large part accounted for by the up-dating of the methods for explosibility testing and for explosion suppression and venting. The identification of hazards in powders which are to be dried is described in Chapter 8. The *Drier Guide* assumes that the materials processed are essentially materials which may be combustible but are not either explosive or liable to decomposition. The following discussion is concerned with such combustible materials.

With regard to the oxygen concentration to prevent ignition, the *Drier Guide* states that if the published values are unacceptably low for efficient plant operation, the minimum oxygen concentration to support combustion should be established by tests performed using the modified vertical tube apparatus described by Field (1982).

There are three forms in which a combustible material being processed in a drier may be ignited: (1) dust cloud, (2) dust layer and (3) bulk dust.

A dust cloud of explosible concentration will normally occur only in driers where the material is dispersed such as in a fluidized bed drier or a spray drier. In other types of driers such as tray and band driers there should be no dispersed dust, provided the air velocity is kept sufficiently low. If there is a dust cloud, it will almost certainly be within the explosible range. The dust cloud may be ignited by an ignition source. Alternatively, ignition may occur if the cloud is raised above its minimum ignition temperature.

Dust may also form in layers inside the drier. A dust layer may be ignited by an ignition source. Alternatively ignition by self-heating may occur if the dust layer is exposed to an ambient temperature above its minimum ambient temperature for self-ignition.

Ignition may also occur in the bulk dust, for which there is a separate minimum ignition temperature. Since the heat loss from the bulk material is less than from a layer, this minimum ignition temperature is lower than that for a dust layer.

A dust explosion may be prevented by the use of inerting. The concentration of inert gas should be such as to reduce the oxygen concentration below the minimum oxygen concentration required to support combustion.

Dust properties relevant to drier design, therefore, include in particular the minimum ignition temperature of the dust cloud, the minimum ambient temperature of ignition of a dust layer, the minimum ignition temperature for the bulk dust and the minimum oxygen concentration to support combustion. The minimum ignition energy of the dust cloud is also relevant. The design of dust explosion venting systems utilizes information on the dust K_{st} class. Particle size is a strong determinant of these properties. Account should also be taken of the fact that if the dust contains any significant amount of flammable liquid, there is a hybrid mixture, with enhanced explosibility.

Many of the regular ignition sources apply to driers. These include hot work, hot surfaces, electrical equipment, and friction and impact. A direct heating system may give rise to hot particles which can act as an ignition source and precautions are taken against this. Air for combustion should be drawn from a source free of dust. Avoidance of dust in this air should be a factor taken into account when considering recirculation of air from the drier. Burners should be cleaned regularly and operated so as to give complete combustion. Erratic operation and flame blow-off should be remedied without delay. Before entering the drier, the hot gases should be passed through a 3 mm mesh to screen out hot particles. The mesh should be able to withstand the high temperatures and should be cleaned regularly. A direct heating system should not be used to evaporate flammable vapours.

Precautions against explosion may be based on prevention or protection. The main preventive measure given in the *Drier Guide* is inerting. The guide gives three main protective measures: venting, suppression and containment.

On the basis of the hazard evaluation a basis of safety should be chosen. The *Drier Guide* states that one measure is sufficient. If inerting is used, there should be continuous on-line monitoring of the oxygen concentration. With some driers there is a facility to recirculate part of the exhaust air to improve thermal efficiency. The gas entering the drier will then have a higher concentration of water vapour and, if it is direct fired, a higher concentration of carbon dioxide also. This provides a degree of inerting and such driers are described as 'self-inertizing'.

The *Drier Guide* gives a detailed discussion of the application of explosion suppression and explosion venting methods to driers. It also discusses the applicability of explosion containment, including pressure shock containment, to which it adopts a cautious approach. It points out, however, that containment may well be a practical option for a vacuum drier, where the initial pressure is much lower.

Measures which protect against a dust explosion, whether explosion suppression, venting or containment, do not necessarily offer protection against a sudden decomposition of the material, with a massive evolution of gas. Measures should also be taken to prevent the spread of dust fire or explosion to other parts of the plant. The process should be specified so as to minimize the hazard. The inlet air temperature is a particularly important variable and the *Drier Guide* discusses in detail the relevant factors and safety margins for different types of drier.

There are various items of equipment which are common to drying plants. They include heating systems, feed systems, dust conveying and recovery systems, and product storage vessels. Dust recovery systems include cyclones, filters, electrostatic precipitators, and scrubbers and washers.

The heating system should be designed in accordance with the codes for gas or oil fired heaters, as the case may be. It should have the appropriate instrumentation, including alarms, trips and interlocks.

Protection should be provided against explosion of a fuel–air mixture in the firing space. Suitable relief should be provided against such an explosion, unless the drier is designed for an explosible dust and is thus already provided with a dust explosion relief which can serve both purposes; where such a dust explosion relief exists, it will generally be adequate for the flammable gas explosion.

Self-heating of material passing hot from a drier to product storage is a hazard. The maximum safe temperature for discharge to storage may be determined for many situations from thermal ignition theory in combination with empirical tests. Measures to reduce the risk of self-heating include limitation of the size of storage vessel and monitoring of the temperature of the material in the vessel.

