It is now common practice to use a process simulator to explore the various features of a process flowsheet. This simulation brings with it a requirement for more powerful database systems that are capable of supporting such work. Conventional database management systems tend to be deficient in a number of ways and the development of database systems for process simulation has been an active area of work. An example is the development of SIMBAD, a process simulator linked to a powerful database, described by Montagna *et al.* (1987). There is also a trend to add object oriented features to traditional relational databases. Huang and Fan (1988) describe a hybrid database that marries an object oriented approach with a relational one.

30.32.4 Process integration as a model

One of the most successful areas of process synthesis is that of process integration, the design of heat exchanger networks. Taking this as a model for process synthesis as a whole, Westerberg (1989) identifies two key features. One is the ability to set targets for the design and the other is the use of an effective domain-specific representation, in this case for heat flow.

30.32.5 Other process design aspects

The problem of handling constraints during design is addressed by Waters and Ponton (1992). The work is concerned with the early identification and correction of design errors and explores the use of an automated checklist to prevent violations of design intent.

An exploration of the applicability of an expert system to the design of batch processing systems is described by Hofmeister, Halasz and Rippin (1989). The authors refer particularly to the importance of problem representation, highlighted in the earlier work of Rippin (1983).

Hanratty and Joseph (1992) have described the application in an expert system for reactor selection of the analytic hierarchy process (AHP) method of Saaty (1980). The AHP is one of the techniques for encoding expert judgement, as described in Chapter 9, and is widely used in the social sciences. It is based on the method of paired comparisons.

Another design problem is the analysis of the flexibility of a design. This has been addressed by Grossman and Floudas (1987) who describe a flexibility criterion and a flexibility test.

Engelmann *et al.* (1989) have described the use of distributed expert systems in process synthesis.

30.33 Plant Design: Synthesis

Moving on to the design of the plant as opposed to that of the process, this too is an important area. Here some modest progress has been made in the development of aids for certain types of task, but there remains much scope.

30.33.1 Inherently safer design

One of the prime aims in the design of process plants is to promote the practice of inherently safer design right from the conceptual design stage. Apart from developments such as those in process synthesis and the selection of a reaction route, which are certainly important aspects of inherently safer design, it is not easy to identify any specific synthesis aid in this area.

30.33.2 Characteristics of design problems

An overview of the expert design of plant handling hazardous materials has been given by Bunn and Lees (1988). What these authors do is to describe a series of design problems, involving various kinds of design expertise, ranging from very simple, even trivial, design activities to designs with deep structure and to designs apparently better suited to solution by machine rather than by man.

The problems considered in this work are (1) the choice of whether or not to fit an emergency isolation valve, (2) the design of a flare system, (3) the design of a pressure relief system and (4) the design of a valve sequencing system; together in each case with the nature of the appropriate Al aid.

The first part of this section gives an account of this work, as an illustration of the potential for Al and expert system aids across the whole synthesis activity in plant design. The second part describes some particular aids that have been developed.

30.33.3 Design as equipment selection: emergency isolation valves

The most simple problem in the set considered by Bunn and Lees is the decision whether or not to fit an emergency isolation valve (EIV). The problem was investigated by studying a published paper in which an expert describes the factors that he took into account in making the decision and gives examples of cases where such valves were installed and of others where they were not. An interview was also held with the same expert.

The account used was that given by Kletz (1975b) of the installation of EIVs on two petrochemical plants. In deciding whether or not to install an EIV both the frequency and consequences of an escape were taken into account. Kletz' paper states:

Three situations should be considered:

(1) The equipment is particularly likely to leak; for example, very hot or very cold pumps.
(2) The equipment is less likely to leak. But if it does leak, a very large quantity of material will run out and there is no way of stopping it; for example, the bottom pump on a still containing more than, say, 50 ton of flammable liquid.
(3) The equipment is less likely to leak, but if it does so, the leak will be very large; for example, a very large pump.

The paper gives two tables, one for an olefins plant and one for an aromatics plant, listing the situations where the installation of an EIV was considered, giving the parameters for these situations and stating whether or not it was decided to install such a valve. One of these tables, that for the olefins plant, is shown in Table 30.6.

From the rules explicitly stated, the examples given and the comments made in the text of the paper, the following extended set of rules was derived. The overt rules are:

(1) Fit if the equipment is particularly likely to leak. This is so if (a) it has a history of leakage or (b) it is pumping liquid at extremes of temperature or (c) it is otherwise thought likely to leak.
(2) Fit if the equipment is less likely to leak, but if it does, it could release a large or very large quantity.

There also appeared to be some covert rules. These include:

(3) Fit if the liquid is above its autoignition temperature.
(4) Fit if it is convenient for process reasons.
(5) Do not fit if there is a control valve that will perform the same function.
(6) Do not fit if there is an alternative means of stopping the leak.
(7) Do not fit if the fluid is a gas in a compressor.

Here the second and third rules given by Kletz have been combined into a single rule.

Some of the rules are stronger than others. Thus Rule 1 is a strong rule. Rules 5 and 6 are also strong rules. Rule 7 is a weak rule and may be overriden by Rule 4. A particular rule also seems to have some influence as a counter-rule. Thus a small inventory weights the decision against fitting an EIV.

Table 30.6 *Emergency isolation valve location: parameters for the provision of emergency isolation valves on an olefins plant (Bunn and Lees, 1988; after Kletz, 1975b) (Courtesy of the Institution of Chemical Engineers)*

Item		*Material*	*Temperature* (°C)	*Pressure* (psig)	*Inventory* (ton)	*Leak history*	*EIV*	*Note*
1. Furnaces	Naphtha	100	120	Small	–	Y	1	
2. Feed pump	Naphtha (gassy)	15	140	70	N	N	2	
3. Bottoms pump	Fuel oil	210	30	100	Y	Y	3	
4. Sidestream pump	Distillate fuel oil	160	25	20	N	Y[a]		
5. Bottoms pump	Fuel oil	210	30	60	Y	Y		
6. Bottoms pump	Gasoline	85	20	25	–	N	4	
7. Bottoms pump 1	Fuel oil	220	30	1	Y	N	5	
2	Distillate fuel oil	180	25	1	–	N	5	
8. Reflux pump	Ethylene	−30	270	30	Y	Y	6	
9. Sidestream pump	Ethylene	−30	270	10	Y	Y	7	
10. Reflux pump	Propylene	40	250	50	N	Y		
11. Cold Al exchanger	Methane	−100	370	30	Y	Y	8	
12. Process gas compressor	Methane, ethylene, propylene, etc.	40	30	50	–	N	9	
13. Compressor	Ethylene	−100	65	40	–	Y	9	
14. Compressor	Propylene	−40	40	100	–	N	9	
15. Bottoms pump	Light gasoline	90	150	5	Y	N	10	
16. Reflux pump	Methane	−100	370	5	Y		11	
17. Reflux pump	Ethane/ethylene	−14	350	5	–		12	
18. Converter	Ethane/ethylene	80/150	350	–	Y	Y	13	
19. Reflux pump	Propylene	5	90	1	–	N		
20. Reflux pump	Propylene	30	175	5	–	N		
21. Bottoms pump	Butylene	120	50	15	–	N		
22. Reflux pump	Butylene	35	50	5	–	N		

[a] Borderline.

Notes:
1. Control values used as EIVs in event of tube failure and reasonably remote hand isolations.
2. No history of leaks, material cold.
3. Close to autoignition temperature. Similar pumps have ignited.
4. Inventory can be pumped out with other pumps.
5. Inventory small and feed to column can be isolated.
6. Pump has leaked.
7. Pump has leaked and ignited.
8. Al heat exchangers more fragile than steel and therefore classified as likely to leak. Isolation by means of remote hand valves, control valves and one extra EIV.
9. Centrifugal machines – no history of leaks except one bad leak on ethylene compressor. Most of inventory would be flared. Leaks would be gas. Leak rate from ethylene and propylene compressors would be small – several tons per hour.
10. Congested area, but remote manual valve accessible.
11. Valve fitted remote by distance – but upstairs. Despite low temperature there is no history of leaks.
12. Valve fitted remote by distance – but upstairs.
13. Valve fitted on inlet and exit and blowdown lines to isolate and blow down vessel to stop runaway reactions. At least five incidents have occurred on plants outside the company.

An analysis of the apparent effects of the rules is shown in Table 30.7.

The decision on whether to provide an EFV appeared to be a relatively straightforward classification problem. The use of an AI aid for classification was therefore investigated, the programs chosen being initially EXPERTEASE and later EXTRAN, which are based on the IDS algorithm.

The class value was taken as EIV fitted/not fitted; and the attributes as (1) fluid, (2) equipment, (3) inventory, (4) temperature, (5) pressure and (6) leak history. The first and second attributes were entered as the process material and the plant equipment, the third to fifth attributes as a number and the last attribute as yes/no.

The 22 cases were run through the program that induced from them a set of rules. However, this first application was not regarded as satisfactory. Among other things, no use was made of leak history, which was supposed to be a strong rule.

The view was taken that the problem should be reformulated. This time the attributes taken were (1) large hazard, (2) leak history, (3) high leak likelihood, (4) large inventory, (5) high temperature, (6) above the autoignition temperature, (7) convenient for process reasons, (8) alternative means of stopping the leak and (9) fluid is a gas in a compressor. The revised data set is shown in Table 30.8 and the set of rules induced is given in Table 30.9.

This set of rules was regarded as more satisfactory. However, in view of the fact that Rule 6 is a strong rule, it was considered that it should probably be the first branch. The fact that this is not so is evidently due to the fact the example set is not sufficiently comprehensive.

The authors conclude from this example that an AI classification tool of this general type can be useful, but that it has to be applied with caution. Care needs to be taken in the definition of the attributes and in the provision of a learning set which is not only sufficiently large but also is specifically designed to cover the domain.

30.33.4 Designs with shallow structure: flare system

The next problem considered by Bunn and Lees is the design of a flare system. They take this as representative of a class of design synthesis problems with relatively shallow structure.

A common design problem is the design of a unit for which there already exists a skeletal design archetype, or stereotype, which is more or less fixed in respect of the basic set of components, but where there exist options both for the details of these components and for add-on features. If it is assumed that all the relief gas flows that are to be handled have already been specified then, the authors argue, flare design might be taken as an example of this type of problem.

Generally, the first step taken by the expert is to define the primitive problem. The understanding that the problem originally posed needs to be redefined and the ability to do this is an essential feature of his or her expertise. In order to do this he or she needs to collect information. In the case of a flare system this includes data on gas flows and composition. He or she is then able to consider whether alternatives to flaring are appropriate. These include, in the case of a flare system, total containment, trip systems,

Table 30.7 *Emergency isolation valve location: apparent influence of expert's rules on the decision to fit emergency isolation valves on an olefins plant (Bunn and Lees, 1988) (Courtesy of the Institution of Chemical Engineers)*

Item	*History of leaks*	*Fit EIV*	*Comment*
1. Furnaces	–	Y	Rule 1(c) apparently. Rule 5
2. Feed pump	N	N	Influence of counterrule 1(a), 3
3. Bottoms pump	Y	Y	Rule1(a) and (b), 2, 3
4. Sidestream pump	N	Y[a]	Rule 1(a) and (b) and 2 not satisfied, but influence of Rules 2 and 4 perhaps
5. Bottoms pump	Y	Y	Rule 1(a) and (b), 2
6. Bottoms pump	–	N	Rule 6
7. Bottoms pump 1	Y	N	Rule 1(a) and (b) but overridden by Rule 6
2	–	N	(Rule 1(a) and (b) not satisfied)
8. Reflux pump	Y	Y	Rule 1(a) and (b)
9. Sidestream pump	Y	Y	Rule 1(a) and (b)
10. Reflux pump	N	Y	Rule 2 apparently
11. Cold Al exchanger	Y	Y	Rule 1(a) and (b). In part Rule 5
12. Process gas compressor	–	N	Rule 7
13. Compressor	–	Y	Rule 7 but overridden by Rule 4
14. Compressor	–	N	Rule 7
15. Bottoms pump	Y	N	Rule 1(a) but overridden by Rule 6. Influence of counterrules 2 and 3 perhaps
16. Reflux pump	Y	?	Meaning of notes not clear. Does
17. Reflux pump	–	?	valve fitted refer to existing valve?
18. Converter	Y	Y	Special case
19. Reflux pump	–	N	(Rule 1(a) and (b) and 2 not satisfied)
20. Reflux pump	–	N	As (19)
21. Bottoms pump	–	N[a]	As (19)
22. Reflux pump	–	N	As (19)

[a] Borderline.

Note: Extremes of temperature taken as $-30°C < T > 180°C$.

22. Reflux pump	N	N	N	N	N	N	N	–[a]	N

[a] Borderline.
[b] Attributes:
1. Does the equipment have a history of leaks?
2. Is the equipment otherwise likely to leak?
3. Is the liquid above its autoignition temperature?
4. Is the liquid being pumped at high temperature?
5. Is the equipment less likely to leak, but the situation such that if it does a large quantity will escape (is there a large hazard)?
6. Is there an alternative means of stopping the leak?
7. Is the fluid a gas in a compressor?
8. Is the fitting of an EIV convenient for process reasons?

Table 30.9 *Emergency isolation valve location: set of rules for the provision of emergency isolation valves on a alkenes plant (Bunn and Lees, 1988) (Courtesy of the Institution of Chemical Engineers)*

- Large hazard
  - Yes: fit EIV
  - No: leak history
    - Yes: fit EIV
    - No: otherwise likely to leak
      - Yes: fit EIV
      - No: pumping at high temperatures
        - Yes: alternative means of stopping leak
        - No: fit EIV
- Otherwise no EIV

relief valve venting to atmosphere, unflared vent stacks and plant flaring.

Given that a flare system is still the appropriate solution for at least some of the relief flows, the expert has then to determine a strategy for the overall system. This may involve controlled blowdown to smooth out peak flows, low and high level flares and multiple flares. A particular aspect of this strategy is segregation of different gas flows: dry from wet gases, normal temperature from low temperature gases, hydrogen sulfide from other gases, and reactive gases from other gases. Only when these various strategic decisions have been made does the design of the flare system itself begin. Some aspects of the design expertise involved in flare system design are outlined in Table 30.10.

A typical flare system is illustrated in Figure 30.11. The basic elements of a flare system are the relief header, the knockout drum, the seal drum, the flare stack, the flare tip and the pilot light. The design of the flare system itself involves: deciding whether to provide various additional features; selecting a means of implementing the basic and additional features both in terms of equipment and of utility fluids such as purge gas and flare tip steam; and a determination of the magnitude of some of these features. Possible additional features include quench drums, vaporizer drums, vapour recovery, molecular seals and flame arresters. Some principal features that need to be specified quantitatively include knockout drum size, flare stack

Table 30.10 *Design of flare systems: some aspects of Glare the design expertise involved (Bunn and Lees, 1988) (Courtesy of the Institution of Chemical Engineers)*

General area	*Specific element or topic*
Gas flows requiring disposal	Normal flows Emergency flows
Gas compositions requiring disposal	Hydrocarbons Hydrogen Hydrogen sulfide Steam Air
Alternatives to flaring	Total containment Trip systems Relief valve venting to atmosphere (air, steam, cold gases) Unflared vent stacks Plant specific flaring
System options	Multiple flare systems Dry gas vs wet gas High vs low level flares Controlled blowdown
Segregation	Dry gas vs wet gas High or low temperature gases Hydrogen sulfide Reactive materials
Flare system, basic elements	Relief header Knockout drum Seal drum Flare stack Flare tip Pilot light
Flare system, additional elements	Quench drum Vaporizer drum Vapour recovery Flame arresters Molecular seals
Purge gas	Fuel gas Nitrogen
Hazards	Blockage Explosion Heat radiation Toxic gases Liquid carryover
Air hazard	Sources Effects
Water hazard	Sources Effects
Extreme cold	High melting point hydrocarbons Steam injection
Other problems	Ignition failure Smoke Pollution Glare Noise Land sterilization
Legislation	Pollution contorl Smoke Noise

diameter and height, flare tip dimensions, purge gas flow and flare tip steam flow. As Table 30.10 indicates, there are many further aspects that must also be taken into account.

Nevertheless, in the case of a flare system the basic structure of the design appears relatively straightforward. The design can apparently be decomposed into a set of subdesigns that have only weak interaction. The design may proceed in a series of sequential stages, using rules appropriate to each stage, and with only a modest degree of iteration.

Bunn and Lees list a number of rules obtained from the literature, from standards and codes and from expert sources, which are used in flare system design. They classify these rules as follows:

Alternative (A)	An alternative option is offered.
Requirement (R)	A requirement to take a particular course of action, add a particular feature or achieve a particular result.
Permission (Pe)	A permission to take a particular course of action or add or omit a particular feature.
Prohibition (Pr)	A prohibition on taking a particular course of action or adding a particular feature.
Design (D)	A rule of thumb giving guidance on some particular aspect, usually a design criterion.

A prohibition is essentially a negative requirement.

The derivation and use of the rules revealed several problems, which were not unexpected. One is that the abstraction of rules from the literature is liable to give rules that are contradictory or out of date. Another is that some rules are stronger than others and a means needs to be found to incorporate this factor. Similarly, some rules are subject to exceptions and this also needs to be taken into account.

The authors identify the following types of expertise as being involved in flare system design:

(1) knowledge of the initial data to be collected;
(2) knowledge of the ways in which the primitive problem may be reformulated;
(3) knowledge of the alternatives to the use of a flare system and of criteria for their selection;
(4) knowledge of options for modification of the flare load to be accepted;
(5) knowledge of the basic configurations of flare systems;
(6) knowledge of the options for additional features and criteria for their selection;
(7) knowledge of the models available for the design of particular features and of the regimes in which they apply;
(8) knowledge of the constraints associated with regulatory controls, standards and codes, and so on.

The authors refer to the creation of a simple research expert system for elementary flare system design incorporating a rule-based production system. The program described uses forward-chaining and the principal conflict resolution methods are context limitation and specificity ordering.

Although the flare design problem is classed by the authors as one with shallow structure, this emphatically does not mean that it is straightforward. The classification refers solely to the structure of the problem and the decomposition required to solve it. In fact, the design rules used by an expert may well be very sophisticated. The point is that the expertise resides in these other rules rather than in rules, or strategies, for decomposition subdesigns which have only weak interaction. The design may proceed in a series of sequential stages, using rules appropriate to each stage, and with only a modest degree of iteration.

30.33.5 Designs with deeper structure: pressure relief system

Bunn and Lees' third problem is the design of a pressure relief system. This problem they take as representative of a class of design synthesis problems with relatively deep structure.

The situations that are considered for pressure relief are operational relief, both normal and abnormal, and fire relief. A relief survey is made based on the piping and instrument diagram. The system is decomposed into subsystems. The decomposition is done on the basis of what is manageable. Typically a subsystem is a functional unit, such as a distillation unit, with up to half a dozen vessels. Another principle which is used is that of pressure breaks, the section of plant between two such breaks being for practical purposes at a uniform pressure level.

A review is made for operational relief of the overpressure sources and load to be relieved. This covers: utility failures, where use is made of standard cases; open inlets and closed outlets; heat inputs; cooling loss; operating excursions; and equipment failures. For fire, a finer subdivision may be used, with a separate consideration of each vessel. Again use is made of standard cases.

Selection is made of the relief sinks, which may be another part of the plant, the atmosphere, the relief header, or another closed system. The capacities and set pressures of the pressure relief valves may then be determined and the pressure relief valves selected.

The foregoing is the barest outline of the design process for pressure relief. It is summarized in Table 30.11.

Table 30.11 *Design of pressure relief systems: outline strategy of system design (Bunn and Lees, 1988) (Courtesy of the Institution of Chemical Engineers)*

- Decompose pressure system
  - Select subsystems
  - (Default assumption: each main vessel is a subsystem)
- Identify pressure breaks
- Locate pressure reliefs
  - (Default assumption: pressure relief is located on each main vessel)
- Identify relief loads on each main vessel
  - Utility failure (including control loop failures)
  - Open inlet (connection to high pressure source)
  - Closed outlet (disconnection to low pressure sink)
  - Heat input
  - Cooling loss
  - Operating excursions
  - Equipment failures (especially valves: NRVs, EIVs)
  - Fire
- Quantify relief loads on each main vessel
  - Utility failure standard cases
  - Fire standard cases
- Select relief sink
  - Other part of plant
  - Flare header
  - Other closed system
  - Atmosphere
- Determine set pressure of RVs
- Determine capacity of RVs
- Select type of RVs

EFV, emergency isolation valve; NRV, non-return valve; RV, return valve.

Some of the topics that may be considered in the review of overpressure sources and loads are listed in Table 30.12. Some of the additional topics that also need consideration are listed in Table 30.13.

The design of pressure relief systems appears therefore to involve appreciable expertise in the selection of a design strategy. There is, in principle, a significant initial decomposition to be performed. Knowledge is required of the range of overpressure sources that need to be reviewed. Some of these are effectively stereotype situations. A credible worst case has to be selected. In making this selection, both for utility failure and for fire, use is made of standard cases to prevent the design worst case being too pessimistic. There is a whole range of design alternatives to be considered and of special situations to be taken into account.

A common strategy for handling problems with deeper structure is to apply a small number of additional rules that simplify the decomposition. In the case of pressure relief system design one such rule is to provide each vessel with a pressure relief valve.

30.33.6 Designs with deeper structure: valve sequencing

The final problem in design synthesis considered by Bunn and Lees is that of valve sequencing. This problem is taken as being representative of a class of design synthesis problems that are characterized by the features that there is a complex problem-solving task, but that this task requires little expertise or common sense knowledge.

The generation of an operating sequence for a set of valves, subject to certain constraints, is very similar to the problem-solving and game-playing tasks commonly addressed in AI. It involves a search to satisfy goals. The knowledge that has to be provided to obtain a solution is, however, relatively limited.

These features imply another characteristic of this type of problem. There tends not to be a recognized expertise. There is provided as part of the design a network of valves that need to be opened and shut in order to operate the plant. An engineer is assigned the task of specifying the operating sequence, but this assignment is unlikely to be made on the basis of a recognized expertise comparable with, say, expertise in flare system design.

Bunn and Lees instance here the work of Rudd and co-workers on the synthesis and analysis of valve sequences. This study is described in Section 30.43 along with other work on the synthesis of operating sequences. This example completes the overview of some characteristic design synthesis problems. The remainder of this section describes some of the design aids that have been developed.

30.33.7 AI applications

Turning now from the structure of plant design synthesis problems to applications of AI to such synthesis, an account of AI applications that deals particularly with plant synthesis and analysis as well as process synthesis is given by Mutton, Ponton and Waters (1990).

At present most such applications appear to be in the area of expert systems. Some of these are considered in Section 30.35. However, the current consensus appears to be that the most promising methods are those that are based on process modelling of the sort described in Section 30.30.

30.33.8 Incremental design and safety constraints

A development of some interest is the concept of incremental design as applied to safety. In conventional plant

***Table 30.13** Design of pressure relief systems: some additional topics to be considered (Bunn and Lees, 1988) (Courtesy of the Institution of Chemical Engineers)*

A list of areas of expertise, by no means complete, is:

- Legal and standards requirements
- Alternatives to or mitigation of PR:
  - Pressure containment
  - Pressure limiting instrumentation
- Mitigation of fire PR:
  - Fireproofing
  - Water drench
  - Ground slope
- Pressure limiting instrumentation:
  - Alternative to PR
  - Mitigation of PR
    - Reduction of flow
    - Reduction of frequency
  - Standard applications
- Economics of alternative solutions
- Overpressure scenarios:
  - Utility failure standard cases
  - Fire standard cases
- Unit operations and equipment:
  - Furnaces
  - Distillation columns
  - Shell and tube heat exchangers
  - Air cooled heat exchangers
  - Centrifugal pumps
  - Pressure storage
  - Steam systems
  - Pipelines
- Selection of disposal systems:
  - Other parts of plant
  - Flare system
  - Other closed system (e.g. absorber)
  - Atmosphere
- Atmosphere disposal:
  - Disposal criteria
  - Safe disposal
    - PRV design and location
- Flare disposal:
  - Segregation of materials
  - Materials of construction
- Minimum venting pressure:
  - Flare header
  - Atmosphere
- Depressurizing arrangements
- Special conditions:
  - Corrosive fluids
  - Cold fluids
  - Fluids containing hydrogen sulfide
- Stepped relief settings
- Selection of PRVs
- Thermal relief
- Hammerblow prevention
- Vacuum relief

PR, pressure relief; PRV, pressure relief valve.

design, the designers proceed with the design, adhering to good design practice, and the design is subjected to safety reviews at prescribed stages. An alternative approach, which emphasizes the application of the safety constraints in an incremental way, has been championed by Ponton and co-workers. The application of this philosophy has been described in respect of the safety constraints on design by Waters, Chung and Ponton (1989) and Waters and Ponton (1992) and in respect of hazard studies by Black and Ponton (1992).

30.33.9 DSPL

Another development is the application of methods developed for equipment design to the design of process plant. An account was given in Section 30.27 of the expert system building tool DSPL. This has been used mainly for mechanical design, but in the process field DSPL has been used by Myers, Davis and Herman (1988) to create an expert system for the design of sieve plate distillation columns.

30.34 Plant Design: Analysis

The synthesis of plant designs is complemented by their analysis. The analysis constitutes the test element in the overall generate-and-test activity. There now exist a large number of computer programs for the analysis of various aspects of plant design. One category is those programs that compute an index and perform a ranking of the hazards of the plant. Another category is those which assist with hazard assessment. Computer aids of this sort have been described in Chapter 29. There are now beginning to appear aids for design analysis that have an AI flavour.

30.34.1 Inherently safer design

Although aids for the synthesis of inherently safer design are not well developed, some work has been done in analysing of plant designs to check the extent to which they conform to this principle. A program of this nature has been developed by Journet (1993). The process is treated as an object or frame and the features of the process and the plant are developed as a hierarchy. Early branches in the hierarchy are the chemical route, the design information, the process streams, the plant units, the nomenclature and the decisions. The treatment is informed by the concepts of elimination, substitution, intensification and attenuation. The program identifies the features with implications for an inherently safer design.

30.34.2 Fault propagation

A number of aids to plant analysis have been described which are based on the qualitative modelling of the propagation of faults through the plant. Fault propagation modelling is therefore a basic enabling technology. It is described in Section 30.36.

30.34.3 Hazard identification

One aspect of plant analysis that has attracted much interest is the creation of an aid to hazard identification that would produce information similar to that yielded by a hazop study. Developments in this area are described in Sections 30.37–30.39.

30.34.4 Fault tree analysis

Another aspect of plant analysis that has attracted a number of workers is the development of an aid for the synthesis of fault trees. Programs have been available for some years for the analysis of fault trees, but the construction of the fault tree is still done manually. Developments in this area are described in Sections 30.41 and 30.42.

30.35 Expert Systems: Some Process Systems

Expert systems were introduced in the process industries in the mid-1980s and are in widespread use. The typical expert system in the process industries is much more modest than the classic expert systems described in the previous section. Most have been created using shells. An appreciable proportion have been developed by a single engineer acting as the expert. The development time has generally been of the order of months rather than years.

Some principal applications are: (1) physical, chemical and thermodynamic properties; (2) selection of equipment, materials of construction, and processes and plants; (3) design of processes and plants; (4) process control; (5) process monitoring and (6) fault administration. The first four of these are considered in this section and the last two in Sections 30.44 and 30.45.

The bulk of these applications is to the handling of fault conditions, either on an individual item of equipment or on a process plant. Before considering these different application areas, it is of interest to consider a statistical profile of process industry applications.

30.35.1 Statistical profile

A survey of expert system applications in the process industries has been described by Sangiovanni and Romans (1987).

These authors found about 200 applications in some 30 companies. They classified these applications as (1) selection, (2) design, (3) planning and scheduling, (4) control, (5) situation analysis, (6) diagnosis, (7) prediction, (8) prescription and (9) instruction. They define: situation analysis as monitoring available data and information and inferring the system's state; diagnosis as inferring the cause of a malfunction or deviation; prediction as inferring the likely consequences of an action or set of actions; and prescription as recommending cures for a system malfunction or deviation.

Of these functions, selection accounted for some 15%. Situation analysis accounted for some 8%, diagnosis for 33%, prediction for 10% and prescription for 21%. Thus one-third of the applications were for diagnosis and the group of four functions related to fault administration (situation analysis, diagnosis, prediction and prescription) accounted between them for 66%. Only about 2% of applications were to design.

Of these expert systems, 30% had been developed by engineers, 29% by a team without the vendor, 29% by a team with the vendor and 12% by an internal AI group. The development time was <3 months for 30% 3–12 months for 40% and >12 months for 27%.

Some two-thirds of the systems were in daily use, including cases where the system was used by different people at a number of locations. Some 90% of applications made use of an expert system shell. Over 60% were implemented on a PC. The dominant contributor to software costs was maintenance of the software, at some 67%, compared with design and coding and with testing and debugging, which each accounted for about 13%.

30.35.2 Physical, chemical and thermodynamic properties

An expert system for physical properties has been described by Banares-Alcantara, Westerberg and Rychener (1985). This system, CONPHYDE, uses the framework of PROSPECTOR and is described as a prototype. It has been applied to the selection of vapour–liquid equilibrium properties.

Gani (1989) has described an expert system for the selection of models of physical properties and phase equilibria.

30.35.3 Selection of equipment

An application of expert systems that has found rapid acceptance in the process industries is equipment selection. Many such applications utilize an induction tool that is provided by an expert with a learning set of examples, and induces the rules that the expert has evidently used in the solutions. This type of tool allows the expert to create his own system, and many experts have taken advantage of this. Equipment selection applications are not, however, confined to the use of induction tools. In other cases use has been made of shells.

An expert system for control valve selection has been described by Royse (1988). ICI has developed an expert system SYSLAG for the selection of thermal insulation (R.A. King, 1986).

30.35.4 Selection of materials of construction

The selection of materials of construction has been an active area of application. Accounts have been given by Baker-Counsell (1985b), Basden and Mines (1986) and R.A. King (1986).

An expert system for general corrosion has been developed by the National Association of Corrosion Engineers (NACE) and the National Bureau of Standards (NBS). Another such system, Achilles, has been created at Harwell. These systems are outlined by R.A. King (1986).

The Achilles system advises on the selection of mild steel and stainless steel for pipes, vessels and bolt assemblies. It exploits the use of graphics to illustrate the system under consideration and to highlight potential corrosion problems.

Expert systems used at ICI are outlined by Berkovitch and Baker-Counsell (1985). One of these is SCC for stress corrosion cracking. Another is AUSCOR for the selection and corrosion properties of stainless steels.

30.35.5 Selection of process and plant

There are also a number of expert systems for the selection of a process or plant, or an ancillary feature.

Lahdenpera, Korhonen and Nystrom (1989) have described an expert system for the selection of solid–liquid separation equipment. An expert system, DECADE, for catalyst selection has been created by Banares-Alcantara, Westerberg *et al.* (1987) and Banares-Alcantara, Ko *et al.* (1988).

30.35.6 Design of process and plant

Process synthesis and plant design, including high level expert system approaches, are considered in Sections 30.32–30.34. In general, design is a difficult application and there are relatively few examples of expert systems in design, as opposed to selection.

An expert system for the design of heat exchanger networks has been described by B. Chen *et al.* (1989). This is an area of design where a well-structured approach has been developed so that the difficulties of creating an expert system are less severe.

Accounts of an expert system for the design of dust explosion relief systems have been given by Santon *et al.* (1991) and Santon (1992). Another expert system, DUSTEXPERT, for the assessment of dust explosion hazards has been described by von Haefen (1992).

30.35.7 Process control

Most applications of expert systems on process plants involve some form of process monitoring and/or fault administration rather than process control as such.

Work on the development of expert systems for the synthesis of control systems has been described by Birky, McAvoy and Modarres (1988) and Birky and McAvoy (1990).

The LINKMan expert system developed by the Scientific Instrument Research Association (SIRA) and the Blue Circle cement company has been used for control of equipment on the latter's plants. Accounts have been given by M. Henry (1985), Durham (1985f) and Tayler (1987b). Applications have included the control of a ball mill and of a cement kiln. The program uses rules for process control based on natural language and fuzzy logic.

The RESCU project (Shorter, 1985; Coulsey, 1986) involves the use of an expert system for the quality control of an ethoxylate plant in ICI. The system detects control variations and upsets, and recommends actions. One outcome of this project has been the development of the knowledge representation language KRL.

A follow-up to this work is the COGSYS system (Anon., 1988n).

PICON is an expert system with capabilities both in process control and also in fault administration. Accounts have been given by R.L Moore (1985) and F. Kane (1986). Since the first applications have evidently involved fault administration, discussion of PICON is deferred to Section 30.45.

30.35.8 Other applications

Expert systems are in use in the process industries for a variety of other purposes. Reviews of applications and potential applications are given by M. Henry (1985), Coulsey (1986) and Barnwell and Ertl (1987).

The SYNICS system (Coulsey, 1986), which is described as not so much an expert system as a 'working textbook', containing both graphics and mathematics, is used both for problem-solving and browsing. Applications have included powder formulations.

The Honeywell MENTOR expert system (Sangiovanni and Romans, 1987) is used in the field by technicians servicing refrigeration systems.

30.36 Fault Propagation

Many of the methods used to identify and assess hazards at the design stage such as hazard and operability studies, failure modes and effects analysis, fault trees and event trees, involve tracing the paths by which faults propagate through the plant. Fault propagation is thus a common feature of these techniques. Fault propagation is also a feature of methods for the diagnosis of alarms in the real-time computer control of processes.

Fault propagation is therefore a generic feature of work in this field. It follows that the computer aids for many of these methods may, in principle, draw on a methodology that is to some extent common. This concept has been elaborated by Andow, Lees and Murphy (1980).

In the following sections computer aids are described for hazard identification, fault tree synthesis and analysis, and alarm diagnosis. Included in this account are some aids developed by Lees and co-workers which explicitly draw on a common methodology (Andow and Lees, 1975; B.E. Kelly and Lees, 1986a–d; Parmar and Lees, 1987a,b; A. Hunt *et al.* (1993a–e). Some features of the fault propagation methodology used in this work are now described.

30.36.1 Fault propagation

The propagation of a fault through a plant may be represented in terms of the initiation of a fault in a unit that is unhealthy, the passage of the faults through units that are otherwise healthy and the termination of the fault in a unit that is thereby rendered unhealthy. A unit may be modelled using a number of representations. Those considered here are: (1) functional, or propagation, equations; (2) event statements and (3) decision tables.

The propagation equations describe the propagation of faults through a healthy unit, while the event statements describe the initiation of a fault in an unhealthy unit or the termination of a fault in a unit that thus becomes unhealthy.

A propagation equation is a functional equation that describes the relation between an output parameter of a unit and the input and other output parameters. A typical propagation equation is

$$L = f(Q_1, -Q_2) \qquad [30.36.1]$$

which signifies that the level L increases if the inlet flow Q_1 increases or the outlet flow Q_2 decreases, and vice versa.

30.36.2 Fault initiation and termination

The propagation equations describe how a fault propagates but not how it is initiated or terminated. This information is provided by event statements. An initial event statement takes the form

Initial fault: parameter deviation

The initial faults are usually mechanical failures. A terminal event statement takes the form

Parameter deviation: terminal event

The terminal events are usually undesired events or hazards. A typical initial event statement is

F PART-BLK: Q_2 LO [30.36.2]

which signifies that outlet flow Q_2 is low if there is a partial blockage. The letter F denotes a failure event. A typical terminal event statement is

P_2 HI: OVERPRES [30.36.3]

which signifies that if the pressure P_2 is high, there is overpressure of the unit.

The third form is a decision table. A typical decision table is

V Q_2 REV V U_2 HI T U_1 HI [30.36.4]

This relation refers to conditions in reverse flow, U being the temperature in reverse flow and subscripts 1 and 2 denote the inlet and outlet ports under normal flow conditions, respectively. The relation signifies that the outlet temperature U_1 is high if there is reverse flow Q_2 and the inlet temperature U_2 is high. The letters T and V denote the top event of a mini-fault tree and a process variable, respectively.

30.36.3 Flow propagation

In fault propagation modelling it is necessary to have a suitable method of modelling flow propagation. There are several features that need to be allowed for. One is that the representation should model correctly the two-way propagation of a fault. Thus, for example, if a valve is shut, a disturbance travels from it not only downstream but also upstream. The method for flow deviations should be compatible with that used for pressure deviations. A flow model that is based on pressure differences can run into difficulty because in some applications the deviations of pressure are not sufficiently well defined to use differences between them to determine flow. A third requirement in some cases is that the flow propagation should be able to handle a large leak from a component such that continuity of flow through that component is not maintained.

In cases where this latter aspect does not need to be taken into account, flow is often modelled by the simple relation

$$Q_2 = f(Q_1) \qquad [30.36.5]$$

For the case where a large internal leak needs to be allowed for, Kelly and Lees (1986a) have modelled flow propagation using, by convention, the following pair of relations:

$$Q_2 = f(G_1, G_2) \qquad [30.36.6]$$

$$G_1 = f(Q_1, Q_2) \qquad [30.36.7]$$

where G is the pressure gradient, and Q is the flow and subscripts 1 and 2 denote the inlet and outlet ports, respectively. Here the pressure gradient G is essentially a surrogate for flow.

30.36.4 Model representation

Fault propagation models may be represented in various ways, which may well be equivalent.

Lees and co-workers (B.E. Kelly and Lees, 1986c,d; Parmar and Lees, 1987a,b) have represented their models initially in terms of propagation equations, event statements and decision tables. They have utilized a proforma that contains slots for a description of the unit and for these relationships. An example of such a proforma is given in the next section.

Most workers, however, have used the digraph representation. An account of digraphs has been given in Section 30.23.

The two representations, are in principle, equivalent. In digraph terms, the propagation equations yield those nodes in the digraph that represent deviations of the process variables and the initial event statements those nodes that represent failures.

The essential requirements for a model format are that (1) the modelling process be straightforward, so that it can be applied by practising engineers as well as research workers, with as little effort and error as possible, and that (2) it support the automation of model creation using model archetypes.

30.36.5 Model library

Models already created are stored in a model library. An essential feature of such a library is a taxonomy that helps the user to distinguish between different models and to identify those required or, alternatively, to confirm that some are not available in the library. The library needs to be governed by a discipline which ensures that appropriate information is provided about each model, such as the person creating it and the extent of its use, and that an incorrect model is not entered.

30.36.6 Model generation

Generally the user will find that some models are not in the library and need to be generated. In this case it is necessary to configure the models and enter them into the library. Since this is liable to be the main and most difficult input that the user has to provide, it is highly desirable that the process of model generation be kept as simple as possible.

The rules governing the manual generation of models should be formulated explicitly and documented.

In many cases the new model to be created differs only slightly from an existing one. There is therefore scope for the use of model archetypes and templates and for core models or model sections. This applies particularly to vessels. It is often the case that the model library already contains the models required for common items such as pipes, fittings, pumps, etc., and for instrumentation, but that there are certain vessels that need to be modelled. There is therefore scope for the provision of vessel archetypes and templates. Of particular significance here are ports on vessels and other units. Although there are a considerable number of different types of port, a given type tends to recur. It is useful therefore provide a taxonomy of ports and a guide to their selection.

Core model elements may be provided for common types of unit such as heat exchangers and reactors.

30.36.7 Ambiguities and loops

Fault propagation deals with the deviations of process parameters but the degree of deviation is not fully defined. In consequence, ambiguities arise. A particular disturbance may apparently give rise to a number of possible alternative responses or interpretations. The problems caused by ambiguities have been discussed by Waters and Ponton (1989).

These ambiguities may arise when faults are being propagated forward from an event, as in an event tree, or backward from an event, as in a fault tree. In either case rules are required for the resolution of the ambiguities. Unresolved parameters also occur due to the presence of loops and recycles. Some of the options for resolution are discussed by Waters and Ponton.

One approach to such resolution is to introduce additional constraints. Work on these lines for digraphs has been described by P. Rose and Kramer (1991), and developed further by Fanti, Chung and Rushton (1993). The digraph representing a process flow structure usually contains loops, there is more than one path that can be traced between nodes and, since the paths may have opposing influences, ambiguities arise. The approach taken by Fanti, Chung and Rushton is the use of high level constraints such as a mass balance. They illustrate their method using the recycle tank system of P. Rose and Kramer shown in Figure 30.12, which also gives the corresponding digraph. Their results for this problem are shown in Table 30.14. Section A of the table shows the possible responses of the variables flow F1–F4, level L1–L2 and pressure P3 to changes in valve resistance R3 and R4. Five interpretations are identified. Section B of the table shows the resolution of these ambiguities using high level constraints.

Another approach is the use of heuristics. An example is furnished by the work of A. Hunt *et al.* (1993e) on fault tree synthesis. A configuration that is liable to give rise to such inconsistencies is a unit with more than two ports. Inconsistencies arise from looping around the unit. In this case use is made of the rule that in the development of the tree at a particular unit only one change of port is allowed.

Although ambiguities and loops undoubtedly present problems and merit further work, they do not appear to have proved a serious hindrance to the development of fault propagation tools for tasks such as hazard identification or fault tree synthesis.

30.36.8 Structure identification

Another problem that arises in modelling for fault propagation is that of identifying structural features in the flow diagram. The structural feature in question may be: a recycle flow; a control loop and the streams affected by its action; a trip loop and the streams affected by its action, whether it be a loop with an open or a closed trip valve; or a divider–header combination, where the divider and the header may be separated by a number of intermediate units, and where there may be a number of dividers and headers nested or staggered.

Some types of structural information are readily provided by the user, and in this case this may be the appropriate course. In other cases it is not easy for the user to identify the structure, but it is feasible to devise an algorithm to identify it, in which case this may be the best approach.

In any event, the identification of structure is a generic problem. Approaches to the problem have been described in a number of different areas for example heat exchanger networks (Pethe, Singh and Knopf, 1989); and fault tree synthesis (A. Hunt *et al.,* 1993a-e).

30.36.9 Alternative representations

As already indicated, fault propagation relations may be represented in a number of different ways. To some extent at least it is possible to map between them. An account of alternative representations and of mapping has been given by Aldersey, Lees and Rushton (1991).

Some forms of representation available include (1) functional equations, (2) program rules, (3) digraphs, (4) block diagrams, (5) logical expressions, (6) truth tables, (7) cut sets, (8) fault trees and (9) event trees.

Figure 30.13 shows a heat exchanger system together with representations of the system in the nine forms just listed. The heat exchanger is a cooler in which a hot process fluid is cooled by cooling water. The cooling water is itself cooled by a chiller prior to entering the main cooler.

Of the three graphical forms, the digraph contains the most information. For a particular event, a fault tree or an event tree may be obtained from the digraph, but with loss of information.

A common method of constructing a fault tree is to start with a digraph and to obtain the required fault tree from it. Accounts of this approach have been given by Lapp and Powers (1977a,b), Lambert (1979) and Andrews and Morgan (1986).

Mapping between fault trees and event trees, and vice versa, has been described by Aldersey, Lees and Rushton (1991).

There are now a considerable number of mathematical models of process plant and it may be desired to derive a qualitative model from an existing quantitative model.

A method of doing this was developed by Andow (1973) in his work on modelling for alarm diagnosis. Consider the relationship

$$\mathrm{RHS} = A \underset{6}{+} B \underset{5}{*} ((C \underset{2}{+} D \underset{1}{/} E) \underset{3}{-} F) \underset{4}{\uparrow} G \qquad [30.36.8]$$

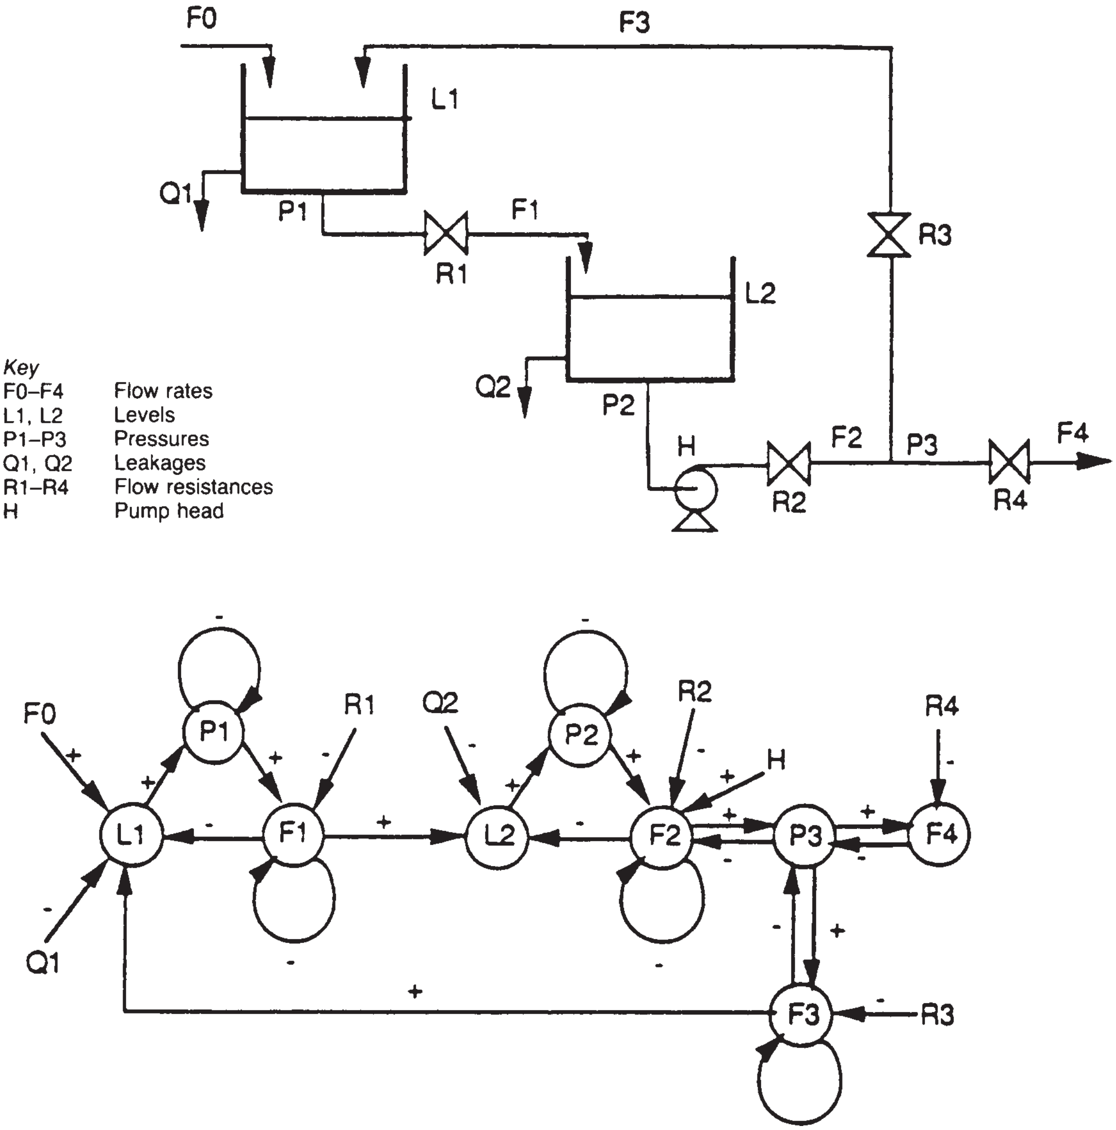

Figure 30.12 A recycle tank system (Fanti, Chung and Rushton, 1993: after P. Rose and Kramer, 1991) (Courtesy of the Institution of Chemical Engineers)

where RHS represents the right-hand side of an equation and the numbers show the order of evaluation following the normal rules of algebra. It can be seen that evaluation does not occur in the order in which the operators are discovered. Converted to Reverse Polish Notation, the relation becomes

$$\mathrm{RHS} = A\ B\ C\ D\ E\ \underset{1}{/}\ \underset{2}{+}\ F\ \underset{3}{-}\ G\ \underset{4}{\uparrow}\ \underset{5}{*}\ \underset{6}{+} \qquad [30.36.9]$$

The operators are now in the correct order, whilst the operands remain in their original order.

This use of this technique to reduce quantitative models to qualitative ones is described by Andow, who gives full details of the transformation.

30.36.10 Generic modelling

Fault propagation modelling may be used to support a range of safety-related techniques such as hazard identification, fault tree synthesis, operating procedure synthesis and alarm diagnosis. There is clearly an advantage to be gained by formulating a type of generic model that supports all these methodologies and others. On the other hand, the development of a particular technique should not be unduly constrained by the requirement for commonality. This

Table 30.14 *Response of recycle tank system (after Fanti, Chung and Rushton, 1993) (Courtesy of the Institution of Chemical Engineers)*

A Initial candidate responses

Disturbance	*Responses*							
	L1	*F1*	*L2*	*F2*	*P3*	*F3*	*F4*	
R3 +	−	−	−	−	−	−	−	Candidate R3A
	−	−	−	−	0	−	0	Candidate R3B
	−	−	+	−	+	−	+	Candidate R3C
	−	−	0	−	+	−	+	Candidate R3D
	−	−	−	−	+	−	+	Candidate R3E
R4 +	+	+	+	+	+	+	+	Candidate R4A
	+	+	+	+	+	+	0	Candidate R4B
	+	+	+	+	+	+	−	Candidate R4C

B Responses after resolution

Disturbance	*Responses*							
	L1	*F1*	*L2*	*F2*	*P3*	*F3*	*F4*	
R3 +	−	−	−	−	0	−	0	Candidate R3B
R4 +	+	+	+	+	+	+	0	Candidate R4B

The supporting argument is as follows. Disturbances R3 + and R4 + each leave F0 unchanged, F0 = 0. Overall mass balance requires F4 = F0. Hence candidate responses R3A, R3C, R3D and R3E and responses R4A and R4C are eliminated.

is illustrated in the work of Lees, Rushton, Chung and co-workers. The models used in early development of particular techniques differed slightly, but a considerable commonality was retained which is built on in the later work.

30.36.11 QUEEN

A code QUEEN, designed to provide a front-end for fault propagation modelling in activities such as hazard identification, fault tree synthesis, operating procedure synthesis and alarm diagnosis has been described by Chung (1993).

30.37 Hazard Identification

In addition to computer aiding of process synthesis and plant design in general, there are a number of types of aid that specifically address hazard and safety issues.

Qualitative modelling, and particularly fault propagation modelling, is an important feature in many of these aids.

The first form of computer aid considered here is aids for the identification of hazards. A number of workers have described systems which perform functions broadly similar to those carried out in a hazard and operability, or hazop, study or which serve as an aid in the conduct of a study of this general type. Systems include: HAZID by Parmar and Lees (1987a,b); a system described by Weatherffl and Cameron (1988, 1989); HAZOPEX by Heino, Suokas and Karvonen (1989a,b) and Suokas, Heino and Karvonen (1990); HAZEXPERT by Goring and Schecker (1992); and COMHAZOP by Rootsaert and Harrington (1992).

The applicability of AI techniques in this area is discussed by Ferguson and Andow (1986). The identification of hazards is in many ways one of the least promising fields for computer methods. It is very difficult to devise a technique that can compete with man's ability to think laterally and to make apparently obscure connections. with those from a conventional hazop study. They also give an account of an application session.

HAZOPEX has been developed using a LISP machine and an expert system shell.

30.37.1 COMHAZOP

The COMHAZOP system is described by Rootsaert and Harrington (1992). The plant configuration is entered and unit models are assigned to the units. The program examines deviations associated with the units and uses rules to identify the causes of these deviations.

30.37.2 HAZEXPERT

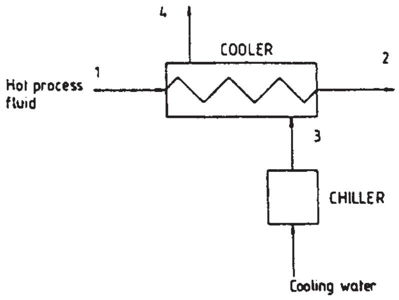
Goring and Schecker (1992) describe the hazard identification system HAZEXPERT. This aid eschews a HAZOP-style approach. The plant configuration is entered. A set of pre-defined consequences such as overpressure, explosion, etc., is used. A search, limited in scope around the set of units under examination, is conducted to discover the causes of these events. The program contains a generic hazard knowledge base in which a key concept is disturbance of the mass or energy balance. HAZEXPERT is implemented using an expert system shell.

30.37.3 PSAIS

PSAIS (Plant Safety AI System) is described by Schöneburg (1992). The program utilizes only a limited number of rules but holds a large collection of design cases. Examination of a plant design is based on accessing 'similar' cases in the design case database. If no similar case is found, a new case is created. Use is made of fuzzy matching. In this way PSAIS benefits from a continuous process of learning.

30.37.4 HAZExpert

The HAZExpert system is described by Venkatasubramanian and Vaidhyanathan (1994). The general approach described appears broadly similar to that used in HAZID. The authors identify as distinguishing characteristics



(a)

Functional equations

$Q_2 = f(Q_1)$

$Q_4 = f(Q_3)$

an emphasis on consequences and the resolution of ambiguities. HAZExpert is implemented in G2 by Gensim (1992).

30.38 Hazard Identification: HAZID

A more detailed account is now given of one particular code for hazard identification. This is the HAZID code described by Parmar and Lees (19876a,b). The method follows closely the general approach taken in a hazop study, but draws on generic fault propagation technology developed for fault tree synthesis. An overview is now given of HAZID, which both illustrates an application of fault propagation modelling and serves as an example of a hazard identification code.

30.38.1 Hazard identification strategy

Initially the problem of hazard identification was approached without any preconception as to the structure of the method. Both top-down and bottom-up approaches used in fault trees and event trees, respectively, were considered as possible candidates. Completeness in the identification of hazards is the crucial feature of an effective method. A top-down method must therefore start from a complete list of consequences and a bottom-up method from a complete list of causes. It is difficult to provide lists that ensure completeness in all situations. In a conventional hazop the starting point is the list of process parameters in a pipe and the list of guidewords. This pair of lists yields a closed set of events but generates an open set of causes and consequences. This characteristic of the hazop approach is the desired one and was therefore adopted for the computer aided method also.

30.38.2 System decomposition

The starting point for the method is the piping and instrument diagram. This is then converted to a block diagram. As in a conventional hazop the analysis is carried out on the pipes rather than the vessels. The block diagram contains the vessels and other major items, but most of the elements in it are pipework items such as pumps, hand valves, control loops, etc. For each unit in the block diagram a unit model is specified, drawing on a library of unit models. Additional models may be configured by the user and entered in the library as required.

30.38.3 Unit models

A unit model is a representation of the propagation of input parameter deviations into output parameter deviations and also of the initiation and termination of these deviations. The fault propagation utilizes the methodology described in Section 30.36. The basic representations used are (1) propagation equations and (2) event statements.

For specific applications it may be convenient to transform these basic representations into alternative forms. Thus, in fault tree work they may be converted to a set of mini-fault trees. In HAZID they are converted into a set of rules written in Prolog.

The initial and terminal events are, respectively, the causes and consequences which the hazard identification procedure seeks to discover. The completeness of the identification depends on the quality of the modelling of these events.

The configuration of the unit models is guided by the use of the following checklist for the initial event statements:

(1) function,
(2) hydraulics,
(3) containment,
(4) impurities,
(5) environment.

A process unit has a particular function. For example, it is the function of a gas absorption column to absorb a solute from a gas stream into a liquid stream. Thus one function fault in such a unit is that maldistribution of the liquid causes the outlet gas solute concentration to be high and the outlet liquid solute concentration low. This may be represented by the initial event statement

maldistribution $> x_2$ hi, x_4 lo

where x is the concentration of the solute and subscripts 2 and 4 refer to the outlet gas and outlet liquid streams, respectively. This is equivalent to the rule that if maldistribution occurs, then x_2 hi and x_4 lo may occur.

A process unit has a hydraulic function in that it should transmit flow, and a containment function, in that it should not leak. It also has functions related to impurities and its environment in that it should not introduce impurities and should not undergo excessive deviations due to environmental changes. Typical initial event statements for various units for these other four functions respectively are:

blockage $>$ q_1 none, q_2 none
leak (major) $>$ qi hi, q_2 lo
broken packing $>$ ia_4
external cold source $>$ t_2 lo

where i is the impurity concentration, q is the flow, t is the temperature and a is the impurity packing debris.

Terminal event statements usually relate to a serious excursion of a process parameter. Some typical terminal event statements are

p_2 hi $>$ overpressure
t_2 lo $>$ undertemperature
t_4 hi $>$ overfilling

where l is the level, p is the pressure and t is the temperature.

Initial and terminal event statements provide the means of entering a fairly comprehensive list of initial and terminal events, and hence causes and consequences.

30.38.4 Fluid and materials models

In addition to the unit models there are models for the process fluids and for the materials of construction. These are used primarily to allow consequences to be made conditional on the existence of a particular process fluid or material of construction susceptibility. For example, low flow may cause blockage, but only if the process fluid contains solids which can deposit out; low temperature may cause brittle fracture, but only if the material of construction is mild steel.

There are special treatments for the common faults leak and blockage, and releases to the environment are consolidated in a special escape model.

30.38.5 Cause and consequence generation

The hazard identifier program receives as input tables giving the configuration of the block diagram and listing the library models to be used for each unit. The program operates on the system line by line. For a given line each parameter deviation is examined in turn and its causes and consequences are generated from the initial and terminal event statements in the unit models.

The link between the causes and consequences listed for a particular parameter deviation is the deviation itself. In general, most of the causes result in most of the consequences and most of the consequences result from most of the causes, but not all. For example, in a pump delivery shut-in is a cause of no flow and results in the consequences pump overheats and loss of level in the downstream vessel, but no changeover to a stand-by pump is a cause of no flow and results in loss of level but not in pump overheating.

With regard to the direction of search for causes and consequences, Figure 30.14 shows two options. In Method 1 the search is from local cause to distant causes, whilst in Method 2 it is from local consequence to distant consequences. HAZID uses Method 1, for two reasons. First, this method involves the evaluation of consequences rather than causes and such an evaluation is considered the prime form of filtering. Second, the method allows the possibility of tracing a consequence linked to a number of causes and is compatible with the search for such causes using a fault tree.

30.38.6 Screening of faults

In the foregoing, attention has been focused on the generation of potential faults. In the absence of some screening mechanism the number of faults generated can be very large. This is a common problem in computer-generated output, but it occurs to a degree in conventional hazop also. Several approaches may be taken. The main distinction is between suppression of the initial generation of the faults and handling of faults after they have been generated.

A particular form of suppression is effected by the fluid and materials of construction models, as already described. In many cases a fault thrown up by the fault propagation modelling has a credible realization only if there is a particular fluid susceptibility, so that where the fluid model contains no such susceptibility, the fault need not be generated. Similar considerations apply to the materials of construction model.

With regard to handling of faults after generation, mention has already been made of the consolidation of similar faults caused by different items in a single line.

The other methods of handling faults involve some form of screening. The simplest approach here is to lay 'masks' over the output. A variety of types of mask may be used for different purposes. A hierarchy of masks may be used which give successively larger amounts of detail. Other specialist masks may be envisaged for particular problem areas.

Another more difficult but worthwhile form of screening is the use of engineering heuristics to evaluate faults. The evaluation may address causes or consequences. Suitable heuristics are of various types, but in each case the purpose is to assist the decision as to whether a fault can be disregarded either because the cause is not credible or the consequence is negligible. Some heuristics relate to the frequency and cost of faults, and require both estimated values and cut-off levels. Other heuristics are based on engineering practices. For example, there are usually company practices that determine whether in a given case a liquid relief valve is provided on a section of pipe which is shut in.

30.38.7 Fault consolidation

For the lines connecting the vessels and other major equipment, use is made of a special pipe model. Faults in the line due to minor units such as pumps, hand valves and control loops are collected up and consolidated so as to avoid excessive proliferation of faults. In this way a fault such as a blockage is flagged in the line only once, but all the causes of the fault are identified.

30.38.8 Model generation and model library

The configuration of a unit model is carried out using a model generation program. The data are entered on a proforma. A typical proforma is shown in Figure 30.15. Items 1–6 are entered by the user and the remaining items are generated by the program. The rules in items 7–9 are in Prolog, as described below.

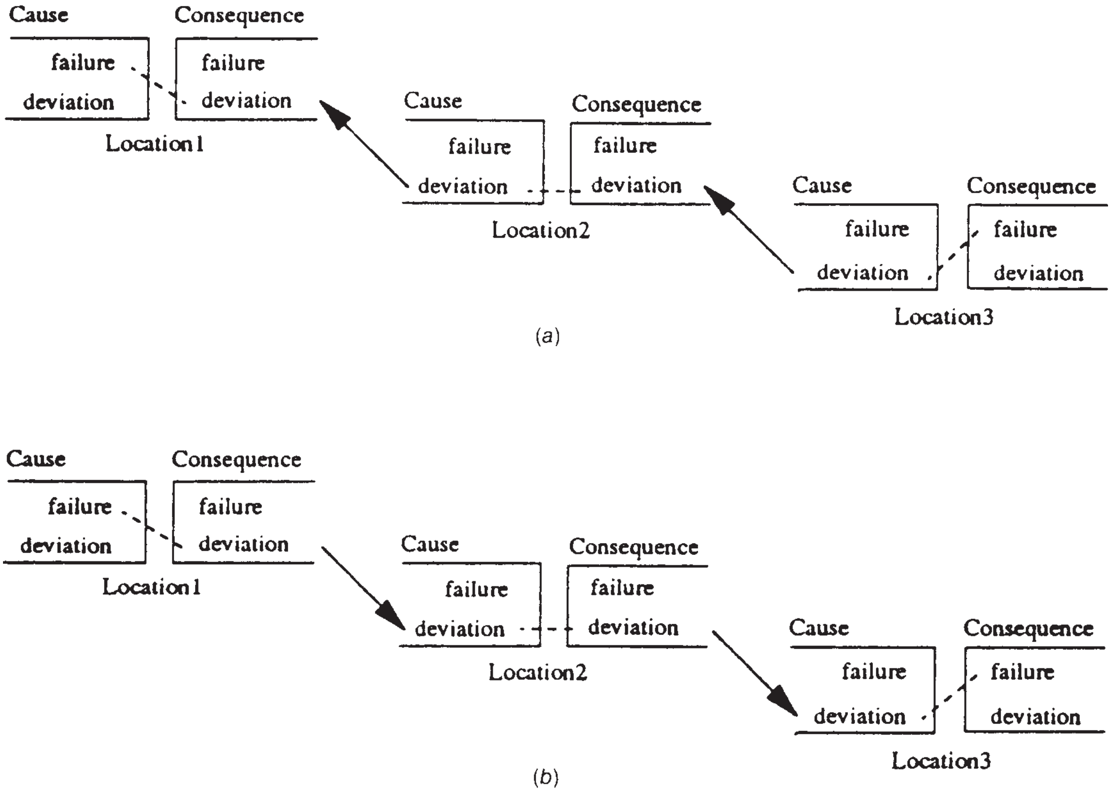

Figure 30.14 *HAZID: generation of causes and consequences (Zerkani and Rushton, 1992): (a) search for causes; (b) search for consequences (Courtesy of Pergamon Press)*

Models are held in a model library. In some applications the user may find all the models required already in the library. Where this is not so, he or she configures the missing models using the model generation program.

There are certain relationships between models that may be exploited to achieve a degree of automatic model generation. One is the hierarchical structure of models. Thus, a pump is a subclass of the class of pressure raisers and inherits certain characteristics. Even where there is no formal hierarchy, a group of models may be related by some shared process or feature. In such cases use may be made of model archetypes, or partial models.

Much modelling centres around ports at the inlet and outlet of vessels and other equipment. A taxonomy of standard ports permits the selection of appropriate sets of equations, or models, for such ports.

30.38.9 Computer codes

The main programs in the HAZID package are: MASTER, which does the housekeeping; CONFIGURATOR, which handles the configuration; IDENTIFIER, which is the core program and generates the cause and consequence lists for the parameter deviations; CONSOLIDATOR, which turns these lists into a table similar in form to that produced by a conventional hazop; and MODGEN, which generates the unit models. There is a unit model library. The task of IDENTIFIER is to handle rules and the program is written in Prolog. The other programs are written in Fortran.

30.38.10 Illustrative example: water separator

An illustrative example of the use of HAZID has been given by Parmar and Lees (1987b). The plant examined is the feed section of the alkene dimerization plant described by Lawley and shown in Figure 8.25. The corresponding block diagram for this plant is shown in Figure 30.16. Table 30.15 gives part of the hazard identification table generated for this example together with extracts from the original table of Lawley, which was given in Table 8.29.

30.39 Hazard Identification: Enhancements

The published work on computer-based aids for hazard identification suggests that there is still much to be done to devise an aid which is useful in identifying hazards prior to conventional hazop, let alone one which might do more than this.

The current state of the art may be summarized by saying that, in general, aids are more successful in identifying causes than consequences, the range of which tends to be rather limited, and both are lacking in richness and are thus rather stereotyped. The overheads for the input of data tend to be too high. The output tends to be lacking in discrimination, and thus excessive.

An aid such as HAZID is built largely around fault propagation, which utilizes models based on engineering principles and which is stronger on the identification than on the evaluation of faults. Fault generation needs to be enhanced

    rule (pipe, effect, [[t, 2, lo]], [[‘leak (rupture)’, ‘ ’, ‘ ’]])
10. Model status:
    Written: JCParmar June 1986
    Checked: FPLees June 1986
    Usage: 3 Configurations

Figure 30.15 *HAZID: proforma for configuration of a unit model (Parmar and Lees, 1987b) (Courtesy of Elsevier Science Publishers)*

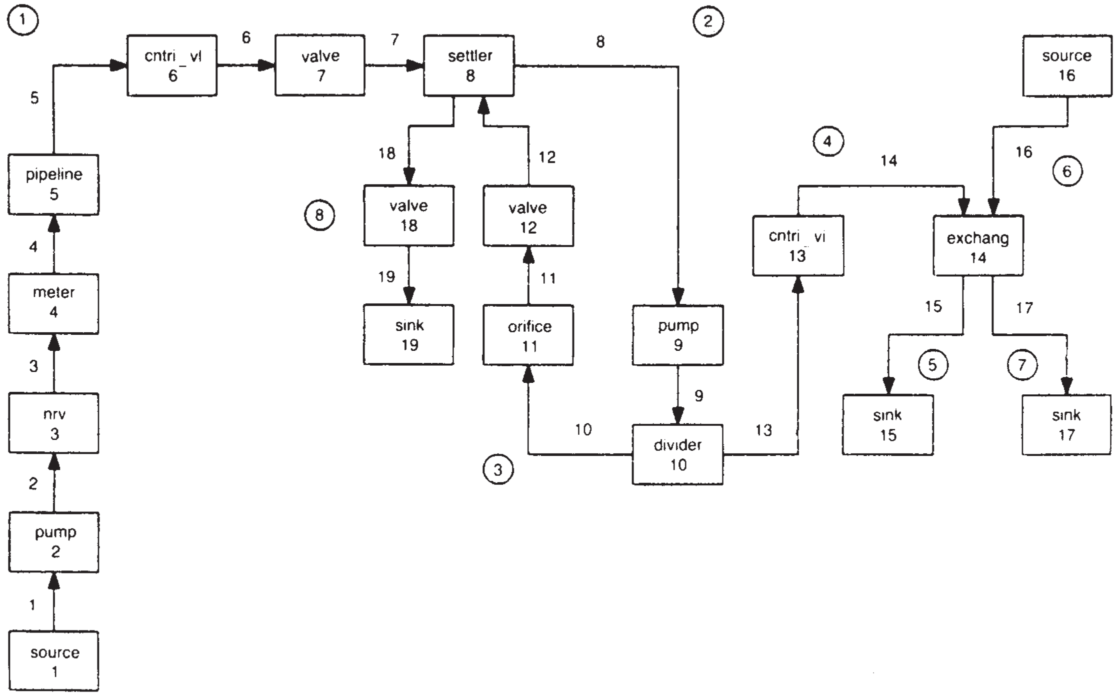

***Figure 30.16** HAZID: illustrative example: block diagram for alkenes dimerization plant (Parmar and Lees, 1987b) (Courtesy of Elsevier Science Publishers)*

by grafting onto this basic mechanism domain expertise. Thus, for example, a heat exchanger may have expertise bearing on tube vibration under abnormal flow conditions, blockage under no flow conditions, pinhole leaks between tubes and the shell, the overpressure hazard following tube burst, the need for space to remove the tube bundle, and so on. Perhaps even more important is the need to strengthen fault evaluation. There are various methods of doing this but most may be broadly classed as forms of expertise.

Features in which enhancement of current methods is likely to be of value include the following: (1) design screening, (2) information acquisition, (3) generation of faults, (4) evaluation of faults and (5) presentation of output.

30.39.1 Design advice and screening tools

The point has already been made that if the designs coming forward incorporate defects which are relatively elementary and numerous, a hazop-style aid may not be the most efficient way of correcting the situation. There may be scope for assisting the designer by providing a design advisor tool. Such a tool is essentially an aid to design synthesis. Likewise, it may be appropriate to provide a design screening tool to filter out certain common and readily identifiable defects. In contrast to the design advice tool, this is a tool for design analysis. A design screening tool is likely to rely largely on an examination of the configuration of the units and of the plant as a whole. Configuration screening is discussed further below. Suffice it to say that it needs to be catered for somehow and that, if it is not performed by a separate aid, it is necessary to incorporate it in the main hazard identification aid.

30.39.2 System discipline

It can be envisioned that over time aids such as those for representing design issues described earlier and the hazard identification aids described here could exert a significant influence on the design process. Such aids tend to require adherence to a more formal discipline involving a more explicit declaration of issues, arguments and intent. This is not only a condition for the effective integration and exploitation of these aids but also a desirable development in the design process itself.

Permitted terminology

One aspect of this is the discipline to be adhered to in the terminology used. It is good practice to use lists of the permitted terminology for units, faults, process variables, deviations and so on.

As a simple example, confusion can be caused if the state of a valve is described on some occasions as 'closed' and on others as 'shut'. More fundamentally, the discipline is of value with respect to generic and specific faults and to the inheritance of faults. Thus, for example, use might be made of the generic faults 'block', indicating complete blockage, and 'outflow', indicating major leak. Realizations of the generic fault block in a line might be the specific faults blockage, closure of valve, freezing of fluid or polymerization of fluid.

30.39.3 Fault generation and evaluation

As already stated, a hazard identification aid is required both to generate faults and to evaluate them. Fault generation is primarily by means of fault propagation models, fluid and materials of construction models, and expert

Table 30.15 *HAZID: illustrative example; hazard identification table generated for alkene dimerization plant (Parmar and Lees, 1987b) (Courtesy of Elsevier Science Publishers)*

Process deviation	*Original hazop causes*	*Computer-aided hazard identification causes*	*Original hazop consequences*	*Computer-aided hazard identification consequences*

rules. The prime means for fault evaluation are the fluid model and expert rules.

30.39.4 Integration of expertise

The generation of faults is done partly by fault propagation, but to achieve a greater richness and completeness it is necessary to introduce in addition various forms of expertise. The following are some of the attachment points, or 'hooks' to which such expert rules may be attached: guidewords; faults; deviations; undesired outcomes; units; lines; configuration of units (including connectivities and elevations); fluids; reactions; impurities and their sources; materials of construction; pressure raisers (pumps, compressors); instrumentation; control computers; protective devices (especially relief valves); small items (drain and sample valves, filters, small bore pipework, etc.); mode of operation (batch, continuous, etc.); operations (usual modes of operation, operating instructions); maintenance; storage; transport; utilities; environmental influences (heat, cold, rain, extreme weather) and environmental impacts (releases).

Expert rules are also a prime means for the evaluation of faults. Once a fault has been generated, any expertise available to the program can be brought to bear to evaluate it. This applies whether the fault generation step has involved fault propagation, the fluid model or fault generation expertise. Often, fault generation and evaluation will be part of the same package of expert rules.

30.39.5 Information requirements

The hazard identification activity requires the availability of a considerable amount of information. The information requirements for conventional hazop have been discussed in Chapter 8.

Minimal requirements for a computer aid are generally (1) the piping and instrument diagram, and information about (2) the main plant units, (3) the fluids and (4) the materials of construction. In addition, however, information may be needed about other aspects such as design intent and operating procedures.

Some comments are now given about some of these types of information.

Fluids

Information is required about the properties of the fluids in the plant. This is discussed in more detail below. Suffice it to say at this point that in large part this is information about fluid properties and susceptibilities. The former should be available in the standard generic fluid properties databases but much of the latter may not.

Materials of construction

Information is also required on the properties of the materials in the plant, essentially on their susceptibilities. Provision of this information is the function of a generic materials of construction database.

Design intent

There is a quite large amount of information on design intent which is not necessarily given in the piping and instrument diagram (P&ID). This category covers a wide range of types of information. One type may be broadly characterized as configurational information. For example, the P&ID may show two pumps piped up in parallel without making it clear whether these are 50 or 100% pumps. Or, again, two pressure relief valves may be shown but with no indication on setting, capacity or stagger. Another category is that which relates to the function of the unit, especially where this involves a dual or subsidiary function or a constraint on function.

Operating procedures

Another important category of information is the operating procedures. Ideally these should be available at the time where the hazard identification is undertaken, but they may well not be.

Resident hazards

It is commonly the case in a conventional hazop that even before the study is commenced the team already knows that the plant is subject to certain hazards, or other problems. In conducting the examination these 'resident hazards' are uppermost in the mind. It makes sense in devising a computer method to find some way of ensuring that the search covers such resident hazards.

Information representation

For some types of information the form of representation appears straightforward. For fluid-materials incompatibilities, for example, a look-up table is a natural format. Moreover, such information is of the type which should in large part be available in standard databases. With other types of information, such as design intent or operating procedures, there are issues both as to the representation most useful to the hazard identification aid and as to the ease of acquisition.

Lack of information: effects and strategies

Lack of information has certain consequences. In some cases the system may fail to generate a fault. More often, it will be unable to evaluate a potential fault that it has identified. There are strategies for coping with a lack of information. One is to conduct a dummy run of the hazard identification aid to establish the information that is missing. This implies that the data are to be provided prior to the main run.

An alternative approach is to use default assumptions about matters such as design intent or operator procedures. It can be envisaged, for example, that for many standard operations a corresponding standard, default operating procedure is attached. The use of default assumptions has obvious dangers, however. In some cases it is precisely the haziness about intent that it is the function of the study to identify. It may well be prudent, therefore, at least to draw attention to the fact that such a default has been used.

30.39.6 Information acquisition and CAD interface

A large amount of generic information on physical, chemical and thermodynamic properties and on materials of construction is, in principle, available in standard databases. Data on the plant itself are available in the design databases. The information acquisition problem relates to that part of the information required which is not available from these sources.

Information may be provided for use by a computer aid by manual input, by retrieval from the system's own database or by accessing the database of another system. Manual input imposes an overhead that can make the use of the aid much less attractive. There is therefore a strong incentive to obtain the information required automatically.

One approach to information acquisition is to provide a database that is intended to meet in full the information needs. Another is to rely completely on the interactive provision of data by the user. An intermediate, or hybrid, approach is to provide the database with a substantial amount of information but to anticipate some user input of data.

As indicated, a method of identifying the items of information needed to solve a particular problem but still missing in the database is to perform a dummy run for the sole purpose of such identification.

Use may also be made of heuristics. One strategy for automatic acquisition is to exploit the implications of the plant configuration. One example is that the presence of a water separator implies free water in the feed to it and hence a hazard of generation of static electricity. Another is that the presence of a trip implies a hazard against which the trip is guarding. And so on.

The aim must be that the hazard identification tool acquires most of its information by accessing a CAD system and its associated databases. Here it is sufficient to note that facilities for interfacing such an aid to the CAD systems in general use are not yet universally available.

30.39.7 Plant configuration features

As mentioned earlier, a plant design may possess configurational features that point to potential hazards. Such undesirable features include those associated with (1) pressure relief, (2) shut-in pipework, (3) water hammer, (4) throttling of pump suction and (5) emergency isolation of hazardous inventories. As a simple example, where a plant configuration shows a long pipeline terminating in a shut-off valve, there is a presumption that water hammer might occur.

It is for consideration at what stage identification of such undesirable configurational features should be undertaken. One policy is to leave them to be identified in the course of the main hazard identification procedure. An alternative, and perhaps preferable, policy is to conduct a preliminary screening for such features.

30.39.8 Plant system decomposition

Success in the analysis of a plant system can often depend on the appropriateness of the decomposition. It is therefore worth devoting some effort to ensuring that the system is decomposed in the way best calculated to achieve the desired results.

In most methods decomposition is into units and lines, together with source and sink units representing the main inflows and outflows across the plant boundaries. Another element that it may be convenient to use is an offtake. This is any feature through which a flow can occur out of a line or unit and includes an atmospheric vent, a pressure relief valve, a drain or sample point, etc.

There is an issue as to whether a line between units should be handled as a whole or decomposed into its constituent parts, with each fitting such as a valve or filter treated separately. Similar choices apply to the units. A pump set or a valve and bypass set may each be treated as a single unit or decomposed further.

30.39.9 Model hierarchies and inheritance

It is becoming increasingly common to model the plant as a hierarchy of objects and to exploit the concept of inheritance. The head of the hierarchy may be taken as the plant itself. In this case the plant object contains the connectivities between the units, which are the next level of object.

The models of the units may also be ordered in hierarchies. Thus, for example, one model hierarchy may be headed by a pressure raiser, which is the parent for compressors, fans, pumps, etc. A given unit may belong to more than one hierarchy. Thus, a centrifugal compressor may belong both to the hierarchy of pressure raisers and of rotating machines. Benefits of ordering the unit models in a hierarchy are that this provides structure in the model library and that models can inherit characteristics.

Inheritance is a valuable feature but needs to be applied with care, particularly where multiple inheritance is involved. Options in respect of inheritance from a parent unit are (1) to accept the whole set of characteristics, (2) to suppress the whole set of characteristics or (3) to accept the set of characteristics but to overwrite some of them. A declaration of the option exercised should be attached to the model.

For inheritance to be practised successfully it is necessary that the characteristics of the parent model be expressed in a way which is sufficiently general. As indicated earlier, one aspect of this is that the faults in the model need to be generic.

30.39.10 Units as objects

One way of generating faults is to list the attributes of a unit as an object. This provides a fault generator for the unit. This concept may be illustrated in terms of the properties of a pump. A pump:

(1) has problems –
    loss of power; loss of lubrication; loss of cooling; cavitation; deadheading; reverse flow; vibration;
(2) causes problems –
    can cause loss of flow; can cause loss of pressure; can cause power surge (start-up and shut-down); can cause vibration;
(3) is an equipment –
    has states; has foundations; has connections; requires operation/control; requires maintenance;
(4) is an equipment which has states –
    has operational state; has short-term stand-by state; has long-term stand-by state (mothballing); has breakdown state; has maintenance state;
(5) is an equipment which requires operation/control –
    requires to be started up; may require preliminary conditions/activities before start-up; requires to be shut-down; may require observable operation (visual, audible cues about start-up, running, etc.); may require remote operation; may require synchronized operation (e.g. with an emergency isolation valve);
(6) is an equipment which requires maintenance –
    requires access; requires mechanical isolation; requires electrical isolation; may require lifting gear;
(7) is a machine –
    (a) requires power; has motion; dissipates energy; has inertia;
    (b) has rotary motion; has bearings; has seals;
(8) is a pressure raiser –
    is a source of low pressure (inlet); is a source of high pressure (outlet);
(9) is a flow device –
    causes turbulence; may have cavitation;
(10) has subsystems –
    may have lube oil system; may have water cooling system;
(11) is a leak source –
    has hazardous area classification;
(12) has reliability engineering requirements –
    has reliability requirement; has availability requirement.

30.39.11 Faults and susceptibilities

Susceptibilities

Closely related to the foregoing is the concept of looking at a unit in terms of its susceptibilities. This also is perhaps best explained by way of example. Consider a water separator. Some rules for this might be:

(1) If the residence time is low, then the outflow liquid may contain free water.
(2) If the operator fails to drain the water, then the outflow liquid may contain free water.
(3) If interfacial effects occur (emulsion), then the outflow liquid may contain free water.
(4) If the liquid is one susceptible to charge generation (low conductivity) and the liquid velocity is high or there is a charge generator (e.g. filter) in the inlet line, then there is a hazard of static charging and discharge.

Similarly, for a heat exchanger:

(1) If the exchanger is new/recently cleaned, then the outflow process liquid temperature may be high.
(2) If the exchanger is old, then fouling may have occurred and the outflow process liquid temperature may be low.
(3) If there is a tube leak and the heating fluid pressure is greater than the process fluid pressure, then the outflow process liquid will have minor component increase consisting of heating fluid.
(4) If the residence time is high and the process fluid is susceptible to polymerization, then the liquid may polymerize in the exchanger.
(5) If the liquid contains minor components that promote fouling, then fouling may occur.
(6) If the liquid contains minor components that attack the existing fouling film, then the outlet process liquid may contain debris.

The richness of the fault representation depends in large part on the imaginativeness with which unit susceptibilities are identified.

Conditional faults

The susceptibilities just described constitute a form of fault with an attached condition. The attachment of conditions to faults is important because it either limits the number of faults generated or increases the proportion eliminated, depending on the stage at which the conditions are applied.

As a further example of a conditional fault, wet steam may be characterized as a fluid that is erosive, but with the attached condition that the velocity is high. The erosiveness of the steam is a generic property, but the velocity is a condition to be met in the specific application.

Faults with external effects

A hazard identification aid should cater not only for faults that propagate through the plant but also to some degree for those which have an impact outside it. Examples are liquid overflow from a storage tank and its implications for the bund around the tank or discharge from a relief and it effects.

30.39.12 Expert rules

As indicated, a unit may be provided with a set of expert rules for both the generation and evaluation, or resolution of faults. In some cases generation and resolution may occur within the same unit, in others use has to be made of fault propagation between units.

As an example of the latter, more complex case, consider a pump with the rule set

Hook	*Generation*	*Resolution*
Has lube oil system	Lube oil system failure may cause flow of lube oil as impurity into process fluid if failure creates a leak path and if the pressure of lube oil is greater than the pressure of process fluid	Response required if and only if lube oil impurity in process creates a significant problem

At this point a potential fault has been generated but not resolved. It is not known whether lube oil in the process fluid is an unacceptable impurity. Now consider the transport of the lube oil impurity into a water separator. Applying the water separator rule, or susceptibility, given earlier:

If interfacial effects occur (emulsion), then the outflow liquid may contain free water.

This rule effectively defines, for this unit, the nature of the potential problem. Whether or not the lube oil impurity is a significant problem depends on whether it is a foaming agent. This is determined from the fluid model, which is now described.

30.39.13 Fluid and stream models

Modelling of the units in terms of fault propagation and expert rules needs to be complemented by modelling of the fluid. A distinction is made between the fluids and the streams. 'Fluid' refers to the chemical substance, or mixture, which has generic properties. 'Stream' refers to the stream at a given location in the specific plant. A stream is defined primarily in terms of the fluid and of the pressure and temperature.

Some elements of the fluid and stream models are (1) stream definition, (2) stream transformations and (3) stream displacements.

Stream definition

A stream at equilibrium is defined basically in terms of its composition and of the pressure and temperature. The composition may be defined in terms of (1) bulk components and (2) minor components, intended and unintended. The stream composition and the operating conditions of pressure and temperature define the phase and the physical properties of the equilibrium fluid.

Stream transformations

Much stream behaviour may be characterized in terms of transformations. These are (1) intended transformations and (2) unintended transformations. The intended transformations are what the process is all about, typically reaction and separation. The unintended transformations are what the exercise seeks to identify.

Stream interactions

Another way of categorizing stream behaviour is in terms of interactions. These are (1) interactions with operating conditions, (2) interactions with other materials and (3) interactions with other features.

Stream interactions with operating conditions

There are three categories of stream interaction with operating conditions: (1) phase, (2) flow properties and (3) reaction.

Phase transformations are (1) vaporization, (2) condensation, (3) melting and (4) solidification. These transformations may be partial or total.

Flow property transformations are any transformation that affects the flow properties of the fluid, for example viscosity change and change to slugging flow.

Reaction may occur within the fluid itself. This reaction may be in a reactor, where the reaction may be the intended reaction or also an unintended one; or it may be in another part of the plant, where it will almost always be an unintended reaction.

Stream interactions with other materials

There are a large number of stream interactions with other materials that may be conceived. The interactions considered here are confined to those which are due to the fluid constitution (composition and properties) and do not extend to the fluid motion.

The interactions include those with other materials such as (1) other fluids (bulk components, minor components), (2) catalyst, (3) materials of construction, or corrosion (main components, minor components), (4) air, (5) water and (6) additives (interfacial agents, promoters, inhibitors). In each case it is necessary to consider the interaction both of the bulk components and of the minor components of the stream.

Interactions of the stream with the materials of construction include interactions of the stream both with the main components and with minor components such as gaskets, seals, trims, etc. Lubricants and sealing fluids may be treated as 'minor components'.

Air and water might be treated on a par with the other unintended minor components, but they are so common, and incidents associated with them so frequent, that they perhaps deserve special status. One aspect of this is that consideration should be given to whether or not they are declared as specific components of the stream.

Stream interactions with other features

Streams also interact with other features in the sense that a problem arises from the combination of the stream and the feature. These features include (1) units, (2) unit faults, (3) operations and (4) maintenance.

An example of an interaction between the stream and a unit is the case where the fluid is flammable and is transferred into a road tanker. There is a recognized hazard of static electricity in some cases.

An example of an interaction between the stream and a unit fault is the case where the stream contains gunk that causes blockage.

An example of an interaction between the stream and an operation is the case where a gravity separator is used to remove water from a toxic solvent with which it is nearly (but not totally) immiscible and the water is drained off the bottom. The water will be saturated with the solvent and the latter will therefore exert its full vapour pressure. If the solvent is toxic, this may affect the operator.

An example of interaction between the stream and maintenance is the case where the fluid is very toxic and special precautions will need to be taken when the plant is broken open.

30.39.14 Fluid and stream models: hydraulics

A quite different set of fluid phenomena are those that fall into the broad category of hydraulic effects. One way of looking at these is in terms of the displacement of one fluid by another.

Displacement of gas by liquid

Displacements of gas by a liquid include (1) displacement in a vessel, (2) displacement in a pipe, (3) condensate hammer, (4) liquid lock and (5) siphon.

The pipe displacements are (1) permanent, flowing displacement (2) a moving liquid slug and (3) an essentially immobile liquid slug.

Displacement of gas by a liquid in a vessel can cause overflow and overpressure. Displacement of gas by a liquid in a pipe can cause erosion and incorrect measurement and control. Condensate hammer can cause damage to pipework and machinery. Liquid lock can prevent gas flow and pressure equalization.

Displacement of liquid by gas

Displacements of liquid by a gas include (1) displacement in a vessel (partial, total), (2) displacement in a pipe and (3) gas lock.

Displacement of liquid by a gas in a vessel can cause loss of head and overpressure. It can also take the form of gas breakthrough when a liquid seal at the bottom of a vessel is lost. Displacement of liquid by a gas in a pipe causes incorrect measurement and loss of control. Gas lock can prevent liquid flow.

Displacement of liquid by liquid

Displacement of liquid by a liquid occurs in rollover. Rollover is caused by the formation of two liquid layers and by inversion of the densities of the two layers.

30.39.15 Fluid and stream models: modelling strategy

A strategy for modelling the fluid needs to deal both with the identification and with the resolution of stream-related problems.

Stream problem identification

Stream-related problems arise from the three sorts of stream interactions and from stream hydraulics. One strategy for dealing with stream interactions is the use of breakpoints. A breakpoint is defined as a point in the plant at which the fluid constitution (composition and properties) and/or the operating conditions undergo or may undergo a significant change. This definition covers both a point where a change is intended and one where no change is intended but may nevertheless occur. It is for consideration what constitutes a significant change.

At each such point the three types of stream interaction are examined, to identify any problems. The default assumption is that unless there is information to the contrary, the stream passes through a breakpoint with its constitution and operating conditions unchanged except as given in the design.

Stream hydraulic problems tend to be related to particular types of line and unit. One way of dealing with these is therefore by using lines and units as the hooks for the appropriate expertise.

Stream problem resolution

Fault generation needs to be followed by fault resolution. The stream model should contain aids to assist in determining whether a generic fault identified by the fault generation process is in fact a significant problem in the specific case. Some types of resolution aid include (1) landmark values, (2) susceptibility rules and (3) other rules. Here rules are taken to include related forms such as truth tables.

30.39.16 Fluid and stream models: information

The implementation of such a strategy requires the handling of information, which may be broken down into (1) information requirements, (2) information representation and (3) information acquisition.

The foregoing approach to the fluid and stream models implies the need for information on (1) inlet streams and (2) intended stream transformations at breakpoints, and information relating to the potential for (3) unintended stream transformations, (4) unintended stream interactions with other materials, (5) unintended stream interactions with other features and (6) unintended stream hydraulic effects.

The set of inlet fluids is those fluids entering at the boundaries and includes process fluids and utility fluids. The set of intended stream transformations is, in effect, the process.

The unintended stream transformations arise from the first two types of interaction (with the operating conditions and with the other materials). The unintended stream interactions with other materials may result in stream transformations, as just mentioned, and/or in other effects.

This part of the information relates to fault generation. The second part is that which relates to fault resolution. In large part this latter is concerned with various types of susceptibility to stream changes.

A large part of the fluid model consists of information about susceptibilities and incompatibilities. These relate to the three types of interaction already described, which are (1) stream–stream interaction, (2) stream–materials interaction, and (3) stream–feature interaction. These interactions occur essentially due to the fluid properties of the stream(s).

There are also interactions due to stream properties such as pressure and temperature. These include (1) pressure–materials interaction and (2) temperature–materials interaction.

Information on susceptibilities and incompatibilities is most naturally represented as rules or look-up tables.

30.39.17 Materials of construction model

Another model required is the materials of construction model. What this model should provide is the susceptibilities of the materials in the plant to undesirable interactions. The most elementary form of model is one that gives the incompatibilities between the materials of construction of the main items of equipment and the fluids. More useful is a model that also gives this information for (1) minor components of the main plant items and (2) for impurities in the fluids.

The materials model should also cater for susceptibilities of the materials to the stream properties of pressure and temperature. The materials model may be extended to give some information on effects. In most cases the basic effect is corrosion. The significance of this, however, varies. It may lie in its potential to cause a leak or in contamination of the fluid.

30.39.18 Filtering of faults

The output given by current computer aids for hazard identification tends to be too indiscriminate and too voluminous. As pointed out in Chapter 8, in a conventional hazop the identification of hazards is only one part of the activity; the other part is the filtering out of those hazards that are unfeasible or negligible.

Four forms of filtering can be distinguished: (1) suppression, (2) consolidation, (3) evaluation and (4) masking. These are now considered in turn.

Suppression of faults

By 'suppression' is meant suppression of the consequences and/or causes during the generation process or immediately thereafter. It has its place, but carries with it certain dangers. Suppression needs to be governed by suitable rules, which may not be easy to devise.

An example of suppression that may well be appropriate is the suppression of generalized blockage and leakage faults which tend to proliferate in certain aids, particularly where each fitting in a line is the subject of a separate examination.

Consolidation of faults

Consolidation of faults involves replacing a set of faults by a more limited set of equivalent faults. It is applicable mainly where a line has been decomposed into its constituent elements, each with its associated fault set. The use of consolidation requires suitable rules, the formulation of which may not be trivial. This contrasts with suppression, which is readily implemented.

Evaluation of faults

Evaluation of faults may take several forms. One is the application of expert rules, another is the use of landmark values and a third is the use of susceptibility data. Some types of rule for evaluation include those associated with (1) consequences, (2) product of consequence and frequency, (3) frequency, (4) classic hazard situations, (5) plant equipments, (6) protective devices, (7) unrevealed failures and (8) process variables. There will be some events so serious that they are unacceptable virtually regardless of the frequency. There will be others where the product of (consequences × frequency) is an appropriate filtering criterion. There may be others, applicable to low consequence events, where only the frequency is of interest. There are certain classic situations such as thermal expansion of blocked-in fluid. There are certain pieces of equipment such as pump sets where there are classic hazards and solutions. There are certain classic aspects of protective devices such as a pressure relief valve where the set pressure may not be exceeded but where capacity may be. There are certain rules, displayed in hazops, as to how to handle unrevealed failures, particularly in instruments. There may be rules governing process variables such as level or pressure. One way of developing evaluation rules is to identify the features that trigger interest on the part of members of a hazop team.

Another method of evaluation is the use of landmark values. These are most likely to be associated with the fluid model. A typical application of a landmark value is to determine whether the fluid is likely to undergo a change of phase such as boiling or freezing.

The third evaluation method mentioned above is the use of data on susceptibility or compatibility. This method is likely to be applicable mainly to the fluid and materials of construction models. Data on susceptibility may take the form of look-up tables or rules.

The account of evaluation that has just been given implies that the way to proceed is to generate all possible faults and then to evaluate each one to determine whether it can be rejected. There is an alternative approach to evaluation which is to reverse the 'burden of proof and to apply the default rule that no fault is retained unless there is good reason to do so. This is possibly closer to the *modus operandi* of a hazop team. Whichever approach is adopted, the information and rules required to support the identification decisions are broadly similar.

Masking of faults

Whatever the extent and effectiveness of the various forms of filtering, there remains the question of whether to display in the output all the faults not removed by the filtering processes described or whether to practice some form of masking.

In principle, masking is a relatively simple operation. It involves defining within the total information a subset that is not to be displayed and laying a mask over it. There may be a number of masks, each with its subset, and they may overlap, like Venn diagrams.

A hierarchy of masks can be envisaged, with distinctions based on the severity of the failures involved, with a stringent mask for coarse hazard studies, etc. Alternatively, the distinction may be based on the discipline involved, for example, control systems, pressure relief systems, etc., for use by different parties to the design. There is also the option of user-configured masks.

30.39.19 Query and action outputs

The output from a conventional hazop study includes a list that is typically a mixture of queries and actions. The actions may vary in status from requirements to suggestions.

The corresponding output for a computer aid is likely to contain a different mix, weighted more to queries, with proposals for positive action probably confined to certain limited areas. Effort is better employed in improving the quality of the queries rather than in extending the aid into a design tool.

30.39.20 Explanation facility

As described earlier, a standard feature of an expert system is the explanation facility. There is, in principle, no reason why such as facility should not be provided as part of a hazard identification aid, to be consulted in the probably small number of cases where the logic of the argument is unclear to the user.

30.40 Fault Tree Analysis

A large number of computer programs have been developed for the analysis of fault trees, which are often very large. The tasks carried out by these programs fall mainly into four categories. These are determination of:

(1) minimum cut sets,
(2) common cause failures,
(3) reliability and availability,
(4) uncertainty.

Some of these codes are listed in Table 29.7. This table gives the references to the codes listed. Further references are given in Table 29.1. One of the first sets of codes was PREP and KITT developed by Vesely and co-workers. PREP obtains the minimum cut sets and KITT evaluates reliability and availability. There are two versions, KITT-1 and KITT-2, the latter having the capability of handling time-dependent failure data. These codes have been widely used and were utilized in the *Rasmussen Report*.

Another group of codes are those developed by Fussell and co-workers. These include MOCUS, BACFIRE and SUPERPOCUS for determining minimum cut sets, common cause failures and reliability and availability.

Codes for the determination of importance include IMPORTANCE, developed by Lambert.

The *Rasmussen Report* included several codes. SAMPLE combines input distributions to give an output distribution. MOCARS determines the distribution of a tree top event.

30.41 Fault Tree Synthesis

As just described, there are available a number of computer codes for the analysis of fault trees. The synthesis of fault trees is a more difficult problem, but some progress has been made in developing aids for this. Again the codes utilize some form of fault propagation modelling.

30.41.1 Fault tree drafting

Some codes for fault tree construction are aids to the manual synthesis of fault trees. They include TREDRA and TREE.

30.41.2 Fault tree synthesis codes

There are a number of codes that have been developed to effect the automatic synthesis of fault trees. The different methods take different starting points, including: functional equations (e.g. B.E. Kelly and Lees, 1986a); graphical methods such as digraphs (e.g. Andrews and Morgan, 1986); reliability block diagrams (e.g. Caceres and Henley, 1976) and reliability graphs (e.g. Camarda, Corsi and Trentadue, 1978); logic models (e.g. Poucet, 1983) and logic flowgraphs (e.g. Guarro and Okrent, 1984); tabular methods, such as decision tables (e.g. Salem, Apostolakis and Okrent, 1977) and transition tables (e.g. J.R. Taylor, 1982; Bossche (1991a–c); and mini-fault trees (e.g. Fussell, 1973a,b; B.E. Kelly and Lees, 1986a).

Some of these codes are summarized in Table 30.16. Most are probably best characterized as research codes. An account is now given of some of these methods.

30.41.3 DRAFT

An early code for fault tree synthesis was the DRAFT code of Fussell (1973a,b). He used models which he termed component failure transfer functions, which are effectively a form of mini fault tree. He applied his method, which he called the Synthetic Tree Model, to electrical systems rather than process plants, although the electrical systems considered were on process plant systems.

30.41.4 FTS

The first fault tree synthesis code for process plants was the FTS code of Powers and Tompkins (1974a,b), further developed by Powers and Lapp (Powers and Lapp, 1976; Lapp and Powers, 1977a,b). These authors model the plant system using digraphs. Figure 30.17(a) shows the nitric acid cooler system used by Lapp and Powers, which has become a classic example, and Figure 30.17(b) shows the digraph given by the authors for this system.

The fault tree is constructed by selecting the node for the top event of interest and then developing the tree for the causes of this event. For a given node, the causes are the inputs to the node. The tree is developed down to the basic events. Causes that violate consistency are deleted.

Control loops are handled by means of an operator, which is essentially a loop structure imposed at the appropriate point in the development of the tree. Separate operators are used for feedback and feedforward loops.

The fault tree obtained in this work has been subject to some discussion in the literature (e.g. Lambert, 1979; Lapp and Powers, 1979; Locks, 1979; Yellman, 1979).

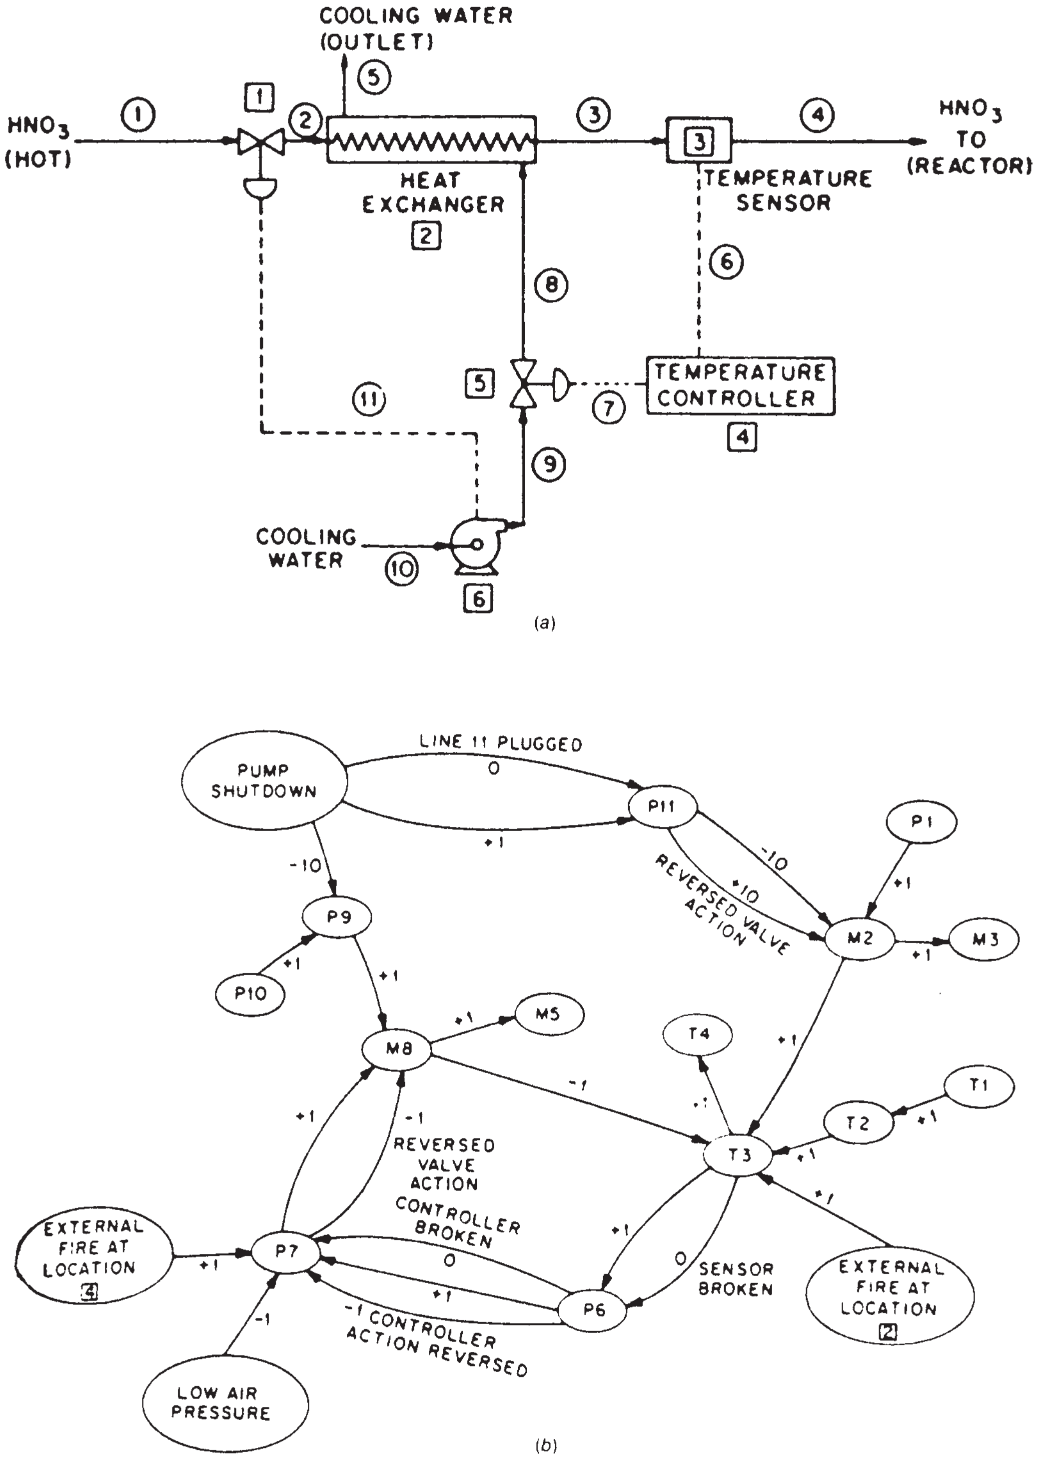
30.41.5 CAT

Another early code for the synthesis of fault trees for process plants was the CAT code of Salem, Apostolakis and co-workers (Salem, Apostolakis and Okrent, 1975a,b, 1977; Apostolakis, Salem and Wu, 1978; Salem and Apostolakis, 1980). In the CAT code the models used are cast in decision table form. The tree is then constructed by nominating a top event and developing its causes by selecting from the appropriate entries of the decision tables, using suitable procedures to maintain consistency.

Table 30.16 *Some computer codes for fault tree synthesis*

Code[a]	*Methodology*	*Reference*
DIRAFT	Failure transfer functions	Fussell (1973)
FTS	Digraphs	Powers and Tompkins (1974a,b); Powers and Lapp (1976); Lapp and Powers (1977a, 1979); Cummings, Lapp and Powers (1983)
CAT	Decision tables	Salem, Apostolakis and Okrent (1977); Apostolakis, Salem and Wu (1978) Salem and Apostolakis (1980)
-	Digraphs	D.J. Allen and Rao (1980); D.J. Allen (1984)
CAFTS	Transfer logic models, mini-fault trees	Poucet and de Meester (1981); Poucet (1983, 1990)
RIKKE	Equation ‘bigraphs’,transition tables	J.R. Taylor (1982)
FAULTFINDER	Propagation equations, mini-fault trees	Martin-Soils, Andow and Lees (1982); B.E. Kelly and Lees (1986a–e); Mullhi *et al.* (1988); A Hunt *et al.* (1983a–e)
AFTC	Decision tables	Sang Hoon Han *et al.* (1989)
FISA	Causal trees, transition tables	Bosche (1991a–c)

[a] Synthesis codes usually have a drafting package also.



(a)

(b)

Figure 30.17 A nitric acid cooler system (Lapp and Powers, 1977a): (a) flow diagram; (b) diagraph (Courtesy of the Institute of Electrical and Electronic Engineers)

30.41.6 RIKKE

The RIKKE code of J.R. Taylor (1982) utilizes the so-called equation 'bigraph', transition table and mini-fault tree models. The construction of the tree proceeds by selecting a top event and developing its causes by tracing through the mini-fault trees, with procedures to maintain consistency. Taylor characterizes his fault construction algorithm as utilizing a component-by-component construction and contrasts it with that of Lapp and Powers, which he describes as a loop-by-loop method. A feature of Taylor's method is the use of a larger set of deviations than simple HI and LO, such as VHI and DIST HI.

30.41.7 FAULTFINDER

Another code for fault tree synthesis is the FAULTFINDER code of B.E. Kelly and Lees (1986a–e) and A. Hunt *et al.* (1993a–e). This is described in the following section.

30.41.8 Loop structure methods

The methodology for fault tree construction described is essentially component oriented, but this is not the only approach that may be adopted. An alternative is a structure oriented method in which the structure of the tree is determined from the outset by that of features such as the control and trip loops. This type of approach is illustrated in the work of Shafaghi, Andow and Lees (1984) and Shafaghi, Lees and Andow (1984).

30.42 Fault Tree Synthesis: FAULTFINDER

A more detailed account is now given of one particular code for fault tree synthesis. This is the FAULTFINDER code described by B.E. Kelly and Lees (1986a–e) and A. Hunt *et al.* (1993a–e).

In this work the models are formulated initially in terms of functional equations of the type described in Section 30.36. The building blocks for the fault tree synthesis, however, are mini-fault trees, described in the earlier work of Martin-Solis, Andow and Lees (1982). The mini-fault trees are constructed automatically from functional equation models.

The overview of FAULTFINDER that follows, both illustrates another application of fault propagation modelling and serves as an example of a fault tree synthesis code. The description is necessarily highly simplified.

30.42.1 System decomposition

The system decomposition is essentially similar to that used in the HAZID code. The piping and instrument diagram is converted to a block diagram and for each unit in the latter a unit model is specified, drawing on a library of models, with additional models configured by the user if necessary.

It is also necessary to provide certain structural information. The main information required relates to the control and trip loops. For each loop the instruments comprising the loop and the streams immediately affected by the action of the loop are identified.

30.42.2 Unit and top event models

The code uses the basic fault propagation methodology described in Section 30.36. A plant unit is modelled in the first instance using any combination of three forms: propagation equations, event statements and decision tables. The propagation equations are used to represent the propagation of a disturbance, or fault, through a unit and the event statement to describe the initiation of a fault in a unit. The decision tables are used mainly to represent relations involving AND gates.

From these three forms of input are constructed the mini-fault trees for the units. For each output from the unit there are at least two mini-trees, one for the deviation HI and one for LO. The top event of a mini-tree, therefore, is a deviation of an unit output. The mini-tree has only one level below this top event, the events in this level consisting of either variable deviations or basic faults.

The derivation of a mini-tree in a unit model proceeds as follows. Consider the relation given earlier for flow through a pipe

$$Q_2 \text{ out} = f(G_1 \text{ in}, G_2 \text{ out}) \qquad [30.42.1]$$

and the event statements

$$\text{PART-BLK } Q_2 \text{ out LO} \qquad [30.42.2]$$

$$\text{LK-LP-EN: } Q_2 \text{ out LO} \qquad [30.42.3]$$

The propagation equation states that Q_2 is LO if G_1 or G_2 is low. The event statements state that Q_2 is LO if there occurs the fault PART-BLK (partial blockage) or the fault LK-LP-EN (leak to low pressure environment). The resultant mini-tree is shown in Figure 30.18(a). Separate but very simple mini-tree models are used for the top events. Figure 30.18(b) shows a top event model for the event VES-RPT (vessel rupture).

The configuration of a unit model is carried out using the model generation program. The data are entered on a proforma essentially similar to that used in HAZID and shown in Figure 30.15, but the output generated by the program consists in this case of the set of mini-fault trees for the unit.

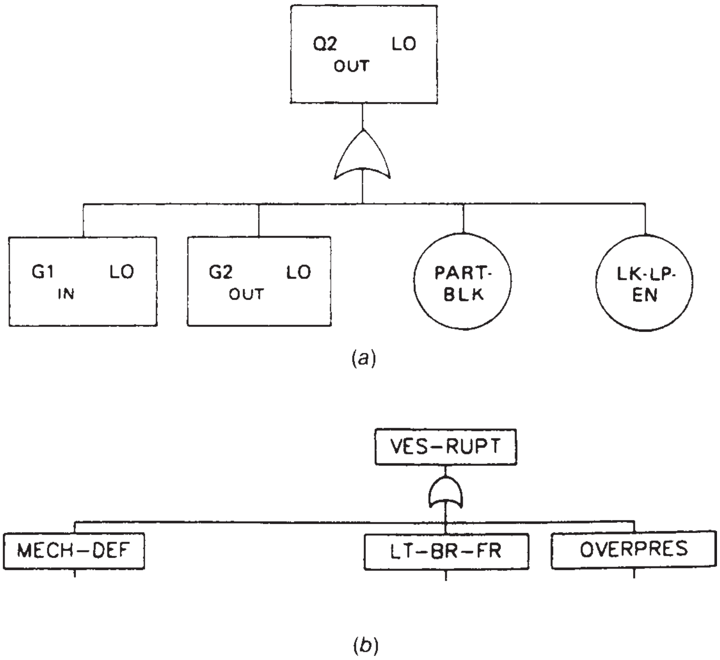
The methodology includes various aids to reduce the modelling effort, and to achieve a degree of automatic modelling. There is a facility to generate automatically the event statements for certain standard faults at ports. There are programs and template models for the configuration of vessels. And there are also some basic archetypes of other units such as reactors and heat exchangers.

30.42.3 Fault tree construction

Fault tree construction starts by nominating a top event, retrieving first the appropriate top event model and then the unit mini-trees that have as their top event the causes of the variable deviations that are the causes of the top event. The causes of the top events in this first set of mini-trees are then in turn developed using further mini-trees. The development continues until the base events in the mini-trees are either basic failures or events crossing the boundaries of the system. The principle of tree construction is therefore very simple. The complications arise mainly in ensuring consistency and in handling certain structures in the plant.

30.42.4 Tree consistency

There are two main types of consistency that need to be maintained: series consistency and parallel consistency. In essence, series consistency means that an event cannot be caused by its obverse. Also it cannot be caused by itself. An event may also be inconsistent with certain faults. Series consistency is checked as the tree is developed. Parallel consistency is the consistency of events in one branch of the tree with events in other branches of the tree



(*a*)

(*b*)

Figure 30.18 *FAULTFINDER: some mini-fault trees (after B.E. Kelly and Lees, 1986a; A. Hunt et al., 1993e): (a) mini-fault tree for event Q_2 LO (LK-LP-EN, leak to low pressure environment; PART-BLK, partial blockage); (b) mini-fault tree for top event VES-RPT (vessel rupture) (LT-BR-FR, low temperature brittle fracture; MECH-DEF, mechanical defect; OVERPRES, overpressure)*

under an AND gate. The check on parallel consistency is made during the rationalization stage that follows construction of the crude tree.

30.42.5 Tree structures

It is found that there are certain structures in a plant which need to be given special treatment, notably control loops, trip loops and divider–header combinations. The fault tree for a plant may be regarded as a composed of a basic demand tree, devoid of all control and trip loops, with the control and trip branches then added to it. Manual construction of a fault tree essentially proceeds by creating first the demand tree and then adding the control and trip branches. The structure of the tree is largely determined by these features.

It is desirable that an automatically constructed tree retain this general structure. But in any case it is found that problems arise in the construction of the tree unless some information on the control and trip loop structure is explicitly provided. It is possible in principle to limit the input information to the basic unit connectivities and to have the program identify the loops, but it is simpler to provide this information as part of the input.

Another type of structure that needs special treatment is combinations of dividers and headers. These occur in many guises, such as the suction and delivery manifolds of a pair of pumps or a control valve with a bypass. In some cases divider–header combinations are nested and in others they are staggered. In the case of divider–header combinations manual identification is complicated, and the program is provided with an algorithm to effect identification.

For the control and trip loops, use is made of templates that impose a structure on the tree at the point in tree development where the loop is encountered. For control loops use is made of three such templates. One of the templates, shown in Figure 30.19, is for a controlled variable in either a feedback or feedforward loop. The other two are for a manipulated variable, one in a feedback loop and the other in feedforward loop.

For trip loops a distinction is made between functional failure (failure to operate on demand) and operational failure (spurious trip). A template is used for functional failure, but not for operational failure, which is treated on a par with any other failure which disturbs the system.

30.42.6 Fluid and materials of construction models

The methodology allows for the supplementation of the unit models by models for the process fluids and for the materials of construction. Essentially, these models handle various kinds of susceptibility, whether to phase change or to corrosion. The general approach is similar to that used in the HAZID code.

30.42.7 Tree rationalization

Once the crude fault tree has been constructed it is necessary to rationalize it. Rationalization involves a number of operations. These include: checking for parallel consistency; elimination of certain branches where the base event is impossible or, alternatively, certain; and rationalization of the branches of control loops. It is at this stage that the attachment of the trip loop functional failure branches occurs, the treatment during the initial construction being

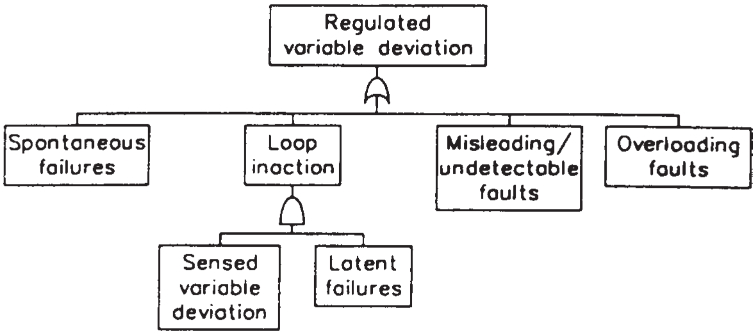


Figure 30.19 *FAULTFINDER: template for a controlled variable deviation, in either a feedback or a feedforward loop (A. Hunt et al., 1993c) (Courtesy of Elsevier Science Publishers)*

limited to identification of the variables that are protected by the loop.

30.42.8 Sequential operations

A sequence of operations may be handled by treating each step separately and re-initializing the configuration at each step. An overall fault tree then takes the form of tree with a top event SEQUENCE FAILS, with the two events ANDed together at the next level down SEQUENCE FAILS AT STEP 1 and SEQUENCE FAILS AFTER STEP 1, and so on.

In this connection, it merits mention that the top event of a fault tree does not need to be a hazardous event. It can also be an event such as SEQUENCE ABORTS in, say, a computer controlled sequence.

30.42.9 Other features

The methodology also accommodates a number of other features. Changes to control and trip loop set points normally receive no special treatment. Control exercised by a human operator or process computer that is equivalent to a conventional control loop is modelled as a notional loop.

Failures of utilities may be modelled either as independent failures in individual units or as inputs from a common supply which is itself subject to complete failure. This latter method may also be used to model other common cause failures.

30.42.10 Model generation and model library

The general approach to model generation and to the model library in FAULTFINDER is that outlined in Section 30.36 for fault propagation in general and in Section 30.38 for HAZID. Unit models are stored in the unit model library as sets of mini-fault trees. Details of the library are given by B.E. Kelly and Lees (1986c) and A. Hunt *et al.* (1993a).

A new model is generated by completing a proforma on which are entered the functional equations, event statements and decision tables, if any, for the unit. The mini-fault trees of the model are then generated automatically. Generation of new models for vessels is assisted by the provision of a taxonomy of ports, by partial automation of the modelling of ports and by the use of a special vessel model generation program and of vessel archetypes, or templates.

30.42.11 Computer codes

The main programs in the FAULTFINDER package are: MASTER, which does the housekeeping; FAULT, which constructs the tree; and MODGEN and EVTGEN, which generate the unit models and top event models, respectively. There are model libraries for unit models and top event models. Use is also made of various other programs for fault tree drawing and of standard programs for fault tree analysis.

30.42.12 Illustrative example: pump changeover

Numbers of examples of fault trees constructed by the program are given in the accounts by B.E. Kelly and Lees (1986a–d) and A Hunt *et al.* (1992a–e). A vaporizer example is given by Mullhi *et al.* (1988).

An illustrative example of fault tree construction using FAULTFINDER is given by B.E. Kelly and Lees (1986d). The system considered is the pump system shown in Figure 30.20. The problem was to identify the potential causes of abortion of a 14-step changeover sequence. The configuration block diagram is shown in Figure 30.21. The fault tree for Step 8 of the changeover is illustrated in Figure 30.22, the key for which is given in Table 30.17. The initial entries in the table of the minimum cut sets for this step, obtained by a fault tree analysis code, are shown in Table 30.18. The original paper gives further details, including listings of the steps in the sequence, the unit models used, the sequence steps and abort conditions, the configuration at each reinitialization and the minimum cut sets.

30.43 Operating Procedure Synthesis

There are relatively few computer aids for the examination of plant operations such as start-up and shut-down, although it is often in these phases that incidents occur, but progress is now apparent in the synthesis of operating procedures through the application of Al planning techniques. Pioneering work in this area was the study of Rivas and Rudd (1974) on the synthesis of operating sequences for valves.

With the progress made in Al planning techniques, operating procedure synthesis (OPS) for process plants has become a more active area. Studies include those done on valve operations by O'Shima (1983), on operating procedures by Fusillo and Powers (1987, 1988b) and Aelion and Powers (1991), on valve operations by Foulkes *et al.* (1988), on purging procedures by Fusillo and Powers (1988a), on operating procedures by Lakshmanan and Stephanopoulos (1988a,b, 1990) and Soutter and Chung (1995a,b) and on

batch processes using qualitative process theory by Rotstein, Lavie and Lewin (1992).

Several of these studies are now described. But first it is pertinent to make one or two points on the relationship of OPS to AI planning.

30.43.1 Unsafe states

In the application of planning to process operations it is obviously necessary to pay particular attention to the avoidance of undesirable, and especially of unsafe, states. Insofar as much AI planning work has been concerned with robots operating in blocks world, the question of unsafe states has tended to be less urgent. Techniques for handling the unsafe state problem are not well developed in AI planning. In process operations, however, the avoidance of unsafe states is very much to the fore. The avoidance of unsafe states is an essential requirement of an OPS planner and may well govern the choice of planning algorithm. In seeking to avoid unsafe states, an advantage lies with a planning strategy in which actions are added one at a time and the safety of the new state is confirmed before proceeding further; in other words with a forward-chaining, linear planner.

30.43.2 Valve operations

Much of the work described on OPS has been concerned with the synthesis of sequences of valve operations. From the point of view of planning, the crucial feature of valve operations is that they are not readily handled by a simple planning operator. The problem is that an action in which a valve is closed or opened does not have a unique set of effects. The effects depend on the state of the whole system. For example, if a line contains two valves in series, the effect of opening the upstream valve is not unique, but depends on whether or not the downstream valve is already open. One solution to the valve operations problem is to make use of domain specific knowledge.

30.43.3 Valve operations: method of Rivas, Rudd and Kelly

Historically, research in this area started with two pieces of work by Rudd and co-workers, one concerned with analysis and the other with the synthesis of valve operating sequences. Strictly, only the latter constitutes OPS, but it is convenient to describe first the work on analysis.

In their study, Rivas, Rudd and Kelly (1974) considered the analysis of a proposed valve sequence to determine whether it was hazardous. Such an analysis may be used to obtain a safe sequence for incorporation in operating instructions or it may be made the basis of a real-time software interlock system which leaves it to the operator to propose a valve sequence, but inhibits any hazardous sequence.

The possible states of the chemical species are shown in Figure 30.23. In pattern (a) the species A flows through the system without other contact; in (b) species A and B join and share a common path through the system; in (c) A is stopped in the system by a closed valve; in (d) A is trapped within the system by two closed valves; in (e) A is eventually flushed from the system leaving the connector empty; in (f) A is held in the system not by closed valves as in (d) but by the driving force causing the flow of species B.

A simple network of connectors is shown in Figure 30.24. It consists of two inlets through which species 1 and 2 (square boxes in Figure 30.24), respectively, can enter, an internal loop of three connectors and one outlet connector. The structure of this network is given in Table 30.19, which shows, according to the nomenclature of Figure 30.25, the number of each connector (plain numerals in Figure 30.24), the numbers of the two nodes associated with it (circled

numerals) and the connectors which are common to the nodes. The connectors that can be closed by valves, in this case all the connectors, are shown by a valve symbol.

Thus, for example, the last entry in the table states that the two ends of connector 6 have been denoted as 3 and 2, that connectors 3 and 5 join at node 3 and connectors 2 and 4 at node 2, and that connector 6 can be closed by a valve.

A proposed valve sequence is shown in Table 30.20 The authors give an analysis of the consequences of carrying out this sequence. The essence of the method is the use of symbolic logic to determine the consequences of proposed operations such as those put forward in Table 30.20.

30.43.4 Valve operations: Rivas and Rudd planner

The second, more difficult, problem in this work is the synthesis of safe valve sequences, considered by Rivas and Rudd (1974). This may be used to generate sequences for incorporation in operating instructions or to carry out real-time automatic sequencing.

Figure 30.26 shows another simple network of connectors. The system is filled with air and the objective is to initiate flow of hydrogen to the low pressure outlet without allowing hydrogen and air to come into contact under pressure.

The method is based on defining a hierarchy of successively more explicit goals, as shown in Table 30.21. Level 0 contains the overall goal; Level I goals are tasks, ordered to satisfy the Level 0 goal; and Level II goals are at the cause and effect level and are expressed as logical propositions. The objective is to get the computer to accept some intermediate level goal and then itself to synthesize the sequence. In this work the goals at Levels 0, I and II were created manually whilst the valve sequence was synthesized by the program from the Level II goals.

The planner used by Rivas and Rudd does not itself use a hierarchy of goals but is of the non-subgoaling type. It proceeds by adding actions in the order in which they will be executed. This facilitates checking to avoid unsafe states.

In order to limit the search space, the heuristic is adopted that an action is not considered unless it contributes immediately to the achievement of a goal. In other words, the planner looks only one step ahead. The planner uses forward chaining without backtracking. As indicated earlier, this type of planner architecture is well adapted to the avoidance of unsafe states. On the other hand, the translation of high level into low level goals has to be done manually and the planner does not handle combinations and interactions of actions.

Table 30.18 *FAULTFINDER: illustrative example – pump changeover sequence; some minimum cut sets of the fault tree for Step 8 (B.E. Kelly and Lees, 1986d)*

30.43.5 Operating procedures: Fusillo and Powers planner

Fusillo and Powers (1987) have extended the work of Rivas and Rudd to the synthesis of operating procedures in general. In this work procedure synthesis is represented as a state space and operators are used to move between states. A state is a vector of physical quantities such as flow, temperature and pressure, and of statuses of equipment such as valves and pumps. An operator represents the manipulation of equipment such as opening or closing a valve.

Salient features of the method are (1) system decomposition, (2) modelling, (3) constraints and (4) planning. These are now considered in turn.

System decomposition and stationary states

A system decomposition is sought which minimizes the interactions between the subsystems. In the approach adopted, a subsystem is one or more major process units, is physically isolable and, preferably, has stationary states.

A stationary state is essentially a quasi-steady-state condition. An example is a distillation column operating under total reflux. Stationary states are stable intermediate states and are invaluable in planning operating sequences.

For a continuous plant, one start-up strategy is to establish the stationary states of the subsystems with the pathways between them closed and then to integrate the subsystems to obtain the desired plant operating state.

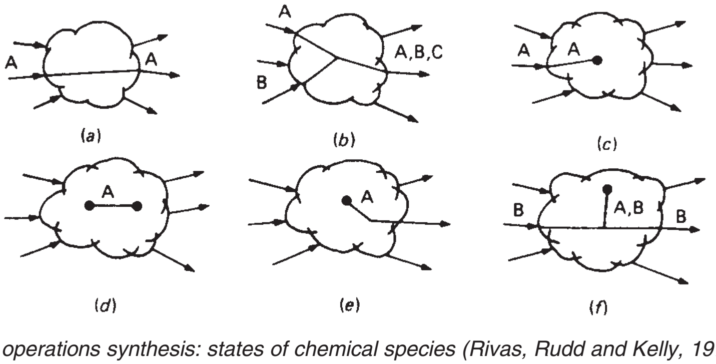

Figure 30.23 *Valve operations synthesis: states of chemical species (Rivas, Rudd and Kelly, 1974) (Courtesy of the American Institute of Chemical Engineers)*

Modelling

For each subsystem a set of global variables is defined. Each unit in the subsystem is modelled in terms of lists of effects that operations of the unit have on the variables in the subsystem. These effects are expressed in terms of a set of multiple discrete values (zero, low–low, low, medium–low, medium, medium–high, high, high–high). To aid planning, each unit type is designated as a source or sink of one or more variables. For example, a heat exchanger may be marked as a source of temperature, or a compressor as a source of flow.

Constraints

Constraints arise from a number of factors. The authors list (1) pre-conditions of unit operations, (2) requirements for a reaction, (3) production requirements, (4) hazards and (5) materials of construction. Use is made of both global and local constraints. A global constraint applies throughout the system. For example, there may be a constraint that two substances that can give an explosive mixture should not be allowed to mix. A local constraint is a pre-condition for some process task. For example, a fired heater should not be started up unless there is flow through the tubes.

Planning

Planning is effected by identifying the conditions that must be changed by the operating procedures, translating the identified changes into tasks, and ensuring that the proposed sequence of tasks will achieve the overall goals.

The planning method used is a modified means–ends analysis. Differences between the current state and the final goal state are computed. A set of intermediate goal states is formulated to reduce the difference between the current state and the final goal state. Movement from one state to another is effected by the application of operators, which are manipulations of units in the subsystems.

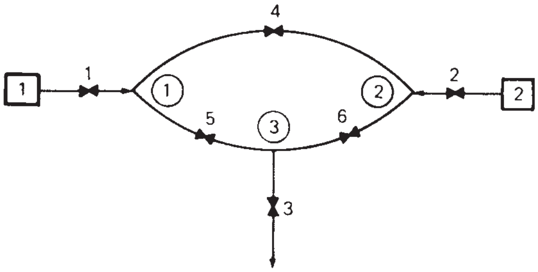

Figure 30.24 *Valve operation synthesis: network of connectors (Rivas, Rudd and Kelly, 1974) (Courtesy of the American Institute of Chemical Engineers)*

Planning proceeds in a hierarchical fashion. For example, the task of starting up a compressor has beneath it in the hierarchy the tasks of starting the seal flush and lubricating oil units. The planner takes an unordered list of manipulations, selects manipulations to achieve the goal and attempts to order the manipulations, using a depth-first search to effect the ordering.

The planning therefore utilizes three main strategies to reduce the search space: (1) constraints, (2) a hierarchy of tasks and (3) stationary states.

Computer program

Fusillo and Powers describe a prototype computer program, POPS, which implements the planning method just described. The program is written in LISP. Use is made of a model library structured in the form of an is-a hierarchy.

Illustrative example

A chlorination plant is used by the authors as an illustrative example of the application of the planning method.

Actions, interactions and unsafe states

The planner of Fusillo and Powers (1987) is characterized by Soutter (1993) as one that attempts to separate action generation and action ordering. It first uses means–ends analysis to generate all the necessary actions and then uses a search to order these actions. Soutter classifies this as a non-subgoaling planner. For such a planner a difficulty is presented by interactions. This is so despite the attempts of the planner, described above, to minimize such interactions.

Fusillo and Powers (1988b) have addressed the problem of interactions. When failure of the plan occurs, new actions are added. However, this modification means that actions are no longer added to the plan in the order in which they will be executed, which means that it is no longer so easy to check for unsafe states.

30.43.6 Purging operations: Fusillo and Powers planner

Another valve operations problem addressed by Fusillo and Powers (1988a) is the synthesis of purging procedures. In purging it is necessary to consider each species separately. Features of a purging procedure are (1) the purging fluid (2) the purging method and (3) the destination of the fluid purge.

The general approach adopted resembles that used in the authors' work on general operating procedures, as described above, in that it involves goal formulation, operator generation and task sequencing. There are,

Table 30.19 *Design of valve sequencing operations: structure of a network of connectors (Rivas, Rudd and Kelly, 1974) (Courtesy of the American Institute of Chemical Engineers)*

Connector	*Node j*	*Node l*	*Connectors joined to node j*	*Connectors joined to node l*	*Species*	*Valves*
1	1		4,5	–	1	X
2	2		4,6	–	2	X
3	3		5,6	–		X
4	1	2	1,5	2,6		X
5	1	3	1,4	3,6		X
6	3	2	3,5	2,4		X

however, certain differences that arise due to the nature of the purging problem. For goal formulation, it is not always possible to discover intermediate goals by the computation of differences as in a normal means–ends analysis. In such cases an alternative method is used which involves the discovery of goals by analysis of the global constraints.

Figure 30.25 *Valve operations synthesis: nomenclature (Rivas, Rudd and Kelly, 1974) (Courtesy of the American Institute of Chemical Engineers)*

Table 30.20 *Design of valve sequencing operations: proposed valve sequence for a network of connectors (Rivas, Rudd and Kelly, 1974) (Courtesy of the American Institute of Chemical Engineers)*

Final state	open	open	closed	open	open

Figure 30.26 *Valve operations synthesis: second network of connectors (Rivas, Rudd and Kelly, 1974) (Courtesy of the American Institute of Chemical Engineers)*

For operator generation, the operators consist of subsystem-wide purge operations. The authors give as an illustrative example the synthesis of a purge sequence for a chloroform reaction system.

30.43.7 Valve operations: Lakshmanan and Stephanopoulos planner

Further work on the synthesis of valve operations has been described by Lakshmanan and Stephanopoulos (1988a,b, 1990).

Lakshmanan and Stephanopoulos (1988a) review the state of planning in AI with particular reference to nonlinear planning and to planning operators. They examine the problem of planning for operations such as valve sequencing and identify as a crucial problem that of the operators to be used. They consider the use of the STRIPS-style operator, which has a single set of preconditions and a single set of post-conditions, and rehearse its limitations. Such an operator cannot handle the situation in process plants where the post-conditions tend to depend on the state of the plant prior to application of the operator. They consider instead the functional operator, which has a number of sets of preconditions and of post-conditions such that a particular set of post-conditions is associated with a particular set of post-conditions. However, they suggest that using functional operators renders planning intractable.

In this and subsequent work, Lakshmanan and Stephanopoulos (1988b, 1990) describe a non-linear planning method based on hierarchical modelling and utilizing domain-specific knowledge. In this method planning proceeds in two principal phases: (1) problem formulation and (2) plan synthesis. The problem formulation phase involves (1) initial state description, (2) goal state description, (3) specification/identification of constraints and (4) specification/identification of stationary states. The plan generation phase involves (1) identification of primitive operations, (2) construction of a partial plan, and (3) synthesis of complete plans.

The approach adopted is domain-specific and utilizes a hierarchy of models. At the first, and lowest level, are the system variables and parameters. Each variable or parameter is formally defined as a collection of structured knowledge with attributes such as current value, current trend, range of values, etc. At the second level are the process 'streams', which include flows of mass, energy and momentum. The third level consists of constraining relationships such as mass, energy and momentum conservation, flow-pressure drop relations, and so on. The fourth level is the constraining relationships of the sets of defined process operating conditions. There is a corresponding hierarchy of structures, starting at the bottom with models of actual and

Table 30.21 *Design of valve sequencing operations: hierarchy of goals for synthesizing valve sequences for second network of connectors (Rivas, Rudd and Kelly, 1974) (Courtesy of the American Institute of Chemical Engineers)*

Level 0 goal	*Level I goal*	*Level II goal*	*Valve operation*
Initiate hydrogen flow to low pressure outlet	Evacuate air	Stop air flow	Close 3
		Open system to low pressure outlet	Close 5
Final sequence (close 3, open 5, open 1)	Initiate hydrogen flow		Open 1

notional ports, and rising through models of composite segments, of process units, of processing segments and of the complete plant. Planning then involves the identification of operators, their application to produce partial plans and a process of generate-and-test. The authors give as an illustrative example a catalyst regeneration problem.

In that it solves valve sequencing operation by the use of domain-specific knowledge, the program is not a general OPS planner. This planner also is characterized by Soutter (1993) as a non-subgoaling planner.

30.43.8 Valve operations: planner of Foulkes *et al.*

Another study of this kind is the work on valve and pump sequencing carried out by Foulkes *et al.* (1988). The authors begin with a statement of the OPS problem. In a typical process system there may be a very large number of potential paths and thus a very large search space. Furthermore there are then likely to be a large number of solutions that are nearly, but not quite, correct.

They give a formal treatment of the combinatorial explosion problem and illustrate it by considering the plant used in the work of Rivas and Rudd (1974), in which the number M of on–off valves was 17. The number of different combinations of valve state is thus $2^M = 131{,}072$.

Foulkes *et al.* argue that where the number of potential valve changes is large, the prior formulation of operating sequences for infrequently performed operations is not practical and is not attempted. The purpose of the work was to devise a system that could be used off line to devise on demand a suitable sequence for a particular operation.

They describe a method in which the plant is decomposed into the elements ‘pipe fragment’ and ‘pump fragment’, which consist of a piece of pipe with a valve or a pump, respectively, on the end. Planning proceeds by searching first for paths and then for sequences of valve and pump operations, subject to constraints.

The program was written in Prolog and illustrates the exploitation of the facilities of that language for declaring ‘operators’, for ‘pattern matching’ and for depth-first search.

30.43.9 Operating procedures: Soutter and Chung planner

An attempt to develop a general-purpose method OPS known as the Chemical Engineering Planner (CEP), is described by Soutter and Chung (1995b). This planner is intended to perform both general OPS tasks and valve operations synthesis.

CEP is a hierarchical planner. It receives higher level goals and translates them into lower level goals. The planning engine is complemented by an inference engine, which performs the goal translation just described. This inference engine uses backward chaining. CEP is believed to be the first planner to use both types of engine.

CEP is described as a STRIPS-based planner, apparently primarily in recognition of its use of STRIPS-type operators. The planning engine in CEP, however, follows the strategy of least commitment, utilizing partial ordering. In other words, CEP is a non-linear planner. These two features of CEP, backward chaining and non-linear planning, keep it compatible with the main thrust of development in AI planning.

The planner in CEP is assisted by ‘agents’ that perform various specialist functions. One agent monitors conflicts, another advises on complex goals, and so on.

The problem of unsafe states is handled in CEP in terms of global constraints. A global constraint is a set of unsafe states. Goals of prevention are used to prevent entry into an unsafe state.

CEP utilizes a problems specification language. This language describes four types of knowledge: (1) the domain objects, (2) the operators, (3) the global constraints and (4) the problem specification.

The inference engine utilizes inference operators. For example, the high level goal *flow* (*inlet, outlet*) is the establishment of flow from inlet to outlet of a pipe. This is translated by the inference engine using the appropriate inference operator into the lower level goals *open* (*inlet, middle*) and *flow* (*middle, outlet*). The latter is further translated in a similar way. The relevant inference operator is:

```
operator FindFlow
(
 pipe?a; pipe ?b
 pipe ?c;

 expand
 *flow(?a, ?b)
 using
    open(?a, ?b)
    flow(?c, ?b)
 end
)
```

In some cases an inference operator that defines a hierarchy is termed a hierarchical operator.

As an illustration of planning using CEP, consider the problem of the start-up of a compressor described by I.S. Sutton (1992), in an account of the writing of operating instructions. The problem may be explained by reference to Figure 30.27. Figure 30.27(a) shows the compressor V-206 itself. The task set is to shut-down compressor C-206. Figure 30.27(b) shows the steps in the shut-down sequence given by Sutton.

For the planner the task is to achieve the goal *shut-down of V-206 is true*. Figure 30.27(c) shows the definition of V-206 as an object. Figure 30.27(d) shows a typical hierarchical operator *DoShutdown*. Figure 30.27(e) shows the translation of the high level goal into the lower level, or induced, goals. Figure 30.27(f) shows a typical planning operator *CheckIdle*.

The operation of the planner is indicated by the following brief outline. The goal is *shut-down of V-206 is true*. This goal is translated by the inference engine using the hierarchical operator *DoShutdown* into the three subgoals:

(1) pressure of V-206 is atmospheric;
(2) isolated of V-206 is true;
(3) turned-off of V-206 is true.

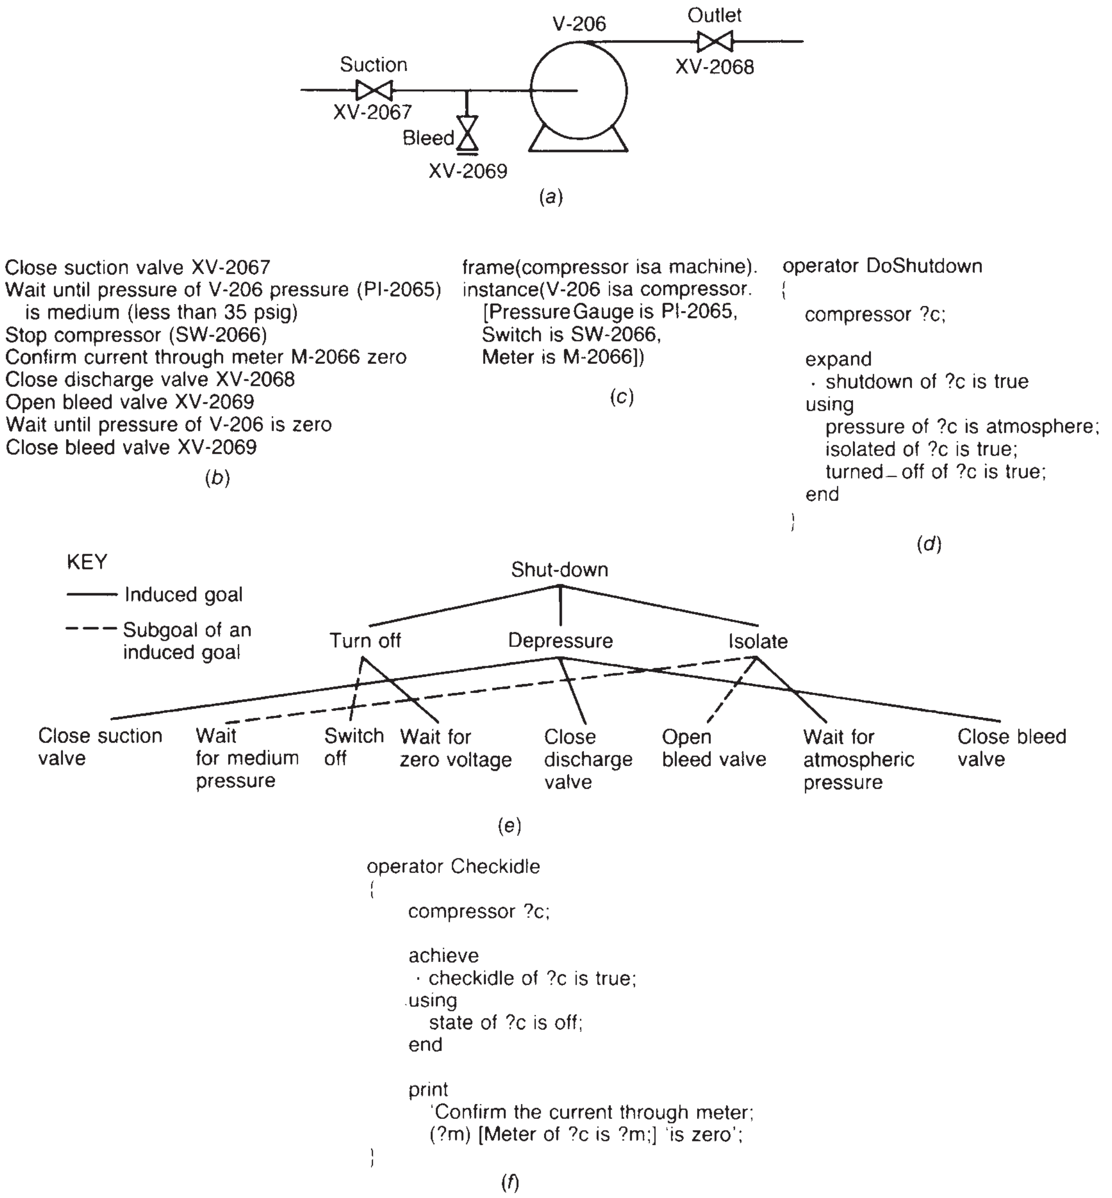
The planner selects the first subgoal and proposes the addition to the plan of the action Depressure. The corresponding operator has the pre-conditions

(1) pressure of V-206 is medium;
(2) bleed of V-206 is open;

and the effect

(1) pressure of V-206 is atmospheric.

However, if this action is entered as the start of the plan, a global constraint is violated. This global constraint is that the bleed valve should not be open when the compressor is on. This constraint is violated because the initial state is



```
Close suction valve XV-2067
Wait until pressure of V-206 pressure (PI-2065)
  is medium (less than 35 psig)
Stop compressor (SW-2066)
Confirm current through meter M-2066 zero
Close discharge valve XV-2068
Open bleed valve XV-2069
Wait until pressure of V-206 is zero
Close bleed valve XV-2069
```

(b)

```
frame(compressor isa machine).
instance(V-206 isa compressor.
  [PressureGauge is PI-2065,
  Switch is SW-2066,
  Meter is M-2066])
```

(c)

```
operator DoShutdown
{
   compressor ?c;

   expand
    · shutdown of ?c is true
   using
      pressure of ?c is atmosphere;
      isolated of ?c is true;
      turned_off of ?c is true;
   end
}
```

(d)

```
operator Checkidle
{
   compressor ?c;

   achieve
    · checkidle of ?c is true;
   .using
      state of ?c is off;
   end

   print
      'Confirm the current through meter;
      (?m) [Meter of ?c is ?m;] 'is zero';
}
```

(f)

Figure 30.27 *Operating Procedure synthesis: shut-down of a compressor (Soutterand Chung, 1995b): (a) Compressor system V-206; (b) steps in shut-down sequence (after Sutton, 1992); (c) definition of compressor V-206 as an object; (d) hierarchial operator DoShutdown; (e) translation of high level goal into low level goals; (f) planning operator Checkidle*

that the compressor is on. In order to prevent violation a new action is added to switch off the compressor before the action *Depressure* is taken.

The OPS output given by the planner is essentially the same as that shown in Figure 30.27(b).

30.43.10 Operation procedures network

Most work on OPS is based on a component oriented approach. Work utilizing instead Forbus' qualitative process theory (QPT) has been described by Rotstein, Lavie and Lewin (1992), who propose the concept of an operation procedures network (OPNet).

The motivation for this approach is the deficiencies of the component based method in the treatment of batch processes. QPT lends itself better to the handling of the basic transformations of mass and energy in such processes.

The method described by the authors involves the following stages: (1) the definition and ordering of the mass and energy balances, (2) their instantiation in a particular plant structure, (3) their ordering in space and time, and (4) the synthesis of the operating procedures.

30.44 Process Monitoring

Process monitoring has several aspects. One is the detection of a disturbance or abnormality which falls short of an identifiable fault and which does not necessarily result in any process alarm. The second is the handling of alarms caused by some fault or operator action, the diagnosis of the fault and the response to it. The third is the detection of a incipient malfunction which has not yet resulted in a fault or an alarm. There are advanced methods, including AI techniques, which address all three of these. The first aspect is considered in this section and the others in the two subsequent sections. An overview of some of the methods available for these functions is given in *Fault Detection and Diagnosis in Chemical and Petrochemical Processes* (Himmelblau, 1978).

30.44.1 Disturbance characterization

One form of monitoring which is in widespread use is data reconciliation. It is important for process operation to have a valid mass and energy balance. Factors such as process transients and measuring instrument errors mean that it is not a trivial matter to obtain such balances.

Data reconciliation is able to draw on a large body of work on estimation and filtering, and some form of data reconciliation is quite common practice. Quite separately from this, the process operator monitors the process and comes to a judgment as to whether it is in a normal condition or whether there is a disturbance or abnormality. In doing this he or she makes use of his or her mental model and of heuristics such as limit, or landmark, values and rules of thumb.

There is now emerging a formal approach to the interpretation of process information. Thus, Cheung and Stephanopoulos (1990) have described a methodology for transforming the information given by trend records into indicators of process state that are sufficiently quantitative to allow the operator to make powerful inferences about trends in variables which are not measured.

Some of the difficulties faced by the process operator in interpreting process information are enumerated by Cheung and Stephanopoulos. Some causes of these difficulties are that there may be (1) process outputs changing at different rates, (2) dead time and inverse responses, (3) interactions between control loops, (4) conflicting information from sensors and (5) incomplete information due to lost' sensors. The operator may therefore find it have difficult to (1) distinguish between normal and abnormal conditions, (2) assess current trends and anticipate future states, (3) identify the causes of these trends and (4) plan and schedule sequences of operating steps leading to a new operating level.

Another approach is that described by Whiteley and Davis (1992). These authors treat the problem in terms of adaptive pattern recognition and develop a qualitative interpretation of the process information.

30.44.2 Trend and state display

Turning to displays of the process trends and state, computer graphics have made it possible to create displays that previously could not be contemplated. The starting point for the design of such displays should be a consideration of the operator's tasks and problems, and a display should evolve as a solution to these. Otherwise there is a danger that the display will be a solution looking for a problem. Various types of display have been developed by computer manufacturers for loop parameters, trend records, etc.

Display of system state is one of the most important types of display. Some illustrative examples of this type of display are given in Figures 30.28–Figure 30.31.

Figure 30.28 represents a mimic diagram. This particularly display is simply a colour slide which the operator uses to help him identify equipments. VDU displays can be provided on similar lines with continuous updating of equipment status.

Figure 30.29, after Wolff (1970), shows a polar plot of eight variables in which the length of each vector is proportional to the measured value. The vectors are scaled so that at the normal values their tips touch a common circle. Figure 30.30, after H.H. Bowen (1967), illustrates a rather similar principle in which the variable vectors are scaled to form a common surface, Figure 30.30(a) showing a normal condition and Figure 30.30(b) an abnormal one. Figure 30.31, after Stainthorp and West (1974), shows a status array for a distillation column with methanol and propanol feeds. The rows represent process variables and the items in them absolute, deviation and rate-of-change alarms or the normal condition as shown in Figure 30.31(a). Figures 30.31(b)–(f) correspond to the conditions normal operation, severe upset, shut-down necessary, clear for start-up and near-normal operation (during start-up), respectively.

Displays have been described for facilities such as manual control (e.g. Crawley, 1968), scheduling (e.g. Ketteringham, O'Brien and Cole, 1970; Ketteringham and O'Brien, 1974), etc. Other displays for activities such as malfunction detection are described below.

The degree of sophistication in the information processing underlying a display varies greatly and may not be apparent from the display itself. Thus, the polar and surface plots illustrated above require only scaling of the measurements, while other displays involve the use of predictive models, estimation techniques, etc.

30.44.3 Multi-media aids

Another development is the use of multi-media aids that exploit the potential of combinations of audio, visual and other forms of information presentation. Accounts are given by Alty and McCartney (1991) and Alty and Bergan (1992).

The approach taken in this work to use multi-media aids under the control of a knowledge based system. Some media that are used in such work include: text, static graphics and diagrams, dynamic graphics, animation, sound, speech and video. There is a wealth of research available in the human factors literature on the relative efficacy of different media for the transmission of different types of information.

A system that uses alternative media needs to be supported by a resource management facility that selects and schedules the media. In the work described, use is made of a knowledge based system for this purpose.

There is no lack of options for the design of such a system, but it is still early days in the development of the principles that should govern such design. Alty and Bergan (1992) have described a laboratory study involving the Grossman water bath experiment on manual control with multi-media aiding. Experiments on the use of multi-media

facilities in industrial process control rooms have been conducted and the reception is said to have been favourable.

30.44.4 Expert systems

There are also developments in the application of expert systems to process monitoring. There is a considerable monitoring element in the expert systems for process control described in Section 30.35. In some expert systems, however, assistance to the process operator in assimilating process information is the prime aim. An example is ESCORT, described by Sachs, Paterson and Turner (1985).

30.45 Fault Administration

The second aspect of process monitoring is fault administration. One of the principal functions of a computer system in process control is to assist the operator in the handling of fault conditions. The use of the computer to enhance the alarm system has been described in Chapter 14. Among the enhancements mentioned there are systems in which alarm diagnosis, or alarm analysis, is performed. In those early systems the alarm diagnosis facilities provided were fairly basic and the data structure for the diagnosis was created manually. Since then a good deal of work has been done on alarm diagnosis systems which have more

advanced facilities and in which the alarm data structure is generated automatically.

The bulk of the work on fault administration has been concerned with alarm handling and diagnosis, although there is some work on other aspects such as on advice for corrective actions and on prediction times at which excursions across alarm limits will occur.

Fault administration has proved particularly attractive to workers in AI and expert systems. For example, estimates of the proportion of applications of process industry expert systems that are in this field range from some one-third to one-half.

A number of distinct phases may be discerned in work on alarm handling and diagnosis: (1) manual design of alarm analysis systems for industrial nuclear power stations; (2) early explorations of the systematic creation of the alarm data structure; (3) disturbance analysis systems, prompted by the Three Mile Island accident; (4) expert systems and (5) various AI approaches, notably those based on modelling and on neural networks. A review of developments to the third of these phases has been given by Lees (1983c).

Fault administration is another field where qualitative modelling, including fault propagation modelling, plays a central role in many of the methodologies developed.

30.45.1 Alarm structure and display

Before describing some of the advanced aids developed for handling alarms, it is pertinent to consider the quality of the basic alarm system provided. It makes little sense to draft a sophisticated alarm diagnosis system onto a fundamentally defective alarm system design. Two aspects of this design are of particular relevance. One is the structure of the alarms and the other their display.

The issue of the structure of the alarm system has been addressed in several different ways. Some of these take as their starting point failures and others take the resulting undesirable events. Thus, one approach is to list the faults that it is desirable to be able to identify because they are in some way significant, and to assess the ability of the system to give an unambiguous indication that a particular fault, and no other, has occurred. In other words, an assessment is made of the degree of fault discrimination. The problem is akin to that of the observability of process variables. Work in this area has been described by Park and Himmelblau (1987).

Another approach, described by Lambert (1977) and based on his concept of the probabilistic 'importance' of the events in a fault tree, is to create fault trees for the principal undesired events on the plant and to identify in each tree measurable events which rank high in importance.

The approach taken by Modarres and Cadman (1986) is not dissimilar, but centres rather on the effectiveness of the alarm system in supporting the activities of the process operator. The method described is based on the use of goal trees for the operation of the plant and of decision trees, which can be constructed in parallel to show all the operator actions required to achieve each goal and also the consequences of failure to achieve the goal.

These various approaches are not, of course, mutually exclusive.

30.45.2 Alarm trees

Work on alarm diagnosis for process plants took as its starting point the use of alarm handling systems in nuclear plants, described in Chapter 14. Thus Welbourne (1965, 1968) gives an account of the use of alarm trees. A simple alarm tree is shown in Figure 30.32. The alarm tree gives the relations between process alarms, and does so economically without duplication of information. There is no emphasis on any particular top event. Deduced alarms may be added to the tree, but the tree is self-sufficient without them.

Early work on alarm diagnosis for process plants was done by Andow and Lees (Andow, 1973; Andow and Lees, 1975) and Powers (1975). Andow and Lees explicitly took the view that alarms diagnosis was likely to find a role on process plants only if the necessary knowledge base could be created with reasonable economy, and that this knowledge base should consist primarily of models rather than rules.

They describe a method for creating the alarm data structure based on fault propagation models of the type described in Section 30.36. The flow diagram is converted into a block diagram of linked unit models. The models used are simple functional models such as that of the mixing tank shown in Figure 30.33. This representation is then converted into a network of interacting process variables, effectively a digraph, and this network is then reduced to the network of those process variables on which there are alarms. The method utilizes list processing to produce the alarm network automatically from the unit models. Figure 30.34 shows two alarm trees for the mixing tank system. Whereas the conventional alarm tree is as shown in Figure 30.34(a), the alarm tree obtained by this method is that given in Figure 30.34(b).