The operation and maintenance of driers also have certain common features. The *Drier Guide* discusses the operational aspects under the headings of pre-start-up checks, start-up, normal operation, normal shut-down and emergency shut-down. The guide gives what amount to checklists for pre-start-up checks and maintenance.

The *Drier Guide* describes some of the principal types of driers such as spray driers, pneumatic conveying driers, fluidized bed driers, rotary driers, band driers, batch atmospheric tray driers, batch vacuum driers and trough driers. For each type of drier it discusses the principle of operation, hazards, ignition sources, preventive and protective measures, process specification, equipment specification, and operation and maintenance. The CCPS *Engineering Design Guidelines* provide a further treatment of driers.

11.8.4 Distillation columns

Distillation columns present a hazard in that they contain large inventories of flammable boiling liquid, usually under pressure. There are a number of situations which may lead to loss of containment of this liquid.

The conditions of operation of the equipment associated with the distillation column, particularly the reboiler and bottoms pump, are severe, so that failure is more probable.

The reduction of hazard in distillation columns by the limitation of inventory has been discussed above. A distillation column has a large input of heat at the reboiler and a large output at the condenser. If cooling at the condenser is lost, the column may suffer overpressure. It is necessary to protect against this by higher pressure design, relief valves or HIPS. On the other hand, loss of steam at the reboiler can cause underpressure in the column. On columns operating at or near atmospheric pressure, full vacuum design, vacuum breakers or inert gas injection is needed for protection. Depostition of flammable materials on packing surfaces has led to many fires on opening of distillation column for maintenance.

Another hazard is overpressure due to heat radiation from fire. Again pressure relief devices are required to provide protection.

The protection of distillation columns is one of the topics treated in detail in codes for pressure relief such as API RP 521. Likewise, it is one of the principal applications of trip systems.

Another quite different hazard in a distillation column is the ingress of water. The rapid expansion of the water as it flashes to steam can create very damaging overpressures.

11.8.5 Activated carbon adsorbers

Experience with activated carbon adsorbers indicates that they are another potentially troublesome operation. An account of this type of adsorber is given in the CCPS *Engineering Design Guidelines*.

Activated carbon adsorbers are prone to fires in the adsorbent bed. This is so particularly where the substance being adsorbed is an oxidizable organic such as an aldehyde, ketone or organic acid. Fires are especially likely to occur during a shut-down.

Countermeasures evolved to minimize the risk of fire include: paying attention to adsorbent purity; maintaining the moisture content of the adsorbent; operating at less than 25% of the lower flammability limit; and avoiding dead spots. The adsorbers should be located outdoors and provided with pressure relief and fire protection.

Among the measures used to prevent fire during a shut-down are maintenance of a gas flow 75% of normal, use of water or steam spray to keep the bed moist, inerting of the bed and removal of the bed.

The *Guidelines* give a checklist of precautions for activated carbon adsorbers.

11.9 Operating Conditions

Operation at extremes of pressure and temperature has its own characteristic problems and hazards. Extreme conditions may occur at: (1) high pressure, (2) low pressure, (3) high temperature and (4) low temperature.

Some general characteristics of these operating conditions are described below, together with some of the associated literature. In relation to extreme operating conditions in general, mention may be made of *Chemical Engineering under Extreme Conditions* (IChemE, 1965/40) and of the series *Safety in Air and Ammonia Plants* (1960–69/17–26), *Operating Practices in Air and Ammonia Plants* (1961–62/27–28) and *Ammonia Plant Safety and Related Facilities* (1970–94/31–53) by the American Institute of Chemical Engineers (AIChE).

A newer development in extreme operating conditions is the use of plasma processing. Selected references on extreme operating conditions and their hazards are given in Table 11.6.

11.9.1 High pressure

The range of pressures handled in high pressure technology is wide. Three broad ranges of pressure may be distinguished: (1) pressures up to about 250 bar, (2) pressures of several thousand bar, and (3) pressures greater than 8000 bar. Most process plants operate at pressures below 250 bar, but certain processes such as high pressure polyethylene plants operate at pressures up to about 3000 bar. Ultra-high pressures begin at a pressure of about 8000 bar, which is the probable limit of the simple elastic cylinder and at which it becomes necessary to use other types of construction such as wire-wound vessels. It is therefore important to minimize leaks by eliminating potential sources such as flanges, vents, bonnet seals, etc.

In general, pressure vessels in process design are not designed for explosive over pressures such as deflagration or detonation with certain exceptions (acetylene). Deflagration can produce over pressure of a factor of 9–10 whereas detonations can lead to a factor 40 or higher. Detonations are not expected in pressure vessels and rarely in pipelines. Appropriate arrestors should be provided for this condition (CCPS, 2000).

Normal high pressure plant is dealt with in numerous standard texts. Mention may be made here of *Theory and Design of Modern Pressure Vessels* (Harvey, 1974) and *Pressure Component Construction* (Harvey, 1980).

Supercritical conditions
Korner (1985); Penninger *et al.* (1985); Randhava and Calderone (1985); McHugh and Krukonis (1986)

Plant for higher pressure is a more specialized technology. It is treated in *The Design and Construction of High Pressure Chemical Plant* (Tongue, 1934), *The Design of High Pressure Plant and Properties of Fluids at High Pressure* (Newitt, 1940), *High Pressure Technology* (Comings, 1956), *Apparate und Armaturen der Chemischen Hochdrucktechnik* (Buchter, 1967), *High Pressure Engineering* (Manning and Labrow, 1971), *High Pressure Technology* (Spain and Paauwe, 1977), *High Pressure in Science and Technology* (Vodar and Marteau, 1980) and *Experimental Techniques in High Pressure Research* (Sherman and Stadtmuller, 1987), and by Homan, Maccrone and Whalley (1983).