The type of display envisaged by Andow and Lees is illustrated in Table 30.22, which is a form of truth table. In a conventional truth table an active alarm is TRUE and an inactive one is FALSE. The truth value of deduced alarm X depends on the truth values of the set of process alarms. This deterministic approach may be replaced by a probabilistic one, as used in Table 30.22. In this table the evaluation TRUE is obtained if the sum of the products of the process alarms A–I and the probability weightings

Table 30.22 *Modified 'truth table' containing probablities for a deduced alarm (Andow and Lees, 1975) (Courtesy of the institution of Chemical Engineers)*

Process alarms and the their probability weightings									*Target value*	*Deduced alarm message*
A	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*I*		
0.7	0.45	0.8	0.3	0.65	–	–	–	–	2.1	Fault X
0.3	0.75	–	–	–	0.9	0.8	–	–	1.85	Fault Y
–	0.2	0.45	–	0.65	0.7	–	0.65	0.3	1.75	Fault Z

exceeds the target value, active alarms having a value 1 and inactive ones 0. The normal truth table is a special case of this more general table.

30.45.3 Fault trees

Another early approach taken to the creation of an alarm data structure is the use of fault trees. A fault tree shows the relation between the top event, which is usually some hazardous condition, and the bottom events, which are typically mechanical faults. It tends to emphasize these top and bottom events. A separate fault tree is needed for each top event.

The use of alarm structures based on fault trees was suggested in early work by Powers and co-workers. An outline of an approach towards the synthesis of fault trees was been described by Powers and Tompkins (1974a,b), whilst Powers (1975) conducted experiments in which a fault tree was used to assist an operator to diagnose inert gas blanketing in a heat exchanger. The use of fault trees to create the alarm data structure was also investigated by Martin-Solis, Andow and Lees (1977). They used fault propagation models to derive mini-fault trees, as already described in Section 30.42, and obtained alarm structures essentially similar to digraphs containing AND gates. The work showed that the veracity of the instrument readings is a significant problem in computer alarm diagnosis, just as it is in human fault diagnosis.

This work on alarm diagnosis by Andow, Lees and co-workers was the origin of their work on fault propagation modelling, which has since found further application in hazard identification and fault tree synthesis.

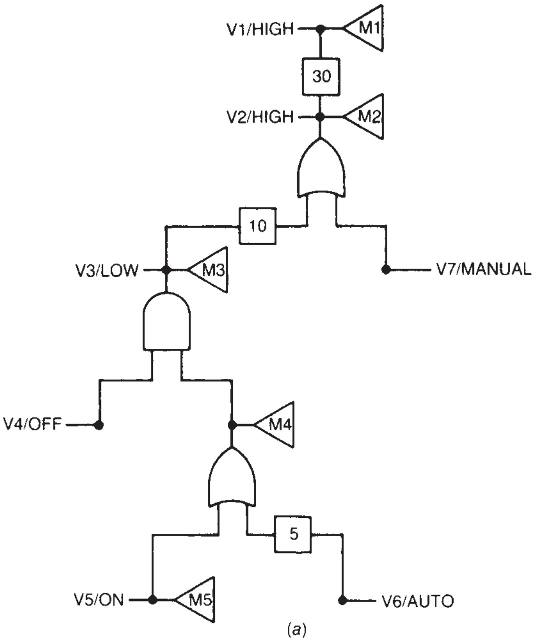
30.45.4 Disturbance analysis systems

The accident in 1979 at Three Mile Island (TMI), described in Appendix 21, highlighted the importance of alarm systems and alarm diagnosis. The problems experienced by the operators led the task force to make recommendations for the use of a safety status display and for work to establish the feasibility of a disturbance analysis system (DAS).

TMI gave impetus to work in course at the Electrical Power Research Institute (EPRI), Palo Alto, California, described by Frogner and Meijer (1978, 1980), Long (1980), Long *et al.* (1980) and Meijer, Frogner and Long (1980).

An initial study was made of the potential benefits of a DAS. The assessment was made by selecting suitable nuclear power station subsystems, obtaining data on the outages of these subsystems in existing stations, and estimating the proportion of these outages which would probably have been avoided using a DAS facility. An initial survey showed that out of 1161 outages there were 274 that appeared preventable by more rapid action aided by a DAS. These authors subsequently did work with an experimental DAS that showed appreciable reductions in operator response time between the two cases where the DAS was not used and where it was.

Long gives an analysis of some of facilities that a DAS might provide. It could upgrade the plant signals and infer important parameters from simple analytical models, could monitor the mode of operation and compare the configuration with simple plant configuration models, and could recognize disturbances and provide assistance with procedures for off-normal conditions.



(*a*)

Time* (s)	Event	Result of the cause–consequence analysis
0	V4 = OFF and V5 = ON	M4 and M5 active M3 potentially active
1	V3 = LOW	M3, M4 and M5 active M2 potentially active
11	V2 = HIGH	M2,...., M5 active M1 potentially active
41	V1 = HIGH	M1,...., M5 active

*Initial conditions: $V_1 \neq$ high, $V_2 \neq$ high, $V_3 \neq$ low.

(*b*)

Figure 30.35 *Disturbance analysis system: conceptual example of a cause-consequence tree and of a sequence of events in the tree (Frogner and Meijer, 1980): (a) cause–consequence tree; (b) sequence of events (Courtesy of the Electrical Power Research Institute)*

The DAS developed in this work utilizes a multi-level methodology. Level 1 is based on decision tables, the inputs to a table being one or more sensor signals and the output a message. Level 2 utilizes the cause–consequence tree (CCT) method. Level 3 provides a facility for the use of quantitative models.

The Level 1 decision tables are relatively simple and serve to reduce the proportion of signals passed on to Level 2. The more complex signal patterns are analysed in Level 2 using the CCTs. The general form of the CCTs and the terminology used are shown in Figure 30.35. The tree in Figure 30.35(a) consists of nodes connected by arcs, the nodes being associated with attributes. These attributes are a variable identifier (V1, V2, . . .), a required condition for the variable (HI, LO, . . .), a message identifier (M1, M2, . . .), a logic gate (AND, OR, . . .) and a time delay (5 s, 10 s, . . .).

The methodology defines a node as observable if it associated with a variable measured by a sensor. An observable node is given a required condition. If this condition is met, the node is active. A time delay is the expected minimum time between two events. If the observed time between two events is less than the time delay, or if the observed sequence does not correspond to that in the tree, it is assumed that the branch is not active. The use of time delays, therefore, contributes to the unique identification of a disturbance. If a node is active and it has associated with it a message, that message is also active. If a node is not active solely because the time so far elapsed is less than the time delay, the node and the associated message are potentially active. A typical sequence of events for the CCT shown in Figure 30.35(a) is shown in Figure 30.35(b).

The status of a variable is shown by one of a set of status indicators. These status indicators are listed in Figure 30.36(a) and the state transition diagram for the indicators is shown in Figure 30.36(b). The normal value of a status indicator for a variable is S_0. If a value goes outside its limit, the indicator is set at S_1. When the disturbance analysis starts, the indicator is set at S_2. The result of a disturbance analysis causes the indicator to be set at S_4 if a satisfactory message is determined or at S_3 if the cause cannot be found. Once the value is outside its limits, this value is latched for a period of T_1 seconds for an S_4 variable or T_2 seconds for an S_3 variable. If the value returns inside the limit, it is set at S_5 once the latching period has elapsed. Again the disturbance analysis is actuated, but this time with low priority and the indicator is set at S_6. When the disturbance analysis is complete, the indicator is set at S_0. Status indicators S_7–S_9 and S_{10} are associated with algorithms that deal with spurious events and failure events, respectively. Methods are given for the treatment of faults on, and of temporary excursions of, sensors.

The data acquisition system (DAS) was tested on a training simulator and operated by process operators from nuclear power plants. In general, it behaved reasonably well, but the reduction in average operator response time from 34 to 30 seconds was not great. The time required for the operator to move physically to the appropriate part of the control room accounted for an appreciable fraction of the total response time in both cases.

A number of human factors points emerged during this work, of which just one may be quoted. Frogner and Meijer (1980) state:

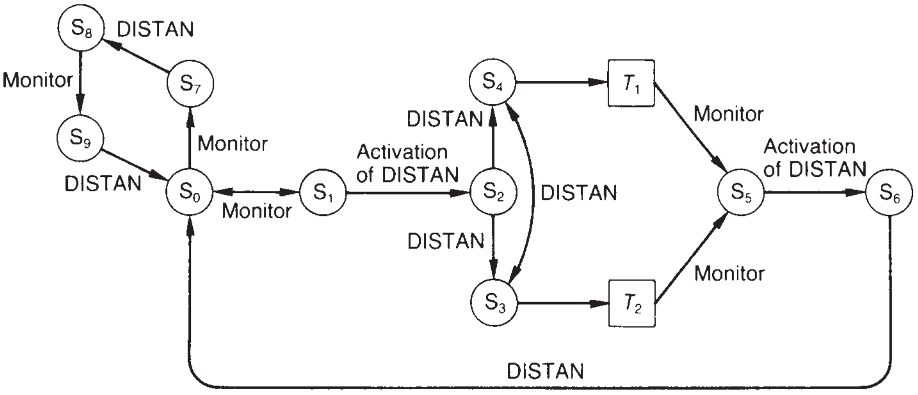
> The DAS effectiveness is reduced if the results of the diagnosis are presented without adequately conveying the status of the process. For the operator to exercise judgement and not just function as an automaton, he must understand the state of the plant and the reason for his action. In this respect, the condensed one-line DAS messages need improvement. It is recommended that future systems incorporate DAS messages into a more informative picture of the state of the process; for example, by using process and instrumentation diagrams.

In this method, the CCTs are created manually by the analyst. Considerable effort was required to produce the model database, which is plant specific, and this effort was seen as a factor limiting application.

Another major project on disturbance analysis which took place at about the same time was the joint project between the Gesellschaft fur Reaktorsicherheit (GRS) at Garching, in then West Germany, and the Institut for Atomenergi at Halden, Norway, involving development of

S_0	Normal condition: variable is within its specified limits
S_1	Value was within limits and it just went outside
S_2	Disturbance analysis is currently performed due to S_1
S_3	Analysis due to S_1 is complete: cause not known
S_4	Analysis due to S_1 is complete: cause known
S_5	Value was outside limits and it just went inside
S_6	Disturbance analysis is currently performed due to S_5
S_7	Too high a frequency of events has been registered for this variable. Analysis is being performed or waiting on DAS
S_8	Variable causing spurious events
S_9	Spurious event causing variable becomes normal. Analysis is being performed or waiting on DAS
S_{10}	False event

(*a*)



(*b*)

Figure 30.36 *Disturbance analysis system (Frogner and Meijer, 1980): (a) status indicators; (b) state transition diagram for status indicators. DISTAN denotes Disturbance Analyser (Courtesy of the Electrical Power Research Institute)*

DAS systems known as STAR for the nuclear power plants at Grafenrheinfeld and Biblis in the former country.

As in the EPRI work the fault propagation is represented by cause–consequence diagrams (CCDs). Some of the differences between the EPRI and GRS systems have described by Frogner and Meijer (1978) and Bastl and Felkel (1981).

30.45.5 Expert systems

One of the modes of operation of the commercial expert system PICON, referred to above in Section 30.36, is the alarm management mode. Accounts of its operation in this mode have given by Berkovitch and Baker-Counsell (1985), R.L. Moore (1985) and Rand (1987). The latter describes the creation of the rule base by observation of operators, interviewing of operators and operator input of rules, with the latter being favoured.

An account of ESCORT, a system for detection and diagnosis of faults and the detection of instrument malfunction is given by Sachs, Paterson and Turner (1985).

Two large expert system projects FALCON (Shirley, 1987) and REACTOR (W.R. Nelson, 1982) on systems with large rule bases have been carried out and are reported to have had success in some applications.

An expert system based on EXPERT has been developed by Mizoguchi (1983). The application described is fault diagnosis on a nuclear reactor primary cooling system. The rule base consists of some 76 rules, of which 6 are finding-to-finding, 60 finding-to-hypothesis and 10 hypothesis-to-hypothesis rules.

In the expert system for malfunction diagnosis described by Shum *et al.* (1988), use is made of a hierarchical structure in which the nodes represent particular malfunction hypotheses. Use is made of the concept of 'specialists', a concept used also in the design language DSPL, referred to in Section 30.27. There is a collection of 'specialists' coordinated to arrive at an overall diagnosis. Each specialist possesses compiled and qualitative knowledge for the evaluation of a hypothesis. The method is claimed to be especially effective at handling multiple symptoms and multiple malfunctions.

There are a number of other systems which are described as expert systems, but which place emphasis on models as well as rules, as described below.

30.45.6 Model-based methods

Iri *et al.* (1979) have used digraph models to represent the alarm structure of a plant. This work has subsequently been developed in a number of studies, including those of Kokawa, Miyaki and Shingai (1983), Shiozaki *et al.* (1985) and Qian (1990).

An expert system MODEX for malfunction diagnosis has been described by Rich and Venkatasubramanian (1987), and its successor MODEX2 has been described by Venkatasubramanian and Rich (1988). The system is based on a two-tier architecture, consisting of a bottom level of process specific, compiled knowledge and a top level of process general, deep level knowledge. An agenda-based inference control algorithm generates malfunction hypotheses from structural and functional information about the process. Diagnostic reasoning alternates between the two levels.

Finch, Oyeleye and Kramer (1990) given an account of a program MIDAS which diagnoses the causes of plant disturbances, including equipment degradation and failure, sensor failure, incorrect operation and external disturbances. The diagnosis utilizes an event model to construct clusters of events, each cluster being associated with a single fault. The program handles features such as variations in order of detection, complex dynamics, sensor failures and multiple plant failures.

In the work of Ramesh, Shum and Davies (1988) the emphasis is on the nature of the tasks involved in diagnosis. One task is associated with the plant sensor and another with the product quality data. Ramesh, Davies and Schwenzer (1992) develop this approach, with an investigation of the information processing tasks underlying diagnostic reasoning.

The approach described by Grantham and Ungar (1990) differs from others in two main ways. It utilizes Forbus' qualitative process theory (QPT), and it can automatically modify the unit models, allowing identification of faults that significantly change unit behaviour. The authors characterize their method as one that operates at a higher level of generality, and hence robustness, by giving the system an ability to create its own models from a description of the substances and objects present and the prevailing process conditions. It has the ability to identify faults that change significantly the mode of operation of a unit, without the need for explicit fault modes.

A prototype expert system PRODES for fault diagnosis is described by Labadibi and McGreavy (1992). The system utilizes fault propagation models elicited from the user and cast in the form of decision tables.

Saelid, Mjaavatten and Fjalestad (1992) have described an expert system for operator support with object oriented features and utilizing an expert system shell. The system detects disturbances in the connections between units, identifies the faulty unit and then initiates diagnosis of that unit. This internal unit diagnosis utilizes a combination of process models, fault trees and Kalman filtering.

30.45.7 Fault-tree-based methods

Ulerich and Powers (1988) have described a method for fault diagnosis based on fault trees. This work extends the earlier work of Powers (1975) on this topic. It utilizes the FTS methodology for fault tree synthesis from digraphs developed by Powers and co-workers, as described in Section 30.41. A prior fault tree is created. From this prior tree there is then created a further fault detection tree in which there is attached to each basic event a verification; the event is treated as valid only if it is verified. The verification consists of a set of process indications that must all be satisfied.

30.45.8 Goal tree–success tree method

The expert system GOTRES for fault diagnosis is described by Chung, Modarres and Hunt (1989). The system is based on the goal tree–success tree (GTST) method illustrated in Figure 30.37. The tree is developed from the

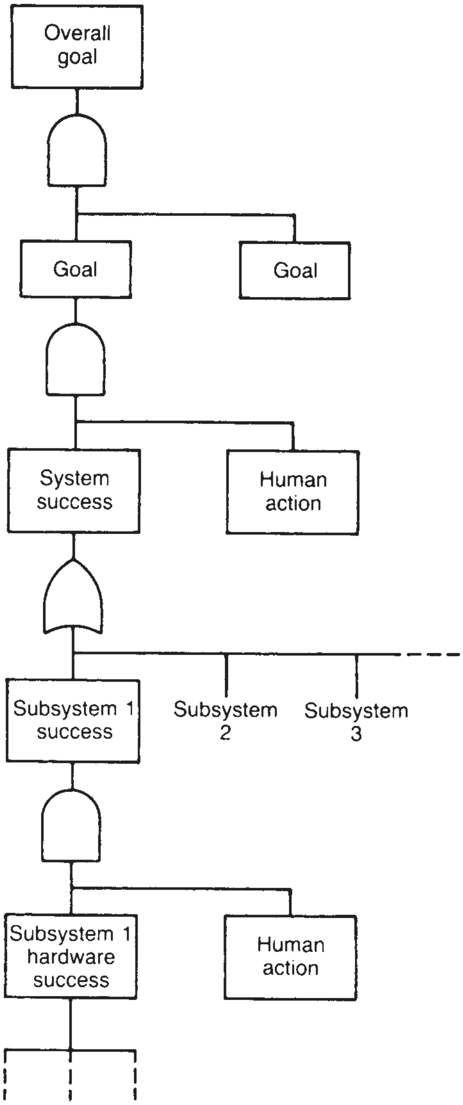


Figure 30.37 An outline goal tree–success tree

process objective at the top, downwards to successively lower levels of goal. Since all goals are necessary for success, the logic gates relating the goals are all AND gates. The nature of the tree changes at the point where it is no longer possible to develop the tree without reference to hardware. Attached to each goal is a goal verification procedure that uses relevant process indicators to determine whether the goal is satisfied.

The authors state that experience shows that the use of a success tree rather than a failure, or fault, tree allows a more succinct treatment. They also suggest that a success orientation corresponds better to human thinking, and illustrate this with the analogy of a car journey, where the driver concentrates on the success paths rather than the failure paths.

Chen and Modarres (1992) describe an expert system FAX for the diagnosis of faults and advice on corrective actions, with emphasis on the latter. The control objective is represented as a goal tree with success paths for both plant and operator inputs, and corrective actions are found by an adaptive search.

30.45.9 Neural networks

A quite different approach to alarm diagnosis is the use of neural networks, for which this appears a natural application, and a number of studies have been published. Neural networks were described in Section 30.21. Most of the work on such artificial neural networks (ANNs) is concerned with back-propagation networks (BPNs). The studies done cover learning, recall and generalization.

Hoskins and Himmelblau (1988) explore the characteristics of ANNs desirable for knowledge representation in processes and illustrate their discussion with an account of the use of an ANN to discriminate between faults in a simple process.

A further exploration of ANNs is described by Ungar, Powell and Kamens (1990). ANNs are able to learn nonlinear and logical relationships as well as linear ones. They describe work using an ANN on a simple process in which a comparison is made between performance with discrete inputs, that is, alarms, and with continuous inputs, that is, sensor readings, and also work on the effect of noise.

Venkatasubramanian, Vaidyanathan and Yamamoto (1990) have studied the performance of ANNs under certain taxing conditions, including multiple faults and sensor faults.

M.A. Kramer and Leonard (1990) consider particularly the problems of extrapolation outside the conditions covered in the learning set. Such extrapolation becomes necessary when the learning set is undersized, when the parent distributions of fault classes undergo shifts, and when input data are corrupted by missing or biased sensors. They identify as a problem the inability of an ANN to detect when it lacks the data to effect a reliable classification.

30.45.10 Response advice systems

An account of a system for providing the operator with advice on the response to failures of critical safety functions is given by Nelson and co-workers (W.R. Nelson, 1984; W.R. Nelson and Blackman, 1985; W.R. Nelson and Jenkins 1985), who describe the Response Tree Evaluation project, one of those initiated following Three Mile Island. The purpose of the system is to select a response to provide by alternative means the safety function that has been disabled. The program creates a goal tree for the provision of the function, evaluates the availability of the various units, and searches for success paths. The search can be quite complex, since in general there is redundancy not only between units but within them.

Reference has already been made to the work of Chen and Modarres (1992) on the expert system FAX for the diagnosis of faults and advice on corrective actions.

30.45.11 Influence modelling and assessment system

The bulk of the work described so far deals with engineering problems of alarm diagnosis. It is necessary, however, to consider the ultimate function of such a system. This function is to provide support to the process operator, unless he be completely eliminated. As discussed in Chapter 14, the provision of an effective computer-based aid for the handling of alarms is fraught with difficulty.

This problem has been addressed by Embrey (1986). He takes as his starting point the fact that whereas for most types of human error the probability of recovery tends to be high, for diagnosis it is low.

In order to aid diagnosis, it is necessary to have some appreciation of the way in which the operator goes about it. In one view, the operator uses two distinct approaches. The first is the use of relationships between symptoms and faults. These are the symptomatic rules, or S-rules. They may be formally represented as a fault-symptom matrix (FSM). The other approach is topographic search. In this mode the operator makes a series of good/bad assessments based on his or her knowledge of the locations of and relationships between system components. These are the topographic rules, or T-rules. Since the use of S-rules involves less effort, the operator will generally apply these first, before resorting to the T-rules.

The FSM has been quite widely used in the process industries, and can be a useful aid to symptom based diagnosis, but it is rather inflexible and does not accommodate changes over time. Alternatively, use may be made of symptom-based procedures. These effectively bypass overt diagnosis and proceed straight to actions. Such procedures have been developed for nuclear plants following the Three Mile Island incident, but seem less applicable to process plants that are much more varied.

The approach proposed by Embrey is the use of an influence modelling and assessment system (IMAS). The purpose of this is to assist an operator in making his or her own diagnosis, and more specifically to support the use of the T-rule approach. His or her understanding of the relationships in the process, both causes and consequences of events, is elicited and encoded as a subjective cause–consequence model (SCCM).

Whatever the merits of this particular system, it is well to give the human aspect of fault administration its due share of attention.

30.46 Malfunction Detection

The third aspect of process monitoring is malfunction detection. The process computer can be used to detect or assist the operator to detect malfunctions before these give rise to alarm conditions. Malfunction detection, particularly in instruments, by the process operator, has been discussed in Chapter 14. Here consideration is given to the exploitation of the computer's potential in this area.

There are two basic methods of detecting malfunction in an equipment. These are to monitor (1) equipment performance and (2) equipment condition. The checking of performance is exemplified by the determination of the characteristic of a pump or of the heat transfer coefficient of a heat exchanger, while the checking of a condition is illustrated by the measurement of a compressor bearing temperature or the observation of leakage on a valve.

A classification of general methods of detecting malfunction in plant equipment such as compressors or heat exchangers, is as follows:

(1) process variable incorrect;
(2) equipment parameter incorrect;
(3) equipment relationship incorrect;
(4) equipment status incorrect;
(5) equipment condition faulty.

Probably the most common method of detection is from the fact that one or more process variables show the wrong value. Another check is that on a single parameter of the equipment, such as the efficiency of a compressor. Or a check may be made on a simple relationship such as the characteristics of a pump. Certain types of equipment, particularly mechanical handling equipment and regulating elements, have discrete states which they should be in at various stages of process operation, and a check may therefore be made on equipment status. Alternatively, the equipment condition may be checked with respect to features such as vibration. The classification of checks for malfunction detection in instruments has been given in Table 14.6.

The condition monitoring of plant equipment is an important activity on process plants and involves the use of specialized instrumentation and the interpretation of the signals obtained, and is described in Chapter 19. The aspect of interest here is the role of the computer as an aid in this area.

The types of function that the computer can perform include scanning, smoothing and comparing signals, calculating indirect measurements, processing information through simple correlations and models, and generating displays.

The use of process computers for malfunction detection as opposed to alarm monitoring was rather slow to develop. For some time the widespread activity of condition monitoring made relatively little use of process computers. There has been, however, a gradual increase in the role of the computer in support of this function.

The use of a computer to monitor reciprocating compressor performance by calculating quantities such as gas leakage and efficiency has been reported by Gallier (1968). Several different schemes are described with different instrumentation requirements. Benefits adduced by the author are the early detection of malfunction and also improvement of the load between parallel compressors.

In another installation where reciprocating compressors are used in the on-off mode to maintain the pressure of air in receivers within fixed limits, the amount of time during which the compressors are on is used as a simple indication of possible trouble.

Models of large centrifugal compressors are sometimes used for optimization purposes, but such models may also be used to monitor compressor characteristics as a means of malfunction detection. Other applications of the use of process computers in detecting malfunction in process machinery have been described in Chapter 19.

Monitoring need not necessarily be confined to process machinery. The calculation of heat transfer coefficients in plant equipment by the process computer is quite widely practised.

The principal method currently used for early detection of malfunction, however, is the measurement and analysis of equipment characteristics such as vibration, using special instruments. The signals obtained are often rather noisy and individual to the equipment. These characteristics suggest that there is scope for the use of the computer's ability for the smoothing and display of information.

Another related development is the monitoring of undesirable operating conditions on the plant. This can be due to maloperation by the operator and it is sometimes possible for the computer to monitor this and display it to the operator. The display to the operator of the rate at which he or she is using up the creep life of furnace tubes is one industrial example of this.

The same principle has been applied in the monitoring of control of ships, where the degree of maloperation is measured by instrumentation and analysed using estimation theory. The data are then displayed to the operator as a signal (Asbjornsen, 1976).

Of particular importance to the computer system itself is the correct operation of the sensors and valves that are connected to it. The detection of malfunction in these instruments is now considered.

30.46.1 Malfunction detection in individual instruments

The detection of incipient malfunction in instruments may follow one of two approaches. In the first the check is made on an individual instrument, or at least a limited set such as a control loop, whilst in the second it is made on an ensemble of instruments, often in different parts of the plant.

Some of the checks made by the process operator on individual instruments and control loops have already been described in Chapter 14. Many of the developments in checks that may be made by the process computer have analogues in those made by the operator. In those systems where computer checks on instruments have been implemented, the favoured methods generally have been checks on 'hardover' zero or full-scale signals and on an excessive rate of change in signals.

These checks, however, by no means exhaust the potential. The noise on a signal is often a useful indication of malfunction. Anyakora and Lees (1973) have described a method in which the noisiness of the signal is used as a check. The smoothed signal is subtracted from the crude signal to yield a noise residue, and a noise parameter is calculated from the sum of the squares of the noise residue taken over a group of readings. The technique has been used to detect the onset of malfunction in a thermocouple and in a flowmeter with freezing impulse lines. A modification of the technique has also been used to detect incipient stickiness in control valves. In this case the noise residue was the difference between the desired and actual valve positions, the latter being measured by a potentiometer.

A method of detecting malfunction in any of the elements in a flow control loop based on a comparison of the measured flow with the control valve position has been developed by Bellingham and Lees (1977b). The principle is that the valve position gives an additional indication of flow with which the actual flow measurement can be compared. The method assumes that the relation between flow and pressure drop through the system remains constant.

In the simplest case where the valve can be stroked over its whole range, the relation between the valve position and flow, or the valve characteristic, can be obtained, and any departures from the original characteristic can be determined. It was found in practice that it is preferable to detect such divergence using a simple tracking estimator that generates an error residual. This method does not require the full stroking of the valve. The detection of faults ranging from flowmeter zero error to valve trim damage was demonstrated.

This approach has also been applied by Bellingham and Lees (1977a) to the general control loop such as level, pressure and temperature, in which the measurements and the valve position are not as directly linked as in the flow control loop. The loop studied was a level control loop. In this work use was made of an estimation method based on Kalman filtering. Again the method was successful in detecting faults ranging from level meter zero error to valve trim damage. A rather cruder check based on the same principle on the feed flow to a cement kiln has been described by Barton *et al.* (1970).

Most of these techniques may be used either to carry out an automatic check or to provide a display to assist the operator in checking. A display specifically developed to allow visual checking by the operator is that of an engine gimbal developed by H.H. Bowen (1967) and illustrated in Figure 30.38. Figure 30.38(a) and (b) show the step response of healthy and unhealthy gimbals, respectively; it is difficult to distinguish between them. Figure 30.38(c) and (d) show the corresponding phase plane displays; the difference is quite clear.

Figures 30.39–30.41 illustrate the type of display which may be generated using the Anyakora and Lees (1973) technique of monitoring the instrument noise. Figure 30.39(a) and (b) show, the noise parameter plots for a healthy and for a failing thermocouple, Figure 30.40(a) and (b) show those for a healthy flowmeter and for one with frozen impulse lines, and Figure 30.41(a) and (b) show those for a healthy and for a sticking control valve.

The display shown in Figure 30.42 is a plot given by Bellingham and Lees (1977b) of the flow in a flow control loop as measured by the flowmeter (dotted line) and as

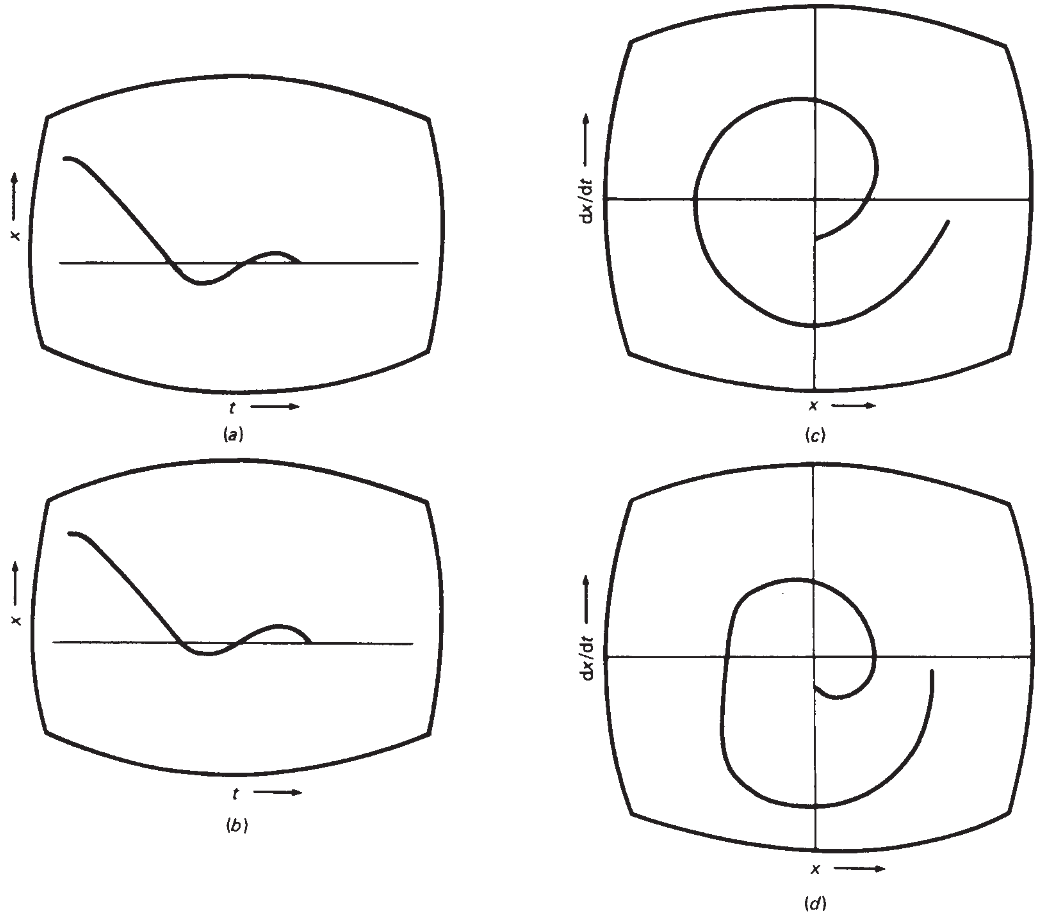

Figure 30.38 *Computer graphic displays for malfunction detection: phase plane plot of engine gimbal (after H.H. Bowen, 1967): (a) step response plot – device healthy; (b) step response plot – device unhealthy; (c) phase plane plot – device healthy; (d) phase plane plot – device unhealthy (Courtesy of Taylor & Francis Ltd)*

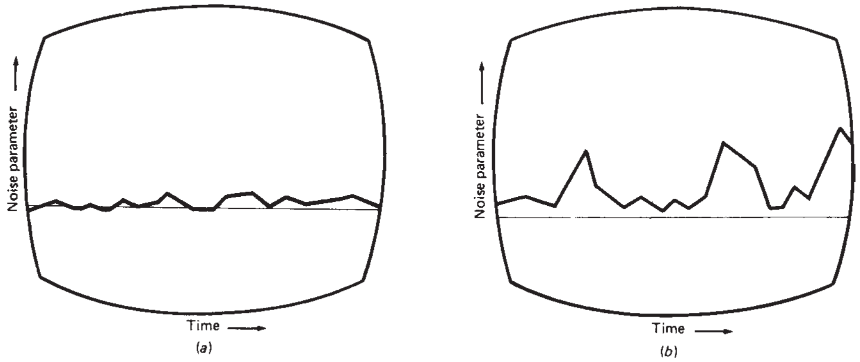

Figure 30.39 Computer graphic displays for malfunction detection: noise parameter plot for a failing thermocouple (after Anyakora and Lees, 1973): (a) thermocouple healthy; (b) thermocouple failing. The horizontal line represents the mean value of the noise parameter for a healthy instrument

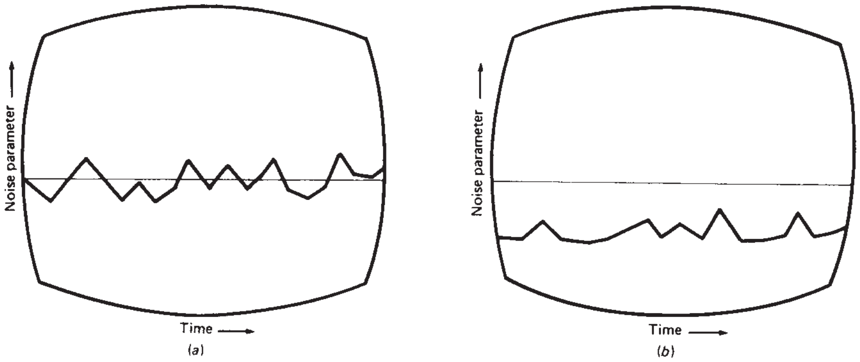

Figure 30.40 Computer graphic displays for malfunction detection: noise parameter plot for a frozen flowmeter (after Anyakora and Lees, 1973). (a) Flowmeter healthy; (b) flowmeter with impulse lines frozen. The horizontal line represents the mean value of the noise parameter for a healthy instrument

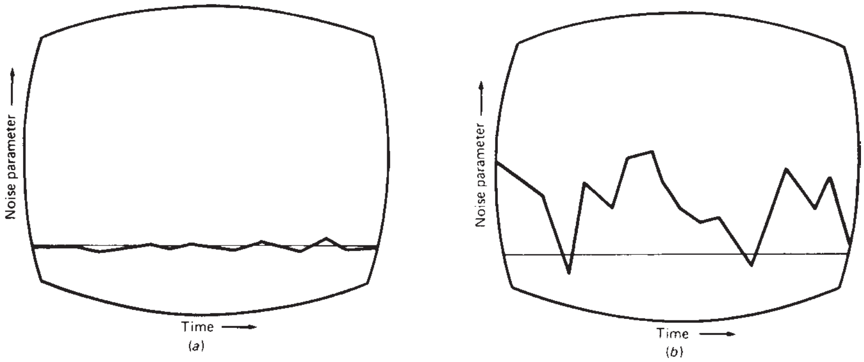

Figure 30.41 Computer graphic displays for malfunction detection: noise parameter plot for a sticking control valve (after Anyakora and Lees, 1973): (a) valve healthy; (b) valve sticking. The horizontal line represents the mean value of the noise parameter for a healthy instrument

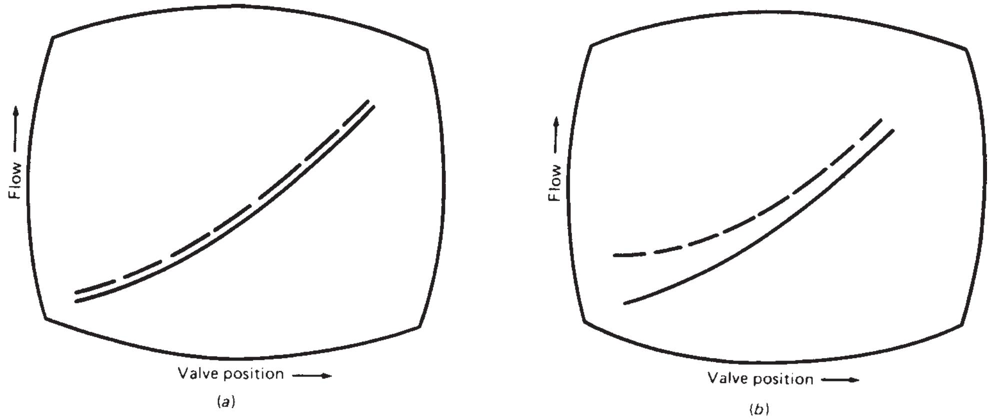

Figure 30.42 *Computer graphic displays for malfunction detection: measured and inferred flow in a flow control loop (after Bellingham and Lees, 1977b): (a) loop healthy; (b) loop with flowmeter zero error. (-----) Measured flow; (———) flow calculated from the valve position*

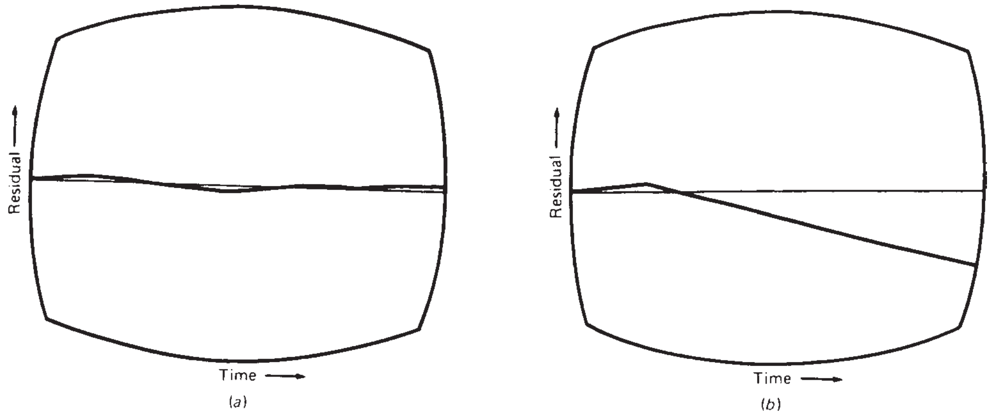

Figure 30.43 *Computer graphic displays for malfunction detection: error residual in a flow control loop (after Bellingham and Lees, 1977b): (a) loop healthy; (b) loop with flowmeter zero error. The horizontal line represents the mean value of the residual for a healthy loop*

inferred from the control valve position (full line). The generation of this display requires the valve to be stroked over the whole range. Figure 30.42(a) and (b) show healthy and unhealthy loops, respectively. Another display is based on the generation of a residual error, which is more suitable if valve travel is limited. Figure 30.43(a) and (b) illustrate the display of this residual for the healthy and unhealthy cases.

This account is perhaps enough to give a flavour of the work on malfunction detection. It illustrates the allocation to the computer and the operator of functions which they perform well, such as signal processing and display generation on the one hand and pattern recognition on the other.

More detailed accounts of malfunction detection have been given by Anyakora and Lees (1972a,b), E. Edwards and Lees (1973) and Whitman (1972).

30.46.2 Malfunction detection in instrument ensembles

The alternative approach to instrument malfunction detection is to check whole ensembles of instruments. As stated in Section 30.44, it is not uncommon to check the consistency of sets of instrument readings which determine a relationship such as a mass or energy balance, although generally the concern here is more with data reconciliation than malfunction detection.

The checking of ensembles of instrument readings for internal consistency has received increasing attention. Reviews of work in this area have been given by Willsky (1976), Himmelblau (1978) and Venkateswarlu, Gangiah and Rao (1992). An early example of work in this area is that of Goldmann and Sargent (1971), who used Kalman filtering to track the unsteady-state behaviour of the system and to detect sensor drift.

Venkateswarlu, Gangiah and Rao classify the quantitative processing of sensor data into three broad categories: data reconciliation and rectification; state estimation; and filtering and parameter identification. Work on data reconciliation is illustrated by that of Mah, Stanley and Downing (1976), Stanley and Mah (1977), Romagnoli and Stephanopoulos (1981), Madron (1985), and Narasimhan and Mah (1987). Work on state estimation methods is illustrated by that of Willsky (1976), Watanabe and Himmelblau (1983) and Frank (1987); and work on filtering and parameter estimation is illustrated by that of Isermann (1984), Park and Himmelblau (1983), Watanabe and Himmelblau (1983, 1984) and Dalle Molle and Himmelblau (1987).

Incident Investigation

Contents

31.1 Preface

Chemical process incidents can be accompanied by significant consequences, both in terms of human life and in financial impact. Many major chemical process incidents are the result of a complex scenario involving simultaneous failures of multiple safeguards. A robust system for incident investigation is usually necessary to determine and understand the causes, as well as implement measures to prevent a repeat event. This chapter is intended to provide an overview of incident investigation by addressing major concepts, principles and characteristics of effective incident investigations of chemical process events. The focus is on incidents pertaining to chemical processes and their associated hazards, and the associated investigation techniques appropriate for complex systems and scenarios. This chapter is based on best practices for incident investigation, and those common concepts (i.e. tools, techniques, definitions) included in root cause investigation methodologies currently in the public domain in use in the process industry. It is not the intention to provide a stand-alone investigation methodology/ guideline, nor address internal or proprietary investigation methodologies.

This chapter is based on:

- process industry best practices for incident investigation;
- investigation concepts from the Mary Kay O'Connor Process Safety Center Root Cause Investigation Course;
- Ted Ferry's book on accident investigation (Ferry, 1988);
- Kuhlman's Professional Accident Investigation (Kuhlman, n.d.);
- CCPS *Guidelines* for Incident Investigation (second edition) (CCPS, AIChE, 2003);
- NFPA 921 Standard for investigation of fires and explosions (NFPA, Standard 921 Investigating Fires and Explosions);
- American Chemistry Council Responsible Care code (CARE®, n.d.);
- US National Safety Council investigation guidelines (National Safety Council, 1995).

This chapter begins with an overview of general incident investigation concepts and definitions to provide a common baseline. Section 31.3 is devoted to collection and analysis of evidence including a segment on investigation witness interviews, Section 31.4 addresses investigation team issues, and Section 31.5 is devoted to identifying root causes. Recommendations, reports and sharing lessons learned are presented in Section 31.6. The chapter concludes with Section 31.7, a review of Incident Investigation Management System issues and sources for additional information related to process industry investigations.

31.2 General Investigation Concepts

31.2.1 Purpose and scope of incident investigation

Effective discovery of root causes is not an easy or simple task. Successful investigation is an iterative process based on scientific principles with the ultimate purpose being prevention of a repeat event. It is systematic, thorough and intellectually honest. There are four stages that must be successfully completed in order to prevent a repeat event of a similar nature:

- Identify what happened and how it happened (identifying and understanding the scenario).
- Determine why it happened (identify the specific underlying and contributing causes).
- Identify preventive remedies (recommendations and action items).
- Implement changes to existing practices and systems (accompanied by sharing lessons learned to all those who could benefit).

Unless and until the preventive actions are actually implemented, the risk exposure level remains unchanged. It is not unusual in the chemical process industry for similar incidents to occur in sister plants or in similar plants owned by another organization. There is a growing recognition of the importance of the actual implementation, resolution and follow-through of investigation recommendations.

31.2.2 Definitions

31.2.2.1 Causes

Incident investigation terminology is, unfortunately, inconsistent across the process industry. This creates communication challenges even within a single organization. In the United States, the term *incident* is generally used in the context of referring to any unplanned event that did, or easily could have, resulted in undesirable consequences. When an incident results in actual undesirable consequences, such as injury to people, the environment, damage to equipment or adverse impact to operating profits, the event is most commonly labelled as an *accident*. The term *near-miss* is used in this chapter to describe an event that generated no actual adverse consequences, but with a slight change in circumstances, could have produced actual adverse consequences.

Examples of near-miss events include:

- dropping a crane load where there is no injury or damage;
- demand challenge to a final protection device (such as emergency shut-down control systems);
- events where there is unintended energy contact to employees without resulting in injury.

One challenge to effective root cause incident investigation is the absence of a consensus definition of the term *root cause*. There are several definitions in use. For the purposes of this chapter the term root cause is used to represent: *the underlying reasons that allow defects in systems (physical equipment and systems and/or administrative systems) to exist, that the organization can correct.* These defects are the result of, and symptoms of, underlying causes. Examples of these defects include faulty design, inadequate behaviour or task execution, improper installation, ineffective training or maintenance. An event itself (such as the breaking of a component) cannot by definition be a root cause. Some conditions or underlying reasons may not be under the control of the organization, and are therefore not considered to be root causes. This issue is discussed in more detail in Section 31.2.3.1.

Root causes = Underlying system-related reasons that allow system defects to exist, and that the organization has the capability and authority to correct.
Events are not root causes.

31.2.2.2 Management system perspective

An understanding of management system perspective is useful in effective root cause identification. The term management system is used in a variety of contexts. When people hear this term for the first time, their initial reaction is to think of the people in the nice offices on the top floor. However, the term management system does not refer to the individuals on the management team or the management team's general approach and organization. For the purpose of this chapter, the term management system is used to represent the total administrative activities and aspects associated with a dedicated task or objective. Root causes are almost always associated with, and can be linked to, one or more weaknesses or breakdowns in administrative management systems.

Management systems have common generic components such as: written procedures, training, performance expectations, required competencies and assignment of different responsibilities. When searching for root causes, the investigation team should examine the components of all management systems involved in the incident (CCPS, AIChE, 2003). Examples of management systems may include: lockout/tagout, training systems, written operating procedures, process hazard analysis systems, management of change systems, mechanical integrity and maintenance systems, and recognition and response to anomalies (process upsets, transfers of material).

In this context, management systems have common generic components as shown in Figure 31.1, including defined inputs, defined outputs, a work process (and/or procedure), a training component, allocation of responsibilities, sustained allocation of resources, documentation, an audit and/or measurement component, a minimum required skillset and knowledge set, accepted ranges of performance defining success, and usually a continuous improvement/ quality assurance component (BS 8800, 1996). The incident investigation system is a good example of a management system. An effective incident investigation system contains all the above generic components as well as those shown in greater detail in Section 31.7, Figure 31.12. The objectives and expectations of the investigation are clearly established. Performance standards are implemented, personnel are trained and specific documentation requirements established. Investigation task activities are well-defined, auditable and effectiveness is periodically evaluated.

31.2.3 Investigation general concepts

31.2.3.1 General concepts for incident investigation

For effective investigations, an honest, thorough and systematic approach is needed. The investigation team should ethically and objectively consider all facts, information and evidence, and use scientific principles to identify and evaluate all plausible cause scenarios. Rejection of proposed scenarios should be based on physical evidence. Wherever and whenever possible, independent verification of information should be sought.

Prematurely stopping before reaching the root cause level is a major and recurring challenge to most process incident investigations. One common error is to identify an event for a root cause, thereby prematurely stopping the investigation before the actual root cause level is reached. Events are not root causes. Events are results of underlying causes. It is an avoidable mistake to identify an event as a root cause (i.e. a loss of containment release, a mechanical breakdown or failure of a control system to function properly).

One fundamental objective is to pursue the investigation down to the root cause level. Effective investigations reach a depth where fundamental actions are identified that can eliminate root causes. The most appropriate stopping point is not always evident. It is sometimes difficult to distinguish between a symptom and a root cause. When the investigation stops at the symptom level, preventive actions provide only temporary relief for the underlying root cause. It is critically important and necessary to establish a consistently understood definition of the term root cause. If the investigation stops before the root cause level is reached, fundamental system weaknesses and defects remain in place pending another set of similar circumstances that will allow a repeat incident. The organization will then be presented with another opportunity to conduct an investigation to find the same root causes left uncorrected after the first incident.

For example, consider the case where the investigation stopped before reaching the root cause level.

Scenario – A massive release of toxic liquid occurred when a small (1/2 in.) bleed valve failed. The valve was found to be installed improperly, and was damaged by internal corrosion.

Facts

(1) One design feature was that the internal valve components could be removed and replaced if they became worn. The valve was designed with a fail-safe provision and intended to be installed in a designated flow direction orientation. Access to the internal components was intended to be made from the inlet (upstream) side of the valve. The inlet port of the valve was provided with a threaded internal sleeve (retention ring) that could be removed for access to valve internal components. If the retention ring were to fail, pressure from the upstream flow would act to prevent the valve's internal components from being ejected from the valve body.

(2) The valve was marked with a flow direction arrow and delivered from the supplier with a conspicuous instruction tag warning of the consequences of improper installation. The investigation team found the valve to be installed in the wrong flow direction orientation.

(3) Examination of the retention ring indicated the threads were corroded to the point of failure, and allowed the retention ring and value internal components to be ejected.

One root cause as found by the investigation team – 'valve installed backwards'

Recommendation submitted by the investigation team – 'refresher training for the mechanic who installed the valve'

Comment

The investigation team stopped the investigation too early and failed to identify the underlying reasons *why* the valve was installed backwards. A more effective team might discover and correct additional underlying causes such as:

- incomplete and out-of-date instructions for installing and verifying proper orientation;
- inadequate system for updating installation instructions and verifying that current instructions are being used;
- inadequate training system with no provision for confirming that the training accomplished the intended objectives and no periodic refresher/reminder component was included within the training program;
- current system does not call for insuring the caution tag supplied by the manufacturer remains on the valve until its point of installation/application;
- a defective system for ensuring that quarter turn quick opening bleed valves in toxic liquid service are capped or plugged when not in use;
- an incomplete system for ensuring that new or temporarily transferred mechanics are aware of the special nature of these bleed valves.

If the investigation team had reached the underlying system defect level, the team would have been able to more effectively eliminate the chances of a repeat incident.

An investigation team may mis-identify 'lack of sufficient knowledge/skill' as a root cause and therefore, generate a recommendation to conduct refresher training. This lack of sufficient knowledge/skill is, in most cases, a symptom and not a root cause. The training recommendation assumes that the person did not know/understand the proper procedure. The training recommendation does not attempt to identify the underlying root cause of the employee's behaviour. If and when a procedure is changed, retraining is necessary and would be a proper component of the recommended preventive actions. Deficiencies in the training management system could be the underlying root causes resulting in the symptom (inadequate knowledge or skill). Training (or refresher training) would be an appropriate action once the underlying root cause deficiency in the training system has been properly identified and corrected.

Different investigation teams often have varying perceptions regarding expected stopping points and may also have different understandings of what is and is not a root cause. Within an organization, there should be a definition of the term root cause that is clearly and consistently understood and applied.

Another requirement is that a root cause must be correctable by the organization. Two extreme examples of this concept are weather conditions and physical properties of materials. The organization does not have the capability to prevent/control adverse weather such as rain, wind or extreme ambient temperatures. It would be incorrect for the investigation team to identify rain or some physical property (boiling point) as a root cause. The organization may have capability to implement protective measures to mitigate the consequences of wet conditions, but it would be incorrect to label rain (or ice) as a root cause. Another example would be a case where one plant (Plant A) causes injury to workers in an adjacent plant (Plant B) and the plants are owned by two different organizations. Plant B management can take certain actions to protect their workers from outside events that originate at Plant A. These protective measures might include gas detectors, alarm and alert systems, constructing safe haven refugees, providing personal protective equipment, training, filing lawsuits, and certain other emergency response and mitigation measures. However, Plant B cannot enter Plant A and implement preventive measures because Plant B lacks the authority or control over Plant A. The root causes of injury to Plant B personnel would be limited to those weaknesses or breakdowns in Plant B systems and measures.

31.2.3.2 Life cycle of an investigation

Figure 31.2 provides a graphical representation of the root cause investigation process. There are several natural and overlapping stages to every process incident investigation. The first phase is determining 'What happened'. This is followed by efforts to identify 'Why it happened.' Evidence is collected and analysed, and information is gathered from direct and contributing witnesses in an iterative process. This is the stage where the root causes are identified. The final stage is the 'Prevention' stage where preventive action measures are identified, implemented and verified and information is shared with all who might have potential benefit from the investigation's outcome.

31.2.3.3 Special investigation challenges for process incidents

Although investigations of process incidents share many common elements with traditional industrial incident investigation, there are a few relatively unique features. Many process incidents involve outside parties such as regulatory agencies, insurance companies and in many instances litigation issues. Process incident investigations by nature carry additional challenges. Actual or potential consequences are significant and can be catastrophic in terms of loss of life, impact to the environment and in terms of financial impact on the organization. Specific design features of the manufacturing process system and sophisticated controls are provided to prevent adverse consequences. Multiple layers of protection are provided and maintained. Safeguard measures can be physical systems and devices (instrumentation interlocks, pressure relief valves and trip devices for example), administrative management systems or combinations of the two. Most process incidents that result in significant consequences are associated with unusual combinations of circumstances and conditions, and multiple breakdowns of preventive measures. In most instances, a single failure of a safeguard does not result in adverse impact. When adverse consequences do occur, it is most often the result of a complex scenario that involves simultaneous failures of several layers of protection.

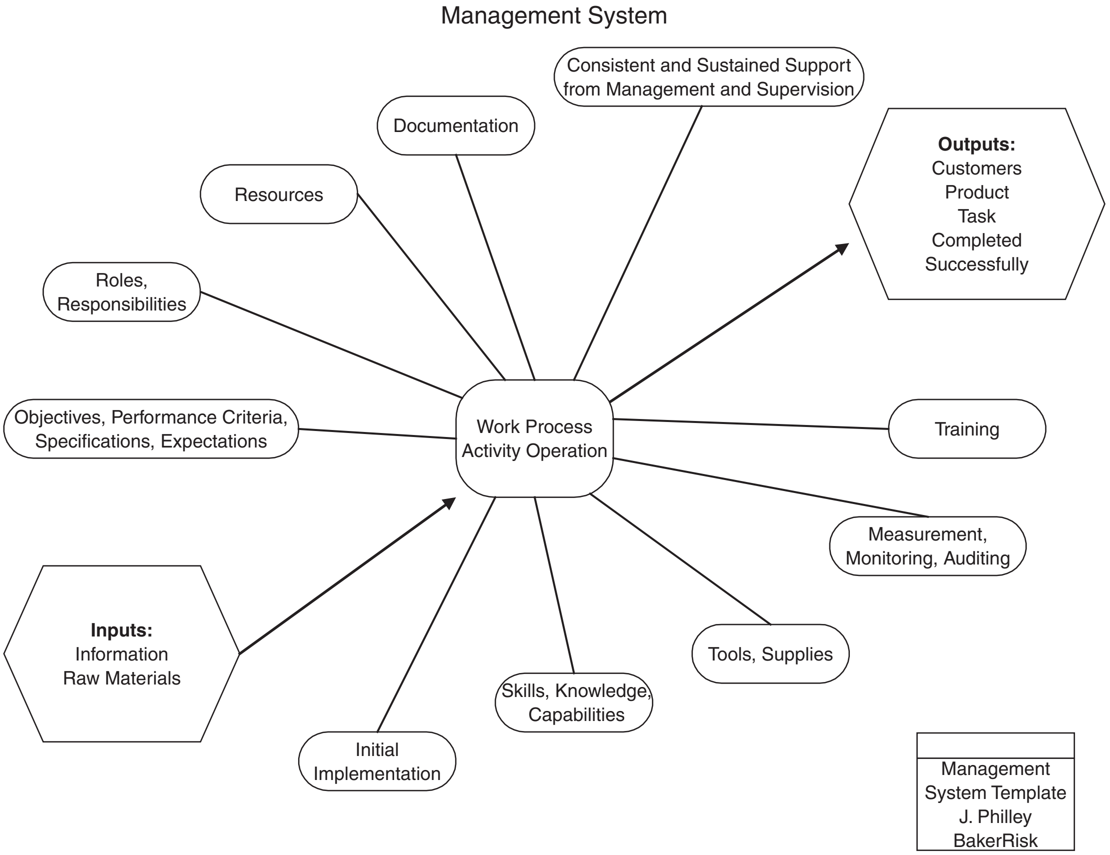

Figure 31.1 *Management system template*

One relatively unique characteristic of modern process designs is the close coupling (Parlow, 1999). Large-scale single train units are now the norm. Surge capacity and intermediate storage are minimized. The design provides minimum selected redundancy and spare equipment. Designs stress reliability and corresponding maximum on-stream time. Intervals between scheduled shut-downs and turn-arounds are maximized. This approach results in potential for a problem in one part of the process to quickly propagate and cause impact to downstream portions of the plant process equipment.

31.2.3.4 Concept of multiple causes

A second major challenge is finding all root causes. One common mistake in root cause incident investigation is to prematurely stop the investigation before *all* root causes are identified. This mistake is sometimes built into the investigation management system, by formally limiting the charter and expectations of the investigation team. Sometimes the investigation team is specifically charged with finding 'the root cause.' Additional root causes are allowed, but the team is asked to discover the one root cause among all other causes most responsible for the event. This erroneous approach ignores an axiom of root cause incident investigation, that is, 'There are always multiple root causes associated with an accident.' Removing only one root cause corrects only part of the problem. If only one root cause is identified and eliminated, the result of the investigation effort would probably prevent a repeat of the exact specific incident sequence, but would leave the other root causes in place ready to cause a similar event.

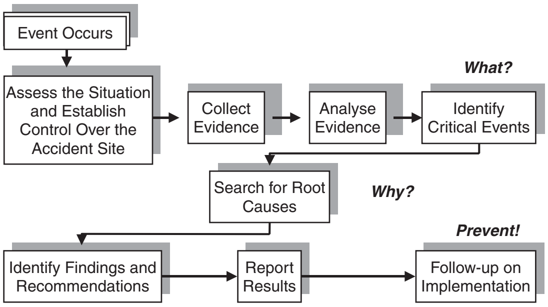

Figure 31.2 *Root cause investigation process*

Each root cause has a specific risk factor associated with it (combination of likelihood and consequence severity).

Some root causes are associated with higher frequency of opportunities for occurrence or exposure, while others are associated with higher degree of severity of consequences. From this perspective, it is accurate to say that some root causes are more significant than others from a risk perspective. However, for most accidents, it is not accurate to say that there is only one root cause associated with the accident. In the Three Mile Island, Bhopal, and Challenger Space Shuttle incidents, there were multiple root causes that acted in concert to allow the accident scenario to progress (Philley, 1992; Chiles, 2001). In each of these three classic incidents, a series of failure events and conditions progressed to a final state of significant adverse consequence. The failure events and breeches of safeguards had different probabilities. If one of the series had not occurred, it is unlikely that the final event would have happened. Each individual failure represented an opportunity to arrest the progression of the scenario. Each failure was associated with a separate and distinct defect in a management system. The investigation would be incomplete and less than adequate if the team finds and corrects only one of the underlying root causes.

For optimum incident investigation results, the concept of multiple root cause should be fully integrated into the incident investigation management system, procedures, training and expectations.

31.2.4 Management's role in incident investigation

Responsibility for prevention of incidents and repeat incidents is a responsibility shared at every level of the organization from the board of directors down to the entry-level employee. However, the ultimate responsibility rests with those in management positions who establish policy and allocate resources. It is a general observation that process facilities and operations with the most successful records share common management leadership attributes and characteristics including:

- personal involvement by line management in the review and approval of draft incident reports;
- rigorous and robust follow-up and implementation of recommendations and action items generated from incident investigations;
- proactive sharing of results, findings and lessons learned from investigations;
- strong and sustained emphasis on reporting, investigating and taking action on near-miss events;
- establishing priorities and implementation schedules for incident investigation action item recommendations.

One critical function of the organization's line management is the responsibility to act on the recommendations submitted by the incident investigation team (Noon, 2000). Managers must fully understand the risk associated with implementing, partially implementing, modifying, delaying or rejecting the suggested recommendations. Once a recommendation is accepted, there is a responsibility to ensure the action is implemented as intended and that the action is indeed successful in correcting the root cause. Follow-up verification, documentation, auditing and monitoring are essential.

Members of line management have the responsibility to implement a management system for incident investigation. This responsibility requires sustained allocation of resources (i.e. financial and personnel). Many incident investigation actions are accompanied by auxiliary (secondary) tasks such as updating training manuals, process safety information packages, or piping and instrumentation drawings (P&ID). These auxiliary tasks also require allocation of organizational resources, prioritization, and tracking to satisfactory resolution.

Line management must establish acceptable risk tolerance criteria. This is most often accomplished by development and adoption of a risk matrix (CCPS, AIChE, 2003). Risk matrices are applied to assist in prioritization of issues and recommended preventive action items. Line management has a responsibility to effectively share the lessons learned from the investigation both internally and externally.

Each level of the management structure must have an adequate and appropriate understanding of the incident investigation policy, procedure and responsibilities (DNV, 1996). In most cases this requires a clear and consistent understanding of the implemented incident investigation management system including: What is an acceptable identification of root causes? What is acceptable regarding quality and wording of action item recommendations? What are the individual responsibilities for each person under the supervision of that manager?

31.2.5 Human factors in incident investigation

Human factors are involved in almost every process safety incident. Since human reliability is less than 100%, all administrative systems and safeguards are less than perfect. Well-designed management systems take human reliability and human performance into consideration when designing safeguards. Well-designed human factor safeguards are error tolerant and allow some opportunity to detect and correct deviations before catastrophic consequences are reached. Well-designed safeguards will include confirmation that the intended protection remains in place. Every safeguard will have discrete periods of unavailability. Some process hazards are significant enough to require protection in depth (layers of protection) and robust barriers.

When evaluating proposed additional safeguard measures, incident investigation team members will often benefit from an understanding of the application of reasonable human performance reliability expectations. In some instances, the human performance expected by system designers (physical systems as well as administrative systems) exceeds realistic or practical limits. In these cases the system design increases likelihood for human error or may call for unrealistic response times or response actions. When considering remedies to root cause defects, the incident investigation team should apply recognized and generally accepted human performance and human reliability expectations. Two excellent examples of applied human factors are the emphasis on inherent safety in system design and the concept of alarm management. Modern distributed control system (DCS) instrumentation allows almost infinite capability to add computer generated alarms and the result can be alarm overload/flood during the initial periods of process deviations and process upsets. The alarm management concept provides an opportunity to prioritize and categorize alarms and the associated expected response actions to alarms.

The Japanese quality control technique of Poka Yoke is a concept that recognizes workers occasionally make mistakes and provides features in the manufacturing process that minimize the incidence rate and consequences of mistakes. Manufacturing processes are provided with features that allow rapid detection of errors made by employees and, therefore, allow an opportunity to recover at minimum expense and consequence.

The written procedure is a common accident prevention safeguard that depends heavily on human reliability (also referred to as standard operating procedure, SOP, or written instruction). The intent of the written procedure is to ensure actions and practices are sufficient to safely complete the designated task. Unfortunately, it is a common and erroneous finding for an investigation team to identify 'Employee failed to follow established procedure' as a root cause. This failure on the part of the employee (behaviour or action) is in most instances a symptom of an underlying root cause (Peterson, 1984). The investigation should try to discover *why* procedures were not followed. In almost every case, there is an underlying system deficiency reason why a person did not follow the established procedure. The investigation team has an obligation to uncover and remove underlying causes for the failure to follow established procedures.

> In most instances '*failure to follow established procedures*' is not a root cause, but is instead a symptom of an underlying system defect that can be corrected.

It is not unusual for employees to consciously deviate from a written and established procedure. In some instances, the failure to follow established procedure may be due to inadequate knowledge. The classic recommendation that accompanies this premature stopping point is to provide training (or refresher training) to ensure the person(s) involved in the incident understands how to follow the established procedure. An example of a typical recommendation action item associated with this mistake might read, 'Review the procedure with the employee to ensure that he understands the proper action expected.' This individual training activity may be beneficial to the person(s) who receives it, but in most cases does not address the underlying reason for the person's lack of knowledge. The individual refresher training does not correct any system defects that resulted in the improper behaviour. In most cases, the other employees remain in a state of inadequate training. Investigation teams often uncover and eliminate underlying system deficiency causes such as:

- Deviation from procedure was commonly accepted practice.
- Employee was following the example set by his supervisor and/or trainer.
- Training program did not adequately inform the employee of the potential consequences associated with deviating from a specific step or action.
- An out-of-date written procedure that no longer reflects current practices, or current configuration of the physical system *due to* defects in the process safety information, document control, or operating procedures management systems.
- Employee perceives that his way is better (safer, and/or more effective) *due to* deficiencies in the system for establishing and maintaining a specific competency and qualification level.
- Employee previously rewarded for deviating from the procedure *due to* a culture of rewarding speed over quality resulting in, and a reflection of, a defective quality assurance management system.
- Employee is experiencing temporary task overload *due to* defects in the scheduling and task allocation system and/or *due to* ineffective implementation of downsizing.
- Employee has physical/mental/emotional reason(s) that causes him to deviate from the established procedure *due to* defects in the fitness-for-duty management system.
- Employee believed he was using the correct version of the procedure, but *due to* defects in the document management system, he was actually using an out-of-date edition.

31.2.6 Preparing for investigating process incidents

A typical investigation environment immediately following an explosion or major fire may include the following circumstances:

- all (or most) plant utilities out of commission (electrical power, steam, water, inerting purge gas systems, plant telephones, radio systems, pagers);
- residual fires and hot spots still being brought under control;
- personnel who were on duty at the time of the event may be injured and therefore, unavailable for interview (in some instances, for weeks);
- environmental consequences still evolving;
- the plant neighbourhood being evacuated;
- regulatory agencies with partial or total control of the accident site;
- local (and in some instances, national) news media demanding information;
- a large portion of the potential evidence being destroyed by the fire or explosion;
- many plant employees traumatized and/or exhausted from the initial emergency response;
- third parties (insurance companies, contractors, customers, suppliers, attorneys) with legitimate needs for information and response action.

This set of circumstances is not unusual, and demands a robust incident investigation management system that can be rapidly and efficiently activated. There may be only a brief opportunity to capture some of the time-sensitive evidence. Organizing and preparing an incident investigation team is addressed in detail in Section 31.4. Composition and configuration of a process incident investigation management system is addressed in Section 31.7. The management system must be developed and implemented prior to the incident, with accompanying training and auditing.

Legal issues are a major component of investigations for process incidents. Many process incidents are accompanied by significant consequences and, therefore, litigation is probable. There may be third party injury or damage, on-site or off-site. Insurance company representatives have certain contractual legal obligations, needs and rights. In many instances in the United States, investigation of a serious process incident is conducted under the direction of an attorney and in anticipation of litigation. Legal counsel for the organization has an obligation to protect the financial impact to the organization and to manage contacts and interactions with regulatory agencies and opposing counsel. There are certain measures the incident investigation team can implement to control access to investigation documents by outside parties. In many instances an attorney is designated as investigation team leader to ensure that all legal aspects are controlled.

In the United States, federal, state, and in some cases, local regulatory agencies have the authority and responsibility to conduct investigation of process incidents. In many cases, control of access to the accident site is assumed by the regulatory agency. Federal (US) agencies that may conduct investigations include:

- OSHA – Occupational Safety and Health Administration;
- MMS – US Minerals Management Service;
- USBM – US Bureau of Mines;
- EPA – Environmental Protection Agency;
- ATF – Alcohol Tobacco and Firearms;
- FBI – Federal Bureau of Investigation;
- USCG – US Coast Guard;
- CSB – US Chemical Safety and Hazard Investigation Board;
- NTSB – National Transportation Safety Board (pipelines).

In many cases these regulatory agencies are interested in determining compliance or lack of compliance with applicable regulations and standards. In some instances, the identification and elimination of root causes is not their top priority. In addition to the federal agencies, there are state and local authorities such as Fire Marshals and Public Safety Departments that have authority and desire to conduct incident investigations and issue reports and recommendations.

In the United States, many process incident scenes are designated as uncontrolled hazardous waste sites under the OSHA 1910.120 Hazardous Waste and Emergency Response regulation, subpart (q). This requires specific training for most personnel who enter the site, and also requires a written safety and health plan be developed and implemented for control of potential hazards that may exist.

31.3 Evidence Issues

31.3.1 Evidence challenges

Evidence collection and analysis is an iterative activity. For optimum results, a formal system of evidence management is necessary. The quality of findings and conclusions of the investigation are a direct reflection of the quality of the evidence examined by the team. Many chemical process incidents present considerable challenges related to gathering evidence. The facility may be significantly damaged by the event and, therefore, critical physical evidence may no longer exist or may not be initially available to investigators. In some instances, the starting point may be a crater. Regulatory agencies such as OSHA, FBI, US CG, EPA, ATF, or Fire Marshal may have total control of the site, and the owner representatives may be prohibited from entry. In the United States, the site for many chemical process incidents is declared an uncontrolled hazardous waste site under the OSHA 1910.120 subpart (q) regulation and certain access controls and actions become required. In some instances, third party legal (or insurance company) representatives may quickly file legal action to prohibit the owner from taking any action that might disturb potential evidence, therefore arresting any investigatory activity related to evidence gathering.

There are several recognized categories of evidence.

- people;
  - eyewitness and personal knowledge,
- physical evidence;
  - parts, things, equipment,
- electronic;
- paper documents;
  - historical, drawings, specifications,
- position/configuration;
- process parameters and conditions;
- physical properties and characteristics.

In many cases the plant infrastructure is severely damaged. Normal utilities and services will be unavailable, such as electrical power, telephones and radio communication systems. In large facilities, undamaged portions of the plant will be demanding permission to resume operations. Critical witnesses such as personnel who were on duty at the time of the incident may not be available due to injuries or may be at home recovering from extended hours spent in initial emergency response activities.

In the most severe explosion cases, a substantial portion of a process unit may be completely destroyed with only a crater remaining in the location of the equipment. Fragments and debris can be thrown considerable distances, sometimes outside facility boundaries. In many instances, sampling will be necessary to evaluate potential exposures to investigation personnel (asbestos, volatile organic compounds, blood-borne pathogens and others).

Some evidence is extremely time-sensitive and requires top priority in the initial stages of the investigation. Witness' perception, understanding and memory recall changes over time, and it is therefore important to place a high priority on gathering evidence from direct eyewitnesses and others who were on-duty at the time of the event. Physical evidence degrades with time (e.g. fracture surfaces, dust and soot samples, residual liquids, and charts, logs and other paper records that are exposed to the elements). Availability and integrity of electronic process data can be impacted by the loss of normal or back-up electrical power. Access to offsite evidence and restoration of this offsite damage is not in the control of the chemical process facility owner. Documentation of the extent of damage and necessary temporary repairs are high priority evidence issues. Within the plant or facility boundaries, evidence collection requires notification and coordination of all employees to minimize loss or inadvertent alteration of the physical evidence. Evidence may be spread over a large area, and all personnel within the plant must be instructed on the proper manner to communicate the location of evidence for collection by a trained team. Collection of chemical samples from vessels that are open to the atmosphere is also a high priority activity to ensure the sample is as representative as possible and to minimize adverse impacts from exposure to the elements (evaporation, moisture and others). Some evidence may be located in access ways and other places that need to be cleared quickly, and these areas may need to be placed on the high priority list.

For explosions, the damage itself may function as a blast gauge if the properties of the buildings and structures are known. The end use of the evidence collection may include:

- calculating blast pressures and impulses at each damaged structure;
- generating pressure contours;
- calculating the explosion energy released;
- determining the type of explosion;
- determining the source of the explosion.

31.3.2 Potential sources of physical evidence

Depending on the type and nature of the event, evidence prospecting may be required across a wide range of potential venues. The location and relative position of physical evidence should be documented and in most instances, photographed in place before anything is moved. A special type of information often highly useful is the 'as-found' position of valves, switches, control devices or sequence indicators. Previous incident reports and reports of process hazard analysis (PHA) studies can provide insight to credibly possible failures and accident scenarios. Operating data such as logbooks, computer records, process flow diagrams, and P&ID are potentially very useful documents. Engineering files, inspection records and repair files contain valuable information on the construction and features of fixed equipment. Another resource is the management-of-change records, providing information related to modifications that may not be updated on the equipment and system drawings. Scorer, scratch and impact marks made by moving objects can be helpful. The investigation team should look for things present that would not be expected to be present, and also look for things absent that would be expected to be present. Typical sources of evidence for chemical process incidents are listed in Table 31.1.

31.3.3 Evidence collection and management

For major chemical process incidents, evidence preservation, storage and management is required. Effective collection and analysis of physical evidence should be conducted in a systematic fashion. All potentially important fragments, debris and other physical items should be documented in place (photography or other) before being moved or disturbed in any manner, noting the location and orientation. It is standard practice to assign individual evidence numbers to each piece of physical evidence collected. In most instances, small items are placed in clear plastic bags. A formal chain-of-custody system is developed and implemented to track the status of, and access to, any evidence not retained in the custody of the incident investigation team. Disassembly of equipment should be documented with photography and annotated at each significant stage. In some instances, disassembly of equipment may require agency or litigant approval before anything is touched or changed. Long-term storage of physical evidence may be required for investigations that involve potential litigation. It is important to arrange for secure storage, restricted access and chain-of-custody management for items that may be retained long after the initial investigation team has concluded its work. Regulatory agencies and other third parties may have need for copies of documentation as well as samples, photographs and portions of physical evidence. It is important to manage the distribution of copies of documents and other evidence in order to avoid unnecessary confusion and differences in interpretation of document evidence.

Table 31.1 *Potential sources of evidence*

Operating data (computer log, alarms, charts)
P&ID
Lab results
Instrument loop diagrams
Instrumentation interlock drawings
Instrumentation ladder logic diagrams
Operating manuals
Training manuals
Material Safety Data Sheets
Management-of-change records
Inspection records
Repair records
Meteorological records
Manufacturer's bulletins and Original Equipment Manufacturers Manual
Retainer samples of shipments and incoming raw materials
'As-found' position of valves, switches and indicators
Rupture disk condition
Anomalies in damage (or non-damage)
Residual liquids
Scorch pattern
Smoke traces
Melting pattern
Missile mapping
Layering of debris
Direction of glass pieces
Analysis of undamaged areas and equipment
Metallurgy analysis
Fracture analysis
Conductivity testing
Security camera tapes
Previous PHA study reports
Material balances
Chemical reactivity data
Corrosion data
Prior incident reports

31.3.4 Evidence photography

Investigatory photography (and video) has multiple purposes. It is most often used to document the 'as-found' position, location, configuration arrangement, damage pattern and layering of physical evidence. In addition, photographic evidence is often useful in presenting the results of the investigation (reports) and in distributing lessons learned (training). Photographs taken by the investigation team find application in evidence analysis and in litigation activities. Photographs can be taken of items that need to be moved or of items and conditions that might change over the course of the investigation. Promptness is important since no accident scene can be considered frozen in time. In most instances, the investigation team should generate a formal log of each image, indicating the date, time, identity of the photographer and intended purpose or contents of the image. If multiple copies are distributed, a record of distribution should be maintained. In some instances, investigators have found it helpful to document the view of each significant witness by going to the position where the witness was located to note what could be seen from his position.

Conventional 35 mm photography, digital photography, instant print and video images all have a place in the investigation process. In some circumstances, the use of a professional photographer may be appropriate, however in most instances, photography will be done by investigation team members. It is important to capture a series of overall orientation views from multiple perspectives and from multiple distances. These views will significantly enhance the value of subsequent photos taken from a closer distance. A sometimes-used resource for video is news media footage taken during the incident. This unedited footage is available directly from the TV station and can provide clues related to the sequence of the event.

Most photographic equipment requires perishable batteries that have, in some cases, unpredictable battery life. It is a good practice to implement a system to ensure that spare batteries are available and that periodic battery change-out and recharging occurs. Photographic film is date-sensitive and in addition, can be adversely affected by airport security screening devices. Storage of electronic digital images needs to be managed, with master copies or back-up copies maintained in a controlled manner.

Photography can present hazards to investigators. The view through the lens is restricted and the photographer may not be aware of tripping and falling hazards. Photographic and flash equipments are not normally designed for use in potentially flammable vapour conditions and require precautions similar to those used for any potentially spark producing tool or piece of equipment.

Good practices for investigation photography include:

- taking multiple orientation views from different positions and distances;
- placing an object of known size in the picture;
- being aware of potential shadows that will be cast by the flash unit;
- managing spare battery supply;
- making a written record of each image that might be confusing to the viewer;
- being aware of limitations of autofocus devices;
- generating a detailed log of all photographs;
- managing and documenting distribution of copies.

31.3.5 Investigation witness interviews (gathering evidence from people)

31.3.5.1 Introduction and general interview issues

Gathering verbal information from witnesses is one of the more challenging aspects of incident investigation. Conducting an effective interview differs from most process safety management activities in that interviewing can be as much an art as it is a science. There are numerous variables that affect interview success. Chemical process industry incidents are often accompanied by severe consequences and can also be accompanied by traumatic effects on human emotions. Chemical process industry incidents can be complex in nature and it is rare for a single witness to have a complete understanding of all the events and underlying circumstances. Each potential witness has a unique combination of perspective, personal experience and understanding of apparent facts. Promptness in obtaining statements and conducting interviews is essential for effective witness interviews and for obtaining the most reliable information.

Incident investigation interviews are conducted in a variety of circumstances. There are several types of investigatory interviews. The most common incident investigation interview is the initial screening interview, conducted for all possible witnesses who might be able to contribute to understanding the cause and event scenario. These initial interviews are usually brief (on the order of 30 min) and explore a wide range of topics and issues. A subset of witnesses is subsequently identified for follow-up interviews, which are more focused and address specific issues emerging from the investigation. These follow-up interviews can last over one hour. In addition, it is not uncommon to conduct group interviews after the initial round of individual interviews. In some instances, the presence of a group can activate synergies that contribute to increased understanding and recall. There are other special types of incident investigation interviews that are not in the intended scope of this chapter, including interviews of injured personnel (usually conducted at the hospital), interviews of non-employees (contractors, visitors, others), interviews conducted by regulatory agencies and interviews conducted by third parties (insurance representatives, legal representatives).

Since witness interviews are verbal communication exercises conducted between two human beings, they are naturally accompanied by human imperfection. In the chemical process industries, incident investigation interviews are seldom conducted by professional interviewers. Following a chemical process incident, the interview atmosphere can be adversely affected by significant emotional or physical trauma. Each person brings their own perception of apparent facts and sequence of events. Human memory is imperfect and can be significantly impacted by passage of time, interaction with other people, and by the witness learning additional facts after the incident. Humans have a capability and tendency to see and hear what we expect to see and hear. Our brains have an inherent tendency to interpret incoming information so that it becomes comprehensible to us, even if the incoming information is incomplete. We have a strong capability to identify patterns and fill in missing pieces of information based on our previous experiences and understandings.

When evaluating incoming information from witnesses, the interviewer should keep in mind that the witness may be:

- traumatized and may not be thinking as clearly as he/she would otherwise;
- unsure about certain information (and may withhold information or make incorrect assumptions);
- overly confident (and not necessarily accurate) about certain information;
- potentially defensive about certain issues;
- apprehensive regarding possible disciplinary action for themselves or others;
- angry at the company or at individuals;
- making assumptions without realizing it;
- second-guessing their own actions;
- interested in accomplishing other objectives and agendas not directly related to this incident.

The person conducting the interview should remember that:

- All information from witnesses may not be accurate, complete, or factual.

- Some information may contain hidden assumptions and stipulations.
- Some information may contain incorrect assumptions.
- The witness may sincerely believe something to be true, yet the information actually is false, incorrect or incomplete.
- Some degree of inconsistency among witnesses is normal. It is not unusual for two eyewitnesses to have different perceptions, understandings and recollection of the incident although they witness the same event.
- The witness may have a vested interest in the outcome of the investigation.

The interviewer should avoid placing blame or any implication of fault-finding. It would be premature to make judgements regarding determinations of fault.

31.3.5.2 Planning

Pre-interview planning can have significant impact on quality and effectiveness of information gathered during initial screening interviews. In almost all cases, information supplied in follow-up interviews will be modulated by the witness' interactions with other people after the initial interview and, therefore, the initial interview represents a unique opportunity to gather information with minimal contamination by others. The investigation team will often designate a single person as interview co-coordinator. This interview co-coordinator may not actually conduct every interview, but this person will have overall responsibility for witness interview evidence gathering. For consistency sake, it is desirable to have a minimum number of designated interviewers (usually no more than two or three investigation team members).

Persons selected as designated interviewers should have strong verbal communication and listening skills. Many technical personnel (such as engineers and chemists) find themselves assigned to investigation teams and often do not have strong verbal communication skills and abilities to communicate with non-technical personnel. Supervisory personnel, on the other hand, are often better suited for the interviewing task, due to their extensive experience and interactions with other people in the normal course of day-to-day activities. Typical practice is to have one interviewer and one witness in the room for the initial interview. In some instances, a second interviewer may be present to take notes or to provide specific knowledge for full understanding of the information the witness may offer. For instances where there are two interviewers, it is a recognized best practice to designate one interviewer to function as 'primary' or lead interviewer and for the other interviewer to take a secondary role. In some instances, the witness may request to be accompanied by another person (i.e. union representative, attorney or other). It is widely recognized and accepted that the one-on-one interview is the most effective format, although in some cases circumstances prohibit this arrangement. There is typically a reduction in the quality and quantity of information gained from the interview if there are too many interviewers present.

Venue for the interview should be neutral and non-intimidating for the witness. The interview location should provide privacy and be free from foot traffic and other interruptions. Interruptions disrupt the witness' train of thought and can severely detract from the interview dynamics. It is a common mistake to conduct the interview in the private office of plant management. This practice generates additional stress on most witnesses, as many hourly personnel will not feel comfortable in such locations, and will be less willing to supply complete and accurate information.

One early and continuing task for the investigation team is identification of potential witnesses. Personnel who were present at the time of the event are in the highest priority category. During the course of the investigation, it is common to identify additional personnel who were not on the initial list of potential witnesses. It is more effective to schedule the interview at a time and place convenient to the witness.

One recommended best practice is for the interviewer to personally visit the scene of the incident before conducting the interview. This adds to the interviewer's understanding and interpretation of the information supplied by the witness, and also provides an opportunity for the interviewer to ask clarifying questions for a more precise and complete set of facts. Before starting, the team must decide how the interview will be documented. The most common documentation method for initial screening interviews is to take hand-written notes. On occasion, audio or video tape recording is done, although these can adversely affect the witness. In cases where there is a second interviewer present in the room, it is a good practice to designate this person as the official note taker. Some investigators suggest that in order to minimize witness apprehension, the interviewer should inform the witness of the intention to take notes and where feasible, offer to supply the witness with a copy of the hand-written notes. In many instances, it is beneficial to have interview aids present such as: paper and pencil, plot plan, P&ID, photographs, flipchart and markers. During the interview, the witness should not be exposed to documents generated by the incident investigation team (such as marked-up diagrams, or listings of credible scenarios and possible causes), because information on these documents could alter the information that the witness provides during the interview.

The remainder of this section will focus on techniques for the initial screening interview, conducted by the organization's internal investigation team, recognizing that third party and regulatory interviews have additional issues beyond the scope and objectives of this chapter.

31.3.5.3 Stages of initial screening interviews

There are four distinct stages in every effective interview:

(1) opening;
(2) witness statement;
(3) interactive dialogue;
(4) closing.

31.3.5.3.1 Opening phase

In many cases, the overall effectiveness of the interview is determined during the first two minutes. If initial rapport and trust are not established, the quantity and completeness of the information offered by the witness will be significantly decreased. It is best to begin with introductions, clarification of the objectives and purpose of the interview and investigation, and a conscious effort by the interviewer to break the ice establishing some degree of rapport between the witness and the interviewer. Some interviewers find it helpful to start with some general background questions before jumping into the more significant issues. This practice establishes a dialogue flow and allows an opportunity for the witness to overcome any initial nervousness and anxiety. It is helpful to discuss how the interview will be documented and, in some cases, it is also helpful to inform the witness how he/she was selected for this interview. If the interview is to be recorded, it is a good practice to explain the purpose of the recording and to seek permission from the witness. Some interviewers find value in asking the witness if he/she has any questions about the interview process, as a means to minimize stress to the witness. In some instances, the interview may be conducted under a confidentiality arrangement, where the interviewer pledges that certain confidentiality will be maintained related to exactly what information was supplied by which witnesses. This confidentiality is common for investigation interviews conducted by regulatory agencies. If there are confidentiality issues, they should be discussed during this opening phase.

31.3.5.3.2 Uninterrupted narrative

Following the opening, a critical segment of the interview is the witness statement of what he/she saw and experienced. It is a best practice to allow the witness to tell their narrative without interruption. If the interviewer interrupts in order to clarify or expand on something the witness said, the witness' train of thought could be permanently derailed. The interruption will most likely cause the witness to omit information he/she would otherwise have included. Listening silently during this narrative is very difficult and challenging even to experienced interviewers. During the narrative, the interviewer should write down items that need additional clarification. In most cases this initial narrative is completed in less than 10 min. During this listening phase, the interviewer should avoid giving non-verbal feedback such as frowning, yawning, looking at the clock or other actions that might distract or otherwise adversely affect the witness.

31.3.5.3.3 Interactive dialogue

During this phase, the interviewer and the witness enter into an exchange dialogue and information is transferred and clarified. This is the proper time to raise questions or receive confirmations from the preceding uninterrupted narrative. In most instances the interviewer will have a prepared list of general issues, items, topics and questions that provide the basis for completing this dialogue phase of the interview. These questions are used if the witness did not address the topic during the uninterrupted narrative segment. Open-ended questions are those questions that begin with what, which, where, when and how and cannot be answered with a simple yes or no response. Closed-ended questions are those that can be answered with a yes or no. Both types of questions have their place in incident investigation interviews. Open-ended questions are usually more productive and effective than closed-ended questions, especially during the earlier stages of the interview. Closed-ended questions are necessary and effective for clarifications and confirmations. Some typically useful questions include:

- 'How and when did you first become aware of the event or that something adverse might be happening?'
- 'What was different this time from previous times?'
- 'What were the operating conditions prior to the event?'
- 'Is this hazard covered in the training program and written procedures? If so, how is it covered?'
- 'Who else might have additional information that could help us determine what happened?'
- 'What are your suggestions/opinions on how this incident could possibly be prevented in the future?'

During the interactive dialogue phase, it is a good practice to use reflective listening techniques to confirm that the interviewer accurately understood witness' statements. This playback allows the witness to correct any gaps or errors in the interviewer's understanding. It is also a good practice for the interviewer to be on the alert for ambiguous or relative words that have different meanings for different people. Examples of these potentially 'fuzzy' words include: fast, faster, slow, slower, usual, normal, typical, sometimes, often, recently. If possible, the interviewer should clarify any words, jargon or acronyms that have potential multiple interpretations.

31.3.5.3.4 Summary closing phase

The majority of initial screening interviews reach a natural conclusion after approximately 20–30 min. The witness has offered his/her version of what happened and has addressed most of the issues on the prepared list of questions and areas of interest. The interviewer should use this phase to summarize his understanding of the information provided by the witness. It is a good practice to invite the witness to submit additional information if the witness remembers something after the conclusion of the interview. The interviewer should ensure the witness knows how to supply additional information and that the additional information is welcomed. The interviewer should thank the witness for his time and cooperation and should alert the witness regarding the possible need for a follow-up interview.

31.3.5.3.5 After the interview

Initial screening interviews are often conducted in series. Therefore, it is important to document thoughts, observations, questions and follow-up issues immediately after each interview. If the interviewer waits until the end of the day, the interviewer will not remember everything and may not be able to recall which witness supplied which information. It is a good practice to allow additional time between interviews, for documentation or an unexpected extension. It is typical practice for the initial screening interviews to last approximately 30 min, with an additional 15–20 min between interviews. In most cases, the interviewer will have visited the general scene of the event before beginning the interviews. In some instances, it may be beneficial after a particular interview for the interviewer to re-visit the scene and place themselves in the witness' location (or to physically retrace the witness' movements) to clarify and further understand statements made by the witness.

31.3.5.4 Optimizing results

A few chronic challenges to effective investigation interviews include the following factors.

31.3.5.4.1 Promptness

Promptness is critical. Witness memory degrades and is strongly moderated by interaction with other witnesses.

The investigation team should conduct initial screening interviews promptly.

31.3.5.4.2 Selective acceptance of information

During early stages of an investigation, the investigation team may identify a most likely scenario among a set of possible cause scenarios, and allow this preliminary finding to affect the conduct of interviews. It is very easy for the interviewer to become selective regarding preferred or non-preferred information being supplied by the witness. The interviewer can become non-objective and may not capture potentially significant evidence.

31.3.5.4.3 Disclosure

Another avoidable mistake is to disclose investigation team preliminary findings to the witness during the interview. This disclosure can cause the witness to modify the information offered during the interview.

31.3.5.4.4 Remaining neutral

An effective interviewer operates in a neutral mode to cause minimum impact on the witness. Interviewers should avoid leading the witness or phrasing questions in such a form as to suggest a desired response. The interviewer should show respect for the witness, even if the interviewer believes the witness to be less than truthful or otherwise difficult.

31.3.5.4.5 Making promises during the interview

Another avoidable mistake is to make promises or commitments to the witness during the interview, especially if the interviewer is not in a position to ensure that the promise is met.

31.3.5.4.6 Written statements

Statements written by the individual witness are a potentially strong augment for enhancing the effectiveness of interviews. In many cases these statements can be developed by the witness prior to the interview as a means to minimize memory degradation and minimize witness intermingling of perceptions. It is a good practice to ask the witness to sign and date the statement that he/she prepares.

31.3.5.4.7 Categories of witnesses

There are several groups of witnesses. Direct eyewitnesses are those who were present and personally experienced the event. Indirect witnesses may not have been present, but nevertheless possess useful knowledge that could assist in determining and understanding the cause scenario. Indirect witnesses can also be helpful in disproving and excluding proposed scenarios that do not apply in this instance. There are several groups of non-employee witnesses who often contribute valuable information including: contractors, visitors, delivery personnel and former employees. Emergency responders who were present at the scene of the incident during the event can provide additional clues as to the sequence of events and condition of equipment before the end of the incident.

31.3.5.4.8 Room arrangements

Interview room configuration can impact the quality and quantity of results. Some interviewers try to avoid a seating configuration where the witness is on one side of a table (or desk) and the interviewer is on the opposing side. A 90° orientation is less threatening and more comfortable for many witnesses.

31.3.5.4.9 Non-verbal communications

Non-verbal communication such as eye contact and body posture can sometimes provide additional clues and insights as to the information being offered by the witness.

31.3.6 Evidence analysis

Evidence analysis can provide objective and scientific independent confirmation of the cause scenario speculated by the investigation team. Damage patterns provide information related to the origin and sequence. Investigators can also make useful determinations based on anomalies and by analysing what remains undamaged.

There are numerous publicly available resources for evidence analysis, including physical property data for melting temperatures autoignition temperatures and chemical incompatibilities. Some methods are nondestructive (Non-destructive Evaluation, NDE), while others require permanent modification of the evidence. Visual examination is the most common and one of the most powerful evidence analysis techniques. NDE Integrity testing can include leak checking, X-ray radiography, ultrasonic thickness testing, physical measurements, magnetic particle testing and others. Two useful references are the National Fire Protection Association standards # 921 for Fire and Explosion Investigations and # 907 Determining Electrical Fire Causes. Although these two references are prepared for use primarily by municipal fire protection agencies and organizations, they contain information helpful to industrial investigators. For example, tables from NFPA 921 present autoignition (table 3.3.4) and melting (table 4.8) temperatures for specific commercial materials. NFPA 921 also includes an interesting section on Human Response to Fire (chapter 8), interview techniques and helpful information on preparing sketches and diagrams. Another useful reference in fire and explosion evidence analysis is the Materials Technology Institute Publication 30, *Guidelines for Assessing Fire and Explosion Damage*. This publication uses a temperature profile to assist in determining fire cause and origin.

Metallurgical and failure analysis of evidence, fractured physical evidence and failed equipment can provide valuable information regarding the nature, sequence and cause of the incident. The mode of fracture (ductile or brittle) can indicate pressure and impulse forces. The direction and style of crack propagation is often helpful. Metallurgical analysis can help determine age, origin and reason for the failure. Cause and type of corrosion attack can be determined and can provide evidence of contaminants or corrosion not expected to be present. Temperature at time of failure can be determined. The actual fracture pattern can provide an indication of conditions at the time of failure.

There are several types of chemical analysis techniques that can be helpful in identifying the cause and sequence of the event. Chemical analysis can be conducted to confirm or refute the presence of compounds, substances, trace impurities or gross contaminants. Retainer samples of raw materials and final products are often re-analysed to help refute low probability scenario. Residues remaining after a fire can still provide useful chemical evidence. Physical property testing is useful in analysing or confirming potential fire, reactivity, stability, solubility or contamination concerns. Gas chromatography and scanning electron microscopy (SEM) are two common methodologies.

Arson is a special case and in many instances will leave tell-tail unique evidence. Most fire departments, law enforcement agencies and insurance companies have in-house experts available to assist if there is a suspicion of malevolent action. There are well-established char and burn patterns for most common building materials and components that can indicate the nature of the fire (Redsicker and O'Connor, 1997). Arson investigators look for atypical patterns and the presence of accelerators and ignition devices.

31.4 The Investigation Team

31.4.1 Team charter (terms of reference)

Most incident investigation teams for significant process incidents are charted, organized and implemented as a temporary task force. Most team members will retain other full-time job assignments and responsibilities. The intention is for the team to disband at the completion of their assignment, usually upon issuance of the official report. It is important and necessary for the team's authority, organization and mission to be clearly established, preferably in writing by a senior management official in the organization. The team charter authorizes expenditures, reporting relationships and designated responsibilities and authority levels for the team. The investigation team charter is usually generated and issued from the upper levels of the corporate organizational structure.

31.4.2 Team composition

The incident investigation team for process-related events is typically composed of a cross-section of skillsets and competencies related to the process and nature of the event under investigation. Team size can vary from as few as three full-time members to as many as 15, with six to eight being most common. In many aspects, the team size and composition are comparable to the team formed to conduct a PHA. There is a designated team leader who brings the investigation methodology expertise to the team. In almost all cases of process safety incidents, there are team members who have operating experience with the process unit that experienced the event as well as a process engineer who understands the control systems. In the United States, in incidents where there are significant consequences and a likelihood of litigation, the nominal or actual team leader may be an attorney. It is a common practice in significant incidents for the team to have a designated sponsor who is a member of the upper level of the organization's management team. In addition to full-time members, it is a common practice to enlist technical speciality help on a part-time basis. These special team members may not attend every team meeting, but nevertheless execute designated tasks that help the team move forward in identifying root causes. Special skillsets might include reactive chemist, instrumentation or control system engineers, material engineer, rotating machinery specialists and industrial hygienist. It is a common practice to use company employees from sister plants or sister units, who may have specific knowledge of the process being investigated, yet who may not be as emotionally connected to the incident. Use of outside personnel can add additional credibility, objectivity or technical expertise where appropriate.

One member of the investigation team will normally be devoted full-time to coordinating the witness interviews. It is a good practice to designate one team member to manage all photography and photographic or video evidence. Another member is often designated as the official spokesperson coordinating all communication external to the team. For many incidents, management of evidence is assigned to a single team member. Another typical team member is a representative of the safety department familiar with the administrative safety management safeguards.

31.4.3 Team preparations

31.4.3.1 Training

Team training occurs in two stages. There is normally an established formal training program for all potential investigation team members that is conducted prior to the event to maintain a pool of qualified potential team members. Some required training is extensive; US Hazardous Waste and Emergency Operations (OSHA 1910.120) and respiratory protection (US OSHA 1910.134) are examples and may require periodic refresher training and certification. The incident investigation management system should be developed and implemented to assure that investigation team member training needs are maintained. Use of respiratory protection devices may also require fit testing and pre-use medical evaluation. It is a major handicap to attempt to conduct all needed and legally required training after an event and before the investigation can begin. Team leaders require training in effective application of the investigation technology method being applied, as well as an understanding of organizational expectations, definitions, reporting requirements and issues related to developing recommended preventive action recommendations.

At the time the investigation is launched, it is common for the personnel selected as full- or part-time team members to receive refresher training focused on the nature of the event. This refresher training may include personal protective equipment training (respiratory and other), the investigation methodology and approach, as well as specific emergency preparedness and emergency response training related to the specific accident site.

31.4.3.2 Supplies and maintaining readiness

Investigation supplies and equipment fall into two general categories, individual and team items. Responsibility for procuring and maintaining individual items is normally placed on each individual team member and will include items such as hard hat, eye protection, safety footwear, fire-protective coveralls, gloves, goggles, boots, raingear, pencil, pen, notepad and flashlight. Team supplies are often collected beforehand and kept on-hand in a ready state. Preparation and maintenance of team supplies should be a component of the incident investigation management system and should be periodically inventoried, refreshed (batteries and film) and audited. In many instances there is a 'team go kit' containing the most often used equipment that might be needed by two people during the first several days of investigation. The equipment needed by the team will vary considerably depending on the nature and location of the incident and the degree of infrastructure support immediately available at, or adjacent to, the incident site. A typical assortment of team supplies and tools is shown in Table 31.2.

31.4.4 Launching the investigation

31.4.4.1 Getting started

A critical first step is organizing the team, identifying potential team members and designating a team leader.

Table 31.2 *Typical investigation team supplies and tools*

Item	*Details*	*Minimum quantity*
Go bag	Empty duffel bag	1
Camera – digital		1
Cell phone		1
Cell phone charger	12 V DC for vehicle	1
Camera – 35 mm		1
Film	35 mm 36 exp, colour 200 speed	4
Evidence tags		50
Battery for flashlight		4
Battery for recording device		4
Battery for camera		2
Wipes	Box of 50	1 box
Zip-lock bags		
Small	Small 4″ × 6″	25
Medium	Medium 8″ × 10″	25
Large	Large 1–2 gallon size	12
Plastic bags – extra-large	10–20 gallon	12
Tie-wraps	Plastic or wire	50
Permanent marker	Fine point and wide point	10
Marker	Yellow solid	1 box of 6
Marker paint stick	Yellow medium point	6
	Yellow fine point	6
	Black medium	6
	Black fine point	6
Tape		
Duct tape	50 ft roll	1
Masking	20 ft roll	1
Tape barrier marking	‘DO NOT ENTER,’ ‘AUTHORIZED PERSONNEL ONLY’	200 ft
Flashlight	Explosion proof	2
Pocket dictating recorder with two cassettes		1
Tool		
Multi-tool	All-in-one, pliers, screwdriver, awl	2
Screwdriver multiple tips	Phillips, Torx, Slot, various sizes	1
Slip joint pliers		1
Wire cutters		1
Fish scale	1–50 pound range	1
Pocket extension mirror		1
Magnifying glass		1
Tool box cutter	Retractable blade	1
Toothbrush		1
Tape measure	6.5 ft big letters	1
	12 ft	2
	25 ft	1
Ruler	6 in.	1
Thermometer	0–100 F range	1
Compass	Pocket type	1
Micrometer		1
Angle finder		1
Yellow string and plumb bob		1
Electric tester		1
Respirator	Half mask, size medium	1
Respirator cartridges		4
Disposable coveralls	Large and extra-large	2 each
Coveralls -Nomex	Large and extra-large	1 each
Disposable booties		6 pairs
Flags with rods	Position markers	24

Table 31.2 *(continued)*

Chain-of-custody forms		6
Helmet liners		2
Gloves, nitrile or latex		1 box 100
Gloves, leather		2 pairs
Earplugs		1 dozen
Eyeglasses	Safety glasses with side shields	2
Goggles		1
First-aid kit	Small pocket size	1
Spray paint	Pressurized cans, red/orange	2
String	1 ball minimum 300 ft	1
Clipboard	Metal box, straps	2
Pocket notebook	Water resistant	2
Post-it notes	2 in. × 2 in.	2
Pencils – mechanical		2
Pens		2
Fanny pack		1
Portable hand-held radios	Set of three with spare batteries	3 hand-talkies
Garbage bags	Large black plastic with tie wrap/closure	6
Rain gear	Large	2
Poncho		2
Insect repellent		1
Sun block cream		1
Health and safety plan for investigation team	Electronic and hard copy	1
Gas detector	Personal, H_2S, O_2, CO, flammable	1

Legal status of the investigation is determined and a formal charter is developed and issued. It is necessary to establish formal contact with emergency responders or regulatory agencies if they are in control of the scene to develop a plan for coordinated actions. The incident team leader should make preliminary arrangements for preservation of potential items of evidence. Sometimes the team leader may need to complete this action even before the initial investigation team meeting due to the time sensitive nature of some evidence. Circumstances may require the team leader (along with members of the investigation team who are immediately available) to:

- plan and begin witness interviews;
- organize and implement information (and evidence) management;
- initiate a listing of factors that may have influenced the event (inherent process potential hazards, known risk and control measures);
- develop a preliminary list of potential cause scenarios;
- develop initial timeline;
- arrange and plan for photography;
- initiate investigation of areas outside restricted area;
- begin to procure supplies and logistics for the team;
- plan for evidence preservation (identification, control, storage, restricted access);
- plan for team meeting – room, supplies and logistics;

31.4.4.2 Initial team meeting

The following section is intended to provide guidance to teams conducting initial team meetings for investigations of major incidents, however many of the items are applicable for all initial team meetings regardless of the nature or severity of the event. The first order of business is usually formal introductions of team members and their individual backgrounds, experiences and skillsets that may have application to the investigation. The next order of business will address any legal and confidentiality issues. Communication protocols and expectations (both internal and external to the team) should be clearly explained with confirmation from each member that he understands and accepts the communication controls. For major incidents, another item for the initial team meeting is coordination and liaison with other entities (inside or outside the organization). Evidence management should be discussed and preliminary arrangements made for collection, identification, documentation, chain-of-custody, storage and access to evidence by team members and others. Witness interviews are an important function in every investigation, and it is typical to assign one team member to coordinate the entire interview process. Arrangements and responsibilities for photography (and video) are usually developed during the initial team meeting. There may be a recognized need for special technical knowledge, competencies or services that should be addressed during the initial and subsequent team meeting.

It is also a good practice to address team supplies, logistics and consumables. There may be a need for training or refresher training in the use of personal protective equipment (such as respiratory protection or portable instrumentation), and the initial team meeting presents an excellent opportunity to identify this need and make appropriate arrangements. As previously mentioned, it is a common practice to conduct specific training during (or immediately following) this initial team meeting. The initial team meeting may also include an overview tutorial on the process operations, materials, credible failure modes, previous incidents and potential hazard exposures than might be encountered by the team.

31.4.4.3 Team member safety issues

Field investigation activities are often conducted in less than ideal circumstances. Investigators can be exposed to a variety of hazards. One common hazard is the constant potential for slips, trips or falls created by unstable working and walking surfaces. Accident scenes are often accompanied by sharp metal edges from debris and broken glass. Investigators can be injured by debris falling from above that becomes unstable by vibration or shifting rubble piles.

Other hazard exposures include radiation from nuclear instrumentation devices, and stored potential energy in the form of hydraulics, pneumatic, spring energy and elevated mass. One initial task conducted by emergency response personnel is to attempt to isolate all sources of energy (electrical, pneumatic, thermal, hydraulic or other form). The investigation team should conduct an independent verification that all electrical power, energy sources and sources of additional fuel (gas pipelines for example) are isolated. It is not uncommon to find energized electrical circuits that were installed during construction and are not accurately depicted on existing electrical power distribution documents. Air-borne contaminates from uncontrolled releases of process materials represent another potential hazard exposure. The team may need to conduct sampling to assess the need for additional clean-up or use of personal protective respiratory equipment.

During the investigation, team members will often have need to access elevated or constricted space to make observations or gather evidence. Access to elevated locations may have to be made by crane basket or special scaffold. Team members may need to be competent in the use of fall protection devices. Sometimes in major accidents, the investigators may need to deal with biohazards. As mentioned earlier in Section 31.2.6 and Section 31.3.1, the site may be classified as an uncontrolled hazardous waste site, therefore, the team may need to implement hazardous waste and emergency response control measures. Regardless, the investigation team should be prepared for emergencies that could occur during the course of the investigation, such as releases of materials or injuries to team members. It is a good practice to implement emergency alarm, alert and communication capabilities for the investigation team.

31.4.4.4 Pre-entry activities

Even before the team sets foot on the accident site, there are certain investigation tasks that can be initiated. Access to the site may be restricted due to emergency response activity or regulatory agencies. In many instances, the team, or portions of the investigation team, may be ready before authorization is received to make the initial entry. The initial team meeting can be conducted and witness interviews can begin, although it is more productive if the initial entry can be made before starting these two activities. Required notifications must be completed and documented. In some cases there is a requirement for follow-up notification. Assembling the list of potential witnesses and scheduling of interviews can begin immediately. If not already completed, the charter for the team, legal considerations, team composition, team leadership and arrangements for any travel, accommodations, team supplies and team refresher training should be conducted or confirmed. Emergency responders can be de-briefed. Arrangements for use of outside photography (such as aerial photography) can be completed. The investigation team meeting room, supplies, logistics and evidence storage arrangements can be made before the initial entry. Areas outside the accident scene (offsite, downwind, adjacent units) can be toured, photographed and evaluated. The team or members of the team can begin to assemble relevant information and evidence (documentation, electronic data, drawings, material safety data sheets, meteorological records). A preliminary timeline can be initiated as well as a compilation of credibly possible scenarios and factors that may have influenced the event.

31.4.4.5 Initial reconnoiter

One important activity is the initial visit to the scene. An effective technique for conducting this important activity is the initial reconnoiter. The objective of this activity is to obtain an overview of the entire incident scene before becoming overly focused on the apparent centre of the event and before any evidence is disturbed. The investigator (or in some cases the entire investigation team) conducts a slow, deliberate and systematic circuit from outside the accident scene. During this circuit the investigator should:

- look for potential safety hazard exposures to the investigation team;
- look at the big picture (forest), not just the micro (trees);
- note what is not damaged;
- note what is present that would not be expected to be present;
- note what is absent that would be expected to be present;
- make intentional pauses to observe the scene from multiple angles and elevations;
- use all senses (such as smell, sounds, physical sensations of pressure, force or heat);

31.4.4.6 Suggested summary checklist for team leader

The following is a suggested model checklist that can be prepared and used by incident investigation team leaders.

31.4.4.6.1 Initial communications

- Clarify known casualties and status of injured.
- Internal notifications done and confirmed – who, when, what info, delivered to whom by whom.
- Confirm legal and regulatory notifications and requirements – legal and regulatory status.
- Confirm team charter – authority, administrative and financial, scope, reporting relationships.
- Team member selection and notification, confirm availability, and identify potential availability problems.
- De-briefing with emergency responders and local site management – initial data gathering request.
- Clarify need for HAZWOPER coverage and training.

31.4.4.6.2 Initial team meeting (agenda and primary assignments)

The following topics are applicable to most initial investigation team meetings. The team should consider each issue and make assignments where needed:

- communication protocols, expectations, responsibilities, internal to team and external;
- Evidence;
  – time-sensitive evidence (electronic and other),

  - stabilization,
  - identification,
  - custody and control of access to evidence,
  - documentation,
  - storage (short term long term and preservation),
  - electronic evidence,
- witness interviews – assign responsibility for coordination, identify potential witnesses, schedule, coordination with other agencies and parties;
- photography – conventional film, digital, video, digital, how to document and control distribution;
- logistics for team – supplies, personal protective equipment (PPE), finances, administrative needs, biological issues;
- special services or technical skills that may be needed;
- liaison with other investigations and third parties (insurance, regulatory, Local Emergency Preparedness Committee (LEPC));
- expectations for interim report;
- requirements, needs of management, review and release authorizations protocol and documentation;
- special training for team (all or part of team, PPE, chemistry, control, special equipments or systems);
- determine involvement of contractors;
- begin listing of known facts;
- develop initial timeline chronology;
- develop initial logic diagram to identify possible cause scenarios;
- identify restart criteria if applicable.

31.5 Identifying Root Causes

31.5.1 General concepts

Root cause determination is an iterative process which systematically seeks to identify and understand the underlying causes that allowed the event sequence to progress to its ultimate consequences. As discussed in Section 31.2, the investigators need a clear understanding of the term root cause in order to determine the proper stopping point for the investigation. Chemical process incidents are most often complex events with multiple root causes (Philley, 1992; CCPS, 2003).

Root cause determination must be systematic and use a scientific approach. All credible explanations should be examined. Alternate scenarios that are rejected should be rejected based on evidence and the reasons for the rejection should be documented. Root cause investigation is similar to root cause analysis, however, there are some important differences between the two terms. Root cause analysis (or root cause failure analysis) is more often used to describe the process by which equipment failures are investigated (Mobley, 1999; Anderson, Bjorn and Fagerhaud, 2000). The term root cause investigation, on the other hand, is used in a broader context to describe the entire incident investigation process and all associated activities. Root cause analysis could be thought of as a subset of root cause investigation. One aspect of the root cause investigation process uses root cause analysis to determine and understand the actual adverse scenario and its underlying causes. Results of root cause investigations should be based on evidence, reproducible and defendable. All comprehensive root cause determination approaches attempt to determine the underlying reasons that allowed a set of circumstances to exist, the trigger events in the adverse chain, and the failures in protective systems (physical systems and administrative systems).

Root cause determination relies on application of the scientific method (BioTech Life Science Dictionary, 1995). The scientific method as universally accepted is an organized approach to the study of a problem that consists of recognized steps of observation (collecting data and evidence), hypothesis (developing a set of credibly possible incident scenarios), testing (confirmation and validation of the speculated cause scenario), analysis (the results of the testing are interpreted and accepted or refuted), and conclusion (the investigation findings) that can be independently evaluated by other investigators. As additional information (evidence) becomes available, investigators gain a more complete and accurate understanding of the cause scenario, then refine and adjust the hypothesis (speculated cause scenario). Rejected scenarios are documented. All evidence is addressed, even information that may not support the speculated cause scenario.

In the second edition of Lees (chapter 27), accident models are discussed along with several approaches for identifying causes. T. Kletz views the accident as a series of events and assigns each event to one of three general layers:

- immediate measures to prevent a repeat event;
- measures to avoid the hazard (implementing or strengthen barriers);
- changes to the management system to eliminate or reduce the risk exposure (moving towards inherently safer design).

Root cause tools are used to gather and analyse additional evidence, information, and reach a more complete and accurate understanding of the actual scenario and its associated underlying reasons. Application of root cause determination tools is an iterative process because of the changing quantity and quality of information. Diagrams and checklist used alone do not automatically yield root causes, but do provide general direction and structure to assist investigators to examine possible issues that may apply to the incident being investigated. The investigators then use the specific evidence, facts, circumstances and available information to determine the root causes. Various methodologies use different types of diagrams, charts, checklists and definition of specific terms such as 'near-root cause,' 'basic cause,' 'causal factors' and others. It is not in the scope of this chapter to present a summary of all root cause determination methodologies currently in use.

31.5.2 Toolbox

31.5.2.1 Chronology

Most root cause methodologies incorporate use of a chronology tool to establish the sequence of events, activities and conditions. Development of a timeline chronology is an iterative activity and allows the investigator to better understand the evidence and witness statements. Some items on the timeline can be precisely positioned because there is hard evidence such as a record of the time of alarms and instrumentation data (see Figure 31.3). Exact time for other information may not be capable of being determined, however, relative sequence may be identified. Some root cause investigators use the timeline to assist in identifying those events that represent adverse consequences, management system breakdowns, unplanned situations or failures of safeguard protective measures. In some root cause investigation methods, these undesirable outcomes are classified as ‘critical events.’ There is no established convention for constructing a chronology diagram. Some investigators prefer a horizontal orientation, while others find value in vertical or diagonal formats. For complex events or where there are simultaneous parallel sets of activities, the timeline can be expanded into branches and parallel tracks.

31.5.2.2 Logic diagrams

Logic diagrams have several applications in investigations, and are most often developed in an iterative fashion. As shown in the event tree logic diagram in Figure 31.4, in the early stages of an investigation they can be used to illustrate credibly possible reasons, conditions and events to assist in determining the cause scenario. As shown in Figure 31.5, they can point the investigators to what specific additional information or evidence might be gathered in order to confirm or refute a postulated cause scenario. In the middle and late stages of an investigation, logic diagrams can be refined and used as a quality control tool to ensure the team is systematically addressing the information and that individual branches of the logic tree are consistent. Another use of logic diagrams is in presenting the findings in a formal written report. A simplified logic tree can be used to present the cause scenario and illustrate conditions and events so that the reader can follow a complex incident. In the early stages of an investigation, the type of logic gate may not be initially known since relationships between facts, events or causes may not be sufficiently understood. At the later stages of the investigation, when the event is better understood, the types of gates (exclusive AND gates, OR gates) can be refined into the iterative diagram. Deductive diagrams similar to the conventional ‘fault tree’ diagrams are the most common type of investigative logic diagrams. On occasion, inductive diagrams (such as the ‘event tree’ shown in Figure 31.4) may be used to determine a most likely match between known facts and possible causes. One special type of investigation logic diagram is the management oversight and risk tree (MORT) (Johnson, n.d.). The MORT investigation method uses a generic logic tree with pre-existing gates. The investigation team gathers and examines evidence to confirm which branches of the tree were applicable in the particular incident being investigated.

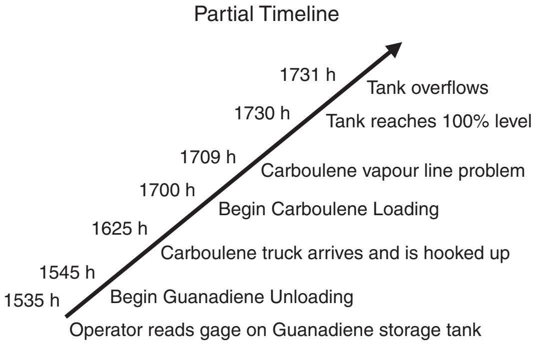

Figure 31.3 *Sample chronology*

The team applies the logic diagram in an *iterative* manner to identify what conditions and actions were present or were needed for the accident to occur. The initial logic diagram may contain several speculated ‘OR’ gates, where the information currently available is insufficient to determine if the branch was applicable. The logic diagram will highlight missing pieces of information thereby guiding the team to gather additional focused information. A logic diagram can highlight evidence that is inconsistent or contradicts a proposed incident cause scenario. Once there is sufficient evidence to refute a particular branch, further development of that particular branch is terminated and documented. Near the final stages of the investigation, the logic diagram can be used in a quality assurance mode to verify known facts meet logic principles and that each branch is in agreement with all other branches of the logic diagram.

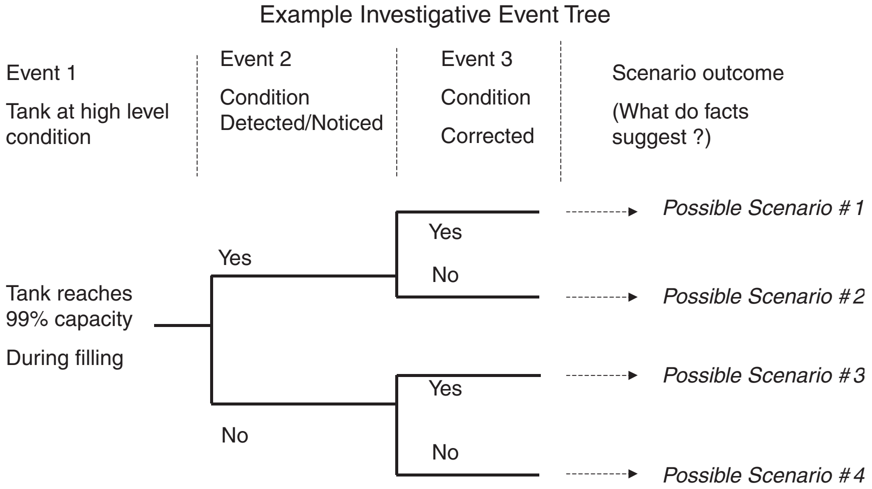

Figure 31.4 *Event tree*

One important limitation is that logic diagrams do not always show time or sequence relationships relative to the information on the diagram. Special charting diagrams use a combination of chronology and logic diagrams to illustrate and understand the event. Some investigation methodologies apply special conventions such as the shape of text boxes and the type of interconnecting lines to further illustrate the event.

Consider the following typical tank overflow event.

Operator was unloading tank truck of liquid solvent while loading railcar of VCM chemical. Solvent storage tank TK102 was overfilled causing it to overflow. Approximately 1735 gallons of solvent spilled into dike area. Level gauge on solvent tank was found to be 16% out of calibration, thus reading low. VCM railcar was experiencing vapour lock problems. Incident occurred just before shift change. Level instrumentation on solvent tank TK102 was 32 years old and was calibrated every 36 months.

The initial logic diagram developed by the investigators might look like something shown in Figure 31.5.

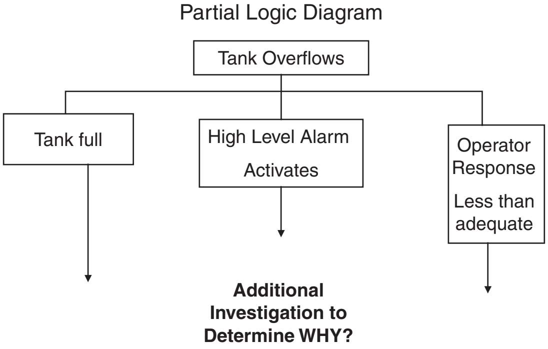

Figure 31.5 *Logic diagram for tank overflow incident*

The investigation team then gathers additional information and evidence and develops an initial chronology.

As additional evidence becomes available the team is able to refine the logic diagram and move closer to identifying underlying root causes (see Figure 31.6). Each branch of the logic tree is then developed to a point where evidence proves that the branch was not applicable, or to the point where underlying root causes can be identified.

Another special diagram is the Ishikawa fish-bone diagram where information and conditions leading to the event are depicted as branches on a horizontal format (see Figure 31.7). The fishbone diagram is not a true logic diagram, however it does provide an effective tool for investigators to systematically gather and examine information relative to the causes of the incident.

31.5.2.3 Application of critical thinking skills/concepts

Critical thinking uses concepts of logic and reasoning in problem solving to produce more accurate and defendable conclusions (Philley, 2000). The investigation team is often initially confronted with conflicting information from witnesses and a large set of credibly potential scenarios, therefore, investigation of chemical process incidents can benefit from application of critical thinking skills. This section discusses several aspects of applying principles of critical thinking, to the investigation. The term ‘critical thinking’ has multiple definitions. One simple definition is, ‘the art of thinking about your thinking in order to make your thinking better’ (thereby making your thinking clearer, more accurate, or more defensible (Center for Critical Thinking, n.d.). Applied to incident investigation, critical thinking helps the investigation team to:

- identify and evaluate potential cause scenarios;
- evaluate evidence in support of (or to refute) a proposed cause scenario hypothesis;
- select the most appropriate (most likely) cause scenario.

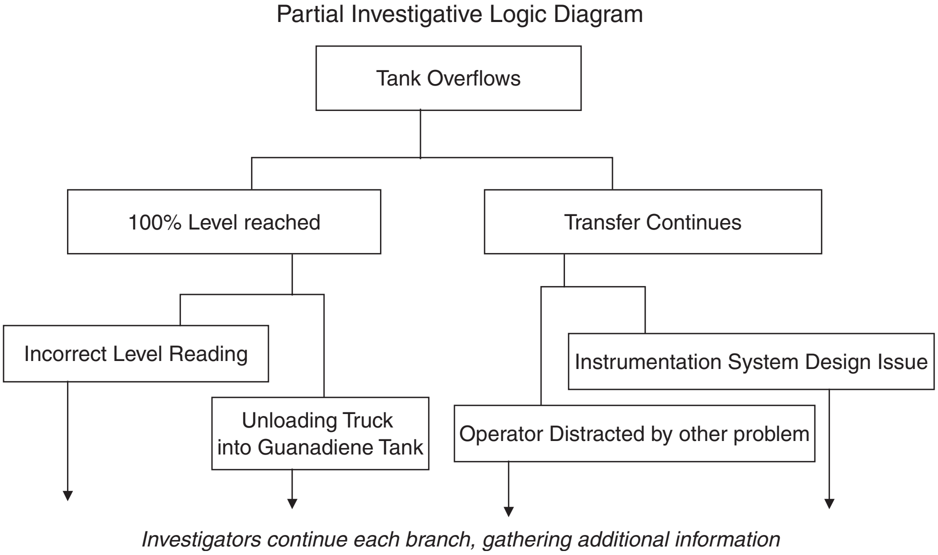

Figure 31.6 *Developing logic diagram*

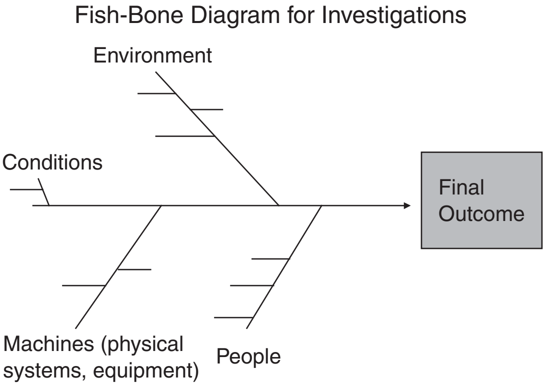

Figure 31.7 *Sample fish-bone diagram*

31.5.2.3.1 Lateral thinking

One important critical thinking concept useful in investigation is lateral thinking. Lateral thinking is sometimes characterized as 'thinking out-of-the-box.' When applying lateral thinking, investigators search for alternate explanations that fit a given set of known conditions and facts. As additional evidence and information becomes available, the alternate explanation will become more or less credibly possible. Lateral thinking is particularly valuable in the early stages of the investigation in order to prevent the team from prematurely locking-onto an incorrect cause scenario and also in evaluating apparent contradictions in evidence. Lateral thinking allows and encourages investigators to deviate from normal explanations, conventions and expectations. Creativity is used to identify possible alternate explanations for the evidence presented. When presented with a set of circumstances, our first response is to find a traditional explanation that fits the facts as we understand them to be. A lateral thinking approach to identifying a cause scenario would not reject the most likely explanation, but would expand the set of possible scenarios to include alternate, less probable, explanations for the same set of facts. Alternate scenarios remain on the table until there is clear reason and evidence for rejecting them. Lateral thinking sometimes generates extra work for the investigation team to document reasons why alternate explanations were rejected. Nevertheless, it adds to the overall quality of the investigation and makes the ultimate findings more credible and defendable.

31.5.2.3.2 Critical thinking validation of cause scenario

One critical challenge is to accurately and quickly determine the cause scenario. Validating speculated possible scenarios is fundamental to investigation success. In a purely scientific setting, a set of validity tests has been developed to prove a theory or hypothesis (Lett, 1997). In practical industrial accident investigations, these validation principles can be used to ensure a quality investigation:

- Is the scenario logical?
- Is it comprehensive in addressing all known evidence?
- Are the identified causes sufficient to create the result?
- Can it be replicated?
- Does it have honesty and integrity?

31.5.2.3.3 Logic

This first validity test confirms that the identified scenario and associated facts agree with accepted logic principles (Webster's II New Riverside Dictionary, 1984). Any argument offered as evidence to support or disprove a suspected incident cause hypothesis must follow accepted rules of logic. Two excellent examples of this logic test are the fact–hypothesis matrix (CCPS, 2003), and the use of truth tables when testing the output of binary electronic circuits or when diagnosing/troubleshooting instrumentation systems. Logical thinking is essential for accurately determining the scenario cause relationships in every process safety incident investigation. Investigators must apply logic and reason effectively.

For example:

1. if the temperature in tank A was higher than in tank B, and
2. if the temperature in tank B was higher than in tank C, then, by logic and reason
3. the temperature in tank A *must* have been higher than in tank C.

31.5.2.3.4 Comprehensiveness

The second validity test, comprehensiveness, confirms that *all* known information has been addressed in the evaluation. The team does not have the prerogative of being selective about which facts it accepts, even if a particular fact may not appear to support the preferred hypothesis. There is a natural tendency to welcome specific information that supports the scenario preferred by the investigators. There is a corresponding tendency to 'reject' information that does not support the desired hypothesis. At the conclusion of the investigation, if there is any evidence available that contradicts the cause scenario, reasons for refuting this contradictory information should be adequately documented. In purely scientific research activity, this comprehensive test is easier to apply. However, in the practical world of industrial incident investigation, there are varying degrees of credibility regarding the accuracy of information. Not all information available to the investigation team has the same degree of truthfulness and accuracy. Often, the team will initially be faced with seemingly contradictory information. In most, but not all cases, apparent contradictions can be resolved by gathering additional clarifying information. Inconsistent or conflicting information is especially common in information gathered from witness interviews.

31.5.2.3.5 Sufficiency

The third validity test is sufficiency. Evidence offered in support of a cause scenario must be adequate (sufficient) to establish proof. If a scenario requires three components to be present, then the investigation team must establish the credible presence of all three components.

31.5.2.3.6 Replicability

The validity test of replicability requires that any evidence that is based on experimental results is capable of being duplicated by others using the same conditions.

31.5.2.3.7 Honesty

The final validity test is honesty. On the surface, this test seems an obvious requirement. However, in handling or presenting evidence, there are opportunities for misleading or incomplete representation of facts. The investigation team must exercise a high degree of honesty and integrity, especially in cases where findings may not be favourable to the organization's reputation. Selected omission of information can have a significant effect and there is an obligation to document any unresolved inconsistencies.

31.5.2.3.8 Cause scenario selection issues

Incident investigators often encounter cases of subjective opinion masquerading as truth. When analysing information, it is important to distinguish between objective fact and subjective opinion. Investigators should be alert for dogmatic statements that may not be supported by actual evidence. Dogmatism is establishing conclusions on rules, conditions, protocols and prescriptions established by some authority. Merely because oxygen tests are required by written procedural instructions does not mean that tests were actually conducted in the instance being investigated. The investigation team must verify assumptions. Stipulations should be clearly and thoroughly identified.

Another challenge to investigators is determining which information is actually true. Investigators will often be faced with apparent contradictory information from witnesses. Witness testimony is a combination of actual true facts, personal opinions and judgements, and recollections. Witness statements often reflect a conglomeration of first-hand information, assumptions, conclusions and hearsay. Information relayed in a verbal manner is subject to distortion and inaccuracy. Absolute truth is not created by consensus of opinion. Merely because a large number of people believe something to be true does not make the information a true fact.

Here are three examples of 'consensus opinion' that at one time were believed to be facts.

- 'The earth is flat.'
- 'The sun revolves around the earth.'
- 'Accurate prediction of the future can be made by autopsy of a human liver' (according to the early Babylonian practice of hepatoscopy, Shick and Vaughn, 1999).

Another critical thinking challenge is the occasional conflict between something that may be logically possible, but is physically impossible. Although it may be logically possible for a cow to jump over the moon, in the practical world there are physical limitations that prevent this statement to be physically possible.

Memory imperfection is another variable that must be addressed using critical thinking. Significant differences in witness statements can be traced to our inefficient memory mechanisms. Investigators must apply critical thinking skills when faced with apparent contradictory information from different witnesses. Our perception can change over time as we gain additional information from interacting with other people and information sources (Gilovich, 1991).

One major obstacle to evidence analysis is natural information filtering mechanisms that are part of normal thinking processes. Our perception of reality is actually a mental construction of several components. When faced with incomplete or potentially contradictory information, our brains will attempt to fill in the blanks to allow us to process and 'make sense' of the incoming information. The most common example of this is the optical illusion where our brain makes a determination when faced with ambiguous input.

Accurate identification of the actual cause scenario can be adversely affected by several factors. One obstacle is premature selection of the cause scenario. The investigation must identify and examine *all* credible potential cause scenarios before selecting one cause scenario as the most likely based on the available facts. Early establishment of 'a most likely scenario' is not a mistake as long as alternate scenarios remain under consideration until there is sufficient evidence to reject them. Premature selection of the cause scenario can create avoidable mistakes. The first problem is the resulting delay in identifying the correct accident sequence, due to the team investing time, money and resources pursuing a false trail. A second potential problem is triggering irrational defence of an invalid scenario. Investigators are slow to abandon a preferred cause scenario, even when faced with evidence that would clearly disprove the scenario. The third potential problem is the loss of credibility generated when the team has to announce that their initial findings and conclusions were incorrect. This decreased credibility has an adverse impact, especially in instances where litigation is involved.

Determination and selection of 'the cause scenario' involves rationalization. According to Psychologist Barry Singer (Gilovich, 1991), numerous experiments have confirmed our natural behaviour regarding how we develop hypothesis and conclusions. It is our normal pattern to quickly (and automatically) form a hypothesis and then begin to seek confirming evidence. We do not inherently place emphasis on seeking evidence that might *disprove* our hypothesis. We tend to stick to (and vigorously defend) our original hypothesis even when faced with conflicting evidence that might disprove our desired hypothesis. Therefore, investigators should make a strong and conscious proactive effort to operate with an open and unbiased approach, especially during the early phases of an investigation.

Another challenge is the false or hidden assumption. It is sometimes easy to make incorrect assumptions regarding the association between truly random events, thus generating a cause and effect correlation where there is not a direct cause and effect. Hidden assumptions can play havoc with an investigation when a team makes an assumption without realizing that an assumption has been made. These hidden assumptions often show up as inconsistencies in the cause scenario. When assumptions are made, they should be clearly identified and documented.

Misjudging likelihood/probabilities can lead to erroneous determinations when the investigation team believes a cause event to be too unlikely and, therefore, fails to thoroughly investigate a particular cause. Most people are not naturally proficient at estimating likelihood or probabilities of events. We remember confirming events much more effectively than we remember events that do not confirm a perception. Numerous examples can be identified that illustrate our inability to accurately estimate probabilities. Perhaps one of the more common examples relates to our general non-appreciation of the odds for winning a typical lottery. Where contestants are asked to select a set of six winning numbers from a field of 50 numbers, the actual odds are on the order of 15 million to one.

A final challenge related to rapid and accurate determination of the cause scenario is misplaced credibility. All other things being equal, we put more credibility on the first version of the story we hear. Subsequent versions that differ from the initial version are given less credibility because we begin to activate some of our natural mental filters (Gilovich, 1991).

31.5.2.4 Truth table matrix

Truth table matrices are common tools in logic and troubleshooting diagnostic activities. This concept has useful application in incident investigations. This tool can be applied effectively to help the investigation team determine the most likely scenario among a set of speculated credible cause scenarios, as well as assist the investigation team in resolving inconsistencies generated during witness interviews. The fact–hypothesis matrix is a special version of the logic truth tables used in developing control system logic and diagnosing/troubleshooting activities (CCPS, 2003). The tool can be used during the early stage of the investigation to allow the investigation team to focus on which evidence and fact issues and information could be further investigated in order to quickly produce a cause scenario that best matches the known facts. The fact–hypothesis matrix can be used in the later stages of the investigation in a quality assurance application to confirm consistency. The concept is simple: known (or suspected) facts are placed on one axis of the matrix and potential cause scenarios are placed on the other axis. Then the facts are analysed in conjunction with the speculated cause scenario for consistency (Table 31.3).

Facts fall into at least one of four categories:

1. + Yes – The fact *supports* the hypothesis (speculated cause scenario);
2. – No – Fact *contradicts* (refutes) the hypothesis;
3. 0 Neutral – The fact *neither* supports nor contradicts the hypothesis (is neutral);
4. ? Insufficient information – The team does *not have enough information* to make a determination regarding category 1, 2 or 3. In this case, the team can then determine what specific information might be gathered that would allow the team to confirm or refute the relationship between the fact and the speculated hypothesis cause scenario.

31.5.3 Specific methodologies and approaches

The following discussion is not an attempt to include all recognized public or private root cause determination methodologies and approaches. This section is intended to present a representative sampling of some common methods currently in use in the process industry. There is no intention to endorse any particular approach/method, and no attempt is made to fully explain contrast or compare one method to another. It is recognized that many organizations have developed and implemented effective internal investigation protocols and methods based on their organization's policies, resources and management styles.

31.5.3.1 MORT

One of the most widely distributed generic logic trees is the MORT developed by the US Atomic Energy Commission. The MORT diagram is part of the MORT system safety analytical procedure, and identifies causes and contributing factors by systematically applying the generic causes and conditions against known facts associated with the incident. MORT diagram is a formal disciplined logic or decision tree to relate and integrate a wide variety of safety concepts systematically (Johnson, n.d.). Potential weaknesses or breakdowns in management systems are considered. A five-stage accident sequence generic model is used and is based on the original Heinrich dominos: (1) (background factors, (2) initiating factors (underlying conditions), (3) intermediate factors (such as environmental and hazard recognition), (4) immediate factors (the trigger events or unsafe acts), and (5) the resulting consequence results. The barrier and barrier analysis

Table 31.3 *Fact–hypothesis matrix/truth table*

Possible cause scenario	*Fact #1*	*Fact #2*	*Fact #3*
	Lab Sample at 0600 showed elevated moisture content	High level alarm and high level condition noted in process sump	Vent compressor tripped twice on the shift before the explosion
A Event triggered by contaminated feedstock raw material	Yes Supports the scenario	? Do not have enough information to decide	0 Neutral effect
B Block valve left in incorrect position allowed backflow contamination	0 Neutral effect	Yes Supports the scenario	No Refutes the scenario
C Leak in heat exchanger created contamination and overpressure condition	? Do not have enough information to decide	Yes Supports the scenario	Yes Supports the scenario

concept is used. The MORT system also considers change, change analysis, risk assessments and risk decisions. When applying the generic tree there are approximately 1600 potential gates that must be evaluated.

31.5.3.2 CCPS A and B approaches

In the second edition (2003) of the *Incident Investigation Guidelines* published by the Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers, there is recognition of two general approaches in wide use in the process industry for root cause determination. Both are iterative and begin with an accumulation of known information, data, and evidence. One approach, method A, applies a logic tree and an iterative loop with an associated set of formal stopping rules and quality assurance gates to ensure the investigation has progressed deep enough to reach the root cause level and broad enough to address multiple causes. The other approach, method B, seeks to identify causal factors and then applies predefined generic trees to identify potential root causes. Both methods are effective.

31.5.3.3 Methods based on sequence diagrams

Sequence diagrams combine the timeline and the logic diagram concept, and attempt to depict the incident scenario events and conditions that allowed the sequence to progress. Sequence diagrams are not necessarily intended to provide a complete incident investigation system, however, they can be used to identify causal factors for subsequent analysis. In some sequence methods such as the multilinear event sequencing (MES) approach (Benner, n.d.; Atkins, 2001), a distinction is made between actors, actions and events. An actor is a person, substance or piece of equipment. Actions are defined as anything carried out by an actor. Events are results of those actions by the actor. There are several versions of causal factors charting currently being applied in the process industries. Rhone Poulanc implemented an events and causal factors charting system. The causal factors charting approach is similar to MES diagram (see Figure 31.8), and breaks down the incident into individual events and causes, developing a diagram that is a cross between a logic diagram and a sequence diagram. A further evolution of this concept can be found in the sequentially timed events plotting (STEP) procedure (Benner, n.d.). In the STEP approach, events are arranged on a horizontal axis and designated actors are arranged in a vertical column, then the relationships between actors and events are connected.

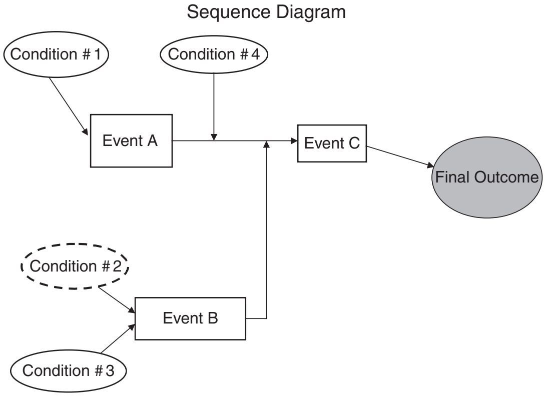

Figure 31.8 *Causal factors chart example*

31.5.3.4 Cause analysis methods

One method for incident investigation focuses on changes (known, unknown, intended and unintended). The Flixbourgh explosion in 1974 was the result of temporary piping changes. One of the causes of the Apollo 13 US Space Mission incident was an ineffective change management system that failed to find and properly modify all electrical components that would be impacted by a change in operating voltage from 28 to 65 V (Goodwin, 2000). The change analysis investigation method guides investigators to identify and analyse all conditions and items that were different for the specific event. Root causes are found in examining the deviations from normal.

The hazard–barrier–target model (Figure 31.9) for accident causation provides a basis for several investigation methods. Accidents are viewed as a 'hazard' (some form of energy), acting on a target (usually a person). In the normal course of events, barriers prevent interaction between the hazard and the target. However, on occasion the barrier is insufficient to prevent the accident. An accident can be described in terms of an unwanted energy flow that comes into contact with a person. Barriers can be physical such as machine guards, instrumentation system interlocks or control systems, or can be administrative such as training, policies, procedures and practices. The number, reliability and robustness of the barriers are proportional to the potential consequences and are related to the risk (likelihood and consequence). Recognizing that any given barrier will have a certain degree of unreliability, these investigation methods seek to identify and examine the barriers (management systems).

Another method sometimes used to identify underlying causes is the job safety analysis (JSA, sometimes called job hazard analysis). A task is broken down into its component actions and each is examined individually to identify potential hazards and the associated safeguard measures that were established to prevent the hazard from acting on the person. JSA can be viewed as a special case of examining the hazards and barriers. Another cause analysis approach is the systematic cause analysis technique developed by the International Loss Control Institute (now Det Norske Veritas (DNV, 1996)). In this approach, the investigation

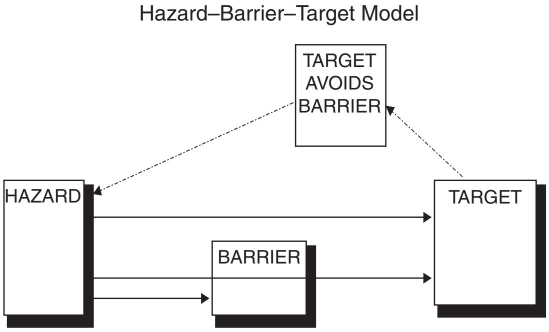

Figure 31.9 *Hazard–barrier–target model*

team is guided through a deepening series of questions that initially examine general safeguards and conditions concluding with a list of possible system defects that the investigators should evaluate based on the evidence and specific circumstances for the incident being investigated.

There are numerous additional analysis and decision making methods that can be applied to portions of the investigation, but that are not considered stand-alone incident investigation methodologies. Two examples are the human reliability assessment (HRA) where human actions are systematically identified and analysed, and the failure mode and effect analysis (FMEA), which is an inductive method for examining failures in systems or components. Several recognized PHA methods can be used in all or parts to assist investigations. When attempting to match up possible scenarios with available evidence, the hazard and operability (HAZOP) approach can be beneficial in searching for credible deviations from intended design and operating conditions. The WHAT-IF method is a helpful brainstorming technique for speculating possible causes and then directing the investigation team in evidence gathering to confirm or refute a speculated scenario.

31.5.3.5 Commercial methods

There are several publicly available commercial root cause investigation methods, three of which are discussed below.

TapRooT,® system is a commercially available process and set of techniques to investigate process safety incidents, analyse and develop corrective actions. It is widely used in the US process industry. The TapRooT® system (process and tools) combines both inductive and deductive techniques for systematic investigation of the correctable root causes of problems. TapRooT® goes beyond the simple technique of 'asking why' or the standard techniques of cause and effect (sometimes known as fishbone diagrams) or fault tree diagrams. Embedded intelligence allows TapRooT® to be used by people in the field to investigate everyday problems and yet, is robust enough for a complex major process safety accident investigation. Tools and techniques are used in all phases of an investigation – from initial planning through the collection of information and root cause analysis to the development of corrective actions and the presentation of an investigation to management or other interested parties. The system is supported by patent pending TapRooT® software and provides a trendable incident/root cause database and corrective action management database (TAPROOT, www.taproot.com).

Another commercial incident investigation methodology is the Apollo incident investigation and problem solving techniques method published by Apollo Associated Services Inc. The Apollo approach uses cause and effects charting and provides investigators with basic problem solving concepts to reach root causes. The reference is accompanied by worked examples and a training video. Guidance is provided to consider personnel performance factors, problems with written procedures and instructions, and general hardware deficiencies.

A third commercial root cause method is the REASON methodology developed by Decision Systems Inc (REASON, www.rootcause.com) This methodology is designed to provide a standard process that allows all options to be identified, modelled and analysed. The approach is presented as a standard operating procedure in a step-by-step format, to guide the investigator to ask the right questions to identify all relevant causes of the event. The REASON root cause analysis is a systematic process and software package for gathering and ordering relevant data, identifying internal causes that generated or allowed the problem to develop, and provides decision makers comparative cost effectiveness benefits of various possible remedies.

The US National Safety Council (1995) published a systematic approach for incident investigation that presents principles of investigation and the role of management leadership. The publication includes a guide for identifying causal factors and corrective actions using a set of workbook charts that lead the investigator to the underlying causes of incidents. Although this methodology is systematic, it may not be sufficiently sophisticated and rigorous for complex process safety events.

31.6 Recommendations, Reports and Lessons Learned

31.6.1 Recommendations

The payoff stage in the incident investigation process is implementation of changes that will eliminate the identified root causes, thus reducing likelihood of a repeat incident. This final stage involves development and evaluation of potential action item recommendations and begins once the root causes have been identified. In many instances, the charter of the investigation team ends with development of recommendations and issuance of a report. When recommendations are submitted to management, responsibility for action (acceptance and implementation) is transferred from the incident investigation team to the organization's management structure. Management must evaluate, accept, reject or modify the recommendation and then implement changes. Until and unless these changes are implemented, the risks for a repeat incident remain unchanged. In some instances, even before the investigation is completed, immediate action is recommended and implemented to take temporary measures to reduce or control the hazardous risk exposures.

All potential recommendations from the incident investigation team should be reviewed for possible negative impact. It is not uncommon to inadvertently create or aggravate a second problem while trying to correct the original problem. Proposed changes should go through the management-of-change system for review and approval. It is not unheard of for incident investigators to develop recommendations that create a new problem while trying to eliminate or reduce an original problem (Kletz, 1993). When considering potential recommendations, the first priority would be to seek remedies that *prevent* the event before seeking remedies that *mitigate* consequences. Principles of inherent safety and layer of protection analysis can be successfully applied when considering remedies for root causes. Sometimes an investigation team will be able to identify and remove common cause failures that act on more than one safeguard. Many organizations now apply cost–benefit analysis to all proposed recommendations. The expected risk reduction benefits are calculated and compared to the expected cost of implementation (initial and continuing costs).

When drafting text for recommendations, it is a good practice to include information related to benefits gained by implementing the action or to include potential consequences that might be incurred by rejecting the recommendation. In a large majority of instances, the actual recommendation text (typically a text block of one or two sentences) is extracted and transferred to a listing or database of action items. The recommendation text block becomes a stand-alone text block, without the supporting information included in the written incident report. The new listing or database document often does not include specific information as to the origin of the recommendation, the context in which the recommendation was developed, circumstances that justified the recommendation, or possible consequences for failing to implement the recommendation. Well-written recommendation statements will begin with a phrase such as, 'In order to minimize the risk of . . . . . . (insert specific consequences related to the specific recommended action), it is recommended that . . . . . . (insert specific action).' The practice of including the consequences-to-avoid or the benefits provided will assist the management team in evaluating and reaching a decision as to implementing the recommendation.

Recommendations should be worded so the intentions of the investigation team and recommendation are clear to the reader. Wording that can be ambiguously interpreted should be avoided or clarified. Specific item numbers should be used wherever possible. A poorly worded recommendation might read, 'Review start-up procedure for by-pass compressor.' A better stated recommendation would read, 'In order to prevent overpressure of the vent blowdown drum D-112, it is recommended that start-up procedure SP-1-22 be modified to clearly include the need for verifying a purge and de-pressure has been completed for By-pass Compressor C-14'. There are two conventions for drafting text for recommendations. Hard recommendations are written in specific clear action terms, such as . . . 'Provide an additional layer of overflow prevention protection for tank T-102.' Soft recommendations are intentionally written to allow flexibility in implementation. Soft recommendations often begin with words such as 'consider' or 'evaluate.' Response actions required by hard recommendations are more rigorous and demand additional documentation in the event that the recommendation is rejected or modified.

Another special case is the 'If X . . . then do Y. . .' recommendation. Investigation teams may not have sufficient information to fully evaluate a specific hazard (or existing safeguard) and may generate a recommendation such as, 'Determine the auto-ignition temperature of reactor intermediate wash water product'. In cases where the investigation team recommends further evaluation or further identification of information, it is a good practice for the recommendation text to include an 'If . . . then . . .' instruction to indicate the investigation team's expectation once the additional information does become available. An example would be the confirmation recommendation. The team may generate a recommendation to the effect of, 'Confirm that aqueous mixtures of chemical X are *not* soluble in chemical Y.' The recommendation text should, in this case, include recommended actions to be taken if the mixture is determined to be *insoluble* in chemical Y, and what actions should be taken if, in fact, the mixture is determined to be *soluble* in chemical Y.

In most chemical process incidents investigated by a team, there are significant consequences and an accompanying likelihood for legal action. In these instances, recommendations require review and approval by the organization's legal representatives, in order to minimize unnecessary litigation exposures. In some cases, normal language used in the manufacturing plant to describe the scenario, causes or suggested action items may trigger unexpected legal responses. The primary objective of the organization's legal staff is to minimize or avoid adverse consequences from litigation or regulatory activities. In this context, there is a benefit in having legal representatives conduct a review and suggested edit of the text of the incident report, findings and recommendations. Legal representatives will normally be able to quickly identify text that may potentially be inflammatory, judgemental, subjective or especially damaging in future litigation.

Some organizations make a distinction between findings and recommendations. Findings are statements of fact and do not include any suggested action. A team may find that there was no lubrication oil in the compressor gearbox or that the material of construction for a component of the piping system was Schedule 40 carbon steel 2-inch in diameter and the required specification for this service was Schedule 80. These findings statements are accompanied by separate recommendations for specific actions to address identified deficiencies Figure 31.10.

The likelihood of a repeat incident remains unchanged unless and until preventive action is actually implemented. Proactive sharing of investigation results with all who could benefit will amplify potential benefits of the investigation. In the United States, there is a regulatory obligation for sharing results of certain process safety incident investigations with all workers (employees as well as contractors) 'whose job tasks are relevant to the findings' of the investigation (OSHA, n.d.).

It is a recognized industry best practice to establish a formal system for promptly addressing and resolving recommended action items from investigations. Recommendations are often risk-ranked and assigned priorities so that the management team can more effectively reach decisions related to implementation schedule. Documentation of the resolution of the recommendation and status tracking are important features of an effective incident investigation management system. If an original recommendation is modified or rejected, there should be documentation stating the reasons for not implementing the recommendation as submitted by the incident investigation team. In some organizations, the investigation team will submit a draft report for management review and approval containing proposed recommendations. After the final version of the recommendations have been accepted by management, completion assignments are made, target dates are established, and the final version of the recommendation is published. In many instances of serious chemical process incidents, review and approval of the recommendations text by the legal department is important and necessary.

Some organizations include verification of implementation as part of routine periodic audits and evaluations of the continued effectiveness of the incident investigation management system.

There is an increasing emphasis and appreciation for the concept of verification and confirmation that the recommendation was implemented as intended and also that the action achieved the intended objective. In some progressive organizations, completion of recommended action items is closely monitored and accompanied by periodic status reports. Items that are not completed as scheduled receive special attention. Timely completion of action items has

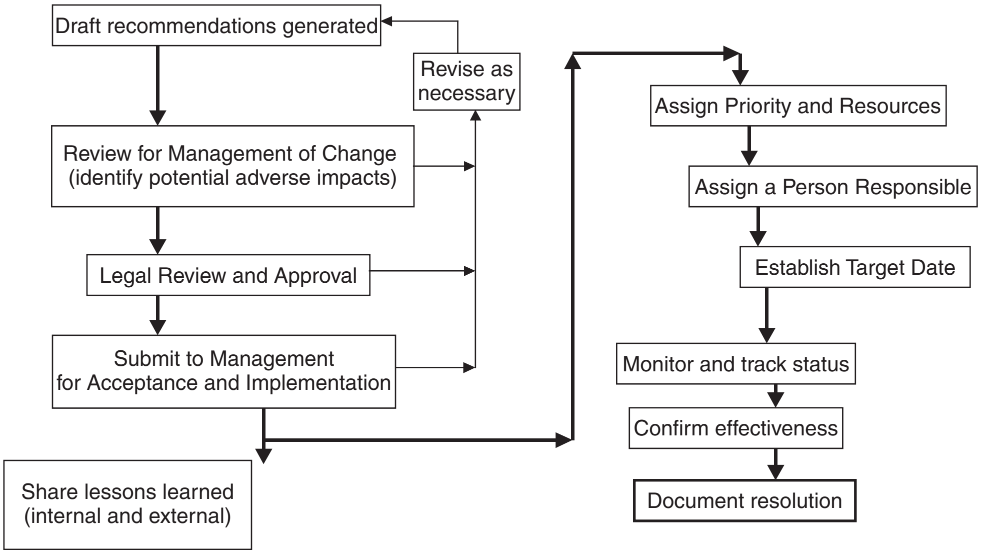

Figure 31.10 *Recommendations flowchart*

been recognized as a leading indicator for more successful safety management systems. Action item resolution can be integrated with other systems such as audits, inspections, quality assurance, PHA, pre-start-up safety reviews and management of change systems.

31.6.2 Reports

The written report is an accident prevention communications tool to share findings and lessons learned from the investigation. There is a wide variety of report style and format. Some reports are highly technical and provide extensive detail on complex systems, failure modes and process operation. Other reports are as brief as one or two paragraphs and function as a heads-up alert communication. A best practice format for internal process incident reports is shown in Figure 3.11. The report begins with a summary. This summary is most effective if limited to a single page highlighting the major items of what happened, why, and what the suggested action items are. For many process incident reports, it is beneficial to prepare a background section to allow the reader to fully understand the process, the associated potential hazards and properties of the materials, control measures, intended safeguards and the nature of the incident scenario. The third section is often a narrative of the scenario, providing an explanation of the incident sequence, events and enabling conditions. This section presents the WHO, WHEN, HOW and WHAT HAPPENED information. The next section is often the 'findings and root causes' section that presents root causes and contributing causes (the WHY information). In some instances, findings are separated and presented in a standalone section of the report. Recommended actions items, both short-term and long-term, are presented in the 'recommendations' segment and are followed by back-up data in the appendix section. It is useful to include diagrams, selected photographs and pertinent documentary evidence in each section as appropriate, with the bulk of the back-up data being located in the appendix.

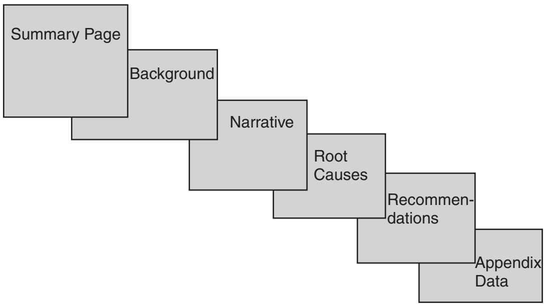

Figure 31.11 *Typical incident report*

The advent of internal intranets allows a new and powerful tool for internal sharing to selected groups, with searchable databases, and multi-levels of report detail. It is now possible to send a broad alert and point interested parties to a file containing appropriate detail. Computer security features also enhance confidentiality concerns. It is possible to track access activity and confirm that personnel actually had an opportunity to open and read the incident report or bulletin. Imbedded hyperlinks are a powerful new addition to sharing lessons learned.

31.6.3 Lessons learned

Applying lessons learned and sharing information and findings from the investigation are important functions that can leverage the work of the investigation team. There is a rising expectation that organizations proactively share information from the investigation with all parties who could potentially be impacted. In the United States, many chemical companies have made significant commitments to industry to share incident investigation findings externally to other organizations as part of the Responsible CARE® (American Chemical Council), American Institute of Chemical Engineers Center for Chemical Process Safety, National Petroleum Refiners Association, Synthetic Organic Chemical Manufacturers Association, American Petroleum Institute and other trade associations.

Unfortunately, there are numerous instances of repeat incidents that might have been prevented if there had been adequate sharing of findings (internal within the organization) or if the implementation had been completed promptly and as intended by the investigation team. In one recent chemical plant fire incident where a specific type of check-valve failed, the US Government Investigation Team discovered that the same organization had previously experienced an almost identical incident in one of its other locations, yet the lessons had not been adequately shared and acted on within the organization (US EPA/OSHA Joint Report, 1998). The investigation of the July 2000 Concorde Air crash uncovered numerous previous incidents related to tire failures. In one of the near-miss events, portions of a tire actually penetrated the fuel tank in the wing and created a fuel leak (Hazards Prevention Magazine, Second Quarter, 2001).

31.7 Management System for Investigations

Section 31.2 introduced the concept of management systems in the context of incident investigation. There is a growing recognition of the value of the application of this management system perspective. In 1999, the British Standards Institute published a non-mandatory specification for Occupational Health and Safety Management Systems (OHSAS 18001, 1999). This suggested template closely parallels the International Standards Organization Standard ISO 14001 for Environmental Management Systems. American Petroleum Institute developed a Recommended Practice Model Environmental Health and Safety Management System 9100 (API 9100 A and B, n.d.). Part A of this focused on initial development and part B was intended to provide guidance for improving an existing system. In the United States, the American National Standards Institute intends to issue a new standard Z-10 for overall management of an organization's safety and health program. British Standard 8800 is intended to provide guidance for developing and implementing safety management systems (BS 8800, 1996).

This section will focus on the development and implementation of a typical management system for incident investigation. As discussed in Section 31.2 chapter, the term management system encompasses the total administrative activities and aspects associated with a dedicated task or objective (see Figure 31.12). In this instance, the objective of the management system is prevention of repeat incidents and the specific functional task is conducting the incident investigation (Table 31.4).

The configuration and content of the incident investigation management system begins with a corporate policy commitment to prevent repeat incidents by investigating, identifying causes and remedies, and then implementing improvements specifically designed to eliminate underlying root causes. A sustained and consistent commitment of organizational resources is required. Inputs to the incident investigation management system are the facts, circumstances, evidence and consequences (human, economic and environmental) associated with accidents, incidents and near-misses. Additional inputs are those facts gathered during the evidence discovery activity and the conclusions reached by the investigation team relative to causes and potential remedies. The outputs of the investigation management system are in two stages. The first stage is the suggested recommendations for action items and the second stage is the actual implemented corrective measures.

Supporting the investigation management system are several critical components, the foundation of which is built on the formal commitment policy developed and implemented by upper level decision makers in the organization. Specific investigation tasks and activities are assigned and a determination is made as to whom specific responsibilities for completion of each designated task are assigned. A written protocol is prepared and various components of the organization are trained in knowledge and skills needed to complete their assigned duties. It is common to have at least three (and sometimes four) different investigation skill or knowledge levels. All employees (as well as contractors and visitors) need a minimum baseline knowledge regarding the reporting of incidents and the general policy commitment to investigate and implement improvements. This baseline segment can be less than one hour of training, but will require periodic refresh training and confirmations that minimum knowledge and awareness level is being maintained.

Line managers and those charged with responsibility to review and approve draft investigation reports need to understand the acceptable incident investigation performance targets and need to have an understanding of how the system works. This competency level is achieved by specific training and periodic audits. Those who participate in or lead investigations need an additional competency in the actual investigation practices (how to do it). In some instances, there is a fourth level of competency for designated subject matter experts or investigation team leaders. This group provides the internal resource for those people who conduct the day-to-day programme activities and those who investigate the less serious incidents.

Almost all incident investigation management systems include designated categories of incidents based on a scale of increasing severity of consequences and regulatory reporting requirements. Best practice organizations have a proactive near-miss investigation component as part of the incident investigation management system. It is common to establish increasing levels of severity and have increasing reporting and investigation requirements as the severity escalates. All successful management systems include an evaluation and periodic improvement component. Effectiveness of investigations should be evaluated on a regular basis and potential improvements noted. Safety audit protocols should include specific questions and items related to incident and near-miss investigation and resolution of recommended preventive actions. The incident investigation management system should include provisions for periodic review and update to ensure it is achieving the intended objectives. There should be a section that addresses how changes (or temporary exceptions and deviations) are to be handled. The incident investigation management system should be integrated with other safety and loss prevention management systems such as the PHA system, training, auditing, change management and emergency preparedness and response system. Figure 31.13 presents a typical table of contents for an incident investigation management system manual.

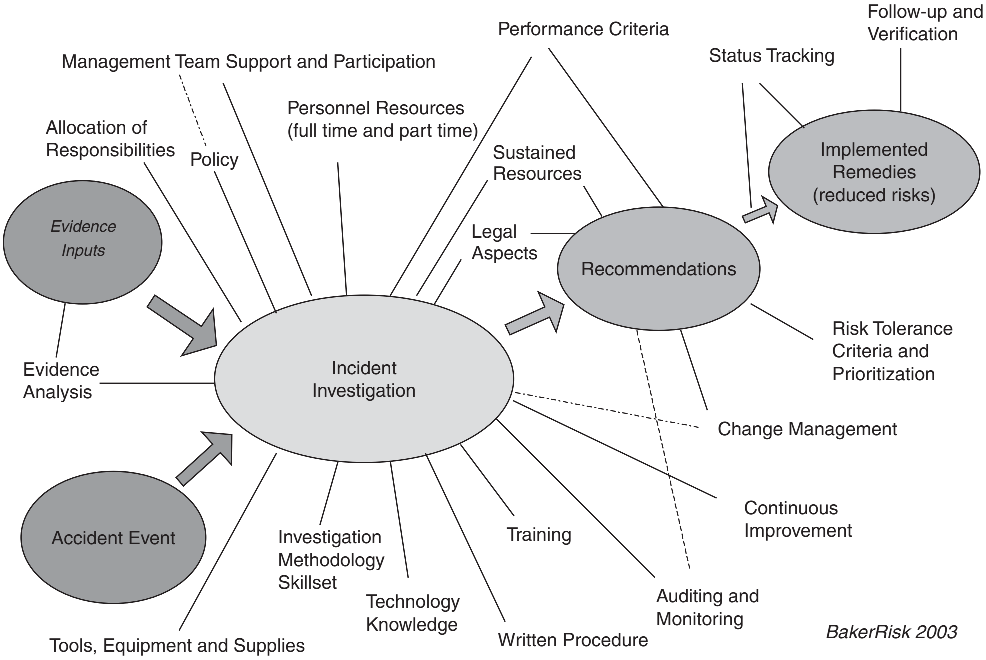

Figure 31.12 *Incident investigation management system*

Table 31.4 *Components for incident investigation management system*

Component category	*Example*
Objective	. . . prevent reoccurrence of safety-related incidents by learning from past experiences with actual events and near-miss events, and implementing preventive measures . . .
Inputs	. . . the event, facts, conditions and circumstances, people, equipment . . .
Outputs. . .	. . . written report, recommendations, action items . . .
Responsibilities	. . . line management establishes charter, degree of severity of consequences for mobilizing full or partial investigation team, team leader has assigned duties, team members have specific tasks and expected performance activitie s. . .
Skills and knowledge	. . . team member knowledge of root cause determination methods, evidence analysis skills, photography expertise, special metallurgical/laboratory test as needed . . .
Performance assessment	trend analysis for common causes and repeat incidents . . .
Documentation	. . . written investigation standard procedures, forms, systematic definitions of terms and cause categories, report format . . .
Resources and Funding	. . . team members temporary full or part-time assignments, team expenditures for evidence gathering, analysis and report preparation, witness overtime, training expenses, maintaining readiness z . . .

In the United States, there are two primary regulations applicable to process incidents involving release of hazardous substances that are on lists published by OSHA and the Environmental Protection Agency. The OSHA Process Safety Management (PSM) Standard 29 CFR 1910.119 section (m) lists several specific investigation requirements including:

- Results of the investigation must be reviewed with all personnel whose job tasks are relevant to the incident findings (including contractor employees where applicable).
- Results of the investigation must be developed into a report.
- There must be a system for promptly addressing and resolving the findings and recommendations from the investigation.
- Resolution and corrective actions are required to be documented.

Table of Contents

1. Management leadership
   - Policy
   - Legal requirements
2. Definitions and categories of incidents
3. Reporting and notification requirements
4. Specific responsibilities
5. Preparing for investigations
   - Criteria for investigators and investigation teams
   - Investigation training and periodic refresher training
   - Methodologies and tools for investigation
6. Conducting the investigation
   - Communications issues internal and external to the investigation team
   - Evidence identification
   - Evidence management
   - Evidence preservation and chain-of-custody
   - Evidence analysis
7. Root cause determination
8. Findings and outputs
   - Developing potential recommendations
   - Review and approval of suggested recommendations and reports
   - Evaluating recommendations for management of change
   - Implementing recommended actions
     - immediate temporary measures
     - permanent changes
     - assignment of priority by risk ranking
     - status tracking, assignment of target dates for completion, assignment of persons responsible for completion of the recommendation
     - verification /confirmation of completion of the recommendation
     - documentation of resolution of recommendations
   - Reports
   - Implementing lessons learned
   - Sharing lessons learned with potentially affected persons
9. Continuous improvement of the II management system
   - Monitoring effectiveness
   - Periodic audits and evaluations
   - Updates and changes to the II management system
   - Monitoring changes in regulations and corporate performance standards
   - Accident and incident trend analysis
10. Appendix
    - Suggested forms
    - Suggested checklists
    - Reference standards and regulatory requirements
    - References for additional help

Figure 31.13 *Typical table of contents for an incident investigation management system manual*

In addition to these mandatory OSHA PSM requirements, there are several 'non-mandatory' expectations contained in the appendix of the regulation. The US EPA promulgated minimum incident investigation requirements in the Risk Management Plan section of the Clean Air Act. These regulations (Risk Management Plan 40 CFR Part 68) apply to a specific list of designated hazardous chemicals, and closely parallel the OSHA PSM investigation requirements with a few additional requirements such as:

- The investigation must determine the quantity of material released and the duration of the release.
- All known offsite impacts must be documented.
- A record must be kept of all operational or process changes resulting from the investigation.

Most incident investigation management systems will include suggested (or mandatory) forms and checklists to guide the team in a thorough investigation and to ensure that relevant information is included in the report. A report format showing level of detail and approval levels is often included in the written procedure/protocol document. Some organizations find value in having the legal department conduct a review of the draft report before it is issued.

The system for resolution of recommendations should be clearly presented in the management system. There should be a status tracking system and requirements for documenting the closure (resolution) of the recommendation. If the original recommendation is rejected or modified, the documentation should include the basis for the decision not to implement the recommendation as submitted by the investigation team. A recognized best practice is the post-implementation verification to ensure that the recommendation was actually implemented as intended and that the recommended action did accomplish the specific intent.

32 Inherently Safer Design

Contents

32.1 Introduction

Inherently safer design is a philosophy which focuses on elimination of hazards or reduction of the magnitude of hazards rather than the control of hazards. Many of the concepts of inherently safer design have been applied by engineers in a wide variety of technologies for many years, without recognizing the common approach. In the late 1970s, in the wake of many large incidents in the chemical industry, Kletz (1978) recognized the common philosophies of hazard elimination and hazard reduction, gave the philosophy the name 'inherently safer design', and developed a specific set of approaches to help engineers in the chemical process industries to design inherently safer processes and plants. Kletz realized that increased expectations for safety, from companies, regulatory bodies, and society in general, combined with the increased potential damage from incidents in the larger plants being built to meet increased demand and global markets, resulted in increased complexity and cost for the safety systems required to satisfy these demands. Furthermore, while hazard control systems can be made highly reliable, they can never be perfect and will always have some failure probability. While this probability can be made very small, there is always some chance that all safety systems will fail simultaneously and the result would be a large incident. Also, the hazard management systems require ongoing maintenance, as well as management and operator training, for the life of the plant. This results in ongoing costs, and the potential for future deterioration of the safety systems. Deteriorated systems will have reduced reliability, increasing the potential for a catastrophic accident. Kletz suggested that in many cases, a simpler, cheaper and safer plant could be designed by focusing on the basic technology, eliminating or significantly reducing hazards and therefore the need to manage them.

A process or plant is best described as 'inherently safer' with respect to a specific hazard or set of hazards, and with respect to other alternative designs. However, it is unlikely that any process or plant can be designed to eliminate all possible hazards, so it is generally inappropriate to describe any technology or plant as 'inherently safe'.

Since Kletz originally introduced the concept of inherently safer design to the chemical process industries, it has received increased interest from the industry. The inherently safer design philosophy has much in common with other important themes in the ongoing evolution of the chemical process industry at the beginning of the twenty-first century. In particular, the industry's increased interest in sustainability and research efforts on 'green chemistry' are often compatible with efforts to identify inherently safer processes. Other areas of research interest such as process intensification, nanotechnology, catalysis and biotechnology have the potential for developing inherently safer products and processes.

32.2 Definitions

32.2.1 Inherently safer design

A dictionary definition of 'inherent' is 'existing in something as a permanent and inseparable element, quality, or attribute'. (Center for Chemical Process Safety (CCPS), 1996) Thus, the basis for safety of an inherently safer process lies in the fundamental characteristics of the materials, operations and conditions of the process, characteristics which are inseparable from the process itself. The process relies on the chemistry, physics and toxicological properties of the materials and process operations for safety. Hazards are eliminated or significantly reduced, rather than controlled with safety equipment and procedures.

32.2.2 Hazard

Because inherently safer design focuses on the elimination or significant reduction of hazards, it is important to understand the definition of the word 'hazard'. Over the years, the literature of process safety and risk management in the chemical process industry has developed many definitions for this word and concept. For the purposes of this discussion, we will use the definition developed by the CCPS (1992) – a hazard is an inherent physical or chemical characteristic that has the potential for causing harm to people, the environment or property. A hazard is an inherent characteristic of a material or of its condition of use. It cannot be changed without changing the material or conditions of use. Some examples of hazards are:

(1) Phosgene is toxic by inhalation.
(2) Acetone is flammable.
(3) Concentrated sulfuric acid is corrosive to the skin.
(4) Nitroglycerine is an unstable material which can decompose explosively.
(5) Steam at 40 bar pressure contains a large amount of energy, both from its temperature and pressure.

These hazards cannot be eliminated or reduced without changing the material or its conditions of use. Thus, a process using acetone as a solvent might be modified to use a less flammable solvent, or perhaps a non-flammable solvent. A process using 40 bar steam as a heating medium might be changed to using a molten salt heating system, or alternative chemistry which operates at lower temperature might be discovered. However, it is important to remember that all processes and materials have multiple hazards, and a change to a material which eliminates or reduces one hazard may increase the magnitude of another existing hazard or create a new hazard.

32.2.3 Risk

Inherently safer design is a philosophy for risk management for a chemical process. Risk has been defined by CCPS (2000) as 'a measure of human injury, environmental damage, or economic loss expressed in terms of the magnitude of the injury, loss or damage and the likelihood of occurrence of the incident'. While inherently safer design is generally considered to be applicable to the consequence (magnitude of injury, loss or damage) portion of the risk equation, it also applies to the likelihood of occurrence. An inherently safer design can either reduce the magnitude of a potential incident arising from a particular hazard, or it can make the occurrence of the accident highly unlikely, or perhaps impossible.

32.3 History of Inherently Safer Design

Elimination of hazards has always been an important approach to improving safety in all technologies. When prehistoric people decided to build a village on a hill above the flood plain of a river, they were choosing an inherently safer location with respect to the hazard of floods. They had other alternatives – monitoring the river level and establishing evacuation plans, building dikes around the village, building houses on stilts, for example. In many cases, local geography, economic considerations or other factors required the adoption of these or other alternatives. Some of these other factors may have included consideration of hazards other than flooding – people on the high ground may have been more likely to be attacked by dangerous animals, appropriate building materials might not have been available and would have to be transported to the site resulting in expenditure of resources and exposure to transport hazards, drinking water might not have been readily available on high ground. But, with respect to the specific hazard of flooding, building the village on high ground was an inherently safer design which often was adopted.

Over the centuries, engineers have invented and developed inherently safer designs in many technologies. A four wheeled wagon is an inherently safer way to transport goods than a two wheeled chariot. A double track railroad, with a dedicated track for each direction of travel, is inherently safer than a single track for both directions of travel. In the 1860s, English chemist James Howden developed a process to manufacture nitroglycerine 'in situ' at the construction sites of the first US transcontinental railroad, eliminating the hazards of transporting nitroglycerine from the manufacturing site to the construction site. A few years later, in 1867, Alfred Nobel invented dynamite, a safer and more stable form of nitroglycerine. Although these and many other examples of inherently safer design can be cited from many different engineering technologies, the common philosophy of hazard elimination or reduction had not been recognized or identified as a generally applicable design strategy.

In the 1960s and later, the rapidly expanding chemical industry was building larger plants than ever before, to meet an expanding and more global market. These large plants had larger inventories of hazardous material than previous generations of plants, and many operated at elevated temperature and pressure. The magnitude of a potential accident in a chemical plant was larger than ever before. While these large plants had extensive engineered safety features to manage and control the hazards, these systems were not perfect. The failure of the safety devices and procedures, while not common, did occasionally occur, and the result was a large accident. One major accident occurred at Flixborough, United Kingdom in 1974, caused by the release of many tons of superheated cyclohexane vapour from a high temperature, high pressure process. Following this accident, Trevor Kletz of ICI suggested that the best way to eliminate the possibility of this type of accident was not to develop ever more reliable safety devices and procedures, but rather to focus on eliminating the need for those safety devices by eliminating the hazard or reducing its magnitude sufficiently that the consequences of an accident would not be serious. Kletz introduced this concept, which he called 'inherently safer design', in the Jubilee Lecture to the Society of the Chemical Industry in the United Kingdom in 1977, and the lecture was subsequently published (Kletz, 1978). Over the years since 1977, Kletz expanded on the inherently safer design philosophy in a series of papers and books (most recently, Kletz, 1998), developing a set of principles to assist engineers in identifying inherently safer design options for chemical processes. Others picked up the concept and have further developed it, including Englund (1990, 1991a, 1991b) and CCPS (1996). The philosophy has become an integral part of process design and process safety for many companies in the chemical industry.

32.4 Strategies for Process Risk Management

32.4.1 Overview of risk management strategies

Process risk management strategies can be considered to fall into four categories (CCPS, 1996):

(1) Inherent – eliminate or significantly reduce the hazard.
(2) Passive – reduce the consequence or likelihood of an incident arising from a hazard through devices which do not require detection of an incident or action by any person or device.
(3) Active – reduce the consequence or likelihood of an incident arising from a hazard by detection of an incipient incident and activation of devices which interrupt the sequence of events resulting in the incident or mitigate the consequences of the incident.
(4) Procedural – reduce the consequence or likelihood of an incident arising from a hazard by detection of an incipient incident followed by implementation of procedures or human activated devices to interrupt the sequence of events resulting in the incident or mitigate the consequences of an incident.

Usually, risk management strategies in the inherent and passive categories are more robust and reliable. They rely on the chemistry and physics of the process and plant, and do not have any active elements which must function properly, or human elements. However, a complete risk management programme for a process will include elements from all of these strategies. This is particularly true when one considers all of the multiple hazards in a process.

32.4.2 Risk management strategy example – combustible powder handling

These categories are best understood with a specific process example. Consider a process which requires pneumatic conveying of a combustible powder from a storage silo to the processing equipment. The hazard of concern for this discussion is the potential for a dust explosion in the closed conveying equipment. Dust explosion testing indicates that the maximum pressure resulting from a confined combustion of the dust is 10 bar. The powder can be ignited by static electric discharge of sufficient energy in the conveying system. The risk arising from this hazard might be managed by any of the following alternatives:

Inherent risk management

(1) Identify a non-combustible solid which can replace the combustible dust in the process.
(2) Increase the particle size of the combustible solid so that a dust explosion cannot occur (use pellets or granules instead of a powder).

Either of these alternatives eliminates the hazard of dust explosion, although there is a possibility of particle attrition of the granules or pellets, which could result in accumulation of fine particles somewhere in the process equipment (perhaps a dust collector) where there would still be a potential for a dust explosion.

Passive risk management

(1) Build a conveying system with a pressure rating of 15 bar.

This does not eliminate the hazard of powder combustion, or reduce its magnitude, but it does contain the pressure from a dust explosion within the process equipment so it cannot injure people or damage other equipment. The higher pressure rated equipment contains the pressure simply by virtue of its existence and design. It does not have to detect a dust explosion, or take any action to perform its function, so it is highly reliable and robust. However, in the event of ignition, the dust explosion still occurs, and it does generate up to 10 bar pressure. Defects in construction of the equipment, age and corrosion, improper assembly or other failures could result in failure of the high pressure equipment and an explosion which impacts the outside environment could occur.

Active risk management

(1) Dust explosion venting panels to relieve the dust explosion pressure to a safe place.
(2) Explosion suppression systems which detect the incipient explosion and inject a fire suppressant to reduce the explosion pressure to less than the failure pressure of the conveying system.
(3) An inerting system, conveying the combustible powder with reduced oxygen gas. This is considered an active system because normal air contains 21% oxygen, sufficient to support combustion, and some kind of a active control system is presumed to be required to establish and maintain an inert atmosphere in the conveying system.
(4) A water deluge system installed in the process rack to put out an external fire following activation of dust explosion vents, which generally will release a significant flame or fireball which could ignite other combustible materials in the area.

All of these systems contain multiple active components which must function properly in order for the active safety system to work. In general, they contain three types of generic elements – a sensor of some kind to detect an incipient hazard; a logic element which receives input from the sensor and determines what action is required and a final action element which will implement the required action. Active safety devices may be designed to prevent an incident (e.g. the inert gas conveying system), or to mitigate the effects of an incident once it has started (explosion venting, explosion suppression, the water deluge system).

Procedural risk management

(1) Procedures to keep metal objects out of the conveying system. These objects could cause sparks in the conveying system which could ignite the powder.
(2) Procedures to ensure that equipment is correctly assembled and that all metal parts of the conveying system are properly electrically bonded and grounded.
(3) A manually controlled inert gas conveying system, relying on the operator to monitor the oxygen concentration (or some other parameter such as nitrogen flow rate which is known to confirm adequate inertion) and make appropriate adjustments to maintain an inert atmosphere.

These risk management strategies rely on proper actions of people. They are subject to failure from human error, inattention and all of the other factors which make people less reliable for repetitive and uninteresting tasks.

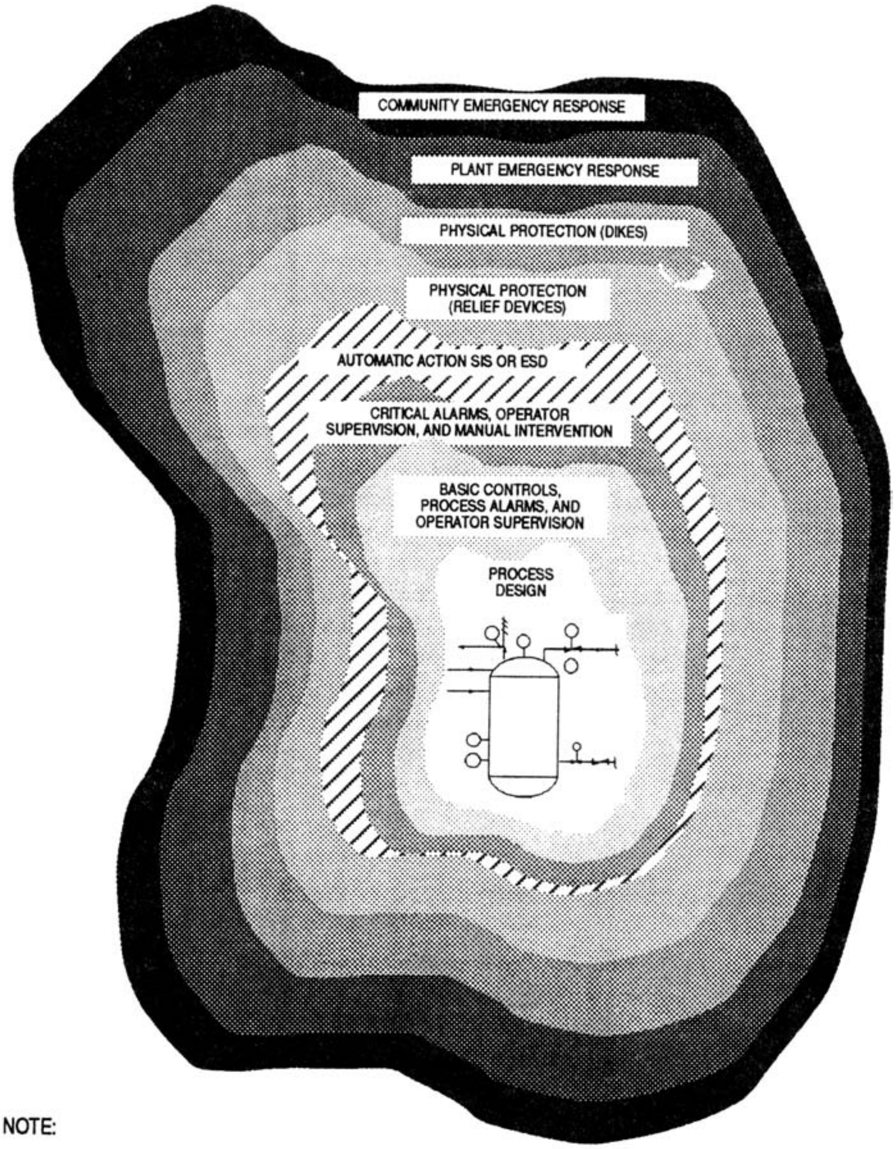
Summary of risk management strategy example

Remember that this example considers risk management strategies with respect to a single hazard – the potential for dust explosion. In selecting an optimum design, the engineer must consider all hazards, as well as the ability of the process to produce the required output. Some of the risk management strategies suggested to reduce the risk of dust explosion may introduce other hazards, increase the magnitude of other existing hazards, or inhibit the ability of the process to produce the required product. For example, inerting introduces the potential for asphyxiation from exposure of people to a low oxygen atmosphere from the conveying system. Perhaps the different, non-combustible substitute for the combustible dust is highly toxic. More likely, there is no non-combustible solid which will work in the application. Pellets or granules may create a slipping hazard if spilled on the floor. Of course, there are ways to manage and control all of these hazards as well (and those strategies will also fall into the inherent, passive, active and procedural categories), and it is the task of the design engineer to understand all of them and select the optimum overall strategy.

In this example, use of pellets in place of a dust will eliminate the risk of dust explosion in the conveying system, but perhaps the available pellets are cylindrical in shape and procedures to clean up spills and keep the floor clean will be required so people do not slip. Dust will still form from particle attrition (although there will be a lot less of it), and explosion suppression or venting may still be required in dust collectors. A complete risk management programme for a complex chemical process will require elements from all of the risk management strategies to properly manage all hazards.

32.4.3 Process risk management and layers of protection

The application of various process risk management strategies to hazard control in the chemical process industries has been described as providing multiple layers of protection to the process (CCPS, 1993, 1996). This is shown graphically in Figure 32.1, with the basic process design at the centre of the figure, and various passive, active and procedural protection layers applied to the process to prevent the hazard from impacting on people, the environment or property. These layers of protection fall into the categories described above. A process that is inherently safer will require fewer, and less robust, layers of protection – in fact a truly ‘inherently safe’ process (which is probably impossible if one considers ALL possible hazards) would not require any layers of protection at all. The layer of protection concept has been developed as a methodology for quantitative risk analysis of a process, called Layer of Protection Analysis (LOPA) (CCPS, 2001).



NOTE:

Protection layers for a typical process are shown in the order of activation expected as a hazardous condition is approached.

ESD – Emergency Shutdown
SIS – Safety Interlock System

Figure 32.1 *Layers of protection for a chemical process (from CCPS, 1992, 1996)*

32.5 Inherently Safer Design Strategies

Kletz (1998) has categorized inherently safer design strategies into four major categories: intensification, substitution, attenuation and limitation of effects. Kletz also describes a number of additional strategies for the design of ‘friendly plants’ which he does not regard as true inherent safety strategies because they do not eliminate or significantly reduce the hazard, but rather make it more difficult for incidents to occur as a result of the hazard. These strategies are listed in Table 32.1, and include

Table 32.1 *Strategies for inherently safer design*

Kletz (1998)	*CCPS (1996)*
Inherent safety strategies	Inherent safety strategies
(1) Intensification	(1) Minimize
(2) Substitution	(2) Substitute
(3) Attenuation	(3) Moderate
(4) Limitation of effects	(4) Simplify
'Friendly plant design' strategies regarded as 'add on' features	Mapping of Kletz's 'friendly plant design' strategies to CCPS inherent safety strategies
(1) Simplification	(1) Simplify
(2) Avoiding knock on effects	(2) Moderate (Limit effects)
(3) Making incorrect assembly impossible	(3) Simplify
(4) Making status clear	(4) Simplify
(5) Tolerance of misuse (error tolerance)	(5) Moderate (Limit effects)
(6) Ease of control	(6) Moderate (Limit effects)
(7) Understandable software for computer control	(7) Simplify
(8) Instructions and procedures	(8) Simplify
(9) Life-cycle friendliness (construction and demolition)	(9) Consider all strategies with regard to all phases of a plant life cycle
(10) Passive safety	(10) Moderate

simplification and error tolerance. CCPS (1996) suggests the same basic inherently safer design ideas as Kletz, but reduces the categories to four – minimize, substitute, moderate and simplify. The CCPS concept of inherently safer design is somewhat broader than Kletz's original concept, considering many of Kletz's 'friendly plant design' principles to be approaches to inherently safer design as well. The distinctions are somewhat arbitrary, and the important point is that all of these principles are highly appropriate considerations for the design and operation of highly robust, reliable, and safe plants. Table 32.1 compares the Kletz inherently safer design and friendly plant strategies to those of CCPS, showing how they encompass the same basic ideas. For this discussion, the simpler CCPS categorization will be followed, recognizing Kletz's more detailed categorization is embedded in the four CCPS strategies.

The examples in the following sections are summarized from Kletz (1998) and CCPS (1996). More details can be found in these books.

32.5.1 Minimize (intensify)

The quantity of hazardous material and energy in a process should be minimized. This applies to all unit operations in a plant as well as to raw material, intermediate and hazardous product storage and to piping which connects equipment. Reducing the size of equipment containing hazardous materials and energy is inherently safer because the direct consequences of the loss of containment of that material or energy will be correspondingly reduced. Ideally, the consequences will be sufficiently reduced that the loss of containment is not capable of causing significant damage or injury, but, in any case, the consequences will be reduced.

The use of smaller equipment may make it feasible to use other risk management strategies which would be impractical or prohibitively expensive for large equipment. For example, consider a process which includes a nitration reaction. Nitration is a highly exothermic reaction process, and there is often a potential for a runaway reaction which could rupture the reaction vessel. The reaction can be done in a large batch reactor, perhaps several thousand gallons in volume. While it is possible to enclose this large reactor in a large bunker (a passive safety feature) capable of containing the explosion from a ruptured vessel, such a bunker would have to be extremely large and strong to contain such a large explosion. An alternative nitration process, using a continuous stirred tank reactor, might have a reactor volume of only a couple of hundred gallons. Now, containment in a bunker becomes more feasible because the bunker is smaller, and it does not have to be as strong because it must contain the rupture of a much smaller vessel. In some cases it may be feasible to do the nitration in a pipe reactor, or an eductor, with a volume of only a couple of gallons, making containment even more feasible. Other safety devices may also become more feasible – for example it is practical to detect the temperature increase from a runaway reaction and dump the small continuous reactor into a large quench tank full of water in a few seconds (an active safety feature), while this cannot be done with the large batch reactor.

How does an engineer identify opportunities to minimize the size of process equipment? An extensive literature is developing on the subject of Process Intensification in recent years, and there are many innovative ideas on how to reduce the size of all types of process equipment. Most of this work is not driven by safety considerations, but rather by economics. Smaller equipment is cheaper to build and operate, and takes up less space in the plant. Innovative technology to reduce the size of process equipment is not only safer, but it also saves money. Smaller equipment also provides better and more uniform control of conditions in the equipment – the temperature gradients are smaller, there is a more uniform concentration, mixing is more efficient and heat can be more easily removed. The key to reducing the size of process equipment is a basic understanding of the physical and chemical processes that occur in the equipment. With this understanding, the engineer can design equipment to optimize the rate limiting steps in the process, reducing the size of the equipment and making it safer, cheaper and more efficient. Stankewiez and Moujlin (2003) provide a good overview of process intensification in general, including examples of its application to various unit operations and chemical technologies.

CCPS (1996) and Kletz (1998) provide many specific examples of inherently safer design through intensification or minimization. Some areas where significant benefits have been realized include:

(1) Reaction
  (a) Continuous stirred tank reactors have replaced batch reactors in many applications, including nitration, chlorination and polymerization.
  (b) Loop reactors, continuous pipe loops with a recirculation pump, provide intensive mixing and efficient heat removal and have been used for hydrogenation, ethoxylation, polymerization, chlorination and other exothermic reactions.
  (c) Reactive distillation combines the unit operations of chemical reaction and distillation into a single piece of equipment. A reactive distillation process for the manufacture of methyl acetate from methanol and acetic acid uses a single reactive distillation column and two auxiliary columns in place of a continuous reactor, an extractor and eight distillation columns.
  (d) Many rapid, highly exothermic reactions can be done in eductors. Examples include the Nobel AB process for nitroglycerine and the manufacture of Caro's acid (Whiting, 1992).
  (e) Tubular reactors can be used for polymerization and many other reactions.

(2) Distillation
  (a) Column packing and tray geometry can be modified to minimize hazardous liquid inventory.
  (b) Column base geometry can be modified to minimize hold-up of hazardous material.
  (c) Centrifugal distillation devices such as HiGee which have much smaller inventory have been developed experimentally, although commercial applications are limited to date.
  (d) Advanced control of a multi-component distillation column can allow a single column to replace multiple columns, with multiple feeds to and product streams from a single column.

(3) Extraction
  (a) Centrifugal extractors have much smaller volume than traditional extraction columns.
  (b) The efficiency of extraction columns can be enhanced (and, therefore, the columns made smaller) by introducing pressure pulses or vibrations, or with a vibrating tray stack.
  (c) Combined mixer–settlers can replace separate mixing and settling vessels.

(4) Heat exchange
  (a) Various types of heat exchangers have vastly different efficiency, in terms of the heat transfer area per unit volume of material inventory. Table 32.2 (from Kletz, 1998) compares the efficiency of a number of common types of heat exchanger.

Table 32.2 *Surface compactness of heat exchangers (adapted from Kletz, 1998)*

Type of exchanger	*Surface compactness* (m^2/m^3)
Shell and tube	70 to 500
Plate	120 to 1000
Spiral plate	Up to 185
Shell and finned tube	65 to 3300
Plate fin	150 to 5900
Printed circuit	1000 to 5000
Regenerative – rotary	Up to 6600
Regenerative – fixed	25 to 15,000
Human lung	20,000

(5) Raw material storage
  (a) Modern inventory control systems reduce the need to store large quantities of hazardous raw materials. However, it is important to consider all hazards when making these decisions, including transportation. Truck transport of a hazardous raw material may allow a smaller on-site storage tank, but it will require more frequent shipments, and more frequent unloading operations.
  (b) storage of hazardous raw materials might be eliminated if a new plant can be located on the same site as the hazardous raw material manufacturing plant, using the existing storage at the supplying plant.

(6) Intermediate storage
  (a) Intermediate storage of hazardous intermediates is often provided as a buffer, so the entire plant will not have to shut-down when a particular piece of equipment or section of the plant must be shut-down for repair or maintenance. Improving the reliability of equipment or sections of a plant may eliminate the need for intermediate storage. In some cases, providing redundancy for critical pieces of equipment may also eliminate the need to store hazardous intermediates.
  (b) There may be choices on what materials to store as in-process intermediates. Perhaps a hazardous material is produced as an aqueous solution, then distilled to produce a pure product, which is subsequently converted to various final products in downstream units. Storage of a large inventory the aqueous solution to supply the downstream processes could be considered as an inherently safer alternative to storage of the pure material.
  (c) Storage and transportation of hazardous raw materials can be reduced or eliminated by locating a downstream plant on the same site as the plant producing the hazardous raw material – for example locating a plant producing a chlorinated pesticide adjacent to a chlorine manufacturing plant.

(7) Piping
  (a) Hazardous material pipe diameter should be minimized, consistent with maintaining sufficient mechanical strength and integrity. A 100 mm diameter pipe contains four times as much material as a 50 mm pipe of the same length.
  (b) Hazardous material pipe length should be minimized, again consistent with providing appropriate spacing of hazardous facilities.

32.5.2 Substitute

In the chemical industry, the two major areas where substitution enhances inherently safer design are substitution of a less hazardous chemical synthesis route for a desired product, and substitution of a less hazardous material for a specific application. Substituting less hazardous chemistry offers the greatest potential for enhancing inherent safety, but must be considered early in process development since alternate chemistry often requires abandonment of an existing plant and construction of a new one.

Recently there has been a major research effort in many developed countries to develop environmentally friendlier 'green chemistry' for the synthesis of many products and for chemical products. Many of these green chemistry alternatives are also inherently safer because they focus on eliminating or reducing the use of toxic and flammable materials. However, this is not always true, and sometimes environmental and safety considerations are in conflict. Perhaps the best known example of this conflict is in refrigerants. Chlorofluorocarbon (CFC) refrigerants were developed in the 1920s and 1930s as inherently safer alternatives to refrigerants then in use. CFCs have low acute toxicity and are non-flammable, eliminating hazards of many of the refrigerants formerly used, such as light hydrocarbons (flammable), ammonia (toxic and flammable) and even sulfur dioxide (toxic, corrosive). Later, in the 1980s and 1990s CFCs were found to cause significant environmental damage, and they can no longer be used in many countries. In many cases, refrigeration systems are going back to earlier refrigerants, but it must be recognized that, while the hazards can be managed using strategies discussed earlier, refrigerants such as ammonia and light hydrocarbons are inherently less safe.

Some specific areas of research which offer potential for development of inherently safer chemical manufacturing processes include the following.

(1) Catalysis – Development of improved catalyst systems which improve reaction selectivity (eliminating the need for extensive product purification systems), allow products to be produced under less severe conditions (lower temperature and pressure), speed up reactions resulting in smaller reactors and improve raw material conversion (eliminating the need for recycle) all can enhance inherent safety.
(2) Catalytic reaction functionality can sometimes be immobilized on a solid substrate, such as solid superacid catalysts in place of hydrogen fluoride or aluminium chloride for some alkylation reactions, or ion exchange resins in place of sulfuric acid for esterification.
(3) Supercritical processing may allow use of solvents such as carbon dioxide or water in place of flammable or toxic organic solvents.
(4) Innovative energy sources such as ultraviolet light, microwaves and laser light enhance some chemical reactions.
(5) Biocatalysis and enzymes may allow synthesis of products at ambient temperature and pressure conditions.
(6) Biological or biochemical synthesis may become feasible for many materials. Advances in genetic engineering and biotechnology in general may broaden the spectrum of products which can be made in this way.

Clearly many of these alternatives have the potential for introducing new hazards. Catalysts may contain hazardous materials, supercritical processing requires elevated temperature and pressure and there are safety and environmental concerns which must be considered for biotechnology.

Much of the literature of green chemistry and engineering has focused on identifying substitute, less hazardous materials for many industrial and consumer applications. Many government environmental agencies have developed extensive resources and databases identifying potential substitutions. Some common examples of substitution of less hazardous materials include:

(1) Use of water base latex paints in place of organic solvent base paints.
(2) Replacement of flammable solvents with alternative solvents with a high flash point for many formulated products such as agricultural chemicals, dyes, adhesives, paints and coatings, and paint removers.
(3) Replacement of chlorinated organic solvents by aqueous systems for degreasing and cleaning in the electronics industry.

32.5.3 Moderate (attenuate)

Inherently safety can be enhanced by changing a material or process to moderate the hazard, or by designing the plant to moderate the impact of an incident arising from the hazard. Kletz (1998) refers to the later approach separately as 'Limitation of Effects,' while CCPS (1996) considers this to be a form of the 'Moderate' strategy.

Moderating hazards of materials

Dilution

Dilution of a hazardous material with a less hazardous material (such as a solvent) offers several inherent safety benefits. Because the hazardous material is diluted, if the material is spilled, the partial pressure of the hazardous material will be lower than for the pure material, and the atmospheric concentration above the spill will be reduced. This will also reduce the downwind concentration in the atmosphere. If the material is flammable, dilution with a non-flammable material such as water may be sufficient to significantly reduce the fire hazard. In some cases, pure materials such as hydrogen chloride or ammonia may require pressurized storage, while relatively concentrated aqueous solutions can be stored at atmospheric pressure. While many applications require use of a pure material, many do not – for example neutralization with ammonia or hydrochloric acid – and aqueous materials should be considered for those applications where feasible.

The stability of some solid materials can also be enhanced by dilution with an inert material. Alfred Nobel's invention of dynamite – nitroglycerine absorbed onto an inert carrier – is an example of inherently safer design. As another example, the stability of benzoyl peroxide is greatly enhanced by handling it as a water wetted powder, compared to the pure, dry material.

Refrigeration

Refrigeration of liquefied gases can improve inherent safety. Refrigeration has a number of potential benefits.

(1) Storage pressure will be lower, in some cases storage at near atmospheric pressure is feasible. This results in a reduced leak rate in case of a loss of containment from the storage system because of a lower pressure. For storage near atmospheric pressure, a leak from the vapour part of the storage tank will be very small because there is practically no pressure to provide driving force for the leak.
(2) A leak from a liquefied gas storage vessel at ambient temperature and elevated pressure will result in significant flashing of vapour into the atmosphere from the leak. A leak from a refrigerated storage tank will flash less, or not at all if the storage is near atmospheric. While the spilled material will boil or evaporate as it absorbs heat from the atmosphere and the ground, this rate of release will often be smaller than that resulting from a pressurized, flashing leak. Also, the designer will have the opportunity to reduce the evaporation rate of the spilled material by dike design to minimize surface area, insulating dike materials, covering the spill or secondary containment.
(3) The amount of release to the atmosphere from a liquefied gas storage vessel may actually be significantly higher than that which would be calculated from the flash calculation. As the material leaks from the storage vessel, a large fraction of the material will flash to vapour as a result of the pressure reduction to the atmosphere. Much, perhaps all, of the material which remains as a liquid according to the flash calculation, will be present as small droplets, an aerosol. These droplets may be too small to rapidly settle out and form a liquid pool on the ground. Instead, they may be carried downwind with the released vapour as a fine mist or fog. As they travel downwind, they will absorb heat from the atmosphere and evaporate. The actual amount of material released to the atmosphere from a pressurized gas leak may be several times larger than would be expected based on the flash calculation. Refrigeration of the pressurized gas eliminates the flashing and aerosol formation.

Some of the materials for which refrigerated storage has been reported to be beneficial include ammonia, chlorine, butadiene, ethylene oxide, propylene oxide, methylamines and vinyl chloride. As for most design choices, again there are potential downsides to refrigeration – for example refrigerated storage facilities will require insulation which makes it more difficult to inspect piping and vessels, and may make them susceptible to external corrosion if water is absorbed into the insulation.

Change physical characteristics

The explosion hazard of a combustible dust is a function of its particle size. If these materials can be handled as a granule or pellet instead of a dusty powder, they will be inherently safer. This will also reduce the potential of exposure of people to airborne dusts.

Some reactive or toxic materials can be immobilized by attaching them to a solid substrate, making them less likely to come into contact with people. For example, acid or basic functionality can be provided as a solid ion exchange resin or a membrane. Metal catalysts are often bonded to an inert carrier.

Moderating hazards of processes

Substitution of alternate chemistry, or development of improved catalysts, as discussed previously, can often allow a process to operate at lower temperature and pressure. This not only improves inherent safety, but it is also almost certain to make the construction of the plant cheaper because equipment rated for lower temperature and pressure will cost less.

There are many approaches to limiting the effects (moderating the effects) of an incident arising from a hazard. In many cases, these are probably better described as passive safety features rather than inherent. They do not reduce the magnitude of the hazard, or eliminate the hazard, but they are very robust and reliable methods for minimizing the potential impact of an incident. Some examples include:

(1) Primary containment. Build stronger equipment. If a reaction has a maximum adiabatic pressure in case of a runaway of 200 psig, a 250 psig reactor will contain a runaway. It is essential to be highly confident of the maximum temperature and pressure in this case – the chemistry must be fully understood, including the potential for unknown reactions or decomposition at the elevated temperature and pressure resulting from the runaway reaction.
(2) Secondary containment. Containment dikes around storage tanks and processing equipment. Also, containment buildings can be used to reduce the release of toxic materials to the atmosphere. Bunkers or explosion proof buildings, with the process equipment operated from a remote location, have been used for explosives manufacture.
(3) Plant siting. Locate hazardous material handling facilities as far as possible from potentially impacted population or equipment.
(4) Batch reactions. For exothermic reactions, avoid batch processes where all of the materials are charged to the batch before the reaction is initiated. With this type of process, if temperature control is lost for some reason, all of the reaction energy is present in the reactor and a runaway reaction is possible. Semi-batch, or fed batch, reactions, where a limiting reactant is gradually added at a rate corresponding to the rate of reaction, are inherently safer. If temperature control is lost, the limiting reactant feed can be stopped, and there is little or no reaction energy in the batch.
(5) Maintain separation between incompatible materials, both for container storage in warehouses, and tank farm storage of bulk materials.

32.5.4 Simplify

Simplification is key to a 'user friendly' plant. If a plant is complicated, it is going to be more susceptible to incorrect operation. While most chemical plants are highly complex of necessity because of the complexity of the technology, designers should always be striving to eliminate all unnecessary complexity. In some cases, simplification will eliminate hazards by making it impossible to conduct operations which result in those hazards. In other cases, simplification will make it more difficult to make errors, perhaps not truly an example of inherently safer design, but still highly desirable.

Some examples of simplification include:

(1) Use stronger (higher pressure rated) equipment can reduce or eliminate the need for complex pressure relief systems, and complex instrumentation and interlocks to protect against overpressure.
(2) Eliminate unnecessary or seldom used piping. While the designer of a plant might think that the operators will someday want to transfer material from the final product tank back to the second distillation column, how often will this really need to be done? If the pipe is not used frequently, perhaps it will be plugged, the valves will be rusted shut, or the gaskets will be degraded several years after construction when somebody finally wants to use the pipe. It may be better to wait until there is a real need, then install a new pipe at that time. In the meantime, the unused pipe is a potential operating error waiting to happen. Question the real need for 'abnormal operation' piping – eliminating it will save money and the plant will be simpler and easier to operate safely.
(3) Gravity flow can eliminate pumps, which require maintenance and can leak.
(4) Make incorrect operation impossible. Many electric power plugs are designed so they can only be inserted in the socket one way, and there are many other examples of equipment which has been designed so it cannot be operated improperly.
(5) Develop processes which are insensitive to variation in operating parameters. Design engineers should challenge research chemists and engineers to invent processes which are insensitive to variation in process operating parameters. While it is possible, for example, to control a reactor temperature to within 0.5°C, it is much easier to control the reactor to within 5°C. If the process can be modified so that it is less sensitive, the plant will be cheaper, more reliable and safer.
(6) Good human factors design. Equipment should be designed to operate the way people expect it to operate, it should provide feedback to the operator to confirm proper operation, it should be designed with consideration for ergonomics and human factors. Kletz (1998) and CCPS (1996) provide many specific examples of both good and bad human factors design, and CCPS (1994) provides an extended discussion of human factors in the chemical industry.

32.6 Inherently Safer Design Conflicts

A chemical plant or process can be described as inherently safer in the context of one or more of its multiple hazards, when compared to other possible design options. However, in general it is unlikely that a particular design can be considered inherently safer with respect to all hazards simultaneously. Some examples of inherent safety conflicts include:

(1) There are two alternative solvents for a process. One is flammable but has low acute toxicity. This solvent is inherently safer with respect to toxicity hazards. The alternative solvent is non-flammable, but has high acute toxicity – this solvent is inherently safer with respect to fire hazards, but inherently more hazardous with respect to toxicity hazards.
(2) A process requires chlorine as a raw material. Chlorine can be supplied in 90 ton rail cars or 1 ton cylinders. A neighbour two miles away from the plant, concerned about exposure from a large leak, considers the cylinders inherently safer because the smaller quantity is less likely to result in exposure at that distance. The process operator, who must connect and disconnect 90 cylinders instead of one rail car, will be in close proximity to the chlorine source and would consider the rail car to be inherently safer with respect to his risk of exposure to chlorine.
(3) CFC refrigerants have low acute toxicity and are not flammable. They are inherently safer with respect to the flammability and acute personnel exposure. However, it is now generally accepted that they cause long-term environmental damage, and their use is being phased out.

It is almost always impossible to simultaneously maximize all desired characteristics of any engineered system. The central problem of all engineering design is to find the optimum combination of characteristics that best meets the overall objectives. This 'best design' depends on the relative importance which is attached to the various desirable characteristics – what is the relative importance of flammability hazards, as compared to acute toxicity hazards, as compared to long-term environmental hazards, as compared to other hazards which might be identified. This relative importance may be impacted by the environment in which the plant is built, the feasibility, reliability and effectiveness of passive, active and procedural safety features for the hazard of concern, and other design specific factors. The inherent safety characteristics of a process become one of the many characteristics which the design engineer must evaluate as he determines his optimum design for a particular facility.

Many decision-making tools have been developed to aid decision-makers in understanding the many conflicting characteristics of a multi-dimensional decision, allowing them to make logical and consistent decisions. CCPS (1995) describes the use of many of these tools, as listed in Table 32.3, to process safety decision-making in general. The INSIDE Project (Inherent Safety in Design (INSIDE) Project Team, 1997) also suggested the use of this type of tool for understanding and resolving inherent safety and environmental conflicts. These decision-making tools can also be applied to resolving conflicts between the inherent safety characteristics of a process with respect to different kinds of hazard, as well as conflicts between inherent safety and other important process characteristics such as environmental impact, various economic parameters,

product quality, reliability and other process measures of importance to different stakeholders. The use of these tools will require some kind of a measure of the inherent safety characteristics of a process, a topic discussed in Section 7.

32.7 Measuring Inherent Safety Characteristics of a Process

32.7.1 Introduction

In a recent global survey on the use and interest of people in inherently safe design, Gupta and Edwards (2002) reported at length that the survey responders, all connected with the process industry, academics or regulatory authorities, were generally familiar with inherently safe design and desired to use it to their advantage. They did not want another enforcing regime from the government requiring its use since they already have enough regulations related to process safety to follow. To use inherently safe design voluntarily, they desired a simple way to determine or measure the inherent safety of a process at the research and development stage before too much time and resources have been invested in the process development. It is so because with more resources invested, it becomes difficult to make drastic changes and justify the expenses. Research chemists will also need to adopt the inherently safe design in process development. So far they have generally been oblivious of the safety issues. For their use of inherently safe design, it is essential that the inherent safety index (ISI) be very simple.

There are no hard and fast rules or methods as to how to make a process inherently safer. One could use any one of several approaches possible (different catalysts, reactants, operating conditions, yield, by-products, etc). Up till now, the choice between competing processes has been guided by their technical feasibility and economic viability. Lately, the safety and environment concerns have also impacted the choice between competing processes due to regulatory requirements. Therefore, if some sort of a measure of inherent safety were available, it would make the decision-making so much easier. Researchers spread over several continents have looked at the problem of measuring inherent safety. Each group has developed ISI, different from the other groups. That is how, probably, progress is made in new fields. After due time and experience, people converge on to a common system, which is then universally adapted. In inherently safe design measurement, we have come to a stage where several approaches are available and it is time to start consolidating the work while not shutting out altogether newer approaches. As experience is gained in using the existing indices, a universally accepted index will develop.

We mention the existing indices followed by a brief description of the inherent safety indices. Thereafter we discuss the work needed to consolidate the efforts.

32.7.2 Existing indices

Dow Fire and Explosion Index (Dow Chemical Company, 1994) and Mond Index (ICI, 1993) are used for determining the hazard level of a process plant. However, to use these, the process design has to be fully in place since a lot of information required pertains to that. Hence, these are unsuitable for use in conceptual design and preliminary process development stages, which is the aim of the inherent safety indices.

32.7.3 Inherent safety indices

Edwards and Lawrence index (Edwards and Lawrence, 1993; Lawrence, 1996)

Called PIIS (Prototype Index of Inherent Safety), this was the first ever index that was developed and has been modified by later workers.

The authors decided upon 17 parameters that they thought affected inherent safety (IS) of a process (Table 32.4). Out of these 17, they picked 7 in the first application of their PIIS index (Table 32.4). They divided the total ranges that each of these parameters could possibly take in the process industry into several sub-ranges and assigned numerical scores to each sub-range. These numerical scores were either based on existing indices including the Dow Fire and Explosion Index and the Mond Index or on their own judgement. Scoring tables for temperature and pressure are given in Tables 32.5 and 32.6 for our discussion purposes. Lawrence (1996) has given tables for inventory, explosiveness, yield, toxicity and flammability also. They applied PIIS to six routes to manufacture methyl methacrylate (MMA) in order to rank their inherent safety (MMA, Table 32.7). They considered each step of each route and noted down the operating pressure and temperature, yield, flammability, toxicity and explosiveness of all the reactants, products and intermediates involved. For inventory, they took a one-hour residence time, and stoichiometric relationship into account for a 50,000 tonnes per year production of the final product, MMA. The worst

Table 32.4 *Parameters listed by Lawrence (1996)*

(1)	Inventory (volume or mass)*	(10)	Side reactions
(2)	Temperature*	(11)	Waste and co-products
(3)	Pressure *	(12)	Reaction rate
(4)	Conversion	(13)	Catalytic action
(5)	Yield*	(14)	Heat of reaction
(6)	Toxicity*	(15)	Phase
(7)	Flammability*	(16)	Phase change
(8)	Explosiveness*	(17)	Viscosity
(9)	Corrosiveness		

* Parameters considered in the MMA example.

Table 32.5 *Temperature scoring table (Lawrence, 1996)*

Temperature (°C)					*Score*
		T	<	−25	10
−25	≤	T	<	−10	3
−10	≤	T	<	10	1
10	≤	T	<	30	0
30	≤	T	<	100	1
100	≤	T	<	200	2
200	≤	T	<	300	3
300	≤	T	<	400	4
400	≤	T	<	500	5
500	≤	T	<	600	6
600	≤	T	<	700	7
700	≤	T	<	800	8
800	≤	T	<	900	9
900	≤	T			10

chemical for flammability, toxicity and explosiveness was taken for each step. Flammability score was based on the flash point and boiling point of a chemical, explosiveness was based on the range of explosive mixture (UEL–LEL) while toxicity was based on the threshold limit value (TLV).

The scores for each step in a given process route for pressure, temperature and yield were added together and called the 'process score', while the scores for inventory, toxicity, flammability, explosiveness were added together and called the 'chemical score'. The two sets of scores thus obtained for each step in a route were added to get a score for each route. These final scores were taken as a measure of the inherently safer (actually, inherently riskier) nature of different routes and the one with the highest numerical value was taken to be the worst route (Table 32.8). Based upon this exercise, acetone cyanohydrin (ACH) route comes out to be the worst. Note that this is the only route in use in major manufacturing facilities worldwide (unless some local laws prohibit the use of hazardous chemicals like HCN, HF, etc., thus forcing the choice of a different route).

Table 32.6 *Pressure scoring table (Lawrence, 1996)*

Pressure (psi)	*Score*
0–90	1
91–140	2
141–250	3
251–420	4
421–700	5
701–1400	6
1401–3400	7
3401–4800	8
4801–6000	9
6001–8000	10
+ 1 point per 2500 psi	

Edwards and Lawrence (1993) then invited eight renowned process safety experts to comment on their work (Table 32.9). The experts first looked at each of the routes in its entirety, then at each of the steps (without referring as to which route the specific step belonged to) and finally at the proposed PIIS index. Their ranking of the different routes matched to a large extent the ranking obtained by Edwards and Lawrence using the proposed index. That is not surprising since, whether with or without an index, a process route with high pressure, high temperature, high values of toxicity, flammability and explosiveness and high inventory is more dangerous (and hence more inherently unsafe) than routes that are otherwise.

This pioneering work of Edwards and Lawrence caught the attention of several other workers. Their indices are described below.

Table 32.7 *Details of six MMA routes (Lawrence, 1996)*

Route 1: Acetone cyanohydrin based route (ACH)

Step 1: $2CH_4 + 2NH_3 + 3O_2 \rightarrow 2HCN + 6H_2O$
Methane + Ammonia + Oxygen → Hydrogen cyanide + Water
Gas phase; Pressure: 3.4 Atm; Temperature: 1200°C; Yield: 64%

Step 2: $(CH_3)_2\,CO + HCN \rightarrow (CH_3)_2\,COHCN$
Acetone + Hydrogen cyanide → Acetone cyanohydrin
Liquid phase; Pressure: Atmospheric; Temperature: 29–38°C; Yield: 91%

Step 3: $2(CH_3)_2\,COHCN + H_2SO_4 + 2H_2O \rightarrow (CH_3)_2\,COHCONH_2 + (CH_3)_2COHCONH_2 \cdot H_2SO_4 \xrightarrow{HEAT} CH_2{=}C(CH_3)CONH_2$
$+ CH_2{=}C(CH_3)CONH_2 \cdot H_2SO_4 + 2H_2O$
Acetone cyanohydrin + Sulfuric acid + Water → 2-Hydroxyl-2-methyl propionamide + 2-Hydroxyl-2-methyl
Propionamide sulfate → Methacrylamide + Methacrylamide sulfate + Water
Liquid phase; Pressure: 7 Atm; Temperature: 130–150°C; Yield: 98%

Step 4: $CH_2{=}C(CH_3)CONH_2 + CH_2{=}C(CH_3)CONH_2 \cdot H_2SO_4 + 2CH_3OH + H_2SO_4 \rightarrow 2CH_2{=}C(CH_3)COOCH_3 + 2NH_4HSO_4$
Methacrylamide + Methacrylamide sulfate + Methanol + Sulfuric acid → Methyl methacrylate + Ammonium bisulfate
Liquid phase; Pressure: 7 Atm; Temperature: 110–130°C; Yield: 100%

Step 5: $H_2SO_4 + 2NH_4HSO_4 + 3O_2 + CH_4 \rightarrow 3SO_2 + CO_2 + N_2 + 8H_2O + O_2$
Sulfuric acid + Ammonium bisulfate + Oxygen + Methane → Sulfur dioxide + Carbon
dioxide + Nitrogen + Water + Oxygen
Gas phase; Pressure: Atmospheric; Temperature: 980–1200°C; Yield: 100

Step 6: $2SO_2 + O_2 \rightarrow 2SO_3$
Sulfur dioxide + Oxygen → Sulfur trioxide
Gas phase; Pressure: Atmospheric; Temperature: 405–440°C; Yield: 99.7%

Similar details were also given about the remaining following five routes:
Route 2: Ethylene (via Methyl propionate) based route (C2/MP)
Route 3: Ethylene (via Propionaldehyde) based route (C2/PA)
Route 4: Propylene based route (C3)
Route 5: Isobutylene based Route (i-C4)
Route 6: Tertiary Butyl Alcohol based Route (TBA)

Heikkilä and Hurme index (Heikkilä, Hurme, and Järveläinen, 1996; Heikkilä, 1999)

These authors argued that the safety is affected both by the properties of the chemicals as well as the equipment used. They have, therefore, included the type of equipment and process structure. The similarities and differences in their approach and that of Edwards and Lawrence are brought out in Table 32.10. In Table 32.11, they bring out nicely how the various parameters are connected to the basic principles of inherent safety. They go on to produce an ISI with subdivisions for different parameters (Table 32.12):

$$\text{ITI} = \text{ICI} + \text{IPI}$$

where ITI is the total ISI, ICI and IPI are the summations of respective worst-case values of the sub-indices for various parameters. These values are chosen from a range of numbers for each parameter (Table 32.13). The ranges for each parameter have been further subdivided. Representative tables for temperature and pressure (Tables 32.14 and 32.15) can be compared with Tables 32.5 and 32.6 given by Edwards and Lawrence (1993). There are significant differences and it is difficult to pick one over the other. The authors have also used ISI as an objective function in the genetic optimization and have come up with a case based reasoning for safe process structure.

Palaniappan, et al. index (Palaniappan, Srinivasan and Tan, 2002; Palaniappan, 2001)

These authors have come up with an i-Safe index. They expanded the Heikkilä and Hurme's chemical and process safety indices to include five other supplementary indices, viz: Hazardous Chemical Index (HCI), Hazardous Reaction Index (HRI), Total Chemical Index (TCI), Worst Chemical Index (WCI) and Worst Reaction Index (WRI). The proposed index has been used by Srinivasan and Meibao (2003) to evaluate the six synthesis routes for methyl methacrylate or MMA, the set first used by Edwards and Lawrence (1993). This was a painstaking work because a lot of information about properties and operating conditions was not available in the literature. They calculated from thermodynamics and atomic contributions and used other similar reaction

situations as well to make estimates. Their results follow the trend of Edwards and Lawrence, with the ACH route coming out to be the worst (Table 32.16). However, the spread of the i-Safe index values, called Overall Safety Index (OSI = sum of TRI for main reaction steps) for the six routes, was in a narrow band of 15, from 51 to 65, compared to the spread of 57, from 47 to 103, in the study of Edwards and Lawrence.

Khan and Amyotte Index (Khan and Amyotte, 2003)

These authors have proposed an Integrated Inherent Safety Index (I2SI). It comprises of two main indices: a hazard index (HI) and an inherent safety potential index (ISPI). Both the ISPI and HI range from 1 to 200. HI consists of a damage index (DI) and a process and hazard control index (PHCI). DI has four subparts related to fire and

explosion, acute toxicity, chronic toxicity and environmental impairment. PHCI has ten subparts related to pressure, temperature, flow, level, concentration, inert venting, blast wall, fire resistance wall, sprinkler system and forced dilution. After the different terms above have been computed from various graphs, the I2SI is given by

$$\text{I2SI} = \text{ISPI/HI}$$

I2SI > 1 implies an inherently safer approach. The higher the quotient, the greater is the inherent safety nature of the process. The authors have utilized their elaborate index to evaluate the six routes for MMA manufacture, the example used by Edwards and Lawrence (1993). Khan and Amyotte's results (Table 32.17) and conclusions follow the trend of Edwards and Lawrence.

Gentile et al. *Index (Gentile, Rogers and Mannan, 2001)*

In all the above indices, except Khan and Amyotte's, there are sudden jumps in the score values at the extreme ends of each subdivision. For example, Table 32.5 shows a score of 2 for a temperature range of 100 to 199, which suddenly jumps to 3 at 200. Thus, while a change of 99 in temperature, from 100 to 199, did not produce any change in the score, a further change of only 1, from 199 to 200, changed the score by 1. Similar situation is encountered in tables for all the parameters in the indices proposed by Edwards and Lawrence (1993), Heikkilä, Hurme and Järveläinen (1996) and Palaniappan, Srinivasan and Tan (2002). Also, the scoring tables proposed by different authors for the same parameter do not always match. This introduces a subjective (or arbitrary) factor in the calculation of the indices. This aspect was addressed by Gentile *et al.* (2001). They used the fuzzy set theory to improve the sensitivity (either excessive or insufficient), as it existed in the ranges selected for the various parameters under consideration. They calculated their ISI based on if–then rules that describe the knowledge related to inherent safety. Each parameter is described by a linguistic variable whose range is divided into fuzzy sets. For each set, a membership function is defined which has a specific shape describing the physical behaviour of the set. This approach eliminates the problems of the interval-type approach used by other investigators as noted above. Gentile proposes to have an index with 4 stages (Gentile, 2003): stage 0 = route selection, 1 = process design, 2 = mechanical design, 3 = operation.

INSET Toolkit (Mansfield, 1997; INSIDE Project Team, 1997)

Experts from several corporations in United Kingdom and Europe worked on an EU sponsored project for an index for inherent safety, health and environment (ISHE). They called it as INSET toolkit. They accounted for many situations and developed several methods (called tools) for rapid as well as detailed analysis of processes for their ISHE performance (Table 32.18). These elaborate tools await intense testing and modifying before these can be used.

Gupta and Edwards Method (Gupta and Edwards, 2003)

These authors expressed three concerns about the additive indices discussed above:

(1) Addition of different types of hazards or parameters is not justifiable.
(2) Arbitrary assignment of scores to different parameters (P, T, Inventory, . . .) without establishing equality of hazard for the same numerical value (Does a number 3 in the table for pressure present the same hazard as 3 in table for temperature, etc.?).
(3) The total score will get biased by the number of steps (e.g. 6 steps in ACH route for MMA), or by one major score (e.g. for pressure in an HDPE plant).

They proposed that the parameters of interest should be plotted individually for each step in a process route without carrying out any mathematical operation and then be compared with each other (Figure 32.2).

Kletz commented on this approach favourably (Kletz, 2003) . . . "Instead of an absolute index we could compare a proposed new design (or designs) with . . . an existing design, using a number of headings. This benchmarking approach would give a comparison of alternatives rather than a position on a scale. This should be satisfactory as

users want to know how different methods of making X compare, not if a plant for making X is safer than a plant for making Y. . . [It] supports my gut feeling that displaying a series of measurements will be more useful than trying to find a single number that measures inherent safety."

To demonstrate, the authors used the MMA example (Lawrence and Edwards, 1993). They plotted the values of temperature, pressure and a combined value for flammability, explosiveness and toxicity (FET) for each step in Figure 32.1 and then compared them. Considering pressure, its maximum value is 7 bars for the ACH route while the next three routes have 49 to 100 bars. The remaining two routes have 7.5 bars. Further, three of the steps in the ACH route operate at atmospheric pressure, which would result in no flashing, if leaks were to occur. Summing up, the ACH route has a significant advantage over other routes as far the pressure is concerned. Considering temperature, two of the steps in the ACH route have a higher temperature than other routes. However, the authors felt that a higher pressure is more of a hazard than a higher temperature, in as far leakage, flashing of a liquid or rupture of a vessel and formation of energetic missiles and/or BLEVE with a possible domino effect, are concerned. This matches with the number of times (41) the experts in Lawrence's thesis (Lawrence, 1996) used pressure as the key feature in describing their assessment of hazards in the MMA routes compared to the number of times (9) they used temperature as an important parameter. Looking at the FET values, the ACH route, in general, has values similar to those in most other routes. Two of the experts downgraded the hazards of the ACH route because of the experience they had had on this process and had found it to be very safe.

Gupta and Edwards also pointed out that in the ACH route, the first two steps relate to the production of the basic material, ACH; the last two steps relate to the disposal of by-products, and only steps 3 and 4 relate to the actual production of MMA (Table 32.7). In the remaining five routes, only the actual production steps of MMA were considered, not the production of the basic materials or disposal of the by-products, if any. Hence, if only the actual MMA production steps (steps 3 and 4) are considered in the ACH route also, it comes out by far the most superior route compared to all the rest of the routes. No wonder, industry uses this worldwide.

According to the authors, the advantage of this simple graphical method of comparing process routes is that one can expand consideration to incorporate economic, regulatory, pollution control and worker health aspects, as well as factors such as the experience one has or the 'comfort level' one feels with each of the processes under consideration. Results from accident databases can be included as a parameter (e.g. frequency of accidents, loss per accident, etc.). As it expands, one can bring into consideration other important aspects, such as, process intensification, where if the process volume is reduced by, say a 1000-fold, one can work at higher pressures, closer to runaway temperatures and with more toxic reactants since the total release and hence consequences there of, in case of an accident, would be rather limited due to the very small amounts of hazardous chemicals involved.

The suggested graphical procedure also meets the users' desire of a simple index. Actually, inherent safety and simplicity go together since simplicity is one important parameter of inherently safer plants.

32.7.4 Future work

The indices developed thus far are expertise intensive. They need to be simplified so that a scientist or an engineer in the process industry can understand and use them easily without having to hunt for a lot of data and information. Most of the work has been done in academic institutions (except INSET Toolkit). Several practical examples from industry need to be evaluated using the proposed indices and modifications made to them to suit the needs of the industry. A holy alliance between the researchers, industry personnel and the regulators would prove beneficial to all.

32.7.5 Measuring inherently safer design – conclusions

Inherent safety is an exciting field that has caught the attention of researchers, plant designers, management and regulators worldwide. An inherent safety measurement method is needed to compare different processes for an end product. This method should work at the research stage itself and not require too much data. Researchers in several countries have produced indices towards this end. These indices are in an evolving stage. These need to be simplified. The intensive work put in by researchers needs to be consolidated and unified. The ultimate proof will be in the thorough testing of the indices by the industry and sharing of their experiences. Some industries have developed their

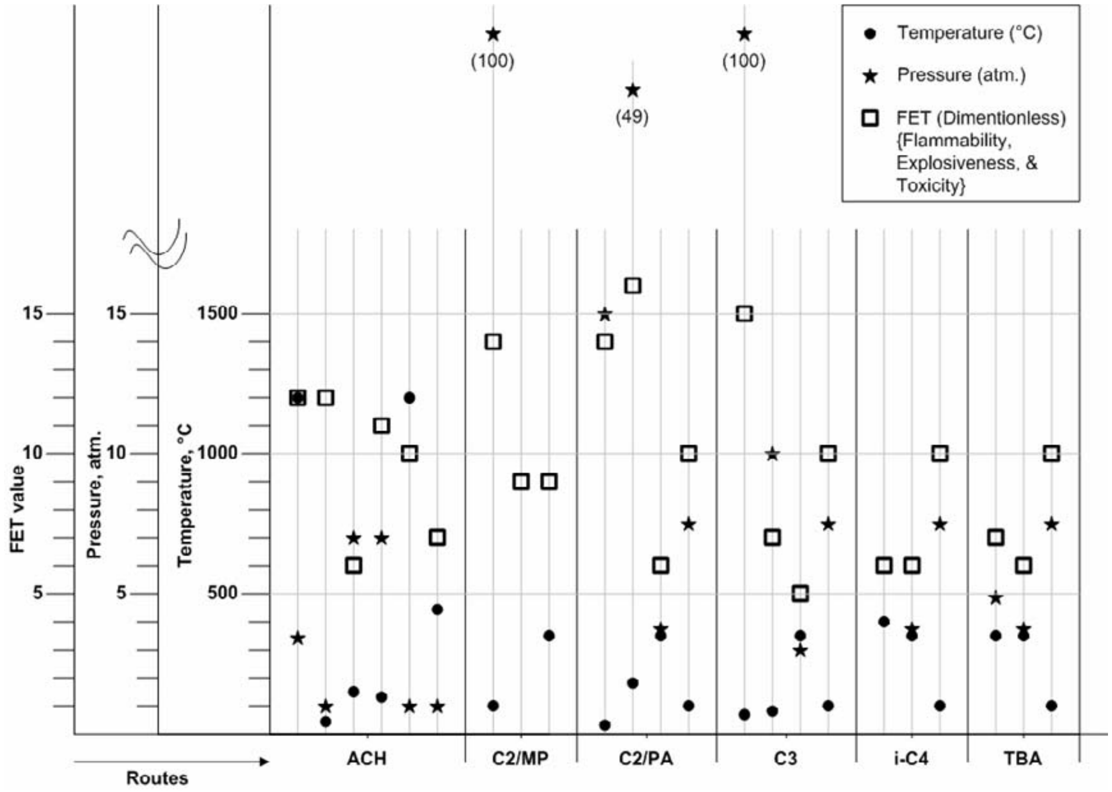

Figure 32.2 *MMA Routes (Gupta and Edwards, 2003)*

own proprietary methods to test for inherent safety but these are not available in open literature.

Once the company personnel starting from research chemists, process engineers and the rest start using inherently safer design, they would actually see the advantages and want to use it more and more. With process plants thus becoming significantly safer, the regulators are likely to gradually relax on process safety protocols. Once inherently safer design is successfully applied to process industries, it can be adapted by other accident-prone industries such as mining, construction, transportation and others.

32.8 Inherently Safer Design and the Process Life Cycle

Inherently safer design applies to a process at all phases in its life cycle, from early process conception, through laboratory development, pilot plant, preliminary and detailed design, construction, operation and shut-down and demolition. However, the designer will be applying inherently safer design principles in different ways at different stages of the life cycle. Early on, he will be considering the basic technology and synthesis routes, and in the later stages of the life cycle the designers and operators will be looking at more specific opportunities for applying inherently safer design concepts to specific pieces of equipment. The greatest opportunities for making major improvements in inherent safety occur early in process development, when the designer may have many choices of basic technology and chemistry available, and may be free to choose less hazardous alternatives. However, it is never too late to apply inherently safer design concepts, and major improvements to the inherent safety characteristics of plants which have been in operation for many years have been reported.

Here are some examples of the kinds decisions in which inherently safer design concepts should be applied by the designer or operator of a process at different life cycle stages.

(1) Conceptual process research and development: selection of basic process technology, raw materials, intermediate products, by-products and waste products, chemical synthesis routes.
(2) Process research and development: selection of specific unit operations, types of reactors and other processing equipment, selection of operating conditions, recycle, product purification, waste treatment.
(3) Preliminary plant design: location of manufacturing facility, location of units on a selected site, size and number of production lines, size of raw material, intermediate, and product storage facilities, selection of specific equipment types for the required unit operations, process control philosophy.
(4) Detailed plant design: size of all equipment, pressure rating and detailed design of all equipment and piping, inventory in processing equipment, location of specific equipment in the plant, length, route, and size of piping,

utility design, layout of equipment, detailed control system design, plant–operator interface design.
(5) Operation: identification of opportunities to modify plant to enhance inherent safety (reduce inventory, upgrade with more modern equipment, identify opportunities for inherently safer operation based on improved process understanding), consideration of inherently safer design when making modifications and changes, 'user friendly' operating instructions and procedures.

32.9 Implementing Inherently Safer Design

Inherently safer design applies at all levels of chemical plant conception, research, design and operation. It is more of a design philosophy or way of thinking than a specific set of tools, review meetings or other specific activities. The initial focus of the designer should be on the elimination and minimization of hazards, rather than the control of hazards. When a hazard is identified at any stage of development, the designer should ask the following questions:

(1) Can the hazard be eliminated from the process?
(2) If the hazard cannot be eliminated, can the magnitude of the hazard, or potential incidents arising from the hazard, be significantly reduced?
(3) Do the alternative designs identified from the answers to Questions 1 and 2 increase the magnitude of other existing hazards, or introduce any new hazards to the process?
(4) If the alternative designs increase other hazards, or introduce new hazards, develop an understanding of these hazards and understand the relative importance of the various hazards.
(5) Identify passive, active and procedural safeguards appropriate for management of all hazards.
(6) Use a logical decision process to select the optimum design, considering inherent safety characteristics, other safety characteristics, and all other relevant design parameters.

Too often, upon identifying a hazard, the designer skips past the first four questions and goes directly to question 5 – identifying 'add-on' safety features to manage and control a hazard whose existence and magnitude the designer accepts. While it will not always be possible or feasible to eliminate or significantly reduce hazards, it is certain that it will never happen if the designer never asks the question. This is the heart of the inherently safer design philosophy – first ask if hazards can be eliminated from the process, or if they can be dramatically reduced. Do not go directly to designing safety systems to manage and control hazards until it has been determined that it is not feasible to eliminate or reduce hazards.

Some companies incorporate inherently safer design into the process hazard analysis (PHA) activities which are already included in their process safety programs. In the course of a safety review, HAZOP, or other process safety review activity, the review team and leader are charged with considering inherently safer design options. Other companies have used separate inherent safety reviews. CCPS (1996) and others have published some checklists which can be used in separate inherent safety reviews, or provided to PHA teams for consideration as they conduct their reviews. Table 32.19 is an example of a general checklist (CCPS, 1996).

CCPS (1998) provides a series of checklists which are useful in identifying hazards associated with various

Table 32.19 *A Checklist for Inherently safer design (adapted from CCPS, 1996)*

1.1 Minimize (or itensify)

1. Do the following strategies reduce inventories of hazardous raw materials, intermediates, and/or finished products?
   (a) Improved production scheduling
   (b) Just-in-time deliveries
   (c) Direct coupling of process elements
   (d) In-site generation and consumption
2. Do the following actions minimize in-process inventory?
   (a) Eliminating or reducing the size of in-process storage vessels
   (b) Designing processing equipment handling hazardous materials for the smallest feasible inventory
   (c) Locating process equipment to minimize the length of hazardous material piping runs
   (d) Reducing piping diameters
3. Can other types of unit operations or equipment reduce material inventories? For example:
   (a) Wiped film stills in place of continuous still pots
   (b) Centrifugal extractors in place of extraction columns
   (c) Flash dryers in place of tray dryers
   (d) Continuous reactors in place of batch
   (e) Plug flow reactors in place of continuous-flow stirred tank reactors
   (f) Continuous in-line mixers in place of mixing vessels
4. Can thermodynamic or kinetic efficiencies of reactors be improved by design upgrades (e.g. improved mixing or heat transfer) to reduce hazardous material volume?
5. Can equipment sets be combined (e.g. replacing reactive distillation with a separate reactor and multi-column fractionation train; installing internal reboilers or heat exchangers) to reduce overall system volume?
6. Can pipeline inventories be reduced by feeding hazardous materials as a gas instead of a liquid (e.g. chlorine)?
7. Can process conditions be changed to avoid handling flammable liquids above their flash points?
8. Can process conditions be changed to reduce production of hazardous wastes or by-products?

1.2 Substitute

1. Is it possible to completely eliminate hazardous raw materials, process intermediates, or by-products by using an alternative process or chemistry?
2. Is it possible to completely eliminate in-process solvents by changing chemistry or processing conditions?
3. Is it possible to substitute less hazardous raw materials? For example:
   (a) Non-combustible rather than flammable
   (b) Less volatile
   (c) Less reactive
   (d) More stable
   (e) Less toxic
4. Is it possible to use utilities with lower hazards (e.g. low pressure steam instead of combustible heat transfer fluid)?
5. Is it possible to substitute less hazardous final product solvents?
6. For equipment containing materials that become unstable at elevated temperatures or freeze at low temperatures, is it possible to use heating and cooling media that limit the maximum and minimum temperature attainable?

1.3 Moderate (or Attenuate)

1. Is it possible to keep the supply pressure of raw materials lower than the working pressure of the vessels to which they are fed?
2. Is it possible to make reaction conditions (e.g. pressure or temperature) less severe by using a catalyst or by using a better catalyst?
3. Can the process be operated at less severe conditions using any other route? For example:
   (a) Improved thermodynamic or kinetic efficiencies of reactors by design upgrades (e.g. improved mixing or heat transfer) to reduce operating temperatures and/or pressures
   (b) Changes to the order in which raw materials are added
   (c) Changes in phase of the reaction (e.g. liquid/liquid, gas/liquid or gas/gas)
4. Is it possible to dilute hazardous raw materials to reduce the hazard potential? For example, by using the following:
   (a) Aqueous ammonia instead of anhydrous
   (b) Aqueous HCl instead of anhydrous
   (c) Sulfuric acid instead of oleum
   (d) Dilute nitric acid instead of concentrated fuming nitric acid
   (e) Wet benzoyl peroxide instead of dry

1.4 Limit effects

1. Is it possible to design and construct vessels and piping to be strong enough to withstand the largest overpressure that could be generated within the process, even if the 'worst credible event' occurs (eliminating the need for complex, high pressure interlock systems and/or extensive emergency relief systems)?
2. Is all equipment designed to totally contain the materials that might be present inside at ambient temperature or the maximum attainable process temperature (i.e. higher maximum allowable working temperature to accommodate loss of cooling, simplifying reliance on the proper functioning of external systems, such as refrigeration systems, to control temperature such that vapour pressure is less than equipment design pressure)?
3. Can passive leak-limiting technology (e.g. blowout resistant gaskets and excess flow valves) be utilized to limit potential for loss of containment?
4. Can process units be located to reduce or eliminate adverse effects from other adjacent hazardous installations?
5. Can process units be located to eliminate or minimize the following?
   (a) Off-site impacts
   (b) On-site impacts on employees and other plant facilities
6. For processes handling flammable materials, is it possible to design the facility layout to minimize the number and size of confined areas and to limit the potential for serious overpressures in the event of a loss of containment and subsequent ignition?
7. Can the plant be located to minimize the need for transportation of hazardous materials?
8. Can materials be transported in the following ways?
   (a) In a less hazardous form
   (b) Via a safer transport method
   (c) Via a safer route

1.5 Simplify/design for error tolerance

1. Is it possible to separate a single, procedurally complex, multipurpose vessel into several simpler processing steps and processing vessels, thereby reducing the potential for hazardous interactions when the complexity of the number of raw materials, utilities, and auxiliary equipment is reduced for specific vessels?

---

2. Can equipment be designed so that it is difficult to create a potentially hazardous situation due to an operating or maintenance error? For example:
   (a) Simplifying displays
   (b) Designing temperature-limited heat transfer equipment
   (c) Lowering corrosion potential by use of resistant materials of construction
   (d) Lowering operating pressure to limit release rates
   (e) Using higher processing temperatures (to eliminate cryogenic effects such as embrittlement failures)
   (f) Using passive vs active controls (e.g. stronger piping and vessels)
   (g) Using buried or shielded tanks
   (h) Using fail-safe controls if utilities are lost
   (i) Limiting the degree of instrumentation redundancy required
   (j) Using refrigerated storage vs pressurized storage
   (k) Spreading electrical feed over independent or emergency sources
   (l) Reducing wall area to minimize corrosion/fire exposure
   (m) Reducing the number of connections and paths
   (n) Minimizing the number of flanges in hazardous processes
   (o) Valving/piping/hose designed to prevent connection error
   (p) Using fewer bends in piping
   (q) Increasing wall strength
   (r) Using fewer seams and joints
   (s) Providing extra corrosion/erosion allowance
   (t) Reducing vibration
   (u) Using double-walled pipes, tanks and other containers
   (v) Minimizing the use of open-ended valves
   (w) Eliminating open-ended, quick-opening valves in hazardous service
   (x) Improving valve seating reliability
   (y) Eliminating unnecessary expansion joints, hoses and rupture disks
   (z) Eliminating unnecessary sight glasses/glass rotometers
3. Can procedures be designed so that it is difficult to create a potentially hazardous situation due to an operating or maintenance error? For example:
   (a) Simplifying procedures
   (b) Reducing excessive reliance on human action to control the process
4. Can equipment be eliminated or arranged to simplify material handling?
   (a) Using gravity instead of pumps to transfer liquids
   (b) Siting to minimize hazardous transport or transfer
   (c) Reducing congestion (i.e. easier to access and maintain)
   (d) Reducing knock-on effects from adjacent facilities
   (e) Removing hazardous components early in the process rather than spreading them throughout the process
   (f) Shortening flow paths
5. Can reactors be modified to eliminate auxiliary equipment (e.g. by creating a self-regulatory mechanism by using natural convection rather than forced convection for emergency cooling)?
6. Can distributed control system (DCS) modules be simplified or reconfigured such that failure of one module does not disable a large number of critical control loops?

---

specific types of process equipment, including vessels, reactors, mass transfer equipment, heat transfer equipment, dryers, fluid transfer equipment, solid–fluid separators, solids handling and processing equipment, fired equipment, and piping and piping components. The checklists also provide examples of inherent, passive, active and procedural design features which have been implemented to address the hazards listed. Table 32.20 is an example of the checklists from CCPS (1998), for dryers.

The INSIDE project (INSET Toolkit, 1997) provide a set of tools for identifying inherently safer design options at various stages of process development. These tools are listed in Table 32.18. The CCPS and the Center for Waste Reduction Technologies (CWRT) has developed a process called MERITT (Maximizing EHS Returns by Integrating Tools and Talents) for enhancing process development by better integrating environmental, health and safety evaluations into the basic process development (CCPS and CWRT, 2001; Mulholland, Bendixen and Keeports, 2001).

There have been some regulatory proposals to require that the chemical industry consider inherently safer design options. In the early 1990s, the United States Environmental Protection Agency considered requiring a ‘Technical Options Analysis (TOA)’ for plants covered by its Risk Management Program (RMP), as required by the US Clean Air Act Amendments of 1990. However, the TOA requirement was not included in the final RMP regulations. In 1999, Contra Costa County, California passed its Industrial Safety Ordinance (Sawyer, 2002), which requires that covered facilities consider inherently safer design options.

Table 32.20 *An example of the equipment failure scenario tables, with potential design approaches, for dryers (excerpted from CCPS, 1998)*

No.	*Operational deviations*	*Failure scenarios*	*Potential design solutions*		
			Inherently safer/passive	*Active*	*Procedural*
1.	Overpressure	Buildup and autoignition of deposits in dryers and ductwork resulting in fire/explosion	(a) Dryer design which minimizes buildup of deposits (smooth surfaces, elimination of potential points of solids accumulation) (b) Use dryer with short residence time (e.g. flash dryer) (c) Design dryer to contain overpressure where practical (d) Permanent bonding and grounding	(a) Automatic sprinkler system/CO_2 total flooding system (b) Use of inert atmosphere (c) Deflagration venting (d) Deflagration suppression system (e) Automatic isolation of associated equipment via quick closing valves	(a) Periodic inspection and cleaning (c) Emergency response procedures (c) Proceduce to process most stable materials first when campaigning multiple products to avoid ignition of unstable materials (d) Procedure for determining maximum tolerable material accumulation (e) Manual activation of fire fighting/inerting system
2.	Overpressure	Ignition of condensing flammable vapor in ductwork resulting in fire/explosion	(a) Dryer design to prevent condensation in ductwork (b) Provision for drainage of ducts (e.g. sloped, low point drains) (c) Eliminate ignition sources within the ductwork (d) Eliminate flammables (e) Design dryer to contain overpressure where practical (f) Permanent bonding and grounding	(a) Automatic sprinkler system/CO_2 total flooding system (b) Ventilation system to keep flammable concentration below lower flammable limit (c) Deflagration vents (d) Use of inert atmosphere (e) Automatic isolation of associated equipment via quick closing valves	(a) On-line flammable gas detection and manual activation of CO_2 total flooding system (b) Manual activation of fire fighting/inerting system (c) Manual bonding and grounding

Bills addressing security issues in the chemical industry, including the potential of inherently safer technology for reducing the attractiveness of a chemical plant as a potential terrorist target, have been introduced in the US Senate in 2001 and 2003, but none have been passed as of the end of 2003.

However, the best way to invent and build inherently safer processes is to make it a part of the thinking of all engineers and chemists as they go about their work. If they recognize the importance and benefits of hazard elimination, their creativity in inventing new ways to eliminate or reduce hazards as they go about their work activities will go further toward enhancing inherent safety than any review meetings possibly could.

32.10 Inherently Safer Design References

The INSIDE Project (INSET Toolkit, 1997), CCPS (1996), and Kletz (1998) provide the most comprehensive overall discussions of inherently safer design. The International Process Safety Group and the Institute of Chemical Engineers (IPSG and IChemE, 1995) developed an excellent training package on inherently safer design. CCPS and CWRT (2001) provide an overall methodology (MERITT) for considering inherently safer process options in conjunction with environmental characteristics of a process at an early stage of process development. Table 32.21 lists a number of literature references which discuss inherently safer technology, grouped into specific topic areas.

Table 32.21 *Selected literature references on inherently safer design*

Reactive Chemicals

Contents

33.1 Background

33.1.1 Motivation

Serious incidents arising from uncontrolled reactivity have taken place since the inception of the chemical industry. The human toll of such incidents has been staggering. In recent decades, greater recognition and resources have been directed toward preventing and mitigating such occurrences. A number of incidents have been so severe as to prompt regulatory initiatives to force better management of reactivity. It would not be surprising to see additional regulation enacted to address the issues. In any event, it is prudent for any company, organization or other group to scrutinize the chemicals being handled and implement measures to limit the risk of a major reactive hazards event.

A sampling of incidents that have substantially heightened concerns regarding reactive hazards in the general public, in governmental agencies and in industry includes:

(1) The 1976 ICMESA incident in Seveso, Italy in which an uncontrolled chemical reaction generated pressure resulting in relief venting of a highly toxic dioxane into the neighbouring villages and countryside.
(2) The 1984 Union Carbide incident in Bhopal, India in which methyl isocyanate was contacted with water, generating highly toxic cyanide gas and leading to thousands of fatalities.
(3) The 1994 Napp Technology incident in Lodi, New Jersey in which an uncontrolled reaction involving gold ore processing led to the deaths of five fire fighters.
(4) The 1999 Concept Sciences incident in Allentown, Pennsylvania in which an explosion arising from a process concentrating hydroxylamine resulted in five fatalities. Another event involving purified hydroxylamine took place in a Nissin Chemical plant in Gunma Prefecture, Japan in 2000 and led to four fatalities.
(5) The 2001 TotalFinaElf incident in Toulouse, France in which ammonium nitrate being processed for nitrogen fertilizers exploded, leading to 30 fatalities.

These events, as well as numerous others, have influenced the perception and approach to reactive hazards.

In 2002, the US Chemical Safety and Hazard Investigation Board (CSHIB or CSB) issued a report examining 1,500 US reactivity-related incidents. Of these, 167 serious incidents between 1980 and 2001 contained sufficient information to warrant further analysis, observations and conclusions. Nearly half of the incidents involved fatalities and nearly half affected the public (i.e. beyond the fenceline of facilities). The report also indicates that these types of incidents continue to occur at a troubling frequency.

The principal hazard is instability of an individual substance or an uncontrolled or 'runaway' reaction. There now exist a bewildering multiplicity of tests for the detection and characterization of substances and reactions, and the apparatus for many of the tests is expensive. Moreover, it is not sufficient to determine the characteristics of the reaction on the laboratory scale. It is necessary also to characterize the reaction and the scale-up features to allow a safe design to be developed. The problem is particularly severe where it is a question of confirming that an existing process is safe, because in this case it is not possible to incorporate the safety margins that might be used in a new process.

Runaway reactions

In a runaway reaction, there is a reaction exotherm in the vessel or tank, the heat evolved is not removed sufficiently rapidly, the temperature of the reaction mass rises and the reaction accelerates. The exotherm may be from the main, intended process reaction or from an undesired side reaction. A high pressure may then be generated by the product gases or by the vapour pressure of liquids in the equipment. If this pressure is not relieved, the vessel or tank may suffer overpressure and fail.

General reactivity incidents

Uncontrolled reactions can occur in any setting or any piece of equipment where reactivity is not managed appropriately. Though it is commonplace to envision such reactions taking place in reactors, the CSHIB investigation found that only 25% of the 167 incidents in the past two decades occurred in reactors. Another 22% occurred in storage equipment, an equivalent percentage in other process equipment (e.g. holding tanks, mixers, dryers), while 13% took place in waste, separation and transfer equipment. In fact, only 70% of the incidents involved chemical manufacturing facilities while most of the remainder occurred in bulk storage/handling facilities.

Reactor incidents

Reactors (particularly, batch) are operated by a wide variety of firms, many of which are quite small. On the other hand, the number of chemicals made by a given firm may be quite large. A work may produce over 1000 different chemicals using a range of reaction types.

Analyses of batch reactor incidents in the United Kingdom reported to the HSE have been given by Townsend and Pantony (1979), Barton and Nolan (1984), Nolan and Barton (1987) and by Marrs *et al.* (1989).

Marrs *et al.* based their study on two sets of data. The first was a set of UK data from the HSE's own records for the period 1970–81 (the UK national data set) and the second, a collection of worldwide incidents made for the HSE (the world data set). The two sets contained 68 and 199 incidents, respectively.

The overall taxonomy used by Marrs *et al.* is given in Table 33.1. The analysis of reactor overpressure incidents by incident mode is shown in Table 33.2, in which the taxonomy is developed in finer detail and which utilizes the worldwide set. The table includes more detailed analyses for (a) sulfonation, (b) nitration and (c) polymerization reactions, for which incidents are relatively common.

Information on reactor relief was obtainable only from the national set. Table 33.3–Table 33.5 give information on overpressure relief arrangements, overpressure incident and relief system behaviour.

These workers also carried out an expert judgment field survey the results of which are shown in Table 33.6. The comparison of the ranking of the relative importance, or frequency, of the incident modes (1 = most important, etc.) is shown in Section A. There is reasonable agreement overall, with two exceptions. Thus, in both rankings, incorrect charging and inadequate cooling are ranked high, undesired catalysis low and excessive heating, incorrect agitation and exotherm from impurity, moderate. The exceptions are unknown exotherm/decomposition, which is ranked much lower by the experts than in the case histories and inadequate batch control. The experts were from companies with expected good practice and the relatively

Table 33.1 Taxonomy for reactor overpressure analysis (Marrs et al., 1989) (Courtesy of the Institution of Chemical Engineers)

A	**System description**
	Chemical reaction

	1.3 Explosion
I2	Toxic release

low ranking of unknown exotherms probably reflects their view that they had taken steps to control this hazard. Sections B–E of Table 33.6 give the corresponding rankings of particular incident submodes.

33.1.2 Regulations and compliance

The rapid development of industrial facilities since 1950 was followed by an increase in incidents involving reactive and toxic substances. Major losses due to these incidents prompted legislation to prevent such incidents.

Seveso I

A release of TCDD (tetrachlorodibenzoparadioxin) in the Seveso, Italy, incident of 1976 contaminated 10 square miles and about 2000 people were treated for dioxin poisoning. In 1982, the European Community adopted the Seveso Directive to identify and control the location of hazardous installations and to assess the hazards of substances above threshold quantities from a list of toxic, flammable or explosive materials.

Seveso II

The Seveso Directive required a review of its scope by the European Community, and in December 1996 the Seveso II Directive was adopted with the objective to prevent major

D5 Impurity reactant decomposition				
E4 Impurity decomposition				
Case 3: C3 Overpressure by water vapour				
D6 Water ingress and vaproization	1			
Case 4: C4 Overpressure by flammable gas (ignition of explosive mixture)				
D7 Air ingress and combustion (7)	7		1	
Case 5: C5 overpressure by other gas/vapour				
D8 High pressure gas ingress	1			
Miscellaneous cases				
X1 Overpressure following unknown exotherm, where it is unclear if exotherm is a decomposition	7		3	
X2 Overpressure following operator attempts to recover from fault conditions	4		2	1
Cases where cause is unknown				
Z1 Cause unknown	12			5

B Summary

	Mode (%)			
	All reactions[d]	*Nitration*	*Sulphonation*	*Polymerization*[d]
Regular reaction inadequate information	3.5 (3.7)	9.1	0	7.1 (8.6)
Incorrect charging	17.2 (18.3)	0	13.8	14.3 (17.4)
Inadequate cooling	13.1 (14.0)	0	6.9	28.6 (34.8)
Excessive heating	9.6 (10.2)	9.1	17.2	14.3 (17.4)
Inadequate agitation	10.1 (10.8)	36.4	13.8	7.1 (8.6)
Incorrect batch control	9.1 (9.7)	0	13.8	3.6 (4.4)
Undesired catalysis	2.5 (2.7)	0	0	3.6 (4.4)
Impurity reaction exotherm	10.6 (11.3)	27.3	3.4	0
Regular reactant unknown decomposition	8.1 (8.6)	18.2	10.3	0
Water ingress and Vapourization	0.5 (0.5)	0	3.4	0
Air ingress and combustion	3.5 (3.7)	0	3.4	0

Table 33.2 (continued)

High pressure gas ingress	0.5 (0.5)	0	0	0
Exotherm of unknown type	3.5 (3.7)	0	10.3	0
Recovery from fault conditions	2.0 (2.2)	0	6.9	3.6 (4.4)
Cause unknown	6.1	0	0	17.9
Total	100	100	100	100
No. of applicable incidents = 199				

[a] In one case cause is assigned to lack of cooling, although there had also been a change in the quality of the reactants.
[b] In one case cause is assigned to a failure of a temperature controller, although a new more active catalyst was also in use.
[c] In one case cause is assigned to gross overheating by steam, although it was also subsequently found that the reaction mixture exhibited instability.
[d] Values in brackets are based on redistribution of 'Causes unknown' among known causes in proportion to relative frequency of latter.

Table 33.3 Analysis of reactor overpressure: relief arrangements (Marrs et al. 1989) (Courtesy of the Institution of Chemical Engineers)

Relief arrangement[a]	*No.*
BD(s)	11
RV	8
RV + BD	2
RV, vent part closed	1
BD, recommend larger BD	2
RV, recommend BD	1

No relief	1
Manual vent valve	1
Small vent(s)	1
Vent, recommend BD	1
Small holes	1
Vessel open	15
Vessel open, recommend BD	1
Unknown	13
Total	68

[a] BD, bursting disc; RV, relief valve.

Table 33.4 Analysis of reactor overpressure: overpressures (Marrs et al. 1989) (Courtesy of the Institution of Chemical Engineers)

Overpressure incident	*No.*	*Proportion* (%)
Vessel open, hazardous release	18[a]	27.3
Glasswork shattered, hazardous release	16[b]	24.2
Vessel ruptured, hazardous release	19	28.8
Vessel ruptured	1	1.5
Explosion	5	7.6
Hazardous release	5	7.6
Catchpot ruptured	1	1.5
Catchpot fire	1	1.5
Total	66	100.0

[a] One case where overpressure was vented through two holes; one where manhole was opened; and one where operator disconnected hose.
[b] One case where reflux divider ruptured – glassware not specifically mentioned.

Table 33.5 Analysis of reactor overpressure: relief system behaviour (Marrs et al. 1989) (Courtesy of the Institution of Chemical Engineers)

Relief system behaviour	*No.*	*Proportion* (%)
Relief operated:		
Glassware ruptured	3	6.3
Vessel ruptured	1	2.1
Explosion	1	2.1
Catchpot ruptured	1	2.1
Catchpot fire	1	2.1
Hazardous release	3	6.3
Relief fitted, but failed:		
Glassware ruptured	3[a,b]	6.3
Vessel ruptured	8	16.7
Explosion	2	4.2
Glassware ruptured	10[c]	20.8
Vessel ruptured	11[d]	22.9
Explosion	2	4.2
Hazardous release	2	4.2
Total	48	100

[a] One case where relief valve (RV) fitted, but vent part closed; and one where bursting disc (BD) fitted, but larger BD recommended.
[b] One case where BD failed to rupture.
[c] Five cases where relief arrangements unknown; three cases where BD recommended; and one where no relief was fitted.
[d] Six cases where relief arrangements unknown; three cases where there was no BD; one case where BD recommended; and one where there was a manual vent valve.

incidents involving dangerous substances and limit the consequences of such incidents to people and the environment. This replacement directive included new requirements relating to safety management system and emergency planning. Whereas the original Seveso Directive focused on technical factors affecting safety, Seveso II focuses on management systems, which were determined to be responsible for the majority of incidents.

OSHA

The Occupational Safety and Health Administration (OSHA) was created by the 1970 OSH Act of the US Congress to establish consistent regulation with regard to industrial personnel and workplace conditions. In 1992, OSHA promulgated the Process Safety Management (PSM) of Highly Hazardous Chemicals – a program with 14 elements including a process hazard analysis (PHA). See Appendix 31 for a discussion of OSHA and PSM.

***Table 33.6** Analysis of reactor overpressure: comparison of rankings from case histories and from expert judgement field study (Marrs et al., 1989) (Courtesy of the Institution of Chemical Engineers)*

	Case histories		*Field study*
	%	*Rank*	*Rank*
A Incident modes			
Unknown exotherm/decomposition	15.1	2	6

Incorrect cycle	16.6	3	4
Excessive holding	22.2	=1	2

EPA

The Environmental Protection Agency (EPA) was created by the Clean Air Act of 1970 of the US Congress to reduce exposures of hazardous substances. In 1996, the EPA promulgated the Risk Management Program (RMP) for Chemical Accident Release Prevention – a program with 11 elements, including a hazard evaluation (similar to the OSHA PHA) and a risk assessment for worst-case and alternative case releases of toxic substances. See Appendix 32 for a discussion of EPA and RMP.

TCPA

According to the US CSHIB report issued in 2002, more than 50% of the 167 reactivity-related incidents analysed were not covered by existing OSHA or EPA regulations.

In response to concern about reactivity incidents, the New Jersey Department of Environmental Protection announced in August 2003 that reactive chemicals were added to the list of extraordinarily hazardous substances (EHS) in the New Jersey Toxic Catastrophe Prevention Act (TCPA) rules. This was the first regulatory rule in the United States to require assessment of reactive chemical hazards compared to assessment of process hazards required by the OSHA PSM in 1992 and by the EPA RMP rule in 1996. When announced, the list of EHS with threshold quantities included 30 chemicals and 43 chemical groups.

33.1.3 Overall strategy

Overall strategy

A strategy for safe reactor design, given in the IChemE *Guide,* largely follows N. Gibson, Rogers and Wright (1987), who describe the strategy developed at ICI, as follows:

(1) definition of the process conditions and plant design;
(2) characterization of the chemical reaction and its hazards;
(3) selection and specification of safety measures;
(4) implementation and maintenance of safety measures.

The stages in and strategies for the assessment and control of hazards of chemical reactors are shown in Figures 33.1 and 33.2, respectively. The characterization of the chemical reaction and its hazards involves:

(1) hazard evaluation of the reaction;
(2) characterization of reaction for scale-up;

and safety aspects of the design of the reactor include:

(3) inherently safer design;
(4) control and trip systems;
(5) emergency safety measures;
(6) overpressure relief.

The strategy will be influenced by the types of reaction operated in the company, by evidence from previous incidents and by the options available for safety measures.

33.2 Technical

33.2.1 Strategies for identifying and characterizing reactive hazards

Chemical reactivity overview

Definition

The US CSHIB has proposed the following definition of a reactive hazard: 'A *sudden* event involving an *uncontrolled* chemical reaction with significant increases in temperature, pressure, *or* gas evolution that has the potential to, or has caused *serious harm* to people, property or the environment'.

Reactive hazards have the potential to cause harm to people or loss of life along with extensive damage to the surroundings due to the uncontrolled release of energy. A common pathway involves overpressurization of equipment, either through buildup of pressure or through weakening of the equipment structural integrity, leading to possible generation of a blast wave or generation of a flammable vapour cloud that can explode upon finding

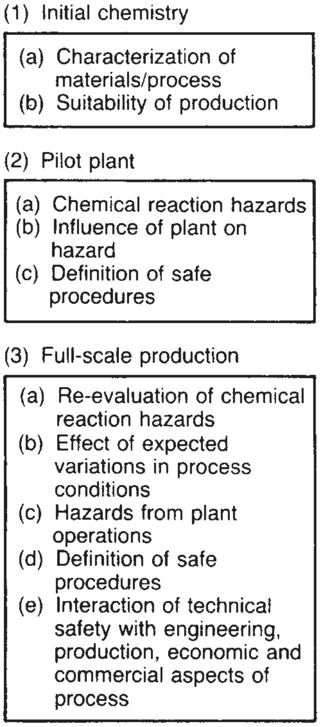

Figure 33.1 *Stages in control of hazards of chemical reactions (N. Gibson, Rogers and Wright, 1987) (Courtesy of the Institution of Chemical Engineers)*

an ignition source. For a *detailed* assessment of reactive hazards risk, an understanding of reaction pathway, stoichiometry, energetics, gas generation and rates is needed.

Strategy

Overall evaluation strategy The strategy for reaction hazard evaluation described in the IChemE *Guide* involves the following:

(1) desk screening;
(2) explosibility tests;
(3) preliminary screening tests;
(4) characterization of normal reaction;
(5) characterization of runaway reaction.

These are now discussed under the categories of

(1) desk screening;
(2) preliminary screening tests;
(3) detailed tests.

Calculational methods are also included as well as a synopsis of various test schemes.

Principal factors A review of the factors that should be taken into account in the reaction assessment has been given in the two ABPI *Guidelines.* The components covered should include: the reactants, the reaction intermediates (whether isolated or not) and the reaction products; the by-products; the solvent; additives; the still residues; and the wastes and effluents.

The review should consider the effect of contaminants on the stability of components and on the reaction rate. Contaminants may include: impurities in the reactants;

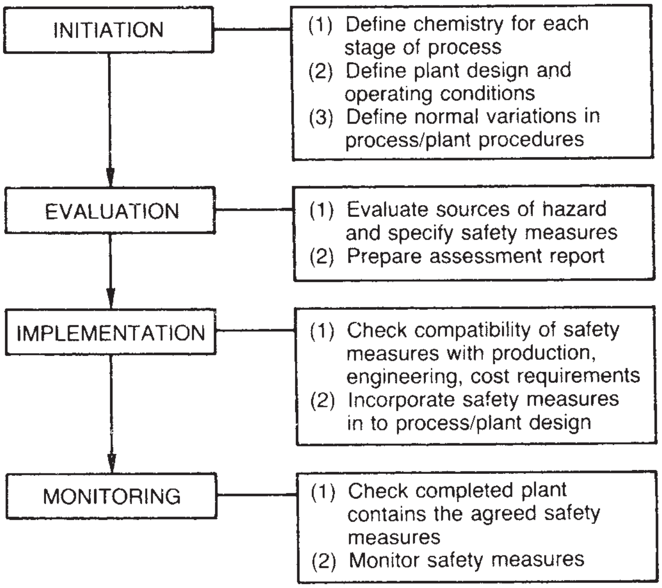

Figure 33.2 *Strategy for control of hazards of chemical reactions (N. Gibson, Rogers and Wright, 1987) (Courtesy of the Institution of Chemical Engineers)*

materials of construction; corrosion products; water, steam, refrigerant and other heat transfer fluids; and materials from elsewhere. Other factors mentioned include:

(1) incorrect use of catalysts;
(2) addition of extra quantities of reagents;
(3) sequence of addition or omission of reagents;
(4) addition of wrong reagent;
(5) drift of pH and sensitivity to buffering in normal or abnormal operation;
(6) effect of process errors on reaction conditions.

Categorizing reactivity types

Stability vs reactivity with other species

Many compounds will undergo degradation or decomposition when subjected to elevated temperature, mechanical impact or other disturbances. Some compounds can polymerize or re-arrange internally. Most compounds will also react when placed in contact with certain other species.

According to the CSHIB report released in 2002, 10% of the 167 reactivity-related incidents analysed involved impact- or thermally-sensitive materials. Another 35% were associated with runaway reactions. About 36% of the incidents involved chemical incompatibility.

Tests for chemical reaction Reactivity information applicable to individual substances should be obtained. Somewhat similar information is required for the evaluation of the hazards of conducting a chemical reaction in a reactor. It is still necessary to determine the behaviour of the individual components – reactant, intermediates and products – but in addition it is necessary to examine the reaction as a whole, including not only the main, desired reaction, but also secondary reactions. In the methods described below, it should be recognized when the methods are being applied to address the stability or reactivity in combination with other species.

Intended vs unintended

It is useful to distinguish between 'intended' and 'unintended' reactions or alternatively 'normal' and 'abnormal' reactions. Intended reactions are clearly those reactions targeted in a process. Unintended reactions are the side reactions that are typically avoided. Usually, there are no intended reactions in blending, distribution, transportation and storage operations. An intended reaction occurring outside of its associated equipment can in that context be considered as unintended. More-extensive stoichiometric and thermokinetic information is generally available for targeted reactions. Moreover, the strategy for managing the risk of reactive hazards can be profoundly affected by whether a reaction of interest is intended or unintended.

Additional factors generally considered when designing equipment for intended reactions include: heat transfer, mixing limitations, phase separation, inlet and outlet flows (properties and rates), and process and relief venting capacity.

Reaction phase

Another characteristic important for understanding reaction behaviour and for determining the appropriate approach(es) for addressing the reactivity is the phase or phases in which the reaction occurs. Reactions commonly take place or initiate in the liquid phase, but some, such as combustion, predominate in the gas-phase. The decomposition of polymers upon heating or of explosives once triggered are examples of solid-phase reactions. Many reactions, such as those that are facilitated by heterogeneous catalysts, are surface reactions. The reactants may reside primarily in the liquid phase or can even be gas-phase (such as in methanation), but the species must travel to and adsorb on the surface to undergo reaction. Finally, the mere adsorption of certain species on solid surface can potentially evolve enough heat to cause significant temperature excursions and further reactivity.

Vapour vs gassy vs hybrid

The ability of a reaction to cause overpressurization of equipment depends heavily on the type of gas or vapour generated. Generally, a 'vapour' refers to a non-condensed species that is in thermodynamic equilibrium with the corresponding species in a condensed phase (usually a liquid, but possibly a solid). A 'gas' describes a non-condensable species that is not in thermodynamic equilibrium. If a vapour–liquid system is heated, the vapour pressure of the species will rise and the pressure of the system is dictated by the temperature and composition. A latent heat is associated with generation of the vapour. Removal of vapour from the system (e.g. by venting) will cause heat (mostly latent) to be discharged. In a 'gassy' system, the pressure is determined by the amount of non-condensable gas generated (a function of reaction stoichiometry, rate and time) and removal of such gas only takes away sensible heat. The term 'hybrid', is applied to systems which exhibit both vapour and gassy features (e.g. when both vapour and gassy species are present, such as for hydrogen peroxide in water decomposing to yield non-condensable oxygen).

Characterizing reactions

It is usual to classify unit processes on the basis of the reaction involved and, as described in Section 11.14 of Chapter 11, these unit processes have certain generic characteristics. A classification of unit processes in terms of their exothermicity has been given by Hoffmann (1985). He classes halogenation, oxidation, organometallic reactions and some polymerizations as highly exothermic; nitration as exothermic; amination, sulfonation, condensation and some hydrogenations as moderately exothermic; and alkylation, hydrolysis and some hydrogenation as mildly exothermic. Thermodynamic schemes such as CHETAH (CHEmical Thermodynamics And energy Hazard evaluation) may be used to evaluate the thermodynamic characteristics of the reaction.

The substances involved in the reaction, whether as reactants, intermediates or products should be screened for explosibility. Basic methods, which have been described in Chapter 8, are examination of reactive chemical groups, computation of the oxygen balance and experimental explosibility testing.

To characterize a chemical reaction adequately, however, it is desirable not only to obtain a qualitative understanding of the behaviour of the reaction, but also to obtain quantitative data on various parameters needed for the specification of the process. It is expected that companies and agencies carrying out intended chemistry will have already acquired sufficient information pertaining to that chemistry to enable appropriate safeguarding. However, in the event that such information is absent, the following approaches can be applied as well to intended chemistry as to unintended chemistry.

Desk screening
Initial desk screening will provide information on the physical and chemical properties and the reactivity of the chemical. Where specific data are lacking, features such as group structure, thermodynamic data, oxygen balance and reactivity of analogous substances provide pointers. Discussions of this aspect are given by Snyder (1965) and by the ABPI (1981, 1989).

The starting point should always be a thorough literature search to determine the data already available on the properties of the chemical. For intended reactions (and some unintended reactions), an organization's internal, proprietary literature may contain a wealth of information pertaining to the stoichiometry, thermodynamics and kinetics. This information might be specific to processing conditions, which limits applicability in safeguarding, but might also feature unique effects such as behaviour in the presence of other process species or reactivity with particular catalysts.

If gaps remain in the knowledge base for reactivity, a search of the open literature should be pursued. For established commercial reactions, it is often helpful to consult the original papers. In certain journals, papers on chemical reactions regularly include information on potential hazards. References frequently reviewed also include: *Dangerous Properties of Industrial Materials* (Sax, 1957–, 1975–, 2000), *Encyclopaedia of Chemical Technology* (Kirk and Othmer, 1963–, 1978–, 1991–) and *Handbook of Reactive Chemical Hazards* (Bretherick, 1999); NFPA 49 and 491M; FM data sheets 7–19 and 7–23; and CMA (MCA) case histories. Frequently, published texts and journal articles can provide insight regarding the chemistry and thermokinetics. Material Safety Data Sheets (MSDSs) should also be consulted for qualitative and limited quantitative reactivity information.

It is instructive to observe that 90% of the US reactivity incidents analysed by the CSHIB involved reactive hazards documented in literature available to the chemical processing industry.

Thermal stability Identification of reactivity of components should be based on a coherent strategy. This will normally involve 'desk' screening, preliminary tests and substantial tests. If an exotherm is identified, tests may be done to characterize it. Other aspects may also need to be investigated such as the extent of gas evolution and the behaviour of the substance under conditions of processing such as drying.

Desk screening and explosibility tests

NFPA classification A general method of categorizing reactivity and instability of individual species is provided in NFPA: 1994 49 *Hazardous Chemicals Data,* which gives materials a Chemical Reactivity Rating as shown in Table 33.7. The code lists the rating for a large number of chemicals.

To demonstrate the importance of examining all likely reactivity scenarios and not depending solely on a screening approach to identify reactive hazards, note that only 10% of the 167 reactivity incidents examined by the CSHIB involved chemicals rated '3' or '4' in the NFPA system; 60% were not rated at all or received a '0' rating.

Table 33.7 *Degrees of reactivity (instability) hazard as defined in NFPA: 1994 49 (Reproduced with permission from NFPA 49 Hazardous Chemicals Data, Copyright, 1994, National Fire Protection Association, Batterymarch Park, Quincy, MA 02269, USA)*

Degree	*Description*
4	Materials that in themselves are readily capable of detonation or explosive decomposition or explosive reaction at normal temperatures and pressures. This degree usually includes materials that are sensitive to localized thermal or mechanical shock at normal temperatures and pressures
3	Materials that in themselves are capable of detonation or explosive decomposition or explosive reaction, but that require a strong initiating source or that must be heated under confinement before initiation. This degree usually includes: materials that are sensitive to thermal or mechanical shock at elevated temperatures and pressures; materials that react explosively with water without requiring heat or confinement
2	Materials that readily undergo violent chemical change at elevated temperatures and pressures. This degree usually includes: materials that exhibit an exotherm at temperatures less than or equal to 150°C when tested by differential scanning calorimetry; materials that may react violently with water or form potentially explosive mixtures with water
1	Materials that in themselves are normally stable, but that can become unstable at elevated temperatures and pressure. This degree usually includes: materials that change or decompose on exposure to air, light or moisture; materials that exhibit an exotherm at temperatures greater than 150°C but less than or equal to 300°C, when tested by differential scanning calorimetry
0	Materials that in themselves are normally stable, even under fire conditions. This degree usually includes: materials that do not react with water; materials that exhibit an exotherm at temperatures greater than 300°C but <500°C, when tested by differential scanning calorimetry; materials that do not exhibit an exotherm at temperatures <500°C when tested by differential scanning calorimetry

General Reactivity of Chemical Structures and Constituents
Certain groups (shown in Figure 33.3) (Kohlbrand, 1985) are known by experience to be unstable or explosive.

Chemical sensitivity to decomposition (reactive conditions)

Instability of materials It is important to know whether a chemical can be safely handled both in process and in storage and transport. The problem has two main aspects. One is the hazard of instability of a single component such

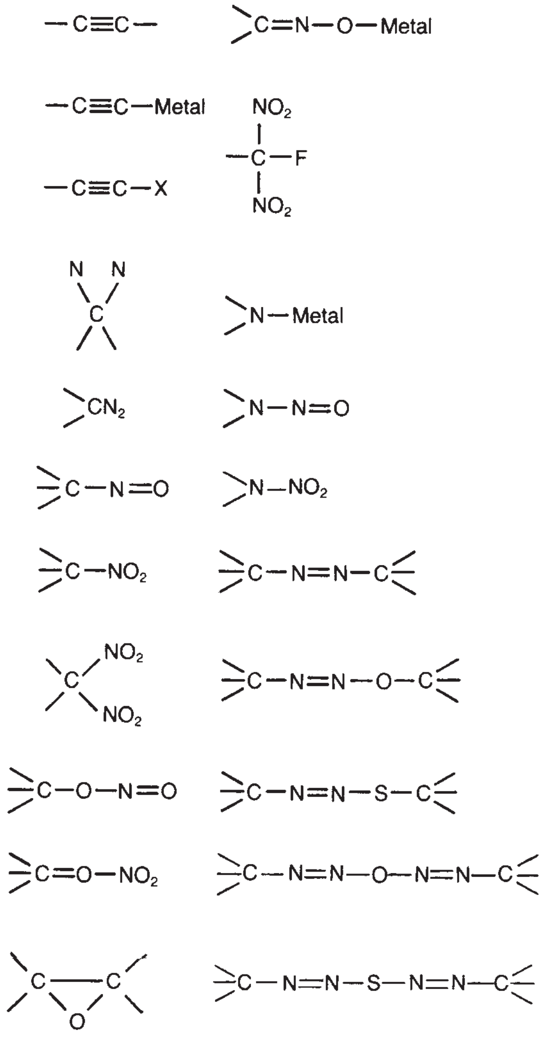

Figure 33.3

as a reactant, intermediate or product when undergoing physical processing on the plant and when stored and transported. The other aspect is the hazard of instability of the reaction mass in a chemical reactor. These two aspects of instability are dealt with here and in Chapter 11, respectively. This section deals with thermal instability and with explosibility.

Accounts of the evaluation of instability of materials include those given in *Guidance Notes on Chemical Reaction Hazard Analysis* by the Association of the British Pharmaceutical Industry (ABPI) (1981) and its successor *Guidelines for Chemical Reaction Hazard Evaluation* ABPI (1989) and by Coates and Riddell (1981a), N. Gibson, Harper and Rogers (1985) and Cronin, Nolan and Barton (1987a).

Oxygen balance A substance may release energy by combustion in air or by decomposition; the main hazard is decomposition. Rapid energy release occurs if the constitution of a substance is such that its carbon and hydrogen are able to react with its own oxygen without needing to obtain oxygen from the surrounding air. If there is just enough oxygen to give a stoichiometric reaction of all the carbon to carbon dioxide and hydrogen to water, there is said to be a zero oxygen balance. The more reactive substances, such as explosives, typically contain enough oxygen to give such decomposition.

The oxygen balance (OB) is an important indicator of stability for some classes of explosive compounds containing nitrogen. For an organic compound of formula $C_xH_yO_z$ it has been defined by Lothrop and Handrick (1949) as:

$$OB = -1600\ (2x + y/2 - z)/M \qquad [33.2.1]$$

where M is the molecular weight. Thus, an unstable, or explosive material having perfect balance to yield carbon dioxide and water has a zero OB value – one lacking sufficient oxygen has a negative OB value, and one containing excess oxygen has a positive OB value.

In principle, therefore, the ideal OB for a substance suitable as an explosive would appear to be zero. Most explosives actually have a negative OB, but Lothrop and Handrick did find that the power of explosives increases as the OB increases and approaches a value of zero. Values of the oxygen balance for some materials of recognized instability are nitrobenzene (−163), dinitro-toluene (−114) and glycerol trinitrate (+3.5).

Chemical incompatibility with other materials The incompatibility of chemicals brought together can pose a significant reactive hazard. Examples include acids combined with bases, pyrophoric materials plus air, and water-sensitive chemicals plus water. It is worth noting that an 'incompatibility' is deemed to be more severe in potential consequence than the lack of 'compatibility' between substances.

Evaluating potential chemistry between components in a process can be a daunting task given that the number of combinations for a moderate number of species can quickly grow into the thousands. Such an evaluation can require considerable resources for reviewing available information or testing, but tools have been made available to assist in this endeavour. A publication from the US CoastGuard (*) and one from the US Environmental Protection Agency (EPA 1980) indicate the presence of potential incompatibilities based on the types of chemical functional groups in the compounds. The US National Oceanic and Atmospheric Administration (NOAA) has posted on its website a program called the Chemical Reactivity Worksheet, which incorporates the EPA methodology and some additional incompatibility guidelines to facilitate chemical incompatibility assessment.

When exploring possible chemical interactions between materials, it is also worthwhile to consider compounds arising from inadvertent forward flow or backflow from other parts of a process or other units, additives, catalysts, utility stream components, contaminants, materials of construction, cleaning agents and species common in the environment (e.g. air, water, pollutants).

---

* U.S. Coast Guard Academy, 'The Evaluation of the Test Procedure for Hazardous Binary Combinations of Materials in Marine Transportation', US Department of Commerce, National Technical Information Service, Aug. 1974, AD-A007 915, Report No. CG-D-85-75.

Related previous incidents Knowledge and analysis of previous incidents is extremely valuable to help identify reactivity hazards including those caused by incompatibilities of a process with materials that the process could easily contact, as in the following cases:

Concepts Science and Nissin Chemical: The 1999 Concept Sciences incident with five fatalities in Allentown, Pennsylvania and the 2000 Nissin Chemical incident with four fatalities in Japan involving explosive decomposition of hydroxylamine. In these incidents, the incompatibility of hydroxylamine/water solutions and iron and oxides of iron is a suspected factor.

Napp Technology: The 1994 Napp Technology incident with five fatalities in Lodi, New Jersey in which an uncontrolled reaction resulted from the incompatibility of water with the process mixture that included the spontaneously combustible sodium hydrosulfite.

Bhopal: The 1984 Union Carbide incident in Bhopal, India in which the incompatibility of methyl isocyanate with water led to the release of toxic cyanide gas and thousands of fatalities.

Screening and detailed computational methods using classical and QM models and correlations

Reactive Hazards Index An attempt has been made by Stull (1970) to find some theoretical basis for reactivity. With unstable materials, there is relatively little difference between the heat of decomposition ΔH_d and the heat of combustion ΔH_0 under stoichiometric conditions, or between the adiabatic decomposition and combustion temperatures. Thus, Stull gives an empirical correlation between the difference between these two heats, $\Delta H_0 - \Delta H_d$, or between the temperatures and the NFPA Chemical Reactivity Rating.

In a refinement of this work, Stull (1973) has introduced kinetic as well as equilibrium considerations and has derived an empirical Reaction Hazard Index (RHI):

$$RHI = \frac{10T_d}{T_d + 30E_a} \qquad [33.2.2]$$

where E_a is the activation energy (kcal/mol), and T_d is the adiabatic decomposition temperature (K). The RHI correlates broadly with the Chemical Reactivity Index.

Determination of energy hazard potentials There are a number of thermodynamic schemes and corresponding computer programs, which have been developed to calculate the equilibrium products and heats of combustion and/or decomposition reactions. These include those of Cruise (1964), of the National Aeronautics and Space Administration (NASA) (Gordon and McBride, 1971, 1976) and of the American Society for Testing of Materials (ASTM) (E.J. Davis and Ake, 1973; Treweek, Claydon and Seaton, 1973). These programs can then be used to determine the energy hazard potential of materials.

The ASTM program, named CHETAH, calculates four quantities, which may be taken as criteria of energy hazard potential (Treweek, Claydon and Seaton, 1973):

(1) heat of decomposition ΔH_d;
(2) heat of combustion, ΔH_0 − heat of decomposition, ΔH_d;
(3) oxygen balance;
(4) *y* criterion.

The *y* criterion is given by:

$$y = \frac{10(\Delta H_d)^2 MW}{N} \qquad [33.2.3]$$

MW = molecular weight
N = number of atoms in the molecule

The energy hazard potentials are related to criteria (1)–(4) as shown in Table 33.8 (see Figure 33.4). These criteria correlate reasonably well with data on shock sensitivity. An account of the updating of the CHETAH program has been given by Frurip, Freedman and Hertel, (1989). CHETAH is now available as an interactive PC program. It includes an interpreter subroutine that uses pattern

	OB < −160	−160 < OB < −80	
4	$y < 30$	$30 < y < 110$	$y > 110$

recognition techniques to combine the four hazard criteria into an overall hazard rating and a data bank.

Molecular group contribution methods The principle of a molecular group contribution method is that molecular properties are the result of added contributions of individual atoms. Benson (1976) demonstrated that a wide variety of thermodynamic properties of a molecule could be estimated from the sum of contributions of the bonds in the molecule with corrections for the influences of side chains.

The CHETAH program (version 7.2) by ASTM (1998) applies a molecular group contribution method for thermodynamic property estimations. A wide range of gaseous thermodynamic properties can thereby be computed, such as heat capacity, C_p, entropy, S, enthalpy of formation, ΔH_f, Gibbs free energy of formation, ΔG_f, enthalpy of reaction, ΔH_r, entropy of reaction, ΔS_r and Gibbs free energy of reaction, ΔG_r. Molecular group contribution methods are limited, however, to available thermodynamic data for molecular groups (Irikura and Frurip, 1996).

Quantum chemistry methods Quantum chemistry methods are based on molecular quantum theory in which the motion and distribution of electrons are represented by electron probability distributions called molecular orbitals (Bruneton *et al.*, 1997). Using these methods, the structure, energy and properties of a molecule or an assembly of molecules can be calculated to varying degrees of accuracy depending on the molecules and the methods employed. Numerical techniques and software programs have been developed to perform the quantum chemistry calculations.

The fundamental quantum chemistry (or *ab initio*) methods are coupled with statistical mechanics to estimate system thermodynamic properties of large numbers of molecules or atoms. These properties include the enthalpy and entropy of formation of the reactants and products, enthalpy and entropy of the reaction, Gibbs free energy of the ideal gas reaction and Gibbs free energy of mixing of the reaction. There exists no single quantum method that yields satisfactory results for all chemical systems, and the usefulness of the various methods depends on the system size and type, the property that is calculated and calculation costs. Therefore, the *ab initio* methods require more experience, compared to group contribution or other classical methods, for selection of appropriate models and assessment of the results.

With the quantum methods a molecular electronic orbital, ϕ_i, is generally represented as a linear combination of a finite number of basis functions, $\chi\sigma$, which are similar to hydrogen atom wavefunctions, with each function multiplied by a weight factor, $c_{i\sigma}$.

$$\phi_i = \sum_{\sigma} c_{i\sigma}\chi_{\sigma}$$

Each orbital will accommodate up to two electrons with opposite spins. Basis function sets used with each level of theory can be minimal with one basis function per orbital of an atom within the molecule or improved in accuracy by the inclusion of multiple functions of the appropriate type per orbital. The total wavefunction of all orbitals for a molecule is represented by a linear combination of Slater determinants (SD) constructed from the molecular orbital functions. The Hartree–Fock model uses the simplest total wave function with a single SD, which approximates the average static interactions among the electrons. Inclusion of instantaneous electron–electron interactions, or electron correlation, requires two or more SDs with models of increasing complexity, computational expense and accuracy. With a given model, accuracy can be enhanced with the use of increasingly large sets of selected basis functions.

Among the most useful quantum methods for engineering calculations are Density Functional Theory (DFT), which is a cost-effective approach that explicitly includes electron correlation for a wide range of molecule sizes, such as B3LYP, the Moller–Plesset perturbative methods at various orders, such as the second order MP2 or third order MP3, highly accurate (energy errors to $\sim$ 1 kcal/mole) composite methods that include electron correlation such as the Gaussian-n (G1, G2, G3) methods and the complete basis set (CBS) series, and the inexpensive, but generally much less accurate, semi-empirical methods, such as AM1 and PM3 (Young, 2001; Morokuma, 2002). Quantum calculations using these various methods are performed on commercial software, such as the Gaussian 98 and Gaussian 03 (Frisch *et al.* 1998) software modules available for supercomputers, servers and personal computers.

For some thermochemical properties, such as heats of formation calculations using with isodesmic reactions, in which the numbers and configurations of electrons are balanced as well as possible on both sides of the reaction, some or much of the electron correlation error cancels. This is not the case for chemical activation energies on which the reaction rates depend exponentially, so even small errors in calculated activation energies will often yield unacceptably large errors, especially for the lower level models, in the calculated reaction rate constants. However, higher level quantum models, such as CCSD(T), coupled cluster with single and double excitation and perturbative triple excitation, with a large set of basis functions can yield energies, such as heats of reactions, that rival or even exceed experimental accuracy (Truhlar, 2001). A discussion of computational accuracy and cost for many approaches and models is provided by Cramer (2002, p. 220).

Once the thermodynamic properties are predicted or estimated for each reactant, intermediate and product in the suggested reaction pathways, enthalpy and Gibbs free energy calculations are performed to identify plausible stoichiometries to follow initial pathway scenarios. Plausible stoichiometries are reactions that are thermodynamically feasible, for which the corresponding Gibbs free energy change, $\Delta G_r < 0$.

The Gibbs free energy of reaction at constant temperature is:

$$\Delta G_r = \Delta H_r - T\Delta S_r$$

The enthalpy of reaction is:

$$\Delta H_r = \Delta H_r^{\text{idg}} - \sum_{i}^{N} v_i\, \Delta H_{\text{vap},i} + \Delta H_r^{\text{mix}} + \Delta H_r^{\text{press}}$$

where,

ΔH_r^{idg}: enthalpy of reaction calculated in the ideal gas phase;

$\Delta H_{\text{vap},i}$: enthalpy of vaporization or sublimation for N condensed species;

ΔH_r^{mix}: mixing and solvent enthalpic effects.

$\Delta H_r^{\text{press}}$: pressure enthalpic effects;

The entropy of reaction is:

$$\Delta S_{\mathrm{r}} = \Delta S_{\mathrm{r}}^{\mathrm{idg}} - \sum_{i}^{N} \nu_i \frac{\Delta H_{\mathrm{vap},i}}{T} + \Delta S_{\mathrm{r}}^{\mathrm{mix}} + \Delta S_{\mathrm{r}}^{\mathrm{press}}$$

where,

$\Delta S_{\mathrm{r}}^{\mathrm{idg}}$: entropy of reaction calculated in the ideal gas phase;
ΔS_{r}: mixing and solvent entropic effects;
$\Delta S_{\mathrm{r}}^{\mathrm{press}}$: pressure entropic effects.

Therefore, the Gibbs free energy change on reaction can be defined by the following equation:

$$\Delta G_{\mathrm{r}} = \Delta G_{\mathrm{r}}^{\mathrm{idg}} + \Delta G_{\mathrm{r}}^{\mathrm{mix}} + \Delta G_{\mathrm{r}}^{\mathrm{press}}$$

Assumptions are often used to simplify these relationships. The pressure effects on the enthalpy and entropy of reaction are usually insignificant compared to the other contributions and can then be neglected. The solvent and mixture interaction enthalpy and entropy contributions are usually small when compared to the enthalpy and entropy of the reaction. It is generally only when the solvent has particularly strong affinities with the solutes, such as polar interactions or formation of hydrogen bonds, that these terms are significant (Bruneton *et al.*, 1998).

Screening for significant reactions to assess potential hazards, thermodynamically non-feasible ($\Delta G_{\mathrm{r}} > 0$) and reaction pathways with low ΔH_{r} or $\Delta H_{\mathrm{r}} > 0$ and low ΔP are generally excluded and the remaining ones are considered for further evaluations.

High exothermic ΔH_{r} is considered an indication of a potential hazard, but such an indication is not sufficient to assess the potential of a reactivity hazard. A more thorough evaluation should be based also on ΔP and on the kinetics of the reaction pathways (i.e. the reaction rates). For confirmation and to provide more information about the system, the activation energies and rate constants are measured experimentally and also computed using quantum models within the context of transition state theory.

Transition state theory methods Chemical reaction rates calculated from classical molecular dynamics are often unsatisfactory, but exact quantum calculations are practical only for systems with a small number of accessible quantum states. Transition State Theory (TST), however, in which a transition state, which is formed from the energetically activated reactants and intermediate along the reaction coordinate between reactants and products, is based not on the details of molecular motions and collisions but on their statistical properties using the principles of statistical mechanics. A bimolecular reaction with reactants A and B, transition state $[AB]^{\dagger}$ in equilibrium with the reactants, and products C can be stated

$$A + B \leftrightarrow [AB]^{\dagger} \rightarrow C$$

At present, this theory combines classical and quantum principles employing simplifying assumptions including a thermal, quasi-equilibrium of the transition state with the reactants (Garrett and Truhlar, 1984). Another assumption of the original approach by Eyring (1935) and Evans and Polanyi (1935) is that motion of the reacting species along the reaction coordinate can be separated from other dynamics and treated as a classical translation.

Even though TST is not a complete quantum model, quantum effects are approximated by the use of quantum partition functions for vibrational motions and a quantum tunneling and reflection correction or transmission coefficient, κ, for motion along the reaction coordinate (Cramer, 2002, p. 486). For a bimolecular reaction in the gas phase with species A and B, the TST absolute rate constant is

$$\begin{aligned} k^{\mathrm{TST}} &= \kappa(T)\frac{k_B T}{h}\frac{Q^{\dagger}}{Q_A Q_B}\mathrm{e}^{-E_0/k_B T} k^{\mathrm{TST}} \\ &= \kappa(T)\frac{k_B T}{h}K_c^{\dagger} \end{aligned}$$

where κ is the transmission coefficient, k_B is the Boltzmann constant, h is the Planck constant, T is the absolute temperature, E_0 is the energy of lowest level (zero point energy) of the transition state relative to the energy of the lowest level of the reactants, Q_A, Q_B are the equilibrium partition functions per unit volume for the reactants A and B, $Q^{\dagger}$ is the transition state partition function minus the partition function for motion along the reaction coordinate, and $K_c^{\dagger}$ is the equilibrium constant for the reactants and transition state species in molar concentration units.

Q_A, Q_B are calculated from statistical mechanics using spectroscopic data to obtain moments of inertia, vibrational frequencies and electronic states. $Q^{\dagger}$ is calculated using quantum mechanics or semi-empirical models, to obtain moments of inertia and vibrational frequencies for the calculated transition state geometry. For the bimolecular reaction, the reaction rate is

$$k^{\mathrm{TST}}[A][B]$$

with A and B in molar concentration units.

For a macroscopic system with the number of particles the order of Avogadro's number, the distribution of molecular energies at a particular temperature are assumed to consistent with the Boltzmann distribution in which all molecular states at the same energy are equally probable. The canonical TST rate constant *k(T)* is a Boltzmann average over a microcanonical TST rate constant *k(E)* at a given energy, (Garrett and Truhlar, 1979).

$$K(T) = \int_0^{\infty} k(E)P(E)\,\mathrm{d}E$$

where *P(E)* is the Boltzmann distribution of energies. This approach is employed in the highly successful Rice-Ramsperger-Kassel-Marcus (RRKM) theory to represent the behaviour of unimolecular reactions (Forst, 1973).

Because the TST equation is based on the highest potential energy along the reaction coordinate and not the free energy of the transition state structure, it does not account for some trajectories that recross the transition state and reduce the actual rate constant. Variational Transition State Theory (VTST) corrects this deficiency by adjusting the transition state along the reaction coordinate, s, to maximize the transition state free energy, minimize the recrossings and, therefore, minimize the TST rate constant (Truhlar and Garrett, 1980; Hase, 1983; Allison and Truhlar, 1989)

$$k^{\mathrm{VTST}}(T,s) = \min_{s} \kappa(T)\frac{k_B T}{h}\frac{Q^{\dagger}(T,s)}{Q_A Q_B}\mathrm{e}^{-E_0(s)/k_B T}$$

The statistical approach and approximations make possible practical computations, and TST and VTST have proved to be highly successful in representing with sufficient accuracy a wide range of chemical behaviour. As a result, this theory has become more commonly used for engineering reaction rate predictions.

Representing the TST expression in thermodynamic terms and using the equilibrium assumption of reactants with the transition state, $\Delta G^{o\dagger} = -RT \ln K_c^{\dagger}$, and the TST rate constant can be expressed equivalently as

$$k^{\mathrm{TST}} = \kappa \frac{k_B T}{h} \mathrm{e}^{-\Delta G^{o\dagger}/RT}$$

where $\Delta G^{o\dagger}$ is the standard free energy of activation, and the superscript o refers to the standard states of the transition state and reactants. Expressing $\Delta G^{o\dagger}$ in terms of standard enthalpy and entropy changes, $\Delta G^{o\dagger} = \Delta H^{o\dagger} - T\Delta S^{o\dagger}$, the TST rate constant becomes

$$k^{\mathrm{TST}} = \kappa \frac{k_B T}{h} \mathrm{e}^{\Delta S^{o\dagger}/R} \mathrm{e}^{-\Delta H^{o\dagger}/RT}$$

which can be related to the traditional Arrhenius rate constant, k^A.

$$k^A = A\mathrm{e}^{-E_a/RT}$$

where E_a, the experimental activation energy (or Arrhenius activation energy) is the average difference between the average energy of the reacting molecules and the average energy of all the reactant molecules (Fowler and Guggenheim, 1939).

For a process at constant pressure, the standard enthalpy and thermodynamic energy are related by $\Delta H^{o\dagger} = \Delta E^{o\dagger} - PM\Delta V^{o\dagger}$, where $\Delta V^{o\dagger}$ is the standard volume of activation. For a unimolecular reaction $\Delta V^{o\dagger}$ is zero and for reactions in solution, $\Delta V^{o\dagger}$ is close to zero, so, $E_{\mathrm{a}} = \Delta H^{o\dagger} + RT$, and the TST rate constant is

$$k^{\mathrm{TST}} = \kappa \frac{k_B T}{h} \mathrm{e}^{(1+\Delta S^{o\dagger}/R)}\ \mathrm{e}^{-E_a/RT}$$

Therefore, the Arrhenius pre-exponential factor can be expressed as

$$A = \kappa \frac{k_B T}{h} \mathrm{e}^{(1+\Delta S^{o\dagger}/R)}$$

For gas phase reactions other than unimolecular and assuming the ideal gas model, $P\Delta V^{o\dagger} = \Delta n^{\dagger} RT$, the Arrhenius activation energy is, $E_a = \Delta H^{o\dagger} + (1 - \Delta n^{\dagger})RT$ and the Arrhenius pre-exponential factor is

$$A = \kappa \exp\left(1 - \Delta n^{\dagger}\right) \frac{k_B T}{h} \mathrm{e}^{(1+\Delta S^{O\dagger}/R)}$$

Such expressions are used to relate the molecular VTST or TST model to the macroscopic Arrhenius model to represent experimental data and the observed reaction rate in terms of molecular behaviour.

For reactions in liquid solution for which static interactions of the reacting species and the solvent are included, the relationship between the solution and gas phase VTST or TST rate constants is

$$k_{\mathrm{s}}^{\mathrm{VTST}} = k_{\mathrm{g}}^{\mathrm{VTST}} \mathrm{e}^{-\Delta G^{o\dagger}_{\mathrm{solv}}/RT}$$

where the free energy of solvation, $\Delta G^{o\dagger}_{\mathrm{solv}} = \Delta G^{o\dagger}_{\mathrm{s}} - \Delta G^{o\dagger}_{\mathrm{g}}$, is the difference between the free energies of activation in the solution and in the gas phase (Ladanyi and Hynes, 1986). Models for calculating $\Delta G^{o\dagger}_{\mathrm{solv}}$ include implicit models in which the solvent is treated as a continuous medium and explicit models in which the solvent molecules are treated individually. The explicit methods, which generally require extensive computation, employ classical molecular dynamics, Monte Carlo or quantum molecular dynamics and often treat a layer of solvent molecules surrounded by a solvent continuum (Cramer and Truhlar, 1999; Cramer, 2002, p. 403).

Important deviations from this model were shown by Kramers (1940) to be due to solvent dynamical effects that increase with velocity along the reaction coordinate. To account for these effects of medium to high solvent friction that increases with solvent density and viscosity, an additional factor to correct VTST or TST is included (Steinfeld *et al.*, 1999).

$$k_{\mathrm{s}}^{\mathrm{VTST}} = k_{\mathrm{s}}^{\mathrm{VTST}} \kappa^{\mathrm{KR}}$$

where $\kappa^{\mathrm{KR}}(\beta, \omega) \leq 1$ is the Kramers transmission coefficient, β is a friction constant and ω is a parameter. For cases of lower friction, $\kappa^{\mathrm{KR}} \approx 1$, but for high friction cases the reaction rate constant decreases with increasing friction of the species in the solvent.

As a result of employing quantum mechanical methods within the statistical TST and VTST, computed rate constants can be calculated cost effectively at increasing levels of accuracy (Maity *et al.*, 2000). For many systems, however, kinetic systems include a large number of elementary reactions and rate constants. A practical approach includes a sensitivity analysis to determine the most significant reactions for which the rates constants are then calculated from the structure, energy and vibrational frequency information of the reactants and transition states. To reduce computation costs, the activation energy can be estimated using models such as the Evan–Polanyi linear free-energy relationship between the activation energy and heat of reaction or bond dissociation energy (Evans and Polanyi, 1938).

$$E_o^i = E_o^0 + \gamma \Delta H_i^0$$

where E_o^0 is an intrinsic activation energy for a family of similar species, ΔH_i^0 is the heat of reaction for the ith reaction within the family of species and γ is a constant. But this empirical estimation of activation energies by itself can lead to large uncertainties in the predicted rate constants. A recent development to increase accuracy is a version of TST, reaction class TST or RC-TST, to estimate rate constants for species within a family or class where each member includes the same reactive moiety. This approach performs a full calculation of the smallest species in the class and takes advantage of relatively similar potential energy surfaces along the reaction coordinate so that rate constants of the other class members can be estimated from differences in activation energies and reaction energies.

Because a modest level of quantum calculations are involved for all but the smallest species in the class, rate constant calculations for the class members can be rapid and cost effective (Zhang and Truong, 2003).

Chemical reaction rate parameters also have been correlated with molecular properties of the reacting species using approaches such as QSPR (quantitative structure–property relationships) to relate the observed parameters to these molecular properties, called descriptors that are based on experimental measurement or computed from the molecular structure. Example descriptors are molecular weight, boiling point, highest occupied molecular orbital and dipole moment.

Overview of tests

In cases where sufficient or reliable reactivity information is not available from a desktop review or from calculations, the gap in information is usually filled through experimental results. Test methods have been developed for evaluating individual component stability as well as reactivity with other species. The test methods used for reactions among species are broadly similar to those used for single components, but there are some important differences. In particular, it is necessary for the design of the reactor system to have much more information. There are two main reasons for this. One is that the design involves selecting not only an operating temperature, but also a number of other parameters and features such as a feed addition rate and a pressure relief system. The other is that the design involves scale-up to full scale. While these factors can be important for individual component stability in a reactor system as well, they must be accommodated in the design for normal operation.

The information sought from tests includes data on the presence and quantitative features of exotherms, rate of heat evolution and rate of gas evolution. One group of tests uses a Carius tube or similar equipment. These include the closed tube test and the delayed onset detection test. Another group utilizes a Dewar flask. This includes tests involving: ramped and stepped heating of the reaction sample in a Dewar flask; ramped heating of the sample and a reference material in a Dewar flask (the simple exotherm test, or dynamic heating test); and the hot storage test using a Dewar flask, or heat accumulation test.

In many tests, the sample is held in an apparatus placed in an oven. Tests employ various temperature control modes. The temperature may be held constant, ramped or stepped. The sample may be held under adiabatic conditions by arranging for its temperature to be tracked by that of the oven. Alternatively, the sample conditions may be made isothermal by holding the temperature of the oven constant at a value slightly below that of the sample.

There are numerous accounts of particular tests and of their interpretation. Some of these are described below.

Experimental test methods and equipment for screening

Thermal Behaviour The information obtained in the various types of tests varies. Some tests merely indicate that an exotherm exists, whilst others permit quantitative evaluation of the exotherm parameters such as the heat evolved. This information gives a quantitative measure of the heat released.

Preliminary tests The starting point for preliminary tests is usually to test for the occurrence of an exothermic reaction when the substance is heated.

Melting point tube test A simple, if crude, test is the capillary melting point tube test in which the sample is heated up at a constant rate of about 10°C/min in a standard melting point apparatus. A result such as that shown in Figure 33.5(a), in which the sample temperature has exceeded that of the heating medium, indicates that there is an exotherm.

Dewar tests A number of tests involve the use of a Dewar flask. These are of three types: (1) ramped temperature tests, (2) differential temperature tests and (3) adiabatic tests.

In the first type, the sample is held in a tube in a heat transfer medium in a Dewar flask and the temperature of the medium is ramped at a constant rate; a typical rate of temperature increase is 2°C/min. If, at a given medium temperature, the sample temperature rises above that of the medium, as shown in Figure 33.5(a), an exotherm is present. A plot of this kind is given by N. Gibson (1984).

Alternatively, the same apparatus may be used, but the temperature of the heating medium may be increased in a series of steps, holding the temperature constant for a period at each step; a typical increment is 10°C. If at a given medium temperature the sample temperature rises, there is an exotherm. Figure 33.5(b) illustrates a result showing an exotherm occurs at 90°C.

These two variants of the first type of Dewar test do not appear to have a specific name, other than the rather ambiguous 'Dewar flask' test. They are referred to here as the 'ramped heating' and 'stepped heating' Dewar flask tests, respectively.

In the second type of Dewar flask test, the procedure is to put the sample and a reference material in two tubes in a Dewar flask filled with heat transfer medium, to heat the medium up at a constant rate and to measure the temperature difference between the sample and the reference material. A plot is made of the temperature difference, ΔT, between the sample and the reference material vs the temperature, T, of the heat transfer medium. A typical result for a material is illustrated in Figure 33.5(c). This test is referred to by the ABPI (1981), which gives details and plots, as the 'dynamic heating test', and by Coates and Riddell (1981a) as the 'simple exotherm test' and the 'dynamic heating test'.

The third type of Dewar flask test is the 'adiabatic test'. The sample is held in a pressure Dewar flask in an oven. The flask simulates the reactor and the process is carried out in the plant. The temperature of the oven is controlled to follow closely the sample temperature allowing measurement of any exotherm that occurs. The test is described by T.K. Wright and Rogers (1986).

Tube Test An alternative to the Dewar flask is an open or a closed tube test. A Carius tube is often used, but if gas evolution occurs, a closed tube is more suitable. It is desirable to establish the extent of any gas evolution in the initial screening. This may be done by a pressure–time test using a closed Carius tube.

Closed Tube Test A closed tube test may be used to detect the onset of an exotherm and gas evolution. A 10 g sample is held in a closed Carius tube in an oven and the temperature of the oven is ramped upwards at a typical rate of 2°C/min. The test is described by N. Gibson (1984) and N. Gibson, Rogers and Wright (1987) and is referred to

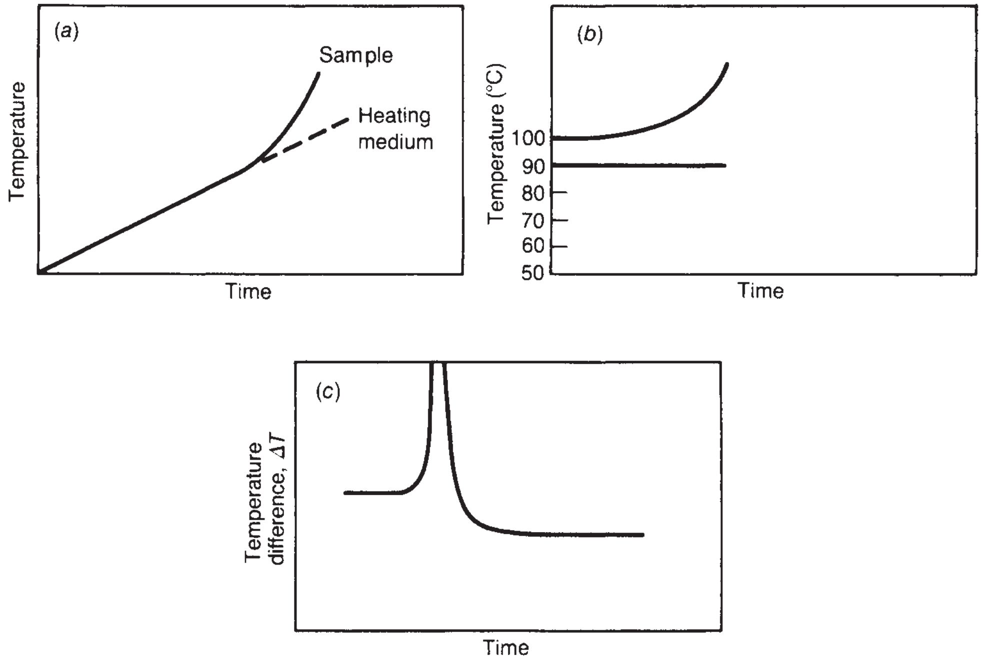

***Figure 33.5** Exotherm profiles in tests for thermal stability of individual substances: (a) sample and heating medium temperatures in melting point tube test or Dewar flask ramped temperature test; (b) sample temperature in Dewar flask stepped temperature test; (c) temperature difference between sample and reference material in Dewar flask dynamic heating test.*

as the Imperial Chemical Industries (ICI) programmed screening test or as the 'ICI 10 g sealed tube test'.

Delayed Onset Detection Test Another test is the delayed onset detection test. The sample, held in a lagged Carius tube placed in an isothermal oven, is maintained isothermally at about 10°C above the oven emperature using a small electric heater. An exotherm is detected by a fall in the electrical power requirement. The test is described by the ABPI (1981).

The tests just outlined can be performed using in-house apparatus and avoid the use of specialist instrumentation, which can be expensive.

Hot Storage Tests It may also be necessary to test the behaviour of the material when held at a high temperature for a long period under adiabatic conditions. In the hot storage test, the sample is held in a container in a Dewar flask under quasi-adiabatic conditions and any exotherm is recorded. The test period is usually at least 7 days. The test is also referred to as the 'heat accumulation test'. The hot storage test is carried out if the material is to be held at or subjected to a temperature relatively close to the exotherm onset temperature T_e, say at $T_e = 50°C$. This applies to in-plant processing, to storage and transporation. The results of this test can be related to the Self-Accelerating Decomposition Temperature (SADT) determined through a United Nations Orange Book test Recommendations on the Transport of Dangerous Goods: Model Regulations, 13th ed., United Nations, NY, 2004.

Insulated Exotherm Test The insulated exotherm test (IET) is a form of Differential Thermal Analysis (DTA), which is described in the next section.

Decomposition Pressure Test The decomposition pressure test (DPT) is carried out in a pressure vessel. The oven temperature is ramped and the sample temperature and vessel pressure are measured.

Explosive Behaviour

Impact Sensitivity If there is reason to suspect that the substance has the potential to explode, it may be subjected to tests for explosibility. These include an impact sensitivity test such as the drop weight test and a detonability test. Explosibility tests are described below.

A detailed account of initial screening tests, of the precautions to be taken and of the interpretation of the results is given by Snyder (1965).

Experimental test methods and equipment for detailed evaluation

Tests using special instruments and calorimeters There are a number of rather more elaborate techniques which may be employed to detect and quantify exotherms and for which special instrumentation has been developed. The principal techniques are DTA, differential scanning calorimetry (DSC) and accelerating rate calorimetry (ARC).

DTA In DTA, the sample is held in a tube in a vessel surrounded by a heat transfer medium and is heated at a constant rate. A typical heating rate is 2°C/min. A plot is made of the temperature difference, ΔT, between the

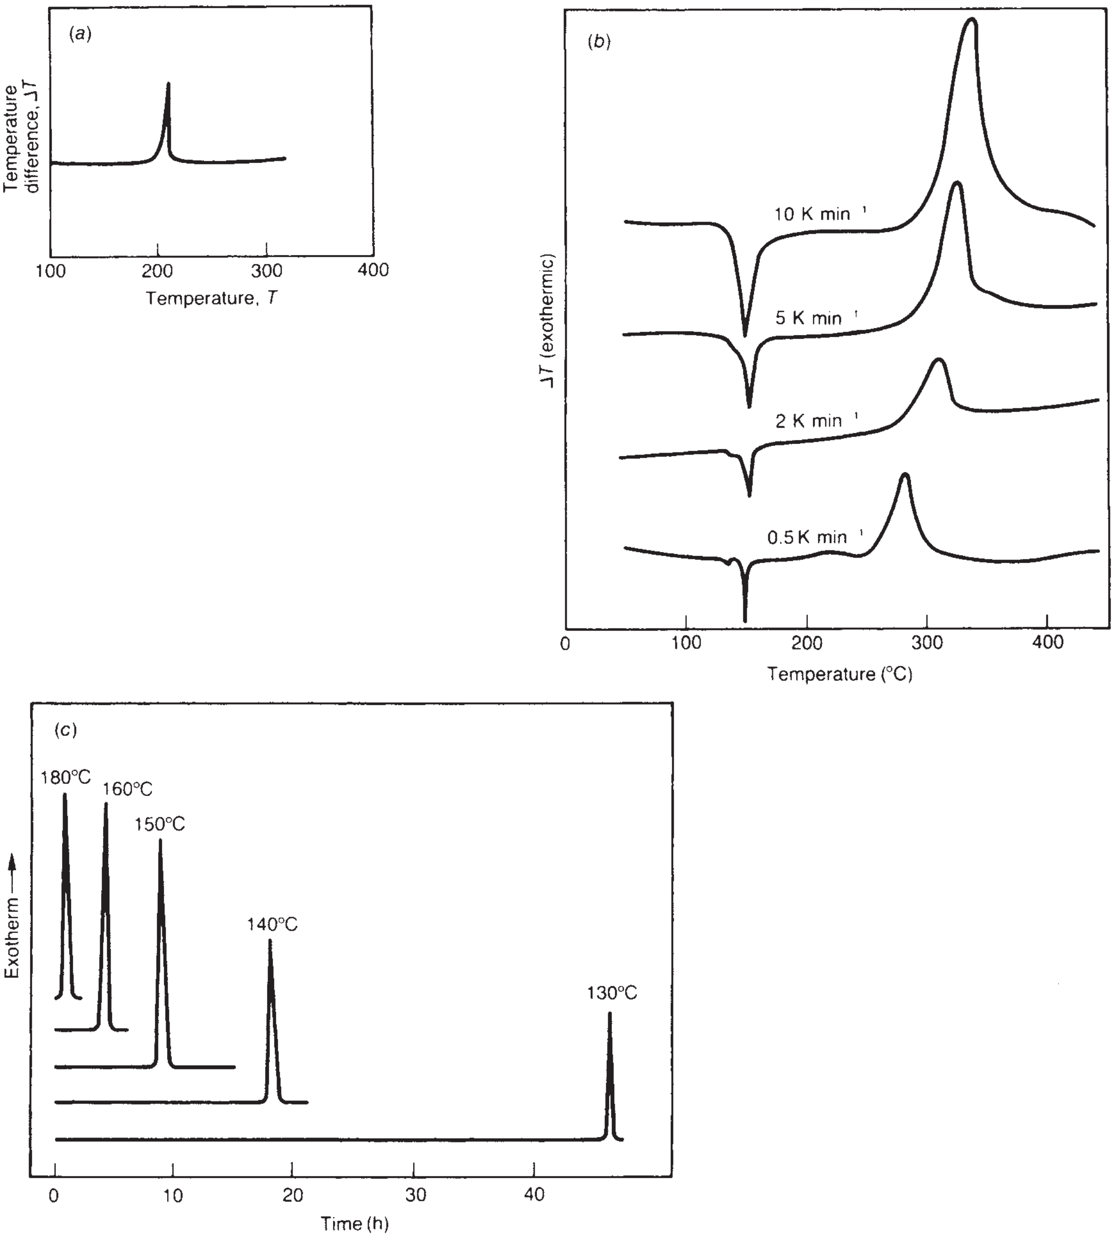

Figure 33.6 *Exotherm profiles in tests for thermal stability of individual substances using differential thermal analysis (DTA): (a) conventional ramped temperature test; (b) ramped temperature tests, showing effect of rate of temperature increase (Grewer et al., 1989); (c) isothermal tests, showing effect of time-dependent material stability (Duval, 1985) (Courtesy of the American Chemical Society)*

sample and the heat transfer medium vs the temperature, *T*, of the latter. A typical result for a material giving an exotherm at 200°C is illustrated in Figure 33.6(a). The use of DTA to detect thermal instability is described by Silver (1967) and Coffee (1969). DTA may be carried out with open or closed tubes, the latter being more appropriate where gas evolution occurs.