Further accounts of high pressure technology and its hazards are given by Stevenston (1959), Munday (1971a), Sykes and Brown (1975), B.G. Cox and Saville (1975), Boyer (1984), Livingstone (1984) and Prugh, Howard and Windsor (1993).

The relevant standard for high pressure plant is BS 5500: 1976 Unfired Fusion Welded Pressure Vessels. There is no UK standard for very high pressure plant.

High pressures are usually associated with high and/or low temperatures.

The use of high pressure greatly increases the amount of energy available in the plant. Whereas in an atmospheric plant stored energy is mainly chemical, in a high pressure plant there is, in addition, the energy of compressed permanent gases and of fluids kept in the liquid state only by the pressure.

Since the economies of scale apply very strongly to compression, the number of compressors used is generally small. Often there is a single compressor for a particular duty. The machines themselves are large and their technology is complex.

Although high pressures in themselves do not pose serious problems in materials of construction, the use of high temperatures, low temperatures or aggressive materials does. Thus, the problem is to obtain the material strength required by high pressure operation despite these factors.

With high pressure operation, the problem of leaks becomes much more serious. The amount of fluid which can leak out through a given hole is greater on account of the pressure difference. Moreover, the fluid may be a liquid which flashes off as the pressure is reduced.

11.9.2 Low pressure

The degrees of vacuum handled in low pressure or vacuum technology span many orders of magnitude. In the present context, it is relatively low vacuum from 760 torr (atmospheric pressure) to 1 torr and medium vacuum from $1-10^{-3}$ torr which are the ranges of prime interest.

Normal vacuum technology is treated in *Industrial High Vacuum* (Davy, 1951), *Principles of Vacuum Technology* (Pirani and Yarwood, 1961), *Vacuum Technology* (Spinks, 1963), *Vacuum Science and Engineering* (van Atta, 1967), *Vacuum Sealing Techniques* (Roth, 1967), *Vacuum System Design* (Dennis and Heppel, 1968), *A User's Guide to Vacuum Technology* (O'Hanlon, 1980), *Process Vacuum System Design and Operation* (Ryans and Roper, 1986), *Modern Vacuum Practice* (N.S. Harris, 1989), *Theory and Practice of Vacuum Technology* (Wutz, Adam and Walcher, 1989) and *Vacuum Technology* (Roth, 1990). Low pressures are not in general as hazardous as the other extreme operating conditions. But a hazard which does exist in low pressure plant handling flammables is the ingress of air, with consequent formation of a flammable mixture.

A major part of vacuum technology is concerned with detecting and preventing leaks. The techniques developed in this field may be relevant, therefore, to plants under positive pressure, particularly those handling very toxic materials.

11.9.3 High temperature

The literature on high temperature technology is relatively diffuse and deals mainly with particular types of plant (e.g. ammonia plants), or particular types of equipment (e.g. fired heaters). Mention may be made, however, of *High Temperature Materials and Technology* (I.E. Campbell and Sherwood, 1967).

As already mentioned, the use of high temperatures in combination with high pressures greatly increases the amount of energy stored in the plant. The heat required to obtain a high temperature is often provided by fired heaters. These have a number of hazards, including explosions in the firing space and rupture of the tubes carrying the process fluid.

There are severe problems with materials of construction in high temperature plants. The main problem is that of creep at high temperatures. But there are other problems also, such as hydrogen embrittlement. The use of high temperatures implies that the plant is put under thermal stresses, particularly during start-up and shutdown. It is essential to take these stresses fully into account in the design.

It is equally necessary to operate the plant with regard to the temperature effects. Its life can be much shortened by excursions inside the high creep range or by transients which cause high thermal stresses. Relatively low cyclical temperatures such as in driers, and absorbers when regenerating, can lead to greatly reduced service life.

11.9.4 Low temperature – cryogenics

The temperatures handled in low temperature technology are those below 0°C. There is a somewhat distinct technology dealing with ultra-low temperatures below 20 K, but this is not of prime interest in the present context.

Normal low temperature technology is dealt with in *The Physical Principles of Gas Liquefaction and Low Temperature Rectification* (M. Davies, 1949), *The Separation of Gases* (Ruhemann, 1949), *Cryogenic Systems* (Barron, 1966–), *Cryogenic Fundamentals* (Haselden, 1971) and *Liquid Cryogens* (Edeskuty and Williamson, 1983). Mention should also be made of the *Cryogenic Safety Manual* by the British Cryogenic Council (BCC, 1970).

Low temperature plants contain large amounts of fluids kept in the liquid state only by pressure and temperature. If for any reason it is not possible to keep the plant cold, then the liquids will begin to vaporize.

Impurities in the fluids in low temperature plant are liable to come out of solution as solids. This is particularly likely to happen if parts of the plant are allowed to boil dry. Deposited solids may be the cause not only of blockage but also, in some cases, of explosion. It is necessary, therefore, to ensure that the fluids entering a low temperature plant are thoroughly purified.