In conventional DTA, the temperature is programmed to rise at a constant rate. Figure 33.6(b) (Grewer *et al*, 1989) illustrates a set of traces obtained for different heating rates. Where the thermal stability of a substance may be a function of time, DTA may be performed isothermally. Figure 33.6(c) (Duval, 1985) shows a set of traces for DTA of a substance exhibiting time-dependent thermal instability.

The use of isothermal DTA is described by Schulz, Pilz and Schacke (1983) and by Duval (1985). DTA may also be performed using in-house apparatus. Cronin, Nolan and Barton (1987) have described an 'insulated exotherm test', which is based on DTA.

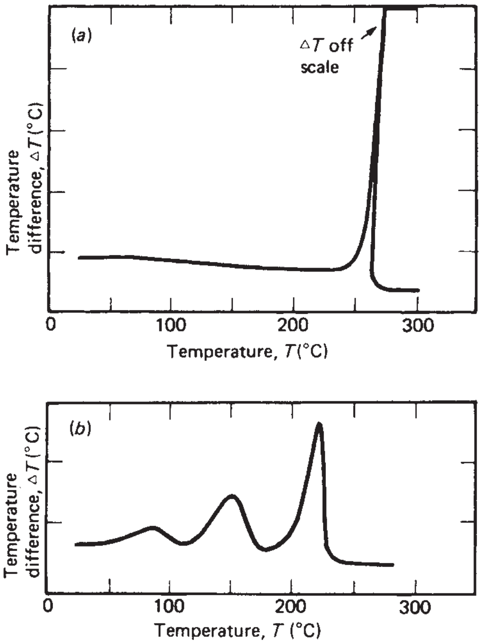

Figure 33.7 *Experimental determination of thermal stability of reaction mixtures – 1 (Grewer, 1974): (a) differential thermal analysis of sulfonation of nitrobenzene; (b) differential thermal analysis of diazotization of 2-cyano-4-nitroaniline in H_2SO_4 (Courtesy of Elsevier Publishing Company)*

Figure 33.7(a) from Grewer (1974) shows a DTA plot for the sulfonation of nitrobenzene in sulfuric acid in which the product has decomposed and Figure 33.7(b) one for the diazotization of 2-cyano-4-nitroaniline in sulfuric acid in which the three peaks correspond to the reactions associated with the CN, N_2 and NU2 groups.

DSC In DSC, the sample and a reference material are held in pans in a vessel and are heated at a constant rate of typically 5–10°C/min. The heating is carried out by a control system that maintains the sample and the reference material at the same temperature. The variation in the heat that must be supplied to the sample to keep it at the same temperature as the reference material gives a quantitative measure of any exotherm in the sample. A plot is made of the rate of change of heat input to the sample with time, dQ/dt, vs the temperature, T, of the reference sample. Again, open or closed pan methods may be used. An account of DSC is given by Wendlandt (1986). Figure 33.8 (Duval, 1985) shows a typical DSC plot.

Some substances must be tested under pressure. One reason for this is that a volatile substance can reach higher temperatures if held under pressure and thus the temperature range over which an exotherm may occur is extended. Another reason is that pressure may enhance an exotherm, especially in air. The conduct of DTA and DSC with the sample under pressure in a pressure cell and the use of a test scheme based on atmospheric DTA(DSC), pressure DTA(DSC) and a confinement test have been described by Seyler (1980). The confinement test is designed to measure the temperature at which a material under confinement will generate heat and pressure while subjected to a constant temperature increase of 1–2°C/min. In the scheme described by Seyler (illustrated in Figure 33.9), if atmospheric DTA(DSC) shows a moderate to severe exotherm, a thermal hazard is established; pressure DTA(DSC) may be bypassed, but a confinement test is required. If atmospheric DTA(DSC) shows a weak exotherm or none,

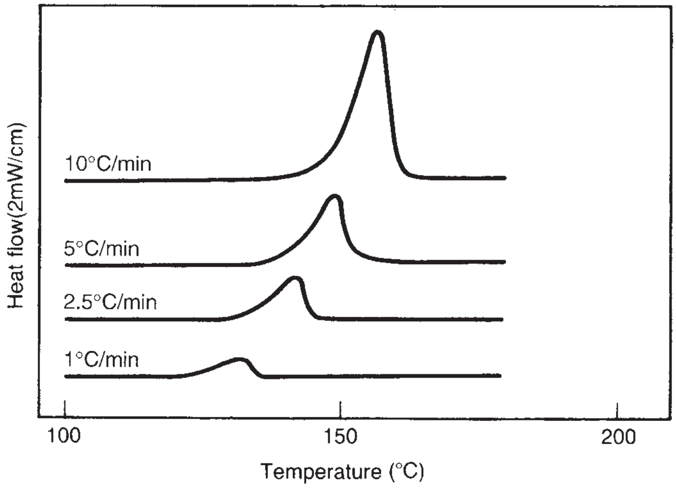

Figure 33.8 *Exotherm profile in test for thermal stability of individual substances using differential scanning calorimetry (DSC) (Duval, 1985) (Courtesy of the American Chemical Society)*

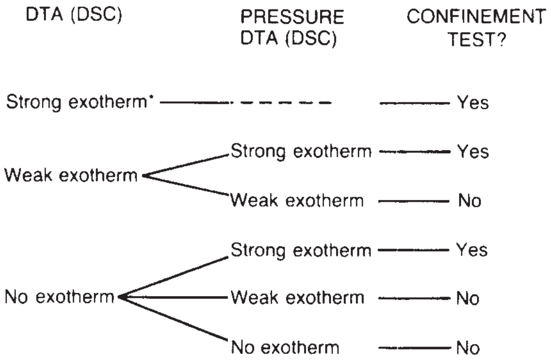

Figure 33.9 *Test scheme using pressure DTA/DSC to identify need for confinement test (Seyler, 1980) (Courtesy of Elsevier Science Publishers)*

pressure DTA(DSC) is carried out and if a strong exotherm is detected, a confinement test is performed.

DTG or TGA Another instrumental technique is differential thermo-gravimetry (DTG), but this is less widely used. It can also be referred to as thermogravimetric analysis (TGA). In combination with compositional analysis tools, such as flame ionization, infrared and mass spectroscopy detectors, it becomes a powerful technique for identifying decomposition products. It can also be combined with DSC to provide an indication of the energetics associated with volatile species generation.

Tests characterizing the normal reaction

Dynamic heating test The dynamic heating test has open and closed tube versions. The oven temperature is ramped and the temperature difference between the sample and a reference material is measured to detect any exotherm. The test is also known as the 'simple exotherm test'.

Adiabatic heating test The adiabatic heating test uses a Dewar flask. The oven temperature is held constant and any exotherm is measured. The test period is at least 8 and preferably 24 h. This test is also known as the 'heat accumulation test'.

Figure 33.10(a) from Grewer (1974) gives a plot for an adiabatic storage test of diazotization solution of 2-cyano-4-nitroaniline in which again there are three steps in the curve corresponding to the exotherm peaks in the DTA test. Figure 33.10(b) shows a plot for an adiabatic reaction test, similar to the adiabatic storage test but conducted at the operating temperature, for the reaction of *p*-nitro-*N*-methylaniline with carbyl sulfate in nitrobenzene under pressure.

AZT24: Further methods of characterizing the reaction and the reactor have been described by Grewer *et al.* (1989). It is common for a product to be brought to an elevated temperature for some 24 h. The adiabatic storage test may be used to determine a suitable temperature limit. The most useful information yielded by the adiabatic storage test is the adiabatic induction time T_ad. Usually this correlates with temperature according to the relation log T_ab vs $1/T$. This correlation can be used to determine the temperature at which the adiabatic induction time is 24 h. This temperature is known as AZT24.

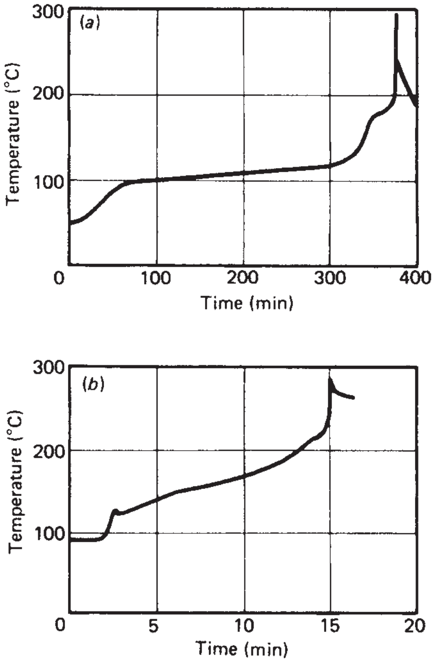

Figure 33.10 *Experimental determination or thermal stability of reaction mixtures – 2 (Grewer, 1974): (a) adiabatic storage test of diazotization solution of 2-cyano-4-nitroaniline in H_2SO_4; (b) adiabatic reaction test of solution of p-nitro-N-methylaniline and carbyl sulfate in nitrobenzene (Courtesy of Elsevier Publishing Company)*

In addition to this storage version of the test, there is a reactor version in which the flask simulates the reactor and the process is carried out as on the plant.

Heat flow calorimetry In heat flow calorimetry, the sample is held in the calorimeter (a jacketed mini-reactor) and a heat transfer medium is circulated so that it removes heat at the same rate as it is generated, maintaining isothermal conditions. A test of this type is described by Coates and Riddell (1981a). The RC-1 of Mettler is an example of a heat flow calorimeter.

One important test carried out using a reaction calorimeter is the determination of the adiabatic temperature rise. This single test provides a large amount of information on the thermodynamic and kinetic and characteristics of the reaction such as the heat capacity of the reaction mass, heat of reaction and the rate of heat production.

Isoperibolic calorimetry Isoperibolic calorimetry is carried out in a simple form of a heat flow calorimeter. The heat transfer medium is held at constant temperature, the temperature difference between this medium and the sample is measured and the heat flow is thus obtained.

Power compensation calorimetry This method utilizes another form of heat flow calorimeter in which a heater in the sample maintains it at the desired reaction temperature, even though it loses heat to a heat transfer medium held at a lower temperature.

Numerous other specialized instruments for the investigation of reactions have been described such as the TZP described by Kunzi (1980). This instrument allows a component or reaction mixture to be investigated in the same oven under isobaric and isochoric conditions and under identical thermal conditions. The author mentions particularly the investigation of decomposition reactions.

There are also available several special calorimeters developed for the study of thermal stability and reaction exotherms.

SIKAREX: One special calorimeter is the SIKAREX described by Hub (1976, 1977a,b). The calorimeter consists of a tube held in a temperature-controlled environment and with a heating element on the tube itself. It can be operated in quasi-isothermal, adiabatic and isothermal modes. In the quasi-isothermal mode, the sample is brought to temperature equilibrium with the environment, the environment temperature is increased and, if an exotherm occurs, the temperature difference between the sample and the environment is measured. In the adiabatic mode, the environment is maintained at the same temperature as the sample. In the isothermal mode, the environment is held at a temperature below that of the sample, the tube heater is used to maintain the temperature of the sample and the heat required to do this is measured.

Another special calorimeter is the SEDEX (SEnsitivity Detector of EXothermic processes) described by Hakl (1981). This instrument is an oven equipped with temperature control and adapted to take various types of sample containers with inlet and outlet tubes, stirrers and so on. The system may be used in various modes.

ARSST: The Advanced Reactive System Screening Tool (ARSST) is an instrument intended to provide rapid screening of chemical reactivity as well as provide some detailed kinetic parameters for reaction characterization. The sample is placed in an open 100 ml round-bottom flask and its temperature ramped by external heaters. An exotherm appears as a reduction in heat required during the ramp. The sample and flask are kept in a containment vessel pressurized to help retain sample liquid in a condensed state. The apparatus can also be equipped with a detector to indicate during venting whether gas/vapour only or gas/vapour plus liquid are leaving the flask.

Adiabatic calorimeters – Adiabatic temperature rise test One test that yields a large amount of information on the reaction parameters is an adiabatic test in which the reaction is taken to completion. Such a test gives a sigmoidal temperature profile, with the temperature initially rising rapidly and then levelling off as the reactants are consumed. A simple analysis of such a test is given by the 1981 ABPI *Guidelines*. The analysis yields the adiabatic temperature rise, the self-heat rate, the velocity constant and the activation energy.

Dewar calorimetry: Dewar calorimetry tests (described also in the previous section) operated in an adiabatic mode can be utilized to determine the adiabatic temperature rise, the heat of reaction and reaction kinetics.

ARC: In the Accelerating Rate Calorimeter (ARC), the sample is held in a bomb calorimeter under adiabatic conditions. Adiabaticity is achieved by heating the surroundings of the sample cell so that the temperature outside the cell matches the temperature in the cell. ARC testing may be done in different ways, but one of the most common is the 'heat, wait and search' method. The temperature is increased in steps, a typical increment being 10°C. The sample is then held for a period at that temperature. The rate of any temperature increase is observed to see if it exceeds a set value, typically about 0.02°C/min. If it does not, the temperature is raised by the incremental amount and the procedure is repeated. If the temperature rises at a high rate, there is an exotherm. Accounts of the ARC are given by Coates (1984a,b) and Ottaway (1986). A typical result, given by N. Gibson *et al.* (1987), for a material giving an exotherm at about 80°C is shown in Figure 33.11 The TIAX, LLC ARC instruments are widely used.

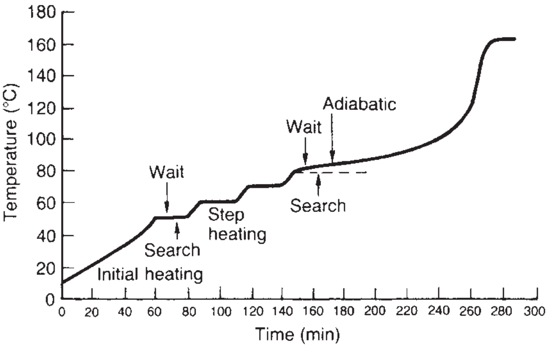

Figure 33.11 *Exotherm profile in test for thermal stability of individual substances using accelerating rate calorimetry (ARC) (N. Gibson, Rogers and Wright, 1987) (Courtesy of the Institution of Chemical Engineers)*

The ARC presents the advantage of studying compound reactivity in an adiabatic environment, more representative of plant and storage conditions than in isothermal or temperature-ramped instruments. The ARC is also equipped to accommodate and measure large increases in sample pressure, which requires a relatively thick-walled cell relative to the amount of sample contained. This leads into the concept of the thermal inertia factor, ϕ, reflecting the amount of heat absorbed by the sample container relative to that retained in the sample itself. The thermal inertia is defined as

$$\phi = 1 + \frac{m_c Cp_c}{m_s Cp_s}$$

where m denotes the mass, Cp the heat capacity, subscript c the cell + stir bar and s the sample. A high thermal inertia factor indicates that much of the evolved heat is utilized to raise the temperature of the sample container instead of the sample itself. In this circumstance, the extent of temperature rise from a reaction can be dampened and subsequent reactions missed. The ϕ factor of commercial equipment approaches a value of unity. A value of 1.5–5 is typical of ARC tests.

Stirring can be accomplished in the ARC through use of a specially designed thick-wall sample cell equipped with an internally mounted magnetic stir bar. An external rotating drive magnet causes the internal stir bar to spin.

The ARC can be viewed as a forerunner of a family of instruments developed to reduce the thermal inertia factor closer to unity. These instruments include the VSP, Phi-Tec and the APTAC. Information obtained from the ARC, VSP, PHI-TEC and APTAC can be employed to characterize runaway reaction kinetics as well as help size appropriate relief vents.

VSP: The Vent Sizing Package or VSP (originally the DIERS Bench-Scale Apparatus) was the first of the adiabatic calorimeters to incorporate pressure-balancing in its design. This feature allows use of a thin-walled sample can while still enabling the sample to reach elevated pressures during a test. The VSP also operates with a 120 cc sample cell. The use of a larger sample with a thin-wall can yields thermal inertia factors typically 1.05–1.20. The VSP has more recently been upgraded to include multi-zone heating elements, solid ceramic insulation and mechanically driven stirring (vs magnetically coupled stirring).

PHI-TEC: Another adiabatic calorimeter equipped with pressure balancing, and thus operating with thin-walled cans and larger sample sizes, is the PHI-TEC. It has many of the newer features described above for the VSP.

APTAC: The Automatic Pressure Tracking Adiabatic Calorimeter (APTAC) is also a VSP-like instrument, but more fully instrumented and automated. The sample resides in a spherical cell and exhibits greater sensitivity for exotherms (0.04°C/min) than the VSP. The instrument can also be purchased with various integrated sample injection and venting options. As the name implies, this calorimeter is designed to operate fully automatically once sample is loaded and the test initiated.

Tests to detect and characterize an exotherm may need to be supplemented by other tests. Mention has already been made of explosibility/detonability and of deflagration tests.

Gas evolution measurement Gas evolution is another important parameter. One measurement method utilizes a tube and another an autoclave. These tests are also described by Coates and Riddell (1981a).

Automated gas burette: Gas evolution measurement is carried out with a burette in which the gas evolved builds up and is then released in a cycle which is then repeated, with the total gas evolution determined from the number of releases made. The releases and the counting are automated.

Thermal mass flowmeter: Gas evolution measurement using a thermal mass flowmeter to measure the flow of gas evolved.

Blowdown tests J. Singh (1988a) describes the use of a reaction calorimeter to determine the maximum pressure resulting from runaway of the main process reaction and thus to assess the option of containment instead of venting.

In the blowdown test, the reaction mixture is brought to the reaction runaway temperature in a test cell, and when the vent pressure is reached, a vent valve is opened full. Venting down to atmospheric pressure occurs, typically over a period of some 6 s. The residual liquid in the cell is measured. If the cell remains over 60% full of liquid, the vent fluid is taken as all vapour. If the cell contains less than about 5% of liquid, the venting is taken as homogeneous, that is the vent fluid is representative of the vapour–liquid mixture in the vessel. For residual fills between these two limits, the venting is taken as two-phase but not homogeneous, that is vapour disengagement and preferential venting of vapour have occurred.

The vent sizing test involves bringing the reaction mixture to the reaction runaway temperature and opening the vent valve, but this time the vapour is vented at a slow, controlled rate. The temperature of the reaction mass levels off and the reaction is tempered, the vapour flow being such as to give thermal equilibrium. The vent valve is then closed momentarily, the temperature rises and the valve is opened again. The rate of temperature rise can then be used to size the vent. The author gives an example of the calculation of vent size.

Combustion tests A combustion test for preliminary screening is the train firing test, which indicates the ability of a flame to propagate through the material in powder form. A train of finely ground material is laid on a heat insulating surface in a line and ignited. In the version described by ABPI (1981), ignition is by heated wire; in that described by N. Gibson, Harper, and Rogers (1985), it is by a gas flame. The extent of fire spread is observed and categorized as shown in Table 33.9, the degree of hazard increasing with the rating number.

Deflagration tests Certain liquids such as peroxides and hydroperoxides are susceptible to violent decomposition, even in the absence of air. In contrast to process reactions in which the reaction rate depends on the temperature according to the Arrhenius equation, these decompositions show no simple temperature dependence, but occur at about 200°C and are characterized as deflagrations (subsonic propagating reactions). Whether a particular mixture will decompose in this way depends on the concentration, the temperature and the presence of an ignition source such as a hot spot, spark or flame. Liquid-phase deflagration tests are carried out in a small cylindrical vessel fitted with rupture discs in which the liquid sample is ignited by a heated wire. The maximum pressure resulting from a liquid decomposition would typically rule out simple containment as a design option.

Deflagration may also occur in the vapour phase. Vapour phase deflagration tests are carried out in a spherical vessel in which the vapour sample is ignited by a fused wire. In this case, containment may be an option, although venting is also widely used.

Table 33.9 *Interpretation of train firing test (after N. Gibson, Harper and Rogers 1986)*

Fire spread	*Result*	*Rating*
No	No ignition	1
No	Brief ignition, rapid extinction	2
No	Local combustion, at most smouldering, slight spread	3
Yes	Hot red glow or slow decomposition without flame	4
Yes	Burning like a firework or slow steady burning with flame	5
Yes	Very rapid combustion with flame or rapid decomposition without flame	6

Drying of powders Two main categories of tests are performed on powders: dust explosivity tests (described in Chapter 17 in conjunction with flammability issues) and drying tests. The ABPI (1981) describes two tests: (1) a 'through air' drying test in which air is passed through a bed, and (2) an 'over air' test in which air is passed over a layer.

Some factors that affect the behaviour of a powder in drying include

(1) chemical composition;
(2) impurities;
(3) effective thermal conductivity;
(4) effect of air;
(5) time-dependent effects.

A more-detailed account is given by N. Gibson, Harper and Rogers (1985, 1986).

The material to be dried may be chemically complex, perhaps incorporating agents to instill special properties, or it may contain impurities. Both of these factors may influence the reactivity of the material. If a reaction occurs, the rate of heat loss depends on the effective thermal conductivity of the material *in powder form*. If the reaction mechanism is predominantly oxidation, the availability of air is an important factor. The reaction may occur only after a certain time, or induction period.

N. Gibson, Harper and Rogers (1985, 1986) also describe the set of tests illustrated in Figure 33.12: a bulk powder test, an aerated powder test and a powder layer test. The configuration selected being that in which the powder is to be dried on the plant. In each test, the powder is subjected to a stream of warm air. The authors discuss the application of the results from these tests to particular drying processes. This aspect is considered further in Chapter 11.

Interpretation and comparison of experimental test methods

Reaction characterization The reaction system may be characterized in terms of the following fundamental quantities:

(1) physical and chemical properties of the components;
(2) reaction stoichiometry;
(3) heat of reaction;
(4) quantity of gas evolved;
(5) kinetics of reaction.

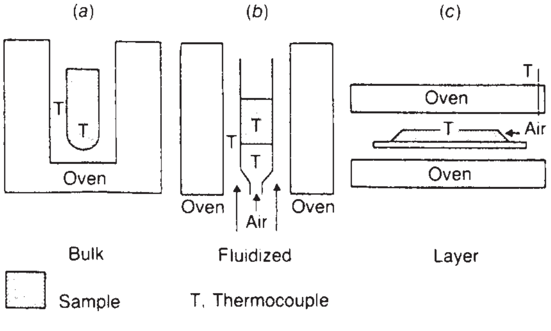

Figure 33.12 *Tests for thermal stability in driers: (a) bulk form; (b) fluidized form; and (c) layer form (after N. Gibson, 1984) (Courtesy of the Society of Chemical Industry)*

Exotherm characterization Some parameters characterizing an exotherm are:

(1) exotherm onset temperature;
(2) adiabatic temperature rise;
(3) heat of reaction;
(4) rate of temperature rise (also known as the self-heat rate);
(5) rate of heat generation;
(6) rate of pressure rise;
(7) velocity constant, activation energy and pre-exponential constant;
(8) adiabatic induction time.

Some of these parameters can be determined from DSC or DTA tests. Most of these parameters can be obtained from an adiabatic Dewar flask test or ARC test.

Interpretation of exotherm onset temperature test

Although the temperature for reaction onset (i.e. 'onset temperature') is a convenient concept, it needs to be borne in mind that even at lower temperatures there is still a non-zero reaction rate. It is important to note that the onset temperature is a measure linked to the detection limit of the instrument utilized. It is not a value unique to the reaction chemistry alone.

A quoted onset temperature is one measured by a particular test and is highly dependent on sample size, degree of adiabaticity, instrument sensitivity, time-temperature history and reaction kinetic features, notably activation energy.

A traditional approach to reactor safety has been to set the temperature of reactor operation at some fixed temperature interval below the exotherm onset temperature measured in the laboratory test. A widely quoted value of this safety margin is 100°C, the '100 degree rule'.

Various authors discuss this safety margin. Coates and Riddell (1981a) state that any material with an exotherm onset temperature within 100°C of the maximum operating temperature as determined by the simple exotherm test is considered a potential hazard. In such a case, the material is subjected to the adiabatic exotherm test. If the exotherm onset temperature in this test is 50°C or more above the operating temperature it is not considered a hazard. If it is within this 50°C safety margin, it is subjected to a long-term hot storage test at 20°C above the operating temperature.

The IChemE *Guide*, which rehearses the factors affecting a measured onset temperature, as just described, states that the 100° rule, or a similar one, should not be used as the basis of safety unless previous experience has shown the rule to be valid for the type of reaction in question.

Interpretation of initial screening tests

Initial screening tests can provide information on the occurrence of a thermal excursion, or exotherm, and on the following of its features: (1) onset temperature, (2) heat release and (3) rate of heat release. The data from screening tests must be interpreted with care. In particular, any onset temperature determined will be a function of the sample size and the heating mode. The IChemE *Guide* gives a method of correcting temperature for sample size.

Comparison of methods for an exotherm

Several authors have given comparisons of different methods of determining exotherm parameters. N. Gibson (1984) has given the following results for the exotherm onset temperature of 3,5-dinitro-*o*-toluamide:

ICI programmed screening test	115–120°C
DTA (fast scan)	274–284°C
ARC	120–125°C

He comments that the limitations of fast scan DTA and ARC are well known.

A comparison of exotherm onset temperatures for a large number of substances, as determined by ARC and by other methods, has been given by Fenlon (1984). Hakl (1981) has given a comparison of exotherm onset temperatures for five substances determined by DSC and by SEDEX. The values determined by the former are consistently higher, the difference ranging from 25°C (80°C against 55°C) for f-xylylchloride with 0.02% Fe and 85°C (380°C against 295°C) for 1-nitroathrachinone.

Interpretation of tests characterizing the normal reaction
The interpretation of the tests characterizing the normal reaction is discussed in the 1981 and 1989 ABPI *Guidelines* and the IChemE *Guide*. These give a number of illustrations of test results together with commentaries.

For equipment and safeguarding design, it is necessary to know

(1) heat transfer parameters;
(2) rate of heat evolution;
(3) rate of gas evolution;
(4) rate of heat removal.

The rate of heat evolution is a function of the the heat of reaction and reaction kinetics. The heat evolution rate also depends on the reaction conditions and circumstances, such as reaction mode, the reaction temperature, the reactant concentration and any thermal events that may occur. The reaction mode may be batch or semi-batch. The reactant concentration is determined by the reaction mode and the initial temperature. The reaction temperature is a design parameter, but an excursion may occur due to an exotherm. Thermal events are those such as mixing, adsorption, phase changes, gas evolution, decomposition and so on.

It is necessary to have full information on the gas evolution and decomposition characteristics. If the reaction is subject to gas evolution, data are needed on the rate of gas evolution, which is a function of the kinetics and the quantity of gas evolved (as reflected by the reaction stoichiometry). If the reaction is subject to decomposition, information is required on the temperature range in which it occurs and on any tendency for autocatalysis.

The rate of heat removal is a function of the reaction temperature attained and of the heat transfer characteristics. The latter, in turn, is governed by the cooling arrangements. For jacket cooling, it depends primarily on the reaction and coolant temperatures, the effective heat transfer area and the heat transfer coefficients.

Test schemes
Preliminary or initial screening tests In the ABPI 1981 scheme preliminary tests, the safety screen test is the melting point tube test and the combustibility test is the train firing test, as described in Chapter 8. The explosion and detonation potential tests are of the type described in that chapter. In the ABPI 1989 scheme, shown in Figure 33.13, the tests are not classified in terms as preliminary or screening tests, but the first six of the tests listed are grouped under the heading of tests for unexpected decomposition. The combustibility test is again the train firing test. The DSC and closed tube tests are ramped temperature tests for the detection of an exotherm. The delayed onset detection test is an essentially isothermal test for the detection of delayed onset of any exotherm. The adiabatic Dewar test, which simulates the reactor under adiabatic conditions, gives information on the rate of any exothermic reaction. The ARC test also provides this information. Details of the tests not already described are given below.

The IChemE *Guide* scheme involves DSC and the 10 g closed tube test along with the insulated exotherm and decomposition pressure, initial screening tests.

Test schemes for material instability Test schemes for thermal instability of materials have been described by a number of authors. Table 33.10 summarizes some of the principal schemes. A test scheme given by Kohlbrand (1985) is shown in Figure 33.14(a) and another given by Cronin, Nolan and Burton (1987) is shown in Figure 33.14(b). Test schemes for powders have been given by N. Gibson, Harper, and Rogers (1985, 1986), as shown in Figure 33.15. Test schemes for reactivity are given in the subsequent subsection.

ABPI Test Scheme The *Guidelines for Chemical Reaction Hazard Evaluation* (ABPI, 1989) address material stability as well as chemical reactivity. Included is a sub-scheme for the screening of the substances involved in the reaction: raw materials, intermediates and products. The overall scheme is illustrated in Figure 33.16. This scheme for individual substances covers (1) explosive properties, (2) unexpected decomposition and (3) maximum safe temperature for storage. For characterizing normal reactions, the dynamic heating and the adiabatic heating tests are employed. The scheme also utilizes the adiabatic Dewar test, ARC, the heat flow calorimeter test and the two gas evolution measurement tests to characterize the intended reaction.

For explosive decomposition, the scheme involves assessment of explosive properties from (1) chemical structure, (2) oxygen balance, (3) energy of decomposition and (4) preliminary small scale tests (e.g. DSC), and if necessary, larger-scale Koenen tube or Trauzl lead block tests.

For unexpected decomposition, five tests are given:

(A) small scale testing using ramped temperatures
    (1) DSC,
    (2) closed tube test;
(B) isothermal testing for delayed onset
    (3) delayed onset detection test,
    (4) ARC,
    (5) adiabatic Dewar test.

Each test is fully described in the *Guidelines,* which also give, in most cases, typical output traces. The purpose and nature of these tests may be summarized as follows: the DSC test determines the onset temperature of any exotherm. The test method referenced is that of Wendlandt (1986). The closed tube test detects the onset of an exotherm and of gas evolution to detect delayed onset and to estimate the heat evolution and gas evolution rates. The test method

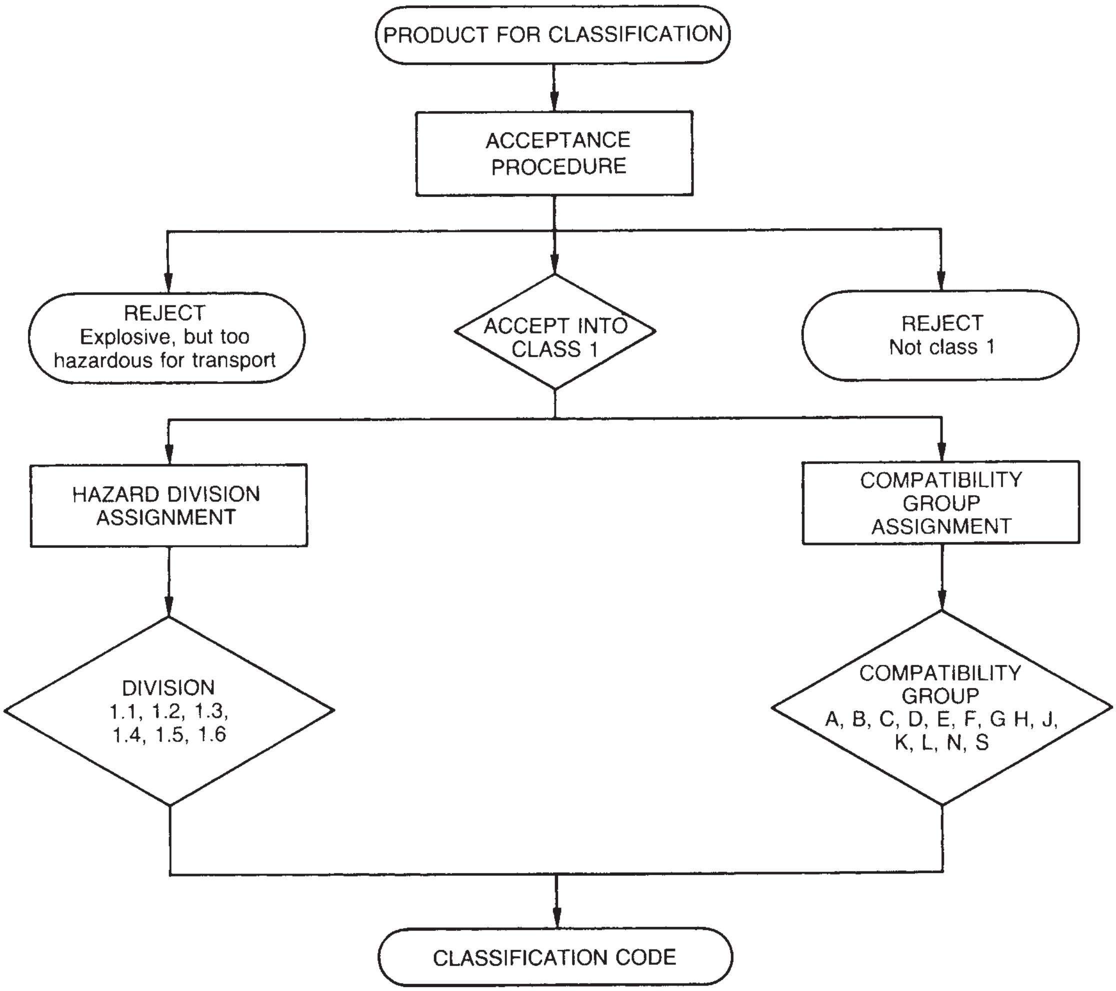

Figure 33.13 *UN transport classification tests; flow chart for classification of a substance or article as class 1 (UN, 1991)*

follows that of N. Gibson, Rogers and Wright (1987). The delayed onset detection test detects the onset of an exotherm and estimates the heat evolution rate. The ARC test detects an exotherm and determines the maximum safe working temperature. The ARC method given is the heat, wait and search technique mentioned earlier and described by Coates (1984a,b) and Ottway (1986). The adiabatic Dewar test, similar to the ARC method, detects an exotherm and gas evolution and determines the maximum safe working temperature. The test method is described by T.K.Wright and Rogers (1986).

The tests for maximum safe storage temperature apply only to liquids. For solids, the temperature may not be uniform throughout the material, making it necessary to treat this situation as a self-heating problem. An account of self-heating is given in Chapter 16.

For powders, the *Guidelines* refer to the methods of N. Gibson, Harper and Rogers (1985).

Test schemes for chemical reactivity A systematic approach to testing requires that it be performed within the framework of a scheme for the acquisition of the complete set of information necessary for reactor design. There are a number of test schemes described in the literature.

The scheme described in the ABPI *First Guidelines* comprised the following tests:

(1) preliminary tests
    (a) safety screen test,
    (b) combustibility test,
    (c) explosion and detonation potential tests;
(2) dynamic heating test;
(3) adiabatic heating test
    (a) reaction exotherm,
    (b) hot storage;
(4) special tests
    (a) drying stability tests.

Table 33.10 *Some test schemes for thermal stability of a single substance*[a]

Test	*Snyder (1965)*	*ABPI (1981)*	*Coats and Riddell (1981a)*	*Duval (1985)*	*N. Gibson (1984)*	*Cronin, Nolan and Barton (1987)*	*Grewer et al. (1989)*	*ABPI (1989)*

Deflagration		x[b]	x				x	x
Drying		x[b]	x[b]		x			x

[a] The table gives the tests principally discussed by the authors; it should not be assumed that no other tests are done.
[b] These references give an account of the test apparatus and method.

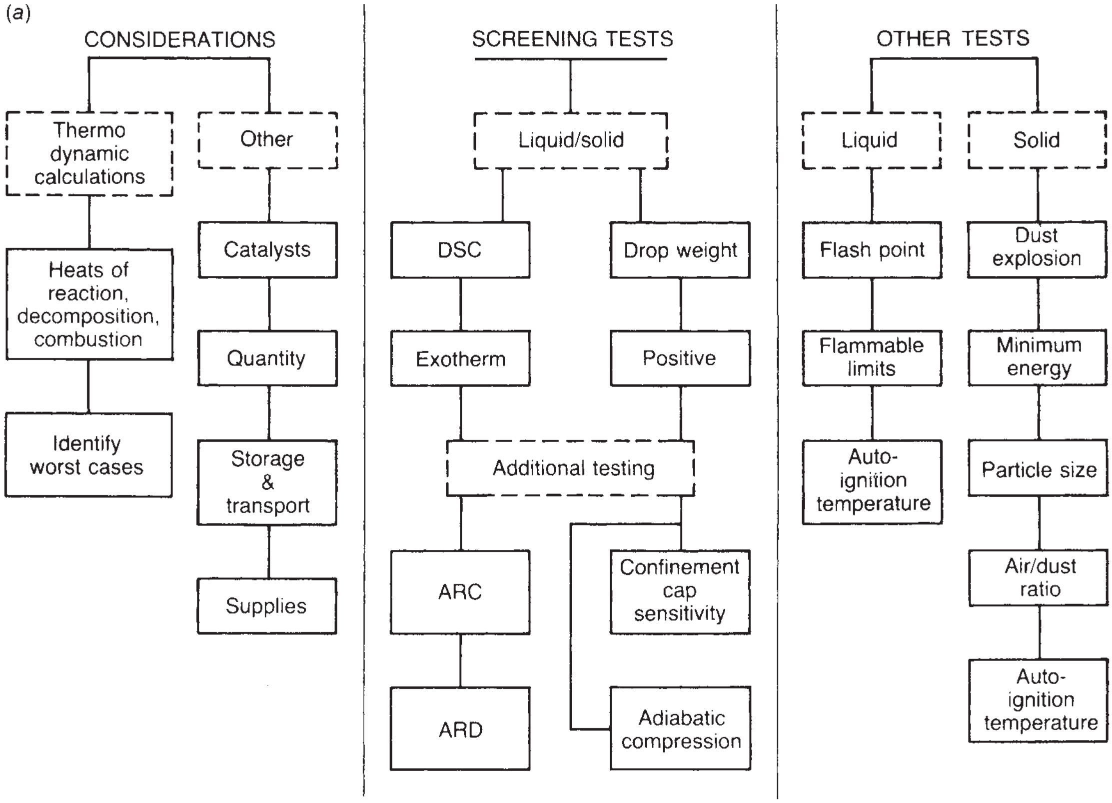

Figure 33.14 *continued*

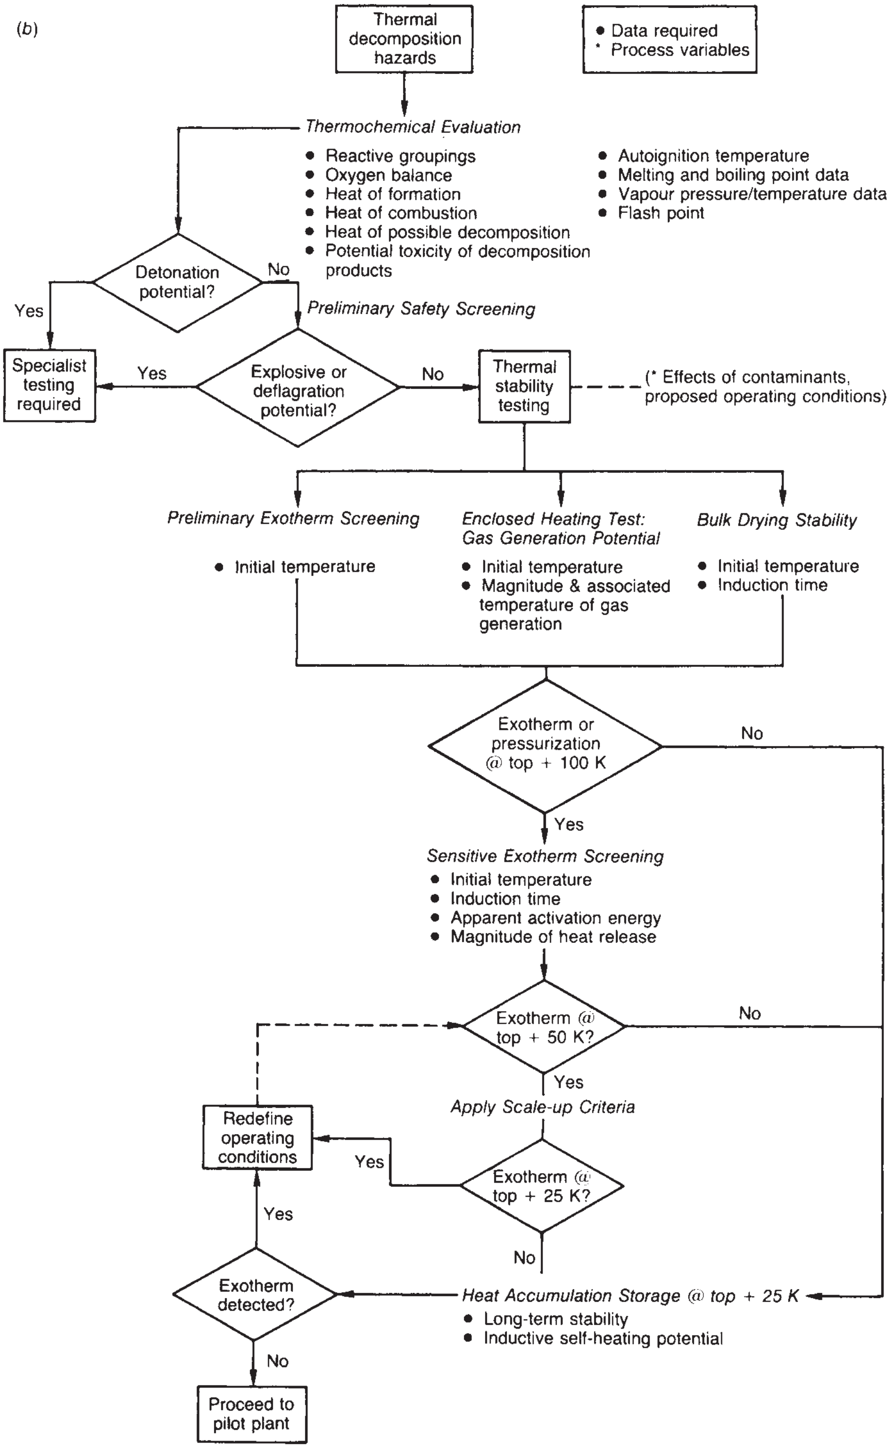

Figure 33.14 *Test scheme for thermal stability of a material: (a) test scheme of Kohlbrand (1985) (Courtesy of the American Institute of Chemical Engineers); and (b) test scheme of Cronin, Nolan and Burton (1987) (Courtesy of the Institution of Chemical Engineers)*

In this scheme, the safety screen test is the melting point tube test; the combustibility test is the train firing test; the adiabatic heating test for the main process reaction is similar to the stepped heating test using a Dewar flask.

The test scheme described by Coates and Riddell (1981a,b) is very similar. Figure 33.17 shows the decision tree given by these workers.

The test scheme given by O'Brien *et al.* (1982) is shown in Figure 33.18. Other test schemes include those of Cronin, Nolan and Barton (1987) and N. Gibson, Rogers and Wright (1987), described below.

Another test scheme is that described by Kunzi (1980), who states that the problem may come in various forms, and outlines the way in which the scheme is used. It may be required to evaluate a complete process, or one stage of a process such as distillation or storage, or a single component. He gives a decision tree for approaching the general problem. Essentially, steps 1 and 2 are desk screening; step 3 is the standard laboratory tests; step 6 involves tests to characterize the process main reaction; step 8 tests to explore undesired reactions; and step 10 tests to study storage. The actual scheme used is based on the availability in the test centre of a range of instruments including the TZP as described above.

The tests in the scheme given in the ABPI *Second Guidelines* described above are:

(1) DSC;
(2) combustibility test;
(3) closed tube test;
(4) delayed onset detection test;
(5) adiabatic Dewar test;
(6) ARC;
(7) heat flow calorimeter test;

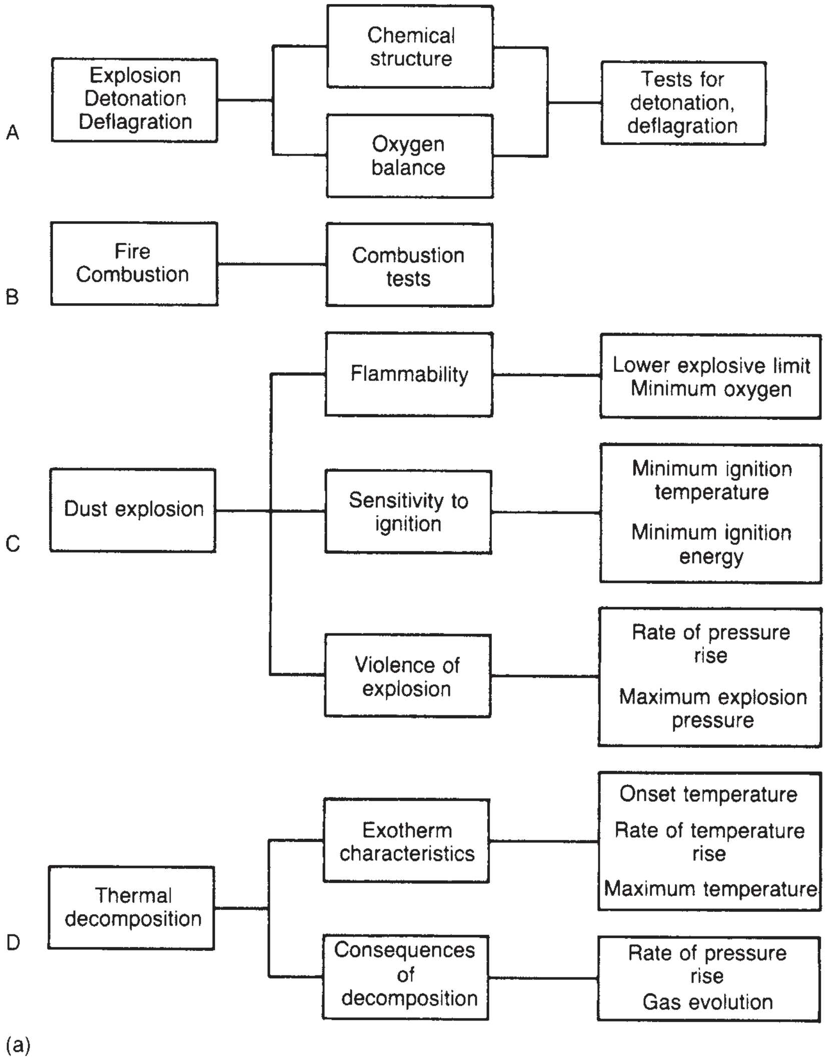

Figure 33.15 *continued*

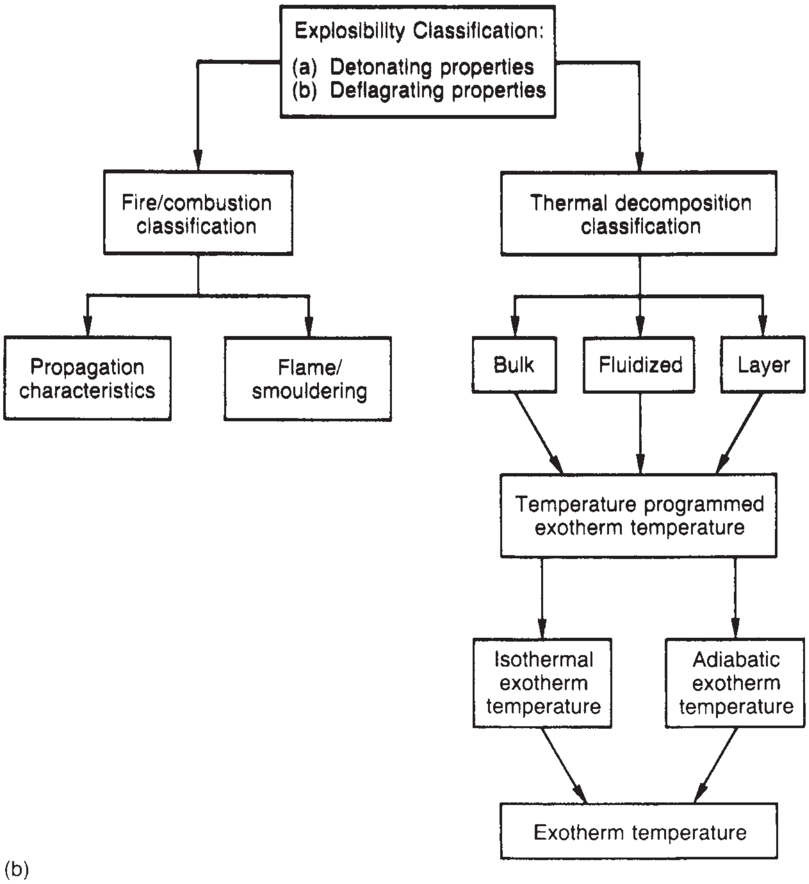

Figure 33.15 *Test schemes for thermal stability of a material with special reference to drying N. Gibson, Harper and Rogers (1985, 1986); (a) and (b) (Courtesy of the Institution of Chemical Engineers)*

(8) gas evolution measurement, using automated gas burette;
(9) gas evolution measurement, using thermal mass flowmeter.

Again, the flowchart is given in Figure 33.13.

The ICI test scheme described by N. Gibson, Rogers and Wright is shown in Figure 33.19.

The IChemE *Guide* gives the test scheme shown in Figure 33.18 and lists the following tests:

(1) initial screening tests:
  (a) DSC,
  (b) insulated exotherm test,
  (c) decomposition pressure test,
  (d) 10 g closed tube test,
(2) tests characterizing normal reaction:
  (a) Dewar calorimetry,
  (b) isoperibolic calorimetry,
  (c) power compensation calorimetry,
  (d) heat flow calorimetry,
  (e) gas evolution measurement, using automated gas burette,
  (f) gas evolution measurement, using thermal mass flowmeter,
(3) tests characterizing runaway reaction:
  (a) adiabatic Dewar calorimetry,
  (b) other types of calorimetry,
  (c) Vent Sizing Package (VSP),
  (d) Reactive Systems Screening Tool (RSST),
  (e) Phi-Tec adiabatic calorimeter.

Quantitative impact of exothermic reactions on system dynamics

Kinetics and heat effects The rate of a chemical reaction is controlled by the reaction kinetics, diffusion processes, and/or supply of reactant. The reaction considered here is the simple, irreversible first-order reaction:

$$A \rightarrow B \qquad [33.2.4]$$

with reaction kinetics which can be expressed as

$$r = \rho k x \qquad [33.2.5]$$

where r is the reaction rate (kmol/m^3 s), k is the velocity constant at reaction temperature (s^{-1}), x is the concentration of reactant A (mole fraction) and ρ is the molar density of feed and of reaction mass (kmol/m^3).

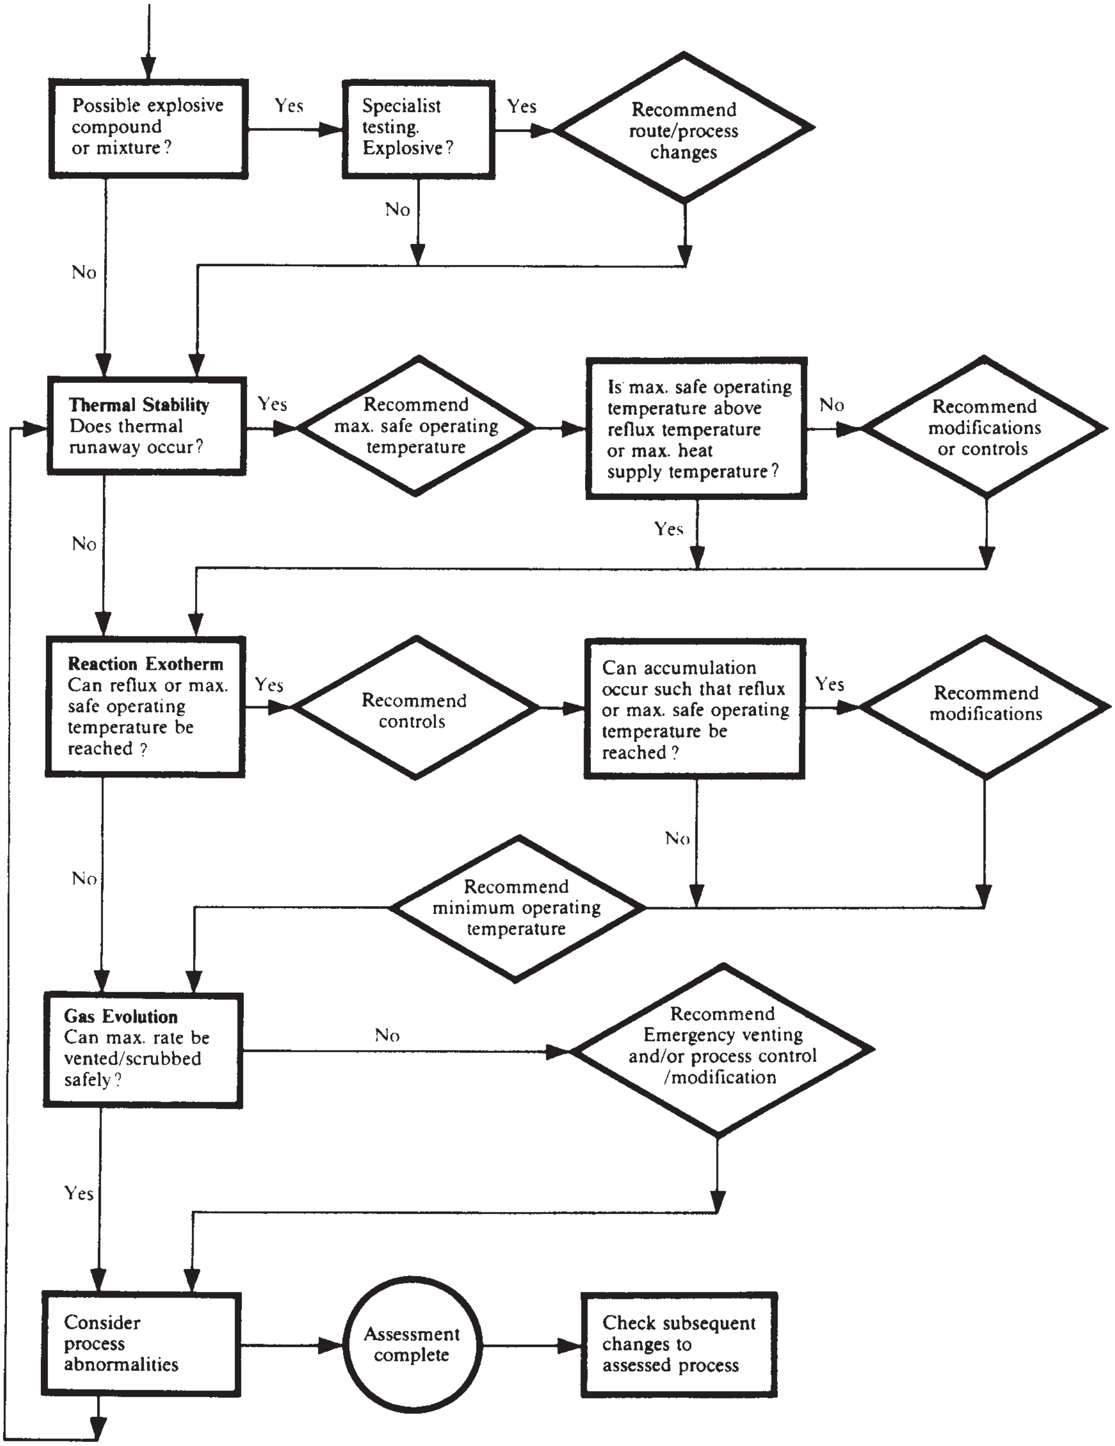

Figure 33.16 *Test scheme for assessment of thermal stability of reactant materials ABPI (1989)*

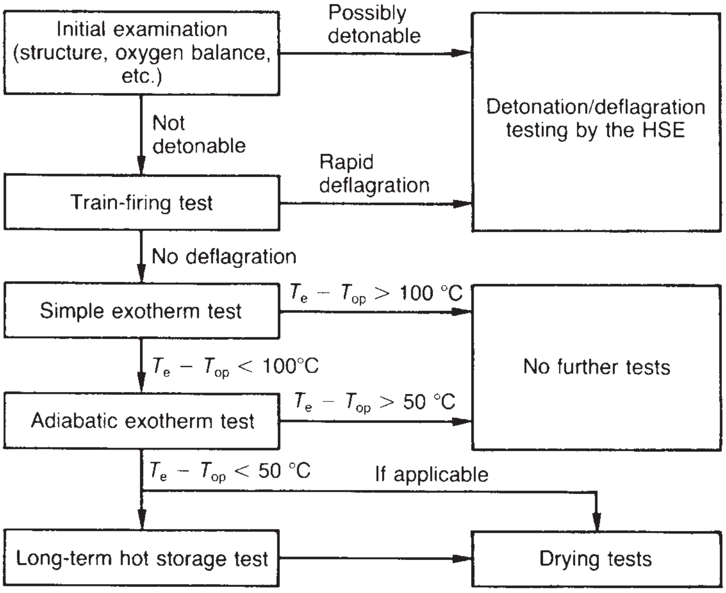

Figure 33.17 *Test scheme for chemical reactivity evaluation. T_e = lowest temperature at which exotherm occurs; T_{op} = mean temperature of intended use (Coates and Riddell (1981b)) (Courtesy of the Institution of Chemical Engineers)*

The variation of velocity constant with temperature is generally expressed in terms of the Arrhenius equation:

$$k = k_0 \exp(-E/RT) \qquad [33.2.6]$$

where E is the activation energy (kJ/kmol), k_0 is the velocity constant at the reference temperature (s^{-1}), R is the universal gas constant (kJ/kmol K), and T is the absolute temperature (K).

The reaction is accompanied by an enthalpy change so that the heat generated is:

$$Q_s = Vr(-\Delta H) \qquad [33.2.7]$$

where ΔH is the heat of reaction, which is negative for an exothermic reaction (kJ/kmol), Q_s is the heat generated by the reaction (kW), and V is the volume of the reactor (m^3). In considering reactor stability, exothermic reactions are of prime importance.

In a closed adiabatic system, the behaviour of a kinetics-controlled exothermic reaction is as shown in Figure 33.20. The reaction generates heat, which causes the temperature and, hence, the velocity constant to increase continuously throughout the course of the reaction. The reaction rate and heat generated at first increase almost exponentially due to the increase in the velocity constant, then pass through a maximum and finally decrease as the reactants become exhausted.

In many practical cases, an exothermic reaction can accelerate almost exponentially and cause overheating or explosion, if the heat is not removed from the system rapidly enough. These effects may occur while the reaction is only part way along the curves shown in Figure 33.20.

There are a number of factors, however, that can limit the acceleration of the reaction rate. One limiting factor, which applies in all cases, is the exhaustion of the reactants. This applies even for a continuous feed of reactants, because once the resident material is consumed, the reaction rate cannot exceed the reactant feed rate. Another important limiting effect is the transition in heterogeneous reactions from a kinetics-controlled to a diffusion-controlled reaction. As the temperature rises, the reaction kinetics become so rapid that they cease to be the limiting factor and diffusion takes over the role. These effects are shown in Figure 33.21(a). The dashed lines represent the reaction rates limited by the kinetics alone and by diffusion alone. The actual reaction rate, shown by the full curve, is determined by the combined effects of the kinetics and diffusion. It is limited at low temperatures by kinetics and at high temperatures by diffusion. Diffusion may be limited by the velocity in the reactor or by intra-particle mass transfer. The change of reaction rate with temperature and velocity for such a case is illustrated in Figure 33.21(b).

Another limiting factor is the relation between the reaction rate and temperature. Some of the relations that occur are shown in Figure 33.22. Figure 33.22(a) gives the normal curve of rapid rise in reaction rate with temperature; Figure 33.22(b) shows diffusion control with a slow increase of reaction rate with temperature; Figure 33.22(c) illustrates an explosion with a sudden increase in reaction rate at the ignition point; Figure 33.22(d) is for a catalytic reaction controlled by the rate of adsorption; Figure 33.22(e) corresponds to the occurrence of a side reaction, which becomes significant as temperature increases; and Figure 33.22(f) indicates a reaction in which conversion is limited by thermodynamic equilibrium effects.

Exothermic reactions in an adiabatic environment

Batch reactors: reaction hazard evaluation A theoretical treatment of an adiabatic reaction has been given by Townsend and co-workers (Townsend, 1977, 1981; Townsend and Tou, 1980). The treatment is for an nth-order reaction, but utilizes a pseudo-first-order reaction approach. For an nth-order reaction:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = -kC^n \qquad [33.2.8]$$

with

$$k = A\exp(-E/RT) \qquad 33.2.9$$

where A is the pre-exponential factor, C is the concentration of reactant, E is the activation energy, k is the reaction velocity constant, R is the universal gas constant, t is the time, T is the absolute temperature, and n is the order of the reaction.

Consider an adiabatic reaction as shown in Figure 33.23. The adiabatic temperature rise ΔT_{ab} is:

$$\Delta T_{\mathrm{ab}} = T_{\mathrm{f}} - T_0 \qquad [33.2.10]$$

where T_{f} is the final absolute temperature and T_0 is the initial absolute temperature. The adiabatic temperature rise is calculated from the heat of reaction by:

$$(-\Delta H_{\mathrm{r}}) = Mc_{\mathrm{v}}\Delta T_{\mathrm{ab}} \qquad [33.2.11]$$

where c_{v} is the constant-volume specific heat of the reaction mixture. ΔH_{r} the heat of reaction, and M is the mass of the reaction mixture.

The appropriate concentration–temperature relationship is approximately

$$\frac{C}{C_0} = \frac{T_{\mathrm{f}} - T}{T_{\mathrm{f}} - T_0} \qquad [33.2.12a]$$

and hence

$$C = \frac{T_{\mathrm{f}} - T}{\Delta T_{\mathrm{ab}}}C_0 \qquad [33.2.12b]$$

where C_0 is the initial concentration of reactant.

The self-heat rate, m_T, is obtained from Equations 33.2.8 and 33.2.12b:

$$\frac{\mathrm{d}T}{\mathrm{d}t} = k\left(\frac{T_{\mathrm{f}} - T}{\Delta T_{\mathrm{ab}}}\right)^n \Delta T_{\mathrm{ab}} C_0^{n-1} \qquad [33.2.13a]$$

$$= m_T \qquad [33.2.13b]$$

A pseudo-reaction velocity constant k^* is defined as:

$$k^* = C_0^{n-1}k \qquad [33.2.14a]$$

$$= \frac{m_T}{((T_{\mathrm{f}} - T)/\Delta T_{\mathrm{ab}})^n \Delta T_{\mathrm{ab}}} \qquad [33.2.14b]$$

From Equations 33.2.9 and 33.2.14a:

$$\ln k^* = \ln(C_0^{n-1}A) - E/RT \qquad [33.2.15]$$

Equation 33.2.15 may be used to obtain the pre-exponential factor A and the activation energy E.

The initial self-heat rate m_0 is obtained from Equation 33.2.13b and is

$$m_0 = k_0 \Delta T_{\mathrm{ab}} C_0^{n-1} \qquad [33.2.16]$$

where k_0 is the reaction velocity constant at the initial temperature. From Equations 33.2.13 and 33.2.16:

$$m_T = m_{\mathrm{o}}\frac{k}{k_0}\left(\frac{T_{\mathrm{f}} - T}{\Delta T_{\mathrm{ab}}}\right)^n \qquad [33.2.17a]$$

$$= m_{\mathrm{o}}\left(\frac{T_{\mathrm{f}} - T}{\Delta T_{\mathrm{ab}}}\right)^n \exp\left[-\frac{E}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)\right] \qquad [33.2.17b]$$

At the maximum self-heat rate:

$$\frac{\mathrm{d}^2T}{\mathrm{d}t^2} = 0 \qquad [33.2.18]$$

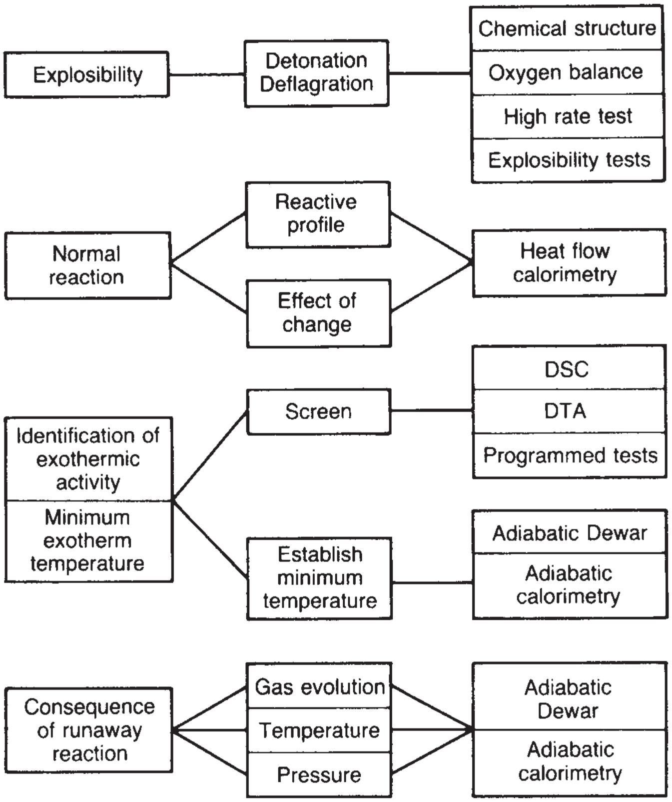

Figure 33.19 *Test scheme for chemical reactivity evaluation (N. Gibson, Rogers and Wright (1987)) (Courtesy of the Institution of Chemical Engineers)*

and hence it can be shown that

$$nRT_{\mathrm{m}}^2 + ET_{\mathrm{m}} - ET_{\mathrm{f}} = 0 \qquad [33.2.19]$$

where T_{m} is the absolute temperature at the maximum rate. Then from Equation 33.2.18:

$$T_{\mathrm{m}} = \frac{E}{2nR}[(1 + 4nRT_{\mathrm{f}}/E)^{1/2} - 1] \qquad [33.2.20]$$

The maximum self-heat rate, m_{m}, is obtained by substituting T_{m} in Equation 33.2.17a. The time to the maximum rate is obtained as follows. Integrating Equation 33.2.13a

$$\theta_{\mathrm{m}} = t_{\mathrm{m}} - t \qquad [33.2.21a]$$

$$= \int_t^{t_{\mathrm{m}}} \mathrm{d}t \qquad [33.2.21b]$$

$$= \int_T^{T_{\mathrm{m}}} \frac{\mathrm{d}T}{k((T_{\mathrm{f}} - T)/\Delta T_{\mathrm{ab}})^n \Delta T_{\mathrm{ab}} C_0^{n-1}} \qquad [33.2.21c]$$

where t_{m} is the time for the temperature to reach the maximum rate value at T_{m} and θ_{m} is the time to the maximum rate from temperature T.

It is possible to obtain an analytical solution of Equation 33.2.21c if it is assumed that

$$A = \alpha T^j \qquad [33.2.22]$$

where α is a constant and j is an integer. It can be shown that for a second-order reaction

$$\theta_{\mathrm{m}} = \frac{RT^2}{m_T E} - \frac{RT_{\mathrm{m}}^2}{m_{\mathrm{m}} E} \qquad [33.2.23]$$

The same equation applies for other nth-order reactions.

If the activation energy E is high, the second term in Equation 33.2.23 is much less than the first, and hence

$$\theta_{\mathrm{m}} = \frac{RT^2}{m_T E} \qquad [33.2.24]$$

Then from Equations 33.2.13b and 33.2.24

$$\theta_{\mathrm{m}} = \frac{RT^2}{k((T_{\mathrm{f}} - T)/\Delta T_{\mathrm{ab}})^n \Delta T_{\mathrm{ab}} C_0^{n-1} E} \qquad [33.2.25a]$$

$$\ln \theta_{\mathrm{m}} = \ln\left[\frac{RT^2}{((T_{\mathrm{f}} - T)/\Delta T_{\mathrm{ab}})^n \Delta T_{\mathrm{ab}} C_0^{n-1} E}\right] - \ln A + E/RT \qquad [33.2.25b]$$

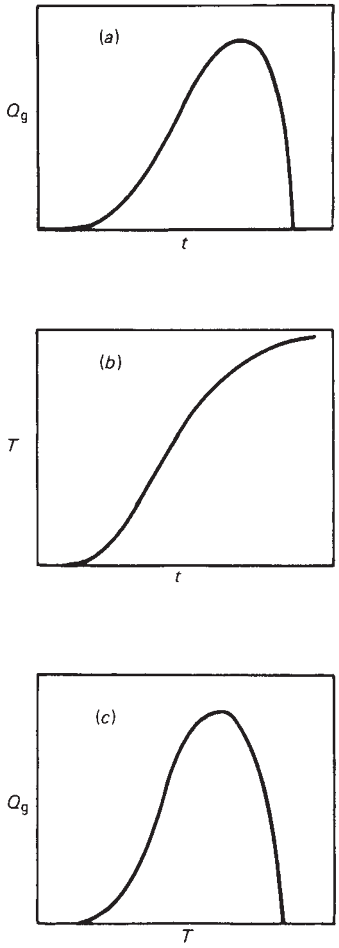

Figure 33.20 *Course of a kinetic controlled exothermic reaction in a closed adiabatic system: (a) heat generated vs time; (b) temperature vs time; (c) heat generated vs temperature*

But, under the same assumption of a high activation energy, the second term in Equation 33.2.25b is much greater than the first, and hence

$$\ln\theta_{\mathrm{m}} = -\ln A + E/RT \qquad [33.2.26a]$$

or, from Equation 33.2.9,

$$\ln\theta_{\mathrm{m}} = \ln k^{*} \qquad [33.2.26b]$$

$$\theta_{\mathrm{m0}} = \frac{RT_0^2}{k_0\Delta T_{\mathrm{ab}}C_0^{n-1}E} \qquad [33.2.27a]$$

The time, θ_{m0}, to maximum rate at temperature, T_0, and thus from the start of the reaction, is obtained from Equation 33.2.25a by substituting k_0 and T_0 for k and T, respectively

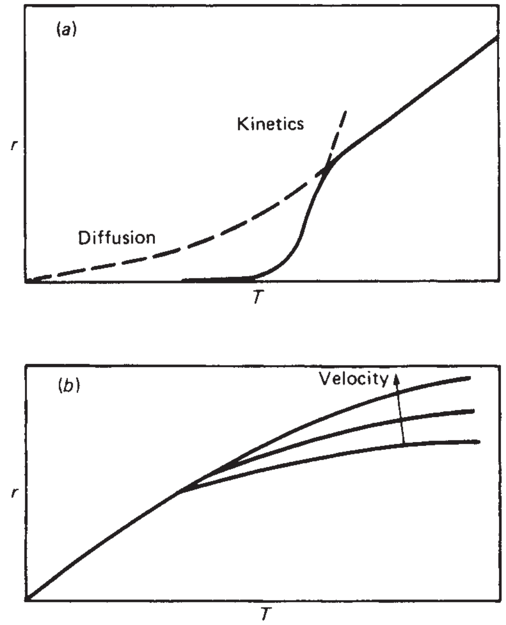

Figure 33.21 *Kinetic and diffusion control of a heterogeneous reaction: (a) transition from kinetic to diffusion control as temperature increases (Denbigh and Turner, 1971) (Courtesy of Cambridge University Press); (b) increase in rate of a diffusion controlled reaction with reactor velocity*

Similarly, substituting T_0 for T in Equation 33.2.26a

$$\ln\theta_{\mathrm{m0}} = -\ln A - E/RT_0 \qquad [33.2.27b]$$

33.2.2 Identification of reactive hazards scenarios

A review should be conducted to determine credible pathways by which the identified reactive hazards can potentially pose significant threats to the process or equipment (Table 33.11). It is important to capture not only the deviation initiating a potential event, but also the sequence events that can follow. Care should be taken not to place too much credit for existing mitigations at this point to ensure that scenarios are not immediately dismissed before a proper assessment of risk is performed. Once reactive hazards scenarios have been identified and developed in such a review, the potential severity and frequency of each event can be evaluated.

Emphasis in the review should focus on potential events that could lead to 'high consequence' events. This will encourage resources to be focused on the more significant scenarios. The definition of 'high consequence' will be specific to the particular company or organization, but as a benchmark, potential events that can be life-threatening, substantially damage assets or cause production loss, severely impact the environment or damage the company's/organization's reputation should be considered. Downtime can be caused by asset damage. It can also arise from a shut-down of facilities to address a violation of code or standard. In this manner, exceedance of more-stringent

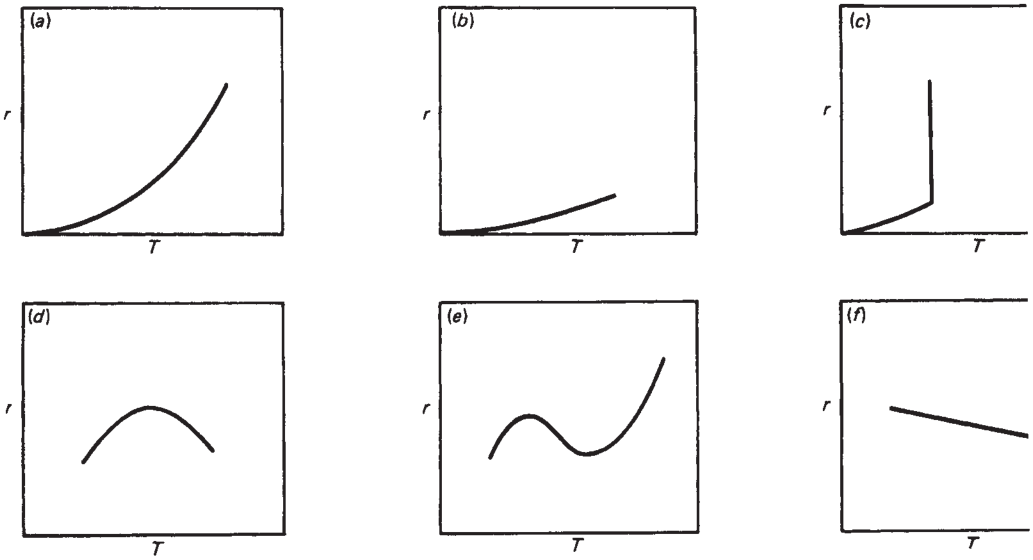

Figure 33.22 *Some principal types of variation of reaction rate with temperature (after Frost and Pearson, 1961): (a) kinetic-controlled reaction; (b) diffusion-controlled reaction; (c) sudden explosive reaction; (d) adsorption-controlled reaction; (e) side reaction; (f) equilibrium-limited reaction (Reproduced with permission from Kinetics and Mechanisms, 2nd edn, by A.A. Frost and R.G. Pearson, Copyright ©, 1961, John Wiley and Sons Inc. Figure 32.22(b) is additional to the figures given by these authors)*

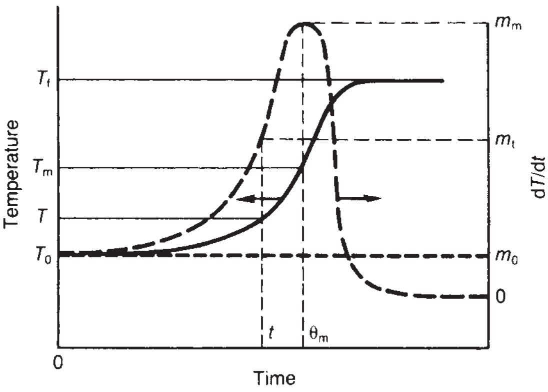

Figure 33.23 *Temperature and self-heat rate of an adiabatic reaction (Townsend and Tou, 1980) (Courtesy of Elsevier Publishing Company)*

local regulations, which could threaten the unit's license to operate, may also be considered a high consequence event.

The review should focus exclusively on reactive hazards. Use of the Hazard Operability (HazOp) method (with standard 'guidewords') can bring a structured, thorough approach to identifying deviations. However, it can also cause the review to spend substantial time on safety matters unrelated to reactivity. It may be most expedient to devote attention to deviations that have some possibility for high consequence outcomes.

Table 33.11 *Examples of standard initiating events and upset scenarios*

1. High start or operating temperature
2. High reactant concentration
3. Low solvent or diluent concentration
4. High level
5. High catalyst concentration
6. Low catalyst concentration
7. Increased heating or decreased cooling to process
8. Fire exposure
9. Loss of power
10. Contact between usually separated, reacting chemical
11. Exposure of air-sensitive or water-sensitive materials
12. Handling of dust-generating material
13. Potential to accumulate or 'pool' reactant (e.g. during unit start-up)
14. Special start-up or shut-down issues
15. Change of catalyst type, grade or supplier
16. Phase separation of reactants
17. Unexpected loss of (catalyst) activity
18. Change in residence time (including extended storage time of reactive intermediates)
19. High flow
20. Low or no flow
21. Low start or operating temperature
22. Sudden change in flow or pressure (gas)
23. Procedure steps out of order
24. Slop tank operation
25. Feed change
26. Disturbances in linked units or shared equipment
27. Transients in recycle streams
28. Backflow or feed upsets from linked units
29. Heat exchanger leakage

Guidewords and pathways pertaining to normal operations, off-normal operations (including start-ups and shut-downs) and deviations from normal operations should be examined. The resultant sequence of events that could ultimately lead to a high consequence incident is then captured. In general, the determination of the *actual* consequence for a particular scenario can require significant time to set up and carry out the needed calculations. Follow-up is therefore assigned to the appropriate resource to validate the *perceived* consequence after the review. Thus, the risk is not assessed in the review; rather it is best carried out subsequently. For this reason, existing and anticipated mitigation measures are not discussed extensively at this stage.

Examples of reactivity-related initiating events appear in Appendix C. This list, as well as a list of previous incidents, can be examined to ensure that these events have been considered in the review.

Given the potential for a high consequence incident arising from a reactivity event, it may be prudent to consider selected multiple jeopardy scenarios (a 'jeopardy' being an initiating deviation, not including a failed response by people or instrumentation to a deviation). The number of combinations of deviations can be quite large, so attention should be directed towards those combinations of jeopardies in which the reactive hazards of the process can be manifested as *high* consequence events. Note that a runaway reaction itself is not a jeopardy but a consequence of operating under upset conditions. This means that, for example, heat input from a plant fire leading to an increased reaction rate is a *single* jeopardy scenario.

Since each facility is unique in equipment configuration, operating conditions, operating procedures and perhaps even in species compositions, care should be taken that scenario identification focus on the specific facility being addressed and that the review be thorough. Similar process units, even if in different manufacturing locations, will likely have many scenarios in common but the unique aspects above can result in generation of distinct scenarios. It is conceivable that two facilities at the same manufacturing location can have differing scenarios.

The review for an entire facility can extend to all process equipment (typically, the vessels and tanks) – that is, not just the reactor. When conducting such reviews, it is good practice to 'divide' a process unit into subsections or 'nodes' to reduce the complexity of the process. Example nodes can be: feed preparation, pre-reactor separations, reactor, post-reactor separations, finishing and product/off-spec/by-product storage. For change management, small projects or incident follow-up studies, a narrower selection of equipment may be acceptable.

It is beneficial to provide to the review team documentation summarizing the reactivity information as well as Process or Engineering Flow diagrams. Process and Instrumentation diagrams can serve as a reference in case more specific information is needed.

To ensure that the process is thoroughly studied with ample consideration for actual operating practice and configurations, the review team should include the following as participants:

(1) Process support engineer;
(2) Plant support engineer;
(3) Plant operator;
(4) RHA specialist.

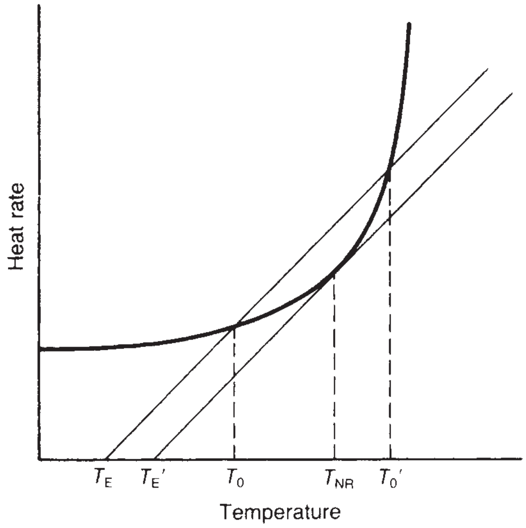

Figure 33.24 *Self-heat rate and heat transfer of a reaction with cooling: (Townsend and Tou, 1980) T_E, temperature of heat exchanger; T_{NR}, temperature of no return; T_a initial temperature; dash (′) indicates alternative set of values (Courtesy of Elsevier Publishing Company)*

In addition, an identified facilitator, scribe and safety specialist may be required (though these roles may be carried out by the listed attendees).

All likely scenarios should be described in detail indicating clearly what the cause of the scenario is, how the unmitigated scenario develops, and what the ultimate consequence might be. In addition, the resource to be employed in follow-up, where needed, and the type of follow-up are recorded.

33.2.3 Reactive hazards risk assessment

Issues during scale-up

Consider a system with external cooling. The heat generation and heat removal curves for such a system are shown in Figure 33.24. As the reaction rate and, hence, the heat evolution increase, a temperature may be reached at which the rate of heat evolution exceeds the heat removal capacity of the system; this is the temperature of no return T_{NR}. From Equation 33.2.16 the rate of heat evolution Q_e is:

$$Q_e = Mc_vK_0\Delta T_{ab}C_0^{n-1} \qquad [33.2.28]$$

The rate of heat removal Q_r is:

$$Q_r = UA_c(T_0 - T_c) \qquad [33.2.29]$$

where A_c is the surface area for heat transfer, T_c is the absolute temperature of the coolant, and U is the overall heat transfer coefficient. Equating the heat evolution and removal rates given in Equations 33.2.28 and 33.2.29

$$Mc_vA\exp\left(-\frac{E}{RT_0}\right)\Delta T_{ab}C_0^{n-1} = UA_c(T_0 - T_c) \qquad [33.2.30]$$

It can be seen from Figure 33.24 that Equation 33.2.30 has two solutions. No runaway reaction should occur if the initial temperature of the reaction mass T_0 is below a critical value T_0 and the temperature of the coolant T_c is below a critical value T_c. But as T_0 increases to the temperature of no return T_{nr}, there is a single solution. At this point, the slope of the line of heat evolution equals that of the line of heat removal. Then from Equations 33.2.9, 33.2.28 and 33.2.29:

$$Mc_v k_0 \left[\frac{E}{RT_0^2}\right] \Delta T_{ab} C_0^{n-1} = UA_c \quad [33.2.31]$$

The time $\theta_{T\mathrm{nr}}$ to the maximum rate at the temperature of no return T_{nr} is, from Equations 33.2.27a and 33.2.31:

$$\theta_{T\mathrm{nr}} = \frac{RT_0^2}{k_0 \Delta T_{ab} C_0^{n-1} E} \quad [33.2.32a]$$

$$= \frac{Mc_v}{UA_c} \quad [33.2.32b]$$

The group (Mc_v/UA_c) is known as the 'equipment time line'.

The case where the maximum self-heat rate coincides with the initial self-heat rate is of interest. For this:

$$m_m = m_0 \quad [33.2.33]$$

and

$$T_m = T_0 = T^* \quad [33.2.34]$$

say, where T^* is the minimum initial absolute temperature above which only deceleration of the reaction occurs.

Then from Equations 33.2.19 and 33.2.34 and noting that

$$T_f = \Delta T_{ab} + T^* \quad [33.2.35]$$

$$T^* = (E\Delta T_{ab}/nR)^{1/2} \quad [33.2.36]$$

Thus, theoretically, there exists a temperature above which the effect of concentration depletion on the reaction rate is greater than that of acceleration due to temperature.

The parameters used in the foregoing analysis are the true parameters of the reaction. In practice, they have to be calculated from experimental measurements, which are affected by the thermal capacity of the container. The true adiabatic temperature rise ΔT_{ab} is related to the adiabatic temperature rise ΔT_{abs} of the sample:

$$Mc_v \Delta T_{ab} = (Mc_v + M_b c_{vb}) \Delta T_{abs} \quad [33.2.37]$$

or

$$\Delta T_{ab} = \phi \Delta T_{abs} \quad [33.2.38]$$

with

$$\phi = 1 + \frac{M_b c_{vb}}{Mc_v} \quad [33.2.39]$$

where c_{vb} is the specific heat of the sample container and M_b is the mass of the container. The quantity ϕ is the thermal inertia and its reciprocal is a measure of the degree of adiabaticity. Similar corrections apply to the other measured quantities:

$$m_0 = \phi m_{os} \quad [33.2.40]$$

$$\theta_m = \theta_{ms}/\phi \quad [33.2.41]$$

where m_{os} is the measured self-heat rate at temperature T_0 and θ_{ms} is the measured time to maximum rate at temperature T.

Consequence assessment

The intent of consequence assessment is to determine which scenarios need prevention or mitigation action. This facilitates effective utilization of resources for evaluation and implementation. Scenarios that have been generated are screened and evaluated for potential to lead to *high* consequence events. Each scenario found to be capable of yielding a high or excessive consequence event is highlighted and may be addressed through likelihood assessment and risk reduction measures, if needed.

In consequence assessment, all scenarios generated should be evaluated based on the consequences with regards to the design of the unit (e.g. design pressure, design temperature or depending on local regulations the temperature where failure in the metallurgy is experienced). If the consequence is not evaluated, then the likelihood directly should be evaluated along with a decision to ensure that the likelihood falls below the corporate or organization's tolerable risk frequency.

Reactive hazards, by definition, lead to an excursion in temperature and/or pressure. To ascertain whether a high consequence event could occur, the extent of temperature and pressure rise associated with each scenario should be evaluated. This test can be carried out by a variety of means, including spreadsheet calculations for simple steady-state operations or a dynamic simulation for more complex systems.

In evaluating the consequences of a scenario, it may be prudent to take no credit for operator procedures and training, instrumentation and mechanical relief (these can be examined during likelihood assessment). However, inherent constraints to the development of the consequence, such as maximum heating medium temperature, equilibrium (thermodynamic)-limited reactant conversion or catalyst deactivation, etc., can be accounted for in the calculations. Continued exposure to an external fire heat input combined with reaction heat, though, can lead to temperatures far beyond the rating of the equipment. In a fire exposure scenario in which reaction is taking place, the consequence can be presumed to be high, and the calculation will essentially determine the time taken to exceed allowable levels. (The appropriate standard, e.g. NFPA 30 or API RP 521, should be applied for the heat input flux.)

For effective use of resources, it may be advisable to identify scenarios, at an early stage, that can serve as worst-case scenarios for similar scenarios. In this manner, if the worst-case scenarios do not yield a high consequence, neither will the lesser scenarios. However, if the more severe scenario does have potential to yield a *high* consequence, the consequences of the successively less severe scenarios should also be evaluated so that proper safeguarding can be performed.

The resultant maximum temperature and pressure should be compared to appropriate criteria (e.g. design temperature, design pressure and material properties) to determine whether the consequences are *high* or not. Internal corporate or organizational criteria can serve as a minimum for this purpose. National, state or local regulations may impose stricter criteria that must be followed. For example, the exceedance of equipment design temperature is prohibited in some countries and can be considered a threat to a facility's license to operate.

Consequence assessment results should be summarized for each corresponding scenario generated from the review. The extent of temperature and pressure rise, what further action (if any) is needed and whether the scenario should be addressed via likelihood assessment should be documented.

Mixing and heat transfer

The reaction and heat transfer behaviour of the reactor is strongly affected by the degree of mixing. There may well be departures from near-perfect mixing, and with highly viscous reaction masses these may be considerable.

The IChemE *Guide* gives two models of the profile of the temperature between the centre of the reaction mass and the wall. The first is a uniform temperature, the Semenov model, applicable where the reaction mass is well mixed. The second is a sigmoidal temperature profile, the Frank–Kamenetsky model, applicable where the mass is unmixed. This latter model is fundamental to thermal explosion, or self-heating theory and is treated in Chapter 16. Reactor situations where the temperature in the reaction mass is liable to rise may be treated using thermal explosion models.

The conventional treatment for the case where the mass is poorly mixed is the Frank–Kamenetsky thermal explosion model, as described in Chapter 16. Specifically, the equations generally quoted are those used in relation to the experimental determination of the critical value of the ignition parameter δ_C, namely Equations 16.6.107–16.6.109.

The *Guide* also quotes the simpler treatment by Leuschke (1981), which yields the relation:

$$\ln\frac{V}{S} \propto \frac{1}{T_d} \qquad [33.2.42]$$

where S is the surface area of the mass, T_d is the minimum decomposition temperature, and V is the volume of the mass.

With regard to heat transfer coefficients, correlations are available for the heat transfer coefficients on the inside of a stirred reactor and on the outside of the vessel in the jacket. Accounts of reactor heat transfer coefficients are given by Chapman and Holland (1965a,b). A method widely used for the film heat transfer coefficient on the inside of the vessel is that of E.E. Wilson (1915). The effect of agitator geometry on this coefficient may be taken into account by the use of a geometric factor, and a correlation is available for this factor also. Details are given in the IChemE *Guide*, which also discusses cases that are non-ideal due to non-Newtonian behaviour, and so on. The *Guide* also gives a treatment of reactors operated under reflux conditions.

Reaction simulation testing

The testing described thus far is fairly formal, employing specific laboratory tests within the framework of a test scheme. One of the recognized tests, however, is the Dewar flask test in which the conduct of the reaction is explored.

There are a number of accounts of various laboratory tests conducted to explore the conduct of the reaction. Coates and Riddell (1981a,b) have described a 'worst case' analysis of a nitration reaction in a semi-batch reactor. The heat of reaction and the rate of heat evolution were determined in a calorimeter and used to select the time over which the fed reactant should be added, or the 'addition time'. Non-normal conditions were investigated such as accumulation of unreacted nitric acid in the reactor and the effect of this on the temperature of the reaction mass when reaction did occur. These authors also describe two other reaction studies.

The IChemE *Guide* describes the use of Dewar calorimetry to mimic the plant reactor and explore reactor configurations, agitation, cooling and heating systems, addition of gases, liquids and solids, and so on.

33.2.4 Batch reactors: basic design

Inherently safer design

The application of the principle of inherently safer design to the choice of reaction route was described in Section 11.7 of Chapter 11. An account is given here of its application to batch reactors, which has been advocated particularly by Regenass (1984). The approach described by this author depends essentially on the avoidance of high concentrations of the reactants. One method of limiting reactant concentration is the use of a semi-batch, or 'fed-batch', reactor in preference to an 'all-in' batch reactor. In the latter, all the reactants are added in the initial charge; in the former, one of the reactants is added continuously. The hazard in the all-in design is that conditions may occur in which there is a sudden massive reaction of the unreacted reactants. This is liable to occur, for example, on resumption of agitation after an agitator failure. In the semi-batch reactor, the continuous feed arrangement, combined with a suitable reactor temperature, keeps the concentration of one of the reactants relatively low and it is possible to effect prompt shut-off of the feed if a potentially hazardous operating deviation occurs.

The full benefit of the semi-batch reaction mode does depend, as just indicated, on the adoption of a suitable reaction temperature. If this temperature, and therefore the reaction rate is too low, accumulation of the fed reactant can occur. The reaction temperature should be high enough to ensure that the reaction proceeds sufficiently rapidly to avoid accumulation.

An example of the application of this principle has been given by Fierz *et al.* (1983, 1984), who describe the design of a semi-batch reactor for the further nitration of a substituted nitrobenzene. Two operating temperatures were investigated—80°C, and 100°C—using a bench scale calorimeter (BSC). At 80°C, shut-off of the feed at the worst instant, when the reactants are present in equimolar proportion, resulted in heat release before and after shut-off of 90 and 180 kJ/kg of final reaction mass, respectively, whilst at 100°C the corresponding figures were 190 and 80 kJ/kg. At the lower operating temperature, the heat release was sufficient under adiabatic conditions to give a temperature rise of 110°C, taking the temperature to 190°C, at which temperature an undesired exotherm would occur, whilst at the higher operating temperature, the adiabatic temperature rise was only 40°C, taking the temperature to only 140°C. Figure 33.25 shows results obtained from the BSC work.

Safe operation criteria

Methods are available for the prediction of safer operating regimes for both batch and semi-batch reactor modes. One approach is based on the application of the Semenov thermal explosion model to the case of a well mixed reactor. This

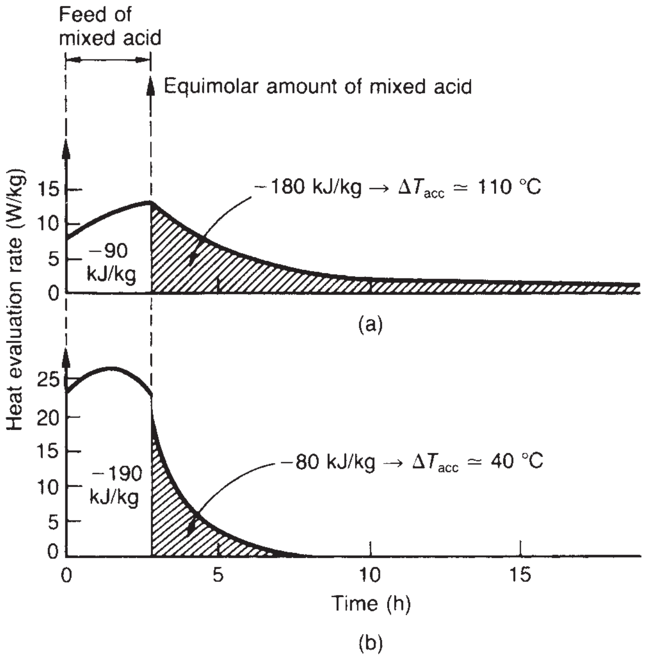

Figure 33.25 *Heat effects in a semi-batch reactor at reaction temperatures of (a) 80° C and (b) 700° C (Fierz et al., 1984) (Courtesy of the Institution of Chemical Engineers)*

model applies to a liquid mass with agitation and convection. An account is given by Grewer *et al.* (1989).

A limiting condition for the reactor with cooling but without reaction can be derived from the adiabatic induction time. This is:

$$\frac{d\theta}{dt} = -\kappa\theta \qquad [33.2.43]$$

with

$$\kappa = \frac{UA_c}{Vc_p\rho} \qquad [33.2.44]$$

where A_c is the surface area for heat transfer, c_p is the specific heat of the reaction mixture, t is the time, U is the overall heat transfer coefficient, V is the volume of the reaction mixture, K is the cooling parameter, θ is a dimensionless temperature difference, and ρ is the density of the reaction mixture. The critical condition for thermal explosion is:

$$\tau_{ad}\kappa = e \qquad [33.2.45]$$

where e is the base of the natural logarithm.

The authors define the degree of conversion X in terms of the fraction of heat released. They state that experience shows that for a batch reaction the following equation may be used:

$$r = r_0(1 - X)^n \qquad [33.2.46]$$

with

$$r_0 = kc_{A0}c_{B0} \qquad [33.2.47]$$

where c is the concentration, k is the reaction velocity constant, r is the rate of reaction, n is the effective order of the reaction and subscripts A, B and 0 indicate reactant A, reactant B and initial conditions, respectively. For a semi-batch reaction a relation which fits most cases is:

$$r = r_0\frac{(1 - X)(t/\tau_D - X)}{1 + V_Dt/V_0\tau_D} \qquad [33.2.48]$$

with

$$r_0 = kc_{A0}c_{BD} \qquad [33.2.49]$$

where V_D is the volume of addition, V_0 is the initial volume, τ_D is the time of addition and subscript D indicates addition.

The authors define a thermal reaction parameter B:

$$B = \frac{E\Delta T_{ad}}{RT^2} \qquad [33.2.50]$$

where E is the activation energy, R is the universal gas constant, T is the absolute temperature, and ΔT_{ad} is the adiabatic temperature rise. They state that in relative terms a reaction can be regarded as non-critical provided that for batch reactions $B < 5$ and for semi-batch reactions $B < 10$.

Another important parameter is the Damköhler number Da, which is a measure of the rate of reaction:

$$\mathrm{Da} = \frac{(-\nu_u)r_0 t}{c_0} \qquad [33.2.51]$$

where c_0 is the initial concentration of the limiting minor component, and ν_u is the stoichiometric coefficient of that component.

For a batch reaction the aim is to have a slow or only moderately fast reaction so as to avoid overloading the cooling capacity. For this $\mathrm{Da}<1$ is a suitable condition. By contrast, for a semi-batch reaction the aim is to maintain a reaction rate sufficiently fast to prevent the accumulation of reactants. This is assured provided that $\mathrm{Da}>100$.

A measure of the cooling capacity is given by the Stanton number St:

$$\mathrm{St} = \kappa t \qquad [33.2.52]$$

where for a batch reactor t is the reaction time and for a semi-batch reactor it is the time of addition τ_D.

For reactors with jacket cooling only a further criterion is the ratio of the Damköhler and Stanton numbers Da/St, known as the 'stability'. For a batch reactor, the ratio Da/St should be $<<1$ and for a semi-batch reactor it should be >1. For a multi-phase reaction, an effective Damköhler number is used which takes into account additional mass transfer phenomena.

The foregoing applies to the case of a well-mixed reactor at more or less constant temperature. Other conditions, particularly stoppage and restart, may be allowed for by using in the Damköhler number a critical temperature. For a batch reactor this critical temperature is the highest temperature which can occur in the reactor, and for a semi-batch reactor it is the lowest which can occur. This latter is the reference temperature T_{ref} defined as:

$$T_{\mathrm{ref}} = \frac{T_f + \mathrm{St}T_c}{1 + \mathrm{St}}$$

where subscripts c, f and ref indicate coolant, feed and reference, respectively. The reference temperature is the temperature produced in the reactor by feed addition and by cooling, but without reaction, and is the lowest which can occur, because the feed temperature is usually less than the jacket temperature. At this temperature, the rate of reaction is lowest and the danger of accumulation of reactants highest.

Reactor modelling

The most fundamental understanding of the reaction system is obtained by modelling it. An account of such modelling has been given by Gordon *et al.* (1982). These authors describe the modelling of the reaction of the amination of o-nitrochlorobenzene (ONCB) with aqueous ammonia under pressure to produce o-nitroaniline (ONAN). The study included the determination of the heat of reaction and the reaction kinetics for the animation and the heat of reaction and reaction kinetics for the decomposition of ONAN. The model was validated by comparing model predictions with ARC results and with temperature and pressure profiles of the plant reactors in normal operation and from a reactor incident.

Difficult reactions

One type of reaction that may be difficult to handle is one with a low activation energy, since this means that the reaction rate increases very rapidly with temperature. Another difficult type of reaction is one in which the vapour pressure of the reaction mixture is low. In this case, high temperatures can be reached before the pressure relief system responds. This problem is discussed by Regenass (1984).

Secondary reactions

In addition to the primary reaction, there may be one or more secondary reactions. If such a secondary, or side, reaction is exothermic, it may constitute a hazard. This problem has been discussed by Grewer *et al.* (1989).

Whether a secondary reaction occurs may be established using DTA. If it does, the temperature T_s at which the secondary reaction takes place is estimated by subtracting 100 K from the start of the reaction as given by the DTA. This estimate of T_s is compared with the reaction temperature T_r or the maximum possible reactor temperature $T_{\max}$:

$$T_{\max} = T_r + \Delta T_{\mathrm{ad}} \qquad [33.2.53]$$

where ΔT_{ad} is the adiabatic temperature rise (K), $T_{\max}$ is the maximum absolute temperature (K), T_r is the reactor temperature (K), and T_s is the absolute temperature of the secondary reaction. If the estimate of T_s is greater than $T_{\max}$ there is no hazard and further investigation is not required.

Use may also be made of the reaction energy of the secondary reaction. This may be obtained from the DTA by integration. A small reaction energy of $<110-220$ kJ/kg or an adiabatic temperature rise of $<50-100$ K indicates there is no hazard.

If the DTA does not yield clear-cut conclusions, it is necessary to obtain T_s more precisely. The AZT 24 may be determined. If this temperature is greater than $T_{\max}$, again there is no hazard.

If T_s lies between T_r and $T_{\max}$ there may be an appreciable hazard, but it may still be possible to carry out the reaction provided it can be ensured that the reactor temperature does not reach T_s during the primary reaction. Alternatively, if this cannot be guaranteed, use may be made of appropriate protective measures. Operation in this region is a specialist matter.

If T_s for a highly exothermic reaction is equal to or less than T_r, it is rarely possible to carry out the primary reaction safely. These guidelines are summarized in Figure 33.26.

Decompositions

Grewer *et al.* (1989) give the following guidance on decomposition reactions. For single phase decomposition of organic substances, if the decomposition energy based on total reaction mass is $<100-200$ kJ/kg, which corresponds roughly to $\Delta t_{\mathrm{ad}} \approx 50-100$ K, the effect of the decomposition is generally not critical. Even for a decomposition energy above the range just quoted, the effect may not be critical if there are other compensating effects such as endothermic reactions or high heat removal capacity. For inorganic substances the criterion decomposition energy should be lower, due to the lower specific heat, whilst for substances containing water it should be higher. The authors state that the decisive criteria are the adiabatic temperature rise ΔT_{ad} or the thermal reaction parameter *B,* which should not exceed about 8.

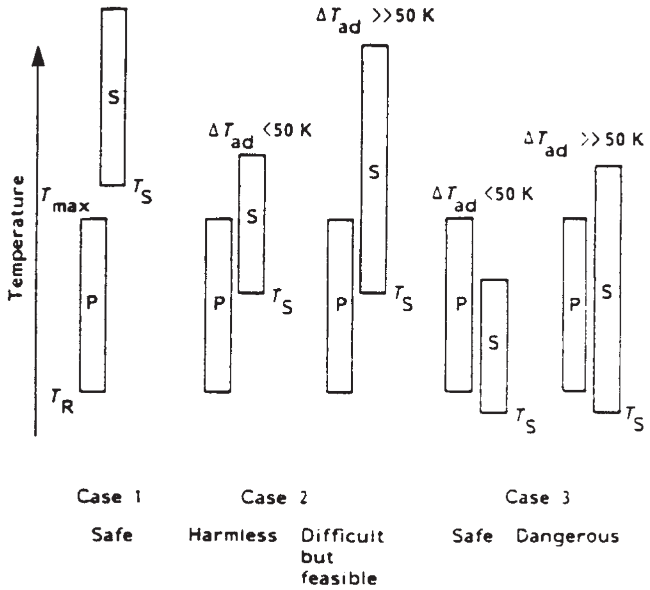

Figure 33.26 *Hazards of side reactions (Grewer et al., 1989) P, primary reaction; S, secondary reaction;* T_{max}*, maximum reactor temperature;* T_R*, temperature of reactor;* T_s*, temperature at which secondary reaction occurs;* ΔT_{ad}*, adiabatic temperature rise*

Spontaneous ignition

Another hazard of batch reactors is spontaneous ignition of vapour–air mixtures in the vapour space of the reactor. Work on this has been described by Snee and Griffiths (1989). The problem arises particularly in resin manufacture. Experiments were performed using cyclohexane as a substrate related to the components of resins, employing vapour-rich mixtures with molar ratios of cyclohexane/air of 1:2, in closed vessels in the size range 0.2–20 dm^3.

The work showed that fuel-rich mixtures undergo autocatalytic isothermal oxidation, that in this situation the temperature may be increased by self-heating and that as a result spontaneous ignition can occur. Self-heating was found to set in at temperatures just below the autoignition temperature. The minimum temperature for spontaneous ignition decreased as vessel size increased. Using the Semenov thermal explosion model, the authors were able to make comparative predictions of the trend of the minimum temperature with vessel size, but state that absolute predictions would require extremely accurate kinetic data.

Heat loss from reactors

Information on the rate of heat loss from a batch reactor has been given by T.K. Wright and Rogers (1986). They give data on cooling, mainly over the temperature range 96–80°C, for a range of reactors, of different sizes, stirred and unstirred, with different thicknesses of insulation and with none, and with jackets full and empty. The data are for reactors in the full condition.

They correlate the data by plotting the rate of cooling against the cube root of the volume, on the assumption that the rate is proportional to the surface/volume ratio of the reactor, which for a sphere is proportional to the reciprocal of the radius or of the cube root of the volume. Their results are shown in Figure 33.27. Also shown in the figure are the rates of heat loss from 250 and 500 ml Dewar flasks. These entries show that these flasks have heat losses comparable, respectively, to 0.5 and 2.5 m^3 reactors and will not give a satisfactory simulation above these reactor sizes.

33.2.5 Likelihood assessment

All scenarios identified as yielding high consequences are examined to determine the risk, if existing safeguarding measures are adequate, and if any additional measures are needed to reduce the risk to tolerable levels. The initial basis for evaluation can be the existing safeguarding philosophy and measures (including instrumentation, mechanical relief, kill systems, etc.) of the unit considered.

The risk associated with a scenario is the combined likelihood and consequence for that scenario. For scenarios that are ranked as 'high' consequence, the likelihood can be evaluated in qualitative terms (e.g. has already occurred in the company, has occurred in industry, etc.); semi-quantitative terms, as determined through, for example, a Layers of Protection Analysis (LOPA); or in quantitative terms, through a fully-executed Quantitative Risk Assessment (QRA). In LOPA, standard failure frequencies for various actions and barriers are combined with the safeguarding scheme logic to yield the likelihood of occurrence of the overall scenario consequence (not just the initiating event). This approach is much more expedient and much less resource-intensive than performing a rigorous QRA, thus making the LOPA an attractive balance between cost and meaningful results.

The likelihood assessment should take into account the availability and reliability of relevant factors in the possible development of a scenario. For example, probability of a

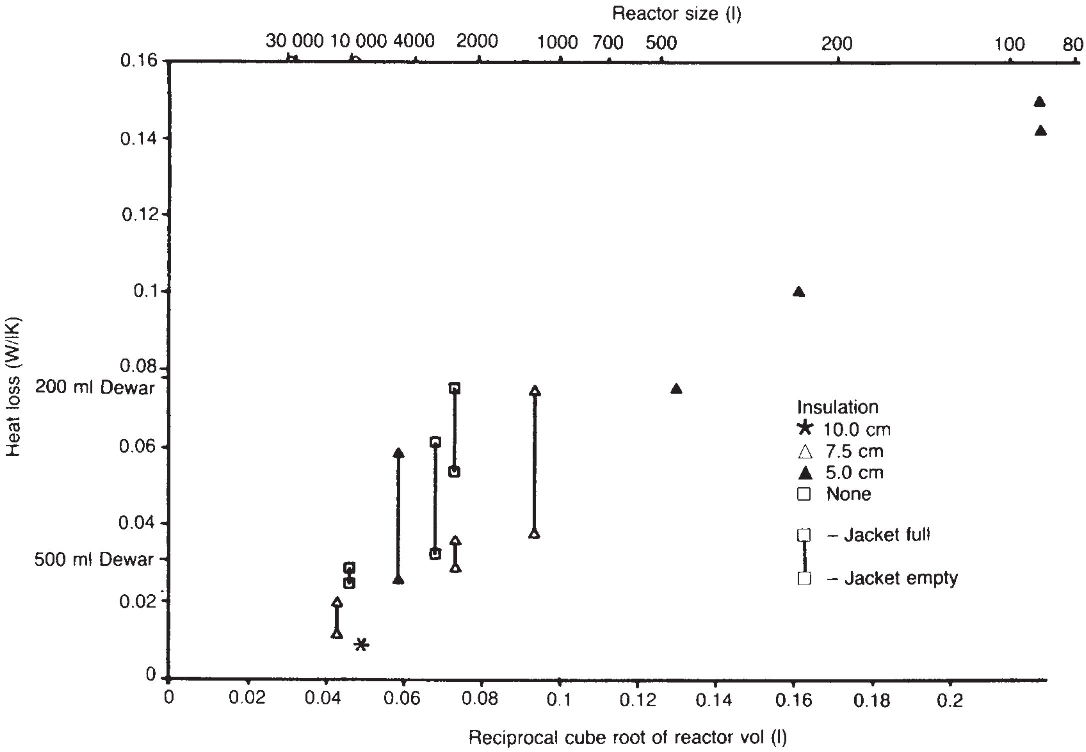

Figure 33.27 *Natural heat loss from reactors (T.K. Wright and Rogers, 1986) (Courtesy of the Institution of Chemical Engineers)*

deviation, process instrument failure, human error and human intervention can all be considered.

A process safety risk specialist with appropriate training should be involved in performing LOPA or QRA to determine the high consequence scenario likelihood. A process support or plant engineer as well as a reactive hazards specialist should provide input and guidance to the risk specialist to aid the likelihood calculations.

Once the likelihood has been obtained, the composite of the likelihood with the consequence gives the risk of the scenario reactive hazard. This risk should not exceed the corporate or organizational risk criteria. If the likelihood of an individual high consequence scenario does not exceed the tolerable threshold, then the scenario may be declared to be adequately safeguarded. In case the existing safeguarding measures cannot adequately reduce the consequence or likelihood of the high consequence scenarios, additional safeguarding or recovery measures are required. This may prompt the need to modify the safeguarding philosophy.

The selected set of measures to address scenarios with unacceptable risk should be based on regulatory requirements as well as technical and economical feasibility. In most cases, it will consist of a combination of several types of measures. The revised safeguarding philosophy should build upon the existing unit safeguarding philosophy and include extensions or changes recommended by plant operations, plant engineering, technical support staff and reactive hazards experts.

33.2.6 Prevention measures

In general, prevention is the preferred route to eliminate or reduce the consequences of high consequence scenarios. However, in practice this often requires significant process modifications that might not be economically feasible for existing units, as equipment might require changes. For new projects, however, this should be a major consideration in the design of the unit. Prevention measures can be divided in two categories – changes in process conditions (process changes) and changes to the hardware (design changes).

Process changes (inherent safety)

Process changes make the process inherently safer as they are inherent to the chemistry and therefore reduce the consequences of a scenario or eliminate a scenario. Some examples are given below:

1. Limiting the concentrations of the reactants (e.g. feedstock specification), which can reduce the maximum adiabatic end temperature and pressure to within the design limits of the unit.
2. Change to a non-reactive solvent.
3. Use of a different catalyst resulting in a lower operating temperature; however, such changes can often be a source of problems because it can make other undesirable reactions occur significantly at even lower temperatures, and the effects should be thoroughly tested.

Hardware changes

Hardware changes comprise any changes in equipment/hardware, excluding mechanical relief systems. Some examples are given below:

(1) Remove heating coil from storage tank to prevent product decomposition;
(2) Remove linework to prevent mixing of incompatible materials;
(3) Upgrade pressure rating of vessel (increased design pressure);
(4) Reduce flow rates by restricting orifices or smaller control valves;
(5) Eliminate or substantially reduce storage of reactive intermediate species.

33.2.7 Mitigation Measures

The initial basis for mitigation is the existing safeguarding philosophy of the unit considered. The actual safeguarding philosophy employed can be dependent on regulatory requirements as well as the amount and type of risk posed by the scenarios. For example, relief venting is frequently a more cost-effective means than high integrity instrumentation to limit pressure build-up in equipment. However, in several countries, relief venting is not the preferred option, particularly when potentially toxic or corrosive materials could be released. Moreover, there are cases where relief venting does not act as a mitigation measure, such as weakening of vessel wall integrity due to temperature excursions during syngas methanation. Two common categories of mitigation measures, instrumentation and emergency relief venting, are discussed in more detail elsewhere.

Addition of any single prevention or mitigation option or a combination thereof can be considered. Once intolerable risk levels are precluded, alternative mitigations can be evaluated through a cost/benefit analysis.

The outcome of this phase of the work should be documented *for each scenario*, indicating whether the existing safeguarding philosophy and safeguards are adequate or, if not, what specific measures are recommended.

Instrumentation and control

Safe operation of a batch reactor requires close monitoring and control of reactant and additive flows to the reactor, of the operating temperature and of the agitation. For the operating temperature, the temperature at which an uncontrolled exotherm will occur under plant conditions is first defined. A safety margin is set between the operating temperature and this plant exotherm temperature. The operating temperature is displayed and provided with an alarm. The reaction temperature is controlled by a coolant.

The measurement of the temperature of the reaction mass should receive careful attention. The instrument should not allow a hot spot to develop undetected and it should not have a large time lag or a high failure rate. It is good practice to have separate measurements for the temperature control loop and the temperature alarm.

Events which may cause the temperature to go out of control, such as agitator or coolant failure, are identified. Actions which can be taken to counter an increase in operating temperature such as shut-off of feed or use of full cooling are identified, and appropriate actions are selected to be activated either by operator intervention or by trip.

Too low an operating temperature may also pose a hazard in that it allows reactants to accumulate. A lower temperature limit should be specified and measures taken to maintain the temperature above this limit.

Loss of agitation has two effects, poor mixing and poor heat transfer. Poor mixing tends to lead to the accumulation of reactants. These reactants are then liable to react at some later time, particularly if the agitation is restored. Poor heat transfer may result in inadequate cooling. Either effect may lead to a runaway reaction. Provision should be made to detect loss of agitation, which may occur due to agitator stoppage or due to loss of the agitator paddle. The first condition may be detected by measuring the rotational speed, the latter by measuring power consumption. The action to be taken on loss of agitation depends on the reaction. In semi-batch reactors, it is common to provide a trip to shut off the feed.

The importance of matching the controls to the reaction and the danger of overenthusiastic use of generic controls has been highlighted by Brannegan (1985). More sophisticated measurement may be provided in the form of an on-line reaction calorimeter. Such a calorimeter has been described by Hub (1977c).

Increasingly, reactor control is based on computers or programmable electronic systems (PESs). The HSE guidelines on PESs give as an illustrative example the control of a nitration reactor. The example includes a full fault tree and failure data for the tree. An account is given in Chapter 13.

Emergency safety measures

There are a number of emergency measures that can be taken if a process deviation occurs that threatens to lead to a reaction runaway. The prime measures are:

(1) inhibition of reaction;
(2) quenching of reaction;
(3) dumping.

The reaction may be stopped by the addition of an inhibitor, or short stop. This involves the use of an inhibitor specific to the reaction in question. The effectiveness of inhibition, including the dispersion of the inhibitor within the reaction mass, needs to be demonstrated.

Quenching involves adding a quenching agent, usually water under gravity, to the reaction mass to cool and dilute it. This method requires that there be sufficient free space in the reactor to receive the quench liquid.

The third method is dumping, which involves dropping the reactor charge under gravity into a quench vessel beneath which contains a quench liquid.

Other methods that can be used to slow the reaction but are not generally ranked as prime emergency safety measures include:

(1) shut-off of feed;
(2) direct removal of heat;
(3) indirect removal of heat:
    (a) full normal cooling,
    (b) emergency cooling.

If the reactor is a semi-batch one, it is often possible to design it so that the reaction subsides when the feed is shut off. This principle has already been discussed. Another possibility is to slow the reaction rate by the addition to the charge of a liquid, which removes heat by vaporization. Heat may also be removed from the reactor by indirect cooling, either by application of full cooling on the normal cooling system or by the use of an emergency, or crash, cooling system.

Disposal of vented materials

The material vented from a reactor has to be safely disposed of. This aspect is intimately related to the venting of reactors and is therefore dealt with in Chapter 17.

33.2.8 Batch reactors: Reactor safety

Hazard identification

The hazard identification methods described in Chapter 8 may be applied to batch chemical reactors. This has been described by Pilz (1986), who refers to the use of a variety of techniques including a cause-consequence matrix, a hazop study, a FMEA, a fault tree, an event tree, and an incident sequence diagram (similar to a cause-consequence diagram).

A number of generic fault trees for reactors have been published. Figure 33.28 shows a fault tree given by the British Plastics Federation (BPF, 1979) and Figure 33.29 one given by Marrs *et al.* (1989).

Although for batch reactor plants the hazard of reaction runaway receives most attention, there are various other potential hazards which should not be neglected. Some of these have been discussed by Brannegan (1985).

The reaction stage of a process tends to involve various operations additional to the actual reaction, such as quenching, scrubbing and disposal. These operations also may involve scale-up problems and should receive careful attention

Basis of safety

For a given batch reaction, it is necessary to decide on an explicit safety philosophy, or basis of safety. Different approaches are appropriate for different reactions. The design may be guided by the characterization of the reaction already described.

Factors which affect the choice of the basis of safety include:

(1) reaction mode (batch, semi-batch);
(2) identified hazards and scenarios;
(3) practicalities of protection options;
(4) effect on reactor system operation;
(5) regulatory requirements.

In some semi-batch reactions the reaction may be, or may be arranged to be, such that shut-off of the feed is sufficient to cause the reaction to die out rapidly. In this case the design may depend mainly on this feature.

Bases of safety treated in detail in the IChemE *Guide* are:

(1) emergency relief;
(2) reaction inhibition;
(3) containment.

There may be practical difficulties with each of these options. For example, with venting disposal may present a severe problem. With containment the cost may be prohibitive. Another option that is increasingly pressed is reliance on control and trip systems. Whether this is permissible depends on the regulatory regime.

Selection of safety measures

Accounts of the measures for the safe design of a batch reactor include those by Christen (1980), Brannegan (1985), Berkey and Workman (1987), and N. Gibson, Rogers and Wright (1987), and the IChemE *Guide*. The application of the principle of inherently safer design has already been described with special reference to the use of a semi-batch reactor and to reaction temperature.

The approach described by N. Gibson, Rogers and Wright (1987) is based on formal process definition. Four levels of the process are defined:

(1) Level 1: fixed operating parameters;
(2) Level 2: normal variations in operating parameters;
(3) Level 3: generic fault conditions;
(4) Level 4: abnormal situations.

In Level 2 consideration is given to normal variation in the operating conditions. Some of the deviations are well recognized, others less so. Thus there may be an expectation that the temperature of a batch reaction could vary by, say, ±10°C. It may be less well appreciated that the holding time at a particular step may extend from a normal one hour to, say, 12 h over a weekend.

The effects of certain failures that are generic in that they apply to many reactions, such as loss of coolant, rupture of an internal coil, or agitator stoppage, is assessed in Level 3. The authors regard Level 3 as the minimum standard that leads to an acceptable level of safety in the majority of processes.

Level 4 is concerned with the large number of abnormal conditions that could conceivably lead to reaction runaway. These conditions may be explored using a method such as hazop.

The process definition should cover the operating parameters and the expected variations of these parameters (e.g. concentrations, temperature, hold times) and the details of the operations (e.g. pumping, agitation, cooling) which do not have assured protection by trips.

The safety measures described by Gibson, Roger and Wright are essentially process control to prevent reaction runaway emergency measures to stop an incipient runaway and measures of containment or venting to provide protection in the event that a runaway occurs.

The IChemE *Guide* takes an essentially similar approach.

Hazard assessment

Where the hazards identified warrant it, the reactor design may be subject to hazard assessment. One case where such an assessment may well be called for is a proposal to provide reactor protection by means of trips rather than venting. Hazard assessment of batch reactors in considered in Section 11.13 of Chapter 11. An illustrative example of such an assessment is given in Appendix 1 of the IChemE *Guide*.

Implementation of safety measures

The implementation of the safety measures selected is discussed by N. Gibson (1986b). His account is in effect an illustration of good practice in this aspect of the development of a process. The design and operating functions need to understand the basis of safety and the critical features of the measures proposed and the measures should be acceptable to them. The effect of any process or plant modification should be evaluated. It is then necessary that the safety measures are maintained.

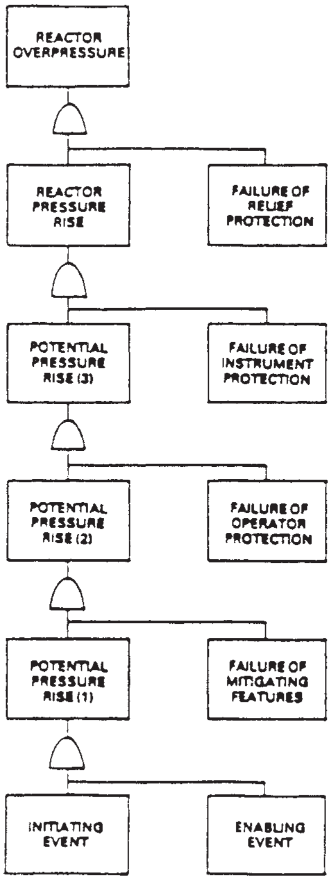

Figure 33.29 *Generic fault tree for assessment of hazards of batch reactors – 2 (Mans et al., 1989) (Courtesy of the Institution of Chemical Engineers)*

Regulatory strategy for reactors

The strategy developed by the HSE for control of the hazard from reactors has been described by Pantony, Scilly, and Barton (1989). From the analysis of incidents the authors conclude that the following are prominent causes:

(1) lack of understanding of the chemistry;
(2) inadequate engineering of the heat transfer;
(3) inadequate control and safety backup system;
(4) inadequate operational procedures.

They identify the need for guidance on:

(1) thermal hazards;
(2) vent sizing;
(3) process control.

For thermal hazards, the HSE has sought both to develop individual test methods to fill perceived gaps and to develop a test strategy.

Furthermore, the HSE has encouraged the development at the South Bank University an independent centre, the Chemical Reaction Hazard Centre (CRHC), where contract testing for thermal stability and process reactions can be carried out, and has sponsored work there. The centre provides a resource potentially of particular benefit to smaller companies. Work there has been described by Nolan and co-workers (Cronin, Nolan and Barton, 1987; Nolan and Barton, 1987). Cronin, Nolan and Barton have described the test instrumentation test scheme used. For venting, the approach is based on the DIERS work with some further development.

For process control, the HSE has sponsored the comparative study by Lees, Marrs and co-workers of protection by venting and by instrumented systems (Marrs *et al.* 1989; Marrs and Lees, 1989), which has already been described.

33.3 Programme management

33.3.1 Resourcing

Staff Skill

It should be evident that the proper assessment of reactive hazards involves

(1) collecting available reactivity information;
(2) developing reactivity information where gaps are apparent;
(3) determining conditions or circumstances in which the reactivity hazards can be manifested;
(4) evaluating the risk and
(5) preventing or mitigating risk where appropriate.

These steps require various and specialized activities and skills. Understanding of chemistry as well as of reactive hazards is needed in Step 1. An ability to recognize the information gaps, familiarity with testing instrumentation and knowledge for designing experiments are skills necessary for Step 2. Experience with plant operations and with potential deviations from those operations is critical for identifying credible scenarios in Step 3 (but not unique to assessment of reactive hazards). Detailed familiarity with estimating scenario consequences and likelihoods, for example, through process simulation and LOPA, respectively, in Step 4 is key to determining risk. Expertise in various prevention or mitigation approaches in Step 5, such as two-phase reactive relief design or protective instrumentation design, is important for handling intolerable risk.

Training and experience are important elements for ensuring that the process is carried out in a sound, technical manner. The skill-set needed for this work is highly specialized and should not be expected to be acquired in a short timeframe.

In principle, different staff could be needed to carry out various phases of the entire process. If this is the case, overlap or a strategy for effective transfer of knowledge between phases is necessary for continuity.

Participation and ownership

Experts in the reactivity area cannot *efficiently* assess the reactive hazards without input from process support and plant operations personnel. Substantial time spent re-discovering chemistry or learning about plant operations can be avoided when a team of reactive hazards experts, process support staff and plant operations staff work in concert.

Moreover, an equally important consideration toward building a cross-functional team is 'product ownership'. Crucial stakeholders, such as the technology and operations organizations, will give greater credibility and more easily accept the work product from a team that also represents them. Without such a team approach, there is a serious risk that the entire effort may be conducted in futility, because, in the end, no changes in the manufacturing facility may ever be implemented.

Timing and cost

The effort required for detailed experimental evaluation, kinetics extraction, process simulation model development and two-phase reactive relief evaluation can be formidable. It would be prudent to develop estimates for the extent of these activities as far in advance as possible and to budget accordingly.

In addition to the cost of staffing for the assessment of reactive hazards, there may be significant costs with acquisition and maintenance of equipment (such as calorimeters) as well as software (such as process simulators).

In addition to the possible significant cost associated with the effort, the amount of calendar time to carry out a complete evaluation (from collecting and analyzing data to designing safeguards) can be months or longer.

33.3.2 Risk management

To effectively manage risk (not just from reactive hazards), a company or organization should have its own definitions and methodology for assigning the level of risk Chapter X. The risk level can then serve as one criterion for prioritizing activities, investments, and expenditures.

An important element for facilitating decisions on issues (that are not driven by regulatory compliance) is the corporate or organization risk tolerance. This simply indicates the chosen level, below which, the risk is deemed to be 'tolerable' or 'acceptable'. A well-defined and documented risk tolerance level is useful for when and how much safeguarding is needed.

33.3.3 Implementation

As can be expected, the potential cost for implementing recommendations can often overshadow the assessment cost. This aspect should be understood by the manufacturing facility at the outset. However, it is also reasonable to presume that the reduced risk from potential reactive hazards-related events will greatly outweigh the combined analysis and implementation cost.

Once recommendations have been presented to a plant, they should be entered into a system for managing their implementation. This can mean combining with requests from other safety-related and operational initiatives. These items may then be prioritized based on risk, regulatory compliance or some other criteria. Handling the reactive hazards recommendations in such a system ensures that the recommendations are addressed, scheduled and executed in an appropriate manner.

Following implementation, it is useful to provide an assurance role to make sure that recommendations were indeed implemented and implemented as envisioned to reduce the reactive hazards risk. It can happen that 'fixes' are installed that bear insufficient resemblance to the original prevention/mitigation approach and do not help manage the risk. Verifying and validating the controls, equipment and systems put in place is therefore, a critical activity.

All documented analyses and recommendations should be integrated with plant process safety information so that there is ready access to the information, that plant personnel are familiar with the hazards and controls, and that the information will be incorporated in other programs and initiatives.

33.3.4 Management of change

The manner in which a facility handles management of change is an extremely important aspect of managing reactive hazards. Risk reduction measures implemented at a point in time can be circumvented or nullified by other seemingly innocuous changes that have been made. An engrained and rigorous management of change programme that includes consideration of reactive hazards is necessary to avoid 'creep' that quietly increases a facility's level of risk.

33.3.5 Program maintenance

Maintenance of a safety program to ensure that efforts are meeting needs requires continuous monitoring of systems, teamwork and a commitment to continual improvement. Development and growth of a safety programme can result from lessons learned from reviews of programmes and procedures, employee experience, audits, management of change, incidents including near miss incidents, equipment maintenance and new technology.

34

Safety Instrumented Systems

Contents

34.1 Introduction

Numerous case histories of process incidents are provided in Appendix A1-A6. The most effective way to prevent these incidents is use of inherently safer design to eliminate or reduce the potential hazard. Chapter 11.7 provides a discussion of inherently safer design principles. In addition, the Center for Chemical Process Safety book *Inherently Safer Chemical Processes: A Life Cycle Approach* (CCPS, 1996) provides an excellent source of information on reducing the inherent risk associated with process operation.

In many processes, technical or manufacturing issues limit the engineer's capability to design an inherently safer process. Further, there is generally a point where the required capital investment is disproportional to the additional risk reduction provided by the process modification. In other words, the derived safety benefit is too low relative to the economic investment.

When this occurs, protection layers or safeguards must be provided to prevent or mitigate the process risk. A safety instrumented system (SIS) is a protection layer, which shuts down the plant, or part of it, if a hazardous condition is detected. Accounts of SISs are given in *Reliability Technology* (A.E. Green and Bourne, 1972) and by Hensley (1968), R.M. Stewart (1971), Kletz (1972a), de Heer (1974), Lawley and Kletz (1975), Wells (1980), Barclay (1988), Rushton (1991a,b) and Englund and Grinwis (1992).

Throughout the years, SISs have also been known as emergency shut-down systems (ESDs, ESSs), safety shut-down systems (SSDs), safety interlock systems (SISs), safety critical systems (SCSs), safety protection systems (SPSs), protective instrumented systems (PISs), interlocks and trip systems. Regardless of what the SIS may be called, its essential characteristic is that it is composed of instruments, which detect that process variables are exceeding preset limits, a logic solver, which processes this information and makes decisions, and final control elements, which take necessary action on the process to achieve a safe state.

For start-up, the various instrumented permissives and operator actions must be defined. These permissives may require that certain process conditions exist prior to allowing start-up. They may also involve the use of temporary bypass of the SIS for start-up, such as the bypass of a low flow shut-down of a pump. From the case histories, it is apparent that the permissive and operator action requirements have often been ill-defined, allowing start-up under unsafe operating conditions.

The required performance or integrity of the SIS must also be defined. Not all SIS provide the same performance. In Figure 34.1, a single process switch is connected to a non-redundant programmable electronic system (PES) that de-energizes a single solenoid operated valve venting air from a process valve actuator, causing the fail-closed valve to go to the safe state. This SIS will not provide the same performance as the SIS shown in Figure 34.2, which shows 2oo3 (two-out-of-three) voting transmitters connected to a redundant PES that de-energizes solenoid operated valves venting air from the process valve actuator, causing the redundant fail-closed valves to go to the safe state. The former has no redundancy and is susceptible to multiple, single points of failure. The latter provides redundancy, fault tolerance, and the opportunity for implementation of on-line and fault tolerance. The latter provides redundancy, fault tolerance, and the opportunity for implementation of on-line diagnostics. The combination of redundancy and diagnostics yields a high level of confidence that the SIS will function when required. The selection between the design in Figure 34.1 and the one in Figure 34.2 is dependent on the amount of risk reduction that the SIS is expected to provide.

The risk reduction that the SIS must provide is defined by process hazards analysis, supplemented with semi-quantitative or quantitative evaluation. Qualitative process hazards analysis techniques, such as what-if analysis, checklists, and Hazard & Operability analysis (HAZOPs), are used to identify the causes and consequences of potential process hazards. Semi-quantitative or quantitative techniques are then used to evaluate the risk reduction requirements.

The semi-quantitative evaluation is typically performed using layers of protection analysis (LOPA). The CCPS book, *Layer of Protection Analysis: Simplified Process Risk Assessment* (CCPS, 2001) states that LOPA is used to determine whether there are sufficient layers of protection against potential process hazards. A brief introduction to LOPA is provided in this chapter, as it relates to SIS specification. In addition, refer to the hazards analysis chapter Chapters 8 and 9 for more information on general hazard assessment principles.

For quantitative risk assessment, the most commonly used technique is fault tree analysis. A brief

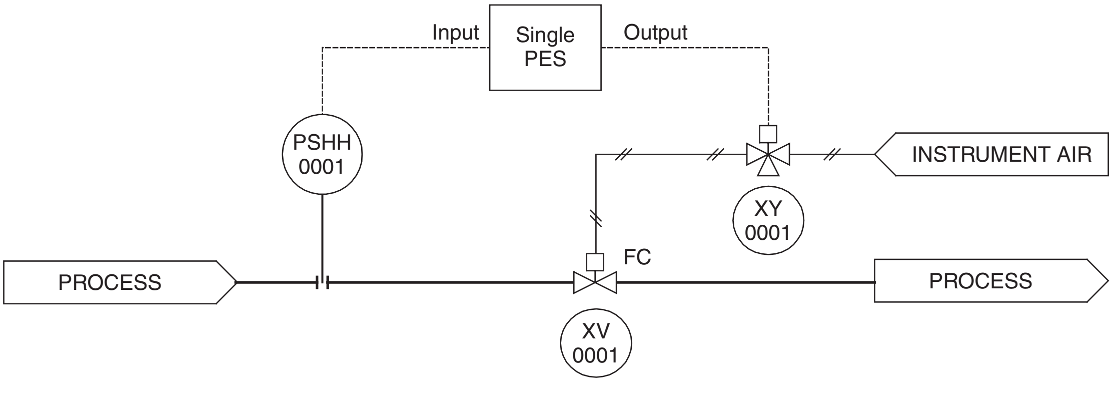

Figure 34.1 Simplex safety instrumented system (Courtesy of SIS-TECH Solutions, LP)

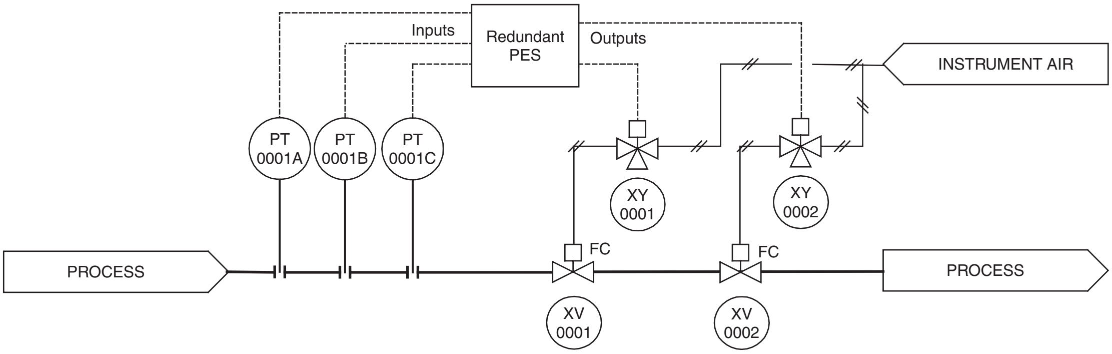

Figure 34.2 *Redundant safety instrumented system (Courtesy of SIS-TECH Solutions, LP)*

introduction to fault tree analysis is provided in Chapters 8.11 and 9.5.

The hazards analysis allocates risk reduction to the SIS. This risk reduction defines the integrity requirement for the SIS. Once the SIS functionality and integrity requirements are known, it is possible to design an SIS that will mitigate the process risk. However, the design simply represents the intended operation of the SIS. How the SIS is actually maintained, tested and managed determines the risk reduction that the SIS will achieve over its lifetime. For this reason, the US standard ANSI/ISA 84.01-1996 and the international standard IEC 61511 emphasize a lifecycle approach to SIS.

34.2 Examples of SIS

Some illustrations of the specification and design of protective systems have been given by Kletz (1972a, 1974a) and by Lawley and Kletz (1975). The applications include a hydrocarbon sweetening plant and a distillation column heating system.

An example of the use of SISs in a hydrocarbon sweetening plant is shown in Figure 34.3 (Kletz, 1972a). The hydrocarbon is sweetened with small quantities of air that normally remain completely dissolved, but conditions can arise that generate an explosive mixture. Initially, it was assumed that the principal problem lay in a change in the air/hydrocarbon ratio, but a HAZOP study revealed that a hazard could arise in a number of ways. One example is the formation of an air pocket, which can occur as follows:

(1) the temperature can be so high that the amount of air normally used will not dissolve;
(2) an air pocket can be left behind when a filter is recommissioned;
(3) the pressure can fall, allowing air to come out of solution;
(4) a fault in the mixer can prevent the air being mixed with hydrocarbon, so that the pockets of air can be carried forward;
(5) a fault in the air/hydrocarbon ratio controller can result in the admission of excess air.

In this case, it is also necessary for the feed to be above its flashpoint, which can occur in a number of ways: (1) the temperature can be above the design flashpoint and (2) the feed can contain low flashpoint material. Alternatively, if there is both a loss of pressure in the receiver and a failure of the non-return valve, hydrocarbon may find its way into the air receiver.

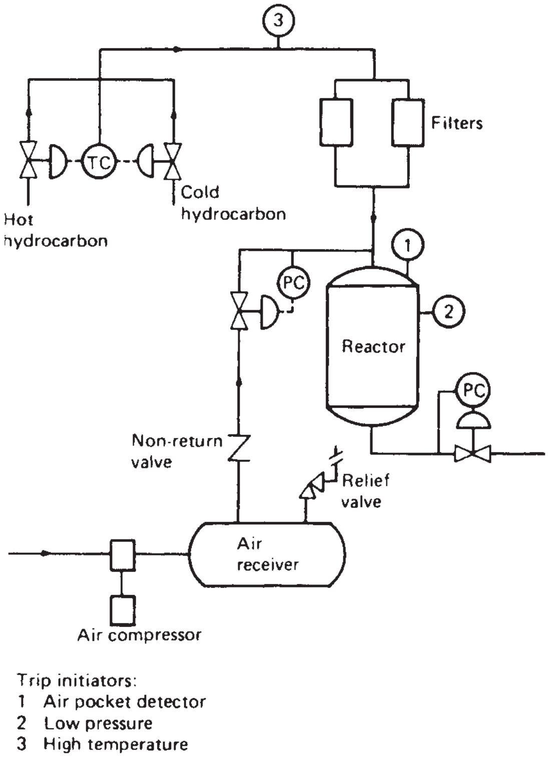

Figure 34.3 *Hydrocarbon sweetening plant (Kletz, 1972a) (Courtesy of the American Institute of Chemical Engineers)*

The fault tree for the hazard is shown in Figure 34.4. The probabilities of the various fault paths were evaluated from this tree and the SIS requirements were identified. The SIS

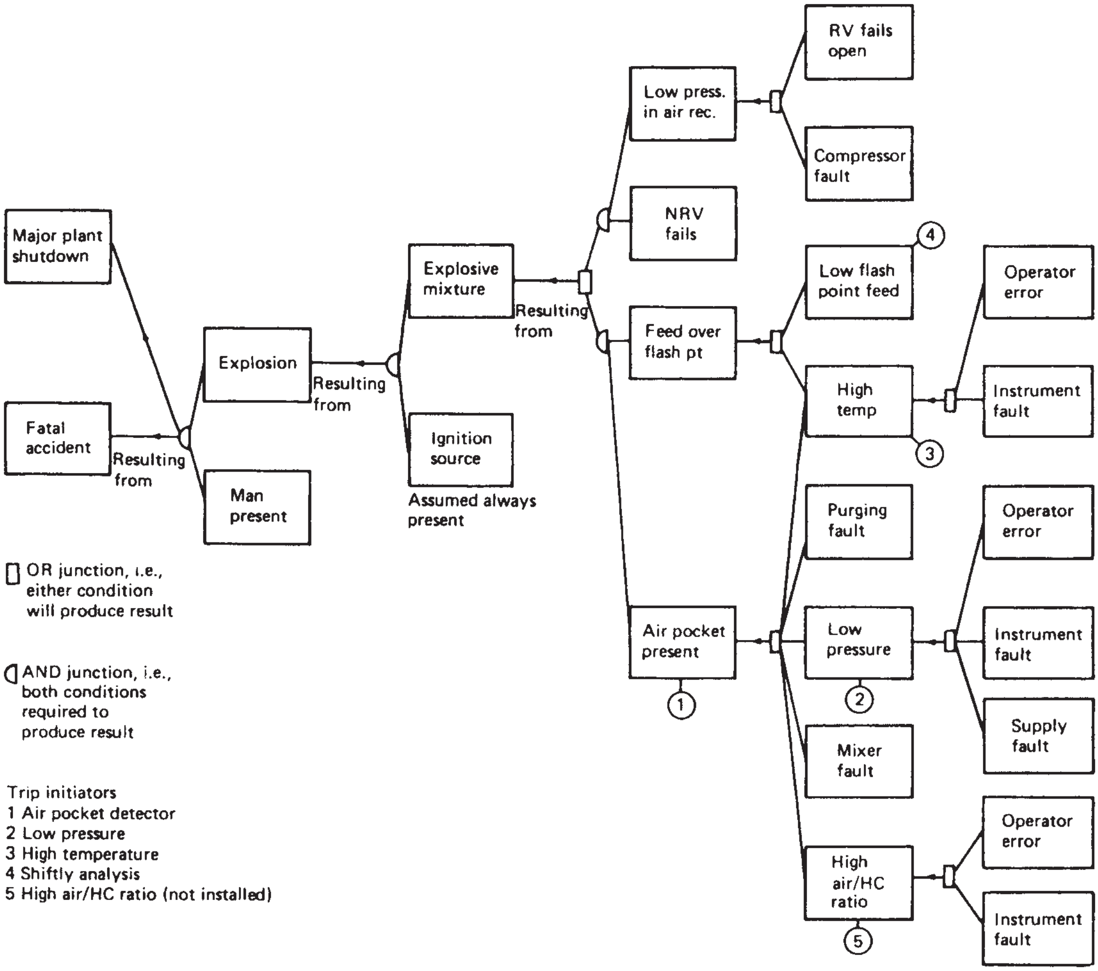

Figure 34.4 *Fault tree for explosion on a hydrocarbon sweetening plant (after Kletz, 1972a) (Courtesy of the American Institute of Chemical Engineers)*

initiators considered, shown by the circles in Figures 34.3 and 34.4, were

(1) a device for detecting a pocket of air in the reactor;
(2) a pressure switch for detecting a low pressure in the receiver;
(3) a temperature measurement device for detecting a high temperature in the feed;
(4) laboratory analysis for detecting a low flash-point feed;
(5) a device for detecting a high air/hydrocarbon ratio.

As the latter condition is detected by the SIS initiator 1, SIS initiator 5 was not used. The shut-down arrangement was that any of the SIS initiators 1–3 closes a valve in the air-line and shuts down the compressor. The use of the laboratory analysis of the feed flashpoint was restricted to ensuring that low flashpoint feeds were only present a sufficiently small fraction of the time to meet the system specification.

Another example is provided for a distillation column heating system, as shown in Figure 34.5 (Lawley and Kletz, 1975). Heat is supplied to the distillation column from an existing steam-heated reboiler and a hot-water-heated feed vaporizer. Plant throughput was to be increased by the addition of another reboiler and vaporizer.

Existing dual pressure relief valves were adequate to handle overpressure from the existing reboiler and vaporizer. The problem was to cope with the overpressure that the new reboiler and vaporizer might cause. Both re-sizing of the existing relief valves and the addition of a third were unattractive in the particular situation. Consequently, there was a requirement for an SIS that would shut-down both the steam to the new reboiler and the hot water pump on the new vaporizer.

Both 1oo1 and 1oo2 SISs were considered. The 1oo1 system consisted of a pressure switch for detecting high pressure on the overhead vapour line, a relay and a contact on the power supply to the hot water pumps and a relay and contact for de-energizing the solenoid operated valve closing the isolation valve on the reboiler steam supply. The summary of the failure rates of a simple SIS for this case is shown in Table 34.1. In the analysis, the authors determined that the simplex system could not achieve the fractional dead time (FDT) requirements. The authors therefore considered a 1oo2 SIS, which was a duplication of the 1oo1 system. It was concluded that a 1oo2 system did meet the target FDT. The spurious trip rate for this system, however, was high, which was unacceptable from a plant reliability standpoint. This led to a requirement for a 2oo3 voting system, which met the target FDT with a lower spurious trip rate.

34.3 SIS Standards

34.3.1 ANSI/ISA 84.01-1996

ANSI/ISA 84.01-1996 (ISA 84.01-1996) was issued in 1996 by the Instrumentation, Systems and Automation society. In 2000, the Occupational Safety and Health Administration (OSHA) acknowledged ISA 84.01-1996 as a standard that provides *generally accepted good industry practice* for the design of SISs. Consequently, the use of ISA 84.01-1996 ensures compliance with the process safety management programme (OSHA 1910.119 regulation). By the end of 2004, IEC 61511 will be accepted as ISA-84.00.01-2004 Parts 1–3 (IEC 61511 Parts 1–3 Mod), leading to a single global standard by which to judge SIS adequacy.

ISA 84.01-1996 is performance-based, using a benchmark called the 'safety integrity level' to define the adequacy of the SIS. During the process hazards analysis, the risk reduction that must be achieved by the SIS is determined. This risk reduction is equivalent to the safety integrity level. The risk reduction provided at each safety integrity level is shown in Table 34.2.

The SIS is designed and implemented to achieve the target safety integrity level (SIL). The standard has few prescriptive requirements, so the engineer designing the SIS relies on his or her experience to select appropriate instrumentation for the process application. The essential

Table 34.1 *Failure rates of trip systems for a distillation column heating system (Lawley and Kletz, 1975) (Courtesy of Chemical Engineering)*

Components	*Failure rate* (faults/year)		
	Fail-to-danger	*Fail-safe*	*Total*
Trip initiator			
Impulse lines – blocked	0.03	–	0.03
– leaking	0.06	–	0.06
Pressure switch (contacts open to give trip signal on rising pressure)	0.10	0.03	0.13
Cable fractured or severed	–	0.03	0.03
Loss of electrical supply	–	0.05	0.05
Total	0.19	0.11	0.30
Steam shut-off system			
Relay coil (de-energize to trip)	–	0.05	0.05
Relay contact	0.01	0.01	0.02
Relay terminals and wire	–	0.01	0.01
Solenoid valve (de-energize to trip)	0.10	0.20	0.30
Loss of electrical supply (to solenoid valve)	–	0.05	0.05
Trip valve (closes on air failure)	0.10	0.15	0.25
Air supply line – blocked or crushed	0.01	–	0.01
– fractured or holed	–	0.01	0.01
Loss of air supply	–	0.05	0.05
Total	0.22	0.53	0.75
Pump shut-off system			
Relay coil, contact, terminals and wire (as above)	0.01	0.07	0.08
	0.01	0.07	0.08

Table 34.2 *Safety integrity levels (SILs) according to ANSI/ISA 84.01-1996*

SIL	*Average probability of failure on demand*	*Risk reduction factor*	*Availability (%)*
1	10^{-1}–10^{-2}	10–100	90–99
2	10^{-2}–10^{-3}	100–1000	99–99.9
3	10^{-3}–10^{-4}	1000–10,000	99.9–99.99

Table 34.3 *Safety integrity levels (SILs) according to IEC 61508 and IEC 61511*

SIL	*Average probability of failure on demand*	*Risk reduction factor*	*Availability (%)*
1	10^{-1}–10^{-2}	10–100	90–99
2	10^{-2}–10^{-3}	100–1000	99–99.9
3	10^{-3}–10^{-4}	1000–10,000	99.9–99.99
4	10^{-4}–10^{-5}	10,000–100,000	99.99–99.999

requirement is that the overall architecture must be capable of achieving the SIL at its designated testing interval. Thus, the engineer has the flexibility to design an SIS to meet the SIS performance target and the operational goals for the facility.

After installation, the complete instrumented loop is tested to validate the SIS functionality. Operation, maintenance and testing procedures are developed to ensure long-term performance of the SIS. Finally, management of change is used to assess the impact of any change on the functionality of the SIS or the SIL that the SIS can achieve.

34.3.2 IEC 61508

IEC 61508, 'Functional Safety of Electrical/Electronic/Programmable Electronic (E/E/PES) Safety-related Systems,' is a global safety standard. IEC 61508 applies to many different industrial sectors, including transportation, manufacturing, medical and process. The standard serves as a framework and establishes minimum requirements for the development of sector-specific standards.

IEC 61508 consists of seven parts:

- Part 1: General requirements;
- Part 2: Requirements for E/E/PES;
- Part 3: Software requirements;
- Part 4: Definitions and abbreviations of terms;
- Part 5: Examples of the methods for the determination of SILs;
- Part 6: Guidelines on the application of parts 2 and 3;
- Part 7: Bibliography of techniques and measures.

IEC 61508 concerns any E/E/PES that is implemented to mitigate safety and environmental hazards posed by the 'equipment under control' (e.g. a distillation column). These hazards are identified during a hazards and risk analysis.

The standard uses a lifecycle approach to establish activities that should occur throughout the lifetime of a safety-related system from conceptual process design to decommissioning. Thus, the standard covers design, operation, maintenance and testing of safety-related systems.

Similar to ISA 84, IEC 61508 uses a risk-based approach for determining the required performance for safety-related systems. IEC 61508 has four safety integrity levels, as shown in Table 34.3.

Specific hardware and software criteria are provided based on the required performance. Further, the standard establishes various techniques and measures to be used to achieve successful implementation of safety-related systems.

IEC 61508 is the standard by which a manufacturer or supplier's product is judged. This provides greater assurance that the equipment used to implement the safety-related system, especially the PESs, meets a minimum burden of proof. This does not mean that the equipment will work well in all applications. It does mean that the supplier met minimum quality standards in terms of design, manufacturing and testing. As with all equipment, the user must still determine whether the device functions as intended when installed and operated in the process environment.

34.3.3 IEC 61511

IEC 61511, 'Safety Instrumented Systems for the Process Sector,' was issued by the International Electrotechnical Commission in 2003. IEC 61511 consists of three parts:

- Part 1: Framework, definitions, system, hardware and software requirements;
- Part 2: Guidelines in the application of IEC 61511-1;
- Part 3: Example methods for determining safety integrity in the application of hazard and risk analysis.

IEC 61511 is the first sector standard developed under the framework of IEC 61508. It represents an important step forward, because, for the first time, there will be a global standard that establishes the requirements for SISs used in the process industry. The worldwide acceptance of IEC 61511 will lead to a higher level of consistency in the SIS specification, design, operation, maintenance and testing. The standard is flexible, since it is performance-based, using the SIL as the benchmark. It then builds upon the performance requirements, using a lifecycle approach for the SIS design. Consequently, the standard does not mandate how an SIS should be designed for a specific application. Instead, it provides a framework for evaluating whether an SIS is needed, specifying the SIS functionality, and establishing the required SIS integrity.

The basic steps for compliance with IEC 61511 are as follows:

(1) Establish the risk tolerance for the process under consideration.
(2) Perform a process hazards analysis to determine the process risk associated with specific hazardous events.
(3) Identify the hazardous events where the process risk exceeds the risk tolerance.
(4) Identify the safety functions that reduce the process risk.
(5) Allocate risk reduction to each safety function.

(6) For non-SIS safety functions, document how the non-SIS safety function achieves the risk reduction and perform proof tests to ensure these functions work as intended.
(7) For SIS, define the functionality and integrity (i.e. required risk reduction) of the SIS.
(8) Document how the functionality and integrity will be achieved in a safety requirements specification.
(9) Design the SIS to achieve the functionality and required integrity.
(10) Develop SIS operation, maintenance and testing procedures to demonstrate functionality and to ensure required integrity.
(11) Quantitatively verify that the SIS design and intended procedures meet the required integrity.
(12) Fully validate the functionality of any new or modified SIS prior to introduction of hazardous chemical into the process.
(13) Use change management processes to ensure that the functionality and integrity are maintained during any SIS modification.
(14) Periodically audit the SIS documentation and installation for agreement with each other and the safety requirements specification.

34.4 Layers of Protection Analysis (LOPA)

LOPA is a semi-quantitative technique for assessing process risk. Dowell (1997, 1998) and Huff and Montgomery (1997) showed how LOPA could be used to determine the following:

- what SIL is required for an SIS;
- how many layers of protection are needed to reduce the risk to a tolerable level.