Careful attention must be paid to the establishment and compliance with the vessel operating parameters. In most cases low temperatures are the result of advertent or inadvertent depressurization of light hydrocarbon materials, which greatly reduces the hazard. Care must be taken on repressurization to allow the materials to reach a safe temperature.

A severe materials of construction problem in low temperature plants is low temperature embrittlement. The materials requirements, however, are well understood. The main difficulties arise from aspects such as installation of incorrect materials or flow of low temperature fluids into sections of the plant constructed in mild steel.

In low temperature as in high temperature operations the plant is subject to thermal stresses, especially during start-up and shut-down. These stresses need to be allowed for and, as far as possible, avoided.

The insulation on low temperature plant frequently takes the form of a cold box. It is not easy to gain access to equipment inside the cold box. It is important, therefore, for the equipment to be as reliable and the fluids processed as pure as possible.

In low temperature plant the temperature approaches used in the heat exchangers are very close, say 3°C. This is done to achieve maximum thermodynamic efficiency, since any inefficiency is paid for directly in the power required for compression. The use of such close temperature approaches is another reason for avoidance of fouling by keeping the fluids free of impurities.

The scale of operation in low temperature technology can be very large. In particular, the largest storages of hazardous liquids, both flammables and toxics, tend to be refrigerated storages.

11.10 Utilities

The process plant is dependent on its utilities. These include in particular:

(1) electricity
  (a) general,
  (b) uninterrupted power supplies,
  (c) electrical heating;
(2) fuels;
(3) steam;
(4) compressed air
  (a) plant air,
  (b) instrument air,
  (c) process air,
  (d) breathing air,
(5) inert gas;
(6) water
  (a) cooling water,
  (b) process water,
  (c) hot water,
  (d) fire water;
(7) heat transfer media
  (a) hot fluids,
  (b) refrigerants.

There may also be other special services on particular plants. Selected references on utilities are given in Table 11.7.

Important features of a utility are its: (1) security, (2) quality, (3) economy, (4) safety and (5) environmental effects.

One of the main causes of failure of supply of a utility is loss of part of the generating capacity followed by rapid overload of the rest, leading to total loss. In order to avoid this, measures may be taken to effect load shedding at the less essential points of consumption. Specific application of this principle is discussed below for electricity and steam.

It is often attractive to use a ring main layout to distribute a service. This allows the supply to a given point to be provided from either side and thus increases reliability. It is necessary, however, to give careful consideration to the flows which can occur in ring mains, particularly those handling steam.

Since service pipes and trunking pass through the plant, they are vulnerable to damage from accidents. The routing of services should be planned so as to minimize such damage.

In particular, cabling for control instruments and other key services should be routed as safely as possible. For critical control functions requiring replication, the cables should go by different routes. A severe accident may well cause damage to certain key services. There may be serious consequences if there is loss of electrical power to machines or control instrumentation, of cooling water or of fire water.

11.10.1 IChemE *Utilities Guide*

A treatment of the principal utilities is given in *Process Utility Systems* (Broughton, 1993) (*The* IChemE *Utilities Guide*). The Utilities Guide deals with the following topics: (1) efficient use of utilities, (2) fuel, (3) compressed air, (4) inert gases, (5) thermal fluid systems, (6) water preparation, (7) the boiler house, (8) steam distribution, (9) electricity use and distribution, (10) air and water cooling, (11) refrigeration, (12) fire protection system, (13) building services, and (14) pipework and safety.

The *Guide* starts by outlining five broad principles of general applicability to process utilities. One is the need for critical examination of all aspects, both the requirements and the means of meeting them, with full exploration of alternatives. Another is integration of utilities not just with individual plants but across the site. The third is the appropriate sizing and location of the utilities units. The fourth is the use of modern, efficient systems. And the fifth, the need for performance targets and monitoring.

11.10.2 Electricity

Electricity is used for a number of different purposes on process plants. These include: (1) machinery, (2) heating and (3) instrumentation. The use of electricity in factories is governed by the Electricity at Work Regulations 1989, which supersede the former Electricity (Factories Act) Special Regulations 1908 and 1944.

UK standards on electrical equipment include: BS 2771: 1986 – Electrical Equipment for Industrial Machines, replacing BS CP 1015: 1967; BS 4683: 1971 – Specification of Electrical Apparatus for Use in Explosive Atmospheres; BS 5345: 1977 – Code of Practice for the Selection, Installation and Maintenance of Electrical Apparatus for Use in Potentially Explosive Atmospheres (other than Mining Applications or Explosive Processing or Manufacture); BS 5501: 1977 – Electrical Apparatus for Potentially Explosive Atmospheres, replacing BS CP 1003; and BS 7430: 1991 Code of Practice for Earthing, replacing BS CP 1013: 1965. Relevant UK codes of practice include the IP Electrical Safety Code (1991 MCSP Pt 1) and the IP Area Classification Code for Petroleum Installations (1990 MCSP Pt 15). The ICI Electrical Installations in Flammable Atmospheres Code (ICI/RoSPA, 1972 IS/91) has also been widely quoted in the safety and loss prevention literature.

Relevant US codes are: NFPA 70: 1993 National Electrical Code; API RP 540: 1991 Recommended Practice for Electrical Installations in Petroleum Processing Plants; and API RP 500: 1991 Recommended Practice for Classification of Locations for Electrical Installations at Petroleum Facilities, replacing API RP 500A, 500B and 500C.

Safety aspects of electricity and electrical equipment are dealt with in *Electrical Safety* (Swann, 1959), *Electrical Safety Engineering* (Fordham Cooper, 1986) and *Hazard of Electricity by the American Oil Company* (Amoco) (Amoco/5).

Electrical power in a chemical works may be provided from the National Grid or from a power station within the works. Since steam is also required, a large works usually has its own power station. There are frequently mutual back-up arrangements between the Grid and the works station.

On some processes loss of electrical power for machinery can be serious. This applies particularly where materials may solidify in the plant, liquefied gases may warm up and vaporize, and refractories may cool and collapse. It may be necessary in such situations to provide a stand-by power supply. This may be done by setting up mutual back-up arrangements, by providing stand-by generators, or by installing engine-driven equipment and/or batteries.

Fluctuations of power supply in the form of voltage dips and outages can also occur and cause motors to cut out, which may result in process upsets. Time delay relays are available which can be used to overcome brief fluctuations.

It is particularly important to ensure the removal of heat from the process, as heat exchange depends primarily on the continued operation of pumps, both those for the process fluid and those for the cooling water. The fans of air-cooled heat exchangers are also dependent on electrical power. The fans on fired heaters are important. Loss of power on these fans can lead to the formation of a flammable atmosphere.

In order to maintain power supply to essential equipment when partial loss of generating capacity occurs, it may be necessary to practice load shedding on other equipment. Load may be shed automatically, using load shedding relays which detect deterioration of the supply frequency and operate to shed the load according to a pre-arranged sequence.

Where electric motors are used to drive pumps, it is not uncommon for sudden overloads to occur on a pump and for the motor overload protection to cut the motor out. This situation tends to occur particularly during a transient condition such as the loss of one pump in a set. In consequence, the reliability of the redundant pumps is not always as good as theoretical reliability predictions suggest. It is necessary, therefore, to give careful consideration to possible causes of pump overload.

Electrical apparatus is a potential source of ignition. It is essential, therefore, to have a system of electrical area classification and to use appropriate equipment in each zone. This is a most important aspect and it is considered in Chapters 10, 16 and 22 in relation to plant layout, fire and storage, respectively.

Stray electrical currents may also be a problem. They can cause corrosion and can act as sources of ignition. The power supplies to instruments as well as to machinery should be such as not to constitute a source of ignition.

11.10.3 Electricity: uninterrupted power supplies

Instrumentation requires a power supply of high quality. Voltage fluctuations, for example, can cause upsets to process computers and programmable electronic systems and to some instrumentation. It is often necessary to provide for such equipment an uninterrupted power supply (UPS), also frequently called an 'uninterruptible power supply'. These terms are used to describe a supply which possesses both high reliability and high quality in the sense that it does not have interruptions even for a few milliseconds. Designs of UPS system are described in the IChemE *Guide*.

The UPS may utilize rotating or static equipment. One method of providing a UPS is a motor–alternator set with diesel engine back-up, other components of the system being an electromagnetic clutch and a flywheel. In normal operation, the alternator is driven by the motor. On mains failure the diesel engine starts and the clutch engages, connecting the engine to the alternator, additional energy being supplied by the flywheel until the engine is up to full power.

An alternative method of providing a UPS is a static system using batteries. In one arrangement, the AC supply passes to the load via a rectifier and an inverter, with the batteries connected between these two. This design is intended to ensure that in normal operation the batteries are kept charged and that on mains failure the batteries maintain the supply. A further discussion of UPSs is given in the CCPS *Safe Automation Guidelines* (1993/14).

11.10.4 Electricity: electrical heating

Electricity may also be used for electrical heating, or electroheat. Although the efficiency of electrical heating is limited by thermodynamics, this factor may be more than offset by the ability of electroheat systems to deliver heat with greater flexibility and precision. Types of electrical heating include immersion heating, resistance heating of pipes, induction heating of vessel walls, and the various forms of surface heating using jackets, mantles, panels, tapes, etc. An account is given in the IChemE *Guide*. Electrical heating is also used instead of a fired heater in smaller heat transfer fluid systems.

11.10.5 Fuels

Process units use both gaseous fuels such as LPG and liquid fuels in the form of fuel oil. Fuel gas is often available as part of an integrated process, as in a refinery, but it is proper to treat it as a utility. A typical fuel gas supply system is illustrated in Figure 11.11, which shows supplies taken from a primary process source, a secondary source and an LPG vaporizer.

Fuel oil is used in burners on the process, in boilers and in fired heaters. The heavier fuel oils are cheaper but are viscous and require heated storage and preheaters so that for smaller systems it is often more economic to use light fuel oils.

11.10.6 Steam

Steam is used for: (1) machinery, (2) heating, (3) process, (4) purging and inerting and (5) snuffing. Steam may provide motive power in steam turbines and also in ejectors. It is extensively used for heating. It may be injected directly into the process as in operations such as steam stripping. It is a principal fluid used for purging and cleaning operations. It is used as a means of snuffing out the flame in fired heaters.

The main source of steam is usually the works power station, but there may be process sources such as waste heat boilers or chemical reactors. On smaller works steam may be supplied by boilers.