The intent of LOPA, according to *Layers of Protection Analysis* (CCPS, 2001) (the CCPS *LOPA book*), is to provide a rational, objective, risk-based approach to identifying and specifying the protection layers that are used to prevent or mitigate process risk. Process risk is defined by the frequency and severity of potential hazards. The severity may be assessed in terms of human impact, such as injuries and fatalities, environmental impact, such as noise, releases or spills, or financial losses, such as production loss or equipment damage.

The process risk is assessed in the absence of the protection layers. The process risk is then compared to the tolerable risk. Tolerable risk may be defined by the owner/operator of a facility, by an insurer, or by a governmental/regulatory body. If the process risk is equal to or less than the tolerable risk, no protection layers are required. If the process risk is greater than the tolerable risk, the gap is closed using protection layers that prevent or mitigate the process risk. The protection layers are designed to reduce the process risk to a tolerable level. Examples of protection layers are provided in Table 34.4 from *Guidelines for Safe Automation of Chemical Processes* (CCPS, 1993/14) (the CCPS *Safe Automation Guidelines*).

Table 34.4 *Layers of Protection (CCPS, 1993/14) (Courtesy of the American Institute of Chemical Engineers)*

1. Process design
2. Basic controls, process alarms, operator supervision
3. Critical alarms, operator supervision and manual intervention
4. Automatic SIS
5. Physical protection (relief devices)
6. Physical protection (containment dikes)
7. Plant emergency response
8. Community emergency response

LOPA builds upon traditional HAZOP techniques, using guidewords to identify process deviations and associated initiating causes that potentially propagate into hazardous events. LOPA determines the frequency of each initiating cause using either an order of magnitude assessment or estimated failure rate. The use of look-up tables can provide a consistent basis for this assessment. Hazards analysis teams often have difficulty when asked to make frequency judgements without any guidance, because they typically have no experience with operating the facility without the protection layers and consequently have little basis for making the assessment.

The consequence of the hazardous event is defined by: (1) the team using qualitative judgment, (2) look-up tables, or (3) consequence modelling for specific scenarios. The method chosen is typically dependent on the nature of the hazards present in a facility. If the hazards are easily understood by the team, the assessment may be completely qualitative with the team instructed to use past experience and process knowledge in its assessment. If the hazards are more complex, such as the overpressure of a vessel at an elevated location with release of hydrocarbons to the atmosphere, look-up tables may be given to the team to provide guidance on whether the release should be considered flammable. When toxic chemicals are involved, dispersion modelling may be required to ascertain the degree of impact to the on-site personnel or to the community.

With the initiating cause frequency and consequence, the unmitigated process risk can be determined:

$$\text{Unmitigated risk} = \text{initiating cause frequency} \times \text{consequence}$$

This unmitigated risk is compared to the risk tolerance criteria to determine whether protection layers are required. The risk tolerance can be defined as a specific, numerical target, such as 1 fatality in 10,000 years, or in general categories using a risk matrix as shown in Figure 34.6.

The consequence categories are defined in terms of safety, environmental and economic impacts. Safety is often evaluated in terms of potential fatalities, serious injuries, lost-time injuries or first-aid injuries. The safety category may also set different requirements dependent on whether these impacts occur on-site or off-site or whether the impacts are to plant personnel or members of the public. The environmental category may examine items such as environmental releases related to permit violations, plant or community response requirements (e.g. shelter-in-place or evacuation), or toxic gas levels. The economic category often examines losses associated with production interruption and equipment damage.

If a risk matrix is used, the required risk reduction can easily be determined once the frequency and consequence is known. For example, using Figure 34.6, with an

REQUIRED RISK REDUCTION MATRIX

CONSEQUENCE	**1**	10	100	1000	10000	TH
	2	NR	10	100	1000	10000
	3	NR	NR	10	100	1000
	4	NR	NR	NR	10	10
		10000	**1000**	**100**	**10**	**1**

FREQUENCY (1 in x years)

Figure 34.6 *Example risk matrix (Courtesy of SIS-TECH Solutions, LP)*

initiating cause frequency of 1 in 10 years and a consequence category of 2, the risk must be reduced by a factor of 1000 to achieve the risk tolerance. When a quantitative risk tolerance is defined, the process risk is compared to the quantitative target to determine the amount of required risk reduction.

When the unmitigated risk does not meet the risk tolerance, protection layers are used to reduce the risk to the risk tolerance. Any protection layer should meet the criteria established by the CCPS *Safe Automation Guidelines* and expanded by the *LOPA book*:

(1) Specific: The independent protection layer (IPL) is capable of mitigating or preventing the consequences of the specified hazard.
(2) Independent: An IPL is independent of the other protection layers associated with the specified hazard. Independence requires that each layer be unaffected by the failure of another protection layer or by the conditions that caused another protection layer to fail. Most importantly, the protection layer is independent of the initiating cause.
(3) Dependable: The protection provided by the IPL reduces the identified risk by a known and specified amount.
(4) Auditable: The IPL is subject to regular periodic validation or function testing.

The dependable criterion is related to the probability of failure on demand (PFD) of the protection layer and thus is a direct measure of the risk reduction that the protection layer can provide. Guidelines are typically developed to support LOPA by providing restrictions on the amount of risk reduction that can be allocated to any protection layer related to the protection layer's design, operation, maintenance and testing philosophy. Tables 34.5 and 34.6 provide examples of guidelines that might be developed for assessing the risk reduction provided by protection layers. The CCPS *LOPA book* also provides an extensive discussion about the protection layers, the range of risk reduction that can be expected from any protection layer, and, most importantly, limitations that should be considered prior to establishing any guideline used in a site-specific LOPA.

The overall risk reduction required to reduce the unmitigated risk to the tolerable risk may be provided by one protection layer or multiple protection layers. It is always important to evaluate the claimed protection layers against the independence criterion.

When the protection layer is a SIS, the risk reduction allocated to the protection layer is the SIL. This establishes the performance requirement for SIS, which must be met by the design, operation, maintenance and testing philosophy.

After allocating the appropriate risk reduction to the existing or planned protection layers, the mitigated risk is again compared to the tolerable risk. If the tolerable risk is not satisfied, recommendations for additional risk mitigation layers or design modifications should be made. LOPA is a tool used to ensure that process risk is successfully mitigated to the tolerable level. LOPA is a rational, defensible methodology that provides a rapid, cost effective means for identifying the IPLs that lower the frequency and/or the consequence of specific hazardous incidents. LOPA uses specific criteria and restrictions for the evaluation of protection layers, eliminating the subjectivity of qualitative methods at substantially less cost than fully quantitative techniques.

LOPA can be used at any point in the lifecycle of a project or process, but it is most cost effective when implemented during front-end loading, as soon as process flow diagrams are complete and the Piping & Instrumentation Diagrams (P&IDs) are under development. For existing processes, LOPA should be used during or after the HAZOP review. LOPA is typically applied after a qualitative hazards analysis has been completed, which provides the LOPA

Table 34.5 Typical risk reduction factors (RRF) used in layers of protection analysis (Courtesy of SIS-TECH Solutions, LP)

IPL	*Further restrictions on considering as IPL*	*RRF (typical)*
Operator intervention using operating procedures	The action should be independent from the initiating cause and any other IPL. If an operator action is the initiating cause, no risk reduction can be assigned to any operator action that solely relies on the same operator to recognize problem and quickly correct it. If the initiating cause is the basic process control system, no risk reduction can be assigned to any operator action that solely relies on BPCS information display (e.g. process conditions, indications) unless a detailed study of the BPCS is performed to ensure sufficient independence and redundancy in order to address common cause failure	
	Process Related Rounds and Inspections. Frequency of operator rounds should be sufficient to detect potential incident. If recognition of process variable is required, the operator should log specific values from sensors or valves that are independent of the initiating cause. The operator log should provide unacceptable out-of-range values. Standard Operating Procedures should describe response to out-of-range values	10
	Observational. Frequency of operator rounds should be sufficient to detect potential incident and mitigate ultimate scenario. Impending incident should be obvious to operator through normal visual or hearing range, that is, loud noise, high vibration, serious leaking, etc.	10
	Review. Independent, supervisory review and sign-off that work is complete and correct prior to start-up or returning component to service	10
	Action. An operator action that uses a different operator, relying on independent observation	10
	Corrective Action: An operator action taken based on a scenario where the event propagation is sufficiently slow that the operator has enough time to recognize the error and to correct it	10
	Alarm: The alarm with operator response should be examined to ensure that it is independent from the initiating cause and any other IPL. This includes not only independent field instrumentation but also an independent channel in the BPCS and independence of the operator (different operator). Only one BPCS-based alarm or BPCS function can be used as an IPL The RRF associated with alarms with operator response is based on the amount of time available for action and the location of the response. See Operator Time Restrictions Table for more information	See Table 34.6
Basic process control system (BPCS)	The BPCS should be independent of the initiating cause and any other IPL. If the initiating cause is a BPCS control loop, another the control loop's within the BPCS should not be designated as a BPCS IPL, unless a detailed study of the BPCS is performed to ensure sufficient independence and redundancy in order to address common cause failure. The RRF associated with a BPCS IPL is limited to 1 in 10 per IEC 61511	
	The control loops normal action will mitigate the scenario. The BPCS IPL should run in automatic mode during all operational phases where the accident scenario exists	10
Other/local	The IPL should be independent of initiating cause and any other IPL. It should be designed to mitigate the scenario	
Check valve (standard design)	Single check valve	(none)
	Dual check valves in series	10
Flame arrester	Should be designed to mitigate the scenario	100
Vacuum breaker	Should be designed to mitigate the scenario	100
Restrictive orifice	Should be designed to mitigate the scenario	100
Pressure regulator	Should be designed to mitigate the scenario	100

Table 34.5 *(continued)*

IPL	*Further restrictions on considering as IPL*	*RRF (typical)*
Special personnel protection equipment	Special personnel protection equipment (PPE) that is not normally worn by operation or maintenance personnel but is part of an established procedure. This PPE would include wire mesh gloves, fire suits, respirators, self-contained breathing apparatus, etc. The user of the equipment should be trained in the use of the PPE	(none)
Safety instrumented system	Should be independent of the BPCS. RRF is based on the SIL that is achieved by the complete functional loop	
	SIL 1	10
	SIL 2	100
	SIL 3	1000
Pressure relief valve (PRV)	Clean Service. PRV should be sized to completely mitigate the scenario	100
	Clean Service. More than one PRV is available to mitigate overpressure scenario. Each PRV listed should be capable of independently relieving the overpressure. Each PRV should be sized to completely mitigate the scenario	1000
	Clean Service. More than one PRV is available, but more than one is required to mitigate the full load. This includes staged release PRVs. To achieve an RRF higher than 10, the PRV calculations should be reviewed to determine whether the load can be successfully handled by each PRV, based on the specific scenario under review	10
	Plugging Service, that is, prone to plugging, polymerization, deposition, or has a history of failure to operate properly when tested. An unprotected PRV used in a plugging service is not considered sufficient for consideration as an IPL	10
	Plugging Service, that is, prone to plugging, polymerization, deposition, or has a history of failure to operate properly when tested. Redundant Pressure Relief Valves with separate process connections. Each PRV should be sized to completely mitigate the event	10
	Plugging Service, that is, prone to plugging, polymerization, deposition, or has a history of failure to operate properly when tested. Pressure Relief Valve with integrated rupture disk. PRV should be sized to completely mitigate the scenario	10
	Plugging Service, that is, prone to plugging, polymerization, deposition, or has a history of failure to operate properly when tested. Pressure Relief Valve with integrated rupture disk with purging. PRV should be sized to completely mitigate the scenario	100
Vessel rupture disk	Should be designed to mitigate scenario. Release should be evaluated for potential risk	100
Blast-wall/bunker	Process-related blast wall. This is not related to the control room design. The blast wall is typically designed to direct/contain the explosion away from the main process unit	1000
Fire detection with water deluge system	Operator initiated response. The RRF is based on operator alarm and response criteria, as listed in Operator Time Restrictions Table	Table 34.6
	Using fire detectors with automatic deluge, for example, foam, water curtain, water sprays, or emergency evacuation	10
Gas monitors with automated deluge	Operator initiated response. The RRF is based on operator alarm and response criteria, as listed in Operator Time Restrictions Table	Table 34.6
	Using gas monitor with automatic response, for example, water cannons, water sprays, or emergency evacuation	10

Table 34.6 *Typical operator time restrictions with associated risk reduction factors (RRF) (Courtesy of SIS-TECH Solutions, LP)*

For all listings in the table below, the alarm and operator response should be evaluated to ensure that the components and actions are independent of the initiating cause. In all cases, the alarm must not be operator re-settable. The operator response time should consider the time it takes to recognize the alarm, to diagnose the problem, and to fully initiate action. This is compared to the process time, taking in account how rapidly the process moves from the alarm condition to the incident condition

Time (min)	*Where*	*How many*	*Restrictions*	*RRF*
<10	Any	Any	Operator must troubleshoot the alarm and determine appropriate response	1
2–10	Control room	Single operator	Drilled response, also known as a '**never exceed, never deviate**' response. If the alarm is received, the operator should execute a specific action every time without delay. Staffing should also be adequate so that there is an operator present at all times to respond to the alarm. If the operator response is to troubleshoot the alarm, less than 10 min is not an adequate amount of time and no RRF is allowed	10
>10	Control room	Single operator	Operator action is complicated, that is, large number of alarms generated by initiating cause and the response is not clear or documented	1
>10	Control room	Single operator	The operator is trained on alarm response, has procedures available to examine and practices the action periodically	10
>10	Control room	Two operators	All operators listed must receive the same information. Both operators can make independent responses, which completely mitigate the event. Alarm must not be operator re-settable. The operators are trained on alarm response, have procedures available to examine and practice the action periodically	100
>20	Field	Single operator	The operator is trained on alarm response, has procedures available to examine and practices the action periodically	10
>20	Field	Two operators	All operators listed must receive the same information. Both operators can make independent responses, which must completely mitigate the event. Alarm must not be operator re-settable. The operator is trained on alarm response, has procedures available to examine and practices the action periodically	100

team with a listing of hazard scenarios with associated initiating causes, consequence ratings and potential safeguards for consideration as IPLs.

34.5 Level of Automation

The allocation of function between the operator and the control system is a principal theme in human factors analysis and is discussed in Chapter 14. Of particular interest is the allocation of control and protective functions to the process operator or the instrumented system.

34.5.1 Illustrative example: steam boiler protective system

A case study of the optimum level of automation has been described by Hunns (1981). The system investigated was the protective system for a large steam plant. The plant consisted of a 100 MW boiler operating at 1500–2000 psi and producing 500 ton/h of steam. The boiler was dual fired with oil and gas. The principle features of the three candidate control and protective systems are shown in Table 34.7.

Each system was assessed for its reliability in the start-up and operational phases of the plant. A variety of start-up sequences was considered, since each shut-down event resulted in the requirement for a different start-up sequence. Some 200 logic diagrams were produced.

The criterion used to determine the optimum system was a function of the type of expected shutdowns, which were. These were classified as low penalty and high penalty. Low penalty shut-downs were unwanted shut-downs due to spurious trips and correct shut-downs in response to a demand. High penalty, or catastrophic, shut-downs were those caused by a demand to which the protective system did not respond.

One such case is an excessive release of unignited fuel into the combustion chamber. Figure 34.7 shows a section of the logic, which the authors term 'matrix logic'. Events identified by the analyst are shown in the left-hand column. A particular event sequence is shown by a vertical column of the matrix containing one or more dots. The circle enclosing the '&' symbol at the head of the column indicates that the events are ANDed together. The set of event sequences is collected under the OR symbol, which indicates that these event sequences are related to the top event, the unignited release, by OR logic.

The device failure data were taken from the Safety and Reliability Directorate SYREL data bank. Human error was estimated based on expert judgement. There were almost 180 human errors estimated by two experienced analysts. Performance shaping factors were assessed, such as available time to react, prior expectancy, conspicuity of task and perception of consequence. Good agreement was obtained between the two analysts for most human errors. Those estimates that were particularly critical, or where a divergence between the two analysts had occurred, were mediated by a third, independent analyst.

The results of the study were expressed in terms of the number of low and high penalty shut-downs per year and the corresponding mean outage time. The mean outage of low penalty events was taken as 1/3 days/event and that of high penalty events as 60 days/event. The manual system resulted in appreciably more high penalty shut-downs but fewer with low penalty and overall a higher outage than the other two systems. The medium automated system yielded slightly more high penalty shut-downs and fewer low penalty shut-downs than the highly automated system, but the same outage time. On a lifecycle cost basis, for which the highly automated system had higher capital and maintenance costs, the medium automated system was superior. The total lifecycle costs of the three systems – manual, medium automated and highly automated – were £0.122, 0.095 and 0.099 million/year, respectively.

34.6 Design

Appropriate SIS design requires that the engineer understand the underlying purpose of the SIS. This entails reviewing the process hazards analysis (PHA) documentation to better define the required SIS functionality and integrity. These basic requirements should then be developed into complete specifications.

The functional specification should include the following:

- Definition of the process safe state;
- SIS inputs, voting configuration and trip points;
- SIS outputs, redundancy requirements and safe state actions;
- functional relationship between inputs and outputs;
- automatic diagnostics for inputs and outputs;
- provisions for bypassing, testing and maintenance;
- provisions for manual shut-down;
- required reset actions;
- response time requirements for SIS actions;
- means by which alarm, trip and diagnostic information is to be communicated to plant operator.

Table 34.7 *Elements of three candidate protective systems for a large steam boiler plant (after Hunns, 1981) (Courtesy of Elsevier Science Publishers)*

Control and protective features	*Protective system design*[a]		
	Manual	*Medium automated*	*Highly automated*
Trip parameters[b]	A	A	A
Boiler purge sequence	M	A	A
Burner flame failure detection	M	A	A
Gas valves leak test	M	M	A
Ignition burner control	M	M	A
Burner fuel valves operation	M	A	A

[a] A, automated; M, manual.

[b] Low boiler drum level; low combustion air flow; low instrument air pressure; low fuel oil pressure; low atomizing steam pressure; low fuel gas pressure; high fuel gas pressure; high knockout drum level; and loss of 110 V DC supplies.

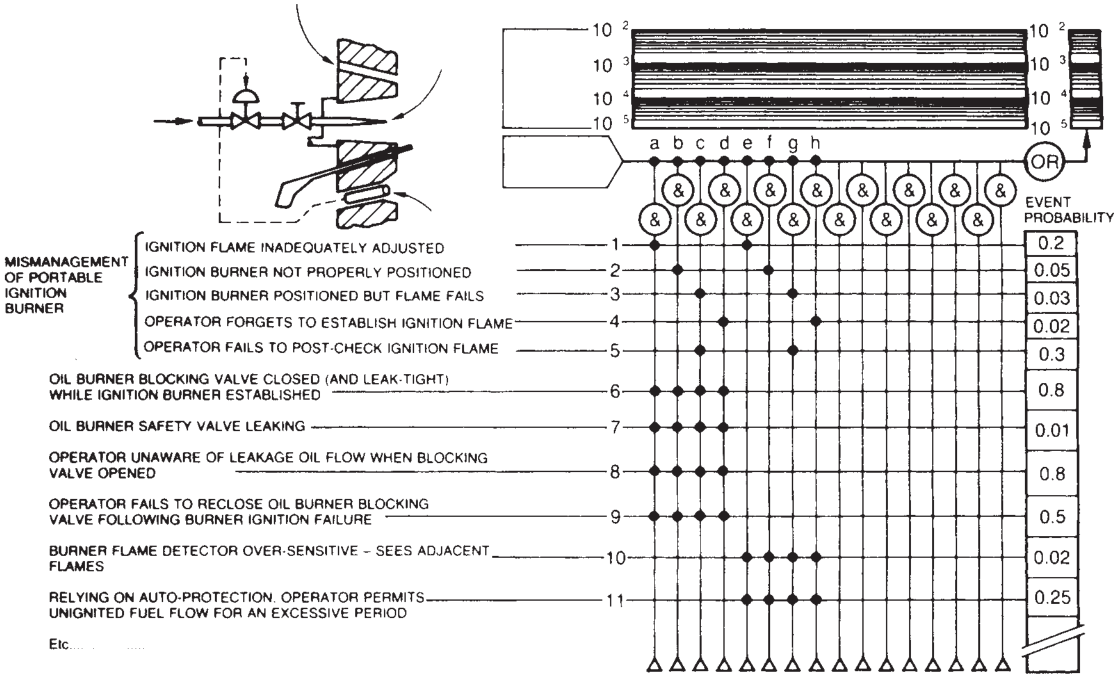

Figure 34.7 *Matrix logic diagram for a steam boiler protective system: event 'excessive unignited fuel release' (Hunns, 1981) (Courtesy of Elsevier Science Publishers)*

The integrity specification should include the following:

- integrity level assigned to the SIS;
- testing interval requirements;
- limitations on acceptable spurious trip rate.

Once the functionality and integrity requirements are fully understood, the design process can begin. The following section will provide a discussion of the following: (1) separation of basic process control system (BPCS) and SIS, (2) response time requirements, (3) power supply, (4) choosing components, (5) integration of SISs and (6) field design.

34.6.1 Separation of BPCS and SIS

Prior to the implementation of modern digital control systems (DCSs), the process industry relied on local control systems for day-to-day operation and local relay systems for shut-down functions. The design was inherently separated. The local pneumatic controller had its own transmitter and control valve. The relay system used separate process switches and dedicated final elements.

As technology changed, there was intense pressure to combine these systems. However, the implementation of complex PESs makes it increasingly important to maintain the independence of the BPCS and the SIS. When these systems are combined, the SIS functions may be impacted by normal activities that take place within the BPCS, such as optimization of process control logic and manual control activities carried out by the operator.

Most process control systems involve some sequential control even if it is largely limited to start-up and shut-down. The sequential logic should operate in such a way as not to cause any safety problems. Its operation should be tested against the SIS logic to ensure that normal operation of the sequential control does not trigger unnecessary SIS action or inhibit any required SIS action. BPCS provides protection against hazardous events by maintaining the process within control tolerances. Process alarms are issued to the operator through the BPCS human–machine interface, notifying the operator that the process has exceeded preset process conditions. This allows the operator the opportunity to bring the process back into control, preventing a unit shut-down.

CCPS *Safe Automation Guidelines* discusses the safety considerations in the selection and design of the BPCS. The topics covered include: (1) the technology selection, (2) the signals, (3) the field measurements, (4) the final control elements, (5) the process controllers, (6) the operator/control interfaces, (7) communication considerations, (8) electrical power distribution systems, (9) control system grounding, (10) batch control, (11) software design and data structures and (12) advanced computer control strategies. The design philosophy of CCPS *Safe Automation Guidelines* requires that the BPCS and the SIS be separate systems. This ensures that the integrity of the SIS cannot be compromised by the BPCS.

IEC 61511 provides restrictions on the assumed failure rate of the BPCS and the risk reduction that can be claimed for it as a protection layer. It also discusses the analysis of common cause failures between the BPCS and other layers of protection including the SIS. The BPCS and SIS must be functionally independent such that no failure of the BPCS can prevent the SIS from functioning.

IEC 61511 also recommends the use of separation and diversity to achieve high SILs. For example, if the control valve can be the initiating cause for the hazard, the control valve should not be used as the primary shutdown device. Instead, a dedicated shutdown device should be provided to mitigate the risk. In the case of high SIL requirements, redundant, dedicated shutdown devices are often implemented.

34.6.2 Response time requirement

The dependability of an SIS is based on its functionality and integrity. An important aspect of functionality is the dynamic response. The dynamic response of instrumentation is illustrated in Figure 34.8. It is assumed in the figure that, when a fault occurs, the variable increases linearly from its normal level to the danger level. The nominal trip point is established somewhere along this ramp using an appropriate safety margin from the hazardous condition. However, the trip often does not occur at the specific point in time corresponding to this process variable condition. There will normally be delays due to (1) sampling, (2) dynamic response of the measuring instrument and (3) normal measuring instrument error. Even when the measuring instrument has responded, there will be delays in the safety circuitry and the closure of the shut-down valve. There will be a further delay in the process itself, due to the amount of time required for the valve closure to affect the process variable. All of these factors, delays and errors erode the available safety margin and should be considered carefully. The maximum rate of rise of the process variable is also critical. If the process variable rises very rapidly, SIS valve closure speed may become a major design factor.

Further reduction of the nominal trip point may be appropriate, but the setting should not be put so low that noise in the process variable measurement activates the trip at normal operational conditions. After all, a spurious trip can arise from a low trip set point, as well as from instrument unreliability.

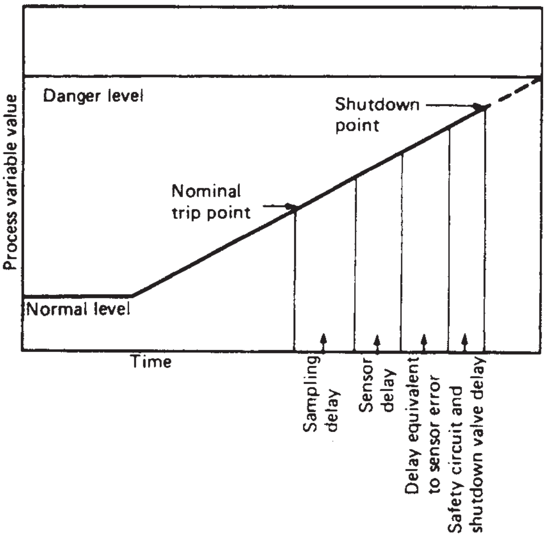

***Figure 34.8** Effect of instrument error and dynamic response on the safety margin in a trip system (after Hensley, 1988) (Courtesy of the institute of Measurement and Control)*

The dynamic response of the hazard scenario against which the SIS is designed to protect may be modelled using standard methods. An account of unsteady-state modelling of process operations is given in *Mathematical Modeling in Chemical Engineering* (Franks, 1967) and the modelling of instrumentation is treated in texts on process control, such as those by Harriott (1964) and Coughanowr and Koppel (1965).

The following treatment is confined to the dynamic response of the measuring instrument or sensor. The inputs to a sensor are generally characterized by a set of idealized forcing functions, of which the main types relevant here are: (1) the step function, (2) the ramp function and (3) the impulse function. The unit step function changes suddenly at time zero from a value of zero to a value of one. The unit ramp function increases linearly with time and has a slope t. The unit impulse is a function that is infinitely large at time zero and zero elsewhere, but also has an area that is unity. These three forcing functions are shown in Figure 34.9(a)–(c).

The device is typically modelled as either a first- or second-order system. Thus a temperature sensor might be modelled as a first-order system:

$$Mc_p\frac{\mathrm{d}T}{\mathrm{d}t} = UA(T_{\mathrm{i}} - T) \qquad [34.6.1]$$

where A is the area for heat transfer to the sensor, c_p is the specific heat of the sensor, M is the mass of the sensor, t is time, T is the temperature of the sensor, U is the overall heat transfer coefficient, and the subscript i indicates input, or forcing. Thus, T_{i} is the temperature of the surrounding fluid.

Equation 34.6.1 may be written in the more general form for a first-order system as:

$$\tau\frac{\mathrm{d}T}{\mathrm{d}t} = T_{\mathrm{i}} - T \qquad [34.6.2]$$

where

$$\tau = Mc_p/UA \qquad [34.6.3]$$

and τ is a time constant. The lag described by Equation 34.6.2 is known as a 'transfer lag'.

In this case, the model obtained is a linear one. If the model obtained is non-linear, it needs first to be linearized. A non-linear model is obtained, for example, if the mode of heat transfer to the sensor is radiation rather than conduction.

The normal approach is then to express each term in the linear model as the sum of the steady-state value and the transient component. Given θ as the transient component of temperature and the subscript ss as steady state, Equation 34.6.2 then becomes:

$$\tau\frac{\mathrm{d}(T_{\mathrm{ss}} + \theta)}{\mathrm{d}t} = (T_{\mathrm{i,ss}} + \theta_i) + (T_{\mathrm{ss}} + \theta) \qquad [34.6.4]$$

The corresponding steady equation is:

$$0 = T_{\mathrm{i,ss}} - T_{\mathrm{ss}} \qquad [34.6.5]$$

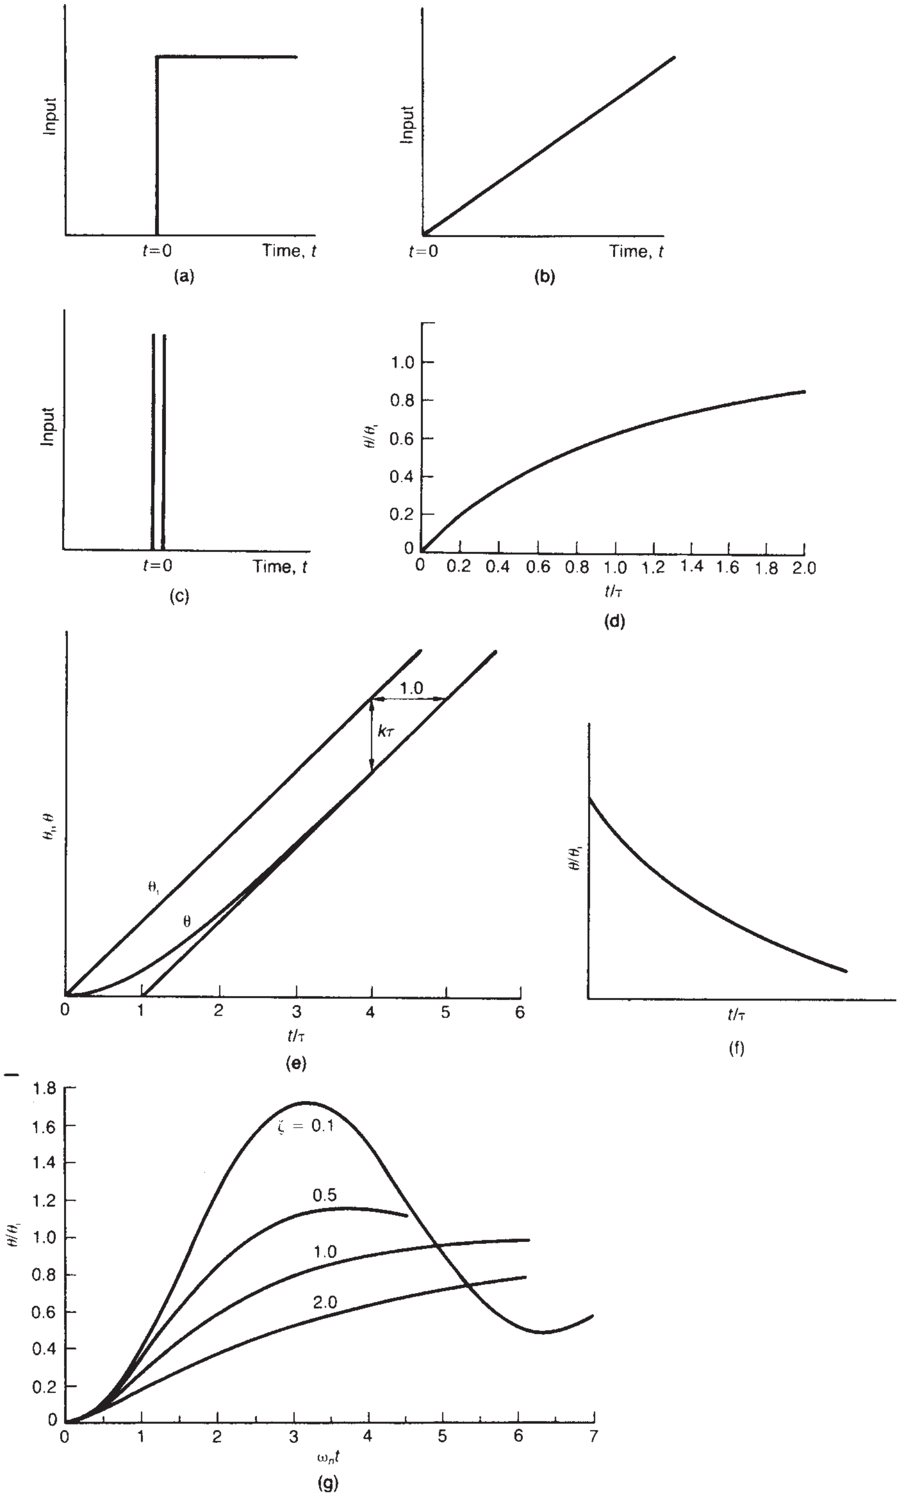

Figure 34.9 *Dynamic response of sensor systems: (a) step forcing function; (b) ramp forcing function; (c) impulse forcing function; (d) response of first-order system to step forcing function; (e) response to first-order system to ramp forcing function; (f) response to first-order system to impulse forcing function; (g) response of second-order system to step forcing function. For second-order system:* ω_n, *natural frequency:* ζ, *damping factor*

Subtracting Equation 34.6.5 from Equation 34.6.4 gives:

$$\tau\frac{\mathrm{d}\theta}{\mathrm{d}t} = \theta_{\mathrm{i}} - \theta \qquad [34.6.6]$$

Equation 34.6.6 is then transformed into the Laplace, or *s*, domain by taking the Laplace transform:

$$s\bar{\theta} - \theta(0) = \bar{\theta}_{\mathrm{i}} - \bar{\theta} \qquad [34.6.7]$$

Taking the initial condition as the steady state with zero deviation gives $\theta(0) = 0$ and hence the ratio of the output to the input, or the transfer function, is:

$$\frac{\bar{\theta}}{\theta_{\mathrm{i}}} = \frac{1}{1 + \tau s} \qquad [34.6.8]$$

The response of the first-order system to the three forcing functions is then as follows. For the step response:

$$\theta_{\mathrm{i}} = k \qquad [34.6.9]$$

where k is a constant. Taking the Laplace transform of Equation 34.6.9 gives

$$\bar{\theta}_{\mathrm{i}} = \frac{k}{s} \qquad [34.6.10]$$

Substituting Equation 34.6.10 in Equation 34.6.8 gives:

$$\bar{\theta} = \frac{k}{(1 + \tau s)s} \qquad [34.6.11]$$

Inverting the Laplace transformed expression in Equation 34.6.11 back into the time domain:

$$\theta = k[1 - \exp(-t/\tau)] \qquad [34.6.12]$$

Equation 34.6.12 is sometimes written as:

$$\frac{\theta}{\theta_{\mathrm{i}}} = 1 - \exp(-t/\tau) \qquad [34.6.13]$$

Where this is done, it should be noted that θ_{i} is a constant, defined by Equation 34.6.9, whereas in Equation 34.6.6 it was a variable.

For the ramp response, θ_{i} is given as:

$$\theta_{\mathrm{i}} = kt \qquad [34.6.14]$$

$$\bar{\theta}_{\mathrm{i}} = \frac{k}{s^2} \qquad [34.6.15]$$

$$\bar{\theta} = \frac{k}{(1 + \tau s)s^2} \qquad [34.6.16]$$

$$\frac{\theta}{\theta_{\mathrm{i}}} = \tau\left\{\frac{t}{\tau}[1 - \exp(-t/\tau)]\right\} \qquad [34.6.17]$$

The ramp response has the important property that

$$\frac{\theta}{\theta_{\mathrm{i}}} = t - \tau \qquad t \to \infty \qquad [34.6.18]$$

In other words, after an initial transient, the measured value lags the actual value by a time equal to the time constant τ.

For the impulse response:

$$\theta_{\mathrm{i}} = k\delta(t) \qquad [34.6.19]$$

$$\bar{\theta}_{\mathrm{i}} = k \qquad [34.6.20]$$

$$\bar{\theta} = \frac{k}{1 + \tau s} \qquad [34.6.21]$$

$$\frac{\theta}{\theta_{\mathrm{i}}} = \frac{1}{\tau}\exp(-t/\tau) \qquad [34.6.22]$$

where $\delta(t)$ is the impulse function. The step, ramp and impulse responses of a first-order system are shown in Figures 34.9(d)–(f).

An over-damped second-order system is equivalent to two transfer lags in series. The basic model is therefore:

$$\tau_1\frac{\mathrm{d}T_1}{\mathrm{d}t} = T_{\mathrm{i}} - T_1 \qquad [34.6.23]$$

$$\tau_2\frac{\mathrm{d}T_2}{\mathrm{d}t} = T_1 - T_2 \qquad [34.6.24]$$

where subscripts 1 and 2 indicate the first and second stages, respectively.

The transfer function of the second-order system is:

$$\frac{\bar{\theta}_2}{\theta_{\mathrm{i}}} = \frac{1}{(1 + \tau_1 s)(q + \tau_2 s)} \qquad [34.6.25]$$

The step response is:

$$\frac{\theta_2}{\theta_{\mathrm{i}}} = 1 - \frac{1}{\tau_1 - \tau_2}[\tau_1\exp(-t/\tau_1) - \tau_2\exp(-t/\tau_2)] \qquad [34.6.26]$$

The impulse response is:

$$\frac{\theta_2}{\theta_{\mathrm{i}}} = \frac{1}{\tau_1 - \tau_2}[\exp(-t/\tau_1) - \exp(-t/\tau_2)] \qquad [34.6.27]$$

The step response of a second-order system is shown in Figure 34.9(g).

It is sometimes required to provide an unsteady-state model of the sensor for incorporation into an unsteady-state model of the total system. In this case, an equation such as Equation 34.6.2 may be used for a first-order system and a pair of equations such as Equations 34.6.23 and 34.6.24 for a second-order system.

The three forcing functions may be illustrated by a flammable gas cloud as seen by a gas detector. The gas cloud may be seen by the sensor as any one of these forcing functions. The gas concentration may rise suddenly from zero to a value that remains constant (step function), it may rise linearly (ramp function) or it may rise momentarily from zero to a high value and then subside as rapidly (approximated by an impulse function).

An account of the time lags that occur in SISs has been given by R. Hill and Kohan (1986), who characterize the dynamic response of a SIS by a ramp function similar to that shown in Figure 34.8 and consider, in turn, the individual time lags. If the time interval from the initial process deviation to the hazard point exceeds 2 min, there is normally no problem in designing the SIS. On the other hand, if the time interval is less than this, there is a potential problem. If the time interval is only a few seconds, an SIS may not be practical.

The signal transmission lags to and from the logic system, and the logic system delay itself are normally negligible. The more significant lags are likely to be in the sampling and the sensor, in the final control element, and in the process itself. For analysers, sampling lags may amount to a dead time of the order of seconds to minutes. For smart transmitters, the sensor lag may be of the order of 100–250 ms. Transfer lags in sensors vary, with temperature measurement lags often being large due to the thermal inertia of the measuring pocket. The lag at the control valve can vary from a fraction of a second up to several minutes, depending on the valve size. The lag in the process itself is also highly variable.

34.6.3 Power supply

Loss of power to the process unit results in the failure of pumps and other electrical driven equipment. During the flare load analysis, as discussed in this volume, the loss of power case was cited as often presenting the largest flare load. How long one can run safely without power is dependent on the process operation. In designing the SIS, the choice must be made between energize-to-trip (ETT) and de-energize-to-trip (DTT).

The SIS standards, ISA 84.01-1996 and IEC 61511, recommend the use of DTT design to provide greater assurance that the safe state is achieved under loss of power conditions. In a DTT design, loss of power causes the final elements to take their fail-safe action. To prevent brief power interruptions from causing process shut-downs, uninterruptible power supplies (UPS) are used. Power is supplied to the SIS instrumentation by the UPS when the power is lost. The UPS can be sized to supply power for any length of time, but for practical reasons generally do not supply power for periods in excess of 30–45 min.

In DTT design, a power outage results in the final elements going to the safe state. Due to historical plant power supply problems, some companies migrated to an ETT design to allow the plant to continue to operate during short power outages. An ETT design requires that power be applied in order for the final elements to achieve their safe state. This migration to ETT improved process reliability, but placed the process at greater risk of an incident during a loss of power condition. ETT SISs are generally limited to SIL 1 applications, because it is difficult to implement back-up power generation and/or alternative power supplies (e.g. UPS) that have a combined failure rate of less than 1 in 100 years. If ETT circuits are used, line monitoring must be performed, because any loose wire or open circuit will inhibit the safety action. But even line monitoring does not guarantee that the SIS will work when a process demand occurs, because fuses or coils may burn-out when power is supplied.

Further, the discussion of the use of DTT or ETT cannot be restricted to examination of the failure rate only. The use of PES-based devices in ETT applications is questionable. At the chip level, the probable operational states are equally likely to be on or off. There is consequently the question of whether the PES can be made fail-safe in an ETT design. This can only be determined by thorough failure modes and effects analysis. Many modern PES are not approved by independent certifying bodies for use in SISs operated as ETT systems due to the question of fail-safe status. For this reason, the CCPS *Safe Automation Guidelines* suggests alternative approaches to achieving process reliability. These are based on use of; (1) devices of proven reliability with self-diagnostic capability, (2) maintenance programmes stressing preventive maintenance, inspection and proof testing and (3) redundancy including inputs, logic solver and outputs.

34.6.4 Choosing components

The choice of which device to use in an SIS is very important. All devices fail eventually due to manufacturing faults, age-related degradation or damage caused by process impact. Some devices are more prone to failure than others. For this reason, it is important to understand how the device performs in the application environment. This concept is called ‘proven-in-use’ or ‘prior use.’ Thus, selecting the right device depends on field experience and available failure rate data, as well as knowledge of the process application and process conditions.

34.6.5 Integration of SISs

As already described, an SIS is normally dormant and operates in a demand mode. An SIS device such as a sensor or a valve may fail in such a way that its failure will remain unrevealed until detected by proof testing or some other means. By contrast, similar devices in a control system are exercised continuously, and these failures are more likely to cause an operational excursion. The failure in the control system is often a revealed one. Yet the actual physical fault in both cases may be identical. A sensor may fail giving a low/zero or high reading, or a valve may stick open or closed. The concept of trip integration, which has been described by Rushton (1992), is based on this contrast between a fault that lies unrevealed in an SIS but is revealed in a measurement and control system. The principle applies to any system that has a protective function. The system is regarded as integrated provided it is regularly exercised, which generally means that it is in use during the normal operation of the plant.

As an illustration, Rushton describes a refrigerated storage tank for a toxic liquid, equipped with a cooling system and a pressure relief valve. Both are protective systems, but the cooling system is in more or less continuous use and is thus integrated, whereas the relief valve is not.

In this case, the integration is benign, but it can also be malign. As an example of the latter, consider the case of a sensor that is common to both a level control loop and a high level alarm. Failure of the sensor results in failure not only of the control loop but also of the alarm. These situations can easily be identified using LOPA. Then, design modifications can be implemented to ensure the independence and integrity of each protection layer.

34.6.6 Field design

34.6.6.1 Configuration of SISs

The configuration of SISs has been discussed by Rushton (1991a,b), who describes a formal approach. According to Rushton, for a fixed proof test interval, the ranking of SISs with respect to their functional and operational reliability is invariant and this is shown in Table 34.8. The SISs most commonly used are the 1oo1, 1oo2, 2oo2 and 2oo3 systems.

Table 34.8 Ranking of SIS configurations with respect to functional and operational failure (Rushton, 1991b) (Courtesy of the Institution of Chemical Engineers)

Functional ranking		*Operational ranking*	
ϕ_{moon}	*System*	γ_{moon}	*System*
Low	1oo3	Low	3oo3
↓	1oo2	↓	2oo2
	2oo3		2oo3
	1oo1		1oo1
	2oo2		1oo2
High	3oo3	High	1oo3

The use of parallel redundant, or 1oo*n* (1-out-of-*n*), systems gives an increase in functional integrity, but a decrease in operational reliability compared with a 1oo1 (1-out-of-1) system. Better overall reliability characteristics can be obtained by the use of a majority voting system, of which the 2oo3 system is the simplest. A comparison of a 2oo3 system with a 1oo1 system shows that the 2oo3 system has a higher functional integrity and operational reliability, while a comparison with a 1oo2 system shows that the 2oo3 system has a slightly lower functional integrity, but a much higher operational reliability. The 2oo2 system has some interesting characteristics. It has a lower functional integrity than a 1oo1 system, but its operational reliability exceeds not only that of the 1oo1 but also that of the 2oo3 system. When 2oo2 systems are used to improve operational reliability, the functional integrity can be improved by increased proof testing or by enhanced diagnostics. The requirement for functional integrity is rarely such as to justify a 1oo3 system and that for operational reliability rarely such as to justify a 3oo3 system.

The criterion given by Rushton for selection of the SIS configuration is an economic one and is:

$$V = nC + \delta\phi_s H + \gamma_s S + \delta(1 - \phi_s)G \qquad [34.6.28]$$

where *C* is the annualized cost of a single channel trip, ϕ is the fractional dead time, γ is the spurious trip frequency, *G* is the cost of a genuine trip, *S* is the cost of realization of a hazard, S is the cost of a spurious trip, *V* is the overall annual cost, and the subscript s indicates the SIS (as opposed to a single channel). The most economic solution is that which minimizes *V*.

For a genuine trip, there is an element of loss related to the process failure that causes the demand. If, for purposes of comparison, this element (which will occur in all cases) is neglected, the cost of a genuine trip is approximately the same as that of a spurious one ($G = S$), so that Equation 34.6.28 becomes:

$$V = nC + \delta\phi_s H + [\gamma_s + \delta(1 - \phi_s)]S \qquad [34.6.29]$$

If the basic parameters of a particular application are known, namely the demand rate δ, the fail-to-danger rate λ_d, spurious failure rate γ_s, the proof test interval τ_p, the repair time τ_r, the costs of hazard realization *H*, and spurious trip *S*, then a plot of *H*/*C* vs *S*/*C* gives a map showing the regions where a particular configuration is optimal. The boundaries of the regions are curves of constant *V*/*C*.

As an illustration, consider the case given by Rushton where the application is characterized by $\delta = 0.01$ demands/year, $\lambda = 0.2$ failures/year, $\gamma = 0.5$ failures/year, $\tau_p = 1/12$ and $\tau_r = 1/52$. The map giving the optimal configurations for this case is shown in Figure 34.10(a). If δ is increased to 1.0 demand/year, the map becomes that shown in Figure 34.10(b).

Rushton also treats the case where there is an element of common cause failure (CCF). Rushton uses the beta method described in Chapter 9. He considers a 1oo2 system:

$$\phi_{1oo2} = \frac{[\lambda(1 - \beta_1)\tau_p]^2}{3} + \frac{\beta_1 \lambda \tau_p}{2} \qquad [34.6.30]$$

$$\gamma_{1oo2} = 2 \times (1 - \beta_2)\gamma + \beta_2\gamma \qquad [34.6.31]$$

$$= (2 - \beta_2)\gamma \qquad [34.6.32]$$

where β_1 is the fraction of the functional failure rate which is common cause, or the functional beta value for that failure rate, and β_2 is the operational beta value.

The effect of CCF may be illustrated by considering the extension given by Rushton of his example to the case of a 1oo2 SIS where $\delta = 1$ demand/year, $\lambda = 0.2$ failures/year, $\gamma = 0.5$ failures/year, $\tau_p = 1/12$, $\tau_r = 1/52$ and where $\beta_1 = \beta_2 = \beta$. Maps of the configuration space for this case are shown in Figure 34.6.3(c) and (d) for different values of β. Table 34.9 gives expressions for the probability of failure on demand and spurious trip rate for different trip configurations.

This cost-based approach allows the different SIS configurations to be put on a common basis for purposes of comparison. Where the hazard includes risk to human life, there will be a target probability of failure or SIL that must be achieved and this will be the overriding factor in the choice of configuration. However, there are often many different SIS configurations that can achieve the necessary integrity. The cost-based approach can be used to judge which configurations are reasonably practicable from an operational reliability standpoint.

34.6.6.2 Field sensors

The SIS field sensors should be independent from the initiating cause for the potential hazardous event and from any other protection layers used to reduce the process risk to the risk tolerance. Independence is necessary to minimize common cause failure. For example, if the initiating cause is the process control transmitter, the control transmitter cannot be used as the sole means for SIS initiation. For enhanced diagnostics, the control transmitter signal can be compared to the SIS transmitter signal to detect faults. Any sharing of the control transmitter with the SIS should be carefully assessed to ensure that potential common cause failures are adequately addressed. Further, the design should ensure that no failure of the control system can disable the SIS.

Field sensor redundancy is related to the required integrity. For SIL 1, redundancy is usually not necessary, though it may be appropriate for a lower integrity (i.e. high failure rate) field sensor or for improving operational reliability. For SIL 2, redundancy is often employed to reduce the required proof test interval and to improve operational reliability. For SIL 3 or 4, there should be full redundancy, such that there are no single points of failure in the SIS design. IEC 61511 requires the demonstration of fault

__Figure 34.10__ Configuration selection map for trip systems: illustrative examples (Rushton, 1991b): (a) case with $\delta = 0.01$, $\beta = 0$; (b) case with $\delta = 0.1$, $\beta = 0$; (c) case with $\gamma = 1$, $\beta = 0.3$; and (d) case with $\gamma = 1$, $\beta = 1$. See text for further details (Courtesy of the Institution of Chemical Engineers)

__Table 34.9__ Fractional dead times and spurious trip rates for trip systems with simultaneous proof testing and common cause failures accounted for by the beta method (Rushton, 1991b) (Courtesy of the Institution of Chemical Engineers)

System	ϕ_{moon}	γ_{moon}
1oo1	$\lambda\tau_p/2$	γ
1oo2	$\dfrac{[\lambda\tau_p(1-\beta_1)]^2}{3} + \dfrac{\beta_1\tau_p}{2}$	$(2-\beta_2)\gamma$
2oo2	$\lambda\tau_p(1-\beta_1/2)$	$2\gamma^2(1-\beta_2)^2\tau_r + \beta_2\gamma$
1oo3	$\dfrac{(\lambda\tau_p)^3}{4}(1-\beta_1)^3 + \dfrac{\beta_1\lambda\tau_p}{2}$	$(3-2\beta_2)\gamma$
2oo3	$(\lambda\tau_p)^2(1-\beta_1)^2 + \dfrac{\beta_1\lambda\tau_p}{2}$	$6\gamma^3(1-\beta_2)^3\tau_r^2 + \beta_2\gamma$
3oo3	$\dfrac{\lambda\tau_p}{2}(3-2\beta_1)$	$3\gamma^3(1-\beta_2)^3\tau_r^2 + \beta_2\gamma$
moon	$\dbinom{n}{r}\dfrac{[\lambda\tau_p(1-\beta_1)]^r}{r+1} + \dfrac{\beta_1\lambda\tau_p}{2}$	$n\gamma(1-\beta_2)\dbinom{n-1}{m-1}[\gamma(1-\beta_2)\tau_r]^{m-1}+\beta_2\gamma$

tolerance for SIL 3 or 4. Depending on the voting configuration selection, the incorporation of fault tolerance may also improve operational reliability.

Other features typically used for SIL 3 are on-line, continuous diagnostics and consideration of the use of diversity in the sensors. Use of diversity that reduces the on-line diagnostic capability should be carefully examined. Diagnostic capability improves functional and operational reliability, where diversity only improves functional integrity. Further, the achievement of diversity may require the use of a lower integrity component, offsetting any potential benefit gained from the diversity.

34.6.6.3 Diagnostics

Diagnostics may be used to detect failures of SIS components, including sensors, logic solvers, final control elements and energy sources. The CCPS *Safe Automation Guidelines* distinguish between passive and active diagnostics. In passive diagnostics, the failure is revealed only when a demand is imposed, either by the system or by a proof test. In active diagnostics, the device is subjected continuously to testing, such as the comparison of analog signals from redundant transmitters. If the analog signals begin to deviate from each other and this deviation exceeds a pre-set tolerance, an alarm is generated notifying plant personnel that maintenance activity is required. An example of passive diagnostics is the use of partial stroke testing, where the solenoid valve that controls the air source to the final control element is used to periodically (e.g. daily, weekly or monthly) move the valve from the fully open position. This test provides early detection of solenoid valve and process valve failures.

34.6.6.4 Logic solver

The SIS technologies given in the CCPS *Safe Automation Guidelines* include: (1) fluid logic (pneumatic, hydraulic); (2) electrical logic, including direct-wired systems, electromechanical devices (relays, timers), solid-state relays, solid-state logic and motor-driven timers; (3) PES technology, involving programmable logic controllers (PLCs) and (4) hybrid systems. The technologies are detailed in Appendix A of the CCPS *Safe Automation Guidelines*.

The hardware of a typical PES consists of a chassis, input modules receiving sensor signals, main processors, output modules sending out signals to final control elements, terminations, power supplies, a BPCS interface, a human/machine interface and an engineering interface. The software of a typical PES consists of embedded software and utility software, which perform the system level fault detection and execute basic PES functions. In addition, an application program within the PES executes the required user functions. The application program is constructed using software that is typically provided by the PES vendor.

The use of software raises a significant issue. Evolution of operating system platforms has resulted in a shortening of the lifespan of the embedded software. In some cases, the life span has decreased to less than 10 years. After this relatively short time, the vendor may no longer support the embedded software. Upgrading the embedded software is a major software modification that must be performed offline and with thorough testing to ensure that the hardware works properly with the new embedded software.

In the case of application software, process design or operational changes often result in the need to change the software. IEC 61511 requires that any change to the software is performed under management of change review. Further, any logic potentially impacted by the change should be tested to ensure that the change does not prevent proper operation of any other SIS.

The SIS logic solver must provide performance that meets the required SIL. It was general practice for many years to design SISs as separate, hardwired systems. Hardwired systems have highly predictable failure modes and exhibit low failure rates. In contrast, PES are composed of hardware and software components with complex failure modes and substantially higher failure rates. The major advantages of PES are the ease of logic sequencing implementation, the ability to perform complex SIS logic and enhanced diagnostics of field components. Over the last 15 years, the practice of using PES has gained wider acceptance.

A PES uses a large number of automatic diagnostic circuits and functions that are implemented in hardware and software. The purpose of the diagnostics is to detect failures, particularly dangerous failures, which would inhibit the operation of the PES. Upon detection of failure, the PES may perform one of the following actions:

(1) For a simplex PES, the SIS fail-safe action is initiated.
(2) For 1oo*n* PES, the SIS fail-safe action is initiated.
(3) For 1oo*n* PES, if the process safety time is sufficiently long, the operational state is continued under alternative operating procedures or by other compensating measures that ensure that safe operation is maintained.
(4) For 2oo*n* PES, the failed circuit is voted toward the trip state. The operational state is continued under alternative operating procedures or by other compensating measures that ensure that safe operation is maintained.

In the event of any detected failure, an alarm is generated by the PES indicating the nature of the failure and that maintenance is required.

It is impossible to have 100% diagnostic coverage of faults. After all, the diagnostics are being performed by hardware or software components and these components are subject to failures that would prevent them from detecting faults. The dangerous failures that are not detected by diagnostics are called dangerous, undetected failures. These failures can only be uncovered by proof testing the PES hardware. The testing should be performed at a frequency that enables the PES to achieve the required SIL.

Software-based SISs are treated in *Safety Aspects of Computer Control* (P. Bennett, 1993). Other accounts are given by P. Bennett (1991a,b), Bologna (1993), Ehrenberger (1993), Malcolm (1993), McDermid (1993) and Pyle (1993). Since software-based SISs are complex, successful implementation requires a disciplined process to achieve functional integrity. Thus, standards are particularly important for software-based SISs. Practical guidance is available in ANSI/ISA 84.01-1996, IEC 61508, and IEC 61511. For particularly complex software systems, analysis methods are necessary to identify hazards associated with the software itself. The application of HAZOP to process computers (CHAZOP) is described in Chapter 8.

There are a number of real-time languages and environments that have special safety-related features. One example is ADA. Accounts are given in *Program Verification Using ADA* (McGettrick, 1982), *ADA for Specfication and Design* (Goldsack, 1985), *ADA in Industry* (Heilbrunner, 1988) and *Developing Safety Systems: A Guide Using ADA* (Pyle, 1991).

An account of the application of PES to functions such as pump change over, fire and gas detection and emergency shut-down has been given by Margetts (1986a,b). He describes the planning of an operation such as pump changeover using hierarchical task analysis, in which the changeover task is successively re-described until it has been broken down into executable elements, and the application of HAZOP to assess the adequacy of the resultant design.

34.6.6.5 Final elements

The final elements used for shut-down action should be independent of the initiating cause of the incident and any other protection layer used to mitigate the incident. The final elements can be valves, circuit breakers, motor starters, protective relays, etc.

Final element redundancy is related to the required integrity. For SIL 1, redundancy is usually not necessary, though it may be appropriate for a lower integrity (i.e. high failure rate) final element. For SIL 2, redundancy is often employed to reduce the required proof test interval. For SIL 3 or SIL 4, there should be full redundancy, such that there are no single points of failure in the SIS design. IEC 61511 requires the demonstration of fault tolerance for SIL 3 or SIL 4.

For valves, the engineer should select the valve type that provides the best performance in the application environment. This includes assessing the impact of the application environment on the valve, the need for tight shut-off, and the required speed of closure. Enhanced valve diagnostics should strongly be considered in SIL 3 or SIL 4 applications. For example, valve diagnostics can be obtained by partial stroke testing the process valve using the solenoid-operated valve that controls the air signal to the valve actuator. The solenoid valve is de-energized for a short time period allowing the process valve to move away from the full-open position. Once valve movement is confirmed, it is returned to the full-open position without process disruption. Since the degree of valve closure is controlled by the test method, any partial stroke test apparatus or procedure should be carefully assessed to ensure that operational reliability is maintained. Improper design of the partial stroke test apparatus or an incorrect procedure may result in full-closure of the valve, resulting in a process disruption.

34.7 Verify

34.7.1 Dependability

Since an SIS protects against a hazardous condition, it is essential for the system itself to be dependable. The dependability of an SIS is related to its: (1) functionality and (2) integrity. It is necessary for the system to have the capability of carrying out its function in terms of features, such as accuracy, dynamic response, etc., and for it to have a high probability of doing so.

The SIS functionality was discussed in Section 34.6. SIS functionality is defined by identifying what must be detected and the response that must be taken to achieve the safe state. The SIS functionality is, therefore, related to the input and output architecture.

The SIS integrity can be improved by the use of: (1) redundancy, (2) diversity and (3) diagnostics. Redundancy involves the use of multiple instruments to detect the potentially hazardous event. With voting, multiple failures are required for the SIS to fail to function. This yields a lower probability of failure than that of a single instrument. But, redundancy is not always the full answer, because there are some dependent failures which may disable the whole set of redundant instruments. This difficulty can be minimized by implementing diversity, which often involves using different process variables to detect the same hazard or different types of instrumentation to measure the same process variable. On-line diagnostics can also be used to detect component failure including dependent failures. Diagnostics allow the operator to be notified that an SIS fault has occurred, significantly improving SIS integrity.

Most SISs consist of a single channel comprising a sensor, a logic processor and a final control element, but where the integrity required is higher than that which can be obtained from a single channel, redundancy is generally used.

In the process industry, hazardous conditions are seldom present, so most SISs operate in a demand mode, that is the SIS is dormant until a process excursion or demand occurs. Thus, functional failures of the system are generally unrevealed failures. Device failure that results in the SIS failing to function when required by a process demand can be predicted using probabilistic techniques. A dependable SIS should have a low PFD.

The SIS should also be reliable and not result in spurious trips, that is, failure that causes the SIS to shut the plant down when no hazardous condition exists. Thus, operational failures of the system are generally revealed failures, due to direct process impact or to system diagnostics.

It is the objective of SIS design and operation to avoid both loss of protection against the hazardous condition, due to functional failures, and plant shut-down, due to operational failure or spurious trip. Since functional failure of the system is generally unrevealed, it is necessary to carry out periodic proof testing to detect such failure.

The simpler theoretical treatments of SISs usually assume that the functional failures are unrevealed, operational failures revealed and failure rates are constant. This treatment draws particularly on the work of A.E. Green and Bourne in UKAEA AHSB(S) R117 (1966) and in *Reliability Technology* (1972).

34.7.2 Frequency of events in an SIS

A method of determining the frequency of events of interest has been described by Kumamoto, Inoue and Henley (1981). These events are the process demand rate, the functional failure rate and the operational failure rate. The method is implemented in the program PROTECT.

The procedure is to designate each of these events in turn as the top event of a fault tree, to create the fault tree and to determine its cut-sets. These cut-sets together with the proof test interval for the SIS are the inputs used by the model to provide estimates of the frequency of the events mentioned.

The application of this program to determine the expected frequency of these events for an ammonia–air mixing plant as a function of the proof test interval has been described by Kumar, Chidambaram and Gopalan (1989).

34.7.3 Fractional dead time

The fractional dead time (FDT) of a device or system gives the probability that it is in a failed state. ANSI/ISA 84.01-1996, IEC 61511 and IEC 61508 use the term ‘probability of failure on demand’ to describe the FDT of a device or system. The equations provided in this section and the functional integrity section can be used to calculate the PFD, as well as the FDT.

If the device failure is revealed, the FDT ϕ depends on the failure rate λ and the repair time τ_r:

$$\phi = \lambda\tau_r \quad \tau_r << 1 \qquad [34.7.1]$$

For a series system with revealed failure, the FDT ϕ of the system is related to the FDT ϕ_i of the individual devices as follows:

$$\phi = \sum_{i=1}^{n} \phi_i \quad \lambda_i\tau_{ri} << 1 \qquad [34.7.2]$$

For a parallel system with revealed failure, the FDT ϕ of the system is related to the FDT ϕ_i of the devices as follows:

$$\phi = \prod_{i=1}^{n} \phi_i \quad \lambda_i \tau_{ri} << 1 \qquad [34.7.3]$$

For a parallel redundant, or 1oo$n$, system with revealed failure, the FDT $\phi_{1\text{oo}n}$ of the system is related to the FDT $\phi_{1\text{oo}1}$ of a single device as follows:

$$\phi_{1\text{oo}n} = \phi_{1\text{oo}1}^{n} \qquad [34.7.4]$$

If, however, the device failure is unrevealed, the FDT depends on the failure rate λ and the proof test interval τ_{p}. The probability q of failure within time period t is:

$$q = 1 - \exp(-\lambda t) \qquad [34.7.5]$$

or, for small values of λt

$$q = \lambda t \quad \lambda t << 1 \qquad [34.7.6]$$

Then the FDT is:

$$\phi = \frac{1}{\tau_{\text{p}}} \int_0^{\tau_{\text{p}}} q \, \mathrm{d}t \qquad [34.7.7]$$

For a 1oo$n$ system with unrevealed failure, the FDT or $\phi_{1\text{oo}n}$ of the system is obtained from the probability $q_{1\text{oo}n}$ of failure of the system within the time period t:

$$\phi_{1\text{oo}n} = \frac{1}{\tau_{\text{p}}} \int_0^{\tau_{\text{p}}} q_{1\text{oo}n} \, \mathrm{d}t \qquad [34.7.8]$$

A detailed account of calculation of FDT is given by A.E. Green and Bourne (UKAEA 1966 AHSB(S) R117).

The calculation of the FDT according to Equation 34.7.8 requires the integration of the instantaneous probability as defined by Equation 34.7.5 or 34.7.6 for the specific subsystem voting. For highly redundant SISs, this integration can be quite complicated. Also, it is necessary to integrate the instantaneous probability of each device over a single testing interval. It is not unusual to have staggered testing where the components in the subsystem are tested at different intervals. To simplify the analysis and to account for the staggered testing, ISA TR84.00.02 provides an alternative method for determining the FDT of a 1oo$n$ subsystem. This method may yield a different FDT for the SIS than Equation 34.7.8, but it has been found to provide a sufficiently conservative approximation of the FDT. The FDT or $\phi_{1\text{oo}n}$ for the 1oo$n$ subsystem is obtained by multiplying the probability q of failure of the individual devices in the system within the time period t.

As described in ISA TR84.00.02, the FDT for each component is determined using Equation 34.7.7. Then, the voting architecture is modelled using Boolean algebra. This greatly simplifies the calculation, because the integration is performed only for the individual device not for the entire subsystem. For a 1oo$n$ system, the FDT can be expressed as:

$$\phi_{1\text{oo}n} = \frac{1}{\tau_{\text{p}}} \prod \int_0^{\tau_{\text{p}}} q_n \, \mathrm{d}t \qquad [34.7.9]$$

34.7.4 Functional integrity

Functional failure of an SIS may be unrevealed or undetected. In this section, the failure rate λ is used to calculate the FDT of the SIS related to unrevealed, fail-dangerous faults.

For a simple SIS consisting of a single channel 1oo1 system with a failure rate λ, the probability q of failure within proof test interval τ_{p} is:

$$q = 1 - \exp(-\lambda \tau_{\text{p}}) \qquad [34.7.10]$$

For small values of $\lambda \tau_{\text{p}}$

$$q = \lambda \tau_{\text{p}} \quad \lambda \tau_{\text{p}} << 1 \qquad [34.7.11]$$

The SIS is required to operate only if a hazardous plant condition occurs. The probability p_δ that such a process demand, with a demand rate δ, will occur during the dead time τ_0 after the failure is:

$$p_\delta = 1 - \exp(-\delta \tau_0) \qquad [34.7.12]$$

But, on average, the dead time τ_0 is half the proof test interval τ_{p}:

$$\tau_0 = \frac{\tau_{\text{p}}}{2} \qquad [34.7.13]$$

Hence:

$$p_\delta = 1 - \exp(-\delta \tau_{\text{p}}/2) \qquad [34.7.14]$$

For small values of $\delta \tau_{\text{p}}$:

$$p_\delta = \frac{\delta \tau_{\text{p}}}{2} \quad \delta \tau_{\text{p}} << 1 \qquad [34.7.15]$$

The probability p_η that a plant hazard will be realized can be written in terms of the plant hazard rate η:

$$p_\eta = 1 - \exp(-\eta \tau_{\text{p}}) \qquad [34.7.16]$$

For small values of $\eta \tau_{\text{p}}$:

$$p_\eta = \eta \tau_{\text{p}} \quad \eta \tau_{\text{p}} << 1 \qquad [34.7.17]$$

Frequently, some or all of the approximations of Equations 34.7.11, 34.7.15 and 34.7.17 apply. If all do, then taking

$$p_\eta = q p_\delta \qquad [34.7.18]$$

gives

$$\eta = \frac{\delta \lambda \tau_{\text{p}}}{2} \quad \lambda \tau_{\text{p}} << 1; \quad \delta \tau_{\text{p}} << 1; \quad \eta \tau_{\text{p}} << 1 \qquad [34.7.19]$$

If the assumptions underlying Equation 34.7.19 are not valid, an expression that has been commonly used is:

$$\eta = \lambda p_\delta \qquad [34.7.20]$$

Alternatively, the plant hazard rate can be expressed in terms of the FDT ϕ of the system:

$$\eta = \delta \phi \qquad [34.7.21]$$

As given earlier, the probability q of failure of the simple SIS within the time period t is:

$$q = 1 - \exp(-\lambda t) \qquad [34.7.22]$$

For small values of λt

$$q = \lambda t \quad \lambda t << 1 \qquad [34.7.23]$$

Then the FDT ϕ of the simple SIS is:

$$\phi = \frac{1}{\tau_p} \int_0^{\tau_p} q \, \mathrm{d}t \qquad [34.7.24]$$

Hence

$$\phi = \frac{\lambda \tau_p}{2} \qquad [34.7.25]$$

and

$$\eta = \frac{\delta \lambda \tau_p}{2} \qquad [34.7.26]$$

as before.

For a parallel redundant, 1oo$n$ or $m$oo$n$ (m-out-of-n) with a majority voting system, the following treatment applies. If there are n devices of which m must survive for the system to survive and r must fail for the system to fail,[1] then

$$r = n - m + 1 \qquad [34.7.27]$$

The probability q_{moon} of failure of this system within the proof test interval can be determined using a binomial distribution as follows:

$$q_{moon} = \sum_{k=r}^{n} \binom{n}{k} q^k (1-q)^{n-k} \qquad [34.7.28]$$

For small values of q:

$$q_{moon} = \binom{n}{r} q^r \quad q << 1 \qquad [34.7.29]$$

The FDT ϕ_{moon} of the system is:

$$\phi_{moon} = \frac{1}{\tau_p} \int_0^{\tau_p} q_{moon} \, \mathrm{d}t \qquad [34.7.30]$$

Then from Equations 34.7.23, 34.7.29 and 34.7.30, the FDT ϕ_{moon} of the system is:

$$\phi_{moon} = \binom{n}{r} \frac{(\lambda \tau_p)^r}{r+1} \qquad [34.7.31]$$

Thus for a 2oo3 majority voting system:

$$\phi_{2oo3} = (\lambda \tau_p)^2 \qquad [34.7.32]$$

For the special case of a parallel redundant, or 1oo$n$, system, Equation 34.7.31 reduces to give the FDT ϕ_{1oon}:

$$\phi_{1oon} = \frac{(\lambda \tau_p)^n}{n+1} \qquad [34.7.33]$$

Thus for a 1oo2 parallel system:

$$\phi_{1oo2} = \frac{(\lambda \tau_p)^2}{3} \qquad [34.7.34]$$

and for a 1oo3 system:

$$\phi_{1oo3} = \frac{(\lambda \tau_p)^3}{4} \qquad [34.7.35]$$

FDT is calculated from Equation 34.7.31. The results are shown in Table 34.11, as a function of $\lambda \tau_p$ and of the FDT ϕ_{1oo1} for a single channel. Table 34.10 assumes that the devices are tested simultaneously at the end of the proof test interval. Some improvement can be obtained by staggered testing, as shown by the data in Table 34.11, which are taken from A.E. Green and Bourne (1972).

The approximation method provided in ISA TR84.00.02 can also be used to calculate the FDT of redundant subsystems. In this method, the FDT is determined for each device within the subsystem using Equation 34.7.25. Then,

Table 34.10 *Fractional dead times for trip systems with simultaneous proof testing*

System	*n*	*m*	*r*	ϕ	
1oo1	1	1	1	$\lambda\tau_p/2$	ϕ_{1oo1}
1oo2	2	1	2	$(\lambda\tau_p)^2/3$	$\frac{4}{3}\phi^2_{1oo1}$
1oo3	3	1	3	$(\lambda\tau_p)^3/4$	$2\phi^3{}_{1oo1}$
2oo2	2	2	1	$\lambda\tau_p$	$2\phi_{1oo1}$
2oo3	3	2	2	$(\lambda\tau_p)^2$	$4\phi^2{}_{1oo1}$

System	ϕ^*	ϕ/ϕ^*
1oo1	$\frac{\lambda\tau_p}{2}$	1
1oo2	$\frac{5}{24}(\lambda\tau_p)^2$	1.6
1oo3	$\frac{1}{12}(\lambda\tau_p)^3$	3.0
2oo2	$\lambda\tau_p$	1
2oo3	$\frac{2}{3}(\lambda\tau_p)^2$	1.5

[a] ϕ, fractional dead time for simultaneous testing; ϕ^*, fractional dead time for staggered testing.

---

[1] In this chapter the number of devices that must fail for the system to fail is r. This notation differs from that used in Chapter 7 for *r-out-of-η* parallel systems, in which r was used for the number of devices that must survive for the system to survive. These two notations are used in order to preserve correspondence with established usage in texts on general reliability (e.g. Shooman, 1968) and on SISs (e.g. A.E. Green and Bourne, 1972).

Boolean algebra is used to combine the resulting FDT into a system value.

For a 1oo2 subsystem, this yields:

$$\phi_{1\text{oo}2} = \frac{\lambda\tau_p}{2} \times \frac{\lambda\tau_p}{2} = \frac{\lambda^2\tau_p^2}{4} \qquad [34.7.36]$$

To generalize, the approximation equation can be derived for *moon* voting subsystems, using Equation 34.7.25 for the value of *r* and Equation 34.7.27 to represent the probability of failure of the individual components:

$$\phi_{moon} = \frac{n!}{r!(m-1)!}\left(\frac{\lambda\tau_p}{2}\right)^r \qquad [34.7.37]$$

34.7.5 Operational reliability

It is also necessary to consider SIS operational failure. Operational failure, as presented in this section, is revealed. The failure rate λ used in the equations in this subsection is applicable to these revealed, fail-safe or fail-spurious faults.

For a simple SIS consisting of a single channel 1oo1 system with a failure rate λ, the operational failure, or spurious trip rate, γ is:

$$\gamma = \lambda \qquad [34.7.38]$$

For a parallel redundant, or 1oo*n*, system the operational failure rate $\gamma_{1\text{oo}n}$ is:

$$\gamma_{1\text{oo}n} = n\lambda \qquad [34.7.39]$$

For a *moon* system, which may be a majority voting system, the following treatment applies. The rate at which the first operational failure of a single channel occurs is $n\lambda$. This first failure only results in a system trip if further operational failure of enough channels sufficient to trip the system occurs within the repair time τ_r. The probability q_γ that this will occur is:

$$q_\gamma = \binom{n-1}{m-1}(\lambda\tau_r)^{m-1} \quad \lambda\tau_r << 1 \qquad [34.7.40]$$

Then the operational failure rate γ_{moon} of the system is:

$$\lambda_{moon} = n\lambda q_\gamma \qquad [34.7.41]$$

$$\gamma_{moon} = n\lambda\binom{n-1}{m-1}(\lambda\tau_r)^{m-1} \qquad [34.7.42]$$

Thus for a 2oo3 majority voting system:

$$\gamma_{2\text{oo}3} = (3\lambda)\cdot(2\lambda\tau_r) \qquad [34.7.43]$$

$$\gamma_{2\text{oo}3} = 6\lambda^2\tau_r \qquad [34.7.44]$$

Operational failure, or spurious trip, rates calculated from Equations 34.7.39 and 34.7.42 are shown in Table 34.12. It is emphasized again that the foregoing treatment is a simplified one. The expressions derived here appear, however, to be those in general use (e.g. Hensley, 1968; Kletz, 1972a; de Heer, 1974; Lawley and Kletz, 1975). Full theoretical treatments of SISs are given by A.E. Green and Bourne (1966 UKAEA AHSB(S) R117) and Wheatley and Hunns (1981). The latter gives expressions for a wide variety of SISs.

***Table 34.12** Spurious trip rates for trip systems*

System	γ
1oo1	λ
1oo2	2λ
1oo3	3λ
2oo2	$2\lambda^2\tau_r$
2oo3	$6\lambda^2\tau_r$

34.7.6 Hazard rate of a single-channel SIS

The hazard rate of a single-channel SIS, when $\lambda\tau_p << 1$; $\delta\tau_p << 1$; $\eta\tau_p << 1$, was shown in Equation 34.7.19:

$$\eta = \frac{\delta\lambda\tau_p}{2} \qquad [34.7.45]$$

When this equation is used outside its range of validity, the results obtained can be not only incorrect but nonsensical. Consider the case where the failure rate is $\lambda = 0.01$ failures/year, the demand rate is $\delta = 3$ demands/year and the proof test interval is $\tau_p = 1$ year. Then, this equation gives for the hazard rate η a value of 0.015 hazards/year, which is actually greater than the failure rate λ.

A treatment is now given for the more general case, based on the work of Lees (1982a) as extended by de Oliveira and Do Amaral Netto (1987). For a single-channel SIS, the possible states are: (1) SIS operational, (2) SIS failed but failure undetected and (3) SIS failed, but failure detected and SIS under repair. The corresponding Markov model is:

$$\dot{P}_1(t) = -\lambda P_1(t) + \mu P_3(t) \qquad [34.7.46a]$$

$$\dot{P}_2(t) = \lambda P_1(t) - \delta P_2(t) \qquad [34.7.46b]$$

$$\dot{P}_3(t) = \delta P_2(t) - \mu P_3(t) \qquad [34.7.46c]$$

where P_n is the probability that the SIS is in state *n*.

With the initial condition that the SIS is operational, the solution of Equations 34.7.4a–c is as follows:

$$P_1(t) = \frac{\mu\delta}{r_1 r_2} + \frac{(r_1+\mu+\delta)+\mu\delta}{r_1(r_1-r_2)}\exp(r_1 t) - \frac{r_2(r_2+\mu+\delta)+\mu\delta}{r_2(r_1-r_2)}\exp(r_2 t) \qquad [34.7.47a]$$

$$P_2(t) = \frac{\lambda\mu}{r_1 r_2} + \frac{\lambda(r_1+\mu)}{r_1(r_1-r_2)}\exp(r_1 t) - \frac{\lambda(r_2+\mu)}{r_2(r_1-r_2)}\exp(r_2 t) \qquad [34.7.47b]$$

$$P_3(t) = \frac{\lambda\delta}{r_1 r_2} + \frac{\lambda\delta}{r_1(r_1-r_2)}\exp(r_1 t) - \frac{\lambda\delta}{r_2(r_1-r_2)}\exp(r_2 t) \qquad [34.7.47c]$$

with

$$r_1 = \frac{-(\mu + \lambda + \delta) - \left[(\lambda + \delta - \mu)^2 - 4\lambda\delta\right]^{1/2}}{2} \qquad [34.7.48a]$$

$$r_2 = \frac{-(\mu + \lambda + \delta) + \left[(\lambda + \delta - \mu)^2 - 4\lambda\delta\right]^{1/2}}{2} \qquad [34.7.48b]$$

Then the FDT and hazard rate obtained from Equations 34.7.47b and 34.7.47c are instantaneous values, and are

$$\phi(t) = P_2(t) + P_3(t) \qquad [34.7.49]$$

$$\eta(t) = \delta[P_2(t) + P_3(t)] \qquad [34.7.50]$$

The FDT and hazard rate obtained from Equations 34.7.49 and 34.7.50 are defined as functions of time. The average value of the hazard rate over the proof test interval is:

$$\eta = \frac{1}{\tau_p}\int_0^{\tau_p} \eta(t)\,dt \qquad [34.7.51]$$

Then, substituting Equation 34.7.50 into Equation 34.7.51 and integrating gives for the average hazard rate:

$$\eta = \frac{\lambda\delta(\mu + \delta)}{r_1 r_2} + \frac{\lambda\delta(r_1 + \mu + \delta)}{r_1^2\tau_p(r_1 - r_2)}[\exp(r_1\tau_p) - 1] - \frac{\lambda\delta(r_2 + \mu + \delta)}{r_2^2\tau_p(r_1 - r_2)}\exp(r_2\tau_p) - 1 \qquad [34.7.52]$$

The foregoing treatment is based on the assumptions that the SIS is fully operational after a proof test is performed and that the test duration is negligible compared with the proof test interval.

Although this model has a high degree of generality, it is based on the assumption that, following detection of an SIS device failure, the plant continues to operate while the SIS device is repaired. If in fact the policy is that the plant operation does not continue while the SIS device is being repaired, different expressions apply. If the state $P_3(t)$ is dropped from the instantaneous hazard rate $\eta(t)$ in Equation 34.7.50 and the repair rate $\mu = 0$, Equation 34.7.52 for the average hazard rate then becomes

$$\eta = \frac{1}{\tau_p}\left\{1 - \frac{1}{\lambda - \delta}[\lambda\exp(-\delta\tau_p) - \delta\exp(-\lambda\tau_p)]\right\} \quad \lambda \neq \delta \qquad [34.7.53a]$$

$$\eta = \frac{1}{\tau_p}[1 - (1 + \lambda\tau_p)\exp(-\lambda\tau_p)] \quad \lambda = \delta \qquad [34.7.53b]$$

This case is essentially that considered by Lees (1982a), who used the joint density function method. Two of the relations which he gives, for the failure density function f_η and the probability p_η of realization of the hazard, are also of interest and are

$$f_\eta = \frac{\lambda\delta}{\lambda - \delta}[\exp(-\delta\tau_p) - \exp(-\lambda\tau_p)] \quad \lambda \neq \delta \qquad [34.7.54a]$$

$$f_\eta = \lambda^2\tau_p\exp(-\lambda\tau_p) \quad \lambda = \delta \qquad [34.7.54b]$$

and

$$p_\eta = 1 - \frac{1}{\lambda - \delta}[\lambda\ \exp(-\delta\tau_p) - \delta\exp(-\lambda\tau_p)] \quad \lambda \neq \delta \qquad [34.7.55a]$$

$$p_\eta = 1 - (1 + \lambda\tau_p)\exp(1 + \lambda\tau_p) \quad \lambda = \delta \qquad [34.7.55b]$$

A number of other relations have been given in the literature for situations where Equation 34.7.45 is not valid. An expression given by Kletz and by Lawley (Kletz, 1972a; Lawley and Kletz, 1975; Lawley, 1976) is as follows:

$$\eta = \lambda[1 - \exp(-\delta\tau_p/2)] \qquad [34.7.56]$$

This is in effect Equation 34.7.20. It may be derived from Equation 34.7.18 together with Equations 34.7.11, 34.7.14 and 34.7.17. It is applicable for small $\lambda\tau_p$ and $\eta\tau_p$, but higher $\delta\tau_p$.

Lawley (1981) has subsequently given the more accurate Equation 34.7.53a,b. The assumptions underlying this equation have just been described.

Wells (1980) has given an expression

$$\eta = \frac{\delta\lambda}{\delta + \lambda} \qquad [34.7.57]$$

as an upper bound on the hazard rate for higher values of $\delta\tau_p$ (>2). This expression is equivalent to taking the probability of failure on demand as $\phi = \lambda/(\lambda + \delta)$. De Oliveira and Do Amaral Netto (1987) give the relation:

$$\eta = \delta\left\{1 - \frac{1}{\lambda\tau_p}[1 - \exp(-\lambda\tau_p)]\right\} \qquad [34.7.58]$$

for low values of δ but higher values of $\lambda\tau_p$.

Numerical results for some of these expressions have been given by Lees (1982a) and by de Oliveira and Do Amaral Netto (1987). Table 34.13 shows some comparative results obtained, mainly by the latter workers.

34.8 Operate

To ensure the control system integrity, the design process must be supported by administrative procedures and actions. The SIS consists of instrumentation and logic processors that can and do fail. When these failures are detected, immediate operator response is essential to ensure safe operation. This response includes issuing a request for repair of the faulted device, monitoring other process variables associated with the unit, and, if necessary, initiating a manual shut-down action.

CCPS *Safe Automation Guidelines* outlines minimum procedural requirements, including: (1) operating procedures, (2) maintenance facilities, (3) testing of the BPCS, (4) testing of the alarms and SIS, (5) test interval requirements, (6) testing facilities, (7) operator training, (8) documentation and (9) auditing of maintenance and documentation.

ANSI/ISA 84.01-1996 and IEC 61511 require that the SIS operating procedures contain the following information:

- description of the hazard that is being prevented with SIS;
- SIS trip set points and SIS actions, including definition of safe state;

Table 34.13 *Some numerical values given by expressions for the average hazard rate of a single-channel SIS (after de Oliveira and Do Amaral Netto, 1987) (Courtesy of Elsevier Science Publishers)*

[a] In equations where μ is used, $\mu = 365$/year.

- correct use of operational bypasses, permissive, system reset, etc.;
- response to SIS alarms and trips;
- detection and response to faults, including when to execute a manual shut-down action;
- provisions for operation with detected faults.

This information enables the operator to understand the purpose and function of the SIS and to recognize when to take action in response to SIS faults.

34.8.1 Bypassing of SISs

Bypasses (or overrides) may be required for start-up, maintenance or testing activities. When a bypass is placed in service, the bypass should be alarmed in the control room to notify operations staff that an SIS is inoperable. Then, compensating measures should be implemented to maintain safe operation, while any portion of the SIS is bypassed. Compensating measures may include, for example, increased process monitoring, increased supervision, revised operational procedures or reduction in production rates. Operation and maintenance staff should be trained on the use and purpose of these compensating measures. The procedures and training should include the operational limits at which manual shut-down should be initiated. To facilitate the above actions, there should be open communication between the control room and field staff.

Administrative procedures are also required to prevent unauthorized bypass of the SIS. Bypass use should be restricted to specific, authorized personnel. This may be supplemented by hardware measures, such as keyed switches, or software measures, such as passwords. There should also be a limitation on how long an SIS can be left in bypass without additional approval under change management.

Bypasses are typically only used during maintenance or testing activities. Occasionally, a start-up bypass is required for start-up and these bypasses must be carefully evaluated to ensure that potentially unsafe process conditions cannot occur during this bypass condition. Timers, operation sequences or process condition-based permissives may be used to automatically bring the SIS out of bypass during start-up to prevent prolonged operation in the bypass condition. For example, to start-up a pump, the low flow SIS on the discharge of the pump must be bypassed. To prevent the pump from being run for too long in the bypass condition, a timer may be used to automatically bring the SIS back in service. The timer allows the bypass for a specified period after the start button has been pressed.

When SISs are bypassed during normal operation, it is generally due to poor SIS reliability. If an SIS proves troublesome, it is prone to be bypassed without appropriate authorization. This is particularly likely to occur if there are frequent spurious trips, due to sensor failure or other causes. For this reason, it is important to have restrictions on when SISs can be in bypass and to intermittently alarm that the SIS is in bypass. Implementing independent process control and SIS increases the level of access security and control. When independence is not implemented, rendering an SIS ineffective may only require alteration of the SIS setpoint.

34.8.2 Restart after a trip

Once an SIS has taken the process to the safe state, the SIS should remain in the safe state until the process has reached safe operating conditions and the operator has reset the SIS. The process industry has had numerous incidents due to restart under unsafe conditions. One situation, which has frequently led to incidents, is the restart of agitation in a batch reactor following an interruption of agitation.

Kletz (1979a) provides an example of an incident that was caused by a valve that reset automatically. A cumene oxidation reactor was protected by an SIS that used high temperature to initiate shutdown of the air to the reactor and to initiate a dump of the reactor contents into a water tank. A spurious trip occurred, the air valve closed and the dump valve opened. When the trip condition cleared itself, the dump valve remained in the open, safe state condition, but the air valve did not remain in the closed, safe state condition. The air valve reopened. Air passed into the reactor, creating a flammable mixture.

Valk and Sylvester-Evans (1985) discuss cases where restart was initiated before safe conditions were reached. In these cases, vessels were repressurized too quickly after emergency depressurization. Treatment of the problem using a model of the blowdown has been described by S.M. Richardson and Saville (1992). The effect of rapid reduction of pressure in a vessel containing a material such as liquefied gas may be to chill the vessel below the transition temperature. If repressurization occurs before the vessel has warmed up sufficiently, the vessel can rupture due to brittle fracture.

34.9 Maintain

The importance of proof testing cannot be overemphasized. Testing and, more generally, SIS maintenance should be of high quality, if the functional and integrity requirements are to be achieved. Accounts of the testing and maintenance of SIS have been given by R.M. Stewart (1971), A. Taylor (1981) and Barclay (1988).

34.10 Test

Testing plays an important role in achieving functional integrity. All devices eventually fail. The most hazardous failure is a dangerous, undetected failure, which results in the device not functioning when a process demand occurs. This type of failure results in the need to periodically test SIS devices to determine if they are functional. Thus, the required proof test interval is related to the device failure rate.

ANSI/ISA 84.01-1996 and IEC 61511 require the testing of SIS devices, including inputs, logic solver and final elements. The test should be complete enough to validate the necessary functions of each device and the overall system. The test should also examine the system response to bad process variables from failed instrumentation.

Perhaps, the most important functional test is the validation of the SIS prior to introduction of hazardous chemicals into the process equipment. This validation is sometimes referred to as the pre-start-up acceptance test (PSAT) or the site acceptance test (SAT). Validation is a full functional test of the SIS performed to determine whether the installed SIS is functioning as intended from a specification, design and installation standpoint. Throughout the lifecycle, verification activities are performed to maintain a quality design process and to ensure that the design remains in agreement with the required functionality and integrity. Validation is the ultimate test of the SIS functionality. Since the majority of testing after start-up will consist of testing individual devices, it is extremely important that complete input to output testing is performed to identify any system level problems.

The test should be conducted using a written procedure, which details the actions to be taken and requires the technician's signature at key steps. In addition, the worksite should be reviewed and approved by an independent person to make certain that all bypasses have been removed and that the SIS devices have been returned to fully the operational state. The procedure is necessary because: (1) the testing process can be quite complex, (2) the individual performing the test may not be familiar with the particular trip and (3) in many cases the test is one of the last tasks done prior to a start-up when there may be considerable pressure to short-cut the test. Changes to the procedure should be managed through a management of change (MOC) process.

The test should cover the entire SIS from sensor to final element. From the point of view of testing, the preferred method is to take the process variable to the trip point using test equipment and to verify the trip action. This method requires a shut-down or provisions for bypass of the final element in order to perform the test. Other methods involve testing the field sensors, logic solver and final elements separately or testing some combination of these. For example, the process variable is taken to the trip point using test equipment, but the final element is held in position. This tests the process sensing device only. Then, the final element would be tested in a separate procedure at a different time. This disintegrated testing must be assessed to ensure that all devices required for successful SIS function are tested at the appropriate interval.

For inputs, the test should include process variable indication leading to alarm and trip initiation. For input devices requiring field calibration, the sensor calibration range should be checked to ensure that it matches the specification and that the trip setpoint is achieved at the corresponding process condition. This is accomplished by inducing the process condition at the sensor and monitoring the corresponding output of the input device. It should be demonstrated that the input device generates the correct signal at the alarm and trip setpoints. It should also be shown that if there is a bad sensor output, there is appropriate indication of this fault to the control room.

Logic solvers should demonstrate that on receipt of an input trip condition that it generates the correct output response. At the simplest level, this involves validating that the logic performed in the logic solver matches the specification. This may include the following validation activities:

- Ensure that redundant devices are subject to the correct voting logic.
- Determine how the logic solver processes bad sensor data (i.e. out of range) and whether this fault is properly annunciated in the control room.
- Verify that computations are being performed correctly and that bad data do not impede program operation.
- Verify that sequenced operations are occurring correctly and that any required triggers (e.g. operation actions or devices) for sequencing are being received at the correct points during logic execution.
- Ensure that any diagnostic alarms are generated according to the specification (e.g. deviation alarms for redundant input devices).

- Determine the action of the logic when power failure occurs.
- Verify what happens to the logic when combinations of inputs occur in an unusual manner (e.g. fault insertion testing).

The test for final elements should determine that the final element can achieve the safe-state condition. The *final element* boundary includes all of the devices from the logic solver output to the control element that takes action on the process. For example, in the case of fail-to-close block valves, the test must ensure that the solenoid valve de-energizes, venting air from the valve actuator, which causes the valve to go to the closed position. If limit switches are used for trip indication or for sequencing operation, these limit switches must be tested. If closure speed is specified, the test should include verifying the actual closure speed.

While testing the functionality of the field devices and logic solver is an obvious requirement, it is also necessary to test auxiliary systems and communications. Auxiliary systems may include electrical power and air supplies. For example, if an air-to-move valve is used, the availability of the air supply is safety-critical. Any communication between the SIS and the basic process control system should be tested to ensure proper transfer of the data between the two systems. The test should demonstrate that no communication failure can occur that would prevent proper functioning of the SIS. Thus, the test should validate all features of the SIS, demonstrating that the SIS meets the design specifications.

The importance of testing on functional integrity cannot be overemphasized. The expressions derived in Section 34.7 show that the condition for high integrity is:

$$\lambda\tau_p << 1$$

As an illustration of the effect of the proof test interval, consider a simple SIS that has a failure rate of 0.05 faults/year on a duty where the demand rate is 1 demand in 10 years:

$$\delta = 0.1 \text{ demand/year}$$

$$\lambda = 0.05 \text{ faults/year}$$

If the proof test interval is 1 month:

$$\tau_p = 730 \text{ h}/8760 \text{ h} = 0.0833 \text{ years}$$

Then the FDT is:

$$\begin{aligned}\phi &= \frac{\lambda\tau_p}{2}\\ &= 0.00208\end{aligned}$$

and the plant hazard rate is:

$$\begin{aligned}\eta &= \delta\phi\\ &= 0.000208 \text{ hazards/year}\end{aligned}$$

The plant hazard rate for a range of proof test intervals is:

τ_p	η (hazards/year)
1 month	0.000208
6 months	0.001250
1 year	0.002500
2 years	0.005000
5 years	0.012500

The example above illustrates how the proof test interval affects the plant hazard rate and the FDT. The PHA, as discussed previously, established a target risk reduction to be achieved by the SIS, which is expressed in ANSI/ISA 84.01-1996 and IEC 61511 as the PFD. While this chapter refers to FDT, the discussions also apply to the PFD. Due to the significant impact of the test interval on the SIS performance, any changes to the test interval should only be made after management of change review, which should include an analysis of the impact of the test interval change on the PFD.

There are practical limitations to the test interval. There is always the possibility that while conducting the test that the device may be damaged or not returned to fully operational state. It is important to consider whether bypassing is required in order to perform the testing. If so, the SIS will become less available to perform its design function, as the test interval is decreased. For example, if the test interval is monthly and the test requires a bypass period of 1 h, the SIS unavailability due to the bypass action is as follows:

$$\begin{aligned}1 \text{ h/test} * 12 \text{ tests/year} &= 12 \text{ h/year} * 1 \text{ year}/8760 \text{ h}\\ &= 0.00137\end{aligned}$$

Thus, it is important to minimize the frequency and duration of proof tests. Due consideration should be given to eliminating the use of bypasses whenever possible. The fewer bypasses that are required, the lower the probability that it will be left in bypass unintentionally.

In some instances, it is desirable to test some of the potential failures of an SIS component at one interval and the other failures at a different interval. For example, full closure of an SIS block valve during normal operation requires a bypass line and valve in order for operation to continue uninterrupted. Instead, a partial stroke can be done, which cannot demonstrate that the valve will close, but will demonstrate that the valve can move. Summers (2000) and Summers and Zachary (2002) discuss various means of performing a partial stroke test of a block valve and how this type of test can improve the SIS functional integrity and reliability.

One example cited by Summers and Zachary (2002) is the use of the solenoid valve to partially close a block valve in de-energize to trip SISs. The test is performed by pulsing the power to the solenoid valve for a period of time necessary to move the valve from the full-open position. This partial test verifies the ability to vent the air from the process valve actuator, including the solenoid valve, the solenoid vent point, the air tubing between the valve actuator and the solenoid valve, and the movement of the valve actuator. To reduce the potential for spurious trips, redundant solenoids can be used.

The PFD of the device that undergoes two partial tests can be evaluated as follows. First, the functional failure rate and proof test interval associated with one of the tests is determined using λ_A and τ_{pA}, respectively. Then, the functional failure rate and the proof test interval associated with the second test is determined using and λ_B and τ_{pB}, respectively. Therefore,

$$q_A = 1 - \exp(-\lambda_A t) \qquad [34.10.1]$$

$$q_A = \lambda_A t \quad \lambda_A t << 1 \qquad [34.10.2]$$

Similarly,

$$q_B = \lambda_B t \quad \lambda_B t << 1 \qquad [34.10.3]$$

Then the PFD is:

$$\phi = \frac{1}{\tau_{\mathrm{pA}}}\int_0^{\tau_{\mathrm{pA}}} q_{\mathrm{A}}\,\mathrm{d}t + \frac{1}{\tau_{\mathrm{pB}}}\int_0^{\tau_{\mathrm{pB}}} q_{\mathrm{B}}\,\mathrm{d}t \qquad [34.10.4]$$

$$\phi = \frac{1}{2}\left(\lambda_{\mathrm{A}}\tau_{\mathrm{pA}} + \lambda_{\mathrm{B}}\tau_{\mathrm{pB}}\right) \qquad [34.10.5]$$

34.11 Special Applications

34.11.1 High integrity protection systems

The use of SISs instead of pressure relief valves is sometimes an attractive proposition, particularly where the relief valve solution involves a large flare or toxic scrubbing system or where the process pressure develops so rapidly that the relief valve size is unreasonably large.

The former case is considered by Kletz (1974a) and by Lawley and Kletz (1975), who suggest that if an SIS is used instead of a relief valve, it should be designed for a reliability 10 times that of the latter. The reason for this is the uncertainty in the relief valve failure rate data and the difference in the modes of failure; a relief valve that fails to operate at the set pressure may nevertheless operate at a higher pressure, whereas an SIS is more likely to fail completely.

API 521 and ASME Code Case 2211 require that any SIS used to protect a vessel against overpressure must achieve the level of risk reduction that would typically be provided by the relief valve. Thus, the PHA is used to determine how much risk reduction is required to mitigate the overpressure. This yields how much risk reduction must be provided by the SIS. *Layers of Protection Analysis* (CCPS, 2001) discusses the use of protection layers to evaluate the risk reduction provided by the relief valves and the use of high integrity protective system (HIPS) for overpressure protection.

Summers (2002, 2003a) discusses the design of HIPS applied to flare load reduction. In many flare load reduction projects, the design intent is to mitigate the overpressure event with the SIS such that the potential load from the vessel under review can be removed from the load calculation. This typically results in a risk reduction requirement equivalent to SIL 3. To achieve SIL 3, the HIPS is fully redundant in the process sensors, logic solver and output devices. The HIPS must also be tested frequently or incorporate diagnostics for all devices.

Summers (2003b) discusses the application of HIPS to reactive hazards management. These HIPS are often more complicated than those used for flare load reduction. The logic required to achieve a safe state for flare load reduction is typically simple, such as high pressure initiating a shutdown of final elements, such as valves, pumps or compressors. For reactive processes, the logic can be complex due to the use of the following:

- multiple process variables, such as the reactive conditions are only achieved after a specific temperature is reached during the batch reaction;
- sequence-oriented, including the modification of trip setpoints at various stages or the enabling of different SISs at different steps of the batch reaction;
- operational state-based, such as the enabling of different trip setpoints dependent on whether the process is in normal operation or in regeneration mode;
- kinetic reaction-based, where the logic contains predictive calculations based on process kinetics.

The risk reduction requirement for reactive hazards management is often a factor of 1000. This risk reduction may be achieved with a single layer SIS or with multiple SIS layers. The former results in an SIL 3 requirement. The latter may involve combinations of layers, and these layers must be examined for potential common mode failure.

34.11.1.1 HIPS example

A major application of advanced SIS design is the ethylene oxide process of ICI described by Stewart and co-workers (R.M. Stewart, 1971, 1974a; R.M. Stewart and Hensley, 1971). The ethylene oxide process is extremely hazardous for two reasons: (1) it operates with a reaction mixture very close to the explosive limit and (2) there is a fire/explosion hazard, as well as a toxic release hazard.

The design of the protective system followed the methods already outlined. The risk criterion was set at a hazard rate of 3×10^{-5} fatalities per year. The hazards were assessed by means of a fault tree, part of which is shown in Figure 34.11.

The system devised is a HIPS, consisting of the high integrity trip initiators (HITIs), the high integrity voting equipment (HIVE) and the high integrity shut-down system (HISS). A schematic system diagram, which omits replicated signal connections, is shown in Figure 34.12.

Redundancy is fully exploited throughout the system. Against each logic path to fire/explosion in the fault tree at least one parameter was selected initially to be a trip initiator. The choice of the trip initiating parameters is important but difficult. Some are obvious such as high oxygen concentration, high reactor temperature or low recycle gas flow. Others are far less obvious, but are needed to guard against combinations of faults or to substitute for other parameters.

The measuring instruments used are carefully selected and, if necessary, modified to ensure high integrity. Each parameter is measured by triplicated input sensors, voting 2oo3. The arrangement of the shut-down valves in the oxygen line illustrates further the use of redundancy. There are two lines each with three valves. A single line represents a 1oo3 shut-down system. Duplication is provided to permit complete testing without bypassing.

The advantages of this SIS design are that the failure of one trip initiator in the fail-safe mode does not cause the plant to be tripped spuriously, the failure of one trip initiator in the fail-dangerous mode does not prevent the plant from being tripped, and the proof testing can be done without bypassing any devices.

The SIS design was subjected to an independent assessment by assessors within the company who were advised by the UKAEA. The assessors checked all feasible faults that could lead to hazardous conditions. They also evaluated the capability of the HIPS to carry out the protective action against the hazardous conditions arising from such faults and the occurrence rate of other hazardous conditions that the HIPS would not prevent. The overall hazard rate was compared with the design target. Table 34.14 shows some of the results generated during this assessment.

The assessment showed that at this stage the plant hazard rate was 4.79×10^{-5}/year, which was higher than the target of 3×10^{-5}/year. An extra HITI was used to reduce the contribution of fault 3 from 2.72×10^{-5} to 0.8×10^{-5}/year, which enabled the SIS to achieve the target FDT.

The assessors also examined the HIPS as installed to ensure that there were no significant deviations from

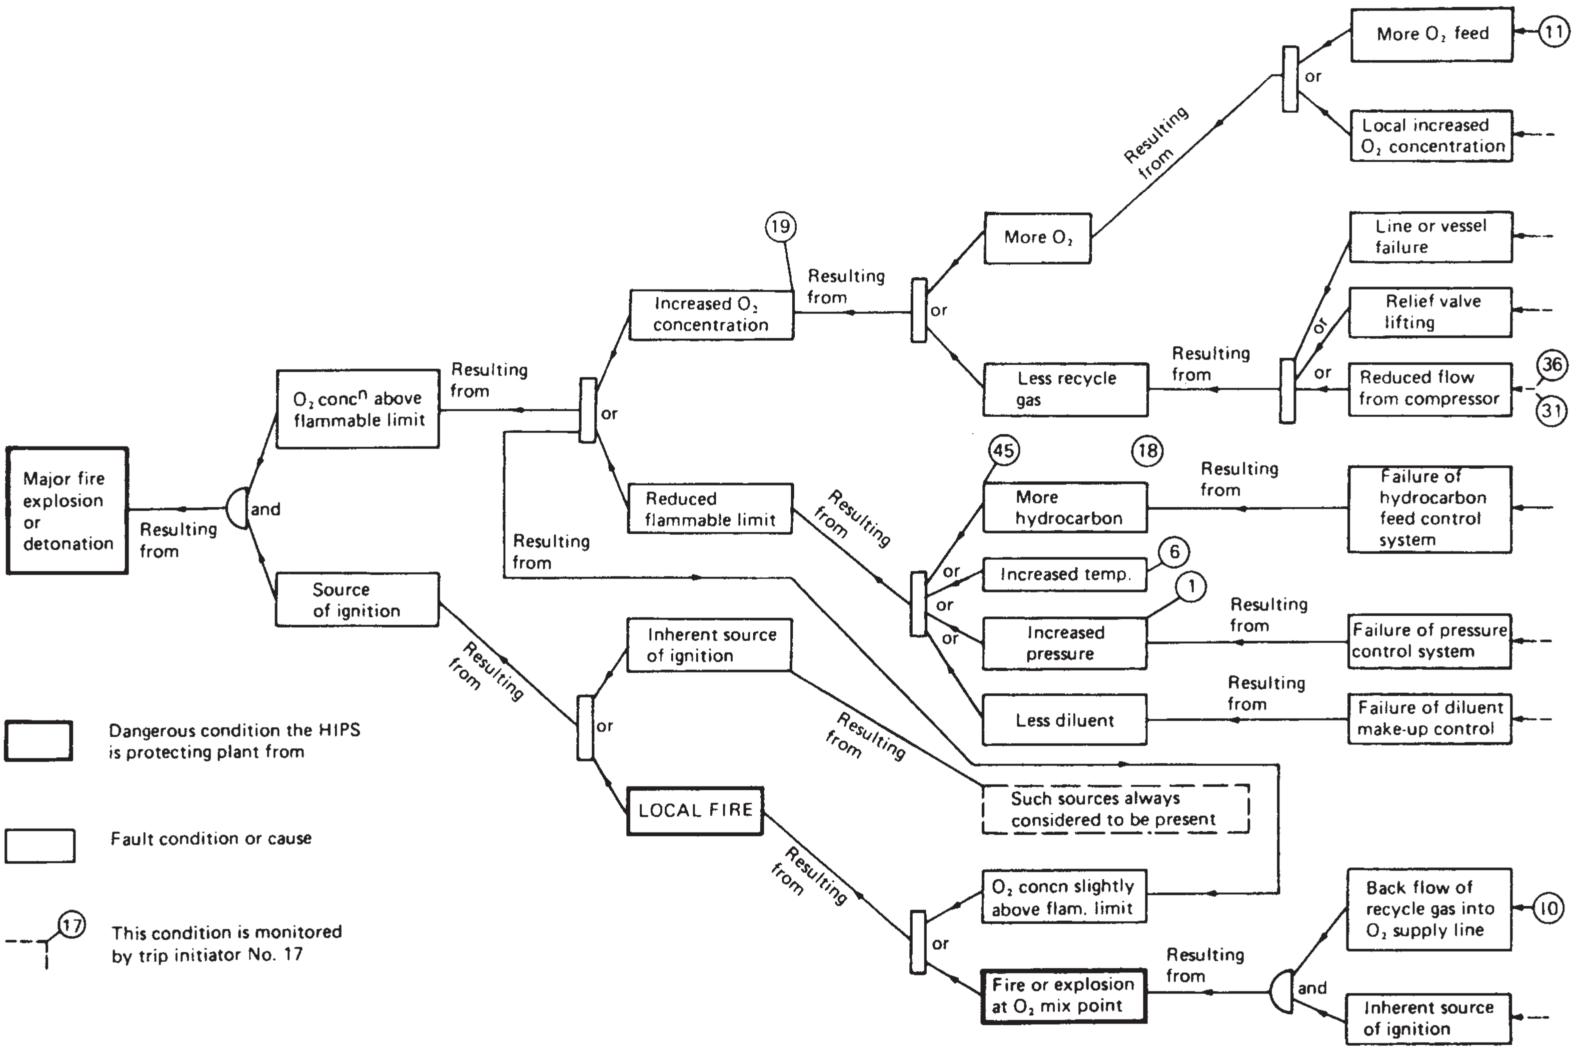

Figure 34.11 *Fault tree for fire/explosion on an ethylene oxide plant (after P.M. Stewart, 1971) (Courtesy of the Institution of Chemical Engineers)*

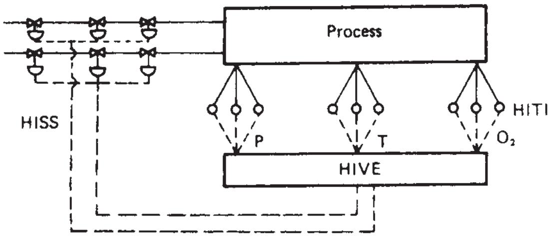

Figure 34.12 High integrity protective system (after Stewart, 1971) (Courtesy of the Institution of Chemical Engineers)

design and reviewed the maintenance, calibration and testing procedures. The quality of the maintenance and testing is crucial to the integrity of a protective system and much attention was paid to this aspect.

It was estimated that an alternative system with 70 1oo1 single trip initiators would result in some 30 spurious trips a year and that the system used reduced this by a factor of over 12. Since the cost of a trip was estimated as £2000, the savings due to avoidance of spurious trips was about £55,000 per annum. The cost of £140,000 for the installation was therefore considered justified on these grounds alone.

A second account of this installation has been given by A. Taylor (1981), who describes the operation of the SIS over the period 1971–80. Analysis of the actual process unit and SIS performance revealed, that in a few cases, the demand frequency was greater than originally estimated by orders of magnitude. The author gives a table listing seven fault conditions, with the event numbering rising to 53, which exemplify the worst discrepancies. The two fault conditions which show the greatest discrepancies are the opening of a certain relief valve and loss of reaction:

Fault description	*Fault condition*		
	Predicted frequency (events/year)	*Actual frequency* (events/year)	*Ratio of actual/predicted frequency*
15 A certain relief valve open	0.001	1.68	1680
48b Loss of reaction	0.01	1.16	116

The relief valve fault was due to shimmering or feathering, which had not been anticipated. The loss of reaction fault is not explicitly explained, but references by the author to the effect of modifications in reaction conditions may bear on this. It is noteworthy that of the seven fault conditions it is those for which the original frequency estimates were lowest that are most in error.

With regard to instrument failure rates, in the case of magnetic float switches, three different failure mechanisms, and three different failure rates, were observed. Switches operating submerged in clean lubricating oil recorded no failures; those operating in recycled gas with occasional slugs of dirty water choked up; and a new type of switch was found to suffer from corrosion. This illustrates that the failure rate of a device is dependent on the specific type of device and the application environment.

The author also noted three examples of dependent failure. One of these relates to the choked level switches just mentioned, which were all on one vessel. On four occasions, testing of the switches revealed that all were choked. The test procedure was altered to require that if one switch was found to be choked, the others should be tested.

There were also mistakes made in the installation of the instruments. In one case, pneumatic pressure switches, of a flameproof type which is not waterproof, were located downwind of a low pressure steam vent pipe and suffered water ingress and corrosion.

34 11.2 Emergency shut-down systems

In many process units, there are SISs to prevent or mitigate specific process risks. In addition, the process unit may be protected by ESDs or emergency isolation systems. One of the principal accounts of ESDs is given in *Offshore Installations: Guidance on Design and Construction, Guidance Notes to the Offshore Installations (Construction and Use) Regulations 1974* issued by the Department of Energy (1984) and *Offshore Installations: Guidance on Design, Construction and Certification* (HSE, 1990b) (the HSE *Design, Construction and Certification Guidance Notes*). In many cases, ESDs are safety-instrumented systems and the principles described previously can be applied. The following is a discussion of ESDs, related to the above referenced texts.

34.11.2.1 Conceptual design of ESD

The function of an ESD system is to detect a condition or event sufficiently hazardous or undesirable as to warrant a shut-down and transition to a safe state. The potential hazards are determined through PHA. Estimates are then made of the frequency and consequences of these hazards. The ESD can then be specified based on the identified operating parameters that must be kept within limits if the hazards are to be avoided and selecting shut-down actions that will act when these limits are exceeded. A shut-down sequence is determined, and the shut-down logic is formulated. It is not always necessary to shut-down the whole plant. There are different levels of ESD, which fall short of this, such as shut-down of an individual unit or of a section of a plant.

34.11.2.2 Initiation of ESD

The configuration of the shut-down initiators of the ESD is critical. If the configuration is poor, the ESD will not be activated when it should be. A balance must be achieved between the functional integrity and operational reliability of the ESD system. It should act when a hazard arises, but should not cause unnecessary shut-downs.

One factor that affects this balance is that the plant is safest in the normal operating mode and that transitions, such as shut-down and start-up, tend to be more prone to hazards and should be avoided unless necessary. Another, related factor is that shut-down of one unit may result in process demands in other process units, causing initiation of other ESDs. These 'cascade trips' increase the hazard rate in the plant and should be avoided.

ESD initiation may be manual or automatic. Manual initiation may use a shut-down button in the control room and/or a local shut-down button in the process unit. Automatic means are accomplished using instrumentation, including the fire and gas system and/or the SIS. Measures

Table 34.14 *Assessment of reliability of a high integrity trip system (after P.M. Stewart, 1971) (Courtesy of the Institution of Chemical Engineers)*

Description	*Fault condition*				*Relevant trip initiator No.*	*Fractional dead time*				*Hazard rate* ($\times 10^5$) *(i = d × h)*
	Occasions per year *a*	*Probability that it leads to rupture* *b*	*Probability that operator's intervention fails* *c*	*Demand rate (demands/year)* *(d = a × b × c)*		*HITI* *e*	*HIVE* *f*	*HISS* *g*	*Overall* *(h = e + f + g)*	
1 Feed filters blocked	0.001	0.2	0.1	0.000 02	10 and 12	10^{-4}	10^{-5}	10^{-5}	1.2×10^{-4}	0.00024
2 Oxygen supply failure	2.0	0.2	0.1	0.04	10 and 38	10^{-4}	10^{-5}	10^{-5}	1.2×10^{-4}	0.48
3 PCV fails open	0.25	0.1	1.0	0.025	11	10^{-3}	8.3×10^{-5}	10^{-5}	1.09×10^{-3}	2.72

5 Gross carryover from absorber	0.1	1.0	0.1	0.01	18.24	10^{-4}	10^{-5}	10^{-5}	1.2×10^{-4}	0.12
6 etc.										etc.

PCV, pressure control valve.

should be taken to avoid inadvertent activation, including failures or errors during maintenance and testing.

34.11.2.3 Action on ESD

There are a variety of actions that an ESD system may take. Three principal types are:

(1) flow isolation;
(2) energy reduction;
(3) material transfer.

Flow isolation includes isolation of feed and other flows. It often involves shut-down of machinery and may include isolation of units. Energy reduction covers shut-off of heat input, as well as initiation of additional cooling. Material transfer refers to pressure reduction, venting, or blow-down.

A fundamental principle in ESD design is failure to a safe state. The overall objective is failure to a safe state for the system as a whole. This is normally performed by applying the principle to individual units, but there may be exceptions, and cases should be considered individually. Each required action of the ESD system should be affected by positive means. Reliance should not be placed on the cascading effect of other trip actions.

34.11.2.4 Detail design of ESD system

It is a fundamental principle that protective systems be independent of the rest of the instrument and control system, and this applies equally to an ESD. The ESD design should generally follow the principles that apply to SISs, as previously described. There should be a balance between functional and operational reliability. Dependent failures should be considered. The reliability may be assessed using fault tree and other methods. The techniques of diversity and redundancy should be used as appropriate. Use may be made of majority voting systems.

The emergency shut-down valves (ESVs) should have a high degree of integrity. Such valves are frequently provided with pneumatic or hydraulic power supplies, in addition to electrical power supply. An ESV should be located so that it is unlikely to be disabled by the type of incident against which it is intended to protect.

The ESD system should be provided with power supplies that have a high degree of integrity. The normal approach is to provide a UPS. This supply should be designed and located so that it is unlikely to be disabled by the incident itself. The cables from the power supply to the final shut-down elements should be routed and protected to avoid damage by the incident.

34.11.2.5 Operation of ESD system

The operator should be notified of any change in ESD status. This includes indication that the ESD is in bypass, under test or under maintenance. Initiation of the ESD should activate audible and visual alarms in the control room. There should be an indication of the source of the initiation, whether manual or instrument. The ESD should also be signalled by an alarm that is part of the general alarm system.

It may be necessary in certain situations, such as start-up, changeover or maintenance, to bypass at least part of the ESD system, but such bypassing should be governed by formal procedures. The principles are analogous to those that apply to an SIS, as described previously.

34.11.2.6 Testing and maintenance of ESD system

The ESD system should be subject to periodic proof testing and such testing should be governed by a formal procedure. The principles of proof testing were discussed previously. As far as is practical, the test should cover the complete system from initiation to shut-down condition.

The need for proof testing and, more generally, for the detection of unrevealed failure should be taken into account in the design. The equipment should be designed for ease of testing. It should be segregated and clearly identified. Techniques for detection of instrument failure should be exploited. In voting systems, the failure of a single channel should be signalled.

34.11.2.7 Documentation of an ESD system

The ESD system should be fully documented. The HSE *Design, Construction and Certification Guidance Notes* give details of recommended documentation.

34.11.2.8 ESD of a gas terminal

The design of systems for ESD and emergency depressurization (EDP) of a gas terminal has been described by Valk and Sylvester-Evans (1985). The design philosophy described is that: (1) the ESD system should operate only in an extreme emergency, (2) the ESD and EDP systems are separate from the control, SIS and relief systems and (3) that the systems should be simple and reliable.

The preliminary design of the ESD and EDP systems was reviewed by means of a HAZOP study. Potential operational failures were studied using general reliability engineering methods and functional failures were studied using, in particular, fault tree analysis. A further HAZOP was conducted on the final design for the ESD and EDP system.

Design studies showed that executing a totally fail-safe concept would result in a relief and flare system of exceptional size. Alternatives considered were to allow an increase in the depressurization time for certain critical equipment beyond that recommended in the API RP 521 and to control the peak depressurization flow in the relief and flare system. In the design adopted, the plant was divided into sections, such that the depressurization of each section could be done independently and the operation of the sections was interlocked. The depressurization time of certain items was extended to 30 min as opposed to the 15 min recommended in API RP 521, but the design compensated for this extension by provision of additional fireproofing and water cooling arrangements.

The authors highlight the differences of philosophy between companies on whether the ESD and EDP systems should be used for normal shut-down and depressurization or reserved as systems dedicated for emergency use. This project reaffirmed the need to consider the ESD and EDP systems at an early stage and to avoid treating them as 'add-on' features to be dealt with late in the design.

34.11.2.9 ESD on Piper Alpha

The ESD system on Piper Alpha illustrates a number of the points just made. Overall, the system was largely effective in achieving shut-down, venting and blow-down, but there were a number of features which are of interest.

The main ESD button initiated closure of the ESV on the main oil pipeline but not on the ESV on the three gas pipelines. One reason for this was that closure of these latter ESVs would impose a forced shut-down on the linked platforms. There were three separate shut-down buttons, one for each of these valves, and shut-down depended on manual action by the control room operator – he was thrown across the control room by the explosion.

The ESVs on the risers of the gas pipelines were located so that they were vulnerable to the fires that developed. This defect was widespread throughout the North Sea and regulations were introduced without delay to require such valves to be relocated. There was also evidence that some of the ESVs did not achieve tight *shut-off*. The explosion damaged power supplies, and, in some cases, closure *of* ESVs occurred, not due to survival *of* the intended power supply, but fortuitously. Further details are given in Appendix 19.

34.11.3 Toxic storage instrumentation

On plants handling high toxic hazard materials (HTHM), the instrumentation and control system assumes particular importance. Some relevant considerations are outlined in *Guidelines for Safe Storage and Handling of High Toxic Hazard Materials* by the CCPS (1988/2) (the CCPS HTHM *Guide*).

Depending on the degree of hazard, the instrumentation and control system should be of high integrity. This requires adherence to the various principles already described for high integrity design, including the application of fail-safe design and the use, as appropriate, of high reliability instrumentation, instrument diversity and redundancy and high quality maintenance. It also involves the application of the techniques of hazard identification and assessment to the design.

With respect to process variable measurement, principal considerations are that the potential for release from the instrument, or its fittings, should be minimized, that the instrument be reliable and that the measurement be accurate. For flow measurements, the use of non-invasive sensors, such as magnetic flowmeters, and avoidance of glass in instruments, such as rotameters is preferred. Orifice flowmeters also have the disadvantage of an extra flange and associated piping. For pressure measurement, diaphragm pressure sensors are preferred to direct-connected gauges of the Bourdon tube type. Precautions to be taken where the latter have to be used include protection by inert liquid filling in corrosive service and installation of isolation valves and, possibly, flow limiters in the form of restriction orifices. For level measurement, weighing methods have advantages, but use of sight glasses should be avoided. For temperature measurement, particular care should be taken in the design of the thermowell, which can be a weak point.

The arrangements for control and protection should address the hazards of particular importance for the storage of toxics. These include: (1) overpressure, (2) overfilling, (3) over-temperature and (4) high release flow. For overpressure, the main requirements are the provision of overpressure protection and of means of disposal for the relief flows. For overfilling, a significant role is likely to be played by SISs. For temperature deviations, which may indicate reaction runaway or thermal stratification with its attendant risk of rollover, the need is for warning. Some methods of dealing with excess temperature are described below. High release flow rates following a failure of containment may be mitigated by the use of suitable control valve trims and of restrictor orifices or excess flow valves.

Storage of a reactive chemical requires close monitoring with respect to temperature and contamination. Methods of temperature control include the use of cooling coils, a reflux condenser, a quench system and short stop arrangement. All these methods depend on good mixing in the tank. Consequently, recirculation of the reactive chemical through a cooler is often used. Contamination can be introduced by putting the wrong chemicals in the tank or by using the wrong materials of construction for the tank, seals, or other peripheral equipment. Procedures and training are necessary to prevent these occurrences.

34.11.4 Interlock systems

Interlocks are another important type of protective device. They are used to: (1) control operations that must take place in a specified sequence or (2) ensure that one piece of equipment is in a specific state relative to other equipment. This definition of an interlock differs from that often used in the American literature, where the term 'interlock' tends to be applied to both SIS and interlock systems (as defined here).

Accounts of interlock systems are given in *Applied Symbolic Logic* (E.P. Lynch, 1980) and *Logical Design of Automation Systems* (V.B. Friedman, 1990) and by D. Richmond (1965), E.G. Williams (1965), Becker (1979), Becker and Hill (1979), Kohan (1984) and the CCPS (1993/14).

In general, interlocks are used to prevent operation of equipment under unsafe condition. There are various means for implementing interlocks. These include mechanical devices, such as a padlock and chain on a hand valve, keyed interlocks and software interlocks implemented using process computers. Interlocks are usually simple in design, but can incorporate redundancy if high integrity is required for the application. Typical applications of interlocks include:

(1) electrical switchgear;
(2) test cubicles;
(3) machinery guards;
(4) vehicle loading;
(5) conveyor systems;
(6) machine start-up and shut-down;
(7) valve systems;
(8) instrumented systems;
(9) fire protection systems;
(10) plant maintenance.

For example, electrical switchgear may be installed in a room where an interlock prevents the door from opening until there is electrical isolation. Similarly, an interlock may be used to prevent access to a test cubicle where high pressure or explosive materials are present until safe conditions are achieved. An interlock may be also used to stop access to a machine or entry into a vessel unless the associated machinery cannot move. In vehicle loading, interlocks are used to prevent a tanker from moving while it is still connected to the unloading arm. Pressure relief valves have interlocks to prevent all the parallel valves from being isolated simultaneously. There may be interlocks on other critical valve systems.

Interlocks may also be used to ensure sequenced operation, as in a conveyor system. Interlocks are used for the start-up of machinery to ensure that all the pre-start conditions are met, that the correct sequence is followed, and that conditions for transition from stage to stage are met. For large rotating machinery, key factors are process conditions and oil pressures.

Interlocks are often a subset of a SIS. An interlock may be used to prevent the disarming of an SIS unless certain conditions are met. Fire protection systems are provided with interlocks as a safeguard against leaving the system in bypass, particularly after testing or maintenance. Plant maintenance operations make much use of interlocks to prevent valves being opened or machinery started up while work is in progress.

Some features of a good hardware interlock are that it: (1) controls operations positively, (2) is incapable of defeat, (3) is simple, robust and inexpensive, (4) is readily and securely attachable to engineering devices and (5) is regularly tested and maintained.

Many interlocks are quite simple, but some are quite complex. When interlocks involve complex logic functions, they are effectively safety instrumented systems and can be designed in the same manner. In particular, there are some very large interlock systems on boilers and gas turbines. For example, control of sequential operations is often executed using numerous checks that must be satisfied before the next stage is initiated and checks that equipment has obeyed the control signals. These checks constitute a form of interlock.

Since an interlock can bring the process to a halt, it is important to provide 'first-out indication,' including adequate status and alarm signals to indicate what initiated the stoppage.

34.11.4.1 Interlock diagrams

As with safety instrumented systems, interlock design may involve a number of parties. For effective design, a common language and approach are needed. Unfortunately, there is substantial disagreement in the field related to the type of diagram used to describe the logic, the representation of symbols and the nomenclature. While standards have been written to cover these areas, the symbols used in some are not in common use and the standards are subject to continuous revision.

Three types of diagrams commonly used in the process industry are: (1) the process flowchart, (2) the logic diagram and (3) the ladder diagram. The last two are sometimes referred to as the 'attached logic diagram' and the 'detached logic diagram,' respectively. A process flow chart can be used to describe the sequence of operations. Process flow chart symbols have been given in *Work Study* (Curie, 1960) and are shown in Table 34.16, Section A. The logic required to implement this sequence may be shown in a logic diagram. This utilizes standard symbols for functions such as OR, AND and NOT, similar to those used in fault tree work, as described in Chapter 9. Standard symbols for fault trees are given in BS 5760 *Reliability of Systems, Equipment and Components*, Part 7: 1991 *Guide to Fault Tree Analysis*. Typical logic symbols are shown in Table 34.15, Section B.

The logic diagram may then be converted to a ladder diagram. Standard symbols for protective logic systems are given in BS 3939: 1985 *Graphical Symbols for Electrical Power, Telecommunications and Electronic Diagrams*. The relevant IEC standard is IEC 617 *Graphical Symbols for Diagrams*. BS 3939: Part 7: 1985 *Switchgear, Controlgear and Protective Devices*, which is identical to IEC 617-7, gives relevant symbols. Other sets of symbols include those given by E.G. Williams (1965) and those of E.P. Lynch (1980). An account of the evolution of logic symbols is given in *An Introduction to the New Logic Symbols* (Kampel, 1986).

Table 34.15 *Interlock logic symbols*

A Work study symbols[a]

Symbol	*Activity*	*Predominant result*
	Operation	Produces, accomplishes changes further the process
	Inspection	Verifies quantity or quality
	Transport	Moves or carries
	Delay	Interferes or delays
	Storage	Holds, retains or stores

B Logic sysmbols[b]

	AND
	OR
	NOT
	Delay

C Ladder diagram symbols[c]

	Pushbutton start
	Pushbutton stop
	Position, or limit, switch
	Relay or solenoid contacts, normally open, closed when relay or solenoid is energized
	Relay or solenoid contacts normally closed, opened when relay or solenoid is energized
	Motor *n*
	Relay *n*
	Solenoid *n*

---

[a] These symbols are given by Currie (1960), who attributes them without reference to the American Society of Mechanical Engineers.
[b] These symbols are given in BS 5670: Part 7: 1991. The alternative symbol for NOT is a common alternative and is that used by E.P. Lynch (1980).
[c] These symbols are those used by E.P. Lynch (1980).

Table 34.16, Section C, shows a selection of symbols, including those used here, from those given by Lynch.

34.11.4.2 Some basic systems

Some of the basic building blocks of interlock systems are illustrated using a simple starting circuit in Figure 34.13. Activation of the circuit occurs when a signal is generated by depression of the start pushbutton AND a signal due to non-depression of the stop pushbutton. Once activated, the circuit is maintained in the 'on' state until reset by the operator by depression of the stop pushbutton.

Figure 34.13(b) shows a time-delayed holding circuit. If following activation by the start pushbutton, the signal X does not appear within the time interval specified, the output signal disappears. A typical application of this circuit is start-up of a motor-driven pump, which is supplied with lubricating oil by a lube oil pump driven from the same motor. If after the time interval specified, the lubricating oil pressure signal is still absent, the pump is shut-down.

Figure 34.13(c) shows a self-extinguishing circuit. Activation of the pushbutton gives an output signal, which continues until the time interval specified has elapsed. Then, the output signal is extinguished. This circuit might typically be used to have a motor-driven equipment run for a period and then shut-down.

34.11.4.3 Illustrative example: conveyor system

As an illustration of an interlock system, consider the conveyor system described by Lynch. The screw conveyor A feeds material from a car vibrator to an elevator, which discharges to screw conveyor B above two storage bins A and B. There is a slide gate on the pipe between conveyor B and each bin, with a limit switch on each gate. Material is fed from a bin by a star feeder into screw conveyor C. The loading equipment can fill the bins at several times the rate at which it can be withdrawn.

Figure 34.14(a) shows a logic diagram for the interlocks for manual operation of this system. Conveyor B can be started only if either A or B slide gate is open. The elevator can be started only if conveyor B is running. Conveyor A can be started only if the elevator is running. The diagram also shows the simple non-interlocked starting circuit for the car vibrator.

The corresponding ladder diagram is shown in Figure 34.14(b). The diagram shows six circuits A–F. Certain relays occur in more than one circuit, for example, relay R1 in circuits A and D, and this imparts the interlocking feature. Circuit A is the starting circuit for conveyor B. This circuit can be activated only if either relay R2 or R3, the relays for the slide gates limit switches (LS), is closed. If this condition is met, depression of the start pushbutton (PB) energizes relays R1 and M1 and causes R1 to close and M1 to operate a relay in the power circuit. When the stop pushbutton is pressed, the circuit is de-energized and R1 opens.

In circuit B, closure of the slide valve limit switch LSI energizes relay R2 and causes it to close, and opening of the switch causes R2 to open. Circuit C implements a similar

Figure 34.13 *Some basic interlock system logic diagrams: (a) simple starting circuit; (b) time delayed holding circuit; and (c) self-extinguishing circuit. PB, pushbutton*

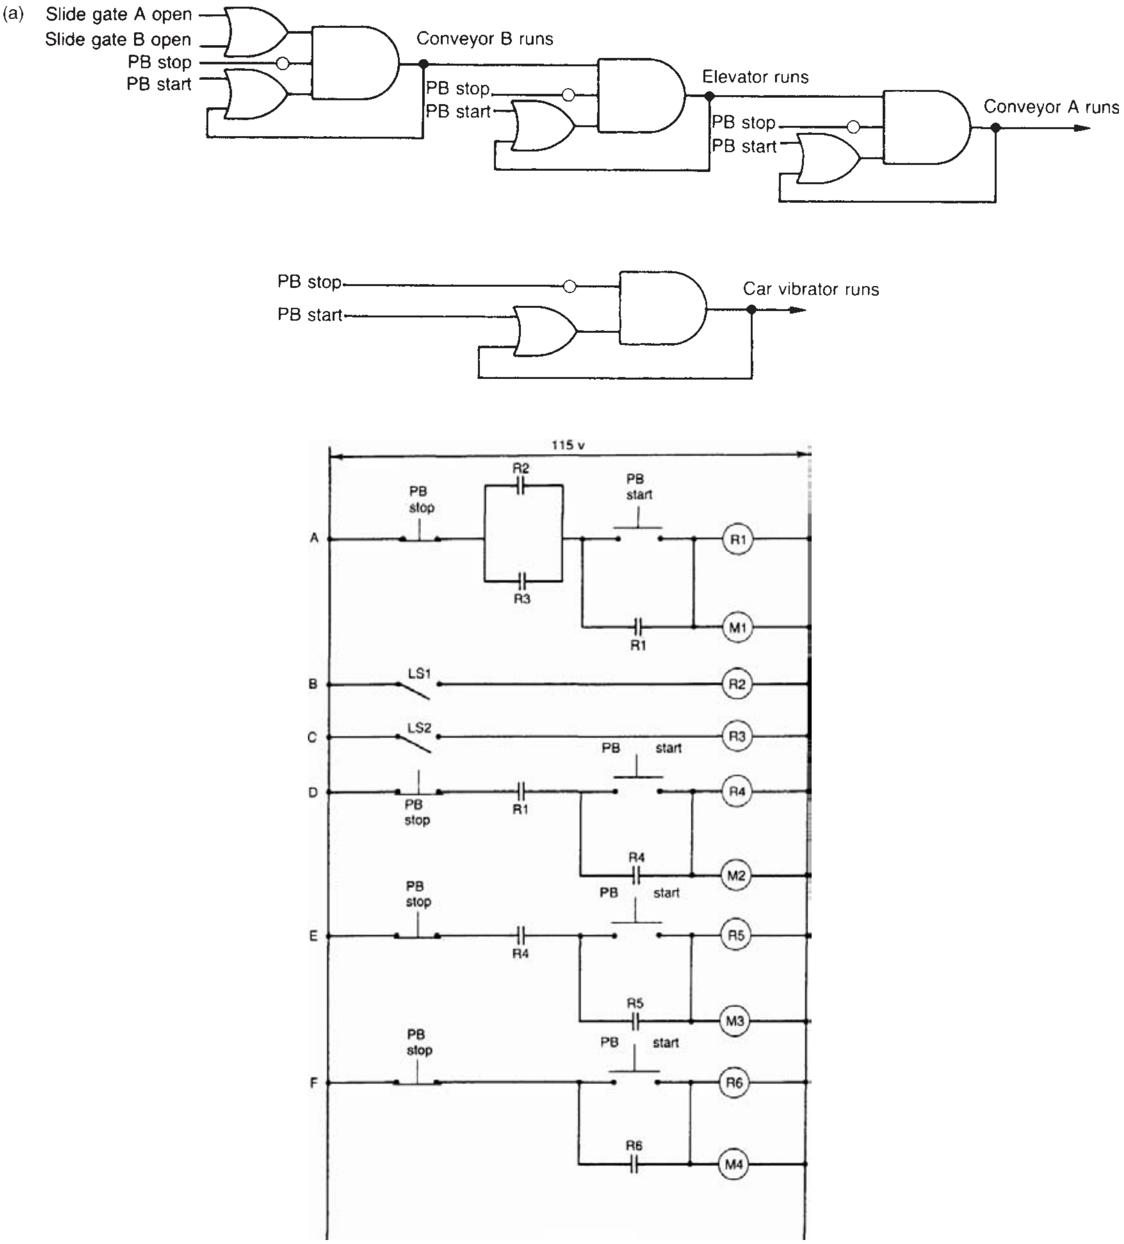

__Figure 34.14__ Conveyor interlock system diagrams: (a) logic diagram, and (b) ladder diagram (E.P. Lynch, 1980) (Reproduced with permission from Applied Symbolic Logic by E.P. Lynch, Copyright ©, 1980, John Wiley and Sons Inc.)

relationship between limit switch LS2 and relay R3. Circuit D is the starting circuit for the elevator. The circuit can be activated only if relay R1 is closed. If this condition is met, depression of the start button energizes relays R4 and M2 and causes R4 to close and M2 to operate. Circuit E is the starting circuit for conveyor A, and is similar to circuit D. The circuit can be activated only if relay R4 is closed. Circuit F is a simple starting circuit and is not interlocked.

34.11.4.4 Illustrative example: reactor system

Another example of a simple interlock system is illustrated in Figures 34.15 and 34.16. Figure 34.15 shows a plant consisting of a water-cooled reactor in which a batch reaction is

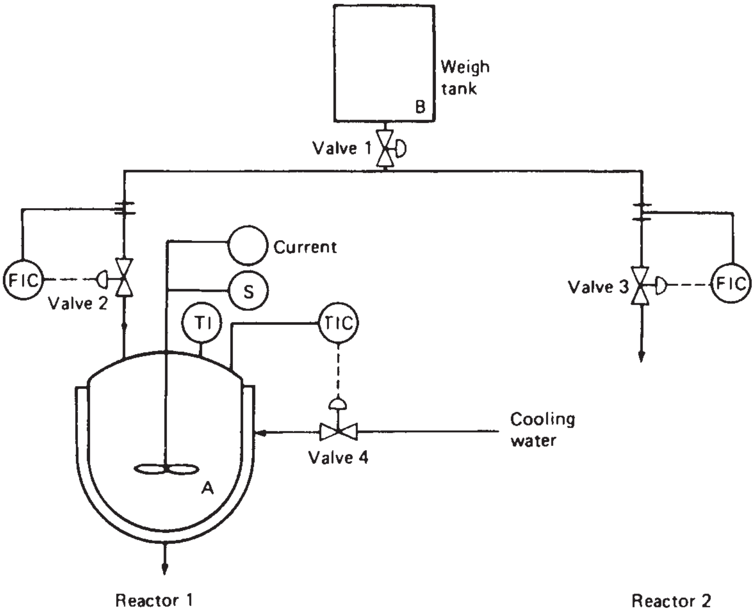

Figure 34.15 Batch reactor system. FIC, flow indicator controller; S, speed measurement; TI, temperature indicator; TIC, temperature indicator controller

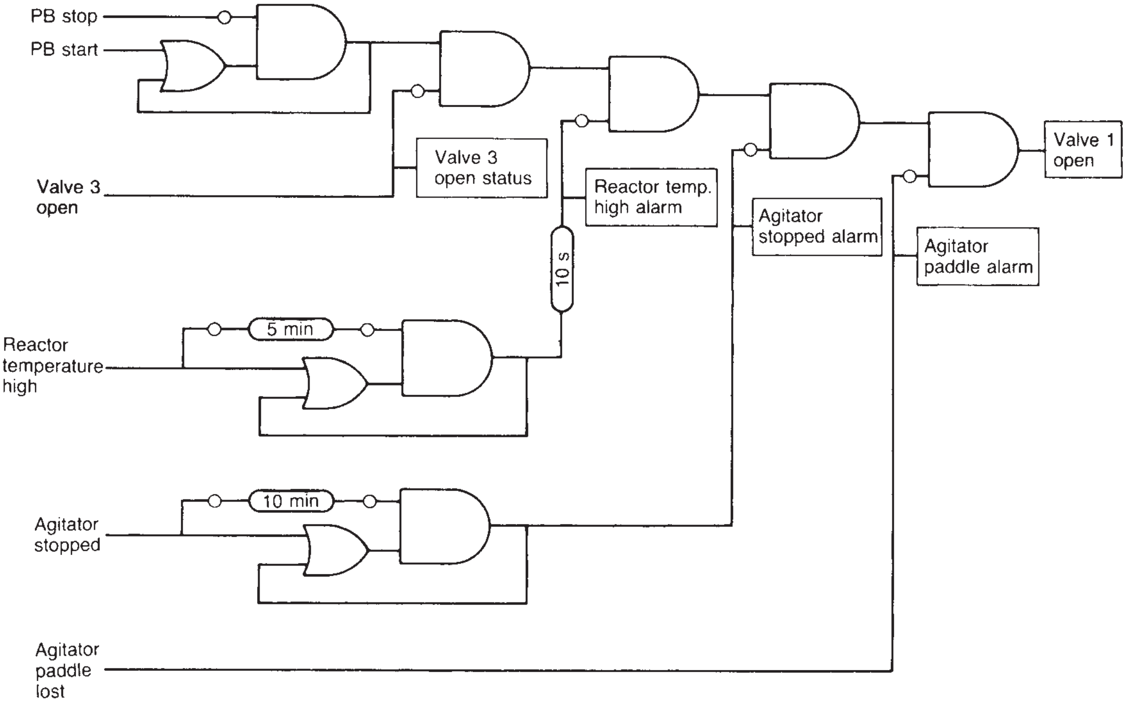

Figure 34.16 Batch reader interlock system logic diagram

carried out. The reactor is charged with chemical A and chemical B is then fed in gradually from a weigh tank as the reaction proceeds. The interlock system is required to cut off the supply of B from the weigh tank if any of the following conditions apply: (1) the shut-off valve V3 on reactor 2 is open, (2) the agitator is not operating, (3) the agitator paddle has fallen off, or (4) the reactor temperature has risen above a fixed limit. The loss of the agitator paddle is detected by a current-sensitive relay on the motor.

An interlock system for carrying out these functions is shown in Figure 34.16. The start input opens valve 1, unless valve 3 is open or the agitator is stopped, which conditions inhibit start-up. If these conditions occur later or if the reactor temperature rises or the agitator paddle falls off, valve 1 is closed. The interlock causing the closure is signalled by a status or alarm display. There is a 10 s delay on the reactor high temperature interlock to allow for noise on that signal. If operation is inhibited by the high reactor temperature or agitator stoppage interlocks, these interlocks are reset at 5 and 10 min, respectively, after the inhibiting condition has cleared. An account of the reliability of interlock systems is given by R.A. Freeman (1994).

35

Chemical Security

Contents

35.1 Introduction

Security is a critical element of the management of a process facility. Security management is required for protecting the assets (including employees) of the facility, maintaining the ongoing integrity of the operation and preserving value of the investment. Process security and process safety have many parallels, and make use of many common programmes and systems for achieving their ends. Process security requires a management systems approach to develop a comprehensive security programme, which shares many common elements to process safety management.

The foundation of the security management system is a security vulnerability assessment (SVA), which is intended to identify security vulnerabilities from a wide range of threats ranging from vandalism to terrorism. With the recognition of threats, consequences, vulnerabilities and the evaluation of the risk of security events, a security management system can be organized that will effectively mitigate the risks.

The world of safety and security in the chemical process industries has certainly changed since the terrorist attack on the United States on 11 September 2001. This and other violent acts pose a new risk paradigm for chemical security. The design and operation of a facility must now consider extreme acts of violence rather than only less severe threats.

35.2 Security Management System

A comprehensive process security management system must include management programme elements that integrate and work in concert to control security risks. The thirteen management practices shown in Figure 35.1 are an example of a management system developed for the chemical industry:

(1)	Leadership Commitment
(2)	Analysis of Threats, Vulnerabilities, and Consequences
(3)	Implementation of Security Measures
(4)	Information and Cyber Security
(5)	Documentation
(6)	Training, Drills, and Guidance
(7)	Communications, Dialogue, and Information Exchange
(8)	Response to Security Threats
(9)	Response to Security Incidents
(10)	Audits
(11)	Third-Party Verification
(12)	Management of Change
(13)	Continuous Improvement

Figure 35.1 *Example process security management system Site Security Guidelines for the U.S. Chemical Industry (American Chemistry Council, October 2001)*

The purpose of the management system is to ensure the ongoing, professional and systematic application of security principles and programmes to achieve a level of specified security. Traditional security management is not based on a management system and so is not necessarily a thorough, ongoing, risk-based, pro-active approach, but is more generally based and is reactive to security incidents primarily.

The process security management system is to ensure the protection of people, property, products, processes, information and information systems and thereby ensure the continuity of the operation and supporting or dependent infrastructure. The chemical industry value chain encompasses company activities associated with the design, procurement, manufacturing, marketing, distribution, transportation, customer support, use, recycle and disposal of products *Site Security Guidelines for the U.S. Chemical Industry* (American Chemistry Council, October 2001).

The *Security Code* published by the American Chemistry Council is designed to help companies achieve continuous improvement in security performance using a risk-based approach to identify, assess and address vulnerabilities, prevent or mitigate incidents, enhance training and response capabilities and maintain and improve relationships with key stakeholders. Each company must implement a risk-based security management system for people, property, products, processes, information and information systems throughout the chemical industry value chain. The chemical industry value chain encompasses company activities associated with the design, procurement, manufacturing, marketing, distribution, transportation, customer support, use, recycle and disposal of our products. The corresponding security management system must include the following thirteen management practices:

(1) Leadership Commitment. Senior leadership commitment to continuous improvement through published policies, provision of sufficient and qualified resources and established accountability.
(2) Analysis of Threats, Vulnerabilities and Consequences. Prioritization and periodic analysis of potential security threats, vulnerabilities and consequences using accepted methodologies.
(3) Implementation of Security Measures. Development and implementation of security measures commensurate with risks, and taking into account inherently safer approaches to process design, engineering and administrative controls and prevention and mitigation measures.
(4) Information and Cyber-Security. Recognition that protecting information and information systems is a critical component of a sound security management system.
(5) Documentation. Documentation of security management programmes, processes and procedures.
(6) Training, Drills and Guidance. Training, drills and guidance for employees, contractors, service providers, value chain partners and others, as appropriate, to enhance awareness and capability.
(7) Communications, Dialogue and Information Exchange. Communications, dialogue and information exchange on appropriate security issues with stakeholders such as employees, contractors, communities, customers, suppliers, service providers and government officials and agencies balanced with safeguards for sensitive information.

(8) Response to Security Threats. Evaluation, response, reporting and communication of security threats as appropriate.
(9) Response to Security Incidents. Evaluation, response, investigation, reporting, communication and corrective action for security incidents.
(10) Audits. Audits to assess security programmes, and processes and implementation of corrective actions.
(11) Third-Party Verification. Third-party verification that, at chemical operating facilities with potential off-site impacts, companies have implemented the physical site security measures to which they have committed.
(12) Management of Change. Evaluation and management of security issues associated with changes involving people, property, products, processes, information or information systems.
(13) Continuous Improvement. Continuous performance improvement processes entailing planning, establishment of goals and objectives, monitoring of progress and performance, analysis of trends and development and implementation of corrective actions.

35.3 Security Strategies

A basic premise is that all security risks cannot be completely prevented. Appropriate strategies for managing security can vary widely depending on the circumstances including the type of facility and the threats facing the facility. As a result, it is difficult to prescribe security measures that apply to all facilities in all industries, but instead it is suggested to use SVA as a means of identifying, analysing and reducing vulnerabilities. The specific situations must be evaluated individually by local management using best judgement of applicable practices. Appropriate security risk management decisions must be made commensurate with the risks. This flexible approach recognizes that there isn't a uniform approach to security in the chemical process industry, and that resources are best applied to mitigate high risk situations primarily.

Security strategies for the process industries are generally based on the application of four key concepts against each threat (*Managing and Analyzing the Security Vulnerabilities of Fixed Chemical Sites* AIChE, August 2002.):

(1) Deterrence
(2) Detection
(3) Delay
(4) Response

In the context of security of a process facility, the security strategies of deter, detect, and delay are defined as follows. *(Managing and Analyzing the Security Vulnerabilities of Fixed Chemical Sites* AIChE, August 2002.):

Deter: A security strategy to prevent or discourage the occurrence of a breach of security by means of fear or doubt. Physical security systems such as warning signs, lights, uniformed guards, cameras, bars are examples of systems that provide deterrence.

Detect: A security strategy to identify an adversary attempting to commit a malicious act or other criminal activity in order to provide real-time observation, interception and post-incident analysis of the activities and identity of the adversary.

Delay: A security strategy to provide various barriers to slow the progress of an adversary in penetrating a site to prevent an attack or theft, or in leaving a restricted area to assist in apprehension and prevention of theft.

Response: The act of reacting to detected criminal activity either immediately following detection or post-incident via surveillance tapes or logs.

A complete security design includes these four concepts in 'Layers of Protection' or a 'Defense in Depth' arrangement. Examples of these physical protection concepts and their associated countermeasures are graphically depicted in Figure 35.2 (adapted from 'Site Security Guidelines for the U.S. Chemical Industry', American Chemistry Council (ACC), October 2001) and Figure 35.3. The most critical assets should be placed in the centre of conceptual concentric levels of increasingly more stringent security measures. In the concept of rings of protection, the spatial relationship between the location of the target asset and the location of the physical countermeasures is important.

In the case of malicious acts, the layers or rings of protection must be particularly robust because the adversaries are intentionally attempting to breach the protective features and can be counted on to use whatever means are available to be successful. This could include explosions or other initiating events that result in widespread common cause failures. Some particularly motivated adversaries might commit suicide attempting to breach the security layers of protection.

35.4 Countermeasures and Security Risk Management Concepts

Countermeasures are actions taken to reduce or eliminate one or more vulnerabilities. Countermeasures include hardware, technical systems, software, interdictive response, procedures and administrative controls.

Security risk reduction at a site can include the following strategies:

(1) Physical Security
(2) Cyber Security
(3) Crisis Management and Emergency Response Plans
(4) Policies and Procedures
(5) Information Security
(6) Intelligence
(7) Inherent Safety

35.5 SVA Methodologies

There are several SVA techniques and methods available to the industry, all of which share common elements.

The following is a list of some available SVA methodologies published by various government, private and trade/professional organizations. Some are merely chapters or sections of documents that address security or risk assessment/risk management in broader terms. Some are SVA/VA publications by themselves. Some of these 'methods' are complete, systematic analytical techniques and some are more checklist in nature.

(11) American Society of Industrial Security, *General Security Risk Assessment Guideline*.
(12) North American Electric Reliability Council, *Vulnerability and Risk Assessment*, Ver 2.
(13) North American Electric Reliability Council, *Security Guidelines for the Electricity Sector*, Ver 1, 14 June 2002.

Ultimately, it is the responsibility of the owner/operator to choose the SVA method and depth of analysis that best meets the needs of his specific location. Differences in geographic location, type of operations, and on-site quantities of hazardous substances all play a role in determining the level of SVA and the approach taken. Independent of the SVA method used, all techniques include the following:

(1) Characterize the facility to understand what critical assets need to be secured, their importance and their interdependencies and supporting infrastructure, and the consequences if they are damaged or stolen;
(2) Identify and characterize threats against those assets and evaluate the assets in terms of attractiveness of the targets to each adversary;
(3) Identify potential security vulnerabilities that threaten the system's service or integrity;
(4) Determine the risk represented by these events or conditions by determining the likelihood of a successful event and the consequences of an event if it were to occur;
(5) Rank the risk of the event occurring and, if high risk, make recommendations for lowering the risk;
(6) Identify and evaluate risk mitigation options (both net risk reduction and benefit/cost analyses) and re-assess risk.

One approach to conducting a SVA is shown in Figure 35.4. This methodology was published by the American Petroleum Institute and the National Petrochemical and Refiners Association in their guidelines *Security Vulnerability Assessment for the Petroleum and Petrochemical Industries*, American Petroleum Institute, May 2003.

35.6 Defining the Risk to be Managed

For the purposes of an SVA, the definition of risk is shown in Figure 35.5. The risk that is being analysed for the SVA is defined as an expression of the likelihood that a defined threat will target and successfully attack a specific security vulnerability of a particular target or combination

Security Countermeasure	Outer Perimeter (Plant Boundary Layer)				Middle Perimeter (Inner Plant/Asset Level)				Inner Perimeter (Asset/Subsystem Level)			
	Deter	Detect	Delay	Respond	Deter	Detect	Delay	Respond	Deter	Detect	Delay	Respond

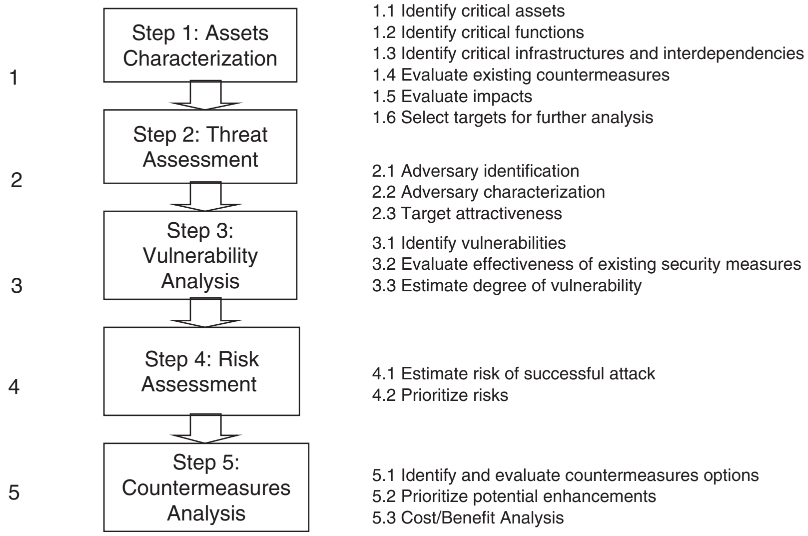

Figure 35.4 *API/NPRA Security vulnerability assessment methodology*

Intentional Release Risk is a function of: Consequences of a successful attack against an asset and likelihood of a successful attack against an asset.	Accidental Release Risk is a function of: Consequences of an accidental event and likelihood of the occurrence of the event.
Likelihood is a function of: the Attractiveness to the adversary of the asset, the degree of Threat posed by the adversary and the degree of Vulnerability of the asset.	Likelihood is a function of: The probability of an event cascading from initiating event to the consequences of interest and the frequency of the events over a given period.

Figure 35.5 *Intentional Release vs Accidental Release – Risk Definitions*

of targets to cause a given set of consequences. This is contrasted with the usual accidental risk definitions. The risk variables are defined as shown in Figure 35.6.

35.7 Overview of a SVA Methodology

The SVA process is a risk-based and performance-based methodology. The user can choose different means of accomplishing the general SVA method so long as the end result meets the same performance criteria. The overall 5-step approach of the API/NPRA SVA methodology is described as follows:

Step 1: Asset characterization
The asset characterization includes analysing information that describes the technical details of facility assets to support the analysis, identifying the potential critical assets, identifying the hazards and consequences of concern for the facility and its surroundings and supporting infrastructure and identifying existing layers of protection. Essentially, this step identifies the assets (people, facilities, information, reputation, business) of value, analyses why it is of value and identifies its importance, determines the interaction of the assets with other neighbouring facilities, suppliers, or customers or other economic interdependencies. Assumptions are made on the worst credible security event consequences to determine the impacts. The estimate of severity of the consequences is one of the four risk factors.

Step 2: Threat assessment
The intentional release risk includes possible attacks by outsiders or insiders, or a combination of the two adversaries.

Consequences	The potential impacts of the event
Likelihood	Likelihood which is a function of the chance of being targeted for attack, and the conditional chance of mounting a successful attack (both planning and executing) given the threat and existing security measures. This is a function of three variables below.
Threat	Threat, which is a function of the adversary existence, intent, motivation, capabilities and known patterns of potential adversaries. Different adversaries may pose different threats to various assets within a given facility.
Vulnerability	Any weakness that can be exploited by an adversary to gain access and damage or steal an asset or disrupt a critical function. This is a variable that indicates the likelihood of a successful attack given the intent to attack an asset.
Target Attractiveness	Target Attractiveness, which is a surrogate measure for likelihood of attack. This factor is a composite estimate of the perceived value of a target to the adversary and their degree of interest in attacking the target.

Figure 35.6 *API/NPRA SVA methodology SVA risk variables (Managing and Analyzing the Security Vulnerabilities of Fixed Chemical Sites, AIChE, August 2002.)*

It may be perpetrated by a number of different adversaries with varying intents, motivations, weapons, tactics and capabilities. These issues need to be sorted out in a threat assessment, which is, in effect, a risk-based assessment that forms the basis of the design basis threat assumption the facility designs and operates to.

The selection of the threats should include reasonable local, regional or national intelligence information, where available. This step also includes determining the target attractiveness of each asset from each adversary's perspective.

A responsible company has to give thought to the possible threats and attempt to organize the many combinations and permutations into a threat matrix. Key to this matrix is the first variable – what is the target? Is the company a direct target or is it affected by a terrorist attack? From a pure risk management standpoint, companies need to be prepared for both contingencies, not only for the possibility of direct physical or cyber attack to their facilities. This shows the multi-faceted aspects of the problem, and the need for industry, community and government cooperation to address the problem.