Steam systems are described in *The Efficient Use of Steam* (Lyle, 1947), *Industrial Boilers* (Gunn and Horton, 1989) and *Steam, Its Generation and Use* (Babcock and Wilcox, 1993). Hazards are reviewed in *Hazards of Steam by the American Oil Company* (Amoco/6).

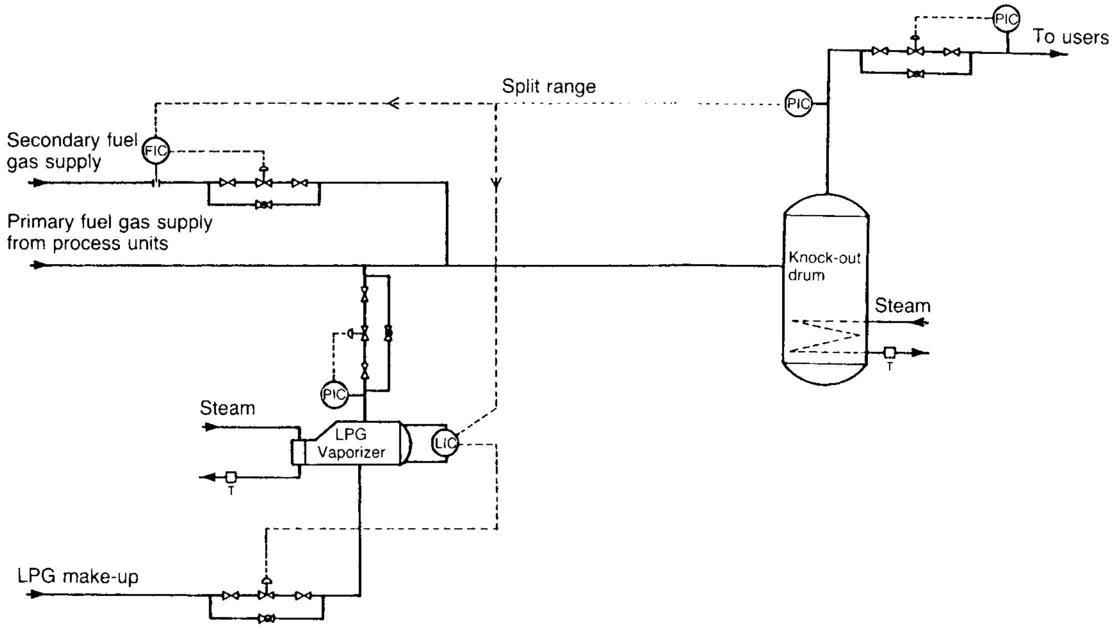

Figure 11.11 Schematic diagram of a composite gaseous fuel supply system (Broughton, 1993). FIC, flow indicator controller; L/C, level indicator controller; PIC, pressure indicator controller (Courtesy of the Institution of Chemical Engineers)

An overview of the boiler house on a process plant site is given in the IChemE *Guide*, which describes the common types of boilers and burners and the ancillary plant required, and gives a checklist for boiler selection.

Boilers are either shell boilers or water-tube boilers. In fire-tube boilers, the water is in the shell, the hot gases are burned in a combustion chamber inside the shell and then pass through the fire tubes, giving up more of their heat. In one arrangement, the boiler is set in brickwork, the Lancashire and Cornish boilers being early workhorses of this type with single and double internal flues, respectively. The economic boiler, by contrast, is self-contained. Package fire-tube boilers are widely used. Electrical boilers are of two types. One is heated by an immersion element akin to that used in domestic systems. The electrode boiler is heated by passage of current directly through the water between immersed electrodes. Both types come as package units. Finally, water-tube boilers are available in a variety of designs and in sizes from package units to the large-field assembled units used in power stations.

All boilers, including waste heat boilers, require feed water treated to prevent scaling. The feed water and boiler water qualities required for different steam pressures are listed in the IChemE *Guide*. Boiler feed water treatment is an important aspect of boiler operation. The reliability of the feedwater treatment plant, including the feedwater pumps, is therefore an issue.

The quantities of steam needed for purging can be large. It is necessary, therefore, to provide for this requirement, otherwise there may be a tendency to use insufficient steam in purging operations.

As with electrical power, it may be necessary to practice load shedding to protect the supply of steam to essential equipment on loss of part of the generating capacity.

Where there is a set of boilers and some are lost, the resultant demand on the remaining boilers is liable to cause fan overload and loss of these boilers also. A limit control system may be used to prevent such overload.

Loss of steam can normally be tolerated and it is not usual to have a stand-by steam supply. The steam system has some capacity, however, and can usually supply steam for a period. For more critical units, the period can be prolonged if steam to other units is cut off.

It is appropriate, however, to consider the effect on a unit if the heating steam is lost. The resultant cooling may lead to condensation of vapours and to underpressure of the unit, and it may be necessary to provide nitrogen injection to counteract this.

Steam from the main boilers, and any waste heat boilers, is distributed to user plants, by a distribution system which may provide steam at low, intermediate and high pressure, pressure being let down at let-down stations.

A serious hazard in steam systems is water hammer. A slug of condensate which has collected in the main may be flung by the steam against the pipework with a very destructive effect.

Steam distribution systems should be designed to effect efficient drainage of condensate. This means that: the lines should be sloped; drainage points should placed at suitable locations and provided with drain pockets so that the condensate collects and does not skim over the top of the drain point; and efficient steam traps should be installed for take-off of the condensate.

Guidance on steam traps is given in *Steam and Steam Trapping* by Spirax-Sarco Ltd (1993). Further treatments of the design and operation of steam distribution systems, with particular reference to the avoidance of condensate hammer, are given in Chapters 12 and 20, respectively.

Erosion is a common feature in steam systems. Steam can be a surprisingly erosive fluid, especially if it is wet.

Leaking steam can cause a build-up of static electricity and can thus constitute a source of ignition. This possibility should be considered where leaks of flammable vapours may also be present.

Air may be present in a steam system on start-up and manual vents located at high points should be provided to allow it to be removed. The IChemE *Guide* suggests this should be the limit of the problem.

In some cases, as discussed by Plummer (1986), the presence of air and other gases in steam does cause operating problems and needs to be addressed. There are various sources of air or other gas in plant. Air dissolved in the boiler feedwater may not be completely removed by deaeration. Chemical reactions in the boiler, such as the release of carbon dioxide from bicarbonates, can generate gas. Air may be drawn into spaces where steam is condensing at a pressure below atmospheric.

These permanent gases can then create problems. Temperature control is often based on pressure control and if, due to the presence of gas, the relation between pressure and temperature departs from the value corresponding to the steam tables, control is upset. Heat transfer across heat exchange surfaces may deteriorate due to blanketing of these surfaces by gas. Corrosion may be promoted by the presence of oxygen or carbon dioxide.

Unwanted gas may be removed by suitable venting. Vent valves are available which operate on temperature, opening when the temperature is below saturation and seating when saturation temperature is reached. Points where such valves may be located are at the boiler, at remote ends of lines, upstream of isolation valves and on heat exchangers.

11.10.7 Compressed air: plant air

Compressed air is required on process plants as plant air for general applications, instrument air, breathing air and process air. General applications include purging and driving pneumatic tools.

Typically plant air is filtered, compressed to 6–7 barg and then cooled in a heat exchanger with condensation of water, but is not dried. The air enters an air receiver which supplies the service stations on the compressed air main. Compressed air, therefore, should be free of solid matter but contains some oil and is saturated with water.

The demand for plant air is subject to large fluctuations and the supply should be able to cope with such peaks, but it is not generally necessary to install stand-by compressors.

11.10.8 Compressed air: instrument air

The requirements for instrument air are somewhat different. Instrument air needs to be dry and its supply reliable. It is important that the instrument air be of good quality and, in particular, that it be free from solids, oil and water. Dirty, oily or wet air is liable to cause instrument error and failure. It follows that it is not good practice to use ordinary plant air for instrumentation.

The IChemE *Guide* states that instrument air should be free of solids, oil, corrosive substances and noxious gases. The solids content should be less than 0.1 $g/N/m^3$ with particle sizes less than 3 μm. With regard to dryness, the Guide quotes the requirement for a dewpoint of −40°C frequently suggested for UK sites, but adds that this can reduce the flexibility of vendor packages and proposes that for temperate climates such as those of central and southern Europe a dewpoint 10°C below the minimum ambient temperature suffices. The compressors used for instrument air should be of the oil-free type.

Instrument air is typically supplied at about 7 barg from an air receiver. The *Guide* states that a pressure of 4 barg is the minimum for satisfactory operation of the instrumentation and that it should not be allowed to fall below this. The supply needs to be adequate to cope with fluctuations. The *Guide* gives typical air consumption figures for instrumentation.

In most applications, the instrument air supply should have high reliability, which will normally mean the provision of stand-by equipment, separate power sources, and so on.

Avoidance of contamination, discussed in Section 11.10.18, is particularly important for instrument air. Connection of another system to the instrument air system creates the possibility of such contamination. It was contamination of the instrument air which initiated the train of events at Three Mile Island, as described in Appendix 21.

11.10.9 Compressed air: breathing air

If the extent of use of air-supplied breathing apparatus justifies it, a dedicated supply of air may be provided for breathing. This is considered in Chapter 25.

11.10.10 Compressed air: process air

Many processes use air as a raw material. Such air is usually obtained by compression of atmospheric air. Generally loss of process air is not critical and special measures are usually not required to ensure security of supply.

Air drawn by the process air compressors necessarily comes from some point in the works. There may be a degree of contamination due to leaks from plants, and in some cases the impurities may have an adverse effect on the process.

Hazards can arise from the build-up of oil from the compressors in the process air lines. Hazards are reviewed in *Hazards of Air by the American Oil Company* (Amoco/2).

11.10.11 Inert gas

The inert gases used in the process industries are mainly nitrogen and carbon dioxide. Alternatively, flue gas from an inert gas generator may be used. The inert gas principally considered here is nitrogen. This is described in *Nitrogen for Industry* (Sittig, 1966) and in the IChemE *Guide*.

Nitrogen is used for a large number of purposes. These include: (1) inerting, (2) process, (3) purging and (4) pressurizing. One main use of nitrogen is inerting. Inert atmospheres are often required in processes such as polymerization, catalyst preparation and drier regeneration, and in plant such as centrifuges and storage tanks. Storage tank atmospheres are frequently inerted with nitrogen.