For example, there is a major difference in the protection set required if the assumed threat is an armed attack by a small band of terrorists who use force to enter the main entrance way, vs a single insider who misuses their access to the process control system to cause a release from the same asset. Which threats are credible and to what extent is the threat potential?

Threat is an important factor in the determination of risk. Prior to 11 September 2001, for example many of the other factors in the risk equation were present, but the threat was considered to be too low to be credible. It is the increased appreciation of threat that prompts us to now take action. Properly done, the threat assessment forms the basis of the process security management strategy for the facility.

The threat definition results in a determination of the design basis threat for the facility. The threat assessment results in a 'fixed' and 'variable' design basis threat. The fixed threat forms the basis for the design and is the baseline threat estimate. The variable design basis threat assessment is an estimate of the change in threat levels given certain possible future conditions. The Homeland Security Advisory System (HSAS) is an example of a national effort to help define varying threat levels. Facilities are urged to take actions given increased threat levels, so these factors need to be considered in the threat assessment.

The concept of fixed and variable design basis threats is useful for making decisions on facility design and operation. If the threat to insiders is considered significant, countermeasures designed to limit those risks are imperative. The fixed threat may determine the need for background screening, limiting the span of control of individuals, strong supervision, monitoring of activities, audits, surveillance, password controls and other measures. In fact, after determining and appreciating that the insider threat potential threat is significant, the facility may be designed or redesigned to avoid use of a type of operation, substitute chemicals or other measures to minimize this potential. If other conditions change, the threat may increase. For example, if there are a large number of visitors such as during a turnaround or in the event of specific threat information or a terrorist attack in the United States, increased threat levels may change or add to the baseline countermeasures.

Threat to a particular asset varies with several factors including the degree of interest that an adversary may have in the asset, as well as the degree of impact possible if the asset was attacked, disables, copied, compromised, or stolen. For this reason, the threat assessment includes a step whereby each asset is analysed from the perspective of each potential adversary to determine the degree of attractiveness

SEVERITY						
		5	4	3	2	1
LIKELIHOOD	5	High	High	High	Med	Med
	4	High	High	Med	Med	Low
	3	High	Med	Med	Low	Low
	2	Med	Med	Low	Low	Low
	1	Med	Low	Low	Low	Low

Figure 35.7 *Risk ranking matrix*

of the asset to the adversary. Attractiveness is therefore another factor in the determination of risk.

Step 3: Vulnerability analysis

The vulnerability analysis includes the relative pairing of each target asset and threat to identify potential vulnerabilities related to process security events. This involves the identification of existing countermeasures and their level of effectiveness in reducing those vulnerabilities. The degree of vulnerability of each valued asset and threat pairing is evaluated by the formulation of security-related scenarios or by an asset protection basis. If certain criteria are met such as higher consequence and attractiveness ranking values, then it may be useful to apply a scenario-based approach to conduct the Vulnerability Analysis. This approach option is very similar to the process hazard analysis (PHA) techniques employed to analyse accidental releases. It includes the assignment of risk rankings to the security-related scenarios developed.

Vulnerability is important to understand as it helps to determination how adversaries may target and execute crimes. Vulnerabilities are ubiquitous, so simply understanding vulnerabilities is not sufficient to make a risk determination. Other factors such as threat, consequence and attractiveness are required for a more complete risk appreciation.

Step 4: Risk assessment

The risk assessment determines the relative degree of risk to the facility in terms of the expected effect on each critical asset as a function of consequence and probability of occurrence. Using the assets identified during Step 1 (Asset Characterization), the risks are prioritized based on the likelihood of a successful attack which is a function of the threats assessed under Step 2 and the degree of vulnerability identified under Step 3.

A risk assessment matrix such as in Figure 35.7 can be used for the purpose of assessing risk.

Risk assessment is only possible when there is some frame of reference. Since the events in question are extremely rate events, it is necessary to (1) use surrogate factors such as attractiveness and threat to determine the likelihood of interest of attack of any particular asset and (2) use vulnerability as a measure of the likelihood of a successful attack given the desire to attack. Then the analyst can use performance criteria to set risk goals. Each scenario is evaluated against those goals. For example, such criteria as the following may be set to determine unacceptable risk:

Example security criteria:

(1) No unauthorized person can easily cross the outer perimeter without delay or detection;
(2) Any intruder is detected within 10 s of breaching the perimeter barrier;
(3) Any intruder is interdicted within 5 min of breaching the perimeter barrier;
(4) Any person entering the secured zone is authorized to be there;
(5) Authorization is comprised of invitation and verification;
(6) No unauthorized vehicle shall be allowed within 500 ft of a critical asset.

These criteria are used as binary risk goals, that is, if the existing situation fails these tests, then additional countermeasures are required.

Step 5: Countermeasures analysis

Based on the vulnerabilities identified and the risk that the layers of protection are breached, appropriate enhancements to the security countermeasures may be recommended. Countermeasure options will be identified to further reduce vulnerability at the facility. These include improved countermeasures that follow the process security doctrines of deter, detect, delay, respond, mitigate and possibly prevent. Some of the factors to be considered are:

(1) Reduced probability of successful attack
(2) Degree of risk reduction by the options
(3) Reliability and maintainability of the options
(4) Capabilities and effectiveness of mitigation options
(5) Costs of mitigation options
(6) Feasibility of the options

The countermeasure options should be re-ranked to evaluate effectiveness, and prioritized to assist management decision making for implementing security programme enhancements. The recommendations should be included in an SVA report that can be used to communicate the results of the SVA to management for appropriate action.

Printed in the United States of America

Preface to Third Edition

The first edition of this book appeared in 1980, at the end of a decade of rapid growth and development in loss prevention. In the preface to the second edition, Frank P. Lees wrote, "After another decade and a half the subject is more mature, although development continues apace. In preparing this second edition it has been even more difficult than before to decide what to put in and what to leave out." Frank Lees' statement in 1996 rings even truer today, another eight years later in 2004. Industrial advances and technology changes coupled with recent events have made it essential to focus on new topics while keeping a complete grasp of all of older technologies and learnings as well. Safety programs today must also consider issues such as chemical reactivity hazards, safety instrumented systems, and layer of protection analysis. In the post 9-11 world, process safety and loss prevention must also include consideration of issues related to chemical security and resilient engineering systems.

The history of safety regulations in the United States can be traced back to the year before the beginning of the twentieth century. The River and Harbor Act, the first known federal legislation relevant to safety was promulgated in 1899. Since then, the total number of legislations has steadily increased. In addition to the federal government, local entities such as the state, county, and cities have also promulgated regulations and ordnances, which impose safety requirements on process facilities. Varying degrees of similar legislative action has also occurred in the rest of the world. These legislation were all promulgated in response to some event, demographic changes, as well as changes in the industry. Also, as our understanding of the hazards associated with industrial processes developed, procedures and practices were put in place to limit or eliminate the damage. Government programs and industry initiatives spurred improvements in the science and technology needed for the recognition of hazards and associated risks.

Management systems have been put in place to implement regulations and industry practices. Government regulations will continue to be a significant driver for safety programs. As such, one of the main objectives of these management systems is to ensure compliance. However, it is also quite clear that profitability is directly related to safety and loss prevention. Thus the management systems for safety are intricately tied into the operational management.

The industrial revolution brought prosperity and along with it the use of hazardous processes and complex technologies. Growing economies and global competition has led to more complex processes involving the use of hazardous chemicals, exotic chemistry, and extreme operating conditions. As a result, a fundamental understanding of the hazards and associated risks is essential. Process safety and risk management requires the application of the basic sciences and a systematic approach. Recent advances, such as overpressure protection alternatives and reactive chemistry allow safer design and operation of processes.

In the multiple barriers concept, plants are designed with several layers so that an incident would require the failure of several systems. Another novel approach to process safety and risk management is to consider various actions in a descending hierarchical order. Inherently safer design consideration should be first in the hierarchy followed by prevention systems, mitigation, and response. The success of these systems is dependent on the fundamental understanding of the process and the associated hazards. Chronic as well as catastrophic consequences resulting from toxic and flammable substances can be reduced and/or eliminated through appropriate design and operating practices.

Managing safety is no easy task, but it makes bottom-line sense. There is a direct payoff in savings on a company workers' compensation insurance, whose premiums are partly based on the number of claims paid for job injuries. The indirect benefits are far larger, for safe plants tend to be well run in general and more productive. The recipe for safety is remarkably consistent from industry to industry. It starts with sustained support of top management followed by implementation of appropriate programs and practices that institutionalize safety as a culture as compared to add-on procedures. The ingraining of safety as second nature in day-to-day activities requires a paradigm shift and can only be accomplished when safety is viewed as an integral and comprehensive part of any activity as compared to being a stand-alone or add-on activity.

This third edition of ***Loss Prevention in the Process Industries*** represents a combination of appropriate revisions of the essential compilations put together by Frank P. Lees, along with several new chapters and additions on new areas that deserve attention and discussion. The third edition includes five new chapters and three new appendices. The five new chapters address incident investigation, inherently safer design, reactive chemicals, safety instrumented systems, and chemical security. The three new appendices address process safety management regulation in the United States, risk management program regulation in the United States, and incident databases.

The chapter on incident investigation provides a summary of incident investigation procedures that can be used not only to determine causes of incidents but also provides a primer on capturing and integrating lessons learned from incident investigations into design, operations, maintenance, and response programs. Chemical process incidents can be accompanied by significant consequences, both in terms of human life and in financial impact. Many major chemical process incidents are the result of a complex scenario involving simultaneous failures of multiple safeguards. A robust system for incident investigation is usually necessary to determine and understand the causes, as well as implement measures to prevent a repeat event. This chapter is intended to provide an overview of incident investigation by addressing major concepts, principles, and characteristics of effective incident investigations of chemical process events. The focus is on incidents pertaining to chemical processes and their associated hazards, and the associated investigation techniques appropriate for complex systems and scenarios. This chapter is based on

best practices for incident investigation, and those common concepts (i.e., tools, techniques, definitions) included in root cause investigation methodologies currently in the public domain in use in the process industry. It is not the intention to provide a stand-alone investigation methodology/guideline, nor address internal or proprietary investigation methodologies.

The chapter on inherently safer design addresses options and issues that can be considered with regard to the design and operation of plants. Inherently safer design is a philosophy that focuses on elimination of hazards or reduction of the magnitude of hazards rather than the control of hazards. Many of the concepts of inherently safer design have been applied by engineers in a wide variety of technologies for many years, without recognizing the common approach. In the late 1970s, in the wake of many large incidents in the chemical industry, Trevor Kletz recognized the common philosophies of hazard elimination and hazard reduction, gave the philosophy the name "inherently safer design," and developed a specific set of approaches to help engineers in the chemical process industries to design inherently safer processes and plants. Trevor realized that increased expectations for safety, from companies, regulatory bodies, and society in general, combined with the increased potential damage from incidents in the larger plants being built to meet increased demand and global markets, resulted in increased complexity and cost for the safety systems required to satisfy these demands. Furthermore, while hazard control systems can be made highly reliable, they can never be perfect and will always have some failure probability. While this probability can be made very small, there is always some chance that all safety systems will fail simultaneously and the result would be a large incident. Also, the hazard management systems require ongoing maintenance, as well as management and operator training, for the life of the plant. This results in ongoing costs, and the potential for future deterioration of the safety systems. Deteriorated systems will have reduced reliability, increasing the potential for a catastrophic accident. Trevor Kletz suggested that in many cases, a simpler, cheaper, and safer plant could be designed by focusing on the basic technology, eliminating or significantly reducing hazards, and therefore the need to manage them.

The chapter on reactive chemicals provides an overview of this critical issue and provides guidance on management systems as well as experimental and theoretical methods for analyses of chemical reactivity hazards. Serious incidents arising from uncontrolled reactivity have taken place since the inception of the chemical industry. The human toll of such incidents has been staggering. In recent decades, greater recognition and resources have been directed toward preventing and mitigating such occurrences. A number of incidents have been so severe as to prompt regulatory initiatives to force better management of reactivity. It is prudent for any company, organization, or other group to scrutinize the chemicals being handled and implement measures to limit the risk of a major reactive hazards event. A sampling of incidents that have substantially heightened concerns regarding reactive hazards in the general public, in governmental agencies, and in industry includes:

- The 1976 ICMESA incident in Seveso, Italy in which an uncontrolled chemical reaction generated pressure resulting in relief venting of a highly toxic dioxane into the neighboring villages and countryside.
- The 1984 Union Carbide incident in Bhopal, India in which methyl isocyanate was contacted with water, generating highly toxic cyanide gas and leading to thousands of fatalities.
- The 1994 Napp Technology incident in Lodi, New Jersey in which an uncontrolled reaction involving gold ore processing led to the deaths of five firefighters.
- The 1999 Concept Sciences incident in Allentown, Pennsylvania in which an explosion arising from a process concentrating hydroxylamine resulted in five fatalities. Another event involving purified hydroxylamine took place in a Nissin Chemical plant in Gunma Prefecture, Japan in 2000 and led to four fatalities.
- The 2001 TotalFinaElf incident in Toulouse, France in which ammonium nitrate being processed for nitrogen fertilizers exploded leading to 30 fatalities.

These events, as well as numerous others, have influenced the perception and approach to reactive hazards.

The chapter on safety instrumented systems addresses systems and procedures that need to be in place with regard to this area of safety and instrumentation. In many processes, technical or manufacturing issues limit the engineer's capability to design an inherently safer process. Further, there is generally a point where the required capital investment is disproportional to the additional risk reduction provided by the process modification. In other words, the derived safety benefit is too low relative to the economic investment. When this occurs, protection layers or safeguards must be provided to prevent or mitigate the process risk. A Safety Instrumented System (SIS) is a protection layer, which shuts down the plant, or part of it, if a hazardous condition is detected. Throughout the years, SIS have also been known as Emergency Shutdown Systems (ESD, ESS), Safety Shutdown Systems (SSD), Safety Interlock Systems (SIS), Safety Critical Systems (SCS), Safety Protection Systems (SPS), Protective Instrumented Systems (PIS), interlocks, and trip systems. Regardless of what the SIS may be called, the essential characteristic of the SIS is that it is composed of instruments, which detect that process variables are exceeding preset limits, a logic solver, which processes this information and makes decisions, and final control elements, which take necessary action on the process to achieve a safe state.

The chapter on chemical security deals with this new and critical element of the management of a process facility following the events of September 11, 2001. Security management is required for protecting the assets (including employees) of the facility, maintaining the ongoing integrity of the operation, and preserving value of the investment. Process security and process safety have many parallels and make use of many common programs and systems for achieving their ends. Process security requires a management systems approach to develop a comprehensive security program, which shares many common elements to process safety management.

The new appendix on process safety management regulation in the United States provides a summary of this regulatory requirement. The fourteen elements of the OSHA Process Safety Management (PSM) regulation (*29 CFR 1910.119*) were published in the U.S. Federal Register on February 24, 1992. The objective of the regulation is to

prevent or minimize the consequences of catastrophic releases of toxic, reactive, flammable, or explosive chemicals. The regulation requires a comprehensive management program: a holistic approach that integrates technologies, procedures, and management practices. The process safety management regulation applies to processes that involve certain specified chemicals at or above threshold quantities, processes that involve flammable liquids or gases on-site in one location, in quantities of 10,000 pounds or more (subject to few exceptions), and processes that involve the manufacture of explosives and pyrotechnics. Hydrocarbon fuels, which may be excluded if used solely as a fuel, are included if the fuel is part of a process covered by this regulation. In addition, the regulation does not apply to retail facilities, oil or gas well drilling or servicing operations, or normally unoccupied remote facilities.

The new appendix on risk management program regulation in the United States provides a summary of this regulatory requirement administered by the U.S. Environmental Protection Agency. In 1996, EPA promulgated the regulation for ***Risk Management Programs for Chemical Accident Release Prevention*** (40 CFR 68). This federal regulation was mandated by section 112(r) of the Clean Air Act Amendments of 1990. The regulation requires regulated facilities to develop and implement appropriate risk management programs to minimize the frequency and severity of chemical plant accidents. In keeping with regulatory trends, EPA required a performance-based approach towards compliance with the risk management program regulation. The EPA regulation also requires regulated facilities to develop a Risk Management Plan (RMP). The RMP includes a description of the hazard assessment, prevention program, and the emergency response program. Facilities submit the RMP to the EPA and subsequently is made available to governmental agencies, the state emergency response commission, the local emergency planning committees, and communicated to the public.

The new appendix on incident databases addresses compilations of incident databases that can used for improving safety programs, developing trends, performance measures, and metrics. Incident prevention and mitigation of consequences is the focus of a number of industry programs regulatory initiatives. As part of these programs and regulations, accident history data are often collected. There are two basic types of information. One is a database consisting of standardized fields of data usually for a large number of incidents. The second are more detailed reports of individual incidents. Analysis of these incident history databases can provide insight into incident prevention needs. While the analysis and conclusions obtained from the incident database are often limited by the shortcomings of the databases themselves, the fact remains that incident history databases are very useful and can be a powerful tool in focusing risk reduction efforts. The conclusions can be used to identify systematically the greatest risks to allow prioritization of efforts to improve process safety. At the plant level this might entail identifying certain processes, types of equipment, chemicals, operations and other factors most commonly associated with incidents. Databases that cover a very large number of facilities are likely to reveal trends and patterns that no one company or facility could determine from their own experience. Statistical knowledge of the likelihood of the release of certain types of chemicals could help emergency responders, state emergency response commissions, and local emergency planning committees determine the most likely and most serious chemical releases in their areas and plan appropriate chemical accident responses. Incident databases may also help identify technologies and practices to prevent chemical accidents, or the need to develop them. For example, the data could indicate that inspection and preventive maintenance of equipment and instruments should become more thorough or more frequent.

Preface to Second Edition

The first edition of this book appeared in 1980, at the end of a decade of rapid growth and development in loss prevention. After another decade and a half the subject is more mature, although development continues apace. In preparing this second edition it has been even more difficult than before to decide what to put in and what to leave out.

The importance of loss prevention has been underlined by a number of disasters. Those at San Carlos, Mexico City, Bhopal and Pasadena are perhaps the best known, but there have been several others with death tolls exceeding 100. There have also been major incidents in related areas, such as those on the Piper Alpha oil platform and at the nuclear power stations at Three Mile Island and Chernobyl.

Apart from the human tragedy, it has become clear that a major accident can seriously damage even a large international company and may even threaten its existence, rendering it liable to severe damages and vulnerable to takeover.

Accidents in the process industries have given impetus to the creation of regulatory controls. In the UK the Advisory Committee on Major Hazards made its third and final report in 1983. At the same time the European Community was developing its own controls which appeared as the EC Directive on Major Accident Hazards. The resulting UK legislation is the NIHHS Regulations 1982 and the CIMAH Regulations 1984. Other members of the EC have brought in their own legislation to implement the Directive. There have been corresponding developments in planning controls.

An important tool for decision-making on hazards is hazard assessment. The application of quantitative methods has played a crucial role in the development of loss prevention, but there has been lively debate on the proper application of such assessment, and particularly on the estimation and evaluation of the risk to the public.

Hazard assessment involves the assessment both of the frequency and of the consequences of hazardous events. In frequency estimation progress has been made in the collection of data and creation of data banks and in fault tree synthesis and analysis, including computer aids. In consequence assessment there has been a high level of activity in developing physical models for emission, vaporization and gas dispersion, particularly dense gas dispersion; for pool fires, fireballs, jet flames and engulfing fires; for vapour cloud explosions; and for boiling liquid expanding vapour explosions (BLEVEs). Work has also been done on injury models for thermal radiation, explosion overpressure and toxic concentration, on models of the density and other characteristics of the exposed population, and on shelter and escape.

Some of these topics require experimental work on a large scale and involving international cooperation. Large scale tests have been carried out at several sites on dense gas dispersion and on vapour cloud fires and explosions. Another major cooperative research programme has been that of DIERS on venting of chemical reactors.

The basic approach developed for fixed installations on shore has also been increasingly applied in other fields. For transport in the UK the *Transport Hazards Report* of the Advisory Committee on Dangerous Substances represents an important landmark. Another application is in the offshore oil and gas industry, for which the report on the Piper Alpha disaster, the *Cullen Report*, constitutes a watershed.

As elsewhere in engineering, computers are in widespread use in the design of process plants, where computer aided design (CAD) covers physical properties, flowsheeting, piping and instrument diagrams, unit operations and plant layout. There is increasing use of computers for failure data retrieval and analysis, reliability and availability studies, fault tree synthesis and analysis and consequence modelling, while more elusive safety expertise is being captured by computer-based expert systems.

The subject of this book is the process industries, but the process aspects of related industries, notably nuclear power and oil and gas platforms are briefly touched on. The process industries themselves are continually changing. In the last decade one of the main changes has been increased emphasis on products such as pharmaceuticals and agrochemicals made by batch processes, which have their own particular hazards.

All this knowledge is of little use unless it reaches the right people. The institutions which educate the engineers who will be responsible for the design and operation of plants handling hazardous materials have a duty to make their students aware of the hazards and at least to make a start in gaining competence in handling them.

I would like again to thank for their encouragement the heads of the Department of Chemical Engineering at Loughborough, Professors D.C. Freshwater, B.W. Brooks and M. Streat; our Industrial Professors T.A. Kletz and H.A. Duxbury and Visiting Professor S.M. Richardson; my colleagues, past and present, in the Plant Engineering Group, Mr R.J. Aird, Dr P.K. Andow, Dr M.L. Ang, Dr P.W.H. Chung, Dr D.W. Edwards, Dr P. Rice and Dr A.G. Rushton – I owe a particular debt to the latter; the members of the ACMH, chaired by Professor B.H. Harvey; the sometime directors of Technica Ltd, Dr D.H. Slater, Mr P. Charsley, Dr P.J. Comer, Dr R.A. Cox, Mr T. Gjerstad, Dr M.A.F. Pyman, Mr C.G. Ramsay, Mr M.A. Seaman and Dr R. Whitehouse; the members of the IChemE Loss Prevention Panel; the IChemE's former Loss Prevention Officer, Mr B.M. Hancock; the members of the IChemE Loss Prevention Study Group and of the Register of Safety Professionals; the editorial staff of the IChemE, in particular Mr B. Brammer; numerous members of the Health and Safety Executive, especially Dr A.C. Barrell, Mr J. Barton, Dr D.A. Carter, Mr K. Cassidy, Mr P.J. Crossthwaite, Dr N.W. Hurst, Dr S.F. Jagger, Dr J. McQuaid, Dr K. Moodie, Dr C. Nussey, Dr R.P. Pape, Dr A.F. Roberts and Dr N.F. Scilly; workers at the Safety and Reliability Directorate, particularly Dr A.T.D. Butland, Mr I. Hymes, Dr D.W. Phillips and Dr D.M. Webber; staff at Shell Thornton Research Centre, including Dr D.C. Bull and Dr A.C. Chamberlain; staff at British Gas, including Dr J.D. Andrews, Dr M.J. Harris, Mr H. Hopkins, Dr J.M. Morgan and Dr D.J. Smith; staff at the Ministry of

Defence, Explosives Storage and Transport Committee, including Mr M.A. Gould, Mr J. Henderson and Mr P. Stone; and colleagues who have taught on post-experience courses at Loughborough, in particular Dr C.D. Jones, Dr D.J. Lewis and Mr J. Madden; BP International and Mr R. Malpas for allowing me to spend a period of study leave with the company in 1985–86 and Mr F.D.H. Moysen, Mr G. Hately, Mr M. Hough, Mr R. Fearon and others in the Central Safety Group and in Engineering Department; the Honourable Lord Cullen, my fellow Technical Assessors on the Piper Alpha Inquiry, Mr B. Appleton and Mr G.M. Ford and the Cremer and Warner team at the inquiry, in particular Mr G. Kenney and Mr R. Sylvester-Evans; other professional colleagues Dr L.J. Bellamy, Professor B.A. Buffham, Dr D.A. Crowl, Mr T.J. Gilbert, Mr D.O. Hagon, Dr D.J. Hall, Mr K.M. Hill, Professor T.M. Husband, Mr M. Kneale, Dr V.C. Marshall, Dr M.L. Preston, Dr J. Rasmussen, Dr J.R. Roach, Dr J.R. Taylor, Dr V.M. Trbojevic, Mr H.M. Tweeddale, Dr G.L. Wells and Dr A.J. Wilday; my research colleagues Dr C.P. Murphy, Mrs J.I. Petts, Dr D.J. Sherwin, Mr R.M.J. Withers and Dr H. Zerkani; my research students Mr M. Aldersey, Mr D.C. Arulanantham, Dr A. Bunn, Dr M.A. Cox, Dr P.A. Davies, Dr S.M. Gilbert, Mr P. Heino, Dr A. Hunt, Dr B.E. Kelly, Dr G.P.S. Marrs, Dr J.S. Mullhi, Dr J.C. Parmar, Mr B. Poblete, Dr A. Shafaghi and Dr A.J. Trenchard as well as colleagues' research students Mr E.J. Broomfield, Mr R. Goodwin, Mr M.J. Jefferson, Dr F.D. Larkin, Mr S.A. McCoy, Dr K. Plamping, Mr J. Soutter, Dr P. Thorpe and Mr S.J. Wakeman; the office staff of the Department, Mrs E.M. Barradell, Mr D.M. Blake, Miss H.J. Bryers and Miss Y. Kosar; the staff of the University Library, in particular Miss S.F. Pilkington; and my wife Elizabeth, whose contribution has been many-faceted and in scale with this book.

FRANK P. LEES
Loughborough,
1994

Preface to First Edition

Within the past ten or fifteen years the chemical and petroleum industries have undergone considerable changes. Process conditions such as pressure and temperature have become more severe. The concentration of stored energy has increased. Plants have grown in size and are often single-stream. Storage has been reduced and interlinking with other plants has increased. The response of the process is often faster. The plant contains very large items of equipment. The scale of possible fire, explosion or toxic release has grown and so has the area which might be affected by such events, especially outside the works boundary.

These factors have greatly increased the potential for loss both in human and in economic terms. This is clear both from the increasing concern of the industry and its insurers and from the historical loss statistics.

The industry has always paid much attention to safety and has a relatively good record. But with the growing scale and complexity involved in modern plants the danger of serious large-scale incidents has been a source of increasing concern and the adequacy of existing procedures has been subjected to an increasingly critical examination.

Developments in other related areas have also had an influence. During the period considered there has been growing public concern about the various forms of pollution, including gaseous and liquid effluents and solid wastes and noise.

It is against this background that the loss prevention approach has developed. It is characteristic of this approach that it is primarily concerned with the problems caused by the depth of technology involved in modern processes and that it adopts essentially an engineering approach to them. As far as possible both the hazards and the protection are evaluated quantitatively.

The clear recognition by senior management of the importance of the loss prevention problem has been crucial to these developments. Progress has been made because management has been prepared to assign to this work many senior and capable personnel and to allocate the other resources necessary.

The management system is fundamental to loss prevention. This involves a clear management structure with well defined line and advisory responsibilities staffed by competent people. It requires the use of appropriate procedures, codes of practice and standards in the design and operation of plant. It provides for the identification, evaluation and reduction of hazards through all stages of a project from research to operation. It includes planning for emergencies.

The development of loss prevention can be clearly traced through the literature. In 1960 the Institution of Chemical Engineers held the first of a periodic series of symposia on *Chemical Process Hazards with Special Reference to Plant Design*. The Dow Chemical Company published its *Process Safety Manual* in 1964. The American Institute of Chemical Engineers started in 1967 an annual series of symposia on Loss Prevention. The European Federation of Chemical Engineers' symposium on *Major Loss Prevention in the Process Industries* at Newcastle in 1971 and the Federation's symposium on *Loss Prevention and Safety Promotion in the Process Industries* (Buschmann, 1974) at Delft are further milestones.

Another indicator is the creation in 1973 by the Institution of Chemical Engineers Engineering Practice Committee of a Loss Prevention Panel under the chairmanship of Mr T.A. Kantyka.

In the United Kingdom the Health and Safety at Work etc. Act 1974 has given further impetus to loss prevention. The philosophy of the *Robens Report* (1972), which is embodied in the Act, is that of self-regulation by industry. It is the responsibility of industry to take all reasonable measures to assure safety. This philosophy is particularly appropriate to complex technological systems and the Act provides a flexible framework for the development of the loss prevention approach.

The disaster at Flixborough in 1974 has proved a turning point. This event has led to a much more widespread and intense concern with the loss prevention problem. It has also caused the government to set up in 1975 an Advisory Committee on Major Hazards. This committee has made far-reaching recommendations for the identification and control of major hazard installations.

It will be apparent that loss prevention differs somewhat from safety as traditionally conceived in the process industries. The essential difference is the much greater engineering content in loss prevention.

This is illustrated by the relative effectiveness of inspection in different processes. In fairly simple plants much can be done to improve safety by visual inspection. This approach is not adequate, however, for the more technological aspects of complex processes.

For the reasons given above loss prevention is currently a somewhat fashionable subject. It is as well to emphasize, therefore, that much of it is not new, but has been developed over many years by engineers whose patient work in an often apparently unrewarding but vital field is the mark of true professionalism.

It is appropriate to emphasize, moreover, that accidents arising from relatively mundane situations and activities are still responsible for many more deaths and injuries than those due to advanced technology.

Nevertheless, loss prevention has developed in response to the growth of a new problem, the hazard of high technology processes, and it does have a distinctive approach and some novel techniques. Particularly characteristic are the emphasis on matching the management system to the depth of technology in the installation, the techniques developed for identifying hazards, the principle and methods of quantifying hazards, the application of reliability assessment, the practice of planning for emergencies and the critique of traditional practices or existing codes, standards or regulations where these are outdated by technological change.

There is an enormous, indeed intimidating, literature on safety and loss prevention. In addition to the symposia already referred to, mention may be made of the *Handbook of Safety and Accident Prevention in Chemical Operations* by Fawcett and Wood (1965); the *Handbook of Industrial Loss*

Prevention by the Factory Mutual Engineering Corporation (1967); and the Industrial Safety Handbook by Handley (1969, 1977). These publications, which are by multiple authors, are invaluable source material.

There is a need, however, in the author's view for a balanced and integrated textbook on loss prevention in the process industries which presents the basic elements of the subject, which covers the recent period of intense development and which gives a reasonably comprehensive bibliography. The present book is an attempt to meet this need.

The book is based on lectures given to undergraduate and postgraduate students at Loughborough over a period of years and the author gladly acknowledges their contribution.

Loss prevention is a wide and rapidly developing field and is therefore not an easy subject for a book. Nevertheless, it is precisely for these reasons that the engineer needs the assistance of a textbook and that the attempt has been considered justified.

The structure of the book is as follows. Chapter 1 deals with the background to the historical development of loss prevention, the problem of large, single-stream plants, and the differences between loss prevention and conventional safety, and between loss prevention and total loss control; Chapter 2 with hazard, accident and loss, including historical statistics; Chapter 3 with the legislation and legal background; Chapter 4 with the control of major hazards; Chapter 5 with economic and insurance aspects; Chapter 6 with management systems, including management structure, competent persons, systems and procedures, standards and codes of practice, documentation and auditing arrangements; Chapter 7 with reliability engineering, including its application in the process industries; Chapter 8 with the spectrum of techniques for identifying hazards from research through to operation; Chapter 9 with the assessment of hazards, including the question of acceptable risk; Chapter 10 with the siting and layout of plant; Chapter 11 with process design, including application of principles such as limitation of inventory, consideration of known hazards associated with chemical reactors, unit processes, unit operations and equipments, operating conditions, utilities, particular chemicals and particular processes and plants, and checking of operational deviations; Chapter 12 with pressure system design, including properties of materials, design of pressure vessels and pipework, pressure vessel standards and codes, equipment such as heat exchangers, fired heaters and rotating machinery, pressure relief and blowdown arrangements, and failure in pressure systems; Chapter 13 with design of instrumentation and control systems, including regular instrumentation, process computers and protective systems; Chapter 14 with human factors in process control, process operators, computer aids and human error; Chapter 15 with loss of containment and dispersion of material; Chapter 16 with fire, flammability characteristics, ignition sources, flames and particular types of process fire, effects of fire and fire prevention, protection and control; Chapter 17 with explosion, explosives, explosion energy, particular types of process explosion such as confined explosions, unconfined vapour cloud explosions and dust explosions, effects of explosion and explosion prevention, protection and relief; Chapter 18 with toxicity of chemicals, toxic release and effects of toxic release; Chapter 19 with commissioning and inspection of plant; Chapter 20 with plant operation; Chapter 21 with plant maintenance and modification; Chapter 22 with storage; Chapter 23 with transport, particularly by road, rail and pipeline; Chapter 24 with emergency planning both for works and transport emergencies; Chapter 25 with various aspects of personal safety such as occupational health and industrial hygiene, dust and radiation hazards, machinery and electrical hazards, protective clothing and equipment, and rescue and first aid; Chapter 26 with accident research; Chapter 27 with feedback of information and learning from accidents; Chapter 28 with safety systems, including the roles of safety managers and safety committees and representatives. There are appendices on Flixborough, Seveso, case histories, standards and codes, institutional publications, information sources, laboratories and pilot plants, pollution and noise, failure and event data, Canvey, model licence conditions for certain hazardous plants, and units and unit coversions.

Many of the matters dealt with, such as pressure vessels or process control, are major subject areas in their own right. It is stressed, therefore, that the treatment given is strictly limited to loss prevention aspects. The emphasis is on deviations and faults which may give rise to loss.

In engineering in general and in loss prevention in particular there is a conflict between the demand for a statement of basic principles and that for detailed instructions. In general, the first of these approaches has been adopted, but the latter is extremely important in safety, and a considerable amount of detailed material is given and references are provided to further material.

The book is intended as a contribution to the academic education of professional chemical and other engineers. Both educational and professional institutions have long recognized the importance of education in safety. But until recently the rather qualitative, and indeed often exhortatory, nature of the subject frequently seemed to present difficulties in teaching at degree level. The recent quantitative development of the subject goes far towards removing these objections and to integrating it more closely with other topics such as engineering design.

In other words, loss prevention is capable of development as a subject presenting intellectual challenge. This is all to the good, but a note of caution is appropriate. It remains true that safety and loss prevention depend primarily on the hard and usually unglamorous work of engineers with a strong sense of responsibility, and it is important that this central fact should not be obscured.

For this reason the book does not attempt to select particular topics merely because a quantitative treatment is possible or to give such a treatment as an academic exercise. The subject is too important for such an approach. Rather the aim has been to give a balanced treatment of the different aspects and a lead in to further reading.

It is also hoped that the book will be useful to practising engineers in providing an orientation and entry to unfamiliar areas. It is emphasized, however, that in this subject above all others, the specialized texts should be consulted for detailed design work.

Certain topics which are often associated with loss prevention, for example included in loss prevention symposia, have not been treated in detail. These include, for example, pollution and noise. The book does not attempt to deal in detail with total loss control, but a brief account of this is given.

The treatment of loss prevention given is based mainly on the chemical, petrochemical and petroleum industries,

but much of it is relevant to other process industries, such as electrical power generation (conventional and nuclear), iron and steel, gas, cement, glass, paper and food.

The book is written from the viewpoint of the United Kingdom and, where differences exist within the UK, of England. This point is relevant mainly to legislation.

Reference is made to a large number of procedures and techniques. These do not all have the same status. Some are well established and perhaps incorporated in standards or codes of practice. Others are more tentative. As far as possible the attempt has been made to give some indication of the extent to which particular items are generally accepted.

There are probably also some instances where there is a degree of contradiction between two approaches given. In particular, this may occur where one is based on engineering principles and the other on relatively arbitrary rules-of-thumb.

The book does not attempt to follow standards and codes of practice in drawing a distinction between the words *should, shall* and *must* in recommending particular practices and generally uses only the former. The distinction is important, however, in standards and codes of practice and it is described in Appendix 4[a].

An explanation of some of the terms used is in order at this point. Unfortunately there is at present no accepted terminology in this field. In general, the problems considered are those of loss, either of life or property. The term *hazard* is used to describe the object or situation which constitutes the threat of such loss. The consequences which might occur if the threat is realized are the *hazard potential*. Associated with the hazard there is a risk, which is the probability of the loss occurring. Such a risk is expressed as a *probability* or as a *frequency*. Probability is expressed as a number in the range 0 to 1 and is dimensionless; frequency is expressed in terms of events per unit time, or sometimes in other units such as events per cycle or per occasion. Rate is also used as an alternative to frequency and has the same units.

The analysis of hazards involves qualitative *hazard identification* and quantitative hazard assessment. The latter term is used to describe both the assessment of hazard potential and of risk. The assessment of risk only is described as *risk assessment*.

In accident statistics the term *Fatal Accident Frequency Rate* (FAFR) has some currency. The last two terms are tautologous and the quantity is here referred to as *Fatal Accident Rate* (FAR).

Further treatments of terminology in this field are given by BS 4200: 1967, by Green and Bourne (1962), by the Council for Science and Society (1977) and by Harvey (1979b).

Notation is defined for the particular chapter at the point where the symbols first occur. In general, a consistent notation is used, but well established equations from standards, codes and elsewhere are usually given in the original notation. A consolidated list of the notation is given at the end of chapters in which a large number of symbols is used.

The units used are in principle SI, but the exceptions are fairly numerous. These exceptions are dimensional equations, equations in standards and codes, and other equations and data given by other workers where conversion has seemed undesirable for some reason. In cases of conversion from a round number it is often not clear what degree of rounding off is appropriate. In cases of description of particular situations it appears pedantic to make the conversion where a writer has referred, for example, to a 1 inch pipe.

Notes on some of the units used are given in Appendix 12[a]. For convenience a unit conversion table is included in this appendix. Numerical values given by other authors are generally quoted without change and numerical values arising from conversion of the units of data given by other authors are sometimes quoted with an additional significant figure in order to avoid excessive rounding of values.

Some cost data are quoted in the book. These are given in pounds or US dollars for the year quoted.

A particular feature of the book is a fairly extensive bibliography of some 5000 references. These references are consolidated at the end of the book rather than at the end of chapters, because many items are referred to in a number of chapters. Lists of selected references on particular topics are given in table form in the relevant chapters.

Certain institutions, however, have a rather large number of publications which it is more convenient to treat in a different manner. These are tabulated in Appendices 4[a] and 5[a], which contain some 2000 references. There is a cross-reference to the institution in the main reference list.

In many cases institutions and other organizations are referred to by their initials. In all cases the first reference in the book gives the full title of the organization. The initials may also be looked up in the Author Index, which gives the full title.

A reference is normally given by quoting the author and, in brackets, the date, e.g. Kletz (1971). Publications by the same author in the same year are denoted by letters of the alphabet a, b, c, etc., e.g. Allen (1977a), while publications by authors of the same surname and in the same year are indicated for convenience by an asterisk against the year in the list of references. In addition, the author's initials are given in the main text in cases where there may still be ambiguity. Where a date has not been determined this is indicated as n.d.

In the case of institutional publications listed in Appendices 4[a] and 5[a] the reference is given by quoting the institution and, in brackets, the date, the publication series, e.g. HSE (1965 HSW Bklt 34) or the item number, e.g. IChemE (1971 Item 7). For institutional publications with a named author the reference is generally given by quoting the author and, in brackets, the initials of the institution, the date and the publication series or item number, e.g. Eames (UKAEA 1965 Item 4).

The field of loss prevention is currently subject to very rapid change. In particular, there is a continuous evolution of standards and codes of practice and legislation. It is important, therefore, that the reader should make any necessary checks on changes which may have occurred.

I would like to thank for their encouragement in this project Professor D.C. Freshwater and the publishers, and to acknowledge the work of many authors which I have used directly or indirectly, particularly that of Dr J.H. Burgoyne and of Professor T.A. Kletz. I have learned much from my colleagues on the Loss Prevention Panel of the Institution of Chemical Engineers, in particular Mr T.A. Kantyka and Mr F. Hearfield, and on the Advisory Committee on Major Hazards, especially the chairman Professor B.H. Harvey, the secretary Mr H.E. Lewis, my fellow group chairmen

---

[a] Appendices 4, 5 and 12 in the first edition correspond to Appendices 27, 28 and 30, respectively, in this second edition.

Professor F.R. Farmer and Professor J.L.M. Morrison and the members of Group 2, Mr K. Briscoe, Dr J.H. Burgoyne, Mr E.J. Challis, Mr S. Hope, Mr M.A. McTaggart, Professor J.F. Richardson, Mr J.R.H. Schenkel, Mr R. Sheath and Mr M.J. Turner, and also from my university colleagues Dr P.K. Andow, Mr R.J. Aird and Dr D.J. Sherwin and students Dr S.N. Anyakora, Dr B. Bellingham, Mr C.A. Marpegan and Dr G.A. Martin-Solis. I am much indebted to Professor T.A. Kletz for his criticisms and suggestions on the text. My thanks are due also to the Institution of Plant Engineers, which has supported plant engineering activities at Loughborough, to the Leverhulme Trust which awarded a Research Fellowship to study *Loss Prevention in the Process Industries* and to the Science Research Council, which has supported some of my own work in this area. I have received invaluable help with the references from Mrs C.M. Lincoln, Mrs W. Davison, Mrs P. Graham, Mr R. Rhodes and Mrs M.A. Rowlatt, with the typing from Mrs E.M. Barradell, Mrs P. Jackson and, in particular, Mrs J. Astley, and with the production from Mr R.L. Pearson and Mr T. Mould. As always in these matters the responsibility for the final text is mine alone.

FRANK P. LEES
Loughborough,
1979

Acknowledgements

Many have helped with the long and tedious production process for this 3rd edition of ***Frank P. Lees Loss Prevention in the Process Industries***. However, I would be seriously remiss if I did not start with Frank P. Lees himself. I have always had great respect and admiration for Frank Lees, the engineer and the educator. After Frank passed away, and late in 2002, our mutual friend, Roy Sanders contacted me with a request from Frank's publisher to take up the job of editing the next version. I had no idea of the enormity of the task and Frank's accomplishment. I must say that this experience has truly humbled me and has given me a new respect and new appreciation for Frank Lees' knowledge, grasp, and mastery of the subject of safety and loss prevention. I am honored and privileged to be the editor of the 3rd edition of ***Frank P. Lees Loss Prevention in the Process Industries***. I have tried to maintain Frank's high standards and appreciate the help that many others have given me, but ultimately any *faux pas* or mistakes in the 3rd edition are all mine.

I want to thank all the people who have helped revise and update the chapters that were carried over from the 2nd edition. In this respect, I would like to mention A.A. Aldeeb, J.A. Alderman, P.C. Berwanger, C.A. Brown, S. Chervin, J. Cowling, W.F. Early, M. Gentile, J.P. Gupta, J.A. Havens, D.C. Hendershot, N. Keren, K. Krishna, S.H. Landis, M.E. Levin, P.N. Lodal, M.E. Livingston, S. Mohindra, D.A. Moore, T.M. O'Connor, S.W. Ostrowski, M. Paradise, J.A. Philley, W.J. Rogers, R.E. Sanders, S.R. Saraf, M.E Sawyer, R.L. Smith, T.O. Spicer, A.E. Summers, Y. Wang, H.H. West, J.L. Woodward, and J. Zanoni. Special thanks go to individuals who helped with the new chapters and appendices: J.A. Philley for the incident investigation chapter; J.P. Gupta and D.C. Hendershot for the inherently safer design chapter; S. Chervin, M.E. Levin, and W.J. Rogers for the reactive chemicals chapter; A.E. Summers for the safety instrumented systems chapter, D.A. Moore for the chemical security chapter and T.M. O'Connor for the new appendix on incident databases.

I also want to thank those who helped with research, literature review, galley proofing, and many other jobs without which such a project is never complete. I would like to specifically mention S. Anand, L.O. Cisneros-Trevino, W. Kowhakul, Y.-S. Liu, Y. Qiao, V. Raghunathan, S. Rajaraman, J. Suardin, M. Vidal, C. Wei, C. Zhang, and Y. Zhou. I would like to make specific mention of K.L. Potucek and L.J. Littlefield who undertook the painful task of converting the pdf files of the 2nd edition to Word format. I would like to thank M.A. Cass and D.K. Startz for administrative support and keeping things going through the long haul.

I would also like to take this opportunity to thank two individuals who have provided more than moral support and encouragement. They are Trevor Kletz and Mike O'Connor. First, I have appreciated Trevor's support for our work at the Mary Kay O'Connor Process Safety Center. I also want to thank him for his pioneering leadership in many areas of process safety. Trevor is really a giant in this field, and as Roy Sanders likes to say, "Trevor does cast a long shadow in the field of process safety." I am proud to have Trevor's friendship and his support. I also want to take this opportunity to thank Mike O'Connor. He has converted his personal tragedy into an opportunity to integrate process safety into education, research, and service activities at universities. He has been a true friend and supporter of the mission and goals of the Center.

I also want to thank Mrs. Elizabeth Lees for being kind, gracious, and helpful throughout this process. I am especially grateful for her hospitality and help during my visit to Loughborough to look through Frank's notes and books.

I am grateful to my mother for her love and everything she has done for me and continues to do. I am indebted to my father for having taught me the desire for learning. He was a humble man who truly believed that, "If you stop learning, you must already be dead." I would also like to thank my wife, Afroza, and our daughters, Joya and Rumki, for their love and support. Quite often a project of this magnitude causes the personal and family life to suffer and my wife and daughters have borne the brunt of it. I appreciate their understanding.

I am sure I have failed to mention everybody who has helped me with the many facets of this project. To them I apologize and want to assure them the oversight is not intended. To everyone who has helped put this 3rd edition together, I extend my heartfelt thanks and warmest gratitude again. I must say that you have helped in a noble cause, spread the word and disseminate information that will, we hope and pray, lead to a safer industry and society.

M. Sam Mannan

Texas, USA
2004

Terminology

Attention is drawn to the availability in the literature of a number of glossaries and other aids to terminology. Some British Standard glossaries are given in Appendix 27 and other glossaries are listed in Table 1.1.

Notation

In each chapter a given symbol is defined at the point where it is first introduced. The definition may be repeated if there has been a significant gap since it was last used. The definitions are summarized in the notation given at the end of the chapter. The notation is global to the chapter unless redefined for a section. Similarly, it is global to a section unless redefined for a subsection and global to a subsection unless redefined for a set of equations or a single equation. Where appropriate, the units are given, otherwise a consistent system of units should be used, SI being the preferred system. Generally the units of constants are not given; where this is the case it should not be assumed that a constant is dimensionless.

Use of References

The main list of references is given in the section entitled References, towards the end of the book. There are three other locations where references are to be found. These are Appendix 27 on standards and codes; Appendix 28 on institutional publications; and in the section entitled Loss Prevention Bulletin which follows the References.

The basic method of referencing an author is by surname and date, e.g. Beranek (1960). Where there would otherwise be ambiguity, or where there are numerous references to the same surname, e.g. Jones, the first author's initials are included, e.g. A. Jones (1984). Further guidance on names is given at the head of the section References.

References in Appendices 27 and 28 are by institution or author. Some items in these appendices have a code number assigned by the institution itself, e.g. API (1990 Publ. 421), but where such a code number is lacking, use is generally made of an item number separated from the date by a slash, e.g. IChemE (1971/13). Thus typical entries are

API Std 2000: 1992	a standard, found in Appendix 27 under American Petroleum Institute
API (1990 Publ. 421)	an institutional publication, found in Appendix 28 under American Petroleum Institute
HSE (1990 HS(G) 51)	an institutional publication, found in Appendix 28 under Health and Safety Executive, Guidance Booklets, HS(G) series
Coward and Jones (1952 BM Bull. 503)	an institutional publication, found in Appendix 28 under Bureau of Mines, Bulletins

Institutional acronyms are given in the section Acronyms which precedes the Author Index.

There are several points of detail which require mention concerning Appendix 28. (1) The first part of the appendix contains publications of a number of institutions and the second part those of the Nuclear Regulatory Commission. (2) The Fire Protection Association publications include a number of series which are collected in the *Compendium of Fire Safety Data* (CFSD). A typical reference to this is FPA (1989 CFSD FS 6011). (3) The entries for the Health and Safety Executive are quite extensive and care may be needed in locating the relevant series. (4) The publications of the Safety and Reliability Directorate appear under the UK Atomic Energy Authority, Safety and Reliability Directorate. A typical reference is Ramskill and Hunt (1987 SRD R354). These publications are immediately preceded by the publications of other bodies related to the UKAEA, such as the Health and Safety Branch, the Systems Reliability Service and the National Centre for Systems Reliability.

References to authors in the IChemE *Loss Prevention Bulletin* are in the style Eddershaw (1989 LPB 88), which refers to issue 88 of the bulletin.

Case Histories

Contents

An essential feature of the learning process in safety and loss prevention is the study of case histories.

A1.1 Incident Sources

The powerful impact of the internet has changed the way we obtain our information on process safety as well as everything else. In recent years, various governmental agencies and private organizations have improved our access to details of recent and past case histories. A number of websites provide a narrative of the event, the technical reasons for the accident as well as the management system shortcomings and valuable lessons learned. Written report sometimes supported by graphics and photos are often published by various agencies and provided on governmental websites. There are also university and corporate organizations that collect incidents and publish on their websites.

Since about 1996, the US Environmental Protection Agency under the Chemical Emergency Preparedness and Prevention has investigated and reported on many high profile US chemical plant and refinery case histories. As a result of these investigations, some Alerts focusing on certain type of incidents have been developed. EPA reports are available at the following internet website:
http://yosemite.epa.gov/oswer/ceppoweb.nsf.

The US Chemical Safety and Hazard Investigation Board (CSB) matured in the late 1990s and their mission is to promote the prevention of chemical accidents. The focus of the CSB is on-site and off-site chemical safety, determining causes and preventing chemical-related incidents, fatalities, injuries, property damage and enhancing environmental protection. The CSB started investigations on selected important chemical plant and refinery incidents in about 1998, and also provide reports on the internet at the following web address:
http://www.chemsafety.gov/reports/.

The Center of Chemical Process Safety, CCPS, of the American Institute of Chemical Engineers started providing brief one-page summaries of types of hazards in late 2001. These high-impact messages were designed with the chemical process operator and others involved with the manufacturing processes to focus quickly on an important topic. The publication is entitled the *Beacon* and can be found at:
www.aiche.org/ccps/safetybeacon.htm.

The Mary Kay O'Connor Process Safety Center at Texas A&M University in College Station is an international leader in process safety and is increasing in stature each year. They have a rich source of process safety information as well as documented case histories. The Center's web address:
http://process-safety.tamu.edu.

The British Institution of Chemical Engineers (IChemE) offers links to a comprehensive list of well over a 150 other websites of incident reports. The IChemE site mainly describes incidents of interest to chemical or process engineers, and includes a time span of incidents from historical to today's events. The collection includes both information and viewpoint. The address of this site is:
http://slp.icheme.org/incidents.html.

The Delft University of Technology of The Netherlands offers a vivid array of about two dozen outstanding fire and explosion photos, an accident database and more. The university's main research effort is focused on measuring and modelling dust and gas explosions. The incident photos can be found at:
http://www.dct.tudelft.nl/part/explosion/gallery.html.

Two other excellent internet sources of process safety information including case histories are:

- www.acusafe.com
- www.hazardview.com

The AcuSafe website provides a comprehensive electronic newsletter entitled AcuSafe News. Their newsletter is devoted to serving industry, government and interested members of the public by providing process safety practices, incident news, lessons, learned and regulatory developments. Hazard View is a source of advice, comment and information for safety, environment and risk professionals with major accident hazards in the process industries. Their View Library has a number of vivid images of the damages from accidents.

A booklet entitled *Large Property Damage Losses in the Hydrocarbon-Chemical Industry – A Thirty Year Review*, continues to be an excellent source of information in print form. This publication presents summaries of large property losses of incidents from around the globe. The valuable information is from a property insurance viewpoint and is presented in an easy-to-understand form. Most of the damages are the result of fires and explosions occurring in refineries, petrochemical plants, gas-processing plants, terminals, offshore and a miscellaneous category. It is updated every few years and the latest one, the twentieth edition, was released in January 2003.

Collections of case histories have been published in *Case Histories of Accidents in the Chemical Industry* by the Manufacturing Chemists Association (MCA) (1962–/1–4) and by Kier and Muller (1983). Specialized collections have been published on particular topics such as major hazards (Harvey, 1979, 1984; Carson and Mumford, 1979; Lees, 1980b; V.C. Marshall, 1987), fire and explosion (Vervalin, 1964a, 1973a; W.H. Doyle, 1969), vapour cloud explosions (Gugan, 1979; Slater, 1978a; D.J. Lewis, 1980d; Davenport, 1987; Lenoir and Davenport, 1993), LPG (L.N. Davis, 1979), instrumentation (W.H. Doyle 1972a,b; Lees, 1976b), transport (Haastrup and Brockhoff, 1990) and pipelines (Riley, 1979). The series *Safety Digest of Lessons Learned* by the API gives case histories with accompanying analyses. Another such series is that published by the American Oil Company (Amoco) of which *Hazards of Water* and *Hazards of Air* are the best known. The Convey Reports and the Rijmond Report give information on certain incidents. The reports of the HSE provide case histories of investigations by a regulator as do those of the NTSB, which deal with rail, road, pipeline and marine accidents. Incidents involving large economic loss are described in the periodic review *100 Large Losses* by Marsh and McLennan.

Case histories are also given in the *Annual Report of HM Chief Inspector of Factories*, the *Chemical Safety Summary of the Chemical Industry Safety and Health Council* (CISHC) and in journals such as *Petroleum Review* and *NFPA Quarterly*. In addition, the *Loss Prevention Bulletin* issued by the IChemE gives case histories. There are also numerous case histories described in much greater detail in various papers and reports. The disasters at Flixborough (R.J. Parker, 1975), at Bantry Bay (Costello, 1979) and on Piper Alpha (Cullen, 1990) are among the most thoroughly documented.

The analysis of case histories to draw the relevant lessons is exemplified pre-eminently in the work of Trevor Kletz's many books and numerous technical articles:

- *Critical Aspects of Safety and Loss Prevention* (1990b),
- *Lessons from Disaster – How Organisations have No Memory and Accidents Recur* (1993##),
- *What Went Wrong? – Case Histories of Process Plant Disasters*, 4th edn (1998##)
- *An Engineer's View of Human Error*, 3rd edn (2001##A) and
- *Learning from Accidents*, 3rd edn (2001##B) and numerous technical articles.

Additional lessons can be examined in Roy Sanders' *Chemical Process Safety: Learning from Case Histories* (1999##).

Selected references on case histories are given in Table A1.1. Some major incidents are listed in Table A1.2. A proportion of these are described in Section A1.10.

A1.2 Incident Databases

There are a number of databases specifically dealing with case histories. They include the following:

- The incident databases Major Hazards Incident Data System (MHIDAS) and the corresponding explosives data system EIDAS are operated by SRD.
- TNO has developed the FACTS incident database.
- The JRC of the CEC at Ispra, Italy, runs the Major Accident Reporting System (MARS), described by Drogaris (1991, 1993).
- The FIRE incident database for chemical warehouse fires has been described by Koivisto and Nielsen (1994).
- An account of the offshore Hydrocarbon Release (HCR) database in the United Kingdom has been given by Bruce (1994).

A1.3 Reporting of Incidents

The extent and accuracy of the reporting of incidents and injuries is variable and this creates problems particularly for attempts to perform statistical analysis of incident data.

Three distinct problems may be identified: (1) occurrence of an incident; (2) injuries associated with an incident; and (3) national injury statistics. These three cases are considered in this section and in the next two sections, respectively.

The awareness of the engineering community worldwide of incidents varies according to the country in which the incident has occurred and the size and impact of the incident. For example, in the recent past incidents in the United States have generally been reported in the technical press but reports of comparable incidents in the USSR have been relatively few.

With regard to the effects of scale and impact, the probability of worldwide reporting of a incident clearly increases with these factors. The probability that an accident of the magnitude of Bhopal is not reported in countries with a free press is negligible. However, as the size of the incident decreases, the probability that it is not reported or at least is not picked up in incident collections and databases increases. The problem has been discussed by Badoux (1983). Figure A1.1 shows schematically the probable extent of underreporting, curve A representing the actual reporting situation and curve B the ideal one.

A1.4 Reporting of Injuries in Incidents

For various reasons, accounts of incidents tend to differ in the number of injuries and, to a lesser extent, fatalities that are reported. A discussion of this problem has been given by Haastrup and Brockhoff (1991).

There are a number of reasons for differences in the numbers quoted. One is that early reports of an incident tend not be very accurate, but are sometimes quoted without sufficient qualification and the numbers then receive currency.

With regard to fatalities, a difference arises between immediate and delayed deaths. A case where a proportion of delayed deaths is fairly common is burn casualties.

The most frequent and large differences, however, are in 'injuries'. Here much of the difference can usually be accounted for by differences in definition.

As an illustration, consider the injuries in the explosion at Laurel, Mississippi on 25 January 1969. The NTSB report on this incident (NTSB 1969 RAR) states that 2 persons died, 33 received treatment in hospital and numerous others were given first aid. Some authors have therefore quoted this as 2 dead, 33 injured. Eisenberg, Lynch and Breeding (1975) refer to the NTSB report but also to a private communication from a railroad source and state that 976 persons were injured, 17 being in hospital for more than a month. This incident is one of those quoted by Haastrup and Brockhoff as an example of the problem.

Another illustration is provided by the explosion at Silvertown, London, on 19 January 1917. The account given later in this Appendix states that 68 were killed, 98 seriously injured, 328 had slight injuries and about 600 are thought to have received treatment in the street or from private doctors. Thus this account gives three separate categories of injury, without even mentioning hospitals.

A1.5 Reporting of Injuries at National Level

It is normal for there to be a regulatory requirement for the reporting, as a minimum, of deaths and injuries. In the United Kingdom the relevant regulations are RIDDOR 1985. The information gathered in this way is published by the HSE in the series *Health and Safety Statistics*.

The reporting is incomplete. A study supplementary to the household-based Labour Force Survey 1990 in the United Kingdom showed that only approximately 30% of non-fatal injuries were reported to the HSE, but that the level of reporting varied significantly across industries (Kiernan, 1992). For the energy industry the proportion of such accidents reported was 75%, and it seems probable that the

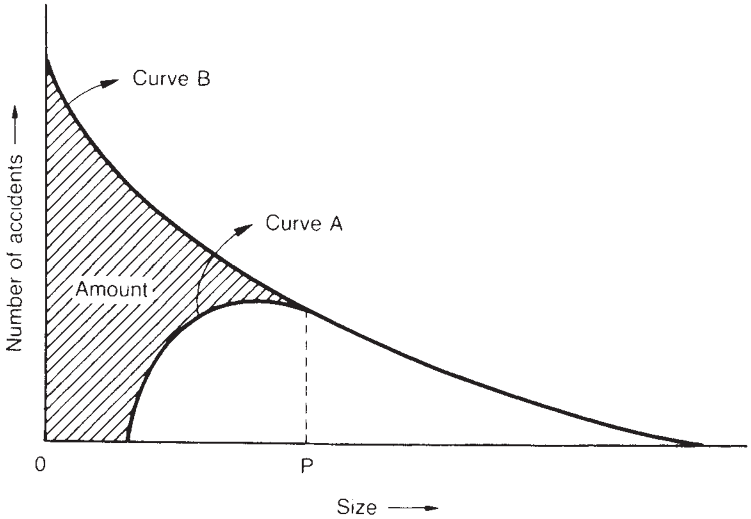

Figure A1.1 *Number of accidents reported (after Badoux, 1983): A, accidents actually reported; and B, total number of accidents (and ideal reporting curve)* level of reporting in process industries such as oil refining, petrochemical and chemicals is similar.

A1.6 Incident Diagrams, Plans and Maps

Many accounts of incidents give diagrams, plans or maps showing features such as derailed tank cars, location of missiles, location of victims, etc. In particular, such diagrams are a feature of the accident reports by the HSE and the NTSB and of case histories described in the Loss Prevention Bulletin.

Typical diagrams showing injury effects at an accident from an HSE report are given in Figure A1.19. A typical diagram of the site of an accident from an NTSB report is shown in Figure A1.16.

The NTSB system of Hazardous Material Spill Maps, documents separate from the accident reports, is described by the NTSB (1979), Benner and Rote (1981) and Lasseigne (1984). One such map is shown in Figure A1.2.

A1.7 Incidents Involving Fire Fighting

A feature of some interest in incidents is the experience gained in fire fighting. Some minimal information about this is given for selected case histories in Series A. Further information may be found in the following accounts:

Brindisi, 1977 (Mahoney, 1990)
Milford Haven, 1983 (Dyfed County Fire Brigade, 1983; Mumford, 1984 LPB 57)
Thessalonika, 1986 (B. Browning and Searson, 1989)
Grangemouth, 1987 (HSE, 1989a)
Port Heriot, 1987 (Mansot, 1989)

A1.8 Incidents Involving Condensed Phase Explosives

A number of the incidents given in the following sections involve explosives. There have been, however, a large number of other explosives and munitions incidents that are of only marginal interest here.

An account of explosions up to 1930 is given in *History of Explosions* by Assheton (1930) and later treatments are *Explosions in History* by N.B. Wilkinson (1966) and *Darkest Hours* by J.R. Nash (1976). Some principal explosions are listed by Nash. His list gives death tolls that in some cases differ from those given elsewhere. The incidents in which the number of deaths is quoted as 200 or more are:

Date		*Location*		*No. of deaths*
1916	Nov. 16	La Satannaya, Belgium	Munitions	1000
1917	Jan. 19	Silvertown, London	Munitions factory	300[a]
	Feb. 20	Archangel, Russia	Munitions shipment	1500
	Jun. 23	Bloeweg, Belgium	Munitions factory	1000
	Aug. 6	Henningsdorf, Germany	Munitions factory	300
	Dec. 6	Halifax, Nova Scotia	Munitions shipment	1600[a]
1918	Aug. 3	Hamont Station, Belgium	Munitions shipment	1750
	Sept. 22	Woellerdorf, Austria	Munitions factory	382
1925	May 25	Peking, China	Munitions store	300
1934	Mar. 14	La Libertad, Salvador	Explosives store	250
1935	Oct. 30	Lanchow, China	Munitions store	2000
1941	Jan. 9	Fort Smederovo, Yugoslavia	Munitions store	1500
1944	Apr. 14	Bombay, India	Munitions shipment	1376[a]
	Jul. 17	Port Chicago, CA	Munitions shipment	321
1956	Aug. 27	Cali, Columbia	Munitions shipment	1200

[a] The death tolls given in the account in Section A1.10 are as follows: Silvertown 69; Halifax 1800; and Bombay Docks 350 (early reports)
This list does not include incidents involving primarily ammonium nitrate.

Other incidents given by Nash, with death tolls shown in brackets, are:

Munitions, explosives, powder factories
1915 Oct. 20 Paris, France (52); Nov. 31 Eilmington, Delaware (31); Dec. 11 Havre, Belgium (110); 1916 Apr. 4 Kent, England (170); Dec. 6 Kent, England (26); 1917 Apr. 10 Chester, PA (133); Oct. 4 Morgan, NJ (64); 1924 Mar. 1 Nixon, NJ (26); 1925 Mar. 1 Kharput, Turkey (160); 1926 Apr. 7 Mannheim, Germany (40); Aug. 12 Csepel, Hungary (24); 1929 Sep. 5 Brescia, Italy (22); 1931 Apr. 30 Nichteroy, Brazil (100); 1935 Jun. 13 Reinsdorf, Germany (52); Jul. 28 Taino, Italy (33); 1936 Jun. 15 Tallinn, Estonia (40); 1937 Jul. 17 Chungking, China (110); 1940 Aug. 29 Bologna, Italy (38); 1941 Jan. 10 Polichka, Czechoslovakia (80); 1943 Dec. 11 Grenoble, France (73); 1947 Aug. 18 Cadiz, Spain (149)

Munitions, explosives stores and arsenals
1916 Feb. 6 Skoda, Austria (185); Feb. 20 Nish, Serbia (43); Mar. 4 Fort Double Coronne, France (30); 1926 Jul. 19 Lake Denmark, NJ (30); 1928 Sep. 26 Ft Cabreriza, Morocco (38); 1929 Mar. 4 Sofia, Bulgaria (28); 1931 May 5 Yuchu, China (100); Aug. 13 Macao, China (26); 1932 Jul. 10 Nanking, China (100); 1935 Oct. 23 Shanghai, China (190); 1944 Nov. 28 Fauld, England (175)[a]; 1945 Feb. 26 Paris, France (20); Jul. 7 Saragossa, Spain (30); Oct. 25 Asnier-en-Bessin, France (33); Dec. 29 Codroipo, Italy (23); 1946 Apr. 8 Saigon, Vietnam (23); 1949 Jul. 26 Tarancon, Spain (25); 1953 Apr. 6 Nantsechu, Formosa (54); 1956 May 17 Takoradi, Africa (25); 1963 Aug. 13 Gauhati, India (32)

Munitions, explosives shipments
1916 Aug. 8 Koenigsberg, Germany (50); 1919 Feb. 1 Longwy, France (64); 1924 Dec. 27 Otaru, Japan (120); 1930 Dec. 3 Midas Garaes, Brazil (36); 1955 Sep. 23 Gomex Palacio, Mexico (40); 1960 Mar. 4 Havana, Cuba (100); 1964 Jul. 23 Bone, Algeria (85)

Munitions, explosives (otherwise unspecified)
1925 Nov. 22 Ahwaz, Persia (70); 1933 Jan. 20 Morelia, Mexico (23); 1934 Aug. 4 Nakang, Japan (25); 1953 Aug. 18 Benghazi, Libya (50); Sep. 12 Wuensdorf, Germany (20)

---

[a] The death toll given in the account in Section A1.10 is 68.

A1.9 Case Histories: Some Principal Incidents

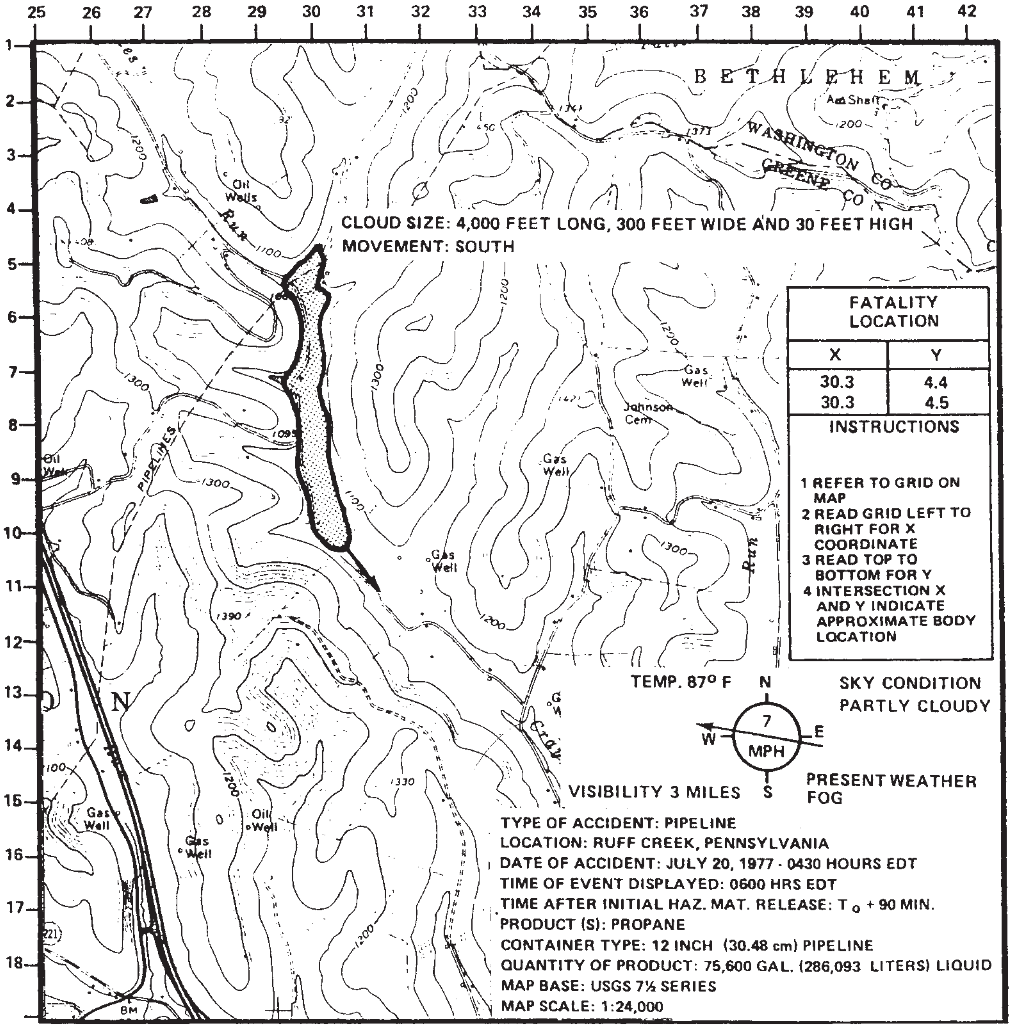
Two series of case histories are given below. Series A consists of case histories chosen according to one or more of the following criteria: (1) the incident is well known, generally by name; (2) it involved major loss of life and/or property; and (3) the physical events and the escalation are of interest.

Series B consists of case histories of incidents which have not been selected for the A series and where in general the loss of life or property damage was less, but which are considered instructive, particularly in respect of the cause.

Generally, in the A series mention is made of deaths and injuries, but the cost of property damage is not given. However, many of the incidents figure in the thirteenth edition of *Large Property Damage Losses in the Hydrocarbon-Chemical Industries.* A Thirty Year Review by Marsh and McLennan (M&M), edited by Mahoney (1990), which gives the 100 largest losses. For these incidents, the cost is shown in Table A1.2.

A1.10 Case Histories: A Series

A1 *San Antonio, Texas, 1912*
On 18 March 1912 at San Antonio, Texas, workers were carrying out repairs on the boiler of a large locomotive. Steam pressure was being raised when something went wrong and the boiler exploded violently. One 1600 vapour fragment travelled 1200 ft and a 900 vapour one fetched up 2000 ft away. Twenty-six workers and residents were killed and another 32 were injured (J.R. Nash, 1976).



CLOUD SIZE: 4,000 FEET LONG, 300 FEET WIDE AND 30 FEET HIGH

Abbreviations: FCC = fluid catalytic cracker; HC = hydrocarbon; HM = hazardous material; VCM = vinyl chloride monomer

Event abbreviations: ANEX = ammonium nitrate explosion; BLEVE = boiling liquid expanding vapour explosion; CD = criminal damage caused by vandalism, sabotage, etc.; DEL = delayed; DET =detonation (internal explosions only); DEX = dust explosion; EQK = earthquake damage; EX = explosion; F = fire; FB = fireball; HEX = high explosive explosion; HUR = hurricane damage; IE = internal explosion; POL = pollution; REL = release; TOX = toxic release; VCE = vapour cloud explosion; VCF = vapour cloud fire; VEEB = vapour escape into, and explosion in, building

Costs

Costs are in US dollars and are taken from the M&M compilations. The great majority are the trended costs as given in the thirteenth, 1990 edition by Mahoney (1990) and are thus in 1990 US dollars. Some values not included in the 1990 edition but given in the eleventh edition by Garrison (1988) have been converted to 1990 values, using a factor of 1.1; these are marked with an asterisk. Values for incidents in 1990 and 1991 given in the fourteenth 1992 edition by M&M (1992) are in 1991 US dollars.

Notes:

[a] Evidently including 'excess deaths', characteristic of a severe pollution incident.

[b] Gugan (1979) gives two incidents in 1966 in the FRG (his Nos 49 and 50). His No. 49 is named as Raunheim, while No. 50 has no more specific location. For both the date is given as January and the reference as Bradford and Culbertson (1967). Incident No. 50 is not quoted by Lenoir and Davenport (1993).

[c] Slater (1978a) cites an incident in Roumania in 1974 involving ethylene as a VCE with Id, 50i; this was given in the first edition of this book. The present entry relies on Anon. (1974k).

[d] The figure for deaths refers to prompt deaths; it does not include abortions.

A2 *Ashton, Manchester, 1917*
On 13 June 1917, a nitrator in an explosives works at Ashton, Manchester, went out of control and 'boiled' over, releasing hot acid onto the wooden staging and starting a fire. The fire took hold in the nitrator house. Spectators were attracted, including children. Soon after there was a large explosion, involving some 5 tons of TNT. The explosion ruptured two gasholders nearby, setting them on fire. The flames were described as half a mile high.

Some 100 houses were demolished. 46 persons died, including 24 employees and 11 children. More than 120 were injured sufficiently to need hospital treatment. The explosion made two craters, one at the location of the TNT drums and one at that of the drier and setting frays. The former was 90 ft × 36 ft × 5 ft deep and the latter 30 ft × 15 ft and relatively shallow. Some 12,000 ft^2 of glass was replaced.

Billings and Copland (1992)

A3 *Halifax, Nova Scotia, 1917*
At about 8.48 a.m. on 6 December 1917, the French ammunition ship Mont Blanc was rammed by the Belgian relief ship Imo in Halifax Harbour, Nova Scotia. The Mont Blanc was carrying in her hold some 4,661,794 lb of picric acid, 450,000 lb of TNT and 122,960 lb of guncotton as well as 488,672 lb of benzol on deck. The Mont Blanc burst into flame and at 9.05 am there was a massive explosion. The inhabitants heard a 'thundering crash' and many ran to their windows to see what had happened. The noise was heard 191 miles away and some windows broke at a distance of 61 miles.

The explosion tore the ship apart and hurled fragments all over the city. The anchor shank fetched up 3–4 miles away. The blast caused almost complete destruction within a radius of about three-quarters of a mile. There was severe structural damage at distances ranging from 1 to 1.75 miles. It was estimated that 95% of the glass in the city was broken. Fires caused by overturned stoves broke out in many parts.

Many people were killed when buildings were demolished. Large numbers suffered injury from flying glass and at least 500 people were totally blinded. In round figures, the death toll was put at 1800 and the number of registered wounded was 8000.

A4 *Silvertown, London, 1917*
On 19 January 1917, an explosion occurred at the Brunner Mond munitions factory at Crescent Wharf, Silvertown, London. A fire broke out at the melt pot room and took hold. It burned for some minutes when there was a massive explosion. Sixty nine people were killed and 98 seriously injured; there were 328 slight injuries recorded and about 600 were believed to have been treated in the street or by private doctors. The report of the inquiry stated:

> At the time of the explosion the total quantity of TNT on the premises amounted to 83 tons, of which 28 were crude, 27 in process and 28 finished, and there were, in addition, 9 tons of TNT oil in iron drums of which 5 tons were subsequently recovered. . . . The outlines of the craters seem to indicate that altogether about 30 tons of TNT and the remaining 4 tons of TNT oil did not explode, but probably burned away. This would leave 53 tons of TNT to take part in the explosion.

TNT oil is alcohol containing the soluble impurities of TNT.

The explosion formed two separate craters. The smaller was circular in shape with a radius of about 25 ft and some 13 tons of TNT had been present in this area. The larger crater, in the area containing the remaining 40 tons of TNT, was kidney-shaped, with approximate dimensions 150 ft × 50 ft.

Anon. (n.d.b); Ministry of Home Security (n.d.a); Sainsbury (1977)

A5 *Oppau, Germany, 1921*
At 7.29 a.m. and again at 7.32 a.m. on 21 September 1921, two terrific explosions occurred at the Oppau works of Badische Anilin und Soda Fabrik (BASF).

Figures for the death toll vary. Commentz *et al.* (1921) give the number of dead as 430, including 50 people in the village. According to V.C. Marshall (1987), following BASF (1958), the explosion killed 561, including 4 in Mannheim 7 km away, injured 1500 and destroyed 1000 houses, including 75% of those in Oppau itself. It created a crater 115 m long × 75 m wide × 10 m deep.

The works after the explosion is shown in Figure A1.3.

Other effects of the explosion were as follows (Commentz *et al.*, 1921):

> Houses in the adjacent city of Ludwigshafen and in Mannheim, which lies opposite to Ludwigshafen on the right bank of the Rhine, were damaged, walls were shaken down and practically all windows were broken. At these places and at Heidevaporerg, which is about 14 miles from Oppau, the effect of the explosion was first felt by two very heavy earthquake-like shocks. In Mannheim some seconds later and in Heidevaporerg 82s after the shocks there came an enormous rush of air which broke windows and doors and caused damage to gas holders, oil tanks, and many river barges. The sound of the explosion reached as far as Bayreuth, at a distance of 145 miles, and the air pressure wave caused considerable damage in Frankfurt, which is about 53 miles from the scene of the explosion.

The explosion involved some 4500 tons of a 50 : 50 mixture of ammonium sulfate and ammonium nitrate. Detonation was set off by blasting powder, which was being used to break up storage piles of material which had become caked, a procedure which had been carried out without mishap some 16,000 times previously.

The danger of using explosives to break up caked ammonium nitrate had been demonstrated earlier in the year in Germany, when on 10 July at Kriewald this procedure led to the explosion of two rail wagons containing 15 te of that substance (D.J. Lewis, 1993).

BASF (1921, 1958); Commentz *et al.* (1921); J.R. Nash (1976); NBFU (1948); HSE (1978b); V.C. Marshall (1987); D.J. Lewis (1993)

A6 *Hamburg, Germany, 1928*
On 28 May 1928, a tank containing phosgene exploded at the Stolzenburg factory on the Hofe-Kanal near the harbour area of Hamburg. The wind was at first northerly and then changed to the south-east. At one location 5 miles away the gas was strongly felt. People were also affected by the gas at locations 6 and 11 miles distant.

The prime source (Anon., 1928) states 'Some 300 or more cubic feet of the gas were released'. V.C. Marshall (1987) suggests that this figure probably refers to the volume of the liquid, which would correspond to about 12 te, close to the figure of 11 te given by N.C. Harris (1981).

11 people were killed and 171 required hospital treatment.

Figure A1.3 *Oppau: BASF works after ammonium nitrate explosion, 1921 (Badische A nilin und Soda Fabrik)*

Anon. (1928); Hegler (1928); N.C. Harris (1981b); V.C. Marshall (1987)

A7 *Neunkircken, Germany, 1933*

On 10 February 1933, an explosion occurred on a waterless gas holder in Neunkirchen in Germany. Work was being done on a bypass pipe between the inlet and outlet mains. Due to a series of actions which is not entirely clear, but which involved measures to bring misaligned flanges into alignment, a small explosion occurred at this bypass and ruptured the outlet main. A flame was seen to go up the side of the gasholder. It had burned for some 5 min when the main explosion occurred. The inquiry found that this explosion involved an air mixture which had formed above the piston.

The explosion caused 65 deaths and several hundred injuries.

Anon. (1933a,b); Kier and Miffler (1983)

A8 *Wichita Falls, Texas, 1939*

On 12 December 1939 an explosion occurred in a 10 in. diameter crude oil pipeline at Wichita Falls, Texas. A 38 mile section of the line had been emptied to locate and repair minor leaks. The method used was to pass a series of scrapers through the line propelled by air, which was odorized to assist in detecting the leaks, and then to displace the column of air by one of oil. During this latter procedure a scraper propelled by the oil struck one that had stuck in the pipe, evidently causing a spark. The result was an oil film explosion, in which the detonation travelled down the pipeline for over 26.8 miles, rupturing the line at intervals of about 80 ft.

The pattern of ruptures in the pipeline is shown in Figure A1.4.

P. Reed (1939); Armistead (1959); D.J. Lewis (1993)

A9 *Tessenderloo, Belgium, 1942*

On 21 July 1942, a massive ammonium nitrate explosion occurred at a chemical works at Tessenderloo in Belgium. The death toll is given as of the order of 200.

J.R. Nash (1976)

A10 *Ludwigshafen, Germany, 1943*

On 29 July 1943, a release occurred from a rail tank car in the BASF works at Ludwigshafen. The tank car contained 16.5 te of a mixture of 80% butadiene and 20% butylene. A vapour cloud formed and ignited. The resultant vapour cloud explosion demolished a block 350×100 m^2 within the factory. Fifty-seven people were killed and 439 injured.

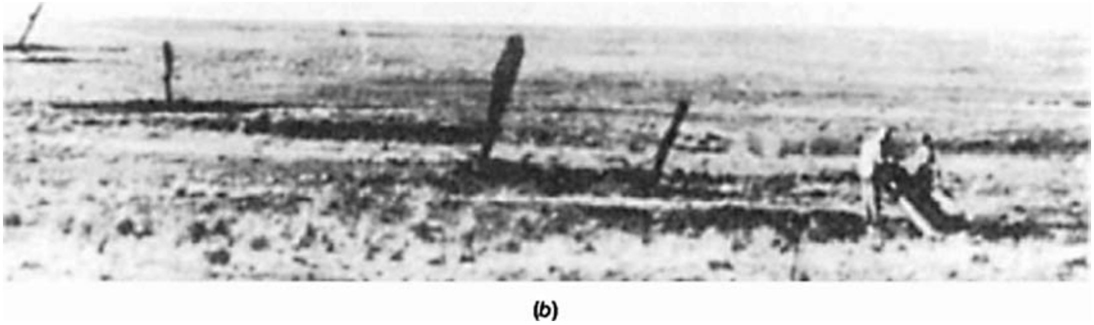
According to Giesbrecht *et al.* (1981), there was a delay of some 10–25 s between the rupture and the explosion. These authors indicate that the cause was hydraulic rupture of the tank due to overheating in the sun. If so, the incident is remarkably similar to one which occurred in the same works 5 years later, as described in Case History A17.

Stahl, Strassman and Richard (1949); J.R. Nash (1976); Giesbrecht *et al.* (1981); D.J. Lewis (1983); V.C. Marshall (1986 LPB 67, 1987)

A11 *Bombay, India, 1944*

Just after 4.00 p.m. on 14 April 1944 in the Victoria Dock, Bombay, India, a massive explosion occurred on the munitions ship Fort Stikine.

(a)



(b)

Figure A1.4 *Wichita Falls, 1939: pipeline after the explosion: (a) aerial view showing blackening where repeated ruptures of the pipeline occurred; and (b) elevation view, showing broken ends of the pipeline projecting through the ground (Bureau of Mines)*

The ship carried some 1400 tons of mixed munitions (bombs, shells, torpedoes, mines, etc.). On its way it had picked up a cargo of cotton. In No. 2 Hold 187 tons of ammunition was stored with cotton bales above, then other material, 1089 drums of lube oil, and finally more explosives. This was contrary to regulations, which stated that cotton is liable to spontaneous combustion if contaminated with oil. Further notes stated that cotton and explosives should be stored at opposite ends of the ship and that oil drums stowed above cotton should be limited to 250 barrels.

By mid-day on 14 April unloading of the ship was well under way. Soon after, crew on a nearby ship saw wisps of smoke coming from No. 2 Hold of the Fort Stikine, but did not inform the latter. Almost two hours passed before the fire was discovered. Water was applied to the hold using the ship's three hoses.

The authorities recognized the seriousness of the situation and considered options such as moving or scuttling the ship, but both appeared impractical, since the ship's engines were down for repair, there were no tugs available and the water was too shallow for scuttling. Moving the ship would also involve disconnecting the fire hoses laid from the dock into No. 2 Hold, which now numbered more than 30.

By 3.30 p.m. although an estimated 900 tons of water had been poured into the hold, the port deck was too hot to walk on and a large patch on the side was glowing red. At 3.50 p.m. a huge column of flame shot up from the hold and at 4.06 p.m. the first massive explosion occurred. Some 34 min later there was a second major explosion.

The first explosion killed 60 firemen and set up fires in a 900 m radius. As a result of the two explosions together 10 ships in the docks were destroyed or declared a total loss. Figures for the death toll differ. According to Patience (1989), early reports gave 350 people killed, 1800 injured and 50,000 rendered homeless. J.R. Nash (1976) quotes 1376 dead.

J.R. Nash (1976); Patience (1989)

A12 *Cleveland, Ohio, 1944*

At approximately 2.40 p.m. on 20 October 1944 a cylindrical LNG storage tank at the Liquefaction, Storage and Regasification Plant of the East Ohio Gas Company at Cleveland, Ohio, ruptured and discharged its entire contents over the plant and the nearby urban area. The LNG vapour ignited almost immediately and an intense fire burned at the plant, causing great loss of life and extensive damage.

More LNG flowed from the plant as liquid down storm sewers, where it mixed with air and exploded.

The final death toll was 128 and the numbers injured were estimated as 200–400. The greatest loss of life occurred within the plant area.

The plant was the first commercial LNG plant of its kind in the work. Its function was to liquefy and store natural gas during off-peak periods and to regasify it during periods of peak demand. The LNG was stored at 5 psi and −250°F. The plant was built on a site which had been in the company's possession for 50 years. The site was close to residential and industrial areas.

The cause of the rupture is uncertain. The Bureau of Mines investigation (Elliott *et al.*, 1946 BM RI 3867) concluded that the low carbon steel used in the construction of the vessel may have been unsuitable and that the failure may have occurred due to vibration or seismic shock.

It was pointed out in the report that most industries handling liquid oxygen or air used not carbon steel but stainless steel or suitable non-ferrous metals. Following this accident, the use of the latter materials became more widely favoured in applications of this kind.

The report recommended that the distance between a plant of this kind and the nearest inhabited building should be greater than half a mile.

Following the rupture large quantities of liquid topped by burning vapour had flowed considerable distances from the tank. The report discussed the argument that a dike is not useful for a relatively volatile material such as LPG or LNG, concluded that a dike would have reduced the hazard and recommended that storages for liquefied gases should have a dike.

The report also made a number of other recommendations. These included the open siting of storage tanks to permit good ventilation; the use of precautions to eliminate sources of ignition to the standard considered necessary in explosives plants; the provision of remote closure for the bottom off-take valve; the installation of reliable level indicators and alarms; and the conduct of emergency drills.

A13 *Fauld, UK, 1944*

On 27 November 1944 a huge explosion occurred in a munitions store at Fauld, Staffordshire. The store was underground in a former gypsum mine, mined on the 'crown and pillar' method. The explosion involved mass detonation of 3500 tons of bombs. Although the store was in the countryside, the explosion killed 68 people and injured 22. It created a massive crater covering 12 acres and 80 ft deep.

The store handled large quantities of bombs for the bombing offensive. This included the repair and re-issue of bombs recovered after jettisoning. The personnel were working under considerable pressure. The inquiry found that the most likely cause was ignorance and disregard of the regulations by personnel working on jettisoned bombs. An armourer testified that he had seen a colleague using a brass chisel to remove a broken exploder from one of the bombs, a practice expressly forbidden. Other witnesses confirmed that such irregularities were by no means uncommon.

J. Reed (1977); Anon. (1992 LPB 103); V.C. Marshall (1992 LPB 105)

A14 *Port Chicago, California, 1944*

On the evening of 17 July 1944 two vessels, the Quinault Victory and the E.A. Bryan, were berthed at Port Chicago, California, taking on large quantities of cordite and TNT when they were rent by a massive explosion. At dawn next day the vessels, and the 321 men on them, had disappeared. The cause of the explosion was never established, although some authorities implicate deteriorated munitions.

J.R. Nash (1976)

A15 *Brest, France, 1947*

On 28 July 1947 the vessel Ocean Liberty with a cargo of ammonium nitrate, exploded in the port of Brest, France, killing some 21 people.

J.R. Nash (1976)

A16 *Texas City, Texas, 1947*

At about 8.10 a.m. on 16 April 1947 fire was observed in bagged ammonium nitrate fertilizer on board the ship Grandcamp in the harbour at Texas City. There were 880 tons of ammonium nitrate in the hold affected and a further 1400 tons in another hold. Frantic efforts were made to extinguish the fire, but the quantity of water used initially was too small and by the time hose lines had been connected to supply larger quantities, the fire was so well established that the crew was ordered to abandon the ship. At 9.15 a.m. the Grandcamp disintegrated with a tremendous thunderclap, killing all persons in the dock, including firemen and a crowd of spectators.

Another ship, the High Flyer, which also had ammonium nitrate on board, was 700 ft away and was blown free of its hawsers. On account of the danger of another explosion, volunteers could not be found to move the High Flyer out of the burning area. At 6.00 p.m. ignition of its sulfur cargo occurred. At 1.10 a.m. the next day the High Flyer was ripped apart by the expected explosion.

The report of the National Board of Fire Underwriters (1948) states:

> When the Grandcamp blew up, the cargo of peanuts, tobacco leaves, balls of sisal twine, and oil-well drilling equipment were blown in all directions. Shrapnel-like fragments of the ship were hurled in high trajectory, 2000–3000 feet into the air; some travelled more than 10,000 feet from the point of origin. Some of the oil-well drill rods (30 feet in length and 7 inches in diameter,

> weighing close to $1\frac{1}{2}$ tons) were hurled almost 2 miles and buried 8 ft into the ground, like twisted hairpins. . . .

It was virtually impossible to separate the effects of the two successive explosions, but, the report continues:

> Daybreak revealed a sickening scene of devastation-demolished concrete structures, masses of twisted wreckage, crippled refineries with battered storage tanks, some crumpled like tin-foil, and sidings of distant warehouses blown apart as if ripped by a tornado. Pitch black columns of smoke from the burning oil tanks spiralled skyward for 3000 feet or more, and were visible for 30 miles. They burned continuously for almost a week. Insurance inspection showed blast damage to over 3,300 dwellings and 130 business buildings, to more than 600 automobiles and some 360 box cars. Approximately 50% of some 250 storage tanks, ranging from 25,000 to 80,000 barrels capacity, were substantially damaged either by concussion, missile or intense fire.
>
> There were 552 deaths and over 3000 injuries in a community of some 15 000 people.

Kintz, Jones and Carpenter (1948 BM RI 4245); National Board of Fire Underwriters (1948); Wheaton (1948); Blocker (1949); Blocker and Blocker (1949); J.R. Nash (1976); V.C. Marshall (1983 LPB 52, 1987)

A17 *Ludwigshafen, FRG, 1948*

On 23 July 1948 a rail tank car containing dimethyl ether ruptured in the BASF works at Ludwigshafen. A vapour cloud formed and after some 6 s was ignited by hot work in a workshop. A block 230 m × 170 m was demolished and severe damage was done within an area 570 m×520 m. The death toll was 207 and the number of injured 3818. The casualties appear to have been confined to the works, the dead all being between 15 and 65 and there being very few women's names listed. The official report by Stahl, Strassman and Richard (1949) considered four hypotheses for the cause of the rupture: (1) the presence of organic peroxides, (2) the presence of non-condensables, (3) overheating leading to hydraulic rupture and (4) mechanical defects. They were able to rule out the first two and settled on the third: that the tank contents had been heated by the hot summer sun and that the tank, lacking a relief valve, had suffered hydraulic overpressure and rupture. This is the account generally given in the literature.

This explanation has been questioned by V.C. Marshall (1987). He points out that in order to obtain the pressure necessary to achieve hydraulic rupture the investigation was constrained to assume both that the tank was at least 4% smaller in volume than the norm, that this had not been remarked in 19 years of use and that the temperature reached was exceptionally high. He refers to the metallurgical analysis done at the time and described in the report, to the effect that the tank had weak spots. In addition, the tank had been involved the year before in an accident in which the valves had been knocked off. Further, the tank belonged to an ammonia plant and the plate giving the tare weight referred to the permissible filling limit for ammonia. Ammonia is known to cause embrittlement in some steels. The significance of the solar heating could well be that it increased the vapour pressure sufficiently to trigger the rupture.

BASF (1948); Stahl, Strassman and Richard (1949); D.J. Lewis (1980, 1983, 1993); Giesbrecht *et al.* (1981); V.C. Marshall (1986 LPB 67, 1987)

A18 *Avonmouth, UK, 1951*

On 7 September 1951 a storage tank exploded at the Royal Edward Dock, Avonmouth, Bristol. The tank was being filled with gas oil from a ship. The gas oil was contaminated with petrol, which had leaked through a partition between the gas oil tank and the petrol tank, and this was known to those concerned. The tank was being splash filled and the explosion occurred as two men on the tank roof were gauging the level using a steel tape. The two men were killed.

Evidently a flammable atmosphere had formed in the vapour space of the tank and had been ignited by a discharge of static electricity. The official report (H.E. Watts, 1951) stated: 'It was therefore quite possible for the steel dip tape to take up a charge of static electricity from the oil in the tank and to discharge it by means of a spark against the edge of the 10 inch manhole in the top of the tank through which the tape had been inserted'.

H.E. Watts (1951); Anon. (1952); Kletz (1983 LPB 52)

A19 *Port Newark, New Jersey, 1951*

On 7 July 1951 a fire and BLEVEs devastated a large LPG storage at Port Newark, New Jersey. The storage comprised one section with 70 horizontal bullet tanks, each with a capacity of about 100 m^3, and a further 30 tanks nearby. The tanks were not provided with thermal insulation or fixed water sprays. The initial event was experienced as a slight explosion followed by a fire. Within the next two and half min there were four small explosions near the seat of this fire, followed half a minute later by a large flash, a muffled explosion and a large fireball. Some 10–15 min into the event a BLEVE occurred. The next 100 min were punctuated by tank explosions and BLEVEs every 3–5 min. In all 73 bullet tanks were destroyed.

The tanks were equipped with emergency isolation valves. Some 30 s into the event the button to close these valves was pressed. It was pressed again after two and a half min, there being some doubt whether the first time it had been pushed for long enough. In fact, it is estimated that on the side of the valves away from the tanks there was some 100 m^3 of LPG, mainly in a 12 in. delivery line from the docks and in 8 in. ring mains; thus there was potentially quite enough fuel to feed the fire even if the tanks themselves were isolated.

In many cases the BLEVEs were accompanied by fireballs rising 750 m into the air. Many of the events registered on the barometer at Newark Airport, showing TNT equivalents of about 25 kg, consistent with the pressure energy in the vapour space of a tank. The damage done by missiles is described as spectacular. One large tank section 17 m long travelled over half a mile, demolishing a filling station and starting a fire. Another fragment ruptured the 12 in. underground water main to the site. Figure A1.5 shows one of the tank section missiles part buried in the ground.

It has been suggested that a possible cause of the initial event was inadequate allowance for thermal expansion in the 8 in. ring mains. These handled propane at two different temperatures, the regular flows and a flow from a vapour recovery unit.

NBFU and FIRONJ (1952); D.J. Lewis (1980, 1993)

A20 *Bakersfield, California, 1952*

On 21 July 1952, the Paloma condensate recycling plant in Kern County, near Bakersfield, California, was struck by an earthquake. The earthquake had its epicentre about 12 miles away, measured 7.7 on the Richter scale and had a

Figure A1.5 *Port Newark, 1951: tank section part buried in ground (The Bettman Archive)*

maximum intensity in the range X–XI. Ground movement was of the order of 0.5 ft vertically and 1 ft horizontally. It was such as to cause a 60 ft high absorption column to swing at the top in an arc of 3 ft and to stretch its foundation bolts some 1.5 in. Figure A1.6 gives an aerial view of the facility following the earthquake.

The plant had five large butane storage spheres which were not designed to earthquake standards. Two spheres collapsed with rupture of the feed lines. Butane escaped and formed a vapour cloud, which ignited some 90 s later at a transformer block. The resultant explosion and fire did extensive damage but there were no deaths or serious injuries.

Jenkins and Oakshott (1955); D.J. Lewis (1980, 1993); Alderson (1982 SRD R246)

A21 *Bound Brook, New Jersey, 1952*

On 22 December 1952 a plant handling phenolic resin moulding powder at Bound Brook, New Jersey, was wracked by a dust explosion. The explosion occurred in a dust collector and then travelled through ducting, emerging at several points into floor areas, where it raised clouds of dusts which in turn underwent violent secondary explosions. The probable sequence of events was that a bearing in a hammer mill overheated, the powder in the mill began to smoulder and the smouldering powder passed into a flammable dust mixture in the dust collector. Five people were killed and 21 injured.

NFPA (1957); D.J. Lewis (1993)

A22 *Whiting, Indiana, 1955*

On 27 August 1955 at the refinery at Whiting, Indiana, a reactor suffered an internal detonation and disintegrated. The reactor vessel was 127 ft tall × 22.5 ft diameter, having a wall 2.5 in. thick and weighing 500 te. A separator with a 6 in. thick wall also fractured. The detonation has been estimated as having a TNT equivalent of 5.6 te. Fragments were thrown 1500 ft, one of 60 te landing on the tank farm and another killing a boy at home. The event started a fire which eventually covered 40 acres and lasted for 8 days. There was the one death just mentioned.

The event occurred in the course of start up of a hydroformer unit. The start up procedure involved the circulation through the reactor and separator of inert gas heated in a furnace. Due to a valving error the gas being circulated was in fact a flammable mixture. In due course, the gas temperature at the exit of the furnace rose to 500–600°F, reaching the autoignition temperature. A detonation occurred in the reactor and another in the separator vessel.

Woodworth (1955); R.B. Jacobs *et al.* (1957); Randall *et al.* (1957); R.B. Jacobs and Bulkley (1967); R.B. Jacobs *et al.* (1973); D.J. Lewis (1980, 1993)

A23 *Cali, Columbia, 1956*

On 7 August 1956 eight trucks carrying dynamite exploded at Cali, Columbia, killing about 1100 people as they slept, and injured another 2000; some 500 of the dead were soldiers in barracks.

Walker (1973); J.R. Nash (1976)

Figure A1.6 *Bakersfield, 1952: recycling plant after the earthquake (The Bettman Archive)*

A24 *Uskmouth, UK, 1956*
On 18 January 1956 an explosion occurred on the No. 5 60 MW turbogenerator set at the Uskmouth power station of the Central Electricity Authority. The low-pressure turbine and generator were totally destroyed and the high-pressure turbine and plant severely damaged. Fragments were ejected with considerable force, causing damage to the turbine house. Two persons were killed and nine injured. The cause of the incident was established as machine overspeed.

Lindley and Brown (1958)

A25 *Montreal, Canada, 1957*
On 8 January 1957, a series of BLEVEs occurred at a set of storage spheres at Montreal, Quebec. There were three spheres in a common bund: one 800 m^3, one 1900 m^3 and one 2400 m^3. The 800 m^3 sphere, which held butane, was overfilled due to a faulty level gauge. A vapour cloud formed and found an ignition source, probably at a service station 180 m away, and the flame flashed back to the sphere, where a pool fire started. After some 30 min the 1900 m^3 sphere, which was less than 20% full, underwent

a BLEVE. Some 15 min later BLEVEs occurred on the other two spheres also.

Selway (1988 SRD R492)

A26 *Signal Hill, California, 1958*

On 22 May 1958 an 80,000 bbl. tank serving as the feed tank to a viscosity-breaking unit at the refinery at Signal Hill, California, erupted. Steam issued, part of the roof was torn off and oil froth flowed out. There was no immediate ignition. The oil froth flowed through the plant in a wave about a metre high. A further eruption occurred and the froth ignited. Eventually it covered an area of 27 acres. The fire burned for 40 h. Two people were killed and 18 injured.

The oil in the tank was at a temperature of 157°C. The source of the water which caused the eruption does not appear to be known: it may have been in the tank already or may have been pumped in by mistake.

Woodworth (1958); Anon. (1959a); D.J. Lewis (1993)

A27 *Deer Lake, Pennsylvania, 1959*

On 2 June 1959 in the township of Deer Lake, Pennsylvania, a road tanker containing LPG slowed to a halt as a school bus in front stopped and was itself struck from behind by a truck. LPG escaped and was rapidly ignited. After some 15 min the fire brigade arrived and were told by the driver of the tanker that it would be protected from explosion by its safety valves. They directed water and foam at a nearby wooden building. A crowd of spectators gathered and police had difficulty in moving them on. After the fire had burned for a time variously estimated as 20–45 min the tanker suffered a BLEVE. Shrubbery at a distance of 150 m was scorched. The tank itself travelled up the street, bouncing off a stonewall. The tank, accompanied by stones and other debris, struck the main group of onlookers, killing most of them. There were 11 fatalities.

Hymes (1985 LPB 65)

A28 *Meldrin, Georgia, 1959*

On 28 June 1959, a derailment occurred of a rail tank cars containing LPG at Meldrin, Georgia, with tank rupture and release of LPG. A vapour cloud formed and reached a nearby leisure park. Ignition occurred and the resultant vapour cloud fire caused 23 deaths.

Anon. (1960–61); Hymes (1985 LPB 65); V.C. Marshall (1987)

A29 *La Barre, Louisiana, 1961*

At about 8.15 a.m. on 31 January 1961 some 6000 USgal of liquid chlorine were spilled from a derailed tank car in the community of La Barre, Louisiana. A cloud of chlorine gas spread of over an area of approximately 6 square miles. For the most part it hung close to the ground, but in places ‘boiled upwards’ to a height of 80–90 ft. Some 1000 people were evacuated. A series of determinations of the chlorine concentration were made by a team using mobile equipment. The first samples were taken at about 11.15 a.m., when a concentration of 10 ppm was measured at the end of a contaminated area some 200 yd long on a highway parallel to the railway. At about 3.00 p.m. a concentration of 400 ppm was measured 75 yd from the wreck. One person died and about 100 were treated for exposure to chlorine. The fatality was an 11-month old infant in a family, which lived in a house approximately 50 yd from the tank car. The chlorine in the house made the infant choke and gasp and the frantic father carried it outside, where the gas concentration was higher still. Although most of the exposure occurred inside the house, this exposure outside was probably critical. The child died in hospital. A 2-month old infant who remained in the house survived.

Joyner and Durel (1962)

A30 *Berlin, New York, 1962*

On 25 July 1962, a tractor tank semi-trailer unit came off the road at Berlin, New York. The vehicle had failed to negotiate a bend, tipped over and jack-knifed. The tank hit a tree and its contents of some 6876 USgal of LPG were released. A vapour cloud formed which covered an area of some 2000 m^2 and was 25 m high. There followed a massive vapour cloud fire which caused the deaths of 10 people and injured 17.

Walls (1963–64, 1964a); Kier and Müller (1983)

A31 *Doe Run, Kentucky, 1962*

On 17 April 1962 at Doe Run, Kentucky, a plant for the manufacture of an ethanolamine from ammonia and ethylene oxide suffered a major explosion. The reactor was supplied with liquid ethylene oxide from a 25 m^3 storage vessel. The reactant transfer pumps were provided with an interlock system but problems had been experienced with this system and the control had reverted to manual. A back flow of ammonia occurred into the ethylene oxide tank. A reaction took place which might have been a reaction runaway or a decomposition. The vessel ruptured, releasing a large quantity of ethylene oxide. The vapour cloud ignited immediately, giving an explosion estimated to have had a TNT equivalent of 16 te. It has been suggested that the mechanism of ignition may have been free radicals from the initial, internal reaction.

Troyan and Levine (1968); D.J. Lewis (1980, 1993); Mahoney (1990)

A32 *Marietta, Ohio, 1962*

On 27 April 1962 at Marietta, Ohio, a benzene recycle pump on a phenol production unit became plugged with residue, and whilst attempts were being made to clear it, pressure built up in a stripper column. A 6 in. relief valve operated, discharging benzene vapour, which ignited. Missiles from the resulting explosion severed pipework, releasing large quantities of flammable liquids, which also ignited. One person was killed and three injured.

Mahoney (1990)

A33 *Attleboro, Massachusetts, 1964*

On 12 January 1964, an explosion occurred in a vinyl chloride polymerization plant at Attleboro, Massachusetts.

An illuminator port had been replaced on one of the reactors but not pressure tested. When the reactor was charged, a small leak developed. As the fitter was tightening the clamping ring, the glass chipped and he was injured; the leak developed. An estimated 4.5 te of vinyl chloride escaped into the building, ignited and exploded with an estimated TNT equivalent of 17.7 te. The explosion broke pipework on all the 20 reactors and released some 68 te of vinyl chloride, which ignited. There was a large fireball. Seven people were killed and 40 injured.

Walls (1964b); D.J. Lewis (1980, 1993); Mahoney (1990)

A34 *Niigata, Japan, 1964*

On 16 June 1964, the refinery at Niigata, Japan, suffered an earthquake of strength 7.7 on the Richter scale which caused two major fires. The first fire was the result of oil spillage from a floating roof storage tank. The oil was ignited by sparks as the roof smashed against the sides of the tank.

Later, a seismic tidal wave engulfed the area and unignited oil spread over the water. For 4 h this oil did not ignite. Six hour into the event an explosion occurred in another part of the refinery 1200 ft from the tank which was seat of the original fire. This second fire spread to within 350 ft of the first fire but the two did not merge. Two people were killed and 97 storage tanks were destroyed.

Mahoney (1990)

A35 *Bow, London, 1965*

On 7 August 1965, a flour mill in Bow, London, suffered a dust explosion. The site of the explosion was a 15 te capacity metal flour bin on the third floor. Welding had been in progress shortly before and may have caused overheating of the metal and hence of the flour inside. Two major fires and many smaller ones broke out. Five people were killed and over 40 injured.

Anon. (1967c); D.J. Lewis (1993)

A36 *Louisville, Kentucky, 1965*

On 25 August 1965 at Louisville, Kentucky, an explosion occurred on a plant manufacturing neoprene by polymerization of chlorobutadiene in a compressor circulating monovinyl acetylene (MVA). The investigation concluded that a mechanical failure had caused local overheating in the compressor and that this had led to decomposition of the MVA. There followed a series of explosions, a total of 10 occurring within 13 min and of 18 within 90 min. The escalation occurred due to transmission through pipework, flame impingement and missiles. Twelve people were killed and eight injured; all the deaths occurred within a radius of less than 100 ft from the original explosion.

Armistead (1966, 1973); Mahoney (1990); D.J. Lewis (1993)

A37 *Natchitoches, Louisiana, 1965*

On 4 March 1965, an explosion occurred on a 24 in. high-pressure natural gas pipeline at Natchitoches, Louisiana. The explosion was apparently caused by the high-pressure gas, there being no evidence of combustion in the pipeline. The splitting action of the pipe propagated the rupture for 27 ft along the pipe. The resultant blowout produced a crater 27 ft long, 20 ft wide and 10 ft deep. Three pieces of metal with a total weight of half a ton were hurled distances of 129–351 ft from the point of rupture. Within 60 s there followed an explosion that 'incinerated' an area of 13.8 acres. Seventeen people were killed.

FPC (1966); D.J. Lewis (1980)

A38 *Feyzin, France, 1966*

On 4 January 1966 at Feyzin refinery in France a leak on a propane storage sphere ignited, caused a fire that burned fiercely around the vessel and led to a BLEVE.

The operator had opened two valves in series on the bottom of the sphere in order to drain off an aqueous layer. When this operation was nearly complete, he closed the upper valve and then cracked it open again. There was no flow and he opened the valve further. The blockage, which was presumably hydrate or ice, cleared, and propane gushed out, but the operator was unable to close the upper valve. He did not think at once to close the lower valve and by the time he attempted this, this valve also was frozen open.

The alarm was raised and steps were taken to stop traffic on the nearby motorway. A vapour cloud about 1 m deep spread towards the road. It is believed that a car about 160 m distant on the motorway may have been the source of ignition. It was afterwards found that its engine was not running but its ignition was on and it may have been stalled by taking in a propane-rich mixture at the air intake. Flames appeared to flash back from the car to the sphere in a series of jumps.

The sphere was enveloped in a fierce fire. Its pressure relief valve lifted and the escaping vapour ignited.

The LPG storage installation of which the sphere was a part consisted of four 1200 m^3 propane and four 2000 m^3 butane spheres. The fire brigade was not experienced in refinery fires and apparently did not cool the burning sphere, presumably on the assumption that the relief valve would protect it. They concentrated instead on cooling the other spheres. About one and a half hours after the initial leakage the sphere ruptured, killing the men nearby. A wave of liquid propane was flung over the compound wall and flying fragments cut off the legs of the next sphere, which toppled so that its relief valve began to emit liquid.

The fire at the storage spheres is shown in Figure A1.7. Plate 32 shows a sphere, toppled and engulfed in flames. Figure A1.8 shows an outline in the ground of one of the victims.

The accident killed 18 people and injured another 81 and caused the destruction of five of the spheres as well as other damage.

Anon. (1966e,g,h); Kletz (1974e, 1975d, 1977d); Anon. (1987 LPB 77, p. 1); Selway (1988 SRD R492); Mahoney (1990); D.J. Lewis (1993)

A39 *LaSalle, Canada, 1966*

On 13 October 1966 at a plant at LaSalle, Canada, there was a runaway reaction in a styrene polymerization reactor. The bursting disc and dump line both operated, discharging material into the outside yard, creating a vapour cloud. A vapour fog also formed inside the building due to failure of a sight glass on the bursting disc vent. Ignition occurred and the vapour inside and outside the building exploded. It has been estimated that the release of styrene was 0.64 te and that the TNT equivalent of the explosion was 6.6 te. Eleven persons died.

Fire Journal Staff (1967, 1973d); D.J. Lewis (1980, 1993)

A40 *Lake Charles, Louisiana, 1967*

Just before dawn at 4.45 a.m. on 8 August 1976, a catastrophic explosion of a cloud of isobutane vapour occurred at the Cities Service refinery at Lake Charles, Louisiana. Seven people were killed and 13 injured and extensive damage was done.

The escape occurred at a valve on a 10 in. isobutane pipeline, which ran between an alkylation unit and two storage spheres. The pipeline ran underground, but the valve was located in an open pit, which had filled with water from recent rain. The bolts on the valve bonnet had suffered severe corrosion by vapours from a leaking sulfuric acid pipeline nearby.

That morning operators observed bubbles in the water and realized that there was a leak on the valve. An operator cleared the isobutane by flushing it with 110 psi water from the alkylation unit to sphere No. 1. He then closed the inlet valve on that sphere and began to open that on sphere No. 2. At this point the weakened valve in the pit failed and a geyser of water rose in the air. The operator, thinking that he had made an error, reversed his procedure, closing the valve on sphere No. 2 and opening that on sphere No. 1. As a result, isobutane from sphere No. 1 passed down the pipe and issued from the failed valve.

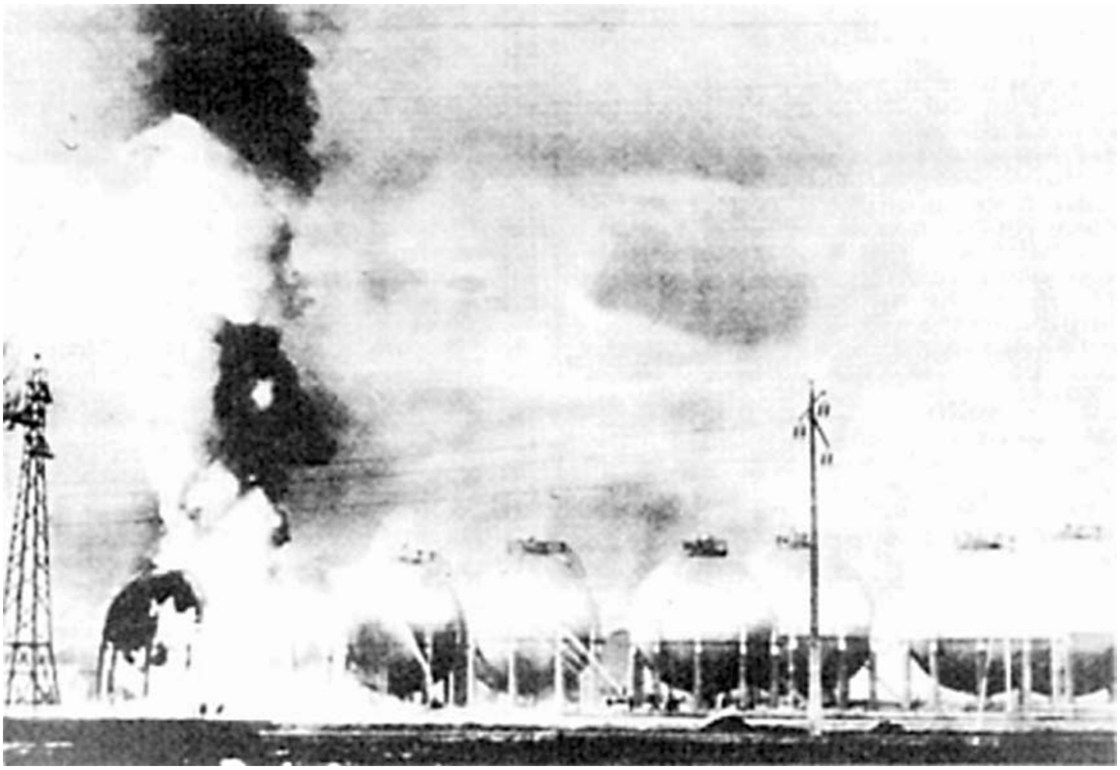

Figure A1.7 Feyzin, 1996: fire at the storage vessels (United Press International)

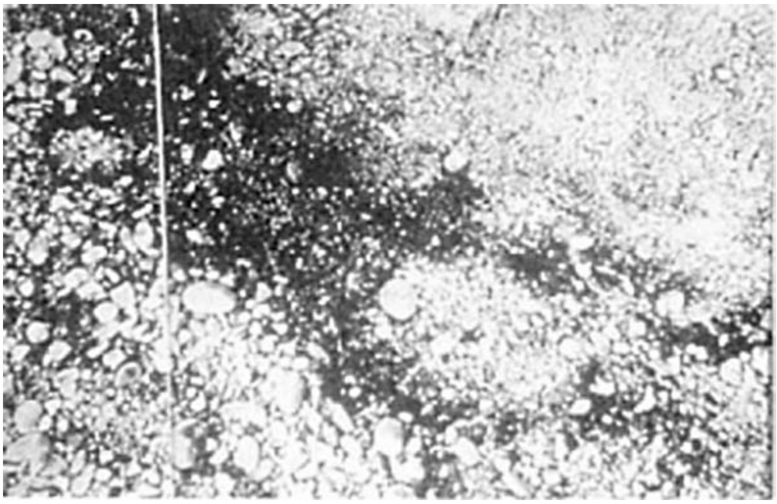

Figure A1.8 Feyzin, 1996: 'shadow' of one of the victims (Courtesy of Compagnie General of Edition et de Presse)z

The amount of isobutane which escaped was estimated as approximately 500 bbl. It formed a vapour cloud, which covered about 5 acres. The explosion had the characteristics of a detonation. Calculations indicated that it was equivalent to 10–12 tons of TNT.

The explosion caused a major fire, which burned for two weeks until the flammable material had been used up.

Goforth (1970); NFPA (1973); Vervalin (1973e); D.J. Lewis (1980, 1993)

A41 *Pernis, The Netherlands, 1968*
At 4.15 a.m. on 20 January 1968 an overflow was observed on slops tank 402 at the Shell refinery at Pernis. A hydrocarbon vapour cloud formed slowly over the adjacent area. At 4.23 a.m., after one or two smaller explosions, a violent explosion occurred which caused extensive blast damage and a large fire. The explosion was estimated to have been equivalent to 20 tons of TNT. The fire covered an area of about 250 × 300 m. Two people were killed and 85 were injured, mainly by flying glass.

Slops tank 402 was a 1633 m^3 cone roof tank. Owing to cold weather during the previous two weeks, it had been necessary to heat the oil in the tank. It is believed that a layer of water-in-oil emulsion had built up, covering the coils and reducing the heat transfer from them to the oil layer above, so that a substantial temperature difference had developed between the two layers, and that vapour formation at the interface between the two layers initiated mixing, causing further vapour evolution so that the tank overflowed, the hydrostatic pressure at the bottom of the tank was reduced and violent boil-up occurred, giving the condition known as 'stopover'.

A42 *Dudgeons Wharf, London, 1969*
In 1969, an explosion occurred at Dudgeon's Wharf, London, while an oil storage tank was being demolished. Six people were killed.

Anon. (1970a)

A43 *Glendora, Mississippi, 1969*
At about 2.45 p.m. on 11 September 1969, a train entered Black Bayou junction near Glendora, Mississippi, pulling 157 rail cars, including eight containing vinyl chloride monomer (VCM). A pedestrian was struck and injured, and application of the emergency brake caused a derailment of 15 cars.

At 3.30 p.m. the VCM manufacturer was informed that his chemical was involved and at 5.00 p.m. that the eight cars were derailed and that one was leaking. A technical expert was requested and the manufacturer sent the VCM plant superintendent, who had 25 years' experience with the chemical.

At about 8.00 p.m. one of the VCM tanks was ruptured and leaking, and by 10.00 p.m. the leak had ignited. A heavy fog was noticed over the area and it was considered that it might be VCM. The railway management consulted the *Handbook of Hazardous Materials*, which stated that phosgene could be formed in VCM fires. They rang the company office, who advised that a hazard from phosgene was highly improbable and that the main problem was likely to be from HCl and smoke. Nevertheless, the railway management, the police, the National Guard and the Civil Defence Authorities continued to be worried by the phosgene hazard. The Civil Defense director consulted university chemists, who advised that burning VCM would release phosgene, which could be a hazard to life at a radius of 35 miles. Accordingly, the police and National Guard evacuated all the towns nearby. The evacuation was reported as involving some 30,000 people.

At 6.45 a.m. the next day an explosion occurred which demolished one of the eight VCM tank cars. The explosion caused a second tank car to rupture and ignite. After the fires were extinguished only five full tank cars were recovered.

A report in The Commercial Appeal of Memphis, Tennessee (13 September, 1969) read Mississippi. There was a explosion followed by a further explosion and fireball. The next 40 min were punctuated by more explosions as one car after another burst or rocketed. The initial fireball set fire to buildings 200–400 ft away. Other fires were initiated by burning fragments up to 10 blocks distant. The blast caused structural damage within about 400 ft. Very little glass survived within about half a mile and windows broke as far out as 3 miles. Two people died and 976 were injured.

Much of the damage was caused by the impact of rocketing tank cars and the fires which they set going. One 37 ft section travelled through the air and bounced first at 1000 ft distance, then bounced again at 300 ft, and again at 200 ft, and finally went another 100 ft, before coming to rest at a total distance of 1600 ft, where it set fire to houses.

At the first explosion people came out to see what was happening. The streets were full when the second explosion and fireball occurred. People became trapped between fences which ran parallel to the track and the towering fireball 200–400 ft away. There were many burn injuries, and many also from panic.

It is of interest that a National Guard ordnance team, in a controversial procedure, successfully used shaped explosive charges to blow holes in two unruptured tank cars to prevent them exploding.

NTSB (1969 MR); Eisenberg, Lynch and Breeding (1975)

A45 *Texas City, Texas, 1969*
On 23 October 1969 at Texas City, Texas, an explosion occurred inside a distillation column of a butadiene unit. The explosion was experienced as a two-part one, first the disintegration of the column and then ignition of the escaping gas. Numerous fragments fell within a radius of 500 ft, some large shell fragments travelled 1500 ft and one 800 lb section fetched up 3000 ft away. All five columns in the butadiene section were toppled or severely damaged. Thirteen people were injured.

The column had been under total reflux. A leak occurred in an overhead line valve so that butadiene was lost and a build-up occurred of vinyl acetylene which on some trays reached a molar concentration of 50–60%. The internal explosion occurred due to thermal decomposition of vinyl acetylene and ethyl acetylenes.

A46 *Beaumont, Texas, 1970*
On 17 September 1970 at Beaumont, Texas, a 60 ft×40 ft oil slops tank was struck by lightning. The tank failed at the shell-floor seam, releasing 11,000 USgal of oil, which burned. The oil spread to involve in the fire another 16 unbunded tanks nearby.

Mahoney (1990)

A47 *Blair, Nebraska, 1970*
On 16 November 1970, an overflow occurred on a 40,000 ton refrigerated anhydrous ammonia storage tank at the Gulf Oil Company's installation at Blair, Nebraska. 160 ton of ammonia was released, but there were no deaths or serious injuries.

The overfilling was the result of an operator error. A factor which may have contributed to the error was the fact that the table of tank levels, or 'strapping table', did not indicate clearly the position of the overflow pipe. In addition, the high-level alarm and shut-down system failed to operate and apparently the overflow discharge valve also failed to operate at the set pressure, so that the liquid level in the tank rose until it reached the roof, at which point the overflow valve did open. There was an isolation valve on the overflow line directly below the relief valve. It was not possible to reach this valve and close it on account of the ammonia cloud. If isolation of the overflow line had been possible, much of the overflow could have been prevented. Once the overflow valve had opened, there was a discharge of ammonia to atmosphere. The discharge continued for 2.5 h.

There was almost no wind and an atmospheric inversion existed, so that initially the weather conditions were at their most unfavourable for dispersion. A low visible cloud of ammonia formed some 8–30 ft thick, covering approximately 900 acres and extending over 9000 ft from the tank. The ammonia cloud shortly after the spill is shown in Figure A1.9. The 'pancake' shape of the cloud is clearly shown in Figure A1.9(c). Later, a light breeze arose and helped to keep the cloud from populated areas.

A48 *Brooklyn, New York, 1970*

On 30 May 1970 a road tanker carrying liquid oxygen was manoeuvring in the yard of a hospital in Brooklyn, New York, when the tank ruptured violently. The tank was 9.15 m^3 capacity but the tanker had just offloaded its first part load. The initial explosion killed the driver and one other person, and windows were broken some 600 ft away. The release of the liquid oxygen resulted in a number of fires. In addition to the two deaths mentioned, 30 people were injured.

The tank was new and had been in service only one month. The investigation found that the $^{3}/_{4}$ in thick aluminium tank shell had suffered appreciable loss of metal, the deficit being 73.5 kg for the shell and internal components. It further found that a chemical reaction had occurred between the oxygen and deposits left in a crevice between a bracket and the tank wall, and that this had generated enough heat to initiate an oxidizing reaction between the shell and the oxygen vapour. This reaction also had the effect of heating the contents and increasing the vapour pressure. The estimated vapour pressure attained was over 100 bar compared with a design pressure of 15 bar.

NTSB (1971 HAR-71-06); D.J. Lewis (1993)

A49 *Corpus Ckristi, Texas, 1970*

On 3 August 1970 a refinery at Corpus Christi was hit by Hurricane Celia with winds of 140–160 miles/h and a rainfall of 6–8 in. The main structure of the catalytic cracker was toppled and some 30 tanks were destroyed.

Mahoney (1990)

A50 *Crescent City, Illinois, 1970*

At 6.30 a.m. on 21 June 1970 a derailment occurred on a railway passing through the streets of Crescent City, Illinois. Nine rail tank cars loaded with LPG were among the derailed vehicles. The force of the derailment propelled the 27th car in the train over the derailed cars on front and its coupler struck the tank of the 26th car and punctured it. Propane was released and ignited.

The safety valves of the other tank cars operated and released propane, which fed the fire. At about 7.33 a.m. the 27th car exploded. Four fragments of the tank car were hurled in different directions for distances of 300, 600 and 750 ft. At about 9.40 a.m. the 28th tank car exploded, hurling one fragment which eventually stopped rolling at a distance of 1600 ft. At about 9.45 a.m. the 30th tank car exploded and at about 10.55 a.m. the 32nd and 33rd tank cars ruptured almost simultaneously. Fragments from these damaged the 34th and 35th tank cars and caused them to release propane.

The main mechanism of damage in this incident was the rocketing of burning tank cars which hurled massive fragments and fresh fireballs up to 850 ft from the site of the derailment.

The fireball produced by the contents of one of these tank cars, which contained 33,000 USgal (120 m^3) of LPG, is shown in Figure A1.10. The fireball was several hundred feet high.

There were no fatalities, but 66 people were injured. There was extensive property damage.

Watrous (1970); NTSB (1972 RAR-72-02); Strehlow (1973b); Eisenberg, Lynch and Breeding (1975); D.J. Lewis (1980, 1991 LPB 101, 1993).

A51 *Linden, New Jersey, 1970*

On 5 December 1970 in a refinery at Linden, New Jersey, local overheating in a hydrocracker unit caused an explosive failure of the 7 in. thick vessel. Severe damage was done to plant over a 300 yard radius, including a catalytic cracker and crude pipe still, where the control room roof collapsed. Shut-down of the other units was effected from a blast resistant control room, which suffered minor damage. Forty persons were injured.

Mahoney (1990)

A52 *Port Hudson, Missouri, 1970*

At 10.07 p.m. on 9 December 1970, an abnormality occurred at a pumping station at Villa Ridge, 15 miles downstream from Port Hudson, Franklin County, Missouri. At 10.20 p.m. there was a sudden increase in throughput at the next upstream pumping station at Rosebud, indicating a major line break. The pipeline failure had occurred near Highway C on high ground and the gas cloud flowed down a sparsely inhabited valley.

At approximately 10.25 p.m. several witnesses became aware of the noise of the escaping jet of propane. A plume of white spray, which was presumably drops of propane and of atmospheric moisture, was seen rising 50–80 ft above

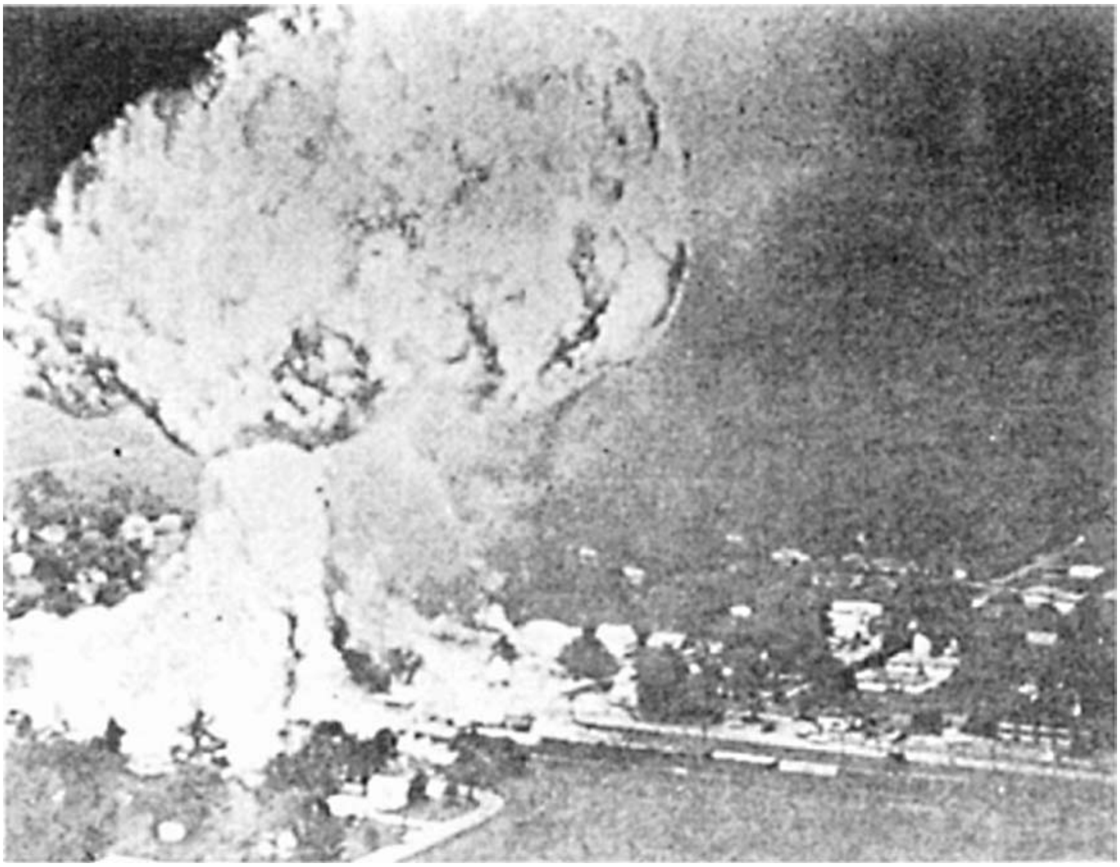

Figure A1.10 *Crescent City, 1970: fireball from rail tank car (Courtesy of Champaign Fire Department)* the ground. By 10.44 p.m. several families had evacuated their houses and had driven to Highway C, from which they observed the cloud.

At approximately 10.44 p.m. the valley appeared to light up. Witnesses reported no observable period of flame propagation but rather a sudden flash as of lightning. There was an almost immediate overpressure which knocked over one person who was walking about half a mile from the centre of the cloud.

In the Bureau of Mines report on the incident, Burgess and Zabetakis (1973 BM RI 7752) state: We think the witnesses has the unusual experience of observing a gas detonation'. In the succeeding seconds a fire storm was seen to roll up the sloping terrain towards Highway C.

At the time and place of the failure the pipeline pressure was believed to be about 942 psig. The amount of liquid propane which is estimated to have escaped in the first 24 min is 750 bbl.

Burgess and Zabetakis estimate that since the propane issued from the pipe at approximately 1°C, the fraction flashing off would be about a quarter, but that a further appreciable fraction formed drops in the 50–80 ft plume seen by witnesses and that these drops derived their heat of vaporization from the air.

For the estimation of the concentration of propane in the vapour cloud Burgess and Zabetakis use the Pasquill–Gifford model, their work antedating the development of models for heavy gas dispersion and for complex terrain. Thus

$$\chi = \chi_{\mathrm{c1}} \exp\left\{-\frac{1}{2}\left[\left(\frac{y}{\sigma_y}\right)^2 + \left(\frac{z}{\sigma_z}\right)^2\right]\right\} \qquad \text{[A1.10.1]}$$

with

$$\chi_{\mathrm{c1}} = \frac{Q}{\pi \sigma_y \sigma_z u} \qquad \text{[A1.10.2]}$$

where x, y, z are the downwind, crosswind and vertical distances (ft); Q is the flow rate of propane (ft^3/s); u the average wind velocity (ft/s); σ_y, σ_z are the standard deviations in the y, z directions (ft); χ is the concentration of propane (volume fraction); and χ_{cl} is the concentration of propane on the centre line (volume fraction).

The calculation given by Burgess and Zabetakis may be summarized as follows. The flow rate Q of propane is 900 ft^3/s at STP, the wind velocity is 8 ft/s and the stability category may be taken as category F in the nomenclature of D.B. Turner (1970). The plume dispersion coefficients σ_y and σ_z are obtained from the graphs given by this author. The lower and upper detonability limits of propane in air given by Benedick, Kennedy and Morosin (1970) are 2.8% and 7.0%, respectively.

The dimensions of the detonable plume thus calculated are shown in Table A1.3 and in Figure A1.11. The total volume of the detonable zone is estimated to be 1,100,000 ft^3. Assuming that the average mixture strength is 4.9%, the volume of propane in the detonable zone is 54,000 ft^3, which is approximately 4.2% of the total quantity released up to the time of ignition. About the same amount of propane is contained in the over-rich part of the cloud. Thus most of the propane is dispersed beyond the lean limit contour.

The mass of gas in 1,100,000 ft^3 of 4.9% propane–air mixture at a temperature somewhat less than ambient is about 100,000 lb. The enthalpy release on detonation is 260 kcal/vapour. This compares with approximately 500 kcal/vapour for TNT. The TNT equivalent of detonable gas is therefore approximately 50,000 vapour.

Burgess and Zabetakis also present a second calculation which attempts to take better account of the heavier-than-air density of propane–air mixtures and uses the following relations given by Singer and Smith (1953) for gustiness category D:

$$\sigma_y = 0.44_x{}^{0.71} \qquad \text{[A1.10.3]}$$

$$\sigma_z = 0.2\sigma_y \qquad \text{[A1.10.4]}$$

This calculation gives the volume of the detonateable zone as 1,500,000 ft^3.

Burgess and Zabetakis give an analysis of the blast damage data in both the near and far fields of the explosion. Estimates of the TNT equivalent of the explosion range, with one exception, from 97,000 to 150,000 lb in the near field, while an estimate in the far field is 98,000 lb. This compares with estimates in the range 50,000–75,000 lb of TNT equivalent inferred from the volume of the detonable cloud.

The efficiency of explosion is calculated by Burgess and Zabetakis as follows. If the 750 bbl. of propane which are estimated to have escaped had detonated as a homogenous stoichiometric mixture with air, the enthalpy release would have been 666×10^6 kcal. The enthalpy of detonation of TNT is 10^6 kcal/ton. The explosion was equivalent to some

Table A1.3 *Calculated dimensions of detonable plume of propane formed at Port Hudson, Missouri, on 9 December 1970 (after Burgess and Zabetakis, 1973 BM PI 7752) (Reproduced by permission of the Bureau of Mines)*

50 ton of TNT. Thus the explosion gave 50/666 or 7.5% of the maximum theoretical yield, based on combustion of the whole cloud.

The source of ignition of the cloud is uncertain, but Burgess and Zabetakis conclude that it was probably located in one of a group of outbuildings enveloped in the cloud.

The explosion caused no deaths.

NTSB (1972 PAR-72-01); Burgess and Zabetakis (1973 BM RI 7752); Strehlow (1973b); Eisenberg, Lynch and Breeding (1975); D.J. Lewis (1980, 1993)

A53 *Houston, Texas, 1971*

At 1.44 p.m. on 19 October 1971, 20 freight cars were derailed at Mykawas Station, which is 10 miles south of the centre of Houston, Texas. Six of the tank cars contained VCM and two others butadiene and acetone. Two of the VCM tank cars punctured. An explosion and fire occurred while the crashed tank cars were still moving. The two punctured tank cars stopped in the burning area. At 2.30 p.m. there was a violent explosion when one of the tanks containing some 100,000 lb of VCM burst, hurling fragments and giving a large fireball. Further tank cars burst, feeding the fire and generating additional missiles.

One fireman was killed and some 50 people, many of them firemen, were injured. The area was sparsely built and populated and damage was slight.

NTSB (1972 RAR-72-06); Eisenberg, Lynch and Breeding (1975); D.J. Lewis (1980)

A54 *La Spezia, Italy, 1971*

On 21 August 1971, a rollover occurred in an LNG tank at the SNAM LNG terminal at La Spezia, Italy. There was a sudden increase in pressure resulting in discharges from the tank safety valves and vent. The safety valves discharged for about 75 min and the vent discharged at a high rate for 3 h and 15 min.

The incident occurred 18 h after the tank had been loaded from the Esso Brega. The loading had been done through a nozzle at the side of the bottom of the tank, with the heavier, hotter cargo staying on the bottom and displacing the lighter, colder ‘heel’ of LNG, which had remained in the tank. These conditions were temporarily stable, but over the subsequent period the density of the upper layer increased and that of the lower layer decreased, eventually inducing the rollover. One factor was that the temperature difference between the two layers caused the upper layer to heat up and to become more dense due to boil-off of the lighter fractions. Another factor was a failure of the control valve some 4 h before the rollover, which caused a reduction in the pressure in the tank which in turn increased the boil-off.

Sarsten (1972)

A55 *Long-view, Texas, 1971*

On 25 February 1971, a $\frac{1}{2}$ in. high-pressure ethylene gas pipe broke in a plant near Longview, Texas, and released 1000 lb of ethylene. The vapour cloud found a source of ignition and exploded. The explosion broke numerous other pipes and caused the release of tonnage quantities of ethylene. The resultant larger vapour cloud in turn was ignited and gave a violent explosion.

Four people were killed and 60 were treated in hospital.

Detailed information on the blast damage is given by Eisenberg, Lynch and Breeding (1975).

Eisenberg, Lynch and Breeding (1975); Lauderback (1975); D.J. Lewis (1980)

A56 *Pensacola, Florida, 1971*

On 11 September 1971, a pipe ruptured on a caprolactam plant at Pensacola, Florida, and released about 74,000 lb of cyclohexane at high pressure and temperature. A dense white cloud of cyclohexane vapour and mist formed which was estimated at over 100 ft high and about 2000 ft across at its maximum. The wind was very calm, but picked up slightly after the rupture.

The cloud was rich enough to stall two trucks enveloped in it from lack of oxygen. Vapour from the cloud was drawn into a powerhouse furnace so that the stack emitted black smoke. However, the cloud did not ignite and eventually dissipated harmlessly.

A57 *East St Louis, Illinois, 1972*
At about 6.20 a.m. on 22 January 1972, a rail tank car loaded with propylene collided with a stationary hopper car in the Alton and Southern Railway Company's Gateway yard at East St Louis, Illinois.

The tank car had come from the hump classification yard at overspeed. The overriding coupler of the hopper car punctured the tank, the propylene escaped and formed a large vapour cloud which then ignited and exploded.

More than 230 people were injured and extensive damage was done.

The NTSB investigation (1973 RAR-73-01) concluded that the accident was probably caused by the failure of the retarding system in the hump classification yard to decelerate effectively heavy tank cars with oil or grease on their wheel rims, by the absence of a backup system to halt cars passing through the retarders at overspeed and by the routine acceptance of such overspeeds.

NTSB (1973 RAR-73-01); Strehlow (1973a); Eisenberg, Lynch and Breeding (1975); D.J. Lewis (1980)

A58 *Hearne, Texas, 1972*
At 12.30 a.m. on 14 May 1972, a rupture occurred on an 8 in. crude oil pipeline near Hearne, Texas. Crude oil sprayed into the air from a 6 in. split in the top of the pipe, showering the surrounding countryside with oil. The oil flowed along a stream beneath a railway and a highway, and collected in a stock pond 1800 ft from the break.

At 5.00 a.m. the crude oil was ignited by an unknown source. The resultant explosion and fire killed a man and seriously burned two other people. An intense fire several hundred feet high and 1800 ft long burned on the surface of the oil and along the stream, at the railway, the road and the stock pond, and scorched the whole area.

The quantity of oil which escaped and burned was 7913 bbl (332,346 USgal). Some 10% of the oil was fractions lighter than hexane. The mode of break was such as to encourage the separation of these light hydrocarbon fractions and the formation of a flammable gas cloud.

NTSB (1973 PAR-73-02); Eisenberg, Lynch and Breeding (1975)

A59 *Lynchburg, Virginia, 1972*
On 9 March 1972 at Lynchburg, Virginia, a tractor semi-trailer tank truck carrying LPG overturned and punctured. A 32 in. hole appeared and some 4000 of the load of 9208 USgal escaped before the liquid level fell below the hole. A vapour cloud formed and gave rise to a fireball. The radius of the fireball was estimated as at least 400 ft. Three eyewitnesses standing beside their cars at 450 ft distance were severely burned by thermal radiation but were not touched by the flames. Two persons died and at least five were injured.

NTSB (1973 HAR-73-03); Eisenberg, Lynch and Breeding (1975)

A60 *New Jersey, Turnpike, 1972*
On 21 September 1972 on the New Jersey, Turnpike, a tractor semitrailer tank truck carrying 7209 USgal of propylene sideswiped a bus. The tractor's fuel tank and the fittings on the propylene tank were damaged and fuel and propylene leaks occurred. A friction spark from the collision ignited the fuel leak and the fire spread to the propylene leak. After some 20–25 min the tank exploded with a huge fireball. Fragments of the tank rocketed: the front section, comprising three-quarters of the tank, was found 1307 ft to the north-east; the rear head was found 540 ft to the south-west and the rear one quarter cylindrical section 229 ft to the south-west; tank components were mainly strung out in a line stretching 850 ft to the south-east. Two persons were killed and 28 injured.

NTSB (1973 HAR-73-04); Eisenberg, Lynch and Breeding (1975)

A61 *Rio de Janeiro, Brazil, 1972*
On 30 March 1972, a BLEVE occurred on an LPG sphere, one of five, at the Duque de Caxais refinery, Rio de Janeiro, Brazil. An operator was engaged in draining water from the bottom of a 1600 m^3 sphere. He went away, leaving open a 2 in. drain valve. When he returned, he found that he could not reach the valve to turn the flow off, because the jet of liquid, now LPG, had created a crater in the crushed stone under the sphere. A vapour cloud formed, ignited and flashed back to the sphere. Some 15–20 min later the relief valve opened and the material released ignited. The sphere then suffered a BLEVE. Thirty-seven people were killed and 53 injured. The other four storage spheres survived.

Mahoney (1990); Selway (1988 SRD R492)

A62 *Austin, Texas, 1973*
At 10.53 p.m. on 22 February 1973 at Austin, Texas a 10 in. pipeline failed and released 278,880 USgal of NGL. The release blew a 10 ft diameter hole in the ground and a vapour cloud spread over the area. Soon after 11.00 p.m. two cars entered the cloud and stalled; their drivers got out. Then a van drove into the cloud and also stalled; the passengers got out, whilst the driver tried to restart. A large spark emerged from beneath the van and flames leaped hundreds of feet in the air. The fire burned through the cloud and the eight people in it were engulfed in flames. Four died immediately, two later and two sustained severe burns.

NTSB (1973 PAR-73-04); Eisenberg, Lynch and Breeding (1975)

A63 *Kingman, Arizona, 1973*
On 5 July 1973, a BLEVE and fireball occurred on a rail tank car containing propane at Kingman, Arizona. The upper surface of the tank had been heated by jet flames from a relief valve and coupling leak.

The event is captured in the NFPA film 'BLEVE' and has been analysed by Crawley (1982). The tank was a 'jumbo' one and he estimates that the tank capacity was 150 m^3 but assumes that it was perhaps half full. He assesses the diameter of the fireball as 400 ft and its duration as 10–15 s. The estimates given by V.C. Marshall (1987) are that some 45 te of propane took part and that the fireball radius was 150 m.

Despite police advice a large crowd of spectators had gathered and more than 90 were injured.

Crawley (1982); Hymes (1985 LPB 65); V.C. Marshall (1987)

A64 *McPherson, Kansas, 1973*
At 4.30 a.m. on 6 December 1973, a major leak occurred on the Mid-America Pipeline System at the Conway pump station near McPherson, Kansas. Prior to the leak an ice storm had been raging for two days and the pump station had lost power for 18 h, although it was partially restored by 3.00 a.m. The pipeline had been shut-down and upon

start-up at 4.12 a.m. a block valve failed to open, the line was overpressured and burst at a point where it had already sustained construction damage.

An estimated 230 tons of anhydrous ammonia escaped over a period of half an hour. A low, visible plume of ammonia formed and drifted over Highway 56, which is some 1000 ft to the south. The weather conditions were very stable with a wind speed of some 5–10 mile/h and the plume remained narrow. Irritation symptoms were experienced and odour was detectable for about 3.5 and 8 miles from the escape, respectively.

The incident caused no serious casualties. Many residents had moved into a nearby town on account of power failures caused by the severe weather. Two truck drivers drove into the gas cloud on the highway. They escaped and were kept in hospital several days. People in dwellings $^3/_4$ mile south of the leak and directly in the cloud path were safely evacuated by the Sheriff's office and company personnel.

By 4.30 p.m. the line had been stopped.

The same pipeline failed again on 13 August 1979 at a point about 22 miles from the first failure. There was a release of some 360 tons of anhydrous ammonia. Again there were no casualties, but there was a large fish kill.

NTSB (1974 PAR-74-06); Luddeke (1975)

A65 *Potchefstroom, South Africa, 1973*

At 4.15 p.m. on 13 July 1973, a sudden failure occurred in an anhydrous ammonia storage vessel at the Potchefstroom works of TRIOMF, a company part-owned by African Explosives and Chemical Industries Ltd. The tank was one of four 50 ton horizontal pressure storage bullets. An estimated 30 tons of ammonia escaped from the tank itself and another 8 tons from a tank car.

The failure gave rise immediately to a gas cloud some 150 m diameter and 20 m deep. At the time of the accident the air was apparently still, but within a few minutes a slight breeze arose which caused the cloud to move towards a township some 200 m to the north-east. The visible cloud then extended some 450 m downwind and 300 m across.

Deaths occurred both inside and outside the factory fence. At the time there were some 350 persons working in the plant, of whom some 30 were within 70 m of the failed tank. One employee was killed by the blast and eight died while trying to escape from points within a 100 m radius of the tank. Three others died of gassing within a few days.

Outside the factory fence four people were killed immediately and two died a few days later. Thus altogether 18 people were killed.

The occupants of the granulation plant control room 80 m south-east of the failure survived. They put wet cloths over their faces and were taken to safety after some 30 min.

The failures occurred in tank No. 3 while it and tank No. 4 were being filled simultaneously from a tank car. Actuation of an excess flow valve on the line between the two tanks prevented the release of the contents of tank No. 4 also. The tank car did not have an excess flow valve and did suffer escape of material.

The cause of the failure was brittle fracture of the dished end of the tank. Evidence suggested that there had been no overpressure or overtemperature of the tank contents and no other triggering event was determined.

The tanks were designed and fabricated in accordance with BS 1515: 1965 and were fabricated and commissioned in 1967. The fabrication is described by Lonsdale (1975):

> The dished ends were fabricated from two plates, cold-formed in the major radius, and hot flanged (at 850°C) at the knuckle. The plates had been passed as being in accordance with the requirements of BS 1501-151-28A. The butt welds in the end plates were checked by 100% X-ray after forming and flanging. (Expert metallurgists re-examining the X-rays of the failed dished end considered that two sections of the weld did not conform to the requirements of the BS code.) The Inspection Authority representative considered that conditions in the flanging furnace rendered subsequent heat treatment unnecessary.
>
> The completed tank was not stress-relieved because it is not required by BS 1515. The tanks were given an hydraulic test at $1^1/_2$ times the design pressure of 250 lb/sq in gauge.

Late in 1971 tank No. 3 was inspected. Two weld faults and a crack were found and were ground out. The tank was hydraulically tested to 347 psig for 30 min. Following repairs to a leaking tank level glass isolation valve, the tank was hydraulically tested to 325 psig for 3–4 h.

Metallurgical testing revealed that the metal of the dished end was below its transition temperature under normal conditions. The minimum Charpy impact testing transition temperatures obtained were 20°C for the fragment and 115°C for the remaining part of the dished end.

Ultrasonic examination of the dished end in No. 4 tank revealed numerous subsurface fissures. Such fissures may have provided the notch from which the brittle fracture in No. 3 tank propagated. After this examination tank No. 4 was withdrawn from service.

Following the inquiry into this accident, the South African authorities laid down that 'All vessels containing dangerous substances shall be given appropriate heat treatment irrespective of the (construction) code requirements.'

Commenting on this Lonsdale states

> Stress-relieving does not overcome fully the damage done by progressive cold-forming of a dished end. This is particularly so where seam welds have had to be made in the dished end. There is a strong case for avoiding the use of progressively cold-formed ends for pressure vessels because of the difficulty of controlling the final state of the metal.

Lonsdale (1975); D.J. Lewis (1993)

A66 *St Amand-les-Eaux, France, 1973*

On 1 February 1973, a road tanker containing 19 tons of liquefied propane skidded and overturned on a wet road surface in the village of St Amand-les-Eaux. A rupture occurred on the tanker and propane began to escape. The driver of the tanker immediately took steps to stop traffic entering the street and to warn the population. The vapour cloud grew and finally exploded, causing 5 deaths and 40 injuries. The death toll might well have been higher but for the prompt action of the driver in carrying out his emergency procedures.

Anon. (1973j); D.J. Lewis (1980)

A67 *Staten Island, New York, 1973*

On 10 February 1973 at Staten Island, New York, an explosion occurred inside a large LNG storage tank in which work was being done. The tank was being repaired for a leak in the inner membrane lining and new liner sections were being installed. The tank had been well ventilated before work began. The source of fuel for the explosion was identified as LNG trapped in the insulation behind the liner and vaporized by the heat-sealing operations on the new liner sections. The explosion lifted up the concrete roof of the tank which then fell back into it, crushing the men there. Forty men were killed and three injured.

US Congress (1973); D.J. Lewis (1989, 1993)

A68 *Aberdeen, UK, 1974*

An incident which occurred at Aberdeen on 17 January 1974, is described by Willcock (1986) in the following terms:

> (1) Butane tanker skids on black ice. Shaken and lightly injured driver regains control and stops safely at nearside kerb; (2) Half an hour later articulated lorry skids on black ice, collides with tanker and shears off emergency discharge valve. Gas starts escaping. Second driver slightly injured; (3) Five minutes later yet another articulated lorry skids and crashes into the other two. One more hurt driver; (4) Police and fire brigade arrive a few minutes later, but before they can get organized a car, trying to stop at the accident, skids into the rear of the tanker. Impact ignites butane.
>
> Willcock (1986)

A69 *Chicago, Illinois, 1974*

Soon after 12.30 p.m. on Friday 26 April 1974 employees at the Bulk Terminals complex in the Calumet Harbor area on the south side of Chicago, Illinois, heard a dull thud and saw fumes rising from the dike of Tank 1502, which contained 3300 m^3 of silicon tetrachloride. Bulk Terminals was a storage tank farm with 78 tanks ranging up to 4900 m^3 in size, containing products such as vegetable oils and chemicals. It was situated in a built-up area.

This was the start of an incident which involved a massive cloud of irritant gas in a built-up area and was to prove very prolonged. At times the cloud was 8–16 km long. It took until May 3 to stop the leak and transfer the material and until May 15 before emissions were finally reduced to tolerable levels.

Investigation found that a pressure release valve on a 6 in. line leading to the tank had been inadvertently closed. A flexible coupling in the line burst under pressure. The whole piping system shifted, cracking a 3 in. line on the tank wall. Liquid silicon tetrachloride escaped, creating a cloud with formation of hydrogen chloride gas.

The initial emergency response was confused. The terminal management awaited action by the owners of the chemical. The fire service first decided not to get involved, because there was no fire. Lime trucks diverted to the scene by the EPA with a view to neutralizing the liquid in the dike were refused entry to the site.

By 3.00 p.m. the cloud was 400 m wide, 300–450 m high and 1600 m long.

Two agents were considered to blanket the liquid in the dike: non-protein high expansion foam and No. 6 fuel oil. At 4.10 a.m. on Saturday 27 April, foam was applied but was not effective. At about 9.00 a.m., fuel oil was added and eight truck loads of lime were tipped in. Within an hour the vaporization was dramatically reduced. By noon matters appeared to be under control with a 16-member US Army chemical warfare team involved in transferring the material from the damaged tank.

About 8.00 a.m. on Sunday 28 April, however, heavy rain began to fall on the hydrogen chloride cloud. Power lines were rapidly corroded and sparked like a firework display. By 9.30 a.m. four pumps had become inoperable due to corrosion. Then power failure put a stop to pumping.

The threat existed that the pipe system would suffer further failure and release the remaining 2300 m^3 of material into the dike, which had been reduced in capacity by the material added to it. A large pit was dug to take any overflow from the dike and an operation was undertaken to seal the leak using quick drying cement.

On the morning Monday 29 April inspection of the pipe system, undertaken in the cloud with a visibility of some 18 in., indicated that the leak had not been sealed, either because the application had been ineffective or because it had been made at the wrong point. A second concrete pour was undertaken and completed by 11.30 p.m.

By the morning of Tuesday 30 April the emission had been greatly reduced. It took, however, another three days to transfer the liquid out of the tank.

In this incident one person died, 160 were hospitalized and 16,000 were evacuated.

Hoyle (1982)

A70 *Climax, Texas, 1974*

On 29 June 1974 at Climax, Texas, a derailment occurred which resulted in the puncture of a rail tank car containing liquid vinyl chloride monomer. The hole in the end of the tank was 4 ft × 4 ft. The vinyl chloride escaped and formed a vapour cloud which travelled 1600 ft to the derailed locomotive, where it ignited. There followed a violent vapour cloud explosion. It was found that the cylinder head had been blown off the diesel engine, which fact led to the hypothesis that vinyl chloride had been ingested into the engine and that the engine explosion had been the trigger for the vapour cloud explosion. The contents of the ruptured tank car continued to burn after the explosion and a flame played on another vinyl chloride tank car which suffered a BLEVE. The explosions occurred in a rail cutting and there were no injuries.

Eisenberg, Lynch and Breeding (1975)

A71 *Decatur, Illinois, 1974*

On 19 July 1974, a vapour cloud exploded in the rail-shunting yard at Decatur, Illinois. During shunting operations, a rail tank car was punctured by the coupler of a boxcar into which it had run, the hole being some 0.3 m^2. The tank car contained 69 te of isobutane, which escaped and formed a vapour cloud. There was a delay of 8–10 min before the cloud ignited. There then occurred a massive vapour cloud explosion which caused extensive damage. Seven people were killed and 349 injured.

This vapour cloud explosion has been of some interest, because on the basis of the assessment of certain injury and damage effects, the yield of the explosion has been estimated as unusually, even anomalously, high. The matter has been considered by V.C. Marshall (1980d, 1987), who gives a detailed comparison between the explosions at Flixborough and at Decatur, and concludes that the latter was certainly no more severe than the former, that its yield has been overestimated and that it was in fact comparable to that in other vapour cloud explosions. He comments, however, that in a shunting yard the wagons serve to promote turbulence and provide on their undersides vertical confinement.