Nitrogen has a number of process uses. In particular, it may be used to dilute the concentration of a reactant such as oxygen in an oxidation process. In high pressure processes the use of nitrogen permits the use of such pressures while limiting the partial pressure of oxygen.

Another use of nitrogen is as a purge gas. Purging of equipment is discussed in Chapters 16, 20 and 21 in relation to fire protection, plant operation and maintenance, respectively. Where purging is carried out to prevent entry of flammable gases into equipment which may spark, nitrogen is not always the most suitable gas to use. Often air is both cheaper and safer. The choice of purge gas for such applications is considered further in Chapter 16.

There are certain situations which can lead to the plant being underpressured so that it may collapse inwards. This may be countered by nitrogen injection. Another application of pressurizing is the use of nitrogen pressure to transfer liquids in order to avoid having to pump them.

The quality of the nitrogen required depends on the application. The IChemE *Guide* distinguishes between general purging (GP) nitrogen and high purity inert medium (HPIM) nitrogen. Supplies of nitrogen may be obtained from gas cylinders or ammonia dissociation; from an inert gas generator in which nitrogen is obtained from combustion of air and removal of other products of combustion; from air separation by pressure swing adsorption (PSA); from air separation by permeation through a membrane; from bulk gas or liquid storage or gas pipeline; or from a low temperature air separation plant on site. Cylinders are economic only for very small quantities and a low temperature air separation plant only for very large ones.

The choice of nitrogen supply method is discussed in the *Guide*. It is essentially a function of the purity and scale. A breakpoint occurs at a demand of about 300 Nm^3/h. Broadly, the *Guide* indicates that the demands below this can be met using a liquid nitrogen storage/vaporizer system and those above using a low temperature separation plant, with PSA and membrane methods an option for smaller demands of GP nitrogen. Thus, in contrast to the other services nitrogen is not always generated on site. Instead, it may be brought in and held in storage. In this case, it is essential to have a sufficient supply.

The Flixborough Inquiry revealed that the nitrogen required for inerting on the plant was sometimes in short supply and that as a result routine procedures were interrupted. The *Flixborough Report* drew attention to the importance of ensuring an adequate supply of nitrogen when plant safety is dependent on it.

11.10.12 Water: cooling water

Cooling water in the process industries is provided using one of three basic systems. One is the 'once-through' system, which is self-explanatory. The other two involve recirculation, either in an open system in which the water is cooled in cooling towers, or in a closed system in which it is cooled in heat exchangers using another fluid. The use of cooling towers is the normal method except where the site is such as to allow the once-through use of river or seawater.

Other cooling facilities may be provided by air-cooled heat exchangers, which depend on electric fans for air circulation.

Since it is essential to assure removal of heat from the process, the security of the cooling water supply is important. This may be achieved by making sure that the power supply is secure, by providing stand-by pumping arrangements and/or by the use of head tanks.

It is not good practice to use cooling water as fire water, as this may result in the loss of ability to ensure essential heat removal from process units. The cooling water system should be operated so that corrosion of process equipment by cooling water is kept to a minimum.

11.10.13 Water: process water

Water is an important raw material for many processes. It is usually taken from the public water supply or from company sources such as reservoirs and springs. Generally, loss of process water is not serious and a stand-by supply is usually not necessary. High security may be needed, however, for the boiler feedwater supply. The water purity required depends upon the process. In some cases, special purification plant may be needed. Such purification is necessary in particular for boiler feedwater. It is not good practice to draw the process water from the cooling water system.

Hazards are reviewed in *Hazard of Water by the American Oil Company* (Amoco/1).

11.10.14 Water: hot water

A supply of hot water may be required for washing down plants. If this is generated by direct mixing of water and steam, a specially designed mixing nozzle system should be used which shuts off on loss of cold water. The water temperature should be controlled at a temperature which will not injure personnel using it. A water temperature exceeding 57°C can give first degree burns.

11.10.15 Water: fire water

The provision of fire water is treated in Chapters 10 and 16 in relation to plant layout and fire protection, respectively.

11.10.16 Heat transfer media: hot fluids

In addition to steam and cooling water, use may be made of other heat transfer fluids (HTFs) for heating or cooling. HTF, or thermal fluid, systems are used to supply heat to process fluids at temperatures up to about 300°C. Such HTF systems exhibit a number of problems which need to be addressed if they are to operate satisfactorily. Accounts are given in the IChemE *Guide* and the CCPS *Engineering Design Guidelines*; both devote a complete chapter to these systems.

The HTFs used are mainly mineral oils, synthetic aromatics, diphenyl–diphenyl oxide mixtures and silicones. Examples of mineral oils are BP's Transcal 65; of synthetic aromatics, Dew's Dowtherm Q and BP's Transcal SA; of diphenyl–diphenyl oxide mixtures, Dow's Dowtherm A and ICI's Thermex; and of silicone, Dow's Syltherm 800.

An HTF generally has a boiling point in the range 260–340°C, a maximum fluid temperature of 350°C and a vapour pressure at the operating temperature of 1–2 barg. Many are subject to autoignition on escape to atmosphere.

Since the fluid circulates continuously, it is subject to degradation, minimization of which is an important feature of the design and operation of HTF systems.