NTSB (1975 RAR-75-04); Eisenberg, Lynch and Breeding (1975); V.C. Marshall (1980d, 1987)

A72 *Los Angeles, California, 1974*

On Saturday 17 August 1974, an explosion occurred on a load of organic peroxides on a semitrailer in a storage shed at Los Angeles, California. The load was a mixed one of several different peroxides, totalling 5.3 te. It had been made up on the Friday, but the customer had declined delivery before the weekend, and the semitrailer was therefore parked in the storage shed until the Monday. On the Saturday smoke and flames were seen coming from the shed and shortly afterwards there was a tremendous explosion. The source of the fire is not known. There were no injuries.

Sharry (1975); D.J. Lewis (1993)

A73 *Petal City, Mississippi, 1974*

On 25 August 1974, a new salt dome storage was being filled with butane when a release occurred. The capacity of the storage had been miscalculated with the result that the head of the brine being displaced fell below that equivalent to the gas pressure and butane issued at high velocity. A quantity of butane estimated as 40–90 te escaped and formed a vapour cloud extending 2 km. The cloud ignited with a small explosion, there followed a second, stronger explosion and the cloud then burned for 5 h. It has been suggested that the initial combustion and associated thermals promoted air entrainment into the mainly over-rich cloud so as to create a large elevated flammable volume which then exploded. Twenty-four people were injured.

Anon. (1974n); D.J. Lewis (1993)

A74 *Antwerp, Belgium, 1975*

On 10 February 1975, an explosion and fire caused extensive damage at a low-density polyethylene plant at Antwerp, Belgium. The cause was a leak of ethylene at high pressure due to fatigue failure of a vent connection on the suction of a compressor. Six persons were killed and 13 injured.

Mahoney (1990)

A75 *Beek, The Netherlands, 1975*

On the early morning of 7 November 1975, the start up of Naphtha Cracker II on the 100,000 tons per annum ethylene plant at the Dutch State Mines (DSM) works at Beek was under way. At about 6.00 a.m., the compressed gas was sent to the low temperature system. At 9.48 a.m., an escape of vapour was observed near the depropanizer. Shortly after, the cloud formed found a source of ignition and there was a massive vapour cloud explosion.

The explosion caused extensive damage and started numerous fires. Fire broke out in the pipeline systems and Tank Farm 2. Six tanks ranging in capacity from 1500 to 6000 m^3 within a common dike were burned out. An aerial view of the plant after the explosion is shown in Figure A1.12.

The explosion killed 14 and injured 104 people inside the factory, and injured three persons outside it.

The accident was investigated by a team from the Ministry of Social Affairs. Their findings are given in the Report on the Explosion at DSM, Beek on November 1975 (the Beek Report) (Ministry of Social Affairs, 1976). The investigation involved TNO and the Department of Steam Engineering (Stoomwesen). A separate investigation was carried out by the company.

van Eijnatten, (1977)

The investigation was hampered by the destruction of the instrument records in the control room. Figure A1.13 shows the state of part of the control panel. A detailed breakdown of the degree of damage done to the instrumentation is given in the report. It was also difficult to obtain useful information from the instruments which were retrieved, due to lack of synchronization, use of wrong recorder charts, lack of ink, inconsistent colour codes and out-of-date instrument diagrams.

The evidence suggested that the escape occurred due to low temperature embrittlement at the depropanizer feed drum, on and around which five fractures were found. Three of these were identified as secondary ruptures, but there were two which could have been primary failures. Two hypotheses were put forward. The principal one considered by the government team was that the initial rupture occurred on a 40 mm pipe connecting the feed drum to its safety valve.

The function of the feed drum was to take the €3* stream from the bottom of the de-ethanizer and a stream from the condensate stripper and pass this mixed liquid and vapour feed to the depropanizer. If the depropanizer were fouled, the feed drum could give a rough cut between the C_3 fraction and the heavier liquids. The normal operating temperature of the drum was 65°C.

At the time of the start-up, the reboiler of the de-ethanizer column was not operating properly. Possibly the circulation of hydrocarbons through the reboiler was reduced by thickening of the liquid. In consequence, the bottom product from the de-ethanizer was a liquid at about 0°C or lower with a high C_2 content. Discharge of this de-ethanizer stream into the feed drum would give flashing and could result in a temperature as low as −10°C.

Coincidentally there was a half-hour interruption in the flow from the condensate stripper due to a failure in the propylene compressor system. As a result, a layer of liquid containing a large proportion of C_2s was deposited on top of a layer of warm C_3^+ liquid in the feed drum. From the evidence the two layers had not mixed to any appreciable extent and the top layer was at about −10°C.

The feed drum material was a carbon steel which can normally be used at temperatures as low as −10 to −20°C. The fracture occurred at an autogenic weld. With such welds ageing can occur which could raise the transition temperature possibly up to 0°C.

An alternative hypothesis which the government team considered was that the rupture had been caused by explosion of organic peroxides which might have been formed from material trapped in a section of flush pipe which was isolated and which was found to have ruptured.

The amount of flammable material which escaped prior to the explosion was estimated at about 5.5 tons of hydrocarbons, mainly propylene, There is some uncertainty, however, about this figure.

The best estimate of the cloud shape from the explosion damage is that shown in Figure A1.14. The location of the damage indicated that the depth of the cloud did not exceed 4 m.

The estimated time which elapsed between the rupture and the explosion is approximately 2 min. From eyewitness accounts the source of ignition was identified as the flash drums in Section 1.

The quantity of flammable material which exploded was estimated as about 800 kg of propylene with an energy release equivalent to 2.2 tons of TNT.

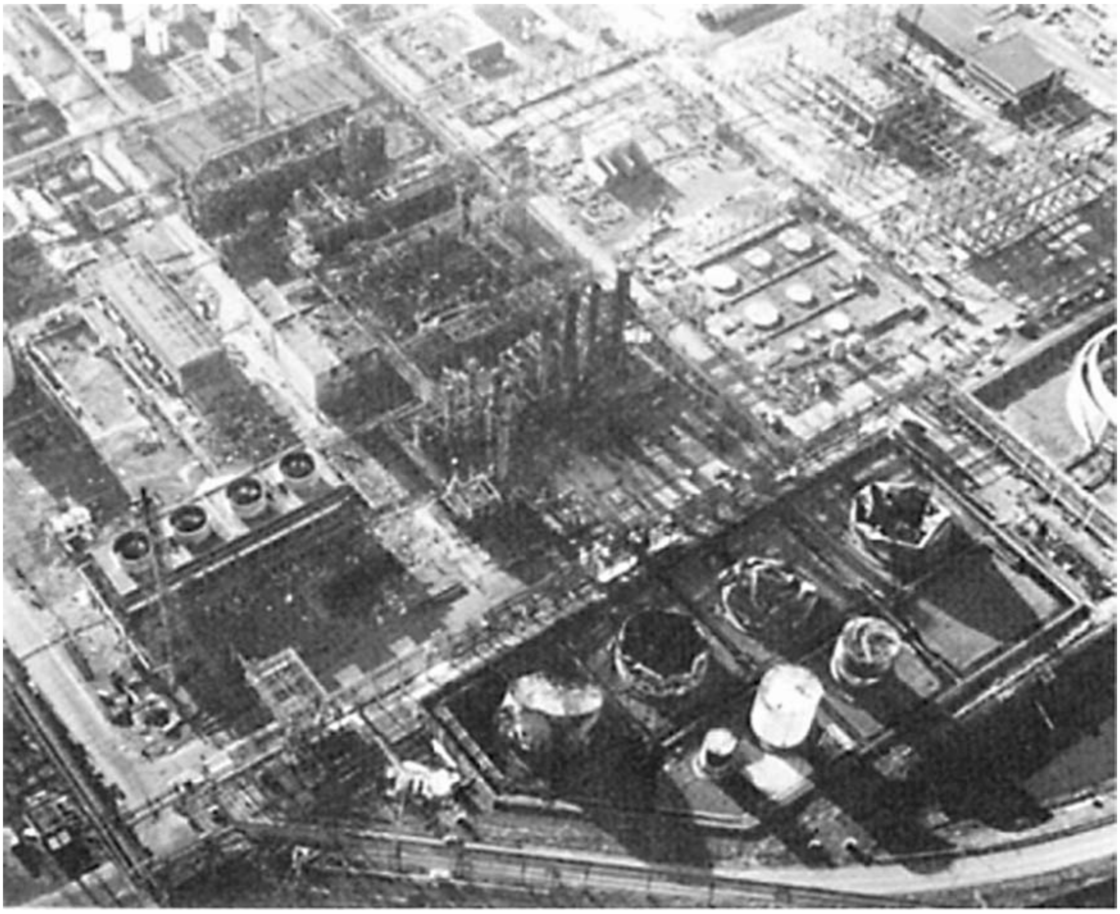

Figure A1.12 *Beek, 1975: DSM works after the explosion (Ministry of Social Affairs, 1976)*

From the damage to the control room it was calculated that an overpressure of 0.2–0.3 bar must have acted on the walls. But the estimated overpressure required to cause the damage to the cold blowdown drum was approximately 1 bar.

The damage outside the factory was entirely breakage of glass. The bulk of the damage was within a radius of 4.5 km. It was believed that the pressure at this distance might have been about 0.005 bar, which is sufficient to break thin glass. It was suggested that damage beyond this distance may have been due to the deflection of shock waves by reflecting layers in the upper atmosphere. Flying glass caused one of the three injuries outside the factory.

The incident illustrates the stress created by a developing emergency of this kind and the confusion liable to ensue. At about 9.35 a.m. the operators were engaged in dealing with start-up problems. One entered the control room and called out 'Something has gone on Cll and there's an enormous escape of gas'. He was distressed and was rubbing his eyes. He staggered against the telephone switchboard. A second operator ran to the entrance and tried to get out, but his view was obscured by a thick mist. He smelled the characteristic odour of C_3–C_4 hydrocarbons and realized there must be a major leak. He gave orders for the fire alarm to be sounded and ran out through another entrance to look at the gas cloud. He was seen from another office by a third man, apparently terrified and pointing to a gas cloud near the cooling plant.

Some witnesses stated that the fire alarm system in the control room failed. The investigation concluded, however, that the fire alarm system was in good working order before the explosion, but that none of the button switches for the fire alarm was operated.

Another aspect of the emergency was that the telephone lines to DSM were partially blocked by overloading. This did not affect rescue work, however, because the rescue services had their own channels of communication.

Ministry of Social Affairs (1976); van Eijnatten (1977); D.J. Lewis (1980, 1993)

A76 *Eagle Pass, Texas, 1975*

At 4.20 p.m. on 29 April a Surtigas tractor tank semi-trailer carrying LPG on US Route 277 near Eagle Pass, Texas, swerved to avoid a car in front which slowed suddenly to

Figure A1.13 *Seek, 1975: damage to instrumentation in the control room (Ministry of Social Affairs, 1976)*

make a turn. The tank semitrailer separated from the tractor, struck a concrete wall and ruptured, releasing LPG. Witnesses described a noise like that of a violent storm, followed immediately by an explosion. Simultaneously, fire covered the area and there was then a second explosion.

The large front section of the tank rocketed up, struck an elevated sign, travelled 1029 ft and struck the ground; bounced up and travelled 278 ft; struck and demolished a mobile home; bounced up again and travelled 347 ft over another mobile home, causing it to burst into flames and be destroyed; and finally fetched up 1654 ft from its starting point.

Sixteen people, including the driver, were killed and 512 suffered burns.

NTSB (1976 HAR-76-04)

A77 *Ilford, Essex, 1975*

At 11.10 a.m. on 5 April 1975, an explosion occurred at the factory of Laporte Industries Ltd at Ilford, Essex. The explosion was in a Lurgi electrolysis plant. The plant suffered extensive damage and one man who was injured subsequently died.

The electrolysis plant produced hydrogen for process use and oxygen as a waste product by electrolysis of potassium hydroxide solution. The investigation concluded that the explosion probably occurred on the oxygen separating drum into which hydrogen had leaked. After the accident the company carried out a mass balance on the hydrogen flows just prior to the explosion and found that no less than 50% was unaccounted for.

The ingress of hydrogen into the oxygen drum was apparently due to corrosion/erosion in the electrolysis cells. The internal breakdown of the cells had probably been initiated some time before the accident. On 2 April a cracking noise was heard in the cell block, which may have indicated minor explosions.

There was a system of monitoring the purity of the hydrogen and oxygen streams by hourly gas analyses performed by the process operator. The evidence suggested that these analyses were not always carried out and that assumed values were entered in the process log. One operator stated that he only did the analyses two or three times in every 12 h.

The report on the accident by the HSE (1976b) estimated that on the basis of the explosion damage the 1690 l oxygen drum contained a 13.5% hydrogen, 86.5% oxygen mixture and the explosion produced a shock wave equivalent to 22 kg of TNT. It was calculated that this explosion would have caused an overpressure of 1.03 kPa at 220 m and of 0.21 kPa at 660 m on an open site.

The most powerful explosion would have been produced by a stoichiometric mixture of 66 $\frac{2}{3}$% hydrogen, 33 $\frac{1}{3}$%

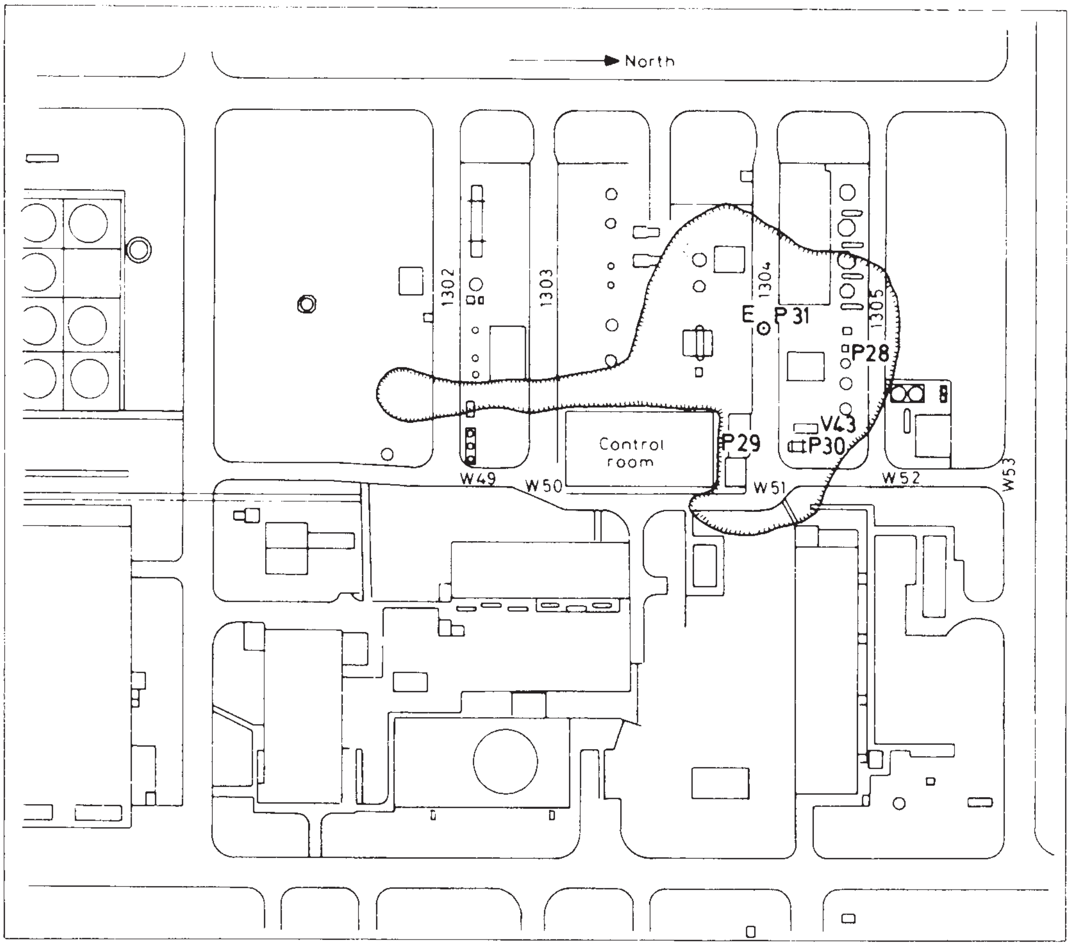

***Figure A1.14** Beek, 1975: simplified site plan of the works showing the estimated dimensions of the vapour cloud (Ministry of Social Affairs, 1976. Reproduced by permission)*

oxygen. Assuming a pressure equal to the set pressure of the relief valve on the drum, 515 psig, this composition would have produced a shock wave equivalent to 90 kg of TNT and this was calculated to cause an overpressure of 1 kPa at 350 m and 0.21 kPa at 1050 m.

The factory was in an urban area with houses 180 m and a school 210 m from the electrolysis plant. Although on an open site some damage might be expected from an explosion of the size described at these distances, none actually occurred. Probably this was due to the fact that the electrolysis plant was housed in a building designed and constructed to direct any blast upwards.

HSE (1976b)

A78 *Scunthorpe, Lincolnshire, 1975*

At about 1.25 a.m. on 4 November 1975 the Queen Victoria blast furnace at the Appleby Frodingham works of the British Steel Corporation (BSC) was tapped. By about 2.00 a.m. some 175 tons of iron had been run into the first torpedo ladle and the stream was diverted into the second ladle. Some 10–15 min later intense flames and sparks began to issue from the blow pipe on No. 3 tuyere. The furnace crew tried to keep the pipe cool by spraying it with water and took steps to bring the furnace off blast to allow a new pipe to be fitted. While this was going on, a substantial water leak was observed coming from the furnace, but its source could not be located because of the flames. The water ran down the casthouse floor and entered the full torpedo ladle.

Just before 2.47 a.m. the shift manager's instruction to remove the full ladle was passed on to the loco driver and shunter by traffic control. The traffic personnel were informed that water was running into the ladle. At 2.47 a.m. an explosion occurred as the ladle was moved.

Some 90 tons of metal were ejected. Four people were killed and 15 injured, and a further seven died later.

The energy of explosion was estimated from the structural damage as 2.5 MJ or the equivalent of 1 lb of high explosive. The energy required to eject the hot metal was estimated to have a maximum value of 12 MJ. The thermal energy in the hot metal was some 10,000 times greater than this.

Investigation revealed that the water leak was probably due to the failure by corrosion of a steel-blanking plug on a cooling water pipe. Such plugs had been in use for at least 20 years. It transpired that there was among the employees considerable collective experience of previous failures of blanking plugs, although in most cases the knowledge of individuals was limited.

HSE (1976a)

A79 *Baton Rouge, Louisiana, 1976*

On 10 December 1976, a massive chlorine release occurred from a storage vessel at Baton Rouge, Louisiana. The vessel was a horizontal bullet tank 125 ft long × 11 ft diameter resting on a load cell weighing system. An internal explosion caused the vessel to fall off its supports so that it was pierced by a metal upstand on the ground. Over a period of 5.6 h 90.7 te of chlorine was released. A gas cloud formed described as a 42 mile long wedge, lying over the Mississippi river and sparsely populated areas. Ten thousand people were evacuated. Three persons were treated for minor irritation.

The cause of the tank displacement was an internal explosion of a natural gas–chlorine mixture at one end of the vapour space in the half full tank which produced a liquid surge along the length of the tank so that the momentum of the liquid caused the tank to jump off its supports. The tank was normally padded with nitrogen. The same nitrogen system was connected to the gland seals of hydrogen compressors in order to exclude air from the hydrogen. There was in addition a natural gas system which could be used on the gland seal as a more economic alternative. Due to the cold weather trouble had been experienced with natural gas condensate and the nitrogen system was in use. At some stage the lines to the nitrogen and natural gas systems were open at the same time and natural gas at higher pressure got into the nitrogen system. When the plant was restarted, an explosion occurred in the chlorine liquefaction system. It then spread via a balance line to the vapour space of the chlorine tank.

Anon. (1976n); Rees (1982); D.J. Lewis (1984b, 1993)

A80 *Geismar, Louisiana, 1976*

On May 24 1976, an explosion occurred on a large polyglycol ether reactor. The cause is believed to have been loss of agitation possibly combined with failure of a temperature transmitter and/or addition of insufficient catalyst. The explosion hurled the reactor head some 1400 ft and fragments ruptured a large polyglycol ether tank and severed the sprinkler system riser. Unreacted ethylene oxide and propylene oxide and other reactor contents escaped and there was a major fire involving the reactor and tank farm areas.

Mahoney (1990)

A81 *Kings Lynn, Norfolk, 1976*

At approximately 5.10 p.m. on Sunday 27 June 1976, an explosion occurred on the Clopidol plant of the Dow Chemical Company at King's Lynn, Norfolk. One man was killed and extensive damage was done to the plant and the buildings. The explosion involved the detonation of Zoalene, a poultry feed additive.

Some months before it has been discovered that stocks of Zoalene had fallen below their normal level of purity and it was decided to remove water, one of the main impurities, by drying the material in a drier on the Clopidol plant.

The drier was provided with dust explosion protection, including nitrogen inerting, explosion suppression devices and explosion relief.

On 25 June at 3.00 p.m. a batch of Zoalene was charged to the drier. At 2.00 p.m. on 26 June the steam to the drier was shut off. The material was left in the drier, however, at a temperature of approximately 120–130°C. At 5.07 p.m. the following day sound was heard coming from the drier and the shift foreman activated the emergency procedures. At 5.10 p.m. the explosion occurred.

Zoalene was known to be a reactive chemical, but, as the incident showed, the hazard of a change to the process which involved holding the material at a moderately high temperature for a prolonged period was not fully appreciated and there were no instructions for the discharge of the material on completion of drying.

The accident also revealed deficiencies in the methods available for screening materials to detect exothermic reactions. Zoalene had been screened by the company using differential thermal analysis, but this had revealed no exotherm at the processing temperature. After the accident samples of Zoalene were tested by RARDE using differential scanning calorimetry. Exotherms were found in the temperature range 248–274° C.

Zoalene samples were also tested by the company using the new technique of accelerating rate calorimetry developed by Dow itself. It was found that samples would self-heat to decomposition if held under adiabatic conditions at 120–125°C. At the time of the accident the company was working through a programme of screening its reactive chemicals, but had not yet checked Zoalene.

The investigation described in the report of the HSE (1977b) concluded that the explosion had been a detonation with an energy release of 200–300 lb of TNT, that a temperature of over 800°C had been reached before detonation occurred and that there had been an extremely rapid pressure rise, probably to over 10,000 psi.

The report gives a detailed map of the locations of the fragments from the explosion.

HSE (1977b)

A82 *Los Angeles, California, 1976*

On 17 December 1976, a violent explosion occurred aboard the tanker Sansinena at Los Angeles, California. The ship had offloaded a cargo of light crude oil and was loading Bunker C oil. It was equipped with neither a vapour recovery nor a cargo tank inerting system. The explosion is believed to have been initiated by a spark from a pump. The force of the explosion threw the centre section and the bridge onto the dockside, leaving the bow and stern sections afloat.

NTSB (1978 MAR-78-06); D.J. Lewis (1984c); Mahoney (1990)

A83 *Plaquemine, Louisiana, 1976*

On 30 August 1976 at Plaquemine, Louisiana, the top was blown off a transfer oil surge tank on an ethylene oxide plant, causing a serious fire and damage to six reactors and other equipment. A leak between the shell and tube sides of a reactor heat exchanger had allowed air at 200 psig to enter the heat transfer system.

Mahoney (1990)

A84 *Southwest Freeway, Houston, Texas, 1976*
At about 10.45 a.m. on 11 May 1976 in Houston, Texas, a tractor tank semi-trailer carrying ammonia went through a bridge rail on the interstate highway 1–610 and fell some 15 ft onto the South-west Freeway, US 59. The interchange was the busiest in the state and at the time traffic was quite heavy. The tank, which held 19 te of liquid anhydrous ammonia, burst.

The crash was caused by the excessive speed of the vehicle and by sloshing of the liquid in the partially loaded tank. However, the speed did not exceed 54 mile/h.

The ammonia was released and formed a visible fog. It was a bright sunny morning with a wind speed of 7 mile/h. The initial height of the cloud determined from photographs was about 30 m. The cloud was observed to reach a width of about 300 m and a length of 600 m. One photograph showed a tail to the left-hand side, indicating the typical slumping behaviour of heavy gas. It is estimated that the ammonia evaporated and the cloud dispersed within about 5 min. The driver of the truck and five other people were killed, 78 taken to hospital and about another 100 injured. Apart from the driver all the casualties were due to gassing.

Anon (1976o); McMullen (1976); NTSB (1977 HAR-77-01); Fryer and Kaiser (1979 SRD R152)

A85 *Breahead, Renfrew, Scotland, 1977*
On 4 January 1977, the Breahead Container Clearance Depot, a chemicals warehouse, was destroyed by a serious fire and explosions. The fire had been started inadvertently by boys who had built a 'den' beside the warehouse and had lit a fire to warm themselves. The explosions caused widespread roof and window damage within a radius of a mile. The warehouse had contained some 67 te of sodium chlorate stored in 1774 steel drums. Investigations showed that under intense heat this substance is capable of giving explosions of the severity which occurred.

This incident drew attention to the hazard of sodium chlorate. It emerged that since 1899 sodium or potassium chlorate had been implicated in six explosions, the then most recent being in Hamilton, Lanarkshire in 1969 and in a ship in Barcelona in 1974. Subsequently there occurred in the United Kingdom two other warehouse explosions involving sodium chlorate, one on 21 January 1980 at Barking, Essex (HSE, 1980a) and one on 25 September 1982 at Salford (HSE, 1983b).

Anon. (1979i,z); HSE (1979b); Matthews (1981)

A86 *Brindisi, Italy, 1977*
On 8 December 1977, a large gas release occurred on an ethylene plant at Brindisi, Italy, resulting in a vapour cloud explosion and fire, with extensive damage. The sewers were unable to handle the firewater and burning hydrocarbon liquids floated on it to a depth of some 18 in. Three persons died and 22 were injured.

Anon. (1977b); Mahoney (1990)

A87 *Puebla, Mexico, 1977*
On 19 June 1977 a leak occurred on one of a group of VCM storage bullets. A fitter had made an error in removing an actuator from a liquid discharge valve on the tank, taking out the wrong bolts so that the valve plug suddenly popped out, allowing an escape through the 3 in. valve body. The release continued for 80 min in calm conditions, the vapour cloud formed being 1100 ft long, 800 ft wide and 5 ft deep. Five minutes later the cloud caught fire and flashed back to the tanks. A further 5 min later one tank suffered a BLEVE. Three more tank explosions followed. One person was killed and three injured.

D.J. Lewis (1991 LPB 100, 1993)

A88 *Umm Said, Qatar, Persian Gulf, 1977*
On 3 April 1977, a catastrophic failure occurred on a storage tank at Umm Said, Qatar, in the Persian Gulf. The tank was a single-wall carbon steel refrigerated atmospheric tank holding 37,000 m^3 of liquid propane at −42°C. A wave of propane liquid swept over the bund, boiling on the sand. It entered the adjacent separation plant and was ignited. There was a massive fire which did extensive damage, burned out of control for two days and was extinguished only after 8 days. Seven persons were killed and 13 injured.

Information on this incident is still hard to come by. The failure is said to have occurred at a weld on the tank. It is reported that the same weld had been responsible for a leak a year before in which a vapour cloud formed and travelled 500 ft but did not ignite.

Anon. (1977c); Whelan (1977); D.J. Lewis (1980, 1993); Kletz (1988 LPB 81)

A89 *Westwego, Louisiana, 1977*
On 23 December 1977, a series of explosions took place in the silos of a large grain elevator at Westwego near New Orleans, Louisiana. There were some 73 reinforced concrete silos 35 m high and ranging in diameter from 8 to 10 m. Contents included corn, wheat and soya beans.

The first explosion, which occurred in the morning, caused the top 20 m of a 75 m high head house to fall onto an office building. Explosions continued through the morning. More than half the silos were completely destroyed and others severely damaged. The wreckage of some of the silos is shown in Figure A1.15.

More than 50 people were working on the complex when the explosions occurred. Thirty-six persons were killed and ten injured. Most of the dead were in the crushed office building.

The source of ignition for the first explosion has not been determined. At the time the relative humidity was low, which would be conducive both to the presence of fine dust suspensions and to static electricity.

This disaster is comparable in scale for dust explosions with that at Flixborough for vapour cloud explosions.

Less than a week later, on 29 December 1977, there was a further series of explosions in another grain elevator at Galveston, Texas, in which 15 people died.

Anon. (1977p,q); Lathrop (1978); Nolan (1979): D.J. Lewis (1993)

A90 *Abqaiq, Saudi Arabia, 1978*
On 15 April 1978, internal corrosion of a 22 in. 500 psig gas transmission pipeline on a gas processing plant at Abqaiq, Saudi Arabia, resulted in a leak which then expanded so that the line parted. A vapour cloud estimated as 405 ft × 435 ft spread through the plant. Some 7 min later ignition occurred at a flare 1500 ft downwind. The escaping gas is described as having a jet/whipping action which threw a 22 ft pipe section 400 ft so that it struck an spheroidal storage

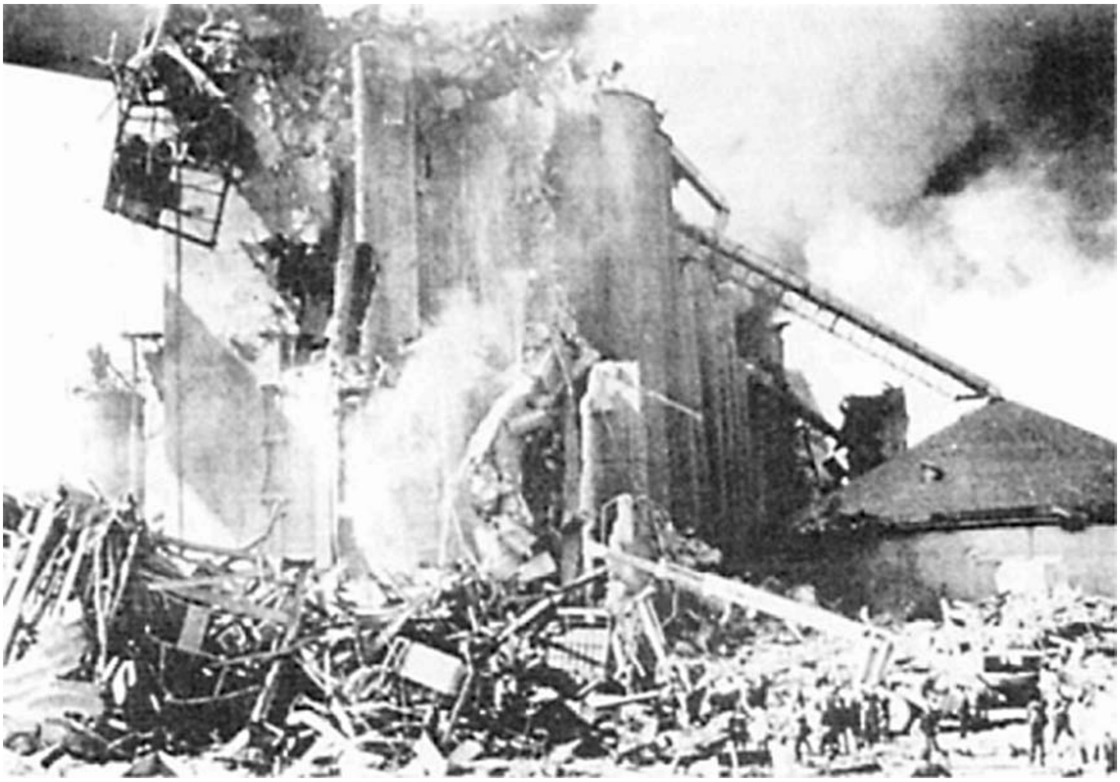

Figure A1.15 *Westwego, 1977: grain silos after the explosion (United Press International)*

tank. A second vapour cloud formed and was ignited by the initial fire, resulting in a vapour cloud explosion.

Mahoney (1990)

A91 *Donnellson, Iowa, 1978*

At 12.02 a.m. on 4 August 1978, a leak of liquid propane ignited on an 8 in. LPG pipeline of the Mid-America Pipeline System (MAPCO) in the rural area of Donnellson, Iowa. The pipeline pressure was over 800 psig and the leak came from a 33 in. split in the pipe. The intense fire killed two people and severely burned three others as they fled their homes; one of the injured later died. Some 157,500 USgal of liquid escaped and 75 acres were burned.

The investigation by the NTSB (1979 PAR-79-01) found that the failure occurred due to a dent and gouge in the pipe sustained in 1962 before the line was complete combined with stresses created when the line was lowered 3 months prior to the incident.

V.C. Marshall quotes this incident as involving 435 te of propane and giving a fireball of 305 m radius. The NTSB report refers to eyewitness reports of a 'bonfire' and states that when firefighters arrived about 12.20 a.m. they found a towering flame 400 ft high.

NTSB (1979 PAR-79-01); V.C. Marshall (1987)

A92 *Texas City, Texas, 1978*

On 30 March 1978, a series of fires and explosions occurred at LPG storage spheres at Texas City, Texas.

There were three spheres, each 800 m^3. One of the spheres suffered overpressure while it was being filled, due to failure of a pressure gauge and also of a relief valve. It cracked and leaked LPG. The leak ignited giving a massive fireball.

Accounts differ in their description of the events which followed. According to Selway (1988 SRD R492), after 20 min a second sphere, which was only partially full, suffered a BLEVE. The third sphere, which was virtually empty, failed due to a heat-induced rupture at the top, but remained upright. Thus all three spheres were damaged, but there was only one BLEVE event. Mahoney (1990) states that during the 20 min following the fireball, five horizontal bullets and four vertical ones were damaged by missiles and that the other two spheres were also damaged in this way. The missiles started fires and hit the firewater storage tank and electrical fire pumps, although two diesel fire pumps remained operable.

Selway (1988 SRD R492): Mahoney (1990)

A93 *Waverly, Tennessee, 1978*

On 24 February 1978, an explosion occurred of an LPG rail tank car at Waverly, Tennessee. Two days before, on 22 February, a freight train conveying two LPG tank cars derailed. There was no immediate release. A check on the following day showed that both tank cars were damaged but no leak could be detected. Both tank cars were underneath box wagons and these were lifted off. On 24 February as preparations were in hand to transfer the contents of the tank cars, one of them, which had suffered a long gouge-like scrape along one side, suddenly ruptured into four pieces and released its contents of 59.4 te of LPG. Seconds later the gas ignited, probably by burning equipment nearby, giving a fireball. There followed a fire which did extensive damage. Sixteen people were killed and 43 injured.

Anon. (1978b); NTSB (1979 RAR-79-01); D.J. Lewis (1992 LPB 105, 1993)

A94 *Youngstown, Florida, 1978*

At about 1.55 a.m. on the night of 26 February 1978, a freight train of the Atlanta and Saint Andrews Bay Railway derailed near Youngstown, Florida. In the derailment a rail tank car containing liquid chlorine was punctured when it struck another tank car. The approximate position of the tank cars following the derailment is shown in Figure A1.16.

A chlorine gas cloud formed and moved towards State Highway 231, which ran parallel to the railroad at a distance of 300 ft. The weather conditions were a temperature of 50–55°F and a light westerly wind of 2–3 knots. There were already some patches of fog around and drivers, used to foggy conditions and unable to see the colour of the cloud as it was night, drove into it. Three vehicles drove right off the road and into the ditch. One motorist said the gas was so thick 'You could not see your hand in front of your face'. Seven motorists abandoned their cars and died while trying to escape, whilst an eighth drove through the cloud but died a short distance down the road.

The train's engineer at the head of the train alerted the conductor at the rear by radio and then tried to escape through the cloud; he became lost and mired in a swamp, being rescued 6 h afterwards. The head brakeman, who had been with the engineer, circled round to the highway and started to alert traffic. The conductor and rear brakeman tried to inform the railroad facility at Panama City, but it was not manned after midnight. They began to rouse local residents and notified the police; almost 30 min had elapsed before the first emergency call was completed. They then went to the highway to assist in alerting traffic. The report by the NTSB (1978 RAR-7807) states.

The head and rear brakeman both imperilled their lives by their repeated exposure to the chlorine gas cloud to stop and warn motorists of the dangerous situation. Their heroic actions saved many people from death or serious injury.

The emergency service evacuated people, first in a 5 mile and then in a 10 mile radius.

At 9.00 a.m. aerial observation revealed a gas cloud 3 miles wide and 4 miles long with a maximum height of 1000 ft. If the wind had been in a less favourable direction, the town of Youngstown would have been engulfed in the cloud.

The chlorine gas killed eight people, as mentioned, and injured another 50. Some 2500 people were evacuated.

Anon. (1978k); NTSB (1978 RAR-78-07)

A95 *Bantry Bay, Eire, 1979*

At about 1.06 a.m. on 8 January 1979, the Total oil tanker Betelgeuse blew up at the Gulf Oil terminal at Bantry Bay, Eire. The ship had completed the unloading of its cargo of heavy crude oil. No transfer operations were in progress. The first sign of trouble occurred at about 12.31 a.m. when a sound like distant thunder was heard and a small fire was seen on deck. Ten minutes later this was spread aft along the length of the ship, being observed from both sides. The fire was accompanied by a large plume of dense smoke. About 1.06–1.08 a.m. a massive explosion occurred. The vessel was completely wrecked and extensive damage was done to the jetty and its installations. There were 50 deaths.

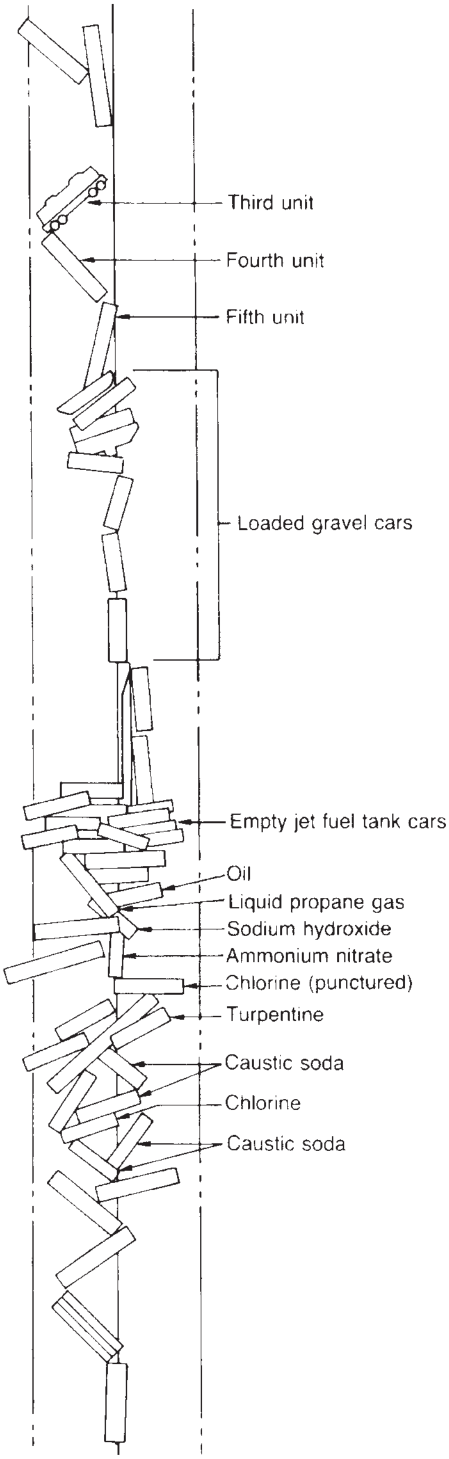

Figure A1.16 *Youngstown, 1978: approximate positions of rail tank cars after the derailment (after NTSB, 1978 RAR-78-07)*

The inquiry (Costello, 1979) found that the initiating event was the buckling of the hull, that this was immediately followed by explosion in the permanent ballast tanks and the breaking of the ship's back and that the next explosion was the massive one involving simultaneous explosions in No. 5 centre tank and all three No. 6 tanks. It further found that the buckling of the hull occurred because it had been severely weakened by inadequate maintenance and because there was excessive stress due to incorrect ballasting.

The ship was an 11-year old 61,776 CRT tanker. The weakened hull was the result of 'conscious and deliberate' decisions not to renew certain of the longitudinals and other parts of the ballast tanks which were known to be seriously wasted, taken because the ship was expected to be sold, and for reasons of economy. The vessel was not equipped with a 'loadicator' computer system, virtually standard equipment, to indicate the loading stress. It did not have an inert gas system, which should have prevented or at least mitigated the explosions.

At the jetty there had been a number of modifications which had degraded the fire fighting system as originally designed. One was the decision not to keep the fire mains pressurized. Another was an alteration to the fixed foam system which meant that it was no longer automatic. Another was decommissioning of a remote control button for the foam to certain monitors.

Another issue was the absence of the dispatcher from the control room at the terminal. It was to be expected that had he been there, he would have seen the early fire and have taken action.

In a passage entitled '*Steps taken to suppress the truth*' the tribunal states that active steps were taken by some personnel at the terminal to suppress the fact that the dispatcher was not in the control room when the disaster began, that false entries were made in logs, that false accounts were given to the tribunal and that serious charges were made against a member of the Gardai (police) which were without foundation.

> The inquiry report gives a long list of measures which might have prevented or mitigated the disaster: Had the vessel been properly maintained. . . Had Total supplied the ship with a loadicator. . . Had the dispatcher in the Control Room observed the initiation of the disaster. . . Had the alert been raised at the beginning of the disaster. . . Had the tug been moored in sight of the jetty. . . Had the decision to discontinue the automatically pressurized fire-main not been taken. . .

and so on.

Anon. (1979l); Costello (1979); Anon. (1980a); Mahoney (1990)

A96 *Good Hope, Louisiana, 1979*

On 30 August 1979, a freighter collided with the butane barge Panama City at a jetty on the Mississippi at Good Hope, Louisiana, striking it amidships, severely puncturing at least one of its tanks and causing a fireball. Twelve persons died and 25 were injured.

NTSB (1980 MAR-80-07); V.C. Marshall (1987)

A97 *Mississauga, Toronto, Ontario, 1979*

At 23.52 on Saturday 10 November 1979 at Mississauga, Toronto, a freight train derailment led to fires, explosions and a chlorine gas release, in an emergency lasting 11 days. The train had 25 rail cars of which 19 held hazardous materials, in a mixed load of flammables and toxics, including propane, toluene, styrene, caustic soda and chlorine.

The derailment occurred due to lack of lubrication of a plain journal axle bearing on the 33rd car, a propane tanker. The red-hot axle, complete with wheels, parted from the tank car. Some 2 km further on at a location where there was a road crossing and points, this vehicle became detached from the front portion of the train. Many of cars in the rear section derailed. Several tanks were ruptured and a fire broke out. The brakes in the front section of the train were applied automatically and looking back the locomotive crew saw a fire and a tank car rocketing off.

There followed a series of explosions, one within a minute and another just after midnight at 00.10. At 00.15 a propane tank suffered a BLEVE in which one half travelled 2300 ft and buried itself 20 ft into the ground. At 00.24 another BLEVE of a propane tank car occurred.

There was a single chlorine tank car containing 90 te of liquid chlorine. This tank lost part of its insulation and a flame impinged on the bare metal. There was an iron – chlorine reaction which burned a 3 ft diameter hole in the tank. Chlorine began to escape through the hole. The effect was less serious than it might have been, since the effect of the fire was to cause the gas to rise in the thermal currents.

The emergency developed over an extended period. Initially the emergency services did not know what was in the train: the manifest was found, but it was in code. There was, however, a strong smell of chlorine. At 1.30 a readable version of the manifest was obtained, identifying the chlorine tank car. At 3.00 the decision was made to evacuate the surrounding population, an exercise which eventually resulted in the evacuation of 215,000 people. The holed chlorine tank car was identified by a helicopter survey.

At 9.00 on Tuesday 13 November an initial attempt was made to plug the hole in the chlorine tank car, but without success; a second attempt succeeded. When subsequently the tank was emptied, only 18 te of chlorine was recovered.

During Tuesday afternoon 143,000 people were allowed back home. The rest did not return until after an absence of six days.

Detailed timetables of the incident itself and of the evacuation are given by Fordham (1981 LPB 44).

The only injuries were those caused to eight firemen by inhalation of the noxious gases.

Mississauga News (1979); Amyot (1980); Grange (1980); Anon. (1981l); Fordham (1981 LPB 44); Lane and Thomson (1981); D.J. Lewis (1993)

A98 *Borger, Texas, 1980*

On 20 January 1980, a refinery at Borger, Texas, suffered extensive damage. Details are lacking, but it appears that a vessel was subjected to a pressure much in excess of its working pressure, the relief valve operated but was ineffective due to ice blockage and the vessel ruptured, releasing 34 m^3 of hydrocarbon liquids. A vapour cloud formed and ignited, giving a vapour cloud explosion with a TNT equivalent of some 15 te. The blast destroyed the alkylation unit and boiler plant and shut-down the whole refinery. Forty-one people were injured.

The ice plug is reported as due to freezing by propane of water which had accumulated in the flare system.

Mahoney (1990); D.J. Lewis (1993)

A99 *Wealdstone, Middlesex, 1980*
About 19.15 on 20 November 1980 an escape of propane began from a storage vessel in the factory yard of Whitefriars Glass Ltd at Wealdstone, Middlesex. The vessel was a 10 te vessel which contained 5 te of propane. The nightwatchman smelled the odorized gas, but searched first inside the building, until he heard a hissing sound and saw a white cloud about 1.2 m deep around the base of the tank. Meanwhile a passer-by had called the fire brigade. The escape lasted several hours. Some 2100 people were evacuated from the area. One person had to attend hospital.

The release was caused by the removal by the works engineer and a fitter of three of the four bolts on an adapter piece on the drain valve of the tank. The valve had two sections. The upper, body section was bolted to the underside of the tank. The lower, adapter section had a spigot which extended into the upper section and held the ring seals in place against the ball. In other words, the adapter was an essential part of the valve.

This was not known, however, to the persons who removed the bolts.

The work on the valve had occurred during the afternoon. The delay between the removal of the bolts and the escape was attributed by the investigators to the accumulation in the vessel of non-volatile, viscous residues due to the removal of propane as gas from the top of the tank over a period of at least 10 years.

HSE (1981c)

A100 *Montana, Mexico, 1981*
At 17.52 on 1 August 1981 a train derailment resulted in a massive release of chlorine near Montana, Mexico. The train consisted of 38 wagons, including 32 rail tank cars containing liquid chlorine. It was moving down a steep and winding valley at a 3% gradient when its brakes failed. The driver radioed to other trains on the single track to warn them, and two trains drew into loops. The train derailed at over 80 km/h on a bend 350 m beyond Montana station.

All the chlorine tank cars were 55 short tons, say 50 te, capacity. The pile-up included 28 of the 32 chlorine cars. Most were badly damaged. One tank car lost its dished end and the shell was propelled 2000 m. A second was split along its side. A third had a 0.5 m diameter hole, probably the result of an iron–chlorine fire, which could well have resulted from ignition of the cork insulation by red hot brakes. Four other tank cars suffered damage to their valves, which were ripped off or dislodged so that they leaked. It is estimated that 100 te of chlorine escaped in the first few minutes and 300–350 te in all.

The population of Montana was some 400 people. There was also a passenger train with some 300 people at the station. The weather conditions to be expected at the time of day would be a warm wind blowing up the valley, towards the village. The vegetation up the valley was bleached by the gas cloud passing up it; there was also discoloration some 50 m down the slope and up the sides for a vertical distance of about 50 m. The highest concentrations appear to have occurred in a strip 1000 m long × 40 m wide. Seventeen persons died, four in the caboose of the train and 13 from gassing. About 1000 people were received in hospital and 256 were detained.

A101 *Stalybridge, UK, 1981*
At about 23.30 on 6 September 1981, a violent explosion occurred at the works of Chemstar Ltd at Stalybridge. Failure of cooling water to the condenser of a still had allowed hexane vapour to issue through the vent, and the escaping vapour found a source of ignition. One person was killed and one injured.

The investigators found that the normal water supply was not available, a temporary supply had been used which proved to be erratic and there was inadequate flow indication; that the vent had not been routed to a point outside the building; and that the training and supervision of the operator were inadequate.

HSE (1982a); Kletz (1983b)

A102 *Caracas, Venezuela, 1982*
At about 6.17 a.m. on 19 December 1982, an explosion blew the top off a large oil storage tank at the electricity company at Caracas in Venezuela. The oil in the tank caught fire and burned. Firemen arrived and attempted to control the fire and people stood watching it. After some hours there was a violent boilover of the tank contents and burning liquid ran down the hill on which the tank stood towards firemen and spectators.

The power station was owned by C.A. La Electricidad de Caracas and was built in 1978. The tank involved was No.8 storage tank, which was one of two cone roof tanks each 55 m × 17 m, the other tank being No.9. Each tank had its individual bund and had two forms of fire protection. One was a 100 mm water drench pipe which ran to the centre of the roof and was designed to cascade water over the roof and shell to prevent overheating and the other was a semi-fixed foam system with five risers.

No.8 tank contained No.6 fuel oil and at the start of the incident the depth of oil was 7.5 m. It had been feeding the boilers for six days prior to the fire.

At 6.15 a.m, while it was still dark, two men went up on the roof of No.8 tank to gauge it, and a third waited in a vehicle. About 2 min later the roof blew off and at the same time the lines within the bund were ruptured. One of the foam risers on the tank was damaged. The source of ignition is not known, but neither man had a flashlight and it is possible a match was lit to read the gauge line.

It is not known if either the water or foam fire protection systems on No.8 tank operated. The power company had no fire brigade and the nearest public fire service was a half an hour journey away over winding roads.

Some 8 h after the fire began a violent boilover of No.8 tank occurred. Burning oil surrounded No.9 tank and flowed down the hill into the sea, but was kept from the power station by a concrete wall. The inrush of air lifted roof panels at the power station 300 m away.

The boilover killed 40 firemen and many civil defence workers and spectators. 153 people are known to have died and 7 were missing.

Boilover is defined by the NFPA as follows:

> Boilover shall mean an event in the burning of certain oils in an open top tank when, after a long period of quiescent burning, there is a sudden increase in fire intensity associated with the expulsion of burning oil from the tank. Boilover occurs when the residues from surface burning become denser than the unburned oil and sink below the surface to form a hot layer which progresses downward much faster than the regression of the liquid

> surface. When this hot layer, called a 'heat wave', reaches water or a water-in-oil emulsion in the bottom of the tank, the water first is superheated and subsequently boils almost explosively, overflowing the tank. Oils subject to boilover must have components having a wide range of boiling points, including both light ends and viscous residues. These characteristics are present in most crude oils and can be produced in synthetic mixtures.

The heat wave travels at a rate which in most crude oils is some 300–460 mm/h but can be as great as 900–1200 mm/h. Its temperature can be as high as 315°C. When water comes into contact with the heat wave, it vaporizes to steam with a volume expansion of 1700 : 1 or more.

Normally No.6 fuel oil is regarded as not being subject to boilover. However, it is common practice in the United States to blend it. It is reported that the power company's specifications allowed 5–20% light fractions, that the oil had a flashpoint of 71°C, that it was intended to be heated in storage to 65°C, but that the oil return temperature shown by the control room records was 80°C and the storage temperature was 82°C. The tank high-temperature alarms had sounded at midnight, some 6 h prior to the incident.

Garrison (1984 LPB 57); M.F.Henry (1986)

A103 *Livingston, Louisiana, 1982*

On 28 September 1982, a freight train conveying hazardous materials derailed at Livingston, Louisiana. The train had 27 tank cars some of them with jumbo tanks of 30,000 USgal. Seven tanks cars held petroleum products and the others a variety of substances, including vinyl chloride monomer, styrene monomer, perchlorethylene, hydrogen fluoride and metallic sodium.

The incident developed over a period of days. The first explosion did not occur until three days after the crash. The second came on the fourth day. The third was set off deliberately by the fire services on the eighth day. The scene is shown in Figure A1.17.

Meanwhile the 3000 inhabitants of Livingston were evacuated. Some were not to return home until 15 days had passed.

One factor contributing to the derailment was the misapplication of brakes by an unauthorized rider in the engine cab, a clerk who was 'substituting' for the engineer. Over the previous 6 h the latter had drunk a large quantity of alcohol.

The incident demonstrated the value of tank car protection. Many of the cars were equipped with shelf-couplers and head shields, and there was no wholesale puncturing and rocketing. Tanks also had thermal insulation which resisted the minor fires occurring for the two or more hours which it took the fire services to evacuate the whole town.

NTSB (1983 RAR-83-05); Anon. (1984t)

A104 *Bloomfield, New Mexico, 1983*

At 12.04 p.m. on 26 May 1983 at the El Paso Natural Gas Company's Blanco Field Plant near Bloomfield, New Mexico, a gasket on a compressor failed and natural gas at 815 psig began to escape into the building. Two operators heard the noise. One tried to shut off the gas supply to the compressors, the other to shut-down the compressor engine. Before they could effect these operations, the gas ignited and exploded, and both were severely burned. One compressor was destroyed and a second severely damaged.

The investigation by the NTSB (1983 PAR-83-04) found that the probable cause was improper tightening of the compressor head bolts and lack of procedures for, and training in, bolt tightening. The report gives a detailed discussion of the bolting problem together with guidance on bolt tightening.

It also criticized the emergency response, in that there was a failure to effect prompt relief of the high-pressure gas by activating the blowdown system.

NTSB (1983 PAR-83-04)

A105 *Bontang, India, 1983*

On 14 April 1983 on an LNG plant at Bontang, India, the main cryogenic heat exchanger, 141 ft long × 14 ft diameter,

Figure A1.17 *Livingston, 1982: rail tank cars burning after the crash (National Transportation Safety Board, 1983)* ruptured during a start-up. The shell side operating pressure was 25.5 psi but it was exposed to gas at a pressure in excess of 500 psi. The explosion gave rise to missiles and a fire. The flow from a pressure controller on the shell and the flows from relief valves on the shell and tube sides of the exchanger vented to a common line. The investigation found that a valve on this line was closed, disabling both the pressure control and the pressure relief. The valve in question had apparently been omitted from the valve checklist for plant start-up.

Mahoney (1990)

A106 *Milford Haven, UK, 1983*

On 30 August 1983, a fire broke out on the roof of a large crude oil floating roof storage tank at the refinery at Milford Haven, Dyfed, Wales. The tank was 78 m diameter × 20 m high with a capacity of 94,100 m^3 and was 59% full. It stood in a very large bund with dimensions 90 m × 180 m. The fire took hold and a massive tank fire ensued with an estimated burn-off rate of 300 te/h of oil. After 12.5 h boilover occurred, thousands of tonnes of burning oil flowed into the bund and a fire column rose 3000 ft high. Two hours later there was a further boilover.

The floating roof had developed a split which allowed vapours and some oil to escape onto the roof. Ignition was attributed to hot carbon particles from the flare. An upset had resulted in a large flow of hydrocarbons to the flare which could have dislodged particles from the stack top.

There was a major fire fighting operation. Oil was pumped out from the bottom of the burning tank at a rate of 700 te/h. The foam supplies available on site were sufficient for a floating roof tank seal fire, but not for the fully developed tank fire, and supplies were sought outside. There were two other storage tanks at a wall-to-wall distance of 61 m from the burning tank, and an early priority was to cool the outside of these and to inject foam inside. Eventually, after the boilovers, enough foam was obtained, some 305 m^3, to mount a full foam attack, first on the fire in the bund and then on that in the tank itself. This process lasted 15 h with the fire fighting being done under conditions of extreme heat. In the boilover events, firemen were affected by flash burns and by dry hot air.

A detailed timetable of the incident is given by Mumford (1984 LPB 57).

A107 *Abbeystead, UK, 1984*

On 23 May 1984, a group of people were assembled in the valve house of the Lune/Wyre Water Transfer Scheme at Abbeystead for a presentation when there was a violent explosion. The explosion occurred soon after the pumping system had been started up. The pumps had not been run for 17 days and the tunnel which conveyed the water was not full of water, its usual condition, but had been emptied through a drain valve which had been opened to remove silt. Subsequent tests showed that during this period groundwater would have leaked into the tunnel at a rate of 1000 te/d. This water contained dissolved methane, which mixed with the air in the tunnel. The only venting of the tunnel was through the grilled floor of the valve house. Thus when the pumps were started and water moved up the tunnel, the methane–air mixture was displaced and came up through the grill into the valve house, where it found a source of ignition. The explosion killed 16 and injured 28; all the 44 persons in the valve house itself were killed or injured.

A108 *Cubatao, Brazil, 1984*

On 24 February 1984 just before midnight a leak of petrol occurred on the Petrobas pipeline passing through the shanty town of Vila Soca at Cubatao in Sao Paulo state, Brazil. The petrol caught alight and a fire devastated the houses. The death toll was 508.

Vila Soca was a shanty town of some 2500 dwellings. The number of people living there is uncertain, but is estimated as 8000, perhaps even 12,000. The pipeline was 30 years old. For 20 years the company had protested that Vila Soco had been built illegally on its land, but had nevertheless provided water and electricity.

A leakage from the pipeline was noticed the day before the fire and a resident telephoned the company. In the leak which led to the disaster some 700 te of petrol escaped from the pipeline. The spread of the flammable liquid through the shanty town and under the houses was aided by water on the ground and by a small stream. A two-minute warning was given but this was not enough for the inhabitants to evacuate. The petrol caught fire and straight away created an inferno. Houses burned and exploded as the petrol beneath them ignited. It was 45 min before the fire brigade arrived by which time most of the shanty town had been destroyed.

Anon. (1984oo); Kletz (1985p)

A109 *Fort McMurray, Avaporerta, 1984*

On 15 August 1984 at Fort McMurray, Avaporerta, hydrocarbon liquids close to their autoignition temperature were released from a 10 in. slurry recycle oil line on a fluidized-bed coking unit. A vapour cloud formed and ignited almost at once. The fire, which did extensive damage, was fed by further releases of hydrocarbon liquids, the flows being largely under gravity but in part from pumps which could not be shut-down. Fire fighting was hampered by rupture of a 900 psig steam line supplying the compressor turbine drives. The failure of the recycle line was due to erosion. Subsequent metallurgical examination showed that an 18 in. long section of carbon steel had been inserted in error into the alloy steel line.

Mahoney (1990)

A110 *Las Piedras, Venezuela, 1984*

On 13 December 1984 in a refinery at Las Piedras, Venezuela, an 8 in. oil line fractured and sprayed hot oil at 700 psi and 650°F across a roadway onto hydrogen units. Ignition occurred, and the ensuing intense fire led to rupture of a 16 in. gas line, which resulted in a massive jet flame, leading to further line ruptures, some of which occurred with explosive force. The initial failure was a circumferential fracture in the heat affected zone in the parent metal about 1.5 in. from the weld.

Mahoney (1990)

A111 *Romeoville, Illinois, 1984*

On 23 July 1984, a column at the Lemont refinery of Union Oil at Romeoville, Illinois, suffered a spontaneous failure. The vessel was an absorption column 8.5 ft diameter × 55 ft high in which a propane/butane feedstock was contacted with methylethanolamine (MEA). Just prior to the burst, an operator noticed a horizontal crack about 6 in. long at the 10 ft level. He went up a ladder to try to shut of the inlet valve and then saw that the crack had grown to some 2 ft. He had initiated evacuation of the area when the column failed. The column tore apart at the 10 ft level weld and the 45 ft top section, weighing some 20 te, rocketed up, landing about 975 m away on a tower carrying a 138 kV power feed line to the area. The tower contents, estimated as 79.5 m^3 of propane/butane and 8.75 m^3 of MEA, escaped and formed a vapour cloud, which ignited within seconds, giving a vapour cloud explosion. Some 30 min later a third explosion occurred when a vessel in the alkylation section suffered a BLEVE with associated fireball and missiles. The explosions and fire caused extensive damage. Seventeen people were killed and 31 injured.

The vapour cloud explosion disrupted the electrical power supply, putting out of service a 2500 USgal/min electrical fire pump. One of the explosions sheared off a fire hydrant, reducing the pressure available from the two 2500 USgal/min diesel-driven fire pumps. A fragment from the BLEVE landed on a unifining unit, initiating a major fire there.

The blast resistant control centre, some 400 ft from the absorber, suffered little structural damage.

The absorber vessel had a history of hydrogen attack problems. Over the years since 1972 repairs and modifications had been done, and the vessel continued in service.

Mahoney (1990); D.J. Lewis (1993); Vervalin (1987)

A112 *Priola, Italy, 1985*

On 19 May a major fire occurred on an ethylene plant at Priola in Italy. A faulty temperature probe initiated isolation of the hydrogenation unit in the cold section, and while the operators were trying to re-establish control, the relief system operated. At the same time fire was observed at the base of the de-ethanizer column. The hydrocarbon released ignited and an intense fire engulfed the adjoining ethylene and propylene distillation columns and spread to the storage area. The water deluge system protecting the storage tanks proved inadequate due to the intensity of the fire. In due course a tall, vertical propane tank exploded, its top section rocketing up some 500 m, and just missing a gasholder. Two propylene tanks fell over, one on a pipe rack and the other against an ethylene tank. In all, five of the eight ethylene and propylene tanks either exploded or collapsed.

Mahoney (1990)

A113 *Schweizerhalle, Basel, Switzerland, 1986*

On 1 November 1986, a fire broke out in Warehouse 956 at the Schweizerhalle (Muttenz) works of Sandoz in Basel, Switzerland. The warehouse held large quantities of agrochemicals. Attempts to extinguish the fire using foam were ineffective and water had to be used, in large quantities. It was not possible to contain this water within the site and, as a result, 10,000 m^3 entered the Rhine carrying with it some 30 te of chemicals, including an estimated 150 kg of highly toxic mercury compounds dissolved in aqueous concentrates. The incident did severe ecological damage.

A not dissimilar incident, though one on a much smaller scale, occurred at Morley, Yorkshire, in 1982, when the river Calder was contaminated by chemicals in water used in fighting a fire which had broken out in a warehouse storing herbicides (V.C. Marshall, 1987).

Anon. (1986v,w,y); Beck (1986); D.Williams (1986); Anon. (1987 LPB 75, p. 11); Stallworthy (1987)

A114 Thessalonika, Greece, 1986

On 24 February 1986, an oil terminal at Thessalonika, Greece, experienced a small fire when a oil spillage in a bund was ignited by hot work. The privately owned terminal had 12 fixed and floating roof storage tanks holding crude oil, fuel oil and gasoline. Over the course of seven days, ground fires escalated until they covered 75% of the terminal area and involved 10 of the tanks. The escalation of the initial small fire was due in large part to accumulation of oil from previous spillages; to leaks from flanges exposed to the fire, which then fed it; and to the failure of fire fighting efforts in the early stages. By the first day seven tanks were affected.

In the course of the succeeding days, several events occurred which led to major escalations. On Tank 3 overpressure caused the shell-floor seam to burst so that the whole contents flowed out, feeding the fire and involving two more tanks. Tank 8 suffered a boilover with a fireball 300 m high and ejection of burning oil over a wide area, some travelling up to 150 m. The fire fighting was hampered, and firemen endangered, by burn-back of flame in areas where the oil fire had already been extinguished by foam.

B. Browning and Searson (1989)

A115 *Antwerp, Belgium, 1987*

On 3 July 1987, an explosion occurred inside an ethylene oxide purification column at the BP Chemicals works at Antwerp, Belgium. The explosion was due to decomposition of the ethylene oxide and was accompanied by a fireball, which started a number of secondary fires. These, together with blast and missiles, caused extensive damage. Fourteen people were injured.

The investigators considered two main hypotheses for the cause. One was that there was a leak of ethylene oxide into the insulation, leading to self-heating and then ignition of the leak, resulting in the heating of the ethylene oxide in the column itself. The other was the development of a hot spot inside the column due to exothermic polymerization of ethylene oxide catalysed by rust. The first explanation was preferred.

Mellin (1991 LPB 100)

A116 *Grangemouth, Scotland, 1987*

In 1987, there occurred at BP plants in the Grangemouth, Scotland, area three incidents, which were the subject of investigations by the HSE (1989a).

Incident on 13 March 1987

On 13 March 1987, a fire occurred when a maintenance team broke a flange in the flare line, hydrocarbons escaped and were ignited. There was a quite serious fire which lasted some hours. Two men were killed and two injured.

The release occurred when two fitters started to break a flange in order to maintain a valve (V17). As they did so, vapour and a little liquid came out. They queried the situation with the process shift supervisor, who inspected the site and assured them that there could only be a small quantity present and it was safe to continue. They did so, and as the last bolt was undone, the crane holding the spacer increased its lift, the spacer sprang upwards, and liquid under pressure poured out. A vapour cloud formed and ignited. The source of ignition was almost certainly the engine of a nearby diesel air compressor.

It was considered that if the fire was extinguished, fuel might continue to issue with the potential for a vapour cloud explosion and that if the flame receded into the pipe, there might be an internal explosion. For a while, therefore, fuel gas was fed into the line to keep the flame alight.

The liquid which escaped had been held in a section of the flare line near a knockout drum. It should have drained via a small bore pipe into the knockout drum, but the entry of the pipe was blocked. The valve on this pipe had been checked as open, but the possibility of blockage had not been taken into account. The liquid was there in the first place because valve V17, thought to be fully closed, was in fact part open. The valves suffered from build-up of pyrophoric scale. They had no indicators showing positively the valve position. It is estimated that there was about 50 m^3 of hydrocarbons in the line at the time and that 20 m^3 may have escaped.

Among the findings of the investigation were that there was a need for position indicators on the valves; that there had been inadequate planning of the work to be done; that the check that the flare line had been drained was ineffective; that the response to the first, small leak was inadequate; that the procedure for flange breaking was incorrect; that when opening lines with pyrophoric scale, air should be excluded positively by a nitrogen purge, rather than reliance placed on its exclusion by flammable gases present; and that the exhaust gas spark arrester was missing. There should have been a requirement that in breaking a flange sufficient bolts remain in place whilst a gradual opening is made using a flange spreader.

Incident on 22 March 1987

On 22 March 1987 an explosion occurred during the start-up of a hydrocracker unit at the Grangemouth refinery. It involved the disintegration of a low-pressure separator. One fragment from the vessel, weighing 3 te, landed on the foreshore 1 km away.

Accompanied by a fireball, the explosion initiated a severe fire. The refinery sustained extensive damage. One person was killed.

The LP separator (V306) was 3.05 m diameter × 9.1 m long with a design pressure of 9 bar and a calculated burst pressure of 50 bar. It was fitted with a 3 in. relief valve designed for fire relief. Its disintegration was caused by breakthrough of gas from the HP separator (V305) due to loss of level control in the base of the latter. The HP separator pressure was 155 bar. The plant was in start-up mode and the process lines on V306 were closed.

The gas breakthrough occurred due to loss of control of the level at the base of the V305. The pipework taking off the liquid split into two lines, one passing through the valve on the level control loop LIC 3-22 and the other through that on H 3-22. The breakthrough occurred through the LIC 3-22 valve. This valve had been fitted with a low-level trip, but this had been removed in 1985. The liquid at the base of V305 tended to give vortices and the trip system suffered from spurious trips which caused production difficulties. There was an extra-low-level alarm, but this had been on for months, until the bulb failed, and was regarded as spurious. The two float switches were fire damaged, but there was evidence that one had been incorrectly assembled and that on the other the small bore piping was blocked. The operators tended to place more reliance on the measurement provided by a nucleonic level gauge. However, this gauge had a zero error, showing a 10% reading when the true reading was zero. An audit had shown that there was a problem in control of the level on the vessel. In the shift in which the incident occurred valve LIC 3-22 was opened manually at least three times. Just before the explosion, it was opened again, and the level was lost. The HSE report states:

> The refinery had procedures for routine monitoring of interlocks, alarms and trips, but on the checklist for the hydrocracker some were omitted. The detection, trip and alarm systems for extra-low level in V305, had been inoperative for a long time and maintenance staff and operators presumed that these were no longer required. Training of new operators carried out by experienced operators helped to perpetuate this misconception. Although the refinery chief instrument engineer noted in 1985 that the LIC 3-22 trip solenoid had been disconnected, this was not followed up. (paragraph 89)

The report states that there should have been both a high-integrity trip system for level control and a pressure relief system capable of handling the maximum anticipated gas flow and that fuller consideration should have been given to proposals to make modifications to the plant.

It emerged that there had been a previous incident on V305 which was probably a gas breakthrough, but on that occasion the process valves on V306 were open.

The force of the blast was mainly downwards, while the fragments travelled upwards. The TNT equivalent of the explosion was estimated as 90 kg.

Major problems were experienced in the fire fighting. Within 12 h 31 foam and water streams were discharging at a rate of 12,000 USgal/min. The drains were unable to cope with this flow. Hydrocarbons bubbled up in other parts of the site and floated on the water. The situation was exacerbated by large quantities of heavy, waxy material which caused blockages.

Incident on 11 June 1987

On 11 June 1987 at Dalmeny, near Grangemouth, a fire broke out during sludge cleaning work by a contractor in a storage tank, and one man died. The men had airline breathing apparatus (BA) to protect against toxics, but there was no mechanical ventilation and no regular monitoring of the atmosphere. The sludge had a flashpoint of less than 0°C. It transpired that the fire broke out when one man, who had taken off his BA, dropped a cigarette end.

The investigation revealed that there were a number of deficiencies in the arrangement of the contract with the contractor and in the conduct of its personnel. The contractor was a specialist one, well known, considered competent and already working on site. There was no written procedure for the work. There was inadequate enforcement of the 'no smoking' rule, and some contractor's personnel had not received the BP refinery rules booklet. Also inadequate was enforcement of the use of the BA. There was no lighting inside the tank and men discovered they could see better if they took the BA off. The team worked largely unsupervised. They wore the BA when entering and leaving the tank, and evidently also when the supervisor was about to visit, but some did not wear it all the time. The supervisor himself had on occasion removed his BA inside the tank to give verbal instructions.

Anon. (1988c,d); Anon. (1987l); Anon. (1989b); Anon. (1989 LPB 89, p. 13); HSE (1989a); Kletz (1989b); Mahoney (1990); K.X.Wilson (1990a,b); D.J.Lewis (1993)

A117 *Pampa, Texas, 1987*
On 17 November 1987 at Pampa, Texas, a vapour cloud explosion occurred on a plant for the liquid phase oxidation of butane to acetic acid and acetic anhydride using air at about 700 psig. There were three reactors with a capacity of 38 m^3. During the start up of one reactor a rupture or explosion occurred in the line taking the air to the reactor or in the reactor manifold, and butane and acetic acid flowed out. The vapour cloud which formed was ignited by gas-fired boilers some 60 m away, the delay before ignition being about 10 s. The resultant explosion did extensive damage. One aspect of this was that the blast severed piping in many of the sprinkler systems and also ruptured the underground fire water main, rendering the water pressure inadequate for its purpose. Three people were killed and 37 injured.

Mahoney (1990); D.J. Lewis (1993)

A118 *Port Herriot, Lyon, France, 1987*
On 2 June 1987, the Shell depot at Port Edouard Herriot, near Lyon, France, with some 76 tanks, experienced a severe fire. Two persons were killed and eight injured.

At the time of the account quoted the cause of the incident was not established. It states that at the relevant time of 13.15 work was in hand on an electric cable for welding equipment and that the power was off but due to be switched on again at 13.30. The initial event was the formation of a spray in the area of the pumps. There was then a flash.

There followed a series of explosions and fires. Twelve minutes into the event a tank holding 250 m^3 rocketed up 200 m and fell outside the compound. There was a rapid escalation with five further tanks rocketing and falling inside the depot. Tank 6 exploded in what was probably a boilover. The associated fireball was 450 m high and 200 m 'wide'. During the night the fire progressed further.

The extent of the escalation was attributed in large part to the fact that the tanks were old, and did not have a rupture seam in the roof, so that they tended to burst at the base, releasing the whole contents.

Control of the fire was not achieved until 11.00 on 3 June after two heavy duty foam monitors, each of 6 m^3/min capacity, obtained from outside, had been brought into play at 6.30. Among the conclusions drawn in respect of fighting such a fire were that the temperature of the wall of the vapour space of a tank engulfed in fire can rise within 2 min to 500°C, above the autoignition temperature for many flammable mixtures; that water cooling used while the foam attack is being prepared may be ineffective and may cause severe degradation of structures; that 4-hour fire insulation may not be sufficient; that concrete bunds may not last out and that earth mounds are preferable; and that an effective foam attack requires heavy duty equipment capable of 4–6 m^3/min.

Another conclusion was the need to review the fire permit system: the number, the nature and relations between the permits.

Mansot (1989)

A119 *Ras Tanura, Saudi Arabia, 1987*
On 15 August 1987, a leak occurred on a gas plant at Ras Tanura, Saudi Arabia. There were two parallel gas fractionation trains with propane feed. Prior to the incident there had been a number of power interruptions which caused shut-down of one or other of the plants. It is believed that a leak of propane developed in one train, the probable source being a flange on a 4 in. relief line and that the release continued for about half an hour. A large vapour cloud formed and ignited. The ignition was probably from a security vehicle which had stalled and was being restarted. Severe damage was caused.

Mahoney (1990)

A120 *Floreffe, Pennsylvania, 1988*
On 2 January 1988, an oil storage tank of the Ashland Oil Company at Floreffe, Pennsylvania, suffered catastrophic failure during its initial filling. The tank was a 120 ft diameter × 48 ft high cone roof tank. It was 40 years old and had been dismantled at a former site and re-erected. The failure was a sudden rupture. The force of the fluid spurting out one side caused the tank to move 100 ft backwards off its foundations. Some 92,400 bbl of diesel fuel were spilled. The oil overflowed the bund and much of it went into the river.

The investigation found that the rupture occurred due to low temperature embrittlement initiated at a flaw in the tank shell base metal, about 20 cm up from the bottom. The flaw had been created by an oxyacetylene cutting torch and had been there since the initial fabrication. The actual fracture was in the shell base metal; it did not follow the welds but crossed them. In its previous service, the tank had stored heated product, while in its new service the product was not heated. It was the first time that in its new service the tank had been filled to maximum capacity in cold weather.

A121 *Norco, Louisiana, 1988*
On 5 May 1988, an explosion occurred on a catalytic cracker at the refinery at Norco, Louisiana. There was a rupture, due to internal corrosion, on an 8 in. elbow in the depropanizer overhead piping, which released 9 te of hydrocarbons. A vapour cloud formed and after about 30 s found a source of ignition, probably the FCC charge heater. The resultant vapour cloud explosion did extensive damage and caused immediate failure of all utilities. It put out of action firewater and the four diesel fire pumps, and for several hours the fire fighting effort was limited. Some 20 major vessel or line failures occurred. Analysis of bolt stretch on columns indicated an overpressure up to 10 psi. Seven people were killed and 28 injured.

Mahoney (1990); D.J.Lewis (1993)

A122 *Antwerp, Belgium, 1989*
On 7 March 1989, the BASF ethylene oxide plant at Antwerp experienced two explosions, each with a fireball. The first occurred in column K303, separating ethylene oxide and acetaldehyde, which disintegrated. The pipework on another column, K302, fractured, so that the column depressurized and flame flashed back into it, causing a second internal explosion, separated from the first by 26 s. The blast, missiles and secondary fires caused extensive damage. Five people were injured.

The investigation found that low cycle fatigue had caused a hairline crack in a welded seam on piping to a level indicator system, resulting in a small leak of ethylene oxide. This led to an accumulation of auto-oxidizable polyethylene glycols in the insulation. Removal of the metal covering of the insulation allowed self-heating to proceed. The insulation reached a temperature which was sufficient to cause decomposition of ethylene oxide stagnant in the piping of the level control system, though it would not have been enough to overcome the cooling effect of flowing vapour.

Mahoney (1990); Kletz (1990e); Anon. (1991 LPB 100, P. 1)

A123 *Baton Rouge, Louisiana, 1989*

On 24 December 1989, an explosion occurred in a refinery at Baton Rouge, Louisiana. An 8 in. diameter pipeline ruptured, releasing a mixture of ethane and propane. A record low temperature (10°F) may have contributed to the failure. The escaping vapour found a source of ignition and there was a vapour cloud explosion. The explosion ruptured a pipe band containing some 70 lines. These included lines for power, steam and firewater, and there was a partial loss of all these utilities. The extensive fire involved two large storage tanks, 12 small tanks and two separator units.

Mahoney (1990)

A124 *Jonova, Lithuania, 1989*

On 20 March 1989, a refrigerated atmospheric ammonia tank failed at Jonova, Lithuania, leading to both a toxic release and a fire of ammonia as well as fire in a fertilizer store. Seven people were killed and 57 injured.

The tank was 29 m diameter × 20 m high of single wall construction with perlite insulation held in place by an outer steel shell and with a surrounding 14 m high reinforced concrete wall. It had a capacity of 10,000 m^3 and at the time held 7000 te of liquid ammonia at −33°C. The capacity of each of the two pressure relief valves was 4200 m^3/h. The site also had two fertilizer stores, one for 15,000 te and one for 20,000 te as well as one for 20,000 te of ammonium nitrate.

The rupture was sudden and the force of the release caused the tank to move sideways from its base, smash through the concrete wall and fetch up 40 m away, leaving its bottom still on the foundations. The devastation around the tank was severe. The escaping liquid ammonia formed a pool which in places was 0.7 m deep. The vapour above the pool suddenly caught fire and the whole area was engulfed in flames. The fire set alight material on a conveyor belt to the 15,000 te store of NPK fertilizer, a ‘cigar burning’ material. The burning conveyor fell into the store and initiated a self-sustaining decomposition.

After 12 h the pool of ammonia had evaporated. The fertilizer continued to burn for 3 days.

The plant was 12 km from Jonova, a town of about 40,000 inhabitants. A large cloud of ammonia and nitrous fumes spread 35 km, covering an area of 400 km^2. The cloud height is described as being 100, 400 and 800 m at distances of 5, 10 and 20 km, respectively. Some 32,000 people were evacuated.

The events leading up to the rupture were as follows. Due to an error, 14 te of warm ammonia at 10°C were transferred to the tank, where they formed a layer on the bottom. In due course this layer rose suddenly to the surface. The event was akin to a ‘rollover’, although this term is normally associated not with a pure liquid but with one of varying composition, such as LNG. The higher vapour pressure of the warmer liquid caused a sudden rise in pressure in the tank, which the pressure relief valves were unable to handle, and the tank burst. At the time the refrigeration compressors were not working, but this probably played little part in the incident.

Kletz (1991a); Andersson (1991a,b); Anon. (1992 LPB, p. 11); Andersson and Lindley (1992 LPB 107); Kukkonen *et al.* (1992); Wilday (1992 LPB 108, 109); Kukkonen *et al.* (1993)

A125 *Peterborough, UK, 1989*

On 22 March 1989, an explosion occurred in the yard of Vibroplant Ltd at Peterborough on a ICI truck carrying commercial explosives. The driver had missed his way and shortly after 9.30 a.m., approximately, entered the yard to turn round, when, as the vehicle passed over a speed ramp, there was a minor explosion inside the load compartment which blew the rear roller shutter door open. The driver stopped the vehicle, and he and the attendant got out to investigate. Smoke and flames were coming through gaps at the side of the door but no fire could be seen inside. They alerted the Vibroplant personnel in the yard and one of the latter telephoned the emergency services. At first only a small amount of black smoke was to be seen coming from the vehicle, but as the fire progressed there were minor detonations, or ‘pops’, and thick yellow smoke began to emerge. At 9.43–9.44 a.m. two fire tenders arrived. At 9.45 a.m. the load exploded. The scene following the explosion is shown in Figure A1.18. One person was killed and 107 were injured, of whom 84 were treated in hospital.

The load was a mixed one, consisting 150 kg of Powergel 800; 500 kg of Powergel E800; 56 kg of Magna Primers; 76 kg of Ammon-Gelit; detonators and fuseheads. The latter included uncut Cerium combs, 2400 in three boxes. The total mass of explosive had a TNT equivalent of some 800 kg.

The cause of the explosion was determined as a box of Cerium fusehead combs which were in unsafe packaging.

The report of the HSE (1990b) gives details of the damage and injury done by the event. With respect to damage, the analysis includes the following:

	Distance (m)	*Overpressure* (psi)
Clean area	14	78
Fireball	18	44
Total destruction of cavity brick/block walls of steel framed building	30	14
Serious damage to concrete frames of building	110	1.7
Window breakage:		
90%	≈225	0.69
50%	≈360	0.37
Up to	≈580	0.19

The clear area is the area of the yard which was cleared of cars, etc. The report also gives a map showing the fall of major fragments.

With respect to injury, plans are given showing the location of the persons exposed and of those who were blown over or suffered eardrum rupture. Two of the plans are shown in Figure A1.19.

At the instant of the explosion there were some 31 persons within 60 m of the vehicle. The plans show

Number of persons			
Distance (m)	<20	20–40	40–60
Exposed	3	12	31
Blown over	2	10	15
Eardrum rupture	2	4	

Figure A1.18 *Peterborough, 1989: Vibroplant works yard after the explosion (Courtesy of the Peterborough Evening Telegraph)*

The person who died was a fireman who was engulfed in the fireball, which extended 18 m. Another fireman at 25 m suffered minor burns. Other information on injuries includes

	Distance (m)	*Overpressure* (psi)
Burns:		
Fireman engulfed in flames	18	44
Fireman suffered slight burns	25	21
Eardrum rupture:		
100%	28	17
50%	30	15
Up to	45	6.6
Blown off feet:		
50%	55	4.7
Up to	70	3.2
Severe injury from fragments other than glass	40	
Cuts from glass:		
Cuts to all	0–50	>5.5
Cuts to many	70–100	3.2–1.9
Cuts to some	100–150	1.9–1.15
Cuts up to	≈200	0.8

Further details are given in the HSE report.

HSE (1990b); Anon. (1991 LPB 98, p. 24)

A126 *Richmond, California, 1989*

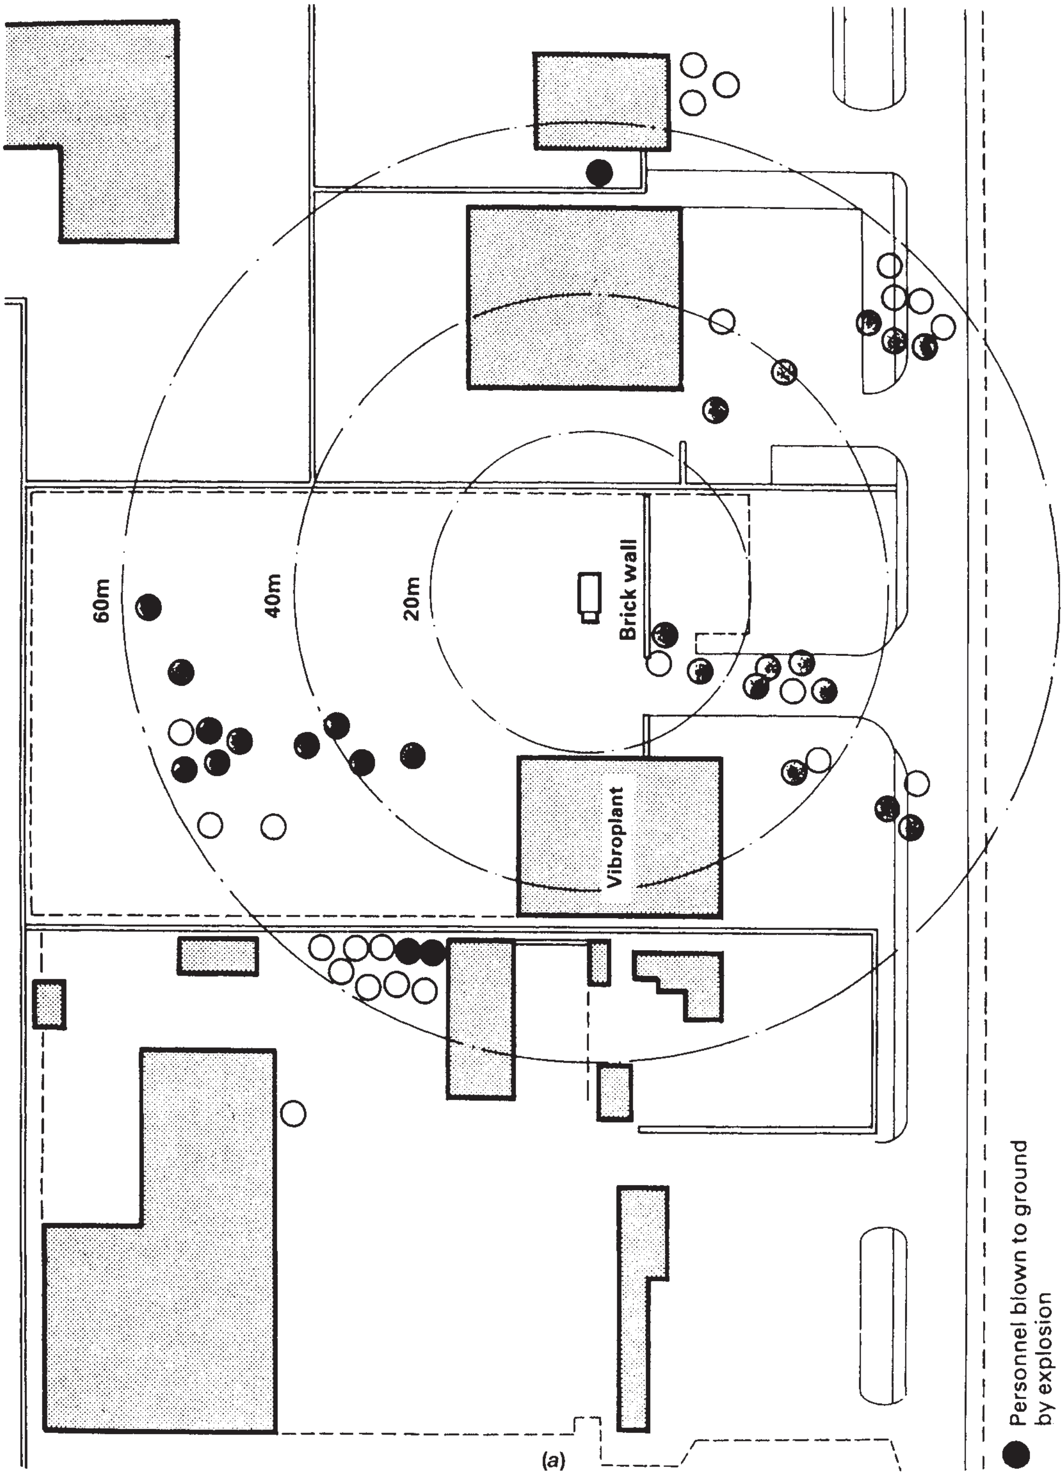
On 10 April 1989, in a refinery at Richmond, California, a 2 in. line carrying hydrogen at about 2800 psi suffered a failure, apparently at a weld, giving rise to a jet flame, which impinged on the support of a reactor, 100 ft high and at least 10 ft diameter and with a wall thickness of 7 in., in a hydrocracker unit. The resultant failure of the reactor led to extensive damage.

Mahoney (1990)

A127 *Ufa, Soviet Union, 1989*

On 4 June 1989, a massive vapour cloud explosion occurred in an LPG pipeline at Ufa in the Soviet Union. A leak had occurred in the line the previous day or, possibly, several days before. In any event, the engineers responsible had responded not by investigating the cause but by increasing the pressure. The leak was located some 890 miles from the pumping station, at a point where the pipeline and the Trans-Siberian railway ran in parallel through a defile in the woods, with the pipeline some half a mile from, and at a slightly higher elevation than, the railway. On the day in question the leak had created a massive vapour cloud which is said to have extended in one direction five miles and to have collected in two large depressions.

Some hours later two trains, travelling in opposite directions, entered the area. The turbulence caused by their passage would promote entrainment of air into the cloud. Ignition is attributed to the overhead electrical power supply for one or other of the trains. There followed in quick succession two explosions and a wall of fire passed through



(a)

Figure A1.19 Continued

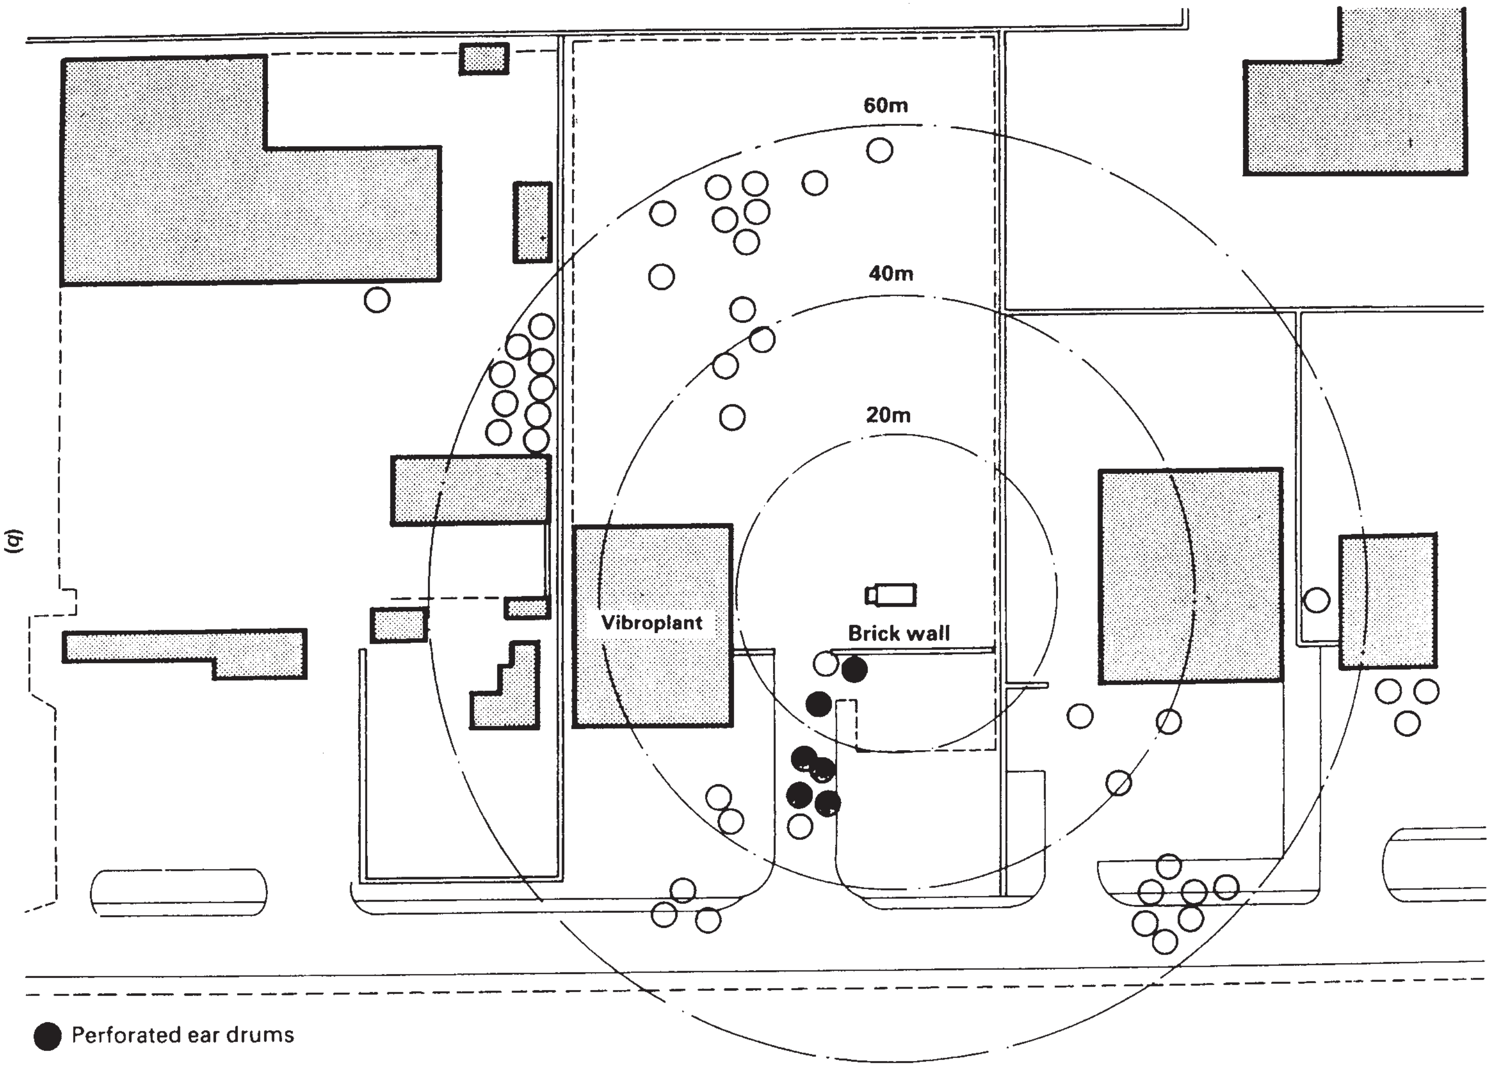


Figure A1.19 Peterborough, 1989: site plan showing location of certain injuries (Health and Safety Executive, 1990c): (a) persons blown to the ground by the explosion; and (b) persons suffering perforated eardrums (Courtesy of HM Stationery Office) the cloud. Large sections of each train were derailed and the derailed part of one may have crashed into the other. The death toll is uncertain, but reports at the time gave the number of dead as 462 and of those treated in hospital as 706, many with 70–80% burns.

Hofheinz and Kohan (1989); D.J. Lewis (1989 LPB 90, 1993)

A128 *Bangkok, Thailand, 1990*

At 22.30 on 24 September 1990, a road tanker carrying LPG was involved in a traffic accident at a busy road junction in the centre of Bangkok. Some 5 te of LPG was released but did not ignite immediately. When the cloud did ignite, there was evidently a flash fire, but accounts spoke also of an explosion, probably from gas which had entered a nearby building. In the worst affected area, almost all the shop houses on both sides of the street were destroyed. Reports gave some 68 persons dead and over 100 injured.

The vehicle was a flat bed lorry carrying two LPG tanks. The two tanks were interconnected by two lines and it appears that these were severed in the accident. The tanker had no license to carry LPG.

Anon. (1991 LPB 101, p. 19)

A129 *Chalmette, Louisiana, 1990*

On 3 November 1990 in a refinery at Chalmette, Louisiana, failure involving a heat exchanger shell led to a release of hydrocarbons. A vapour cloud formed, was ignited by a heater and gave a vapour cloud explosion which did extensive damage.

Marsh and McLennan (1992)

A130 *Nagothane, India, 1990*

On 6 November 1990 at Nagothane, India, a leak occurred on a pipeline transporting ethane and propane to a gas cracker complex. A vapour cloud formed and ignited at an offsite gas treatment and compression facility. The cracker was not damaged by the resultant vapour cloud explosion, but serious damage was done to the offsite units. There were 31 deaths.

Marsh and McLennan (1992)

A131 *Stanlow, Cheshire, 1990*

On 20 March 1990, a reactor at the Shell plant at Stanlow, Cheshire, exploded. The explosion was due to a reaction runaway.

The vessel was a 15 m^3 batch reactor containing some 13.5 te of reaction mixture. The reaction was the Halex production of 2,4-difluoronitrobenzene (DFNB), using *N*, *N*-dimethylacetamide (DMAC) as solvent. The DFNB was then reacted to obtain the final product 2,4-difluoroaniline (DFA).

The batch had been heated from ambient to 165°C over 3 h, in the normal way. It then rose above 170°C, instead of starting to dip slightly, and, unusually, began to vent gas. In the following 10 min the heating was switched over to cooling, but the temperature and pressure in the reactor continued to rise, at an increasing rate. The control room operators were unaware of the runaway; they were looking at a different display on the VDU. They were alerted to it by an outside operator.

The pressure in the vessel reached a value later assessed as about 60–80 barg, which compares with the relief valve set pressure of 5 barg. The event generated blast, a fireball and missiles. The vessel body unwrapped into a flat plate and the cover was hurled 200 m; other missiles went up to 500 m. The reactor structure collapsed, the fluoroaromatics plant was devastated and structural damage was done to nearby buildings. One man subsequently died, and five others were injured.

There was evidence, from an eyewitness and from a severely burned lamp fitting which became a missile (Missile 47), that prior to the explosion there had been a jet flame above the reactor for some 30–120 s before the explosion, the leak coming from a flange or crack. The blast damage in the works had some unusual characteristics, decreasing only slowly with distance. The reactor had a vapour space of 3 m^3, but the blast damage was much greater than could be accounted for by a physical explosion involving such a volume, and a combustive event was indicated. Analysis pointed to an event giving a long impulse with a duration time of perhaps 400 ms, compared with, say, no more than 50 ms for a vapour cloud explosion on the one hand and 10 s for an unconfined fireball on the other. The relatively long duration of the explosion would be due to the rate limitation imposed by air entrainment. The investigators called the event which occurred a 'highly congested fireball'. The fetch of the missiles pointed to a pressure at the source in the range 60–80 barg. It was estimated that some 10 te of material had been ejected from the reactor at about 70 barg in a congested area and had been ignited by the jet flame above the vessel acting as a strong ignition source. These 10 te had an energy of combustion of 230,000 MJ; the event was consistent with an energy release of about one-fifth of this.

Much of the damage done was due to the rarefaction wave. Many components were more sensitive to a negative that to a positive pressure deviation.

The investigation found that the runway was due to the presence of acetic acid. This was detected by smell in the contents of a vent knockout vessel, and, much later, it was identified in a sample of the DMAC from the batch. Investigation revealed a rather complex chemistry. It showed that, when added to a Halex reaction mixture, acetic acid causes exothermic reaction and gas evolution. The DFNB process involved a later stage of batch distillation in which the successive fractions were toluene, DMAC and DFNB. The investigators discovered that during one such batch water had entered the still via a leaking valve. The water had been removed by prolonged azeotropic distillation, using toluene. Under these conditions, DMAC undergoes slow hydrolysis, giving dimethylamine and acetic acid. However, for there to be any significant yield of acetic acid, the presence of DFNB is necessary, since this reacts with the dimethylamide, and thus shifts the equilibrium. On this occasion, the DMAC had then been further distilled to purify it. It turned out, however, that DMAC and acetic acid form a maximum boiling azeotrope with a boiling point close to that of pure DMAC. The presence of the acetic acid in the DMAC was not detected by the measurement of boiling point nor by the particular gas chromatograph method in use. Thus the water ingress incident evidently led to a batch of recycled DMAC which was contaminated with acetic acid, with the consequences described.

Anon. (1991k); Kletz (1991 LPB 100); Mooney (1991); Redman and Kletz (1991); Cates (1992); van Reijendam *et al.* (1992)

A132 *Coode Island, Mevaporourne, Australia, 1991*
On 21 August 1991, an explosion occurred at A Terminal of Terminal Pty at Coode Island, Mevaporourne, Australia. The site involved had 45 storage tanks, none pressurized, with a vapour recovery system. A 230 te acrylonitrile tank was lifted off its base and projected over four other tanks into the forecourt. There followed a series of bund and tank fires and tank explosions, at the end of which only 13 tanks were left undamaged. There were no deaths or serious injuries.

The cause of the initial explosion has not yet been established. Some of the explanations considered are rehearsed by I. Thomas (1991), including his own of exothermic polymerization in the vapour recovery system. A critique of this explanation is given by Croudace (1993 LPB 112).

Anon. (1991b); I. Thomas (1991); Anon. (1992c); Alexander (1992a); Marsh and McLennan (1992); Croudace (1993 LPB 112)

A133 *Seadrift, Texas, 1991*
At 1.18 a.m. on 12 March 1991, an ethylene oxide redistillation column at the Union Carbide plant at Seadrift, Texas, exploded. A large fragment from the explosion hit pipe racks and released methane and other flammable materials. All utilities at the plant were lost. There was a substantial loss of firewater from water spray systems damaged or actuated by loss of plant air. The explosion and ensuing fire did extensive damage and one person was killed.

The plant had been down for routine maintenance. Start-up began in the late afternoon of 11 March, but the plant was shut-down several times by trip action before the cause was identified and rectified. Operation was finally established around midnight. The plant had been operating normally for about an hour when the explosion occurred.

The explosion was attributed to the development of a hot spot in the top tubes of the vertical, thermosiphon reboiler such that the temperature reached over 500°C instead of the normal 60°C, combined with a previously unknown catalytic reaction, involving iron oxide in a thin polymer film on the tube, which resulted in decomposition of the ethylene oxide.

A low recirculation ratio in the reboiler could give in some of the tubes low flow, loss of liquid film and stagnant vapour. The account by Viera, Simpson and Ream (1993) gives a detailed discussion of measures to ensure that all the heated surfaces of the reboiler are kept wetted.

Marsh and McLennan (1992); Viera, Simpson and Ream (1993)

A134 *Bradford, UK, 1992*
On 21 July 1992, a series of explosions leading to an intense fire occurred in a warehouse at Allied Colloids Ltd, Bradford. None of the workers at the factory was injured but three residents and 30 fire and police officers were taken to hospital, mostly suffering from smoke inhalation. The fire gave rise to a toxic plume and the run-off of water used to fight the fire caused significant river pollution.

The HSE investion (HSE, 1993b) concluded that some 50 min before the fire two or three containers of azodiisobutyronitrile (AZDN) kept at a high level in Oxystore 2 had ruptured, probably due to accidental heating by an adjacent stream condensate pipe. AZDN is a flammable solid incompatible with oxidizing materials. The spilled material probably came in contact with sodium persulfate and possibly other oxidizing agents, causing delayed ignition followed by explosions and then the major fire.

The warehouse contained two storerooms. Oxystore No. 1 was designed for oxidizing substances and Oxystore No. 2 for frost-sensitive flammable products; this second store was provided with a steam heating system. In 1991, an increase in demand for oxidizers led to a change of use, with both stores now being allocated to oxidizing products. A misclassification of AZDN as an oxidizing agent in the segregation table used led to this flammable material being stored with the oxidizers.

In September 1991, the warehouse manager, after discussions with the safety department, submitted a works order for modifications to the oxystores, including Zone 2 flameproof lighting, temperature monitoring equipment, smoke detectors and disconnection of the heater in Oxystore 2. An electrician made a single visit in which he did not disconnect the heater but simply turned the thermostat to zero. Although safety-related, the work was given low priority and 10 months later none of it had been started.

The explosion started at 2.20 p.m. and the first fire appliance arrived at 2.28 p.m. The fire services experienced considerable difficulties in obtaining a water supply adequate to fight the fire. At 3.40 p.m. power was lost on the whole site when the electricity board cut off the supply because the fire was threatening the main substation. The loss of power led to the shut-down of the works effluent pumps and escape of contaminated firewater from the site.

The fire services made early contact with the company's incident controller and strongly advised the sounding of the emergency siren, but this was not done until 2.55 p.m., when the incident had escalated. The fire gave rise to a black cloud of smoke, which drifted eastward over housing. The company stated on the day that the smoke was non-toxic. The HSE report, which gives a map of the smoke plume, states that 'it was in fact smoke from a burning cocktail of over 400 chemicals and only some of them would have been completely destroyed by the heat of the fire'.

The HSE report cites evidence that the warehouse had not been accorded the same safety priority as the production functions. It came under the logistics department, none of whose 125 personnel had qualifications as a chemist or in safety.

HSE (1993b); Anon. (1994 LPB 119, p. 15); V.C. Marshall (1994 LPB 117)

A135 *Castleford, UK, 1992*
At about 1.20 p.m. on Monday, 21 September, 1992, a jet flame erupted from a manway on the side of a batch still on the Meissner plant at Hickson and Welch Ltd at Castleford. The flame cut through the plant control/office building, killing two men instantly. Three other employees in these offices suffered severe burns from which two later died. The flame also impinged on a much larger four-storey office block, shattering windows and setting rooms on fire. The 63 people in this block managed to escape, except for one who was overcome by smoke in a toilet; she was rescued but later died from the effects of smoke inhalation.

The flame came from a process vessel, the '60 still base', used for the batch distillation of organics, which was being raked out to remove semi-solid residues, or sludge. Prior to this, heat had been applied to the residue for three hours through an internal steam coil. The HSE investigation (HSE, 1993b) concluded that this had started self-heating of the residue and that the resultant runaway reaction led ignition of evolved vapours and to the jet flame.

The 60 still base was a 45.5 m^3 horizontal, cylindrical, mild steel tank 7.9 m long and 2.7 m diameter. The still was used to separate a mixture of the isomers of mononitroluene (MNT, or NT), two of which (oNTand mNT) are liquids at room temperature and third (pNT) a solid; other by-products were also present, principally dinitrotoluene (DNT) and nitrocresols. It is well known in the industry that these nitro compounds can be explosive in the presence of strong alkali or strong acid, but in addition explosions can be triggered if they are heated to high temperatures or held at moderate temperatures for a long period.

The still base had not been opened for cleaning since it was installed in 1961. Following a process change in 1988 a build-up of sludge was noticed, the general consensus being that it was about 1820 l, equivalent to a depth of about 10 cm, though readings had been reported of 29 cm and, the day before the incident, of 34 cm. One explanation of this high level was that on 10 September the still base had been used as a Vacuum cleaner' to suck out sludge left in the 'whizzer oil' storage tanks 162 and 163, resulting in the transfer of some 3640 l of a jelly-like material. The intent had been to pump this material to the 193 storage but transfer was slow and was not completed because the material was thick. The batch still was used for further distillation operations, which were completed on September 19. The still base was then allowed to cool and on September 20 the remaining liquid was pumped to the 193 storage.

On September 17 the shift and area managers discussed cleaning out the still base. The former had been told by workers that the still had never been cleaned out and he realized that the sludge covered the bottom steam heater battery. It was agreed to undertake a clean-out. The area manager gave instructions that preparations should be made over the weekend, but when he arrived on the Monday morning nothing had been done. He was concerned about the downtime, but was assured that this could be minimized and gave instructions to proceed.

At 9.45 a.m. the area manager gave instructions to apply steam to the bottom battery to soften the sludge. Advice was given that the temperature in the still base should not be allowed to exceed 90°C. This was based solely on the fact that 90°C is below the flashpoint of MNT isomers. However, the temperature probe in the still was not immersed in the liquid but in fact recorded the temperature just inside the manway. Further, the steam regulator which let down the steam pressure from 400 psig (27.6 bar) in the steam main to 100 psig (6.9 bar) in the batteries was defective. Operators compensated for this by using the main isolation valve to control the steam. This valve was opened until steam was seen whispering from the pressure relief valve on the battery steam supply line. This relief valve was set at 100 psig but was actually operating at 135 psig (9 bar), at which pressure the temperature of the steam in the battery tubes would be about 180°C.

The clean-out operation, which had not been done in the previous 30 years, was not subjected to a hazard assessment to devise a safe system of work, and there were defects in the planning of and permit-to-work system of the operation. The task was largely handled locally with minimal reference to senior management and with lack of formal procedures, although such procedures existed for cleaning other still bases on the site. The permits were issued by a team leader who had not worked on the Meissner plant for 10 years prior to his appointment on September 7. At 10.15 a.m. he made out a permit for a fitter to remove the manlid. The fitter signed on about 11.10 a.m. and shortly after went to lunch. Operatives who were standing by offered to remove the manlid and the same team leader made out a permit for them to do so. When the fitter returned from lunch it was realized that the still base inlet had not been isolated and a further permit was issued for this to be done.

Meanwhile, the manlid had been removed. The area manager asked for a sample to be taken. This was done using an improvized scoop. He was told the material was gritty with the consistency of butter. He did not check himself and mistakenly assumed the material was thermally stable tar. No instructions were given for analysis of the residue or the vapour above it. Raking out began, using a metal rake which had been found on the ground nearby. The near part of the still base was raked. The rake did not reach to the back of the still and there was a delay while an extension was procured. The employees left to get on with other work and it was at this point that the jet flame erupted.

The HSE report states that analysis of damage at the Meissner control building at 13.4 m from the manway source indicated that at this building the jet flame was 4.7 m diameter. The jet lasted some 25 s and had a surface emissive power of about 1000 kW/m^2. The temperature at 6 m from the manway would have been about 2300°C.

The company employed some highly qualified staff with considerable expertise in the manufacture of organic nitro compounds. The HSE report describes some of the investigations of thermal stability, safety margins, etc., in which these staff were involved. It also comments in relation to the incident in question, 'Regrettably this level of understanding was not reflected in the decision which was made on 21 September when it was decided that the 60 still base would be raked out.'

As soon as the personnel at the gate office saw the flame one of them made a '999' emergency call. The employee requested the ambulance and fire services, but spoke only to the former before the call was terminated at the exchange. Thereafter incoming calls prevented further outgoing calls for assistance.

Just over a year before the incident the management structure had been reorganized. This involved replacing a hierarchical structure with a matrix management system, eliminating the role of plant manager and instituting a system in which production was coordinated through senior operatives acting as team leaders. The area managers had a significant workload. In addition to their production duties they had taken over responsibility for the maintenance function, which had previously been under the works engieering department. Managers were not meeting targets for planned inspections under the safety programme, and this was said to be due to lack of time.

C. Butcher (1994); HSE (1994b); Kletz (1994 LPB 119)

A136 *Sodegaura, Japan, 1992*

At 15.52 on 16 October 1992 at the Fuji Oil Sodegaura refinery at Sodegaura City, Japan, a large release of hydrogen occurred from a rupture on a feed/reactor effluent heat exchanger on the heavy oil indirect desulfurization unit as the plant was being started up after a shut-down. There was a delay of a few minutes, during which personnel took measures to try to stop the release, before the leak found a source of ignition and exploded. Ten were killed and seven injured.

The investigation found that the leak occurred at a gasket retainer on the heat exchanger as illustrated in Figure A1.20. The gasket retainer had shrunk due to repeated thermal cycling and it suffered wear at the point shown as X on the diagram. The defect was detected and during a shut-down the surface was repaired by grinding. However, the effect of this was to cause the retainer to ride beyond the groove so that when the retainer was heated during start-up, a gap opened up and the escape occurred.

High Pressure Gas Safety Institute of Japan (1993 LPB 116)

A137 *Hoechst Incidents, Germany, 1993*

On 22 February 1993, an accident occurred at the Griesheim works of Hoechst, which was unprecedented in the company's 130-year history. By April 2, there had been at five sites a series of no less than 14 incidents, comprising 11 releases, two fires and one explosion, of which three were considered serious by the company.

Incident on 22 February 1993

The first of these, at 4.14 a.m. on 22 February, was a reaction runaway which occurred when a reactor for the production of *o*-nitroanisol was charged with reaction mixture with the agitator off and the latter was then switched on. Some 10 te of material was discharged through two safety valves. The ambient temperature was −2°C and most of the material solidified, but the residual gas cloud spread across the Main and affected an area of some 30 ha in Frankfurt.

The information available to the works manager, a materials safety data sheet conforming to the DIN standard, was that *o*-nitroanisol is 'slightly toxic', and he gave this description to the press. As it happened, the previous Friday this data sheet had been the subject of a revision, to the effect that the substance had been found to be carcinogenic to rats when administered in large doses over a long period. The revision had been known to the company's specialists since November 1992 but not to the works manager. The toxicity of the substance was the subject of press comment.

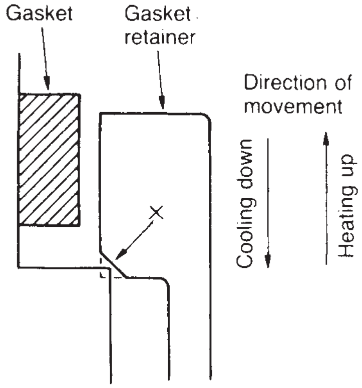

Figure A1.20 *Sodegaura, 1992: simplified diagram of heat exchanger gasket retainer. The gasket retainer suffered wear at the point marked X and repair was made by grinding, with loss of metal broadly as shown by the dotted portion (after the High Pressure Gas Safety Institute of Japan, 1993 LPB 116)*

Incident on 15 March 1993

The second serious incident, was on 15 March, on one of four parallel trains for the production of polyvinylalcohol. At the location in question in normal operation the material was in gel form on a conveyor belt inside an enclosure, but at the time the belt was stopped and empty. That morning the enclosure, which was normally kept inerted with nitrogen, was inspected. A precutter was still operating. An explosion occurred which killed the shift supervisor and injured the section manager. There followed a fire, which gave rise to a large column of smoke visible for some distance but which was rapidly brought under control.

An investigation by the authorities concluded that the enclosure had contained flammable vapours, that air had entered the enclosure during the inspection and that tramp metal had entered, giving rise to a spark at the precutter.

Incident on 2 April 1993

The third incident, on 2 April, involved a release of oleum. The release occurred when air pressure was applied to a vessel containing oleum and, due to a blockage in an outlet pipe, caused by crystallization, the oleum passed instead into an absorber where it reacted violently with the absorbent. A glass pipe ruptured and some 50 kg of oleum was released.

Owing to difficulties experienced with the alarm system some 13 people at the research centre came in contact with the cloud and received treatment at the medical centre.

Ondrey (1993a,b); Schonfeld (1993); Vennen (1993)

A138 *Dronka, Egypt, 1994*

On 2 November 1994, blazing liquid fuel flowed into the village of Dronka, Egypt. The fuel came from a depot of eight tanks each holding 5000 te of aviation or diesel fuel. The release occurred during a rainstorm and was said to have been caused by lightning. Reports put the death toll at more than 410.

Reuter (1994)

A139 *Ukhta, Russia, 1995*

Early in the morning on 27 April 1995, an ageing gas pipeline exploded in a forest in northern Russia. Reports described fireballs rising thousands of feet in the air and the inhabitants of the city of Ukhta, some eight miles distant, as rushing out in panic. At Vodny, six miles away, the sky was so bright that people thought the village was on fire. The pilot of a Japanese aircraft passing over at some 31,000 ft perceived the flames as rising most of the way towards his plane.

Anon. (1995)

A140 *Terminal Fire Savannah, Georgia, 1995*

On April 10, 1995, at approximately 11:30 p.m., explosions and fire occurred at Powell Duffryn Terminals, Inc. (PDTI), a commercial bulk liquid chemical storage and transfer facility, in Savannah, Georgia. Flames and thick black smoke from the fire forced the residents of the adjacent townhouse development to evacuate immediately. It took firefighters almost 3 days to finally put out the fire. The fire was within a concrete walled enclosure area containing six large storage tanks. During the fire, part of the enclosure wall was breached releasing contaminated firewater. The run-off from the fire contaminated an adjacent marsh on the Savannah River resulting in a fish kill. (This first paragraph and the four following it were taken almost verbatim from the Executive Summary of the EPA's Chemical Emergency Preparedness and Prevention Office report entitled *EPA Chemical Accident Investigation Report*, PDTI. It is EPA Report 550-R-98-003.) (A summary report by David Chung entitled *Explosion and Fire* at Powell Duffryn Terminals – Savannah, Georgia was also used.)

After the fire, chemicals leaking from the storage tanks in the enclosure area reacted and produced toxic hydrogen sulfide gas. The hydrogen sulfide gas release forced residents within one-half mile of the facility to evacuate. As many as 2000 people were involved in the evacuation. An elementary school nearby was also forced to close. Approximately 300 people went to hospital emergency rooms complaining of symptoms attributed to hydrogen sulfide exposure. For many nearby residents, the evacuation lasted more than 30 days because of the continued evolution of hydrogen sulfide gas from the PDTI site. After the incident, extensive cleanup of the site and neighboring area was required.

Powell Duffryn Terminals Inc is fully enclosed by a security fence with locked gates. On April 10, 1995, the last employee left the site for the day at 5:50 p.m. The gates were locked, and no employees were on-site until after the explosions and fire had occurred.

On the day of the fire, contractor employees had been installing a sealed foam chamber on the storage tanks containing crude sulfate turpentine (CST), a flammable liquid. This closed the CST tanks to the atmosphere and directed CST vapour to the vapour control (VC) system. The VC system was designed to control fume and odour from the CST by capturing the CST vapour using activated carbon in two 50-gallon drums connected to the CST tanks using PVC piping. According to PDTI modification plans, each CST storage tank was supposed to be equipped with a flame arrester at its connection to the PVC piping. These flame arresters had been delivered but not yet installed. In addition, a fixed-piping foam fire protection system was not completed at the time of the fire.

The explosions and fire at PDTI involved CST, which the facility began to store on 17 January 1995. Prior to 1995, the facility was permitted only for storing non-flammable liquids. The facility had not completed modifications to accommodate the storage of flammables when the fire occurred. The CST was stored in three storage tanks (two 237,000 and one 422,000 gallon capacity) in a walled enclosure that contained a total of six tanks. The three CST storage tanks were connected by the partially completed VC system used to remove CST vapour from any venting that may occur. In the same enclosure were three other storage tanks (one 340,000 and two 323,000 gallon, respectively) containing sodium hydrosulfide solution (pH 10.4 to 11.5); Briquest, an acidic cleaning solution (pH of 1) and Antiblaze 80, a fire retardant chemical. These tanks and associated pipes were damaged by the explosions and fire and leaked their contents into the six-tank enclosure area. Reaction of the sodium hydrosulfide with acids present in the enclosure area produced hydrogen sulfide, a toxic, foul smelling gas (EPA May 1998).

The EPA Chemical Accident Investigation Team identified the following as root causes and contributing factors in the accident:

- *The design for the Vapour Control System was inadequate*. There is a documented history of fires in drums containing activated carbon where the organic vapour control design permitted the backflow of air through the drums. Organic sulfur compounds in CST can produce heat when they are adsorbed by the activated carbon. Due to the incomplete vapour control installation, air was permitted to backflow into the CST contaminated drums of activated carbon when the ambient temperature drops and the vapours within the tank contract or if the tank is pumped out.

  It was a very hot afternoon when a tank truck of CST was unloaded. As the evening temperatures cooled, the tank vapour space cooled and the vapour contracted. Air drawn into the drums provided oxygen for the spontaneous combustion.
- *The storage tanks were not equipped with flame arresters*. The lack of these purchased, but not-yet-installed protection devices in the vent piping allowed the fire to travel from the carbon bed to the tank vapour space.
- *The foam fire suppression piping system was not completed on the tanks containing CST.* Despite the fact that flammable CST was being stored, the designed foam suppression system was incompletely installed.
- *Incompatible chemicals were stored in the same walled enclosure area*. A large quantity of sodium hydrosulfide solution was stored in the same enclosed area as an acidic cleaning solution. When the tanks leaked the chemicals reacted generating toxic hydrogen sulfide (H_2S). This noxious H_2S gas caused injuries, forced evacuations and hampered a quick response and cleanup.

For detailed recommendations, see either the EPA Report or David Chung's article.

A141 *West Helena, Arkansas, 1997*

On the afternoon of 8 May 1997, a massive explosion and fire occurred at Unit Two of the Bartlo Packaging Incorporated (BPS) facility located in West Helena, Arkansas. Three West Helena firefighters were killed and 17 required medical attention during the response. (This write-up is taken directly from EPA/OSHA Joint Chemical Accident Investigation Report, EPA 550-R-99-003. April 1999. Portions are taken word for word from the report.)

Hundreds of residents and patients at a local hospital were either evacuated or sheltered-in-place. The Mississippi River traffic and major roads were closed for approximately 12 h due to the release of toxic materials from the facility.

BPS employees observed smoke in the Unit Two warehouse and all employees evacuated the building prior to the explosion. Members of the West Helena Fire Department responded to the scene within minutes. A reconnaissance team of four firefighters was outside of the building when an explosion occurred in the warehouse. Three firefighters were killed when they were struck by materials from a falling wall. The fourth firefighter was injured seriously.

EPA and the OSHA conducted a joint investigation of the incident. The team determined that the incident was most likely caused by the decomposition of a bulk sack containing the pesticide Azinphos methyl (AZM) 50W which had been placed against or close to a hot compressor discharge pipe. Under this scenario, the heat from the discharge pipe would have caused the pesticide to decompose and give off flammable vapours, which resulted in the fatal explosion.

A142 *Longford, Victoria, Australia, 1998*

On Friday September 25, 1998, about 12:26 in the afternoon a reboiler ruptured at the Longford Gas Plant. The fracture released hydrocarbon vapours and liquid. The vapours travelled towards the area of the fired heaters where it ignited.

Two gas employees were killed and eight others were injured. Property damages were estimated initially to be over $187,000. Supplies of natural gas to domestic and industrial users were interrupted between 9 and 19 days. The State of Victoria, which is highly dependent on natural gas, suffered substantial disruption to the economy.

The unit in which the release and fire originated was designed to remove ethane, propane, butane and other higher chain hydrocarbons by absorbing them in 'lean oil'. The oil, now saturated with light hydrocarbons was called 'rich oil.' 'Rich oil' was distilled to release these hydrocarbons and it was now lean again. The exchanger that ruptured was the reboiler. The cold rich oil was in the tubes and heated by warm lean oil.

Investigators determined that the loss was attributed to the fracture of a heat exchanger following a process upset that was set in motion by the unintended, sudden shutdown of warm lean oil pumps. Following the loss of the lean oil flow, the condensate flowing from the absorbers was flashing at lower and lower temperatures. Ice formed on the outside of the heat exchanger. Simulations indicate that the temperature reached as low as −48°C (−54°F). The reduction in temperature caused embrittlement of the heat exchanger's steel shell.

When hot lean oil was reintroduced into the vessel it ruptured releasing about 22,000 pounds of hydrocarbon vapour which exploded. (Technically it was reported not as a vapour cloud explosion, but a deflagration or flash fire.) An estimated 26,000 pounds of hydrocarbon vapour burned as a jet fire.

After the initial fire, the flame front travelled back to the source and a prolonged fire developed. This fire was beneath a critical pipe rack called 'King's Cross.' The flames impinging on this rack lead to three other rapid releases of flammable inventories and fireballs. The pipelines in this fire-affected area were major interconnections between three gas plants. It was difficult to isolate under these conditions. It required nearly 2.5 days for the total isolation of the piping network to stop the fire.

The Australian Government ordered a Royal Commission to investigate the cause of the accident. Follow-up reports provided some significant major lessons for the industry.

1. The Safety Management System was judged incomplete. This included the lack of operator training associated with the loss of lean oil flow, the circumstances in which brittle fracture might occur and the lack of discussion of this potential problem in procedures for shut-down or start-up.
2. One report listed the operator training emphasized the training was provided for the operators to do their job, rather than have the deeper understanding they needed to deal with unforeseen problems.
3. Changes in organization during the 1990s is also mentioned as a major contributor to this accident. Organizational changes were not subject to Management of Change scrutiny at this location. Until 1991 engineers worked at the Longford Plant on a daily basis. In 1992, as part of a restructuring of the company, all of the plant engineers were moved to Melbourne. The Commission's official report states, 'The physical isolation of the engineers from the plant deprived operations personnel of engineering expertise and knowledge which previously they gained through interaction and involvement with engineers on site. Moreover the engineers themselves no longer gained an intimate knowledge of plant activities.' The number of supervisors and associated staff was reduced from 25 to 17 between 1993 and 1998. The maintenance staff was also reduced from 67 to 58 during that time.

The Commission stressed that the Audit and Review functions of the Safety Management System provides opportunities to discover gaps. It stressed the need for challenging rigorous corporate audits. The commission concluded that the methodology employed by the assessment team earlier in 1998 was flawed and failed to identify significant deficiencies (Coco, 2001; Boult, 2001; Kletz-2001).

Augusta, Georgia, 2001

On March 13, 2001, three people were killed as they opened a process vessel containing hot plastic in Augusta, Georgia. They were unaware that the vessel was pressurized. The workers were killed when the partially unbolted cover blew off the vessel, expelling hot plastic. The force of the release caused hot oil tubing breakage, and a leak ignited. (Due to the serious nature of this incident, the US Chemical Safety and Hazard Investigation Board (CSB) initiated an investigation. Their results were reported in *Investigation Report: Thermal Decomposition* – BP Amoco Polymers – Report No. 2001-03-1-GA, June 2002. This write-up is an abbreviated version of the CSB Report and some is copied verbatim.)

Workers were attempting to open a cover on a polymer catch tank. The tank was designed to receive partially reacted waste diverted from a chemical reactor during periods of start-up and shut-down.

Twelve hours prior to the incident, an attempt was made to start the production unit. The start-up was aborted due to problems downstream of the reactor. However, prior to shut-down an unusually large amount of partially reacted material had been sent to the polymer catch tank. Hot molten plastic inside the tank continued to react and also began to slowly decompose, thereby generating gases and causing the contents of the tank to foam. The material expanded as foaming continued, and eventually the entire tank was filled. The material then forced its way into connecting pipes, including the normal and emergency vents.

Once in the pipes, the plastic solidified as it cooled, resulting in a hardened layer 3–5 in. thick around the entire inner wall of the tank. The core of the plastic mass remained hot and molten, and likely continued to decompose over several hours, generating gases that pressurized the vessel.

Before opening the polymer catch tank, personnel may have relied on a pressure gauge and a transmitter on the vent piping from the vessel. However, any reading from the pressure gauge would likely have been unreliable because plastic had entered the vent line and solidified.

The workers proceeded to remove the 44 bolts from the cover. When half of the bolts had been removed, the cover suddenly blew off. Hot plastic spewed throughout the area, travelling as far as 70 ft. The cover and the expelled plastic struck the workers, killing them.

The force created propelled the polymer catch tank backward and bent the attached piping. A section of hot oil, 370°C, supply tubing for a heating jacket to the catch tank broke, and the fluid spilled into the area. A flammable vapour cloud formed and ignited within a few minutes. Several hours of fire-fighting efforts were required to extinguish the fire.

The US Chemical Safety Board Key Findings include:

1. The manufacturing process was not subjected to a specialized design review to identify thermal decomposition hazards from unintended and uncontrolled reactions, and the risks posed by decomposition of the plastic were not recognized.
2. More than the normal amount of hot plastic entered the polymer catch tank during the aborted start-up. Reactions and decomposition of the plastic-produced gases. These gases caused the plastic to foam and expand. The expanded plastic forced its way into connecting pipes, where it solidified and plugged the inlet to the vent line. Once this occurred, the gases could not escape and the vessel became pressurized.
3. Operating experience revealed that the design of the polymer catch tank did not afford a practical and reliable method for workers to check for hazards before opening the vessel. Drains were often plugged with solidified plastic, making it impossible to verify the absence of pressure or hazardous chemicals.
4. Process safety information inadequately described the design basis and operating principles for the polymer catch tank. There was no discussion of the means by which overfilling could occur and its consequences.
5. The possibility of overfilling was increased when the original start-up procedures were revised; the diversion of output from the reactor to the polymer catch tank was extended from 30 to 50 min. This modification of procedures was not subjected to a management of change (MOC) review.
6. Process hazard analyses were inadequate. Other findings, root causes and recommendations are available in the Chemical Safety Board's report (CSB).

Martinez, California, 1999

On 23 February 1999, a fire occurred in the crude unit at an oil refinery in Martinez, California. Workers were attempting to replace piping attached to a 150-foot-tall fractionator tower while the process unit was in operation. During removal of the piping, naphtha was released onto the hot fractionator and ignited. The flames engulfed five workers located at different heights on the tower. Four men were killed, and one sustained serious injuries.

(Due to the serious nature of this incident, the US Chemical Safety and Hazard Investigation Board (CSB) initiated an investigation. The investigation was to determine the root and contributing causes of the incident and to issue recommendations to help prevent similar occurrences. This write-up is an abbreviated version of the CSB Report and much of the write-up is verbatim. The CSB examination led to 'Investigation Report – Refinery Fire Incident – Tosco Avon Refinery' Report No. 99-014-1-CA.)

On February 10, 1999, a pinhole leak was discovered in the crude unit on the inside of the top elbow of the naphtha piping, near where it was attached to the fractionator 112 ft in the air. Plant personnel responded immediately and attempted to isolate the piping. The unit remained in operation.

The naphtha piping was inspected and showed that it was extensively thinned and corroded. A decision was made to replace a large section of the naphtha line. Over the 13 days between the discovery of the leak and the fire, workers made numerous unsuccessful attempts to isolate and drain the naphtha piping. Nonetheless, supervisors proceeded with scheduling the line replacement while the unit was in operation.

On the day of the incident, the piping contained about 90 gallons of naphtha, which was being resupplied from the running process unit through a leaking isolation valve. A work permit authorized maintenance employees to drain and remove the piping. After several unsuccessful attempts to drain the line, a maintenance supervisor directed workers to make two cuts into the piping using a pneumatic saw. After a second cut the piping began to leak naphtha, the supervisor directed the workers to open a flange to drain the line. As the line was being drained, the naphtha ignited, most likely from contacting the hot surfaces of the fractionator, and quickly engulfed the tower structure and personnel.

Chemical Safety Board key findings

1. The removal of the naphtha piping with the process unit in operation involved significant hazards. This non-routine work required removing 100 ft of 6-in pipe containing naphtha, a highly flammable liquid. Workers conducting the removal were positioned as high as 112 ft above ground, with limited means of escape. The hot process unit provided multiple sources of ignition, some as close as 3 ft from the pipe removal work. One isolation valve could not be fully closed, which indicated possible plugging.

   On three occasions prior to the incident, the naphtha pipe resumed leaking from the original pinhole and felt warm to the touch, indicating that one or more isolation valves were leaking. Numerous attempts to drain the piping were unsuccessful.
2. The naphtha pipe that was cut open during the repair work was known by workers and the maintenance supervisor to contain flammable liquid. Although procedures required piping to be drained, depressured and flushed prior to opening, this was not accomplished because extensive plugging prevented removal of the naphtha. Although the hot process equipment was close to the removal work, the procedures and safe work permit did not identify ignition sources as a potential hazard.
3. The naphtha stripper vessel level control bypass valve was leaking, which prevented isolation of the line from the operating process unit.
4. The refinery's job planning procedures did not require a formal evaluation of the hazards of replacing the 100 ft of naphtha piping. The pipe repair work was classified as low risk maintenance. Despite serious hazards caused by the inability to drain and isolate the line – known to supervisors and workers during the week prior to the incident – the low risk classification was not reevaluated.
5. The refinery's permit for the hazardous non-routine work was authorized solely by a unit operator on the

day of the incident. Operations supervisors were not involved in inspecting the job site or reviewing the permit.

6. Operations supervisors and refinery safety personnel were seldom present in the unit to oversee work activities.
7. Deficiencies in auditing of maintenance line breaking, lockout/tagout procedures were noted as well as a lack of a Management of Change review as one of the contributing factors. See the full CSB report for details.

Root causes identified by the Chemical Safety Board

1. The refinery's maintenance management system did not recognize or control serious hazards posed by performing non-routine repair work while the crude processing unit remained in operation.
   - Refinery management did not recognize the hazards presented by sources of ignition, valve leakage, line plugging, and inability to drain the naphtha piping. Management did not conduct a hazard evaluation[1] of the piping repair during the job planning stage.
   - Management did not have a planning and authorization process to ensure that the job received appropriate management and safety personnel review and approval. The involvement of a multidisciplinary team in job planning and execution, along with the participation of higher level management, would have likely ensured that the process unit was shutdown to make repairs safely once it was known that the naphtha piping could not be drained or isolated.
   - The organization did not ensure that supervisory and safety personnel maintained a sufficient presence in the unit during the execution of this job. The refinery relied on individual workers to detect and stop unsafe work, and this was an ineffective substitute for management oversight of hazardous work activities.
2. The refinery's safety management oversight system did not detect or correct serious deficiencies in the execution of maintenance and review of process changes.
   - Neither the parent corporation nor the local facility management audited the refinery's line breaking, lockout/tagout, or blinding procedures in the three years prior to the incident. Periodic audits would have likely detected and corrected the pattern of serious deviations from safe work practices governing repair work and operational changes in process units. These deviations included practices such as:
     - Opening of piping containing flammable liquids prior to draining.
     - Transfer of flammable liquids to open containers.
     - Inconsistent use of blind lists.
     - Lack of supervisory oversight of hazardous work activities.
     - Inconsistent use of MOC reviews for process changes.
3. Refinery management did not conduct an MOC review of operational changes that led to excessive corrosion rates in the naphtha piping.

Management did not consider the safety implications of process changes prior to their implementation, such as:

Running the crude desalter beyond its design parameters.
- Excessive water in the crude feed.
- Prolonged operation of the naphtha stripper level control bypass valve in the partially open position.

These changes led to excessive corrosion rates in the naphtha piping and bypass valve, which prevented isolation and draining of the naphtha pipe (CSB).

Toulouse, France, 2001

This devastating accident will be discussed in much more detail in future editions as all of the details emerge.

A massive ammonium nitrate explosion occurred on Friday 21 September 2001, at the Azote de France (AZF) fertilizer factory on the outskirts of Toulouse, France. The blast occurred in a storage facility that held 200–300 tons of granular ammonium nitrate. During the tragedy, 29 people were killed; about 2500 were injured. One wounded person died later.

Ammonium nitrate is primarily used as a fertilizer, however, if it combined with certain additives it can be used as an explosive.

The AZF (Azote de France) started up in 1924 on the left branch of the Garonne River outside of Toulouse. The plant is in an industrial zone, but with urban sprawl the site is surrounded by housing and buildings used by the general public.

The blast crated a crater that was about 50–60 m with a depth of over 7 m. Windows were shattered within a radius of 1–1.5 km and windows were blown out in the city centre 3 km away. The strength was estimated to be equivalent to 30–40 tons of TNT.

This incident occurred just 10 days after the attack on the World Trade Center in New York. As a result, tens of thousands of people assumed that Toulouse was under a terrorists' attack and ran into the streets in panic or attempted to flee.

An investigation is still ongoing and more details will be available at a later date.

Information from (R.J.A. Kersten, A.C. van der Steen, A.F.L. and G. Opschoor. The Ammonium Nitrate Explosion in Toulouse, France: The Incident and Its Consequences for Industrial Activities. A paper delivered at the Center for Chemical Process Safety – October 2002).

A1.11 Case Histories: B Series

One of the principal sources of case histories is the MCA collection referred to in Section A1.1. There are a number of themes which recur repeatedly in these case histories. They include:

Failure of communications
Failure to provide adequate procedures and instructions
Failure to follow specified procedures and instructions
Failure to follow permit-to-work systems
Failure to wear adequate protective clothing
Failure to identify correctly plant on which work is to be done
Failure to isolate plant, to isolate machinery and secure equipment
Failure to release pressure from plant on which work is to be done

Failure to remove flammable or toxic materials from plant on which work is to be done
Failure of instrumentation
Failure of rotameters and sight glasses
Failure of hoses
Failure of, and problems with, valves
Incidents involving exothermic mixing and reaction processes
Incidents involving static electricity
Incidents involving inert gas

In the 2108 case histories described the most frequently mentioned chemicals and the corresponding number of entries are

Ammonia	48	Chlorine	37
Caustic soda	88	Sulphuric acid	46

The most frequently mentioned operations are

Loading	38	Steaming	32
Maintenance	82	Tank entry	39
Pipe fitting	27	Transfer	46
Process reaction	66	Unloading	64
Sampling	24	Welding	36

The most frequently mentioned equipments are

Centrifuge	24	Machine	27
Cylinder	26	Pump	60
Drum	76	Rotameter, sight glass	27
Hose	57	Tank	46
Industrial truck	31	Tank car	59
Laboratory	85[a]	Tank truck	35
line	105	Valve	86

[a] In the first 1623 case histories.

It is emphasized, however, that in many instances it is not appropriate to assign a single cause.

Accounts of some typical case histories, many of which are taken from the MCA collections, are given below. The descriptions are generally briefer than those given in the original sources, which should be consulted for further details.

Bl A pilot plant batch reactor was started at 5.40 a.m. As soon as catalyst was added the temperature and pressure began to increase. In accordance with normal operation venting was carried out. But this was slow and difficult due to carryover of liquid and solids from the reactor into the vent lines. At about 6.45 a.m. the agitator stopped as a result of overload. The vent lines blocked, the pressure increased rapidly and the building had to be evacuated. It was re-entered at about 7.20 a.m., when the pressure was found to be 750 psi. Thereafter the reaction subsided as the reactants were used up. The pressure relief valve was set at 750 psi, but was found to be blocked as a result of the incident. The cause of the reaction runaway was overcharging of reactants at the start of the batch. (MCA 1966/15, Case History 867.)

B2 A batch chlorinator exploded suddenly killing employees and doing extensive damage. The reaction temperature was controlled automatically by manipulating the chlorine flow. During the batch the measured temperature fell sharply and it was realized that the thermocouple had failed. The agitator was stopped and the brine cooling was shut off while the instrument was repaired, but delay in stopping chlorine flow resulted in a high temperature giving decomposition reactions. The explosion blew the reactor cover through the roof and the reactor itself was driven down into the floor. Flammable gases were released which burned and caused the casualties mentioned. The explosion also ruptured chlorine and ammonia lines.

The works emergency plan was activated, involving both local area services and mutual aid from other chemical firms. (MCA 1962/14, Case History 371.)

B3 In a process involving chlorination of paraffin in a reactor, chlorine gas was piped into the system in a carbon steel pipe. The pipe ruptured and released paraffin and chlorine, which caused a fire and did extensive damage. Subsequent investigation revealed that the contents of the reactor had leaked into the pipe and had reacted with the chlorine vapour. Severe oxidation of the steel pipe by chlorine and/or hydrogen chloride led to the pipe rupture. (NFPA 1973.)

B4 An explosion occurred in a batch reactor which blew the top right off the vessel. The vessel was supported by steelwork two-thirds of the way up its side. The force of the explosion pushed the reactor 2.5 ft into the floor, which was 3 ft below, as shown in Figure A1.21. Fragments of the lid of the vessel, which contained a bursting disc, were scattered over the countryside. (Anon. 1977n.)

B5 The loaded basket of a 48 in. suspended-type centrifuge suddenly became unbalanced and in consequence the shaft flew out and broke the outlet pipe of an adjacent centrifuge. The investigation indicated that the imbalance had been caused by a sudden escape of cake from one side of the basket due to a hole in the cloth. (MCA 1966/15, Case History 645.)

B6 A 2000 ft^3 diborane surge tank disintegrated causing severe loss. The failure fragmented the tank and reduced to rubble a 24 in. thick reinforced concrete wall barricading it on three sides. Fragments travelled 2200 ft and one cut four process lines in a unit 1800 ft distant. The tank was 8 ft inside diameter × 30 ft long. It was designed for a working pressure of 296 psi with a safety factor of 4. Prior to the installation it had been completely radiographed and stress-relieved. At the time of the explosion the tank pressure and temperature were 192 psig and 12°C. The cause of the explosion was not certain, but the most probable explanation appeared to be a defect in the tank aggravated by high stresses at the attachment weld of the platform support. (MCA 1966/15, Case History 730.)

B7 A safety shut-off valve on the gas supply to the burner in the combustion chamber of a drier remained open after the unit was shut-down. There was no indicator to show whether the valve was open or closed. On relighting the burner the operator made several errors, including that of opening the main valve on the gas supply to the burner before lighting the pilot burner. When the lighted taper was inserted into the combustion chamber, there was an explosion. (MCA 1966/15, Case History 1068.)

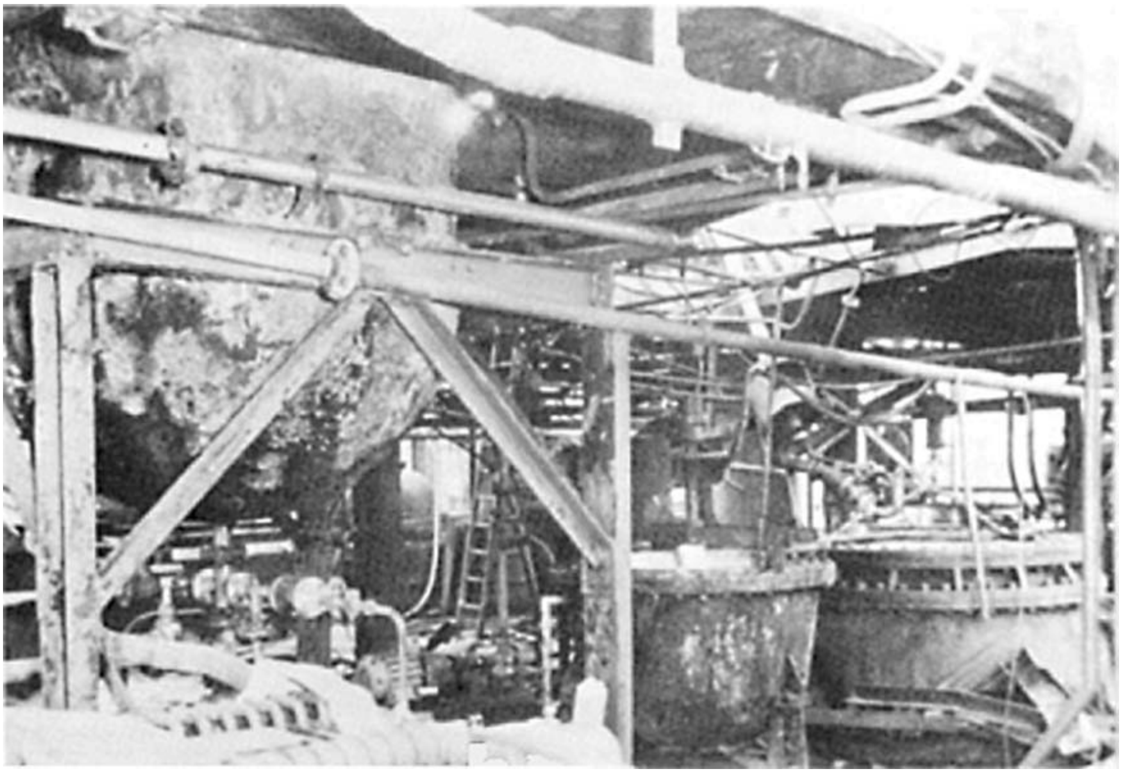

Figure A1.21 *Batch reactor after explosion (Anon., 1977n)*

B8 A reactor with a water jacket collapsed inwards due to overpressure in the jacket, the water from the jacket mixed with the reaction mass, and hot steam, and chemicals erupted violently through a sight glass and a rupture disc on the reactor. The overpressure of the jacket took place during the initial heating of the reactor charge and occurred because the inlet and outlet valves on the jacket were closed and there was no pressure relief device on the jacket, although there was a bursting disc on the reactor itself. (MCA 1966/14, Case History 353.)

B9 A cabinet containing sparking electrical equipment was pressurized with nitrogen to exclude flammable gases. Nitrogen from the same main was used to 'egg' acetone out of a process vessel. The nitrogen pressure fell as a result of heavy demand, acetone passed back into the nitrogen and got into the cabinet. Subsequently the nitrogen flow to the cabinet was shut off, air leaked in and mixed with the acetone, and there was an explosion. (Kletz, 1976b.)

B10 Butadiene from a reactor passed back up a line used for adding emulsifier through an obstructed non-return valve. The emulsifier tank had an open vent, so that the butadiene got out into the building and exploded. The explosion caused flames 75 ft high and was heard 10 miles away. Damage was minimized, however, by the light construction of the building which ruptured at the roof and at two of the walls. (Mallek, 1969.)

B11 In a pilot plant acetaldehyde oxidation column the arrangements involved purging the column with nitrogen and then supplying acetaldehyde to the column by nitrogen pressure. The oxidation was carried out by admitting a controlled flow of oxygen to the column. The pipework allowed the nitrogen to be used to purge the column and part of the oxygen pipe. There was nothing to stop oxygen at higher pressure passing into the nitrogen in case of a leaking valve or of incorrect operation. During operation the operator observed a leak on the acetaldehyde supply drum and was told to shut the plant down. A few minutes later an explosion occurred which killed four people. From the investigation it appeared that oxygen had leaked via the nitrogen purge line into the acetaldehyde drum, in which reaction occurred with large rises in temperature and pressure and eventually a detonation. (MCA 1962/14, Case History 117.)

B12 A malfunction of the control equipment allowed raw gas to accumulate in a direct-fired textile fibre drier. When circulating fans were turned on, the drier exploded. (Doyle, 1969.)

B13 In an air liquefaction plant an electrical failure caused the control valve on an oxygen line to open and pass oxygen into a nitrogen line. The nitrogen was compressed and then used as wash liquid for the offgas from an ethylene plant. The nitrogen wash cold box exploded. (Doyle, 1969.)

B14 In a chlorine liquefaction system 'gunk' was warmed prior to removal from a cold trap. A leaky steam valve allowed overheating of the gunk. This contained sufficient nitrogen trichloride to explode. (Doyle, 1969.)

B15 A vacuum system failed on a small still distilling a chloronitro compound. This allowed the temperature to rise and give a self-accelerating decomposition. A large still adjacent to the small one was seriously damaged. (Doyle, 1969.)

B16 A reboiler distilling epichlorhydrin from a mixture with tar was heated by steam. The thermocouple on the steam control loop tarred up and gave an incorrect reading. The only control of conditions in the column became the operator's response to the temperature at the top of the column. This proved inadequate, the reboiler overheated and an explosion occurred. (Doyle, 1972a.)

B17 In a furnace cracking ethylene dichloride to vinyl chloride under computer control the flow of ethylene dichloride to the furnace was controlled to maintain an optimum temperature in the cracked gas exit line. A furnace tube split and reduced the cracked gas flow and the cracked gas temperature. The control action increased the flow of ethylene dichloride. The furnace tubes burned up. (Doyle, 1972a).

B18 A common type of 'Dowtherm' vaporizer is a single coil in which the liquid is superheated, followed by a flash chamber. There is an interlock between a flowmeter on the liquid line to the coil and the fuel flow controller, so that the coil is not heated unless liquid is flowing through it. A vapourizer of this type was started up after a shut-down and the coil immediately exploded. The impulse lines to the differential pressure transmitter had frozen just before the shut-down, showing a normal flow, and during the shut-down the exit line from the coil also froze up. On start-up the interlock did not work owing to the incorrect signal from the flowmeter and the heating of the coil caused pressure to build up and rupture it. (Doyle, 1972a.)

B19 Excess water was removed from a hydrogen peroxide–water mixture by vacuum distillation. As a precaution against attempting to vaporize a dangerous concentration of peroxide, the liquid level and vapour temperature were measured: a low level or a high temperature signal operated a valve to dump de-ionized water into the reboiler. The hydrogen peroxide solution produced large quantities of heavy foam. The float-type level instrument measured the foam rather than the liquid level. After some erratic readings it gave a seriously inaccurate one while the level was low, and the reboiler exploded. (Doyle, 1972a).

B20 The agitator on a batch nitration reactor was stopped, but the process operator was unaware of this. Instrumentation which should have cut off the acid feed to the reactor and given an alarm signal of agitator stoppage apparently failed to work. When the agitator started up again, the reactor exploded. (Fritz, 1969.)

B21 In an ethylene cracking furnace the flow of fuel to the furnace was manipulated to control the temperature of the gas leaving the furnace. The temperature measuring instrument failed and gave a low reading. The control action increased the heat to the furnace. The furnace was designed to supply mainly latent heat of vaporization to the process stream with a small amount of superheat. Thus the vapour temperature was sensitive to the additional heat input and rose rapidly. The piping overheated and ruptured, releasing ethylene gas which was ignited by the burners of an adjacent furnace. The resultant fire did severe damage. (H.D. Taylor and Redpath, 1971.)

B22 Ammonia synthesis gas at 2000 psig was passed through a scrubber which was fed with weak aqueous ammonia. The liquid from the bottom of the column passed to a vertical holdup tank with a 2 in atmospheric vent. The level of liquid in the base of the column was controlled automatically. The control valve in this loop stuck in the open position. Liquid and gas from the column surged into the hold-up tank and ruptured it. The escaping gas was approximately 75% hydrogen and it ignited, causing a fire. (MCA 1966/15, Case History 598.)

B23 A flow ratio control loop failed and allowed excess hydrogen to enter a catalytic tower. Hot spots developed, causing thermal decomposition of the hydrocarbon–hydrogen stream and rupture of the tower. (MCA 1966/15, Case History 609.)

B24 A flame failure occurred on the burner of a Dowtherm vapourizer and the procedure for relighting the burner was initiated. The firebox was checked and the automatic control system which purges and lights the flame was activated. A short developed across the fuelselector switch of the system, causing fuel gas to enter the combustion chamber during the purge cycle and thus creating a flammable fuel–air mixture. When the purge cycle was complete and the pilot light was ignited, an explosion occurred. (MCA 1966/15, Case History 821.)

B25 An inert gas generator was found to have produced a flammable oxygen mixture. The 'fail safe' flame failure device had failed. The trip system on the oxygen content of the gas generated had caused shut-down when the oxygen content in some of the equipments reached 5%, but did not prevent creation of a flammable mixture in the holding tank. (MCA 1966/15, Case History 679.)

B26 An air supply enriched with 2–3% oxygen was provided for flushing and cooling air-supplied suits after use. A failure of the control valve on the oxygen–air mixing system caused this air supply to contain 68–76% oxygen. An employee used the supply to flush his air-supplied suit, disconnected the lines, removed his helmet and lit a cigarette. His oxygen-saturated underclothing caught fire and he received severe burns. (MCA 1966/15, Case History 884.)

B27 A chlorine cellroom was experiencing operational difficulties. A failure of the control system caused a back pressure to develop. When the operating personnel tried to shut the system down using manual controls, a failure of this equipment caused a serious chlorine release. One of two compressors taking hydrogen from a low-pressure gasholder continued to operate and failure of a low level trip created a negative pressure, allowing air to leak in. An explosion occurred in the cooling coils of the compressor. Hydrogen from another part of the process was introduced into the holder in an effort to maintain production. The hydrogen–air mixture in the holder diffused into the catalyst purification unit, where a high temperature developed, causing a second explosion. The failure of the gasholder trip to operate was due to the fact that the timer had been bypassed by a 'jumper'. (MCA 1966/15, Case History 694.)

B28 An explosion occurred on a vinyl chloride polymerization plant at Minamata, killing four and injuring eight other people inside the factory and slightly injuring two people outside it by flying glass. The polymerization reaction in No. 3 reactor was complete and the operators intended to discharge the contents, but No. 4 reactor was discharged in error. The reaction in this reactor was incomplete and the VCM escaped and exploded. (MCA 1966/15, Case History 816.)

B29 A rigger was removing manhole covers from a vinyl chloride reactor when he apparently became confused and removed the cover from a reactor which was operating under pressure. A large quantity of vinyl chloride vapour was released. It ignited to give a flash fire, which killed the rigger and two labourers. (MCA 1970/16, Case History 1132.)

B30 In an ethylene oxide plant inert gas was circulated through a process containing a catalyst chamber and a heat removal system. Oxygen and ethylene were continuously injected into the inert gas and ethylene oxide was formed over the catalyst, liquefied in the heat removal section and passed to the purification system. On shut-down of the circulating compressor an interlock stopped the flow of oxygen and the closure of the valve was indicated by a lamp on the panel. During one shut-down the lamp showed the oxygen valve closed. The process operator had instructions to close a hand valve on the oxygen line, but he expected the maintenance team to restore the compressor within 5–10 min and did not close the valve. The process loop exploded. The oxygen control valve had not in fact closed. A solenoid valve on the control valve bonnet had indeed opened to release the air and it was the opening of this solenoid which was signalled by the lamp on the panel. But the air line from the valve bonnet was blocked by a wasps' nest. (Doyle, 1972a.)

B31 A catalyst bed was regenerated by circulating nitrogen through an electric heater, the bed and a cooler. The flowmeter on the nitrogen line choked with dust early on and the process operators learned to make do without it, controlling the plant by the nitrogen temperature at the bed inlet. One day the cooler blocked with dust and the temperature at the bed inlet stuck at its normal value. The heater over-heated and at 740°C its high temperature trip operated and cut off the power. The operator, seeing that the other instrument readings were normal, assumed the trip to be faulty and switched the power back on. The trip operated and was overridden three times in 1 h. There was a shift change during this hour. Finally the heater shell burst. (Kletz, 1974b.)

B32 A tank had to be filled with enough raw material to last a day. The operator watched the tank level and switched off the pump when the required level was reached. One day after several years operation and some 1000 fillings, the man let the tank overflow. So a trip system was installed as an additional safeguard. The operator, however, got in the habit of using the trip system as a replacement and got on with something else. The plant manager knew about this, but was happy to see the improvement in productivity. However, since the trip system can be expected to fail about once in 18 months, the overall system had actually become less reliable. (Kletz, I974d.)

B33 An explosion occurred in the open air in the vicinity of a hydrogen vent stack and caused severe damage. It was normal practice to vent hydrogen for periods of approximately 45 min. On this particular occasion there was no wind, the hydrogen failed to disperse and the explosion followed. (MCA 1966/15, Case History 1097.)

B34 An operator was adding charcoal impregnated with catalyst from a plastic bag into a reactor containing caustic soda blanketed with nitrogen. The charcoal dust ignited and there was a flash fire. It is believed that the ignition was caused by static electricity. (MCA 1966/15, Case History 1094.)

B35 An employee was repairing a blower on the vent stack of a dissolver. When he had finished the work, he switched the machine on, but observed that it was not operating. He reached into the stack to give the fan blades a turn and there was an explosion. The vent stack had contained a flammable mixture, which was probably ignited by static electricity from the man's body. (MCA 166/15, Case History 703.)

B36 A man was filling his cigarette lighter from a gallon can of naphtha when he dropped the lighter. It apparently struck on the wheel and gave a spark. Flammable vapour from a nearby drum filling plant ignited and caused a violent explosion. (MCA 1970/16, Case History 1175.)

B37 A substantial section of lagging along the pipework of a process heating fluid system became contaminated with the fluid, which was a low volatility mineral oil, due to a pump gland leak. A lagging fire occurred, the symptoms of which were that first smoke was seen rising from the lagging, then the heating fluid rose 50°C above its set temperature of 270°C and finally the pump and a considerable length of pipe became enveloped in flames. The latter were quickly dealt with, but the temperature of the heating fluid continued to rise. Soon afterwards a small explosion occurred in a covered oil header tank housed inside a building. There was a large release of oil and fumes from the tank and these then exploded violently, causing severe damage to the building. The probable explanation was that some of the oil had been heated above its spontaneous ignition temperature and had been forced by expansion back up into the header tank, where its vapour met air and ignited. (Gugan, 1974a.)

B38 A large spray drying plant with direct heating from a combustion chamber was being run in. The combustion system had been operating at a very low firing rate under manual control for some 24 h. The fuel oil to the burner was pumped by a positive displacement pump through thermostatically controlled heaters, excess oil being bypassed around the pump. After firing had continued unsupervised for some hours, there was a sudden eruption of flame through a hinged explosion panel near the combustion chamber and a man walking past was enveloped. Investigation showed that the eruption of flame could be explained by a gross increase in fuel flow to the burner, even though a manual valve on the fuel line was still at its original setting. It was also discovered that a fire had developed in the lagging of the fuel oil system, the lagging having become saturated with oil due to leaks from pipe joints occurring during the initial pressure testing. The reason for the increase in fuel oil flow was probably a rise in the oil temperature to a value much in excess of that set on the thermostat, so that there was a decrease in oil viscosity and an increase in the quantity flowing through the valve. (Gugan, 1974a.)

B39 Dried material from a double-drum steam drier was passed from a bag packer via a spout with a cotton apron to a leverpak. A small dust explosion occurred at the apron and led to a fire in the bagging plant and leverpak. It was considered from investigation that the dust had been ignited by a spark discharge of static electricity. The cotton apron was non-conducting and the bag packer was not earthed. (MCA 1966/15, Case History 653.)

B40 An operator was in the process of unloading titanium carbide dust from 2 ft conical ball mill. He had removed 95% of the material. The mill was being rotated in order to clean it when a dust cloud ignited. He received severe burns from which he later died. The product had been milled to a finer size than desired and thus rendered highly reactive. (MCA 1966/15, Case History 618.)

B41 A set of air compressors comprising four three-stage 740 h.p. machines with a discharge pressure and temperature of 350 psi and 350°F had been in operation for about 8 h following a plant shut-down. The third-stage cylinder in one of the compressors was faulty and the 125 psi relief valve between the second and third stages began to relieve air intermittently. The third-stage discharge temperature went off the instrument scale at 400°F before the compressor could be shut-down. Some 15 min later the overhead discharge line was observed to be glowing red hot. Before the other compressors could be shut-down, the line ruptured and a flash fire occurred. Investigation indicated that lubricating oil had ignited in the compressor cylinder and discharge line. (MCA 1962/14, Case History 35.)

B42 An explosion occurred in a vinyl chloride pump and seriously injured an operator. The pump was on the 'recovered' vinyl chloride monomer (RVCM) system. The line sections before and after the pump had been removed and the explosion occurred in the idle vented pump about an hour later. The investigation showed that the entire RVCM system was contaminated with vinyl chloride polyperoxide, which is an unstable material. There had been three abnormal occurrences on the plant prior to this accident. The RVCM gas compressors had not shut-down at low pressure due to the failure of a pressure switch. There had been an accumulation of RVCM liquid in the storage tanks for 20 days. And the acidity level in the vinyl chloride feed to the polymerizers had been high. (MCA 1970/16, Case History 1551.)

B43 A four-stage reciprocating compressor used to compress nitrogen from 15 to 3000 psig exploded with a 'brilliant flash' and projected fragments up to 160 ft from the building. Previous to the explosion the machine had been shut-down to change the third-stage suction and discharge valves and again to correct an error in the installation of the former. Investigation showed that the discharge valve had been installed in the reversed position and that compression of the gas under these conditions could give a pressure of 16,800 psig and a temperature of 1310°F. This temperature exceeded the autoignition temperature of the lubricating oil. There may have been oxygen present due to the maintenance operations. These conditions resulted in the explosion. (MCA 1966/15, Case History 1056.)

B44 A 40,000 gal horizontal tank was used to produce aqueous ammonia by introducing water at the top and anhydrous ammonia at the bottom. The tank was emptied and the water flow was started to make the next batch. The tank imploded due to the vacuum created by the absorption of the ammonia vapours by the water. (MCA 1966/15, Case History 916.)

B45 A holding tank containing 'heavies' from cracking furnaces suddenly erupted blowing oil, water and steam over the adjacent area. It is believed that condensate had come in contact with the hot oil, which was at a temperature of 600–700°F, thus generating large quantities of steam. (MCA 1962/14, Case History 455.)

B46 A storage tank was not in use and was boxed up with some water inside. Rusting took place, the oxygen of the air in the tank was depleted and the tank collapsed inwards. (Anon., 1977n.)

B47 A storage tank was cleaned out and filled with a high purity liquid. A polyethylene bag was put over the vent to prevent contamination. It was a hot day and the temperature of the liquid in the tank rose. There was a sudden shower, vapour in the tank condensed and the tank collapsed inwards. (Anon., 1977n.)

B48 Cold liquid was pumped into a storage tank containing hot liquid. The liquid in the tank was cooled, the vapour pressure fell and the tank collapsed inwards. (Anon., 1977n.)

B49 Modifications were required to a high-pressure chlorine main. The main was isolated and men began work. The supervisor then realized that there might be some chlorine present in a section of pipework at the tank car rack. The pipework was connected to the main, but there was an isolation valve between the main and the pipework. He assumed that this valve was shut and initiated measures to remove any chlorine present in the pipework section. There was liquid chlorine in this pipework and it passed via the isolation valve into the main and gassed the fitters working there. The isolation valve was subsequently found to be frozen in the part open position. (MCA 1966/15, Case History 707.)

B50 An employee went into a water cistern to install some control equipment and immediately collapsed into water 2 ft below. A second employee who had accompanied him ran to fetch assistance. Minutes later he came back with several others, two of whom entered the cistern and also collapsed. Meanwhile the alarm had been raised. The fire services arrived and a crowd gathered. While the fire officer was putting on his self-contained breathing apparatus, one of the by-standers, saying that he could swim, descended into the cistern. The fire officer then went in, but took off his mask, presumably to call for some equipment, and collapsed. All five people died due to hydrogen sulfide poisoning. (MCA 1970/16, Case History 1213.)

B51 'A double fatality occurred in a steel works whilst two fitters were changing a gearbox valve for a blast furnace system. One or both men opened a valve allowing gas to escape at a rate of 50,000 cu. ft. per hour. Of another two men who went to investigate the volume of gas passing through the valve, one was overcome by gas (but later recovered) and the other escaped to summon assistance. Safety precautions should have included either the isolation of the system upstream from the valve or the use of suitable breathing apparatus by the workmen. Although both maintenance men had been issued with compressed airline breathing apparatus it was found after the accident that only one of these was connected with the air supply and neither was being worn. The fatalities highlighted the dangers of complacency which can occur when a system has operated without incident for years and also the need to ensure that workers employed in such situations are adequately trained in the use of breathing apparatus.' (Annual Report of HM Chief Inspector of Factories, 1974.)

B52 During plant commissioning a temporary filter was put in a compressor suction line, as shown in Figure A1.22. The filter was located between the compressor and the low suction pressure trip. The filter blocked, the suction pressure fell below atmospheric, air was sucked in and a decomposition reaction occurred further on in the process where there was a higher pressure. Two pipe joints sprung and gas escaped and ignited. The resulting fire caused £100,000 damage and delayed the commissioning many months. (Henderson and Kletz, 1976.)

B53 An olefins plant was severely damaged during commissioning by a fire in the refrigeration section of the gas separation plant. Although no one was seriously injured, the fire burned for 15 h and caused delay to the commissioning and considerable damage and consequential loss. The cause of the fire was that the low-pressure refrigeration section, which was designed for 50 psig pressure, was subjected to a pressure of 400 psig. The overpressure occurred because of closure of a 12 in. valve on the exit of this section, installed during construction to allow high pressure gas to be used to assist in drying the plant prior to commissioning. The installation of the valve had been well debated in the plant operating team and with the process design contractor. But the installers did not follow the well-established requirement of providing pressure relief protection on the low-pressure system. (Heron, 1976.)

B54 A works had a special network of air lines installed some 30 years ago for use with breathing apparatus only. The supply to this network was taken off the top of the general purpose compressed air main as it entered the works, as shown in Figure A1.23. One day a man wearing a face mask inside a vessel got a faceful of water. He was able to signal to the anti-gas man and was rescued. Investigations revealed that the compressed air main had been renewed and that the branch to the breathing apparatus network had been connected to the bottom of the compressed air main. As a result a slug of water in the main would all go into the catchpot and fill it more quickly than it could empty. (Henderson and Kletz, 1976.)

B55 Pressure relief on a low-pressure refrigerated ethylene tank was provided by a relief valve set at about 1.5 psig and discharging to a vent stack. When the design had been completed, it was realized that if the wind speed was low, cold gas coming out of the stack would drift down and might then ignite. The stack was not strong enough to be extended and was too low to use as a flare stack. It was suggested that steam be put up the stack to disperse the cold vapour and this suggestion was adopted. The result was that condensate running down the stack met cold vapour flowing up, froze and completely blocked the 8 in. pipe. The tank was overpressured and it burst. Fortunately the rupture was a small one, the ethylene leak did not ignite and was dispersed with steam while the tank was emptied. (Henderson and Kletz, 1976.)

B56 A metal chute used to transfer a powder from a metal hopper into a metal vessel was replaced by a plastic hose. The flow of powder down the chute caused a charge of static electricity to build up in the hose and, although the hose was a conductor, the polypropylene end pieces used to connect it to the hopper and the vessel were not, and the charge was unable to dissipate. A spark occurred and the dust was ignited. (Heron, 1976.)

B57 A relief valve weighing 258 lb was being removed from a plant. A 25 ton telescopic jib crane with a jib length of 124 ft and a maximum safe radius of 80 ft was used to lift the valve. The driver failed to observe this maximum radius and went out to 102 ft radius. The crane was fitted with a safe load indicator of the type which weighs the load through the pulley on the hoist rope, but this does not take into account the weight of the jib, so that the driver had no warning of an unsafe condition. The crane overturned on to the plant, as shown in Figure A1.24. (Anon., 1977n.)

B58 Halfway through the unloading of a tank truck of anhydrous ammonia a stream of liquid was observed leaking from the bonnet of the stop valve on the unloading line.

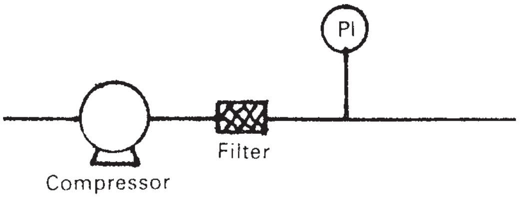

Figure A1.22 Compressor system after modification (Henderson and Kletz, 1976) (Courtesy of the Institution of Chemical Engineers)

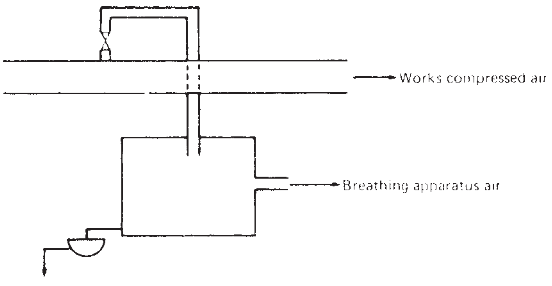

Figure A1.23 Air offtake for breathing apparatus as originally installed (Henderson and Kletz, 1976) (Courtesy of the Institution of Chemical Engineers)

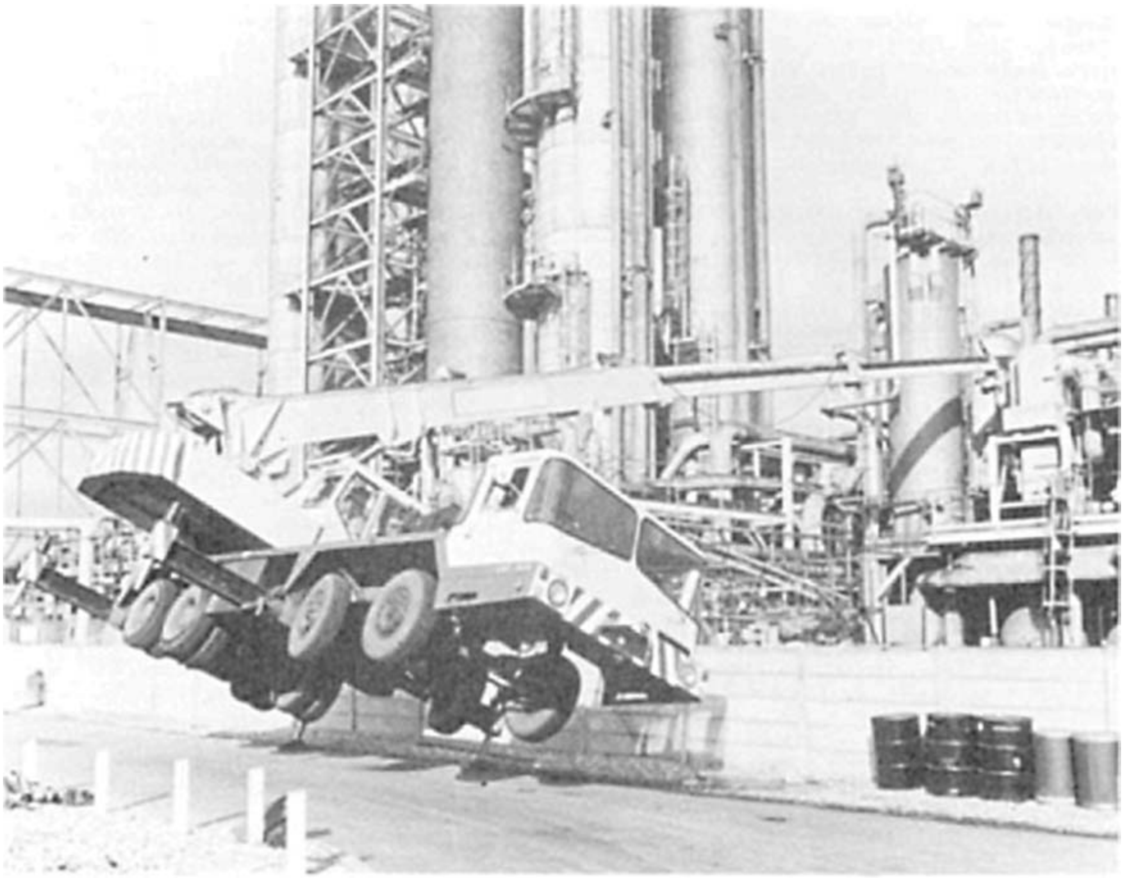

Figure A1.24 *Mobile crane overturned on to plant (Anon., 1977n)*

The truck was taken off line and the storage tank was vented to a neutralizing pit to relieve its pressure. Considerable difficulty was experienced in reducing the pressure in the tank sufficiently to stop the flow of liquid ammonia. There was no shut-off between the leaking valve and the tank. Eventually the pressure was reduced by using a compressor and exhausting it to atmosphere. Investigation indicated that the failure of the valve was caused by a combination of a flaw in the body and strain induced by excessive pressure on one of the stud bolts. (MCA 1970/16, Case History 1114.)

B59 A storage tank 108 ft diameter × 49 ft high containing refrigerated propane at a pressure less than 1 psig was overpressured and ruptured at Ras Tanura refinery, Saudi Arabia. The propane caught fire and gas from pilot-operated relief valves on two similar tanks, one containing propane and one butane, was also set alight. The ruptured tank burned out in some 36 h, while the butane and propane tank vent fires burned for 3 and 6 days, respectively. One person was killed and 115 were injured, and serious damage was done.

Just prior to the incident the refrigeration plant had been shut-down. The intention was to go over to autorefrigeration in which the propane tank would be cooled by boiling off liquid and venting it into the blowdown system. But this autorefrigeration could not be established, because the blowdown line was blocked with liquid butane. The reason for the presence of the butane was that a remotely operated isolation valve had not fully closed, because the valve spring was prevented from operating properly by paint and corrosion products.

There was a steady rise in the pressure in the propane tank up to and then beyond the relief valve set pressure of 1 psi. The operators, both at the end of one shift and at the beginning of the next, tried to find out the cause of the rise in pressure, but they did not alert the supervisors. (Laney, 1964.)

B60 An operator checked the level in a storage tank and then began pumping in a volatile monomer from a tank wagon. The vent pipe of the storage tank was blocked, however, and a large quantity of monomer flowed out of the dip leg. (MCA 1970/16, Case History 1192.)

B61 A tank truck was being loaded with ethyl acetate. The loader heard what he described as a 'sizzling' sound and looked in, but could see nothing. Soon after an explosion occurred. The investigation showed that the earthing arrangements on the tank were in good order. The evidence suggested that the explosion was caused by static charge on the surface of the liquid. (MCA 1966/15, Case History 986.)

B62 A tank trailer containing 6876 gal of propane under pressure ruptured on the highway 560 ft from the centre of the town. The propane escaped and exploded, causing 10 deaths, 17 injuries and extensive damage. The investigation revealed various undesirable features of the tank, including weld defects which would create areas of enhanced stress concentration, differences of alignment between the cylinder and the end parts, and possible embrittlement of the plates due to the use of a heating process to effect chamfering. (MCA 1966/15, Case History 879.)

B63 Acetic acid was being pumped out of one compartment of a two-compartment trailer. The manhole cover was propped open. The operator climbed on the tanker to obtain a sample. In order to do this he had to lift the manhole cover back. When he had taken the sample, he closed the manhole cover completely. A few seconds later the tank imploded as a result of the vacuum generated by the continued pumping. The tank was equipped with a spring-loaded vacuum breaker, but either this failed to open or it was undersized. (MCA 1966/15, Case History 1011.)

B64 A tractor semitrailer transporting 7000 gal of propane was modified by inserting a tee-piece between the excess flow valve and the manual shut-off valve on the 3 in. discharge line. The joint was connected to the tractor fuel tank by a $^3/_4$ in. hose to allow the vehicle to be filled en route. There was another manual shut-off valve on the $^3/_4$ in. line. The hose broke in transit. The leakage flow rate was too small to activate the excess flow valve. The driver stopped the vehicle, shut-off the engine and told the trainee driver to shut-off the smaller hand valve. When the latter touched the valve, the propane vapours ignited and he was engulfed in flames. The gas continued burning for another 1.5 h. The trainee driver died in the fire, which also caused other injuries and damage. (MCA 1966/15, Case History 995.)

B65 An explosion occurred in a terraced house in East Street, Thurrock, in 1969 that blew a hole in the floor at the foot of the staircase. The wife of the householder fell in while carrying her child and both were injured. The Times (9 April, 1969) reported

> Investigators found that the explosion had been caused by the ignition of a mixture of petrol vapours and air and that the vapour was the result of a spillage of petrol two years before.

The spillage involved 367 tons of petrol on rail sidings in July, 1966, and the investigation suggested that there was probably an eight-foot thick band of petrol vapour lying well beneath the surface of the ground in the East Street area. The vapour had been raised to the surface because of exceptionally heavy rainfall.

The distance from the point of spillage to the house was several hundred yards. (Kletz, 1972b.)

B66 On 30 November, 1962 at Cornwall, Ontario, a chlorine rail car was in a siding when a failure of the anchor section occurred and 30 ton of chlorine escaped. The siding was on the downwind side of town. Police and firemen organized prompt evacuation of the several hundred people in the rural area downwind of the spillage. Some 89 people were gassed. (Simmons, Erdmann and Naft, 1974.)

B67 On 9 August, 1963 in Philadelphia, Pennsylvania, a chlorine rail tank car was rammed and a 1 in. loading line was broken. For a short period there was an escape of chlorine, amounting probably to no more than 1 ton. The release was in the middle of a built-up area, however. The number of people gassed was at least 430. (Simmons, Erdmann and Naft, 1974.)

A1.12 Some Other Incidents and Problems

Some other incidents and problems related to safety and loss prevention are listed in Table A1.4 under the following heads: (1) power loss, weather and earthquake; (2) safety and safety legislation; (3) transport and transport legislation; (4) pipelines and pipelines legislation; (5) toxic chemicals in the workplace; (6) pollution; (7) pollution legislation; (8) abandonment of actual or planned production and (9) litigation.

The references in Table A1.4, which are quoted by date only, are to accounts given by 'Chementator' in Chemical Engineering. The information given refers primarily to the United States.

The table shows very clearly the increasing public concern with health and safety and with pollution in the process industries that began to build up from the early 1970s.

A1.13 Notation

Q	flow rate of propane (ft^3/s)
u	average wind velocity (ft/s)
x, y, z	downwind, cross-wind and vertical distances (ft)
σ_y, σ_z	standard deviations in crosswind, vertical directions (ft)
χ	concentration of propane (volume fraction)
χ_{cl}	concentration of propane on centreline (volume fraction)

Appendix

2

Flixborough

Contents

At about 4.53 p.m. on Saturday 1st June 1974, the Flixborough Works of Nypro (UK) Ltd (Nypro) were virtually demolished by an explosion of war-like dimensions. Of those working on the site at the time, 28 were killed and 36 others suffered injuries. If the explosion had occurred on an ordinary working day, many more people would have been on the site, and the number of casualties would have been much greater. Outside the Works injuries and damage were widespread but no one was killed. Fifty-three people were recorded as casualties by the casualty bureau, which was set up by the police; hundreds more suffered relatively minor injuries, which were not recorded. Property damage extended over a wide area, and a preliminary survey showed that 1821 houses and 167 shops and factories had suffered to a greater or lesser degree. (R.J. Parker, 1975 – the *Flixborough Report*, para. 1)

The Flixborough explosion was by far the most serious accident which had occurred in the chemical industry in the United Kingdom for many years.

The explosion was in the reactor section, Section 25A, of the caprolactam plant.

Within a month of the disaster a Court of Inquiry under the chairmanship of Mr R.J. Parker was set up under Section 84 of the Factories Act 1961 to establish the causes and circumstances of the disaster and to point out any lessons which might be learned.

The Court's report *The Flixborough Disaster, Report of the Court of Inquiry* (R.J. Parker, 1975) (the *Flixborough Report*) is the most comprehensive inquiry conducted in the United Kingdom into a disaster in the chemical industry.

The Flixborough disaster was of crucial importance in the development of safety and loss prevention in the United Kingdom. It made both the industry and the public much more aware of the potential hazard of large chemical plants and led to an intensification both of the efforts within industry to ensure the safety of major hazard plants and of the demands for public controls on such plants.

The setting up of the Advisory Committee on Major Hazards (ACMH) at the end of 1974 was a direct result of the Flixborough disaster.

The impact of Flixborough was reinforced by that of the Seveso disaster 2 years later.

The description of the Flixborough disaster given below is necessarily a brief one, and is mainly based on the *Flixborough Report* and on the work of Sadée, Samuels and O'Brien (1976–77). Other accounts at the time include those of J.I. Cox (1976b) and Gugan (1976). Further critical accounts are described in Section A2.9.

Selected references on Flixborough are given in Table A2.1.

A2.1 The Company and the Management

A2.1.1 The company

The *Flixborough Report* (paras 12–14) states

> The site was originally occupied in 1938 by a company called Nitrogen Fertilisers Limited, a subsidiary of Fisons Limited and used for the manufacture of ammonium sulphate. In 1964 Nypro was formed, owned jointly by Dutch State Mines (DSM) and Fisons Limited. It acquired the site from Nitrogen Fertilisers Limited. Between 1964 and 1967 plant was built for the production of caprolactam, which is a basic raw material for the production of Nylon 6, by a process, the first step of which was the production of cyclohexanone via the hydrogenation of phenol. The works were commissioned and production commenced in 1967. They were then and remained until the disaster the only works in the UK producing caprolactam.
>
> In 1967 Nypro was reconstituted with DSM owning 45%, the National Coal Board 45% and Fisons Limited 10%. Almost at once design began for additional plant to increase the capacity of the works from 20 000 tons of caprolactam per annum to 70 000 tons per annum. This additional plant, referred to as Phase 2, was completed at a cost of some £15 m. in 1972. Its distinguishing feature for present purposes is that in it the cyclohexanone necessary for the production of caprolactam was produced by the oxidation of cyclohexane instead of via the hydrogenation of phenol. In 1972 DSM acquired the holding of Fisons Limited and from then until after the disaster Nypro was owned as to 55% by DSM and as to the remaining 45% by the NCB.
>
> From the safety point of view, the oxidation process introduced new dimensions. Cyclohexane, which is in many of its properties comparable with petrol, had to be stored. More importantly, large quantities of cyclohexane had to be circulated through the reactors under a working pressure of about 8.8 kg/cm^2 and a temperature of 155°C. Any escape from the plant was therefore potentially dangerous.

Nypro (UK) Limited was therefore a relatively small, single-site company operating a major hazard process.

A2.1.2 The management

The management of the company is described in the *Flixborough Report* (paras 19–27). The description includes the following information of particular relevance to the caprolactam plant:

Managing Director Mr R.E. Selman, qualified chemical engineer (HTS, Delft)
General Works Manager Mr J.H. Beckers, qualified chemical engineer (MTS, Heerlen)
Plant Manager Area 1 and Utilities Mr C.L. Bell, chartered chemical engineer
Plant Manager Area 2 Mr P.M. Cliff (to 1 May, 1974), chartered engineer (fuel); Mr R. Everton (from 1 May, 1974), HND in chemistry
Works Engineer Vacant (formerly Mr Riggall)
Areas 1 and 2 Engineer Mr A.B. Blackman
Services Engineer Mr B.T. Boynton, ONC in electrical engineering, NCB (Class 1) engineering certificate
Safety and Training Manager Mr E. Brenner, Manager

Area 2 covered Section 25A of the cyclohexane plant.

The previous Works Engineer, Mr Riggall, had left and steps were being taken to replace him, but at the time of the accident there was no Works Engineer. In the absence of a Works Engineer a co-ordinating function was exercised by the Services Engineer. In addition, the engineering staff were told that if they had problems, they could call on the assistance of Mr J.F. Hughes of the NCB.

The *Flixborough Report* (para. 27) states that following the departure of Mr Riggall 'There was no mechanical engineer on site of sufficient qualification, status or authority to deal with complex or novel engineering problems and insist on necessary measures being taken'.

The report is critical of the fact that the Area 2 and Services Engineers had been asked to assume responsibilities which they should not have had to shoulder.

A2.2 The Site and the Works

The Flixborough works is on flat, low-lying land on the east bank of the River Trent some 6 miles to the south of the point where that river joins the Humber. The nearest villages are Flixborough itself and Amcotts, both of which are about half a mile away. The town of Scunthorpe lies at a distance of approximately 3 miles.

The works is surrounded by fields and the population density in the neighbourhood beyond is very low.

A site plan is shown in Figure A2.1. The diagram also shows the vapour cloud, as described below. An aerial view of the works before the explosion is given in Figure A2.2.

Other plants on the site included an acid plant and a hydrogen plant. There was also a large ammonia storage sphere.

A2.3 The Process and the Plant

The cyclohexane plant, shown in Figure A2.3, consisted of a train of six reactors in series in which cyclohexane was oxidized to cyclohexanone and cyclohexanol by air injection in the presence of a catalyst. The feed to the reactors was a mixture of fresh cyclohexane and recycled material. The product from the reactors still contained approximately 94% of cyclohexane. The liquid reactants flowed from one reactor to the next by gravity. In subsequent stages, the reaction product was distilled to separate the unreacted cyclohexane, which was recycled to the reactors, and the cyclohexanone and cyclohexanol, which were converted to caprolactam. The design operating conditions in the reactor were a pressure of 8.8 kg/cm^2 and a temperature of 155°C. The reaction is exothermic.

The heat required for initial warmup and for supplementation of the heat of reaction during normal operation was provided by a steam-heated heat exchanger on the reactor feed. The steam flow to the exchanger was controlled by an automatic control valve. There was a bypass around this valve, which was needed to pass the larger quantities of steam required during start-up.

Removal of the heat of reaction from the reactors during normal operation was effected by vaporizing part of the cyclohexane liquid. The cyclohexane vaporized passed out in the off-gas from the reactors. The rest of this off-gas was mainly nitrogen with some unreacted oxygen.

The off-gas passed through the feed heat exchanger (C2544) and then through a cooling scrubber (C2521) and an absorber (C2522), in which the cyclohexane was condensed out, and thence via an automatic control valve to a flare stack.

The atmosphere in the reactor was controlled using nitrogen from high-pressure nitrogen storage tanks. The nitrogen was brought into the works by tankers.

The reactor pressure was controlled by manipulating the control valve on the off-gas line. Safety valves venting into the relief header to the flare stack were set to open at 11 kg$_f$/cm^2.

A trip system was provided which shut off air to, and injected nitrogen into, the reactors in the event of either a high oxygen content in the off-gas or a low liquid level in the nitrogen supply tank. This trip could be disarmed, however, by setting to zero the timer fixing the duration of the purge.

The layout of the reactors in Section 25A is shown in Figure A2.4.

A2.4 Events Prior to the Explosion

On the evening of 27 March 1974, it was discovered that Reactor No. 5 was leaking cyclohexane. The reactor was constructed of $^1/_2$ in. mild steel plate with $^1/_8$ in. stainless steel bonded to it on the inside. A vertical crack was found in the mild steel outer layer of the reactor. The leakage of cyclohexane from the crack indicated that the inner stainless steel layer was also defective. It was decided to shut the plant down for a full investigation. The following morning inspection revealed that the crack had extended some 6 ft. This was a serious state of affairs and a meeting was called to decide action. The decision was taken to remove Reactor No. 5 and to install a bypass assembly to connect Reactors No. 4 and 6 so that the plant could continue in production.

The openings to be connected on these reactors were 28 in. diameter, with bellows on the nozzle stubs, but the largest pipe which was available on site and which might be suitable for the bypass was 20 in. diameter. The two flanges were at different heights so that the connection had to take the form of a dog-leg of three lengths of 20 in. pipe welded together with flanges at each end bolted to the existing flanges on the stub pipes on the reactors. The bypass assembly is shown in Figure A2.5.

Calculations were done to check (1) that the pipe was large enough for the required flow and (2) that it was

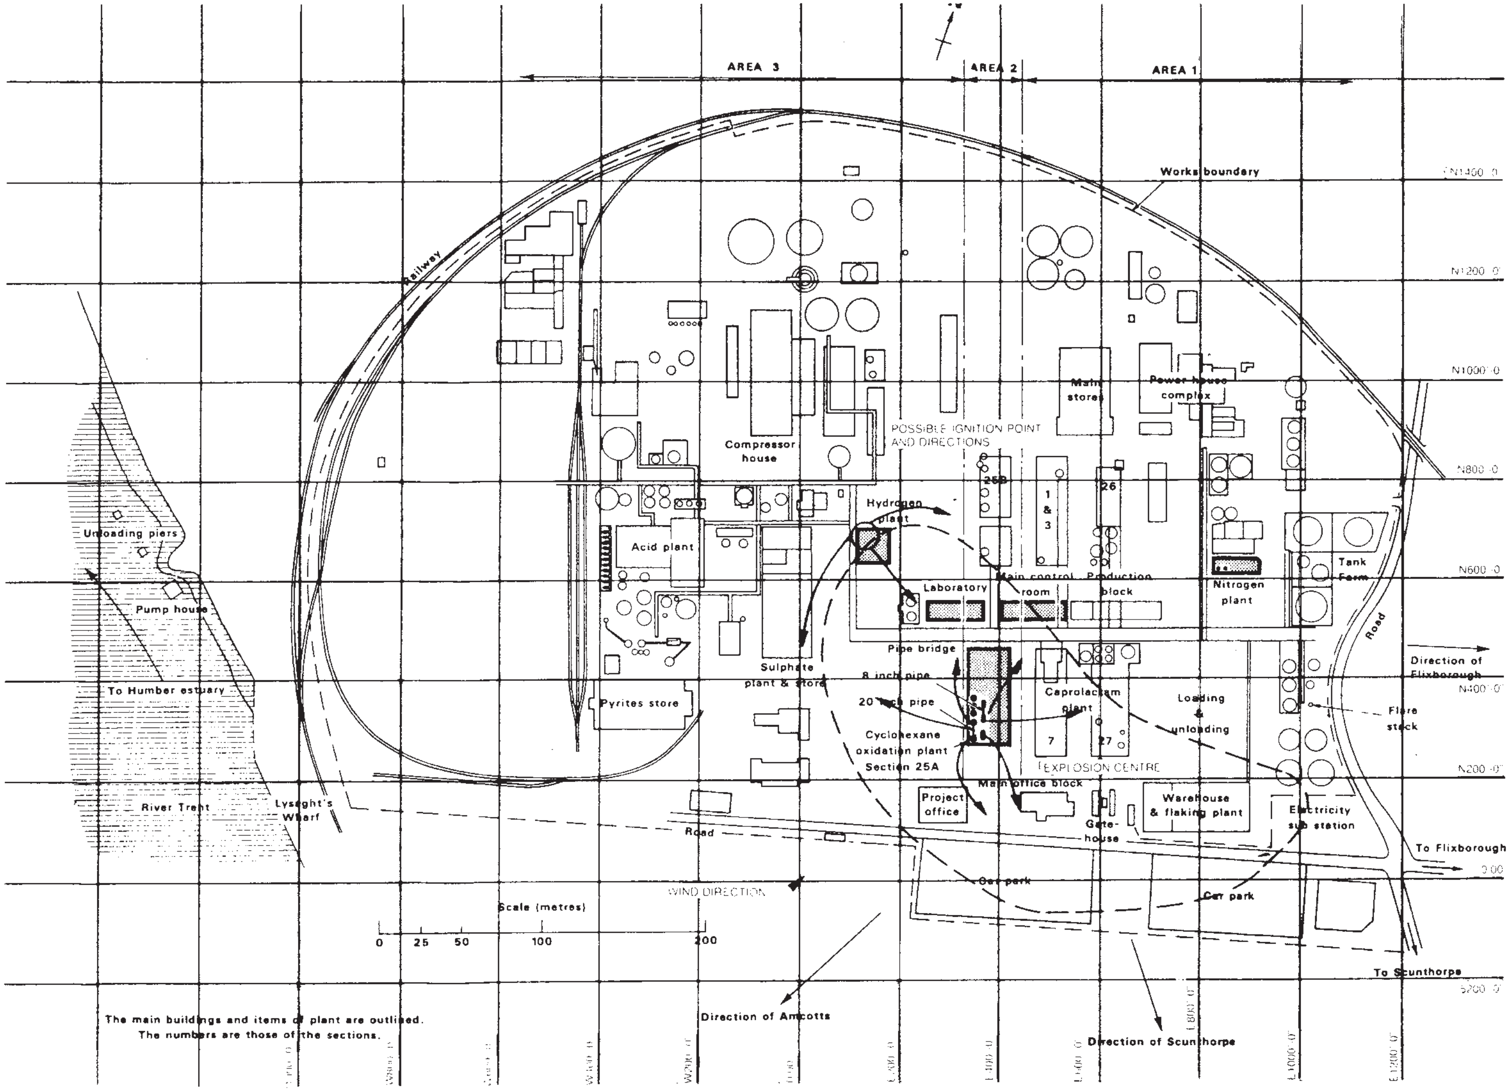

Figure A2.1 *Simplified site plan of the works of Nypro (UK) Ltd at Flixborough (Sadée, Samuels and O'Brien, 1976–77) (Courtesy of HM Stationery Office). The diagram also shows the estimated dimensions of the vapour cloud*

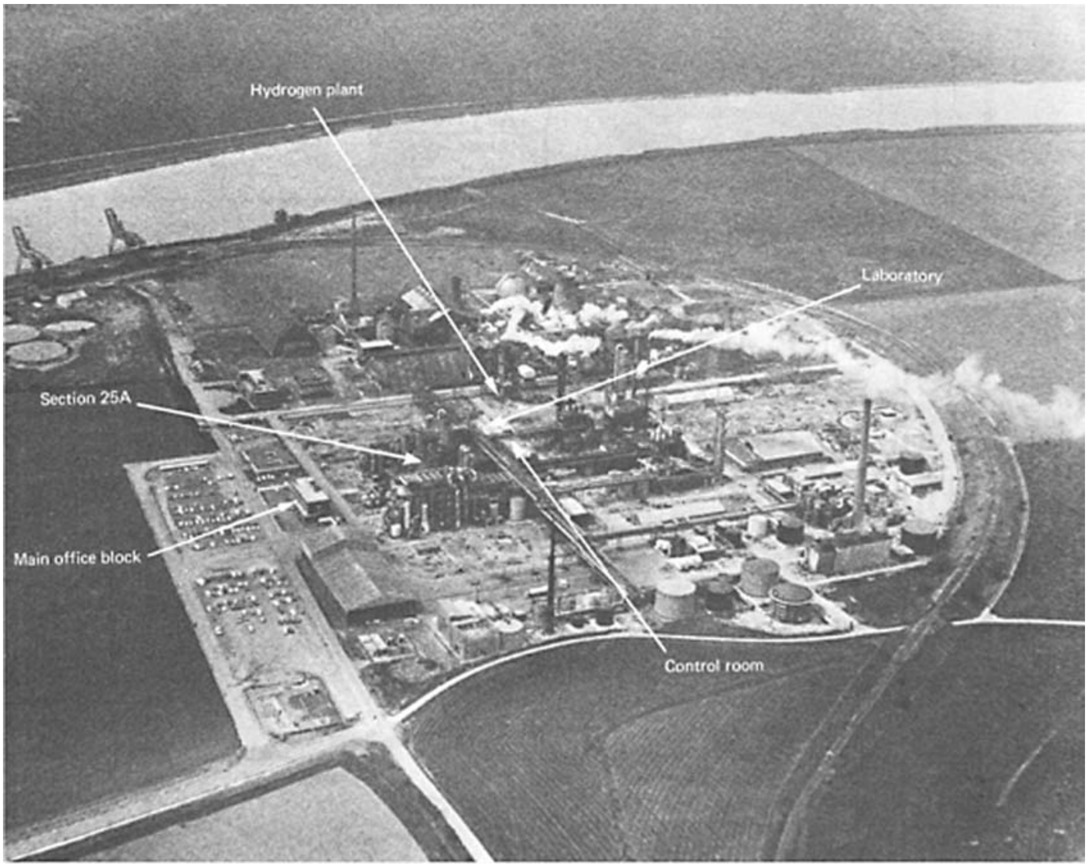

Figure A2.2 Works of Nypro (UK) Ltd at Flixborough before the explosion (Nypro (UK) Ltd)

capable of withstanding the pressure as a straight pipe. No calculations were made which took into account the forces arising from the dog-leg shape of the pipe.

No drawing of the bypass pipe was made other than in chalk on the workshop floor.

The existing stub pipes were connected to the reactors by bellows, as shown in Figure A2.5. No calculations were done to check whether the bellows would withstand the forces caused by the dog-leg pipe.

The bypass assembly was supported by a scaffolding structure, as shown in Figure A2.5. This scaffolding was intended to support the pipe and to avoid straining of the bellows during construction of the bypass. It was not suitable as a permanent support for the bypass assembly during normal operation.

No pressure testing was carried out either on the pipe or on the complete assembly before it was fitted. A pressure test was performed on the plant, however, after installation of the bypass. The equipment was tested to a pressure of 9 $\mathrm{kg_f/cm^2}$, but not up to the safety valve pressure of 11 $\mathrm{kg_f/cm^2}$. The test was pneumatic not hydraulic.

Following these modifications the plant was started up again. The bypass assembly gave no trouble. There did appear, however, to be an unusually large usage of nitrogen on the plant and this was being investigated at the time of the accident.

On 29 May, the bottom isolating valve on a sight glass on one of the vessels was found to be leaking. It was decided to shut the plant down to repair the leak.

On the morning of 1 June start-up began. The precise sequence of events is complex and uncertain. The crucial feature, however, is that the reactors were subjected to a pressure somewhat greater than the normal operating pressure of 8.8 $\mathrm{kg_f/cm^2}$.

A sudden rise in pressure up to 8.5 $\mathrm{kg_f/cm^2}$ occurred early in the morning when the temperature in Reactor No. 1 was still only 110°C and that in the other reactors was less, while later in the morning, when the temperature in the reactors was closer to the normal operating value, the pressure reached 9.1–9.2 $\mathrm{kg_f/cm^2}$.

The control of pressure in the reactors could normally be effected by venting the off-gas, but this procedure involved the loss of considerable quantities of nitrogen. Shortly after warmup began, it was found that there was insufficient nitrogen to begin oxidation and that further supplies would not arrive until after midnight. Under these circumstances the need to conserve nitrogen would tend to inhibit reduction of pressure by venting.

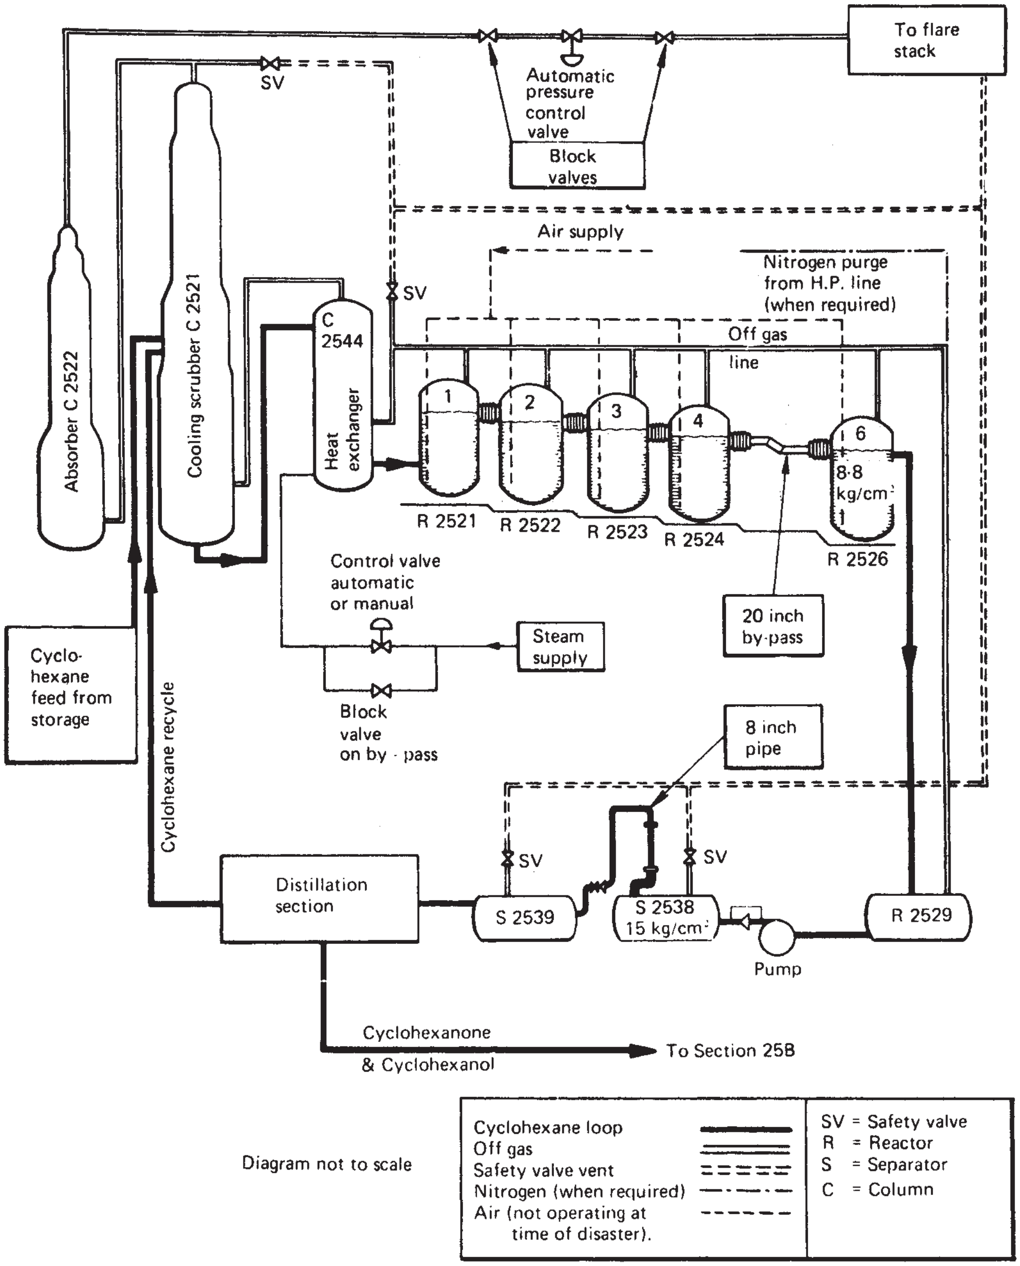

Figure A2.3 *Simplified flow diagram (not to scale) of the cyclohexane oxidation plant at Flixborough (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

A2.5 The Explosion – 1

During the late afternoon an event occurred which resulted in the escape of a large quantity of cyclohexane. As already explained, this event was the rupture of the 20 in. bypass system, without or with contribution from fire on a nearby 8 in. pipe. The cyclohexane formed a vapour cloud and the flammable mixture found a source of ignition.

At about 4.53 p.m. there was a massive vapour cloud explosion.

The explosion caused extensive damage and started numerous fires. Aerial views of the plant after the explosion are shown in Figures A2.6 and A2.7.

Reactors No. 4 and 6 and the debris of the bypass assembly are shown in Figure A2.8. The blast and the

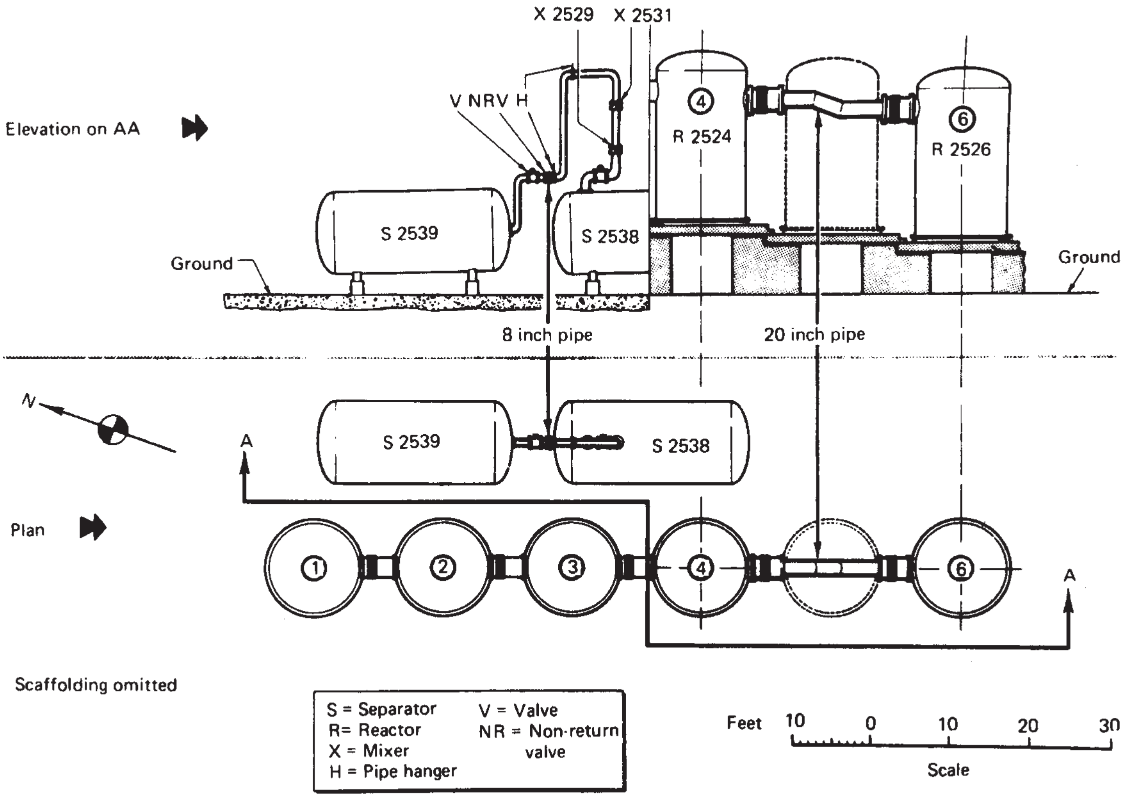

Figure A2.4 *Simplified plan and elevation of part of Section 25A of the cyclohexane oxidation plant at Flixborough (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

fires destroyed not only the cyclohexane plant but several other plants also. Many of the fires were in the tank farm.

The blast of the explosion shattered the windows of the control room and caused the control room roof to collapse. Of the 28 people who died in the explosion, 18 were in the control room. Some of the bodies had suffered severe injuries from flying glass. Others were crushed by the roof. No one escaped from the control room.

The main office block was also demolished by the blast of the explosion. Since the accident occurred on a Saturday afternoon, the offices were not occupied. If they had been, the death toll would have been much higher.

The locations of the control room and main office block are shown in Figures A2.1 and A2.2 and the states of these buildings after the explosion in Figures A2.6 and A2.7.

The fires on the site burned for many days. Even after 10 days the fires were hindering rescue work on the site. The large ammonia sphere was lifted up a few inches. It leaked slightly at a flange, but the leak was not serious.

A2.6 The Investigation

An immediate investigation of the disaster was made by the Factory Inspectorate, which issued an interim report. On its appointment, the Court of Inquiry took control of the main investigations. The work of recovering, identifying and examining wreckage and of conducting relevant tests, was undertaken by the Safety in Mines Research Establishment (SMRE). The Court appointed the consulting engineers Cremer and Warner as its technical advisers. Other government bodies, consultants and universities were involved in the numerous studies undertaken.

Some of the possible causes of failure of the bypass assembly were outlined early in the inquiry by the DSM counsel. They included (1) failure of the 20 in. pipe due to a small pressure rise; (2) prior failure of the 8 in. pipe; (3) prior failure of some other part of the system and (4) an explosion in the air-line to the reactors. He suggested several possible causes for a pressure rise in the 20 in. pipe: (1) entry of high-pressure nitrogen into the system due to instrument malfunction; (2) entry of water into the system; (3) temperature rise in the system due to excessive heating by steam in reboiler of C2544; (4) leakage of steam from a tube in C2544; (5) explosion of peroxides formed in the process and (6) explosion due to air in the system.

The inquiry established (*Flixborough Report*, para. 6) that the cause of the disaster was 'The ignition and rapid acceleration of deflagration, possibly to the point of detonation, of a massive vapour cloud formed by the escape of cyclohexane under a pressure of at least 8.8 kg/cm^2 and

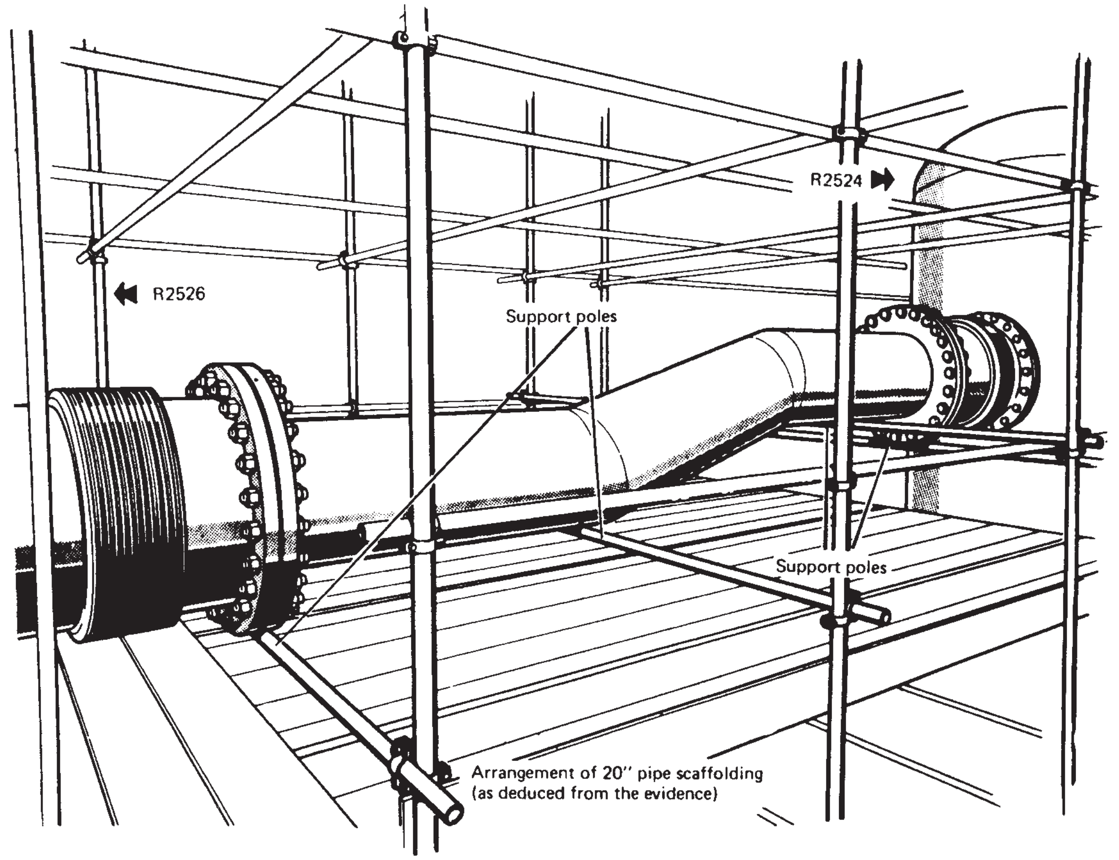

Figure A2.5 *Arrangement of the 20 in bypass pipe and scaffolding at Flixborough (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

a temperature of 155°C and that the escape was from Section 25A of the cyclohexane plant'.

There was no dispute that the main part of the cyclohexane came from the 20 in. bypass assembly, but there was come uncertainly whether the mechanical failure of the assembly was the primary failure or whether it was a secondary failure caused by another event elsewhere. Three hypotheses were advanced: (1) the 20 in. pipe hypothesis, (2) the 8 in. pipe hypothesis and (3) the superheated water hypothesis.

A large proportion of the report is concerned with a discussion of the first and second hypotheses, but the Court decided emphatically in favour of the first.

The 20 in. pipe hypothesis is that the 20 in. bypass pipe ruptured in one stage as a result of the internal pressure and temperature conditions which probably occurred in the final shift.

The site investigation revealed that the 20 in. pipe had yielded at the lower mitre, or 'jack-knifed', and that the bellows had undergone gross permanent deformation, or 'squirm'.

The arrangement of the pipe was such as to subject the bellows to shear forces due to the internal pressure in the pipe as shown in Figure A2.9. The two thrusts PA are parallel and separated by a distance $2e$ and thus give a turning moment $2PAe$ which is balanced by shear forces $F = PAE/L$. The shear forces give rise to bending moments and the maximum bending moment is at the mitre joints and is $PAEl/L$. This system of forces can lead to failure in two ways. The shear force may cause squirm of the bellows. The bending moments may cause failure of the pipe by buckling one of the mitres. As already mentioned, these effects had been neglected in the calculations done on the bypass assembly.

These mechanisms were studied in comprehensive, full-scale investigations by SMRE, by Nottingham University and the Mining Research and Development Establishment, Bretby. The results of the tests are complex, but, in brief, they showed that squirm of the bellows could occur at pressures at or near the operating pressure. They did not show jackknifing and rupture following squirm. A mechanism for the latter was given by Newland (1975), who developed a theory based on the energies involved, which showed that at pressures above normal operating pressures but below the safety valve pressure there could occur squirm of both the bellows, followed by jackknifing of the

Figure A2.6 *Works of Nypro (UK) Ltd at Flixborough after the explosion – 1 (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

pipe, resulting in complete rupture. The pressures for jackknifing and rupture to be a consequence of squirming were estimated to be as follows:

	Low (kg_f/cm^2)	*Probability* 50% (kg_f/cm^2)	*High* (kg_f/cm^2)
150°C	9.3	9.9	10.6
160°C	9.1	9.7	10.4

Other mechanisms of squirm alone and jackknifing alone were investigated, but appeared less probable.

The Court concluded that the rupture of the 20 in. pipe assembly was a probability, albeit a low one, under the pressure and temperature conditions which occurred in the last shift.

The 8 in. pipe hypothesis is somewhat more complex. The 8 in. pipe ran between separators S 2538 and S 2539. The location and details of the pipe are shown in Figures A2.4 and A2.10, respectively. There was a block valve, a non-return valve and a lagging box on the pipe. The pipe was made of stainless steel.

Essentially the hypothesis was that a directed flame had occurred from the lagging box and had caused rupture of the pipe from which cyclohexane then escaped to form a vapour cloud. This hypothesis was advanced by Cox and Gugan.

The hypothesis had its origin in eyewitness accounts of the events immediately prior to the explosion and in the condition of the equipment found in the site investigation. The latter revealed that there was a 50 in. split on the elbow of the 8 in. pipe and subsequent studies showed that the crack was caused by creep cavitation. The 50 in. split also exhibited a petal crack which was due to zinc embrittlement and a separate 3 in. crack due to the same cause was found on the straight vertical section of the pipe. In addition, two loose bolts were found on the non-return valve. There was some doubt as to whether these had been loose before the explosion, but the Court concluded that this was probably the case.

The 8 in. pipe hypothesis may be summarized as follows. There were two loose bolts on the non-return valve. Then either there was a slow leakage of material over an extended period and a lagging fire which caused further expansion of the bolts and growth of the leak, or there was a sudden gasket burst and ignition of the leak by static electricity. In either case there was a directed flame from the lagging box. A sprinkler sensor head near the non-return valve failed to detect the fire. The flame burned off the lagging on the pipe elbow and caused a vapour blanket in the pipe and a vapour lock at the intrados so that the pipe overheated. The pipe suffered creep cavitation at the intrados and the 50 in. rupture occurred. Zinc from galvanized wire dripped onto the pipe and caused zinc embrittlement, but this was not responsible for the main failure. The

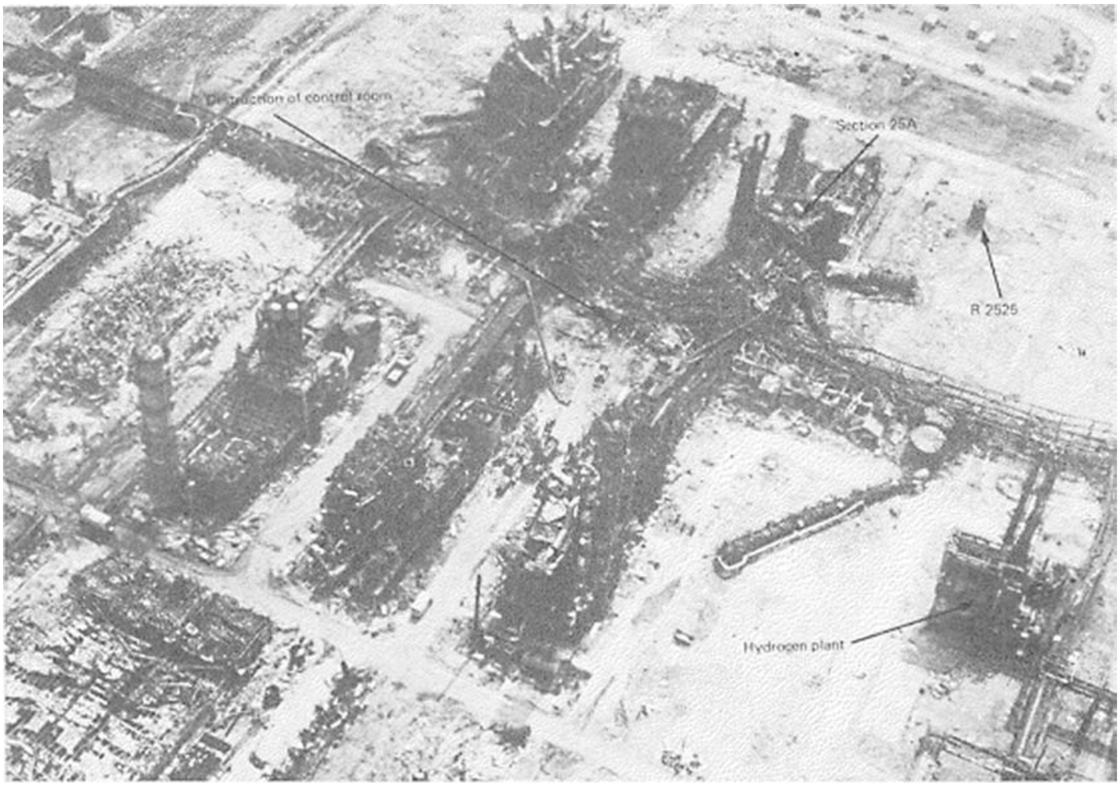

Figure A2.7 *Works of Nypro (UK) Ltd at Flixborough after the explosion–2 (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

cyclohexane issued from the 50 in. crack and put out the flame. A fire then occurred in the region of the fin fan coolers which melted the zinc on the finned tubes and raised them to a temperature at which zinc embrittlement occurs. There followed an explosion in the region of one of the fan motors which caused the 20 in. bypass to jackknife and rupture.

The foregoing account is a necessarily highly simplified summary of a very complex argument. The Court's report gives a detailed account of this hypothesis but rejects it. It draws an analogy between the sequence of events required by the hypothesis with the balancing of billiard balls one on top of another and states 'This balancing of ten balls is analogous to what is postulated for the 8-inch pipe hypothesis'.

The third hypothesis is that the failure of the 20 in. bypass assembly was due to sudden evolution of vapour from a layer of superheated water at the bottom of Reactor No. 4. The water might have been present in the reactor initially or might have come from a leak in the steam-heated heat exchanger on the feed. Such a water layer was able to build up in the vessel more easily because the reactor agitator was not in use. This theory, advanced by R. King, was mentioned, but did not figure prominently at the inquiry. It has been described in a number of articles by King (1975a–c, 1976a,b, 1977).

A2.7 The Explosion – 2

Another aspect of the Flixborough investigation is the studies conducted on the explosion itself. Accounts of the explosion have been given in the *Flixborough Report*, by Gugan (1976) and by Sadée, Samuels and O'Brien (1976–77).

According to Sadée, Samuels and O'Brien the quantity of cyclohexane available in the five reactors and one after-reactor was 120 te. The normal operating pressure and temperature were $8.8\,\mathrm{kg_f/cm^2}$ and 155°C, respectively. After the explosion it was found that the vessels still contained 80 te, so that the maximum quantity involved in the explosion was 40 te. These authors estimate that about 30 te escaped before the explosion and they take this quantity as the basis of their calculations.

The flow from each of the two pipe stubs, which were opposite each other, but at slightly different heights, would form a turbulent momentum jet with the two opposing jets impinging on each other, thus giving very effective mixing.

It is estimated by Sadée, Samuels and O'Brien that 50%, or 15 te, of the cyclohexane would flash off as vapour and that the other 50% would form a mist. Whether or not the mist would then evaporate depends on the amount of air entrained by the jet. The authors state that evaporation is possible provided that the concentration of cyclohexane does not exceed 10%.

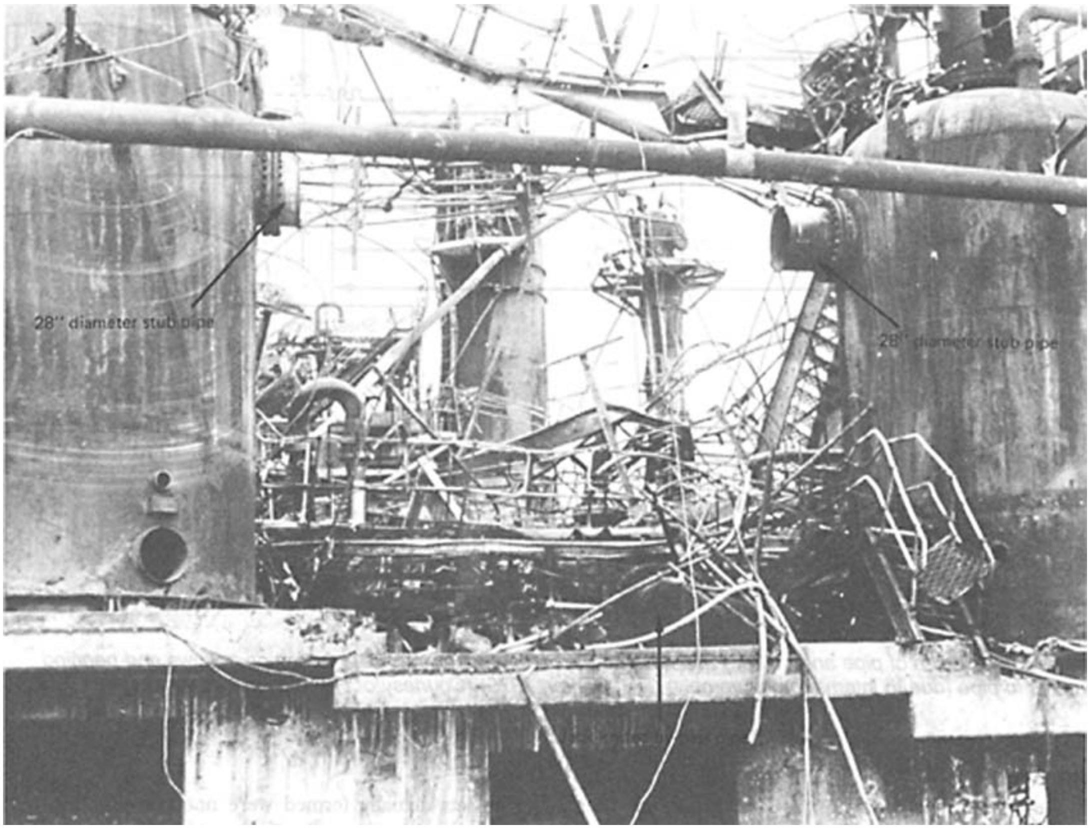

Figure A2.8 *Reactors No. 4 and 6 and the bypass assembly at Flixborough after the explosion (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

Sadée, Samuels and O'Brien have calculated the dimensions of a stationary, free jet of cyclohexane at 1 MPa and 150°C emitted from a 700 mm diameter opening and forming a cloud containing equal masses of vapour and liquid in air. This jet is shown in Figure A2.11. The jet is 215 m long and has a maximum diameter of 25 m. The jet volume with a concentration exceeding the low flammability limit (1.2%) is 64,400 m^3 and that with a concentration within the flammable range (1.2–8%) is practically the same. The average concentration in the flammable part of the jet is 1.85%, which is close to the stoichiometric proportion. The quantity of cyclohexane within the flammable part of the jet is 4 te. If two such jets are assumed, the quantity is 8 te.

The jets actually formed were not free jets, but were affected by the ground and the reactors. Taking these factors into account, the authors estimate the quantity of cyclohexane within the flammable part of the two jets as 22.4 te.

Sadée, Samuels and O'Brien present calculations on the assumption that the quantity of cyclohexane involved in the explosion was 30 te. This amount of cyclohexane mixed with air to yield a flammable concentration of 2% gives a cloud volume of 400,000 m^3.

The precise shape of the cloud is uncertain, as is the source of ignition. From the carbon deposition and explosion damage the estimate of the cloud ground zero and shape is that shown in Figure A2.1. The source of ignition may have been the hydrogen plant. An alternative estimate of the cloud shape has been given by J.I. Cox (1976b).

Various estimates have been made of the time which elapsed between the times of rupture and of the explosion, mostly ranging between 30 and 90 s. An estimate of 45 s has been widely quoted.

There is evidence from carbon deposition and from eyewitness accounts that there was a flash fire as well as an explosion in the vapour cloud.

From eyewitness accounts it appears that there may have been a short period during which the cloud had found a source of ignition and combustion was occurring at the edge of the cloud, but the cloud was expanding faster than the flame speed. Assuming a constant flow of vapour into the cloud, the velocity of outward expansion would fall as the cloud diameter increased and a point would be reached at which the velocity would fall below the flame speed. The flame would then travel rapidly towards the centre of the cloud.

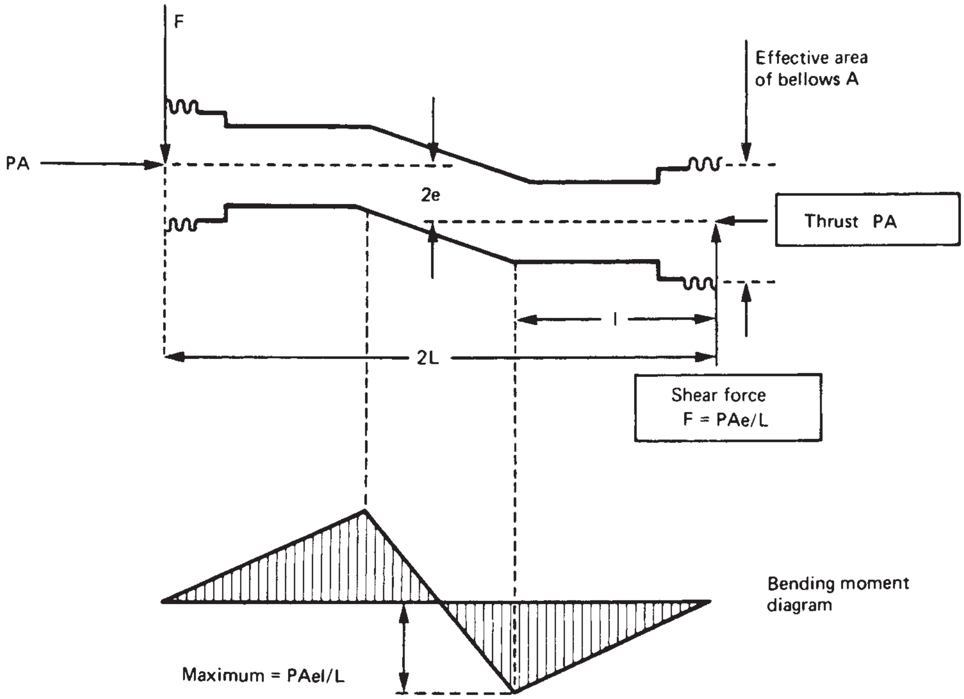

Figure A2.9 *Sketch of pipe and bellows assembly at Flixborough showing shear forces on bellows and bending moments in pipe (due to internal pressure only) (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

One effect of such a flash fire would be to cause a sudden and lethal depletion of the oxygen concentration.

There was evidence of two explosive events. An ionosphere recorder trace obtained at Leicester University (T.B. Jones and Spracklen, 1974; T.B. Jones, 1975) showed two disturbances, a smaller precursor followed by the main event. The time interval between them was some 45 s.

Estimates of the energy of explosion were made in several ways, including estimation from ionospheric readings (T.B. Jones, 1975), from the barograph of a glider in the vicinity (Gugan, 1975a) and from a blast damage survey (A.F. Roberts, 1975; Samuels and O'Brien, 1975).

The most detailed estimates of explosion energy are those derived from the blast damage survey. The results of this survey have been discussed by Gugan (1976), Munday (1975b) and Sadée, Samuels and O'Brien (1976–77). The latter gave a detailed listing and photographs of structural damage.

The blast damage effects caused by the explosion have been assessed by Sadée, Samuels and O'Brien and are shown in Figure A2.12, in which the individual data bars give the ranges of peak overpressure determined from structural damage vs distance from the assumed epicentre of the explosion.

The estimates of the energy of the explosion made by different workers depend on the explosion model used.

Most estimates are based on the simplest model, in which the only parameter is the mass of TNT. These estimates are generally in the range 15–45 te of TNT.

An alternative two-parameter model describes the explosion in terms both of the mass of TNT and the height of the explosion. Using this model, Sadée, Samuels and O'Brien estimate that the explosion was equivalent to 16 ± 2 te of TNT at a height of 45 ± 24 m above ground. 16 te of TNT have a calorific equivalent of about 1.6 te of cyclohexane; the calorific value of TNT is 1600 kcal/kg and that of cyclohexane is 11,127 kcal/kg.

The curve given by Sadée, Samuels and O'Brien in Figure A2.12 is based on this two-parameter TNT model.

If the cloud contained 30 te of cyclohexane and gave an explosion equivalent to the combustion of about 1.6 te, the explosion efficiency was about 5%. This efficiency is based on the total quantity of cyclohexane in the cloud.

The maximum overpressure at the centre of the cloud is uncertain. The maximum overpressure obtained from the structural damage, as described by Sadée, Samuels and O'Brien, was 0.7 bar. These authors state, however, that the theoretical curve in Figure A2.12 indicates an overpressure of 1 bar at the cloud boundary.

Some estimates of the pressure developed within the cloud are considerably higher. These estimates are typically based on calculation of the forces required to give damage effects such as the bending of steel lamp posts or crushing of steel vessels. Thus, for example, V.J. Clancey (1977a) states that where local effects occurred as a result of features such as confinement, pressures of up to perhaps 5–7 bar have been estimated. The pressures calculated in this way would normally be reflected pressures.

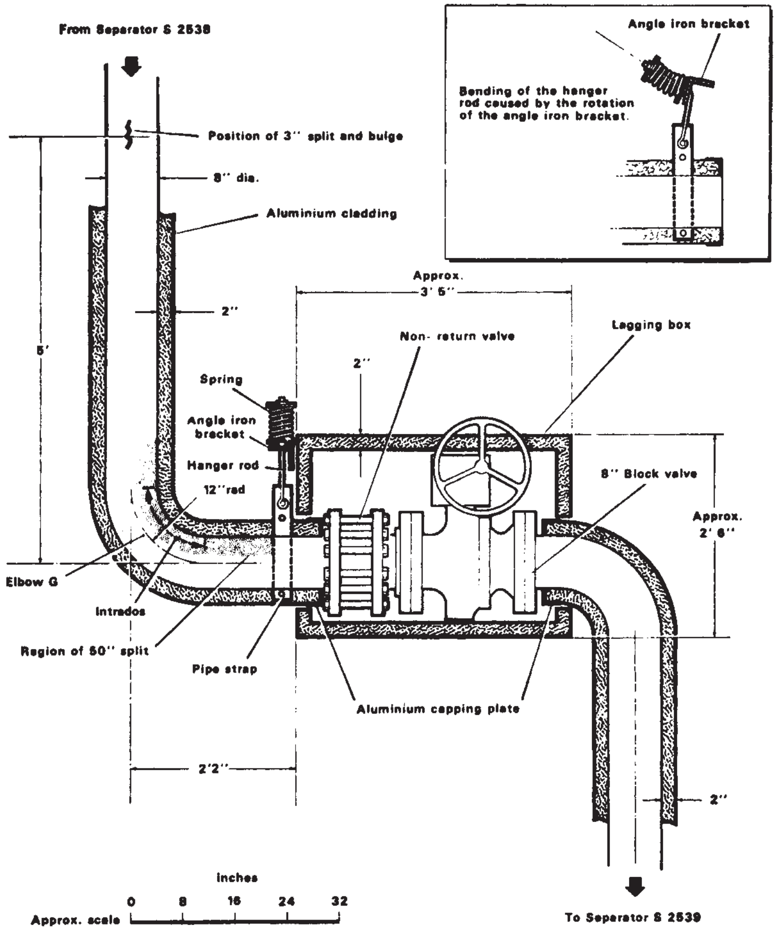

Figure A2.10 *Elevation view of 8 in. line at Flixborough, showing typical lagging box around valve (R.J. Parker, 1975) (Courtesy of HM Stationery Office)*

A2.8 Some Lessons of Flixborough

There are numerous lessons to be learned from the Flixborough disaster. A list of some of these is given in Table A2.2. Many of these lessons were highlighted in the Court's report.

The lessons include both public controls on major hazard installations and the management of such installations by industry. In the latter area there are lessons on both management systems and technological matters and on both design and operational aspects.

The fact that alternative hypotheses were advanced concerning the cause of the explosion does not detract from these lessons, but rather means that a greater number of lessons can be drawn.

Some of these lessons are now considered.

Public controls on major hazard installations

The effect of the Flixborough disaster was to raise the general level of awareness of the hazard from chemical plants and to make the existing arrangements for the control of major hazard installations appear inadequate.

The government therefore set up the ACMH to advise on means of control for such installations. The committee issued three reports (Harvey, 1976, 1979b, 1984). Its recommendations are described in Chapter 4.

This work was a major input to the development of the EC Major Accident Hazards Directive, which was implemented in the United Kingdom as the CIMAH Regulations 1984. These require the operator of a major hazard installation to produce a safety case.

Major hazard installations receive a greater degree of supervision by the local Factory Inspectorate. The CIMAH safety case plays an important part in this.

Siting of major hazard installations

As the *Flixborough Report* (para. 11) points out, the casualties from the explosion might have been much greater if the site had not been in open country.

The siting of major hazard installations is a matter of utmost importance. On the one hand distance is the only sure guarantee of safety, but on the other provision of increased spacing may be very wasteful of land.

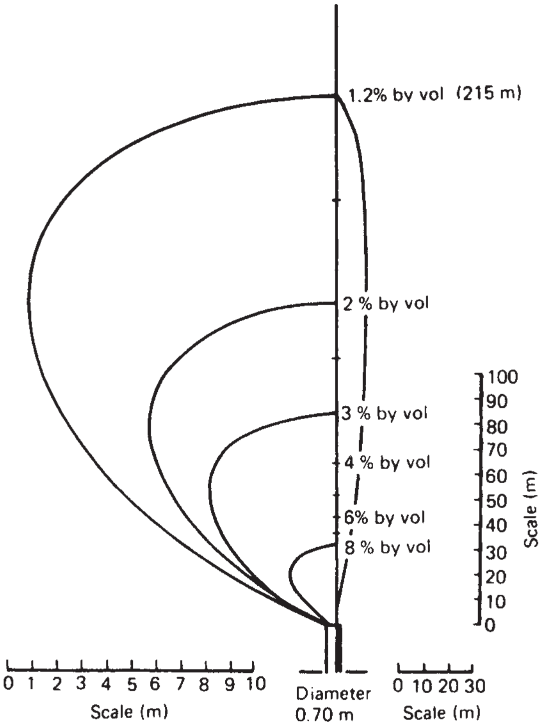

Figure A2.11 *Dimensions of and concentration distribution in a stationary, free jet of cyclohexane in air from an opening 700 mm diameter (Sadée, Samuels and O'Brien, 1976–77) (Courtesy of HM Stationery Office)*

The question of the siting of major *hazard* installations, or more generally land use planning in relation to such installations, became a principal concern of the ACMH, and is treated in its three reports. Controls on major hazards through land use planning are discussed in Chapter 4 and Appendix 25. Siting is also considered in Chapter 10.

Licensing of storage of hazardous materials

The *Flixborough Report* (para. 194) states

> As at 1st June 1974 Nypro were storing on site 330,000 gallons of cyclohexane, 66,000 gallons of naphtha, 11,000 gallons of toluene, 26,400 gallons of benzene and 450,000 gallons of gasoline. The storage of these potentially dangerous substances is nominally controlled by the local authority issuing licences under the Petroleum (Consolidation) Act 1928. In fact the only licences that had been issued related to 7000 gallons of naphtha and for a total of 1500 gallons of gasoline. The unlicensed storage of large quantities of fluids had no effect upon this disaster but it is clearly useless to have a licensing system which is so ineffective that it can lead to such results.

The situation at Flixborough revealed the need for better methods of notification of major hazard installations to the local planning authorities and for greater guidance to these authorities by the HSE.

The notification of major hazard installations is a requirement of the NIHHS Regulations 1982 and of the CIMAH Regulations 1984. These notification requirements and the advice now given by the HSE to local planning authorities are discussed in Chapter 4.

Regulations for pressure vessels and systems

The escape of cyclohexane at Flixborough was caused by a failure of the integrity of a pressure system.

Current legislation on pressure systems in the United Kingdom consisted of regulations for steam boilers and receivers and air receivers. It failed to cover the Flixborough situation in two crucial respects. It applied only to steam and air and not to hazardous materials such as cyclohexane. And it dealt only with pressure vessels and not with pressure systems. This latter point is relevant, because at Flixborough the failure occurred in a pipe not a vessel.

The *Flixborough Report* (para. 209) recommends that existing regulations relating to the modification of steam boilers should be extended to apply to pressure systems containing hazardous materials.

Following Flixborough the HSE set about developing comprehensive regulations for pressure systems, which finally emerged as the Pressure Systems Regulations 1989. These regulations are described in Chapters 3 and 12.

The management system for major hazard installations

The *Flixborough Report* (paras 207, 209, 210) places much emphasis on deficiencies in the management system at the Nypro Works.

The works did not have a sufficient complement of qualified and experienced people. Consequently, management was not able to observe the requirement that persons given responsibilities should be competent to carry them out. In particular, there was no works engineer in post and no adequately qualified mechanical engineer on site.

Moreover, individuals tended to be overworked and thus more liable to error.

The management system, however, is more than the individuals. It includes the whole structure which supports them. Thus the system should provide, for example, for the coverage of absence due to resignation, illness and so on.

The use of a comprehensive set of procedures is another important aspect of the management system. A crucial procedure which was deficient at Flixborough was that for the control of plant modifications.

The role of the safety officer at Flixborough was not well defined.

The importance for major hazard installations of the management and the management system was the single most prominent theme in the work of the ACMH. Emphasis by the HSE on management aspects has steadily grown. The *Cutten Report* on the Piper Alpha disaster recommended that offshore the safety case should cover the safety management system and this is implemented in the offshore regulations. This aspect is discussed in Chapters 4 and 6.

Relative priority of safety and production

The *Flixborough Report* (paras 57, 206) drew attention to the conflict of priorities between safety and production. It states

> We entirely absolve all persons from any suggestion that their desire to resume production caused them knowingly to embark on a hazardous course in disregard of the

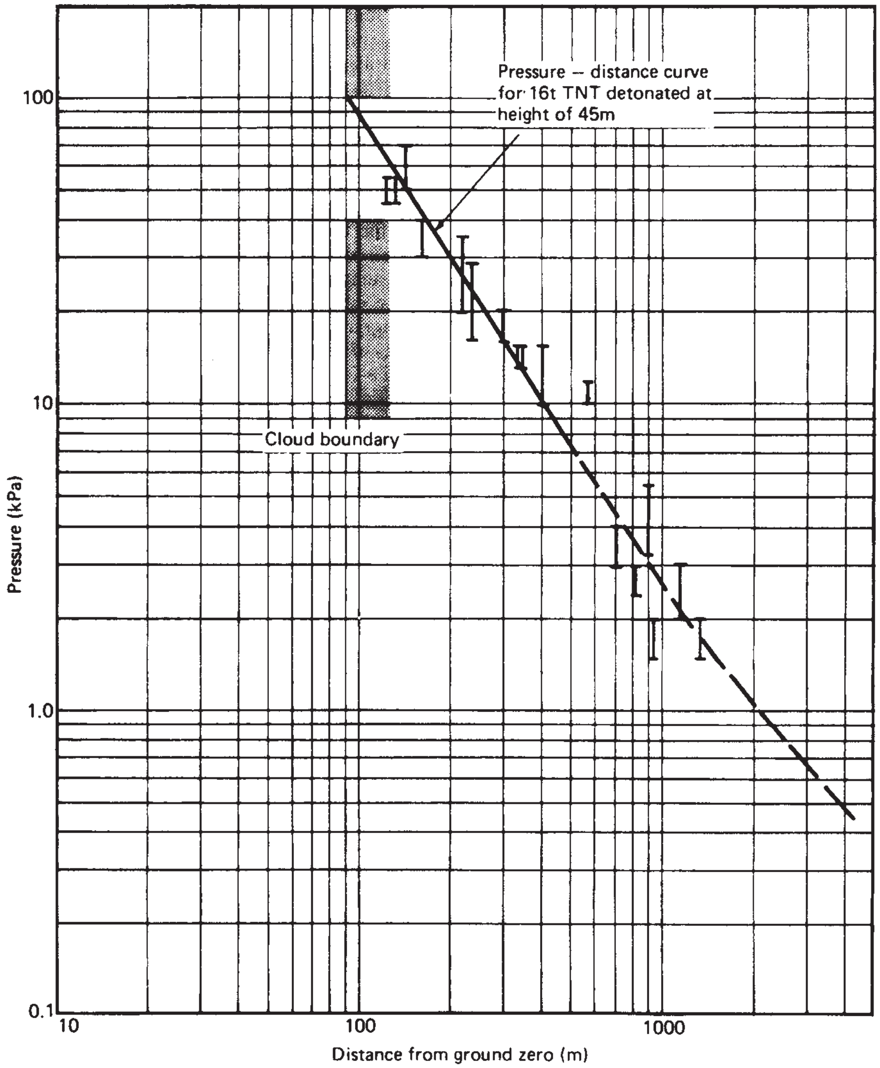

Figure A2.12 Peak overpressure vs distance at Flixborough estimated from blast damage (Sadée, Samuels and O'Brien, 1976–77) (Courtesy of HM Stationery Office)

> safety of those operating the Works. We have no doubt, however, that it was this desire which led them to overlook the fact that it was potentially hazardous to resume production without examining the remaining reactors and ascertaining the cause of the failure of the fifth reactor. We have equally no doubt that the failure to appreciate that the connection of Reactor No. 4 to Reactor No. 6 involved engineering problems was largely due to the same desire.

Use of standards and codes of practice

As the *Flixborough Report* (paras 61–73) describes, the 20 in. bypass assembly was not constructed and installed in accordance with the relevant standards and codes of practice.

The principal standard relevant to the modification was BS 3351: 1971. The report quotes extracts from this standard:

> 4.6.2. For axial bellows, the piping shall be guided to maintain axiality of the bellows and anchored at adjacent changes in direction to prevent the bellows being subjected to axial load due to fluid pressure. 5.4.2.1 . . . . When expansion joints are used, the advice of the manufacturer should be sought with regard to the guiding, anchoring and support of the adjacent pipework.

The bellows manufacturer, which was Teddington Bellows Ltd, produced a *Designers Guide* which made it clear that two bellows should not be used out of line in the same pipe without adequate support for the pipe.

Investigation of disasters and feedback of information on technical incidents

The use of standards and codes of practice is described in Chapters 3, 6 and 12.

Limitation of inventory in the plant

The *Flixborough Report* (para. 14) makes it clear that the large inventory of flammable material in the plant contributed to the scale of the disaster.

The *Second Report* of the ACMH proposes that limitation of inventory should be taken as a specific design objective in major hazard installations.

The limitation of inventory is a particular aspect of the more general principle of inherently safer design, which is now widely recognized. This is discussed in Chapter 11.

Engineering of plants for high reliability

The explosion at Flixborough occurred during a plant start-up. The *Flixborough Report* (para. 206) suggests that special attention should be given to factors which necessitate the shut-down of chemical plant so as to minimize the number of shut-down/start-up sequences and to reduce the frequency of critical management decisions.

The reliability of plant is considered in Chapters 7 and 12.

Dependability of utilities

The high-pressure nitrogen required for the blanketing of the reactors at Flixborough was brought into the works by tankers. There was insufficient nitrogen available during the start-up when the explosion occurred. The *Flixborough Report* (para. 211) emphasizes the importance of assuring dependable supplies of nitrogen where these are necessary for safety.

The dependability of utilities is discussed in Chapter 11.

Limitation of exposure of personnel

The *Flixborough Report* (para. 1) states that the number of casualties would have been much greater if the explosion had occurred on a weekday instead of on a Saturday.

The *First Report* of the ACMH (para. 68) suggests that limitation of exposure of personnel be made a specific design objective.

Aspects of limitation of exposure are controls on access to hazardous areas and design and location of buildings in or near such areas.

The limitation of exposure of personnel is described in Chapters 10 and 20.

Design and location of control rooms and other buildings

Of the 28 deaths at Flixborough 18 occurred in the control room. The *Flixborough Report* (para. 218) refers to various suggestions made to the inquiry concerning the siting of control rooms, laboratories, offices, etc., and the construction of control rooms on blockhouse principles.

The construction of buildings for chemical plant is considered in the *First Report* of the ACMH (para. 69).

The design and location of control rooms and other buildings is discussed in Chapters 10 and 20.

Control and instrumentation of plant

The control and instrumentation system was not a prominent feature in the Flixborough inquiry. The *Flixborough Report* (para. 204) considered that the controls in the control room followed normal practice. But it also states ‘Nevertheless we conclude from the evidence that greater attention to the ergonomics of plant design could provide rewarding results’.

Control system design and human factors in process control are described in Chapters 13 and 14.

Decision making under operational stress

The *Flixborough Report* (para. 205) draws attention to the problem of decision making under operational stress and emphasizes the desirability of reducing the number of critical management decisions which have to be made under these conditions.

Such critical decisions are not necessarily confined to management, however. Process operators may also be required to take important decisions in emergency conditions.

The process operator in emergency situations is discussed in Chapter 14.

Restart of plant after discovery of a defect

Following the discovery of the serious defect in Reactor No. 5 at Flixborough, the reactor was removed, a bypass assembly was installed and the plant was started up again. The *Flixborough Report* (para. 57) is critical of the fact that the remaining reactors were not examined and the cause of the failure in the fifth reactor was not ascertained before plant start-up.

The procedures for restart of the plant after discovery of a defect are discussed in Chapter 20.

Control of plant and process modifications

The *Flixborough Report* (para. 209) states

> The disaster was caused by the introduction into a well designed and constructed plant of a modification which destroyed its integrity. The immediate lesson to be learned is that measures must be taken to ensure that the technical integrity of plant is not violated.

As it happens, there was also a process modification at Flixborough, although this is not emphasized in the report. The agitator in Reactor No. 4 was not in use at the time of the disaster. The absence of agitation in the reactor could have allowed a water layer to accumulate more easily in the bottom of the vessel. The sudden evolution of vapour from superheated water was advanced by King as a possible cause of the rupture of the bypass pipe assembly.

The control of plant and process modifications is discussed in Chapters 6 and 21.

Security of and control of access to plant

The *Flixborough Report* (para. 194) draws attention to the fact that there were two unguarded gates through which it was possible for anyone at any time to gain access, although this fact did not contribute to the disaster. The security of plants is considered in Chapter 20.

Planning for emergencies

The *Flixborough Report* (para. 222) calls for a disaster plan for major hazard installations. Emergency planning is described in Chapter 24.

The metallurgical phenomena

The Flixborough disaster drew attention to several important metallurgical phenomena. Thus the *Flixborough Report* describes the nitrate stress corrosion cracking of mild steel (paras 53, 212); the creep cavitation of stainless steel (para. 214); the zinc embrittlement of stainless steel (para. 213); and the use of clad mild steel vessels (para. 224).

The HSE subsequently issued *Technical Data Notes* (1976 TON 53/1, 53/2; 1977 TON 53/3) on the first three of these problems.

It was apparent from the discussion in the engineering profession following publication of the report that although metallurgical specialists were aware of failure due to zinc embrittlement, the phenomenon was not well known among engineers generally.

The metallurgical features of pressure systems are discussed in Chapter 12.

Vapour cloud explosions

The explosion at Flixborough was a large vapour cloud explosion. Although such explosions had become more common in the preceding years, none compared with Flixborough in scale and impact. The *Flixborough Report* (para. 215) draws attention to the marked lack of information on the conditions under which a vapour cloud can give an explosion.

Since Flixborough, a large amount of work has been done on vapour cloud explosions. An account is given in Chapter 17.

Investigation of disasters and feedback of information on technical incidents

The Flixborough disaster was investigated by a Court of Inquiry. There was some feeling in the engineering profession that a legal inquiry of this kind is not a satisfactory means of establishing the facts concerning technical incidents. This aspect is considered in the following section.

The *Flixborough Report* (para. 216) states that the inquiry would have been greatly assisted if the essential instrument records in the control room had not been destroyed in the explosion and recommends that consideration be given to systems for recording and preserving vital plant information such as the 'black box' recorder used in aircraft.

The investigation of disasters and the feedback of information from technical incidents is considered in Chapter 27.

The points just outlined by no means exhaust the lessons to be learned from the Flixborough disaster. In particular, there are many instructive aspects of the 8 in. pipe hypothesis relating to such features as lagging fires, directed flames and sprinkler sensor performance.

A2.9 Critiques

The Flixborough inquiry has been the subject of a number of critiques which have centred mainly on (1) the form of the inquiry; (2) the examination of the hypotheses; (3) the design of the plant (4) the management of the plant and (5) technical issues. These include those of R.L. Allen (1977b), Mecklenburgh (1977a), D.J. Lewis (1989a), R. King (1990) and I. Thomas and Gugan (1993), and the mainly technical discussions of Gugan (1979) and V.C. Marshall (1987).

King gives a detailed description of the plant and it operation and diagrams showing the original plant and the modified plant.

Mecklenburgh, King and Thomas and Gugan argue that the legal format is not conducive to elucidating the facts about technical issues. The question is discussed in detail in Chapter 27.

With regard to the examination of hypotheses, Thomas and Gugan argue that the possible role of explosive reactions, described by Alexander (1990b,c), was insufficiently explored. With regard to the 8 in. pipe hypothesis, while accepting that the inquiry devoted considerable effort to exploring it, they are critical of the arguments used in dismissing it.

Thomas and Gugan rehearse various aspects of the 20 in. and 8 in. pipe hypotheses. Aspects of the 8 in. pipe hypothesis are also discussed by Marshall.

King gives an account of his own hypothesis that there was a pressure rise in Reactor No. 4 due to the evolution of water vapour from water present in that reactor. He also gives the background to the removal of the agitator from Reactor No. 4.

King is critical of the conclusion that the crack in Reactor No. 5 was due to nitrates in the cooling water, the finding of a DSM report. He quotes an HSE source to the effect that the reactor vessel drawing specified a maximum thrust on the 28 in. stubs of 9 te, whereas at normal operating conditions the thrust was 38 te. He suggests that the nitrates found were from cooling water sprayed on the already-formed crack.

The design of the plant is also criticized by Marshall, who argues that it would have been better to use not gravity flow involving the 28 in. pipe connections but pumped flow which would have allowed the use of much smaller diameter pipes.

With regard to the operation of the plant, King is critical of the decision to remove the agitator from Reactor No. 4, which, among other things, increased the hazard from water accumulation in the vessel.

Thomas and Gugan point to the facts that the plant was shut-down to deal with leaks and was then restarted because ‘the leaks had cured themselves’ that the oxygen trip was disarmed; the production was continued even though there was a shortage of nitrogen; and that the plant was started up again after the failure of Reactor No. 5 without inspection of the other reactors.

One technical issue discussed by King is the thrust exerted by unrestrained bellows on the systems to which they are connected, which tends to be underestimated.

Lewis gives some alternative estimates of the size of the release. He states that the inventory of the cyclohexane oxidation unit exceeded 120 te. Re-examination of the reactor section at a pressure of 8.6 bar shows that it had an inventory of 230 te with another 150 te in the attached distillation section at 14.7 bar.

He also discusses the problem of determining the efficiency of the explosion compared with TNT. Estimates were made from long-range effects and from medium range damage surveys, and both point to a TNT equivalent of 15–20 te. There were major difficulties, however, in fitting TNT curves to the damage observed.

The TNT efficiency is difficult to assess, depending as it does on the estimate of the mass within the flammable region and on the blast curves used.

Gugan gives a detailed discussion of certain particular damage effects. They include crushing of a vessel, from which he estimates an overpressure of 0.76 MPa (110 psi); damage to drain covers, for which his overpressure estimate is 1 MPa; and bending of a reactor agitator shaft and deformation of lamp standards. He suggests that in general the analysis of the damage relied too much on the effects of overpressure to the neglect of the influence of impulse and dynamic pressure.

Marshall regards the vapour cloud explosion at Flixborough as of particular interest in that it is the best documented and most studied case, and is thus an exemplar. He gives a detailed analysis of the estimates of overpressure made from the damage effects, treating separately those in the near and far fields. The results show wide scatter, and he concludes that it is peculiarly difficult to estimate the energy release of such an explosion from damage.

Appendix 3

Seveso

Contents

At 12.37 on Saturday 9 July 1976, a bursting disc ruptured on a chemical reactor at the works of the Icmesa Chemical Company at Meda near Seveso, a town of about 17,000 inhabitants some 15 miles from Milan. A white cloud drifted from the works and material from it settled out downwind. Among the substances deposited was a very small amount of TCDD, one of the most toxic chemicals known. There followed a period of great confusion due to lack of communication between the company and the authorities and the latter's inexperience in dealing with this kind of situation. Over the next few days in the contaminated area animals died and people fell ill. A partial and belated evacuation was carried out. In the immediate aftermath there were no deaths directly attributable to TCDD, but a number of pregnant women who had been exposed had abortions.

A Parliamentary Commission of Inquiry, drawn equally from the Chamber of Deputies and the Senate and chaired by Deputy B. Orsini, was set up. The Commission's report (the Seveso Report) (Orsini, 1977, 1980) is a far-ranging inquiry not only into the disaster but also into controls over the chemical industry in Italy.

The impact of the Seveso disaster in Continental Europe has in some ways exceeded that of Flixborough and has led to much greater awareness of process industry hazards on the part of the public and demands for more effective controls.

The EC Directive on Major Accident Hazards of 1982 was a direct result of the Seveso disaster, and indeed this Directive was initially often referred to as the 'Seveso Directive'.

In addition to the Seveso Report, there are other accounts of the Seveso disaster and of TCDD in *The Superpoison* by Margerison, Wallace and Hallenstein (1980) and *The Chemical Scythe* by A. Hay (1982) and by A. Hay (1976, 1979, 1981), Bolton (1978), V.C. Marshall (1980), Theofanous (1981, 1983), Rice (1982), Sambeth (1983) and W.B. Howard (1985).

Selected references on Seveso are given in Table A3.1.

A3.1 The Company and the Management

The site at Seveso was operated by the company Industrie Chimiche Meda Societa Azionara (ICMESA), using a process developed by its parent company Givaudan, which was itself owned by Hoffmann La Roche.

Icmesa started in Naples in 1926 and began operations in Meda in 1946. Givaudan acquired a majority shareholding in Icmesa in 1965. In the same year Givaudan was itself taken over by Hoffmann La Roche. Icmesa was an Italian company and the other two companies were Swiss.

The management of the three companies and the officials of the local authorities involved are described in on *The Superpoison*. The following information is relevant:

Icmesa
General Manager, H. von Zwehl
Technical Manager, C. Barni
Production Manager, P. Paoletti
Factory Doctor, E. Bergamaschini

Givaudan
Managing Director, G. Waldvogel
Technical Director, J. Sambeth
Director of Dubendorf Laboratories, B. Vaterlaus

Hoffman La Roche
Technical General Manager, R. Seheff
Clinical Research Director, G. Reggiani

Local Authorities
Mayor of Seveso, F. Rocca
Mayor of Meda, F. Malgrati
Medical Health Officer, G. Ghetti
Acting Health Officer, F. Uberti

Regional Minister of Health, V. Rivolta
Chief Medical Officer, Milan Province V. Eboli
Chief Medical Officer, Lombardy V. Carreri
Director of Provincial Health Laboratory, Milan A. Cavallaro
Magistrate, S. Adamo

A3.2 The Site and the Works

When Icmesa built its works at Meda the site was surrounded by fields and woods. Over the years, however, the area near the site was developed.

The reactor, Reactor A101, in which the runaway occurred was in Department B of the works.

A3.3 The Process and the Plant

The process which gave rise to the accident was the production of 2,4,5-trichlorophenol (TCP) in a batch reactor.

TCP is used for herbicides and antiseptics. Givaudan required it for making the bacteriostatic agent hexachlorophene. It manufactured its own because the herbicide grades contained impurities unacceptable in this application. Between 1970 and 1976 some 370 te of the chemical were produced.

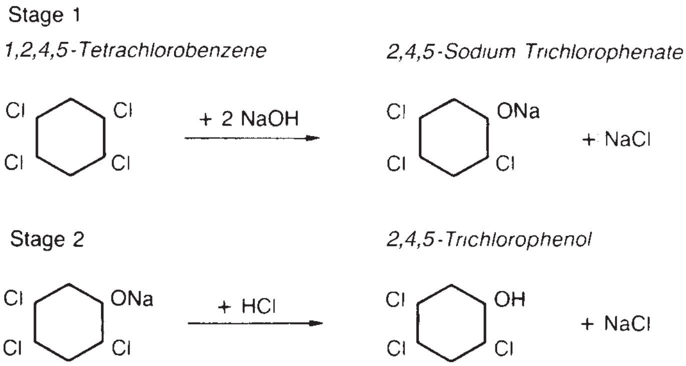

Figure A3.1 *Reaction scheme for production of 2,4,5-trichlorophenol (TCP)*

The reaction was carried out in two stages. Stage 1 involved the alkaline hydrolysis of 1,2,4,5-tetrachlorobenzene (TCB) using sodium hydroxide in the presence of a solvent ethylene glycol at a temperature of 170–180°C to form sodium 2,4,5-trichlorophenate. The reaction mixture also contained xylene, which was used to remove the water by azeotropic distillation. In Stage 2 the sodium trichlorophenate was acidified with hydrochloric acid to TCP and purified by distillation. The reaction scheme is shown in Figure A3.1.

On completion of the Stage 1 reaction some 50% of the ethylene glycol would be distilled off and the temperature of the reaction mixture lowered to 50–60°C by the addition of water.

The process was a modification by Givaudan of a process widely used in the industry. The conventional process used methanol rather than ethylene glycol and operated at some 20 bar pressure.

In this reaction the formation of small quantities of TCDD as a by-product is unavoidable. At a reaction temperature below 180°C the amount formed would be unlikely to exceed 1 ppm of TCP, but with prolonged heating in the temperature range 230–260°C it could increase a thousand-fold.

During manufacture nearly all (99.7%) of the TCDD formed concentrated in the distillation residues from which it was collected and incinerated. Only 0.3% found its way into the TCP, giving a maximum concentration of 10 ppb.

The reactor was a 138751 vessel with an agitator and with a steam jacket supplied with steam at 12 bar. The saturation temperature of steam at this pressure is 188°C. The controls on the reactor were relatively primitive. There was no automatic control of the heating. The reactor system is shown in Figure A3.2.

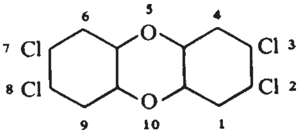
The reactor was provided with a bursting disc set at 3.5 bar and venting direct to atmosphere. The prime purpose of this disc was to prevent overpressure when compressed air was being used on the reactor.

The works had an incinerator for the destruction of hazardous plant residues at temperatures of 800–1000°C.

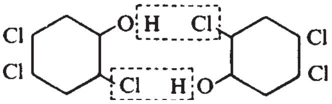
A3.4 TCDD and Its Properties

The properties of TCDD are given the *Seveso Report* and in *Dioxin, Toxicological and Chemical Aspects* by Cattabeni, Cavallaro and Galli (1978) and by Rice (1982).

2,3,7,8-tetrachlorodibenzo-p-dioxin, which is also known as TCDD or dioxin, has the formula



It is generated by the elimination of two molecules of HCl from 2,4,5-trichlorophenol



TCDD is one of the most toxic substances known. In 1954, an accident at the Boehringer TCP plant in Hamburg led to a painstaking investigation by Schulz (1957) of the causes of chloracne in people who had been exposed. He found that the cause was not the TCP itself but an impurity which he identified as TCDD, or dioxin. Actually there is a family of dioxins, TCDD being the most toxic.

The toxicity of TCDD is reviewed in the *Seveso Report*. The LD_{50} data quoted in the report are shown in Table A3.2, Section A. The lowest LD_{50} quoted is for guinea pigs and is 0.6 μg/kg, that is a dose of 0.6×10^{-9} per unit of body weight. The report also gives a table showing the toxicity of TCDD relative to that of other well-known poisons. An extract from this is shown in Table A3.2, Section B. TCDD is therefore an ultratoxic substance.

TCDD can be taken into the body by ingestion, inhalation or skin contact. A leading symptom of TCDD poisoning is chloracne, which is an acne-like skin effect caused by chemicals. A mild case of chloracne usually clears within a year, but a severe case can last many years. Other effects of TCDD include skin burns and rashes and damage to liver, kidney and urinary systems and to the nervous system. It appears to have an unusual ability to interfere with the metabolic processes. There are varying degrees of evidence for carcinogenic, mutagenic and teratogenic properties. These are reviewed in the report.

TCDD is a stable solid which is almost insoluble in water and resistant to destruction by incineration except at very high temperatures.

Strychnine	1.5×10^{-6}
Sodium cyanide	2.0×10^{-4}

A3.5 Previous Incidents Involving TCP and TCDD

The manufacture of TCP had resulted in a number of accidents prior to Seveso and its hazards and problems were recognized, to the extent that some companies had withdrawn from the business.

A list of incidents, based on that given in the *Seveso Report*, is shown in Table A3.3.

The original method of making TCP was to heat TCB and sodium hydroxide with methanol at about 200°C and 20 bar.

In 1949, there was a large release from a pressurized TCP reactor at the Monsanto plant at Nitro, West Virginia, when a valve ruptured. A total of 228 people were affected to some degree. In 1953, a TCP reactor explosion at BASF, affecting 42 people. Another TCP reactor explosion occurred at the Boehringer plant at Hamburg in 1954, 40 workers being affected. It was this incident which led to the discovery by Schulz of the ultratoxic properties of TCDD. At the Rhone-Poulenc TCP plant at Pont de Claix near Grenoble there were 100 cases of dioxin poisoning in the period 1953–70 and explosions in 1956 and 1966, affecting 17 and 20 people, respectively. In 1963, at the Philips-Duphar plant on the North Sea Canal near Amsterdam a reaction runaway on a pressurized TCP reactor blew the top off the reactor, even though the relief valve had blown, and affected some 30 people. In 1964, the operating procedure at the Dow plant at Midland, Michigan, was changed and an accident occurred which affected 60 people. In some of these incidents a small number of those exposed subsequently died, apparently from the exposure.

The incidents did not cause any direct exposure of the public, but they did reveal the difficulties of preventing the workers' families being affected and of decontaminating the plant. In the Ludwigshafen accident one man got chloracne just by using his father's towel.

Table A3.3 *Some incidents involving TCDD*

Date	*Location*	*Injured*	*Comments*
1949	Nitro, WV (Monsanto)	117	Overheating leading to explosion
1953	Ludwigshafen (BASF)	55	Overheating leading to explosion
1954	Hamburg (Boehringer)	37	Exposure during plant operation
1956	Pont de Claix (Rhone-Poulenc)	17	Explosion
1956	USA (Hooker)	?	Overheating
1960	USA (Diamond Shamrock)	?	Overheating
1963	N. Sea Canal (Philips-Duphar)	30	Overheating leading to explosion
1964	Midland, MI (Dow)	30	Explosion
1964	Neuratovice (Spolana)	72	Exposure during plant operation
1966	Pont de Claix (Rhone-Poulenc)	21	Explosion
1968	Bolsover (Coalite)	79	Overheating leading to explosion
1970?	(Bayer)	5	Exposure during plant operation
1972	(Linz Chemic-Werke)	50	Exposure during plant operation
?	(Thompson Hayward)	?	Overheating leading to explosion
1976	Seveso (Icmesa)		Overheating

Various attempts were made at Ludwigshafen to remove the dioxin from the plant building, including the use of detergents, the burning off of the surfaces, the removal of insulating material and so on, but these were not effective. Eventually the whole building was demolished under controlled conditions and the debris buried. At Duphar some 50 people were involved in cleaning up the plant, of whom four died within 2 years, though the connection between the incident and the deaths was unproven. The plant was sealed for 10 years and then dismantled from the inside brick by brick, the rubble was embedded in concrete and the concrete blocks were sunk in the Atlantic.

In 1968, an accident occurred at the Coalite TCP plant at Bolsover. Coalite utilized a modification of the Givaudan process, using ethylene glycol and operating at atmospheric pressure, but with ortho-dichlorobenzene (ODCB) as the second solvent to remove the water formed. The use of this second solvent reduced the amount of expensive ethylene glycol which had to be used and not all of which was recovered after the batch. Research indicated that further reduction might be made in the amount of ethylene glycol used and a trial was carried out on the plant using half the normal quantity. A reaction runaway occurred, blew the top off the reactor and released flammable vapours which exploded and killed the shift chemist.

The workers who had been in the building were affected but appeared to recover after 10 days and the undamaged part of the plant was thoroughly cleaned and brought back into use, the damaged part being sealed off. Some weeks later chloracne symptoms appeared not only among those who had been in the plant at the time of the accident but among others who had worked in the building occasionally after it had been cleaned. Within 7 months there were some 79 cases of chloracne. Stringent hygiene measures were instituted and the cases gradually cleared. The most seriously contaminated part of the plant was dismantled and buried in a deep hole.

The causes of the accident were investigated by Milnes (1971). He found that an exothermic reaction occurs between ethylene glycol and sodium hydroxide starting about 230°C and rising rapidly to about 400°C. He also showed that TCDD is formed by reaction of sodium trichlorophenate and sodium hydroxide as described above. Further, he demonstrated that whereas at the normal reaction temperature of 180°C the amount of TCDD formed is only a few ppm, at 250°C large amounts are formed. Subsequent work has shown that formation of TCDD is zero below 153°C, less than 1 ppm at 180°C but 1600 ppm in 2 h at 230–260°C (Orsini, 1980).

A3.6 Events Prior to the Release

The start of the batch began at 16.00 on Friday, 9 July (Table A3.4). The reactor was charged with 2000 kg TCB, 1050 kg sodium hydroxide, 3300 kg ethylene glycol and 600 kg xylene.

After the reaction had taken place, part of the ethylene glycol was distilled off, but the fraction removed was only 15% instead of the usual 50% so that most of the solvent was left in the vessel. Distillation was interrupted at 5.00 on 10 July and heating was discontinued but water was not added to cool the reaction mass. The reactor was not brought down to the 50–60°C temperature range specified. The temperature recorder was switched off, the last temperature recorded being 158°C.

The shift ended at 6.00. This time coincided with the closure of the plant for the weekend. The reactor was left with the agitation turned off but without any action to reduce the temperature of the charge.

During the weekend, with the steam turbine on reduced load, the steam supply to the reactor jacket became superheated, its temperature being about 300°C.

A3.7 The Release – 1

At 12.37 on 9 July, the bursting disc on the reactor ruptured. The maintenance staff heard a whistling sound and a cloud of vapour was seen to issue from a vent on the roof giving rise to 'the formation of a dense cloud of considerable altitude'. The release lasted some 20 min.

A maintenance foreman, G. Bruno, who was passing, heard the disc rupture and realized something was wrong. He ran with two colleagues, R. Vito and C. Galante, to the boiler room to start-up the large firewater pump, then to the stores to get protective clothing. They approached Department B, where they felt the heat from the reactor. Bruno called in the technical manager, C. Barni, who arrived at

Table A3.4 *Timetable of events at Seveso*

Jul.	9 Friday	16.00 Final reactor batch started
	10 Saturday	5.00 Final reactor batch interrupted 12.37 Bursting disc on reactor ruptures Barni visits houses near plant to warn against eating garden produce. He asks carabinieri to repeat warning but they refuse
	11 Sunday	Barni and Paoletti inform von Zwehl. They are unable to contact Ghetti or his deputy. They inform Rocca and Malgrati. Von Zwehl informs Sambeth
	12 Monday	Rocca and Uberti visit ICMESA. Letter of von Zwehl to Health Officer
	13 Tuesday	Report of Uberti to Rocca and Malgrati
	14 Wednesday	Sambeth and Vaterlaus inspect Dept B and contaminated area. Uberti writes to Provincial Health Officer in Milan
	15 Thursday	Dubendorf Laboratories give first analyses showing high TCDD content. Sambeth telegraphs Waldvogel in Turkey and asks von Zwehl to inform local authorities. Sambeth informs Hoffmann La Roche and seeks clinical advice and permission to close plant. Rumours grow in Seveso. Citizens invade Uberti's office. Rocca and Uberti meet von Zwehl. They decide to declare polluted zone and to post warning notices
	16 Friday	Workforce go on strike. Efforts are made to contact Ghetti in remote holiday farmhouse. Warning notices are erected. Rocca, Uberti and others meet von Zwehl again. Uberti insists on evacuation. Rocca requests and obtains permission for evacuation from Deputy Prefect of Milan. Rocca contacts journalist friend
	17 Saturday	Il Giorno carries front-page headlines on 'Poison gas' at Seveso. Press descend on town. Uberti contacts Cavallaro.
	18 Sunday	Cavallaro's team of health inspectors investigate contaminated area. Rocca, Ghetti, Cavallaro and Adamo meet von Zwehl. Cavallaro presses to know identity of poison released. Adamo threatens to arrest ICMESA management
	19 Monday	Waldvogel arrives in Seveso and offers local authority financial compensation, which is refused
	20 Tuesday	Cavallaro and Ghetti meet Vaterlaus in Zurich. Vaterlaus reveals that poison released was TCDD. Uberti's letter to Provincial Health Officer in Milan arrives. 16.00 Ghetti telephones Rocca to say substance was TCDD. Prefect in Milan is informed
	21 Wednesday	9.30 Meeting at prefecture. Rivolta and Carreri take over responsibility. Carabinieri arrest von Zwehl and Paoletti
	23 Friday	9.00 Meeting at prefecture. Rivolta decides against evacuation. Reggiani visits Rocca and urges evacuation. Reggiani asked to leave Deputy Prefect's meeting unheard 14.00 Rivolta reassures meeting in Seveso town hall. Reggiani argues with Rivolta and calls for evacuation. Carabinieri try unsuccessfully to arrest Reggiani, who returns to Switzerland
	24 Saturday	9.30 Meeting of regional health council. Vaterlaus presents map of locations affected. Council decides to recommend evacuation and defines evacuation zone (part of Zone A)
	26 Monday	179 people evacuated
	29 Thursday	Zone A extended and further 550 evacuated

13.10 as the escape was subsiding. About an hour after the release began Vito and Galante were able to begin gingerly admitting cooling water to the reactor system.

The release contaminated the vicinity of the plant with TCDD. Figure A3.3 is a map of the area, showing the zones later established and Table A3.5 gives the concentrations later measured in these zones.

The area of Zone A was 108 ha (1.08 km^2) with concentrations of TCDD averaging 240 $\mu g/m^2$ and rising to over 5000 $\mu g/m^2$. The area of Zone B was 269 ha (2.69 km^2) with concentrations averaging 3 $\mu g/m^2$ but rising to 43 $\mu g/m^2$. In the Zone of Respect, Zone R, which had an area of 1430 ha (14.3 km^2), the concentrations varied from indeterminable to 5 $\mu g/m^2$.

A3.8 The Emergency and the Immediate Aftermath

The release set in train a series of events which were to have profound repercussions. They are described in detail in *The Superpoison*. It is possible here to give only a brief outline.

When the situation had been brought under control in the works, Barni visited houses near the plant and warned people not to eat the garden produce. He asked the carabinieri to repeat the warning, but they refused, unless there was authorization from the municipal health officer.

There were few obvious signs of an accident, although surfaces were covered with a thin, oily film.

The municipal health officer, G. Ghetti, was on holiday in a remote farmhouse not on the telephone.

On Sunday 11 July, Barni visited P. Paoletti, the production director, and they together contacted the general manager, von Zwehl, who was on holiday in the Alps. They then visited the mayor of Seveso, F. Rocca, and recommended that people living near the plant be warned not to eat garden produce. Rocca agreed to inform the carabinieri. He also brought in the mayor of Meda, F. Malgrati, since the Icmesa plant lay within the Meda boundaries.

The same day von Zwehl informed J. Sambeth, technical director of Givaudan. Sambeth realized that there was a dioxin hazard and asked what temperature the reactor had reached. He told von Zwehl to close off Department B

and have samples from the reactor sent to the Dubendorf laboratories of Givaudan at Zurich. Normally he would have discussed the problem with the managing director of Givaudan, G. Waldvogel, but the latter was on holiday in Turkey.

On Monday 12 July, Rocca together with the acting health officer for Meda and Seveso, F. Uberti, visited Icmesa and saw von Zwehl, who convinced them that there was no serious health hazard. Von Zwehl wrote a letter to the health officer. On the material released the latter said:

> Since we are not in a position to evaluate the substances present in the vapour or to predict their exact effects, but knowing the final product is used in manufacturing herbicides, we have advised householders in the vicinity not to eat garden produce.

On Tuesday 13 July, Uberti sent a report to Rocca and Malgrati, enclosing a copy of von Zwehl's letter. He believed the release was one of the minor accidents which occur periodically.

On Wednesday 14 July, Sambeth and Vaterlaus, director of the Dubendorf laboratories, came to Seveso, inspected Department B and tried to work out how high a temperature the reactor had reached. They also inspected the contaminated land.

Uberti wrote the same day to the provincial health officer in Milan. The letter did not arrive until 20 July.

On Thursday 14 July, the first analyses from the Dubendorf laboratory came through to Sambeth. They showed high dioxin contents. Sambeth telegraphed Waldvogel in Turkey. He warned von Zwehl to advise the local authorities that the release may have contained toxic by-products.

He also contacted Hoffmann La Roche to seek clinical advice and permission to order closure of the plant. The clinical research director of Hoffmann, G. Reggiani, was not familiar with TCDD, but agreed to take over the health aspect and began to inform himself about the substance.

Meanwhile rumours were growing in Seveso and a group of citizens invaded Uberti's office.

Rocca and Uberti met von Zwehl again. He agreed to pay compensation for any damage, produced a map of the polluted area, and suggested that people be advised not to eat garden produce and that warning notices be posted. He was not, however, prepared to say what the poison was. The visitors decided to declare a polluted zone and post notices.

On Friday 16 July, the erection of warning notices began. At this point the workforce at Icmesa went on strike. Rocca and Uberti had a further meeting with von Zwehl where they again pressed to be told the identity of the poison.

Uberti now urged Rocca to carry out an evacuation. Ghetti was contacted in his remote farmhouse, agreed to return but left the decision to Rocca. Rocca requested and obtained permission to evacuate from the Deputy Prefect of Milan. He also contacted a journalist friend.

On Saturday 17 July *Il Giorno* carried front-page headlines about the 'Poison gas' at Seveso. The accident became a national issue and the press descended on the town.

The same day Uberti contacted A. Cavallaro, director of the provincial health laboratories in Milan.

On Sunday 18 July, Cavallaro's team of health inspector arrived to investigate the contaminated area.

Rocca, Ghetti, Cavallaro and a local magistrate, S. Adamo, met again with von Zwehl. Cavallaro pressed to know the poison involved. Adamo threatened to arrest the Icmesa management

On Monday 19 July, Waldvogel arrived in Seveso. He offered the local authorities compensation, which they refused.

On Tuesday 20 July, Cavallaro and Ghetti met Vaterlaus in Zurich. He revealed that the poison was TCDD. Ghetti telephoned Rocca with this information. The Prefect in Milan was informed.

On Wednesday 21 July, a meeting was held at the prefecture. The regional minister of health, V. Rivolta, now took charge of the medical aspects together with V. Carreri, director of health services for Lombardy.

On the same day the carabinieri arrested von Zwehl and Paoletti.

On Friday 23 July, there was another meeting at the prefecture. Rivolta was against evacuation. Meanwhile Reggiani had decided that evacuation was essential and arrived in Seveso to urge this view. He saw Rocca, who told him the decision was out of his hands. He came into the meeting at the prefecture but was asked to leave unheard.

Later that day Rivolta addressed a meeting in Seveso town hall and gave reassurances about the hazards. Reggiani stated his disagreement with Rivolta and called for evacuation. He was unable to make his view prevail. At his hotel in Milan he was warned that the carabinieri were about to arrest him and drove north in haste to Switzerland.

There followed a meeting in Lugano between Waldvogel, Sambeth and Vaterlaus, who had a map of the contaminated areas based on the analyses carried out by his laboratories. Reggiani told the Givaudan men of his experiences. It was agreed that an attempt must be made to persuade the Italian authorities to evacuate and that Vaterlaus, who was deemed less likely to be arrested, should do this.

On Saturday 24 July, a meeting of the regional health council was held in Milan. Vaterlaus presented his map of the areas affected. An evacuation zone was defined and the decision was taken to recommend evacuation.

On Monday 26 July, 179 people were evacuated from an area which was later defined as part of Zone A. On Thursday 29 July, a further 550 people were evacuated from another area which was also part of what became Zone A.

Eventually three zones, Zone A, Zone B and the Zone of Respect were defined, as described above. 733 people were evacuated from Zone A and 5000 in Zone B were put under medical surveillance, but allowed to remain in their homes.

The release posed a severe problem for the Italian authorities, who were obliged to seek assistance from international experts in medical diagnosis and treatment and in analytical and decontamination procedures.

A3.9 The Investigation

The work of the Commission took place against a background of intense national concern.

The terms of reference of the Commission were wide-ranging. They have been described by V.C. Marshall (1980c) as follows: 'These terms of reference appear to have combined the functions in UK terms of the Flixborough inquiry, the Major Hazards Advisory Committee and the Royal Commission on the Environment'.

The report produced by the Commission, the *Seveso Report* (Orsini, 1980), covers a large number of topics, including the history of TCP production, the history of Icmesa, the toxicity of TCDD, the causes of the accident, the consequences of the accident in terms of contamination and health effects, the health measures taken, the reclamation of the contaminated land, the actions and responsibilities of the management and of the local and regulatory authorities and the recommendations. The report adduces four causes of the accident:

(1) Interruption of the production cycle.
(2) Method of distillation.
(3) Set pressure of bursting disc.
(4) Failure to install collection/destruction system for material vented.

The production cycle was interrupted at 5.00 on 10 July and the reactor was left without agitation or cooling.

In the process described in the original Givaudan patent the charge was acidified before distillation. In the process used at Icmesa the order of these two steps was reversed.

This allowed prolonged contact time between the ethylene glycol and sodium hydroxide.

Another modification to the original process was a change in the molar proportions of the reactants from

1 TCB: 2 NaOH: 11.5 ethylene glycol

to

1 TCB: 3 NaOH: 5.5 ethylene glycol

which increased the molar concentration of sodium hydroxide.

The setting of the bursting disc was 3.5 bar. The function of this device was to guard against overpressure from the compressed air, which was used to transfer materials to the reactor. The inquiry found that if the set pressure had been lower, venting would have occurred at a lower, and less hazardous, temperature.

No device was installed to collect or destroy any toxic materials vented. The bursting disc manufacturer's catalogue stated 'Bursting discs may be preferred in the case of fluids of great value and high toxicity where the loss of such fluids should be avoided. In this case a second receiver tank is required to recover the discharged fluid'. There was no such tank on the plant.

Besides listing these four points the report makes a number of other comments. On the reactor itself it states

> Proof has been provided both of the inadequacy of the measuring equipment for a number of fundamental parameters and also the absence of any automatic control system. Measurement of acidity was carried out manually by immersion of a rod with an indicator chart (sic) through a secondary inspection window.

The reactor vessel was not given a hydraulic test as the reactor was considered to operate at atmospheric pressure. The fitting of the bursting disc was not reported to the state pressure vessel inspectors.

The report recommends improved regulatory arrangements for the control of hazardous plants and, in this connection, places some reliance on the introduction of the EC Directive which came to be known as the 'Seveso Directive'.

The viewpoint of the companies has been given in several publications. The accident itself has been described by Sambeth (1983). The view of Hoffmann La Roche has been stated by Homberger *et al.* (1979).

A3.10 The Release – 2

The contents of the reactor at the time of the accident have been given as 2030 kg sodium trichlorophenate, 540 kg sodium chloride, *c.*1000 kg ethylene glycol and 1600 kg sodium ethylene glycolate, diethylene glycol and polyethylene glycol.

It is known that above 230°C such a mixture will undergo an exothermic decomposition reaction. Accidents had been known to occur involving a reaction runaway above this temperature.

The actual temperature profile in the reactor has been given by Sambeth (1983) and is shown in Figure A3.4. Due to the interruption of the batch the usual sharp reduction in the temperature of the charge at the termination of the reaction did not take place and after 7.5 h the explosion occurred.

Investigations carried out after the accidents using differential thermal analysis showed that there exist two slow exotherms (Theofanous, 1981, 1983). One starts at about 185°C, peaking at 235°C and giving a 57°C adiabatic temperature rise. The other starts at about 255°C, peaking at 265°C and giving an estimated 114°C temperature rise. The adiabatic induction times for the two exotherms are 2.1 and 0.5 h, respectively. The decomposition exotherm starts at about 280–290°C and shows a rapid pressure rise at about 300°C.

A mechanism for the reaction runaway has been proposed by Theofanous. This is that due to layering of the

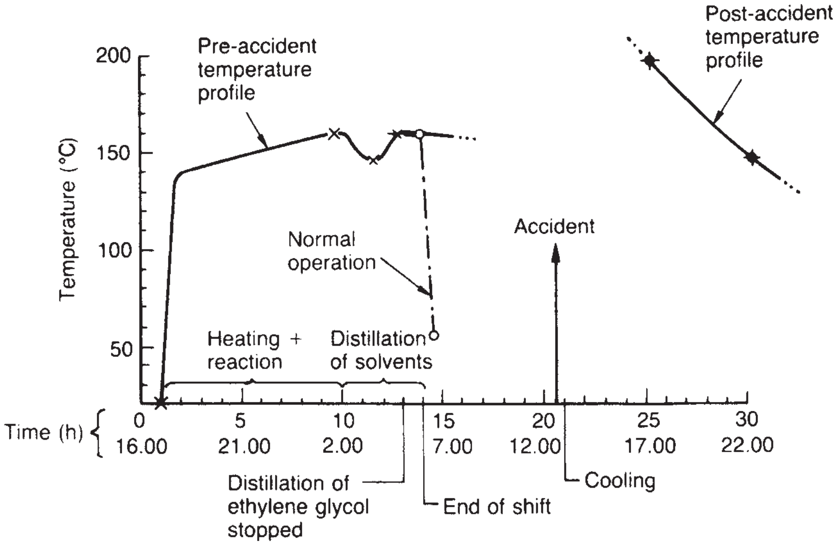

Figure A3.4 *Reactor temperature profiles measured for accident at Seveso (Sambeth, 1983) (Courtesy of Chemical Engineering)*

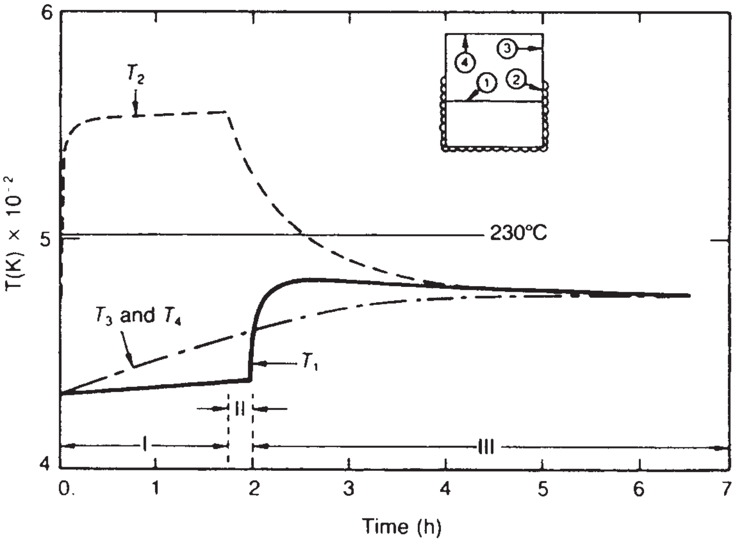

Figure A3.5 *Reactor temperature profiles calculated for period preceding accident at Seveso (after Theofanous, 1981) (Courtesy of Nature)*

reaction mix the amount of residual heat in the upper section of the reactor wall was sufficient to raise the temperature of the top layer of liquid to *c*.200–220°C, a temperature high enough to initiate exotherms leading to decomposition. The calculated temperature profiles for this theory are shown in Figure A3.5.

In the conduct of the final batch there were failures of adherence to operating procedures. W.B. Howard (1985) instances (1) failure to distil off 50% of the glycol; (2) failure to add water; (3) failure to continue agitation; (4) switching off of the reactor temperature recorder and (5) failure to bring the reactor temperature down from its value of 158°C to the normal value of 50–60°C.

A3.11 The Later Aftermath, Contamination and Decontamination

As described above, there was a prolonged period in which the authorities tried to assess the situation and determine measures for dealing with it. They were advised by a team from Cremer and Warner (C&W), and an account has been given by Rice (1982).

The release was modelled using fluid jet and gas dispersion models and predictions made of the probable ground level concentrations of TCDD. Accounts have been given by Comer (1977) and Rice (1982). In this work the reaction mass was taken as 2800 kg ethylene glycol, 2030 kg trichlorophenol 2030, 542 kg sodium chloride and 562 kg sodium hydroxide.

Estimates of the amount of TCDD generated in the reactor and dispersed over the countryside vary. Cattabeni, Cavallaro and Galli (1978) give an estimated range of 0.45–3 kg released. The amount assumed in the C&W modelling work was 2 kg.

Other parameters used in the modelling were bursting disc rupture pressure 376 kPa; vent pipe diameter 127 mm; discharge height above ground 8 m. The bursting disc rupture was assumed to a first approximation to be due to the vapour pressure of ethylene glycol at 250°C. From these data the value obtained for the vapour exit velocity was 274 m/s. Two limiting cases were considered for the discharge: Case A, pure vapour (density 1.61 kg/m^3) and Case B, a two-phase vapour–liquid mixture (density 8.99 kg/m^3). Eyewitness accounts indicated that the actual event was intermediate between these two extremes. For Case A the total plume rise was estimated as 83 m with the downwind distance to the maximum height as 103 m and the corresponding figures for Case B were 55 and 95 m, respectively. Figure A3.6 shows the estimated ground concentration contours for a 2 kg release taken from this work.

The modelling work proved useful in defining the problem and planning the decontamination. The results showed that beyond about 1.5 km there was little difference in the concentration estimates for the two cases. There was good agreement between the predicted and the measured concentrations. This gave some confidence that the amount released was indeed about 2 kg. There had been some speculation by scientists that an amount as high as 130 kg had been released.

Initially, various methods of decontamination were put forward by various parties. TCDD is virtually insoluble in water, which reduces the threat to the water supply, but means that the effect of rain is to transfer it from the vegetation to the soil rather than to remove it. One method of removal suggested was burning and proposals were made to burn the contaminated ground with flame-throwers. It was feared, however, that unless a temperature of at least 1000°C were attained, the TCDD would not be destroyed but simply swept up and deposited elsewhere. Another method proposed was to apply a mixture of olive oil and cyclohexanone to the ground, so that the TCDD would dissolve in the oil and be broken down by the ultraviolet radiation of the sun. This was abandoned, because instead of sun there was rain, and it was feared that the dissolved

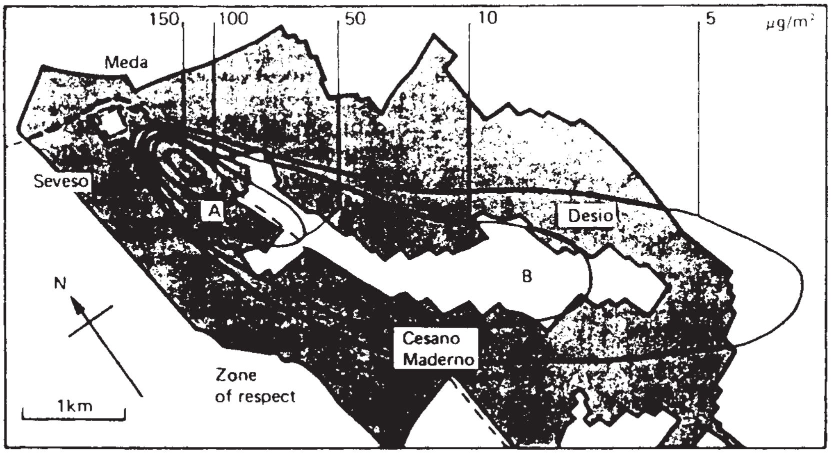

Figure A3.6 *Estimated concentrates of TCDD at Seveso (Comer, 1977. Reproduced by permission.)*

TCDD would be washed into the rivers and might penetrate the water table. A third approach involved the use of specially bred microbes capable of digesting toxic substances. Mixtures of more than a dozen strains of microorganisms bred on chemical substrates were already used to degrade chemical wastes, including cyanides and herbicides.

The decontamination measures actually carried out are described by Rice. They include collection of vegetation and cleaning of buildings by high intensity vacuum cleaning followed by washing with high-pressure water jets.

It is worth mention that people may also have been affected by materials in the reactor charge other than TCDD. V.C. Marshall (1980) indicates that on the basis of the ground concentrations found in the contaminated area a minimum of 0.25 kg was released. He points out that there were some 5–10 te of charge in the reactor and that several tonnes of material including sodium hydroxide must have been ejected. He suggests that burns around the hands and other parts of the body suffered by 413 persons who did not develop chloracne were probably caused by sodium hydroxide.

Figure A3.7 gives plots of the actual ground concentrations, showing the change with time, obtained by Cavallaro, Tebaldi and Gualdi (1982).

Data from the official report on ground concentrations in zones A and B are given in Table A3.5.

A3.12 Some Lessons of Seveso

Some of the numerous lessons to be learnt from the Seveso disaster, many of which were brought out in the Commission's report, are listed in Table A3.6. Some of them are similar to those from Flixborough, while others are different, reflecting both the different substances and processes and the different company and national situations involved. Some of these lessons are now considered:

Public control of major hazard installations

The Seveso disaster had the effect of raising the general level of awareness of the hazard from chemical plants in Italy and in Europe generally and highlighted the deficiencies in the existing arrangements for the control of major hazards.

The Italian government set up the Commission of Inquiry to investigate the cause of the disaster and to make recommendations. It also gave strong support to the development of the EC Directive.

Siting of major hazard installations

The release at Seveso affected the public because in the period since the site was first occupied housing development had encroached on the area around the plant. The accident underlined the need for separation between hazard and public.

Acquisition of companies operating hazardous processes

A lesson which has received relatively little attention is the problem faced by a company which becomes owner by acquisition of another company operating a hazardous process. At Seveso the problem was compounded by the fact that Icmesa was owned by Givaudan and the latter by Hoffmann La Roche, so that the company ultimately responsible was at two removes. As a result the directors of the latter were not familiar with the hazards.

Hazard of ultratoxic substances

Seveso threw into sharp relief the hazard of ultratoxic substances. The toxicity of TCDD is closer to that of a chemical warfare agent than to that of the typical toxic substance which the chemical industry is used to handling.

As it happened, the British Advisory Committee on Major Hazards was presenting its *First Report*, giving a scheme for the notification of hazardous installations, when Seveso occurred. It contained no notification proposals for ultratoxics. In the *Second Report* this deficiency was rectified. The EC Directive places great emphasis on toxic and ultratoxic materials.

Hazard of undetected exotherms

The characteristics of the reaction used had been investigated and the company believed it had sufficient information. It was well aware of the hazard from the principal exotherm. Subsequent studies showed, however, that other,

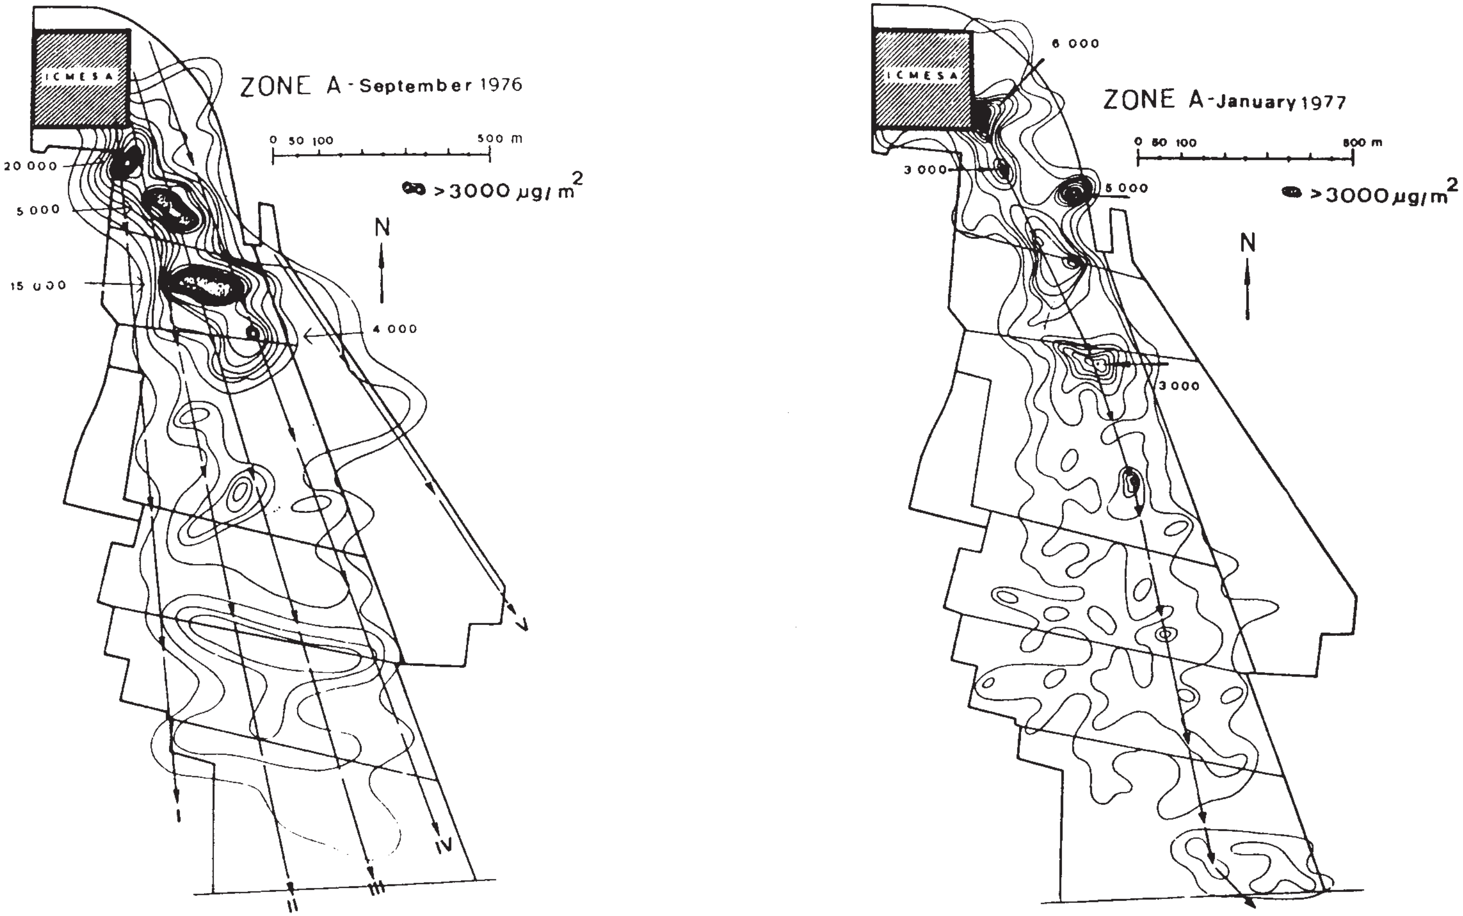

Figure A3.7 *Measured concentrations of TCDD at Seveso, showing reduction of concentration with time (Cavallaro, Tebaldi and Gualdi, 1982) (Courtesy of Atmospheric Environment)*

Table A3.6 *Some lessons of Seveso*

Public control of major hazard installations

Difficulties of decontamination

weaker exotherms existed which, given time, could also cause a runaway.

The complete identification of the characteristics of the reaction being operated is particularly important. If these are not known, or only partially known, there is always the danger that the design will not be as inherently safe as intended, that operating modifications will have unforeseen results and/or that protective measures will be inadequate.

Hazard of prolonged holding of reaction mass

The interruption of the reaction and the holding of the reaction mass for a prolonged period after the main reaction was complete without reducing the temperature gave time for the weak exotherms to occur and lead to runaway.

Inherently safer design of chemical processes

The reactor was intended to be inherently safe to the extent that the use of steam at 12 bar set a temperature limit of 188°C so that the contents could not be heated above this by the heating medium. Unfortunately this feature was defeated by allowing the reaction charge to stand hot for too long so that there occurred the weak exotherms, which the company did not know about.

The bursting disc was not intended for reactor venting, but, as the Commission pointed out, if the set pressure of the disc had been lower, the reactor would have vented at a lower temperature and hence with less dioxin in the charge.

Control and protection of chemical reactors

The control and protection system on the reactor was primitive. Operation of the reactor was largely manual. There was no automatic control of the cooling and no high temperature trip.

The reactor was not designed to withstand a runaway reaction. It was not rated as a pressure vessel to withstand pressure build-up prior to and during venting, the disc was not designed for reaction relief and there was no tank to take the ultratoxic contents of the reactor.

Adherence to operating procedures

The conduct of the final batch involved a series of failures to adhere to the operating procedures.

Planning for emergencies

As the account given above indicates, the handling of the emergency was a disaster in its own right. Information on the chemical released and its hazards was not immediately available from the company. There was failure of communication between the company and the local and regulatory authorities and within those authorities. Consequently there was lack of action and failure to protect and communicate with the public. These deficiencies might in large part have been overcome by emergency planning.

Difficulties of decontamination

The incident illustrates the difficulties of decontamination of land where the contaminant is both ultratoxic and insoluble in water.

Appendix 4

Mexico City

Contents

At about 5.35 a.m. on the morning of 19 November 1984, a major fire and a series of explosions occurred at the PEMEX LPG terminal at San Juan Ixhuatepec (San Juanico), Mexico City. Some 500 people were killed and the terminal was destroyed.

The accident was investigated by a team from TNO which visited the site about 2 weeks after the disaster and has published its findings (Pietersen, 1985). A further account has been given by Skandia International (1985).

Selected references on Mexico City are given in Table A4.1.

A4.1 The Site and the Plant

The site of the PEMEX terminal is shown in Figure A4.1 and an aerial photograph of the installation itself in Figure A4.2.

Table A4.1 *Selected references on Mexico City*

Anon. (1985v, hh); Berenblut *et al.* (1985); Cullen (1985); Kletz (1985p); Pietersen (1985, 1985 LPB 64, 1986a,b, 1988a); Skandia International (1985); Hagon (1986)

The oldest part of the plant dated from 1961 to 1962 and was thus over 20 years old. In the intervening period residential development had crept up to the site. This process of encroachment is clearly visible from the aerial photographs shown in Figure A4.3. By 1984, the housing was within 200 m of the installation with some houses within 130 m.

The terminal was used for the distribution of LPG, which came by pipeline from three different refineries. The main LPG storage capacity of 16,000 m^3 consisted of 6 spheres and 48 horizontal cylinders. The daily throughput was 5000 m^3. The layout of the terminal with storage tank capacities is shown in Figure A4.4. The two larger storage spheres had individual capacities of 2400 m and the four smaller spheres capacities of 1600 m^3. The site covered an area of 13,000 m^2.

The plant was said to have been built to API standards and much of it to have been manufactured in the United States.

A ground level flare was used to burn off excess gas. The flare was submerged in the ground to prevent the flame being extinguished by the strong local winds.

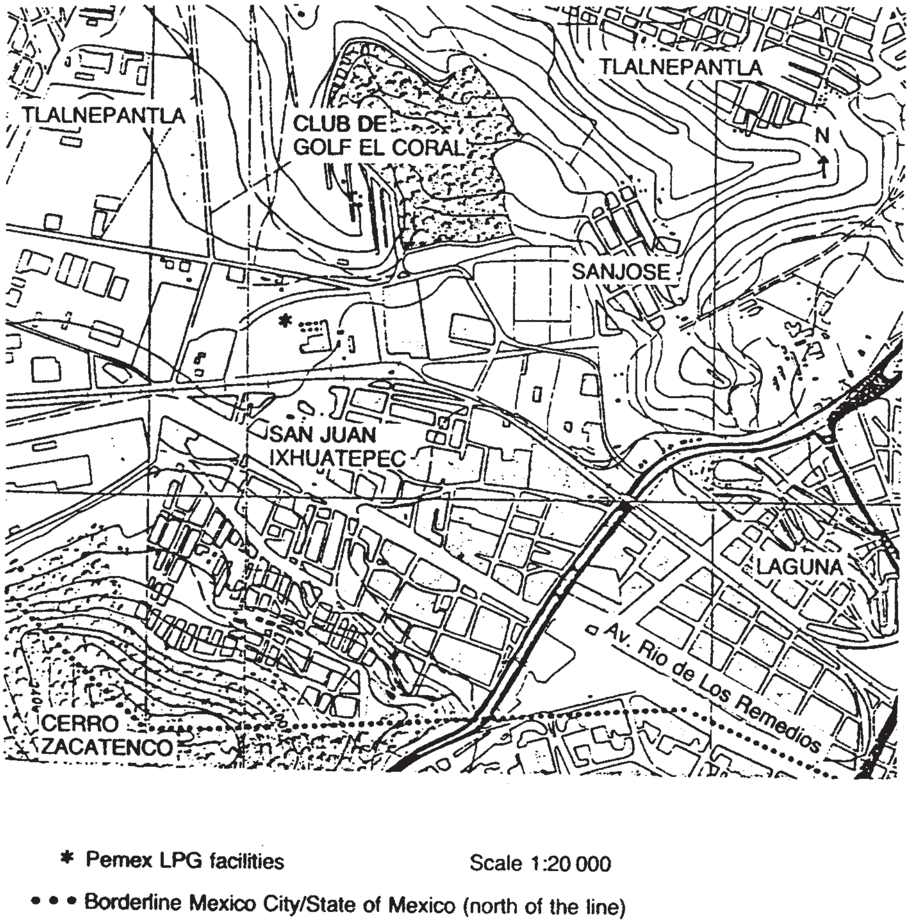

Figure A4.1 *Area plan of the PEMEX site at Mexico City (Pietersen 1985) (Courtesy of TNO)*

Figure A4.2 PEMEX plant at Mexico City before the accident (Skandia, 1985) (Photograph: State of Mexico)

(a) (b) (c)

Figure A4.3 Growth of housing near the PEMEX plant at Mexico City (Pietersen 1985): (a) 1962; (b) 1972; (c) 1982 (Reproduced by permission of TNO.)

Adjoining the PEMEX plant there were distribution depots owned by other companies. The Unigas site was some 100–200 m to the north and contained 67 tank trucks at the time of the accident. Rather further away was the Gasomatico site with large numbers of domestic gas cylinders.

A4.2 The Fire and Explosion – 1

Early in the morning of 18 November, the plant was being filled from a refinery 400 km away. The previous day the plant had become almost empty and refilling started during the afternoon. The two larger spheres and the 48 cylindrical vessels had been filled to 90% full and the four smaller spheres to about 50% full, so that the inventory on site was about 11,000 m^3, when the incident began.

About 5.30 a.m. a fall in pressure was registered in the control room and also at a pipeline pumping station 40 km distant. An 8 in. pipe between sphere F4 and the Series G cylinders had ruptured.

The control room personnel tried to identify the cause of the pressure fall but without success.

The release of LPG continued for some 5–10 min. There was a slight wind of 0.4 m/s. The wind and the sloping terrain carried the gas towards the south-west. People in the nearby housing heard the noise of the escape and smelled the gas.

When the gas cloud had grown to cover an area, which eyewitnesses put at 200 × 150 m with a height of 2 m, it found the flare and ignited. It was 5.40 a.m. The cloud

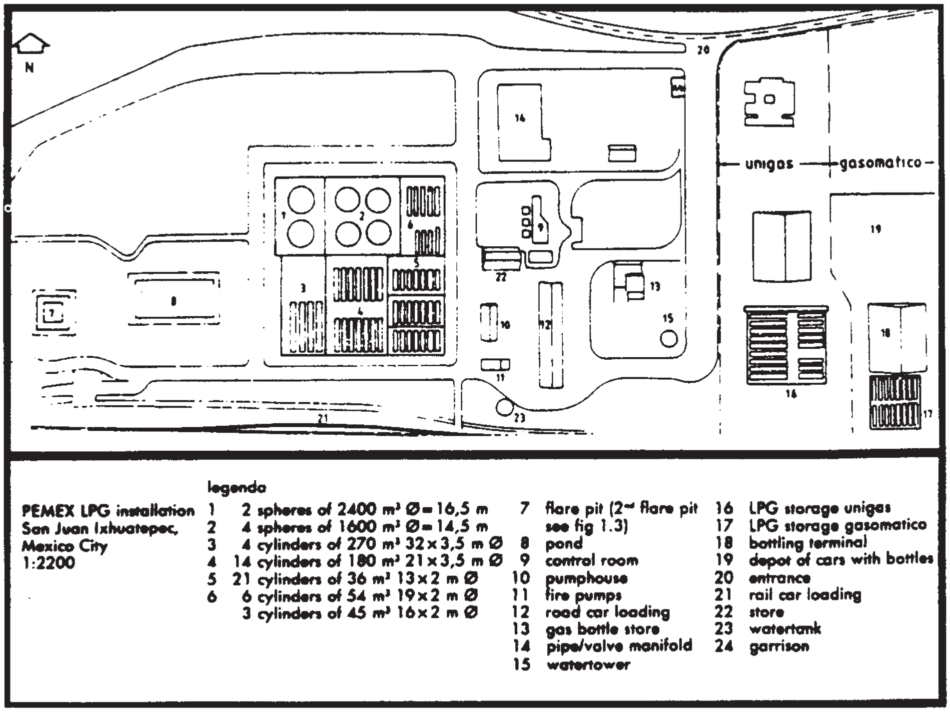

Figure A4.4 *Layout of the PEMEX site at Mexico City (Pietersen 1985) (Courtesy of TNO)*

caught fire over a large area, giving a high flame and causing violent ground shock.

When this general fire had subsided, there remained a ground fire, a flame at the rupture and fires in some 10 houses.

Workers on the plant now tried to deal with the escape. One drove off to another depot to summon help. Five others who may have been on their way to the control room or to man fire pumps were found dead, and badly burned. At a late stage someone evidently pressed the emergency shutdown button.

In the neighbouring housing some people rushed out into the street, but most stayed indoors. Many thought it was an earthquake.

At 5.45 a.m. the first BLEVE occurred. About a minute later another explosion occurred, one of the two most violent during the whole incident. One or two of the smaller spheres BLEVEd, giving a fireball 300 m diameter.

A rain of LPG droplets fell on the area. Surfaces covered in the liquid were set alight by the heat from fireballs. People burned like torches.

There followed a series of explosions as vessels suffered BLEVE. There were some 15 explosions over a period of an hour and a half. BLEVE occurred of the four smaller spheres and many of the cylindrical vessels.

The explosions during the incident were recorded on a seismograph at the University of Mexico. The timing of the readings is shown in Table A4.2 Section A. As the footnote indicates, it is suggested by Skandia that the initial explosion, or violent deflagration, was probably not recorded.

The damage caused is shown in Figure A4.5, which shows the area of main housing damage and the fall of

Table A4.2 *Timetable of events at Mexico City*

A Seismograph readings

1	5 h	44 min	52 s	6	6 h	49 min	38 s
2	5 h	46 min	01 s	7	6 h	54 min	29 s
3	6 h	15 min	53 s	8	6 h	59 min	22 s
4	6 h	31 min	59 s	9	7 h	01 min	27 s
5	6 h	47 min	56 s				

Disturbances 2 and 7 were the most intence with a Richter scale intensity of 5 Skandia suggest that the first violent combustion may not have been recorded.

B General timetable

5.30	Rupture of 8 in. pipe. Fall of pressure in control room
5.40	Ignition of gas cloud. Violent combustion and high flame
5.45	First explosion on seismograph, a BLEVE Fire department called
5.46	Second BLEVE, one of most violent
6.00	Police alerted and civilian trafffic stopped
6.30	Traffic chaos
7.01	Last explosion on seismograph, a BLEVE
7.30	Continuing tank explosions[a]
11.00	Last tank explosion
8.00–10.00	Rescue work at its height
12.00–18.00	Rescue work continues
23.00	Flames extinguished on last large sphere

[a] Explosions of cylindrical vessels.

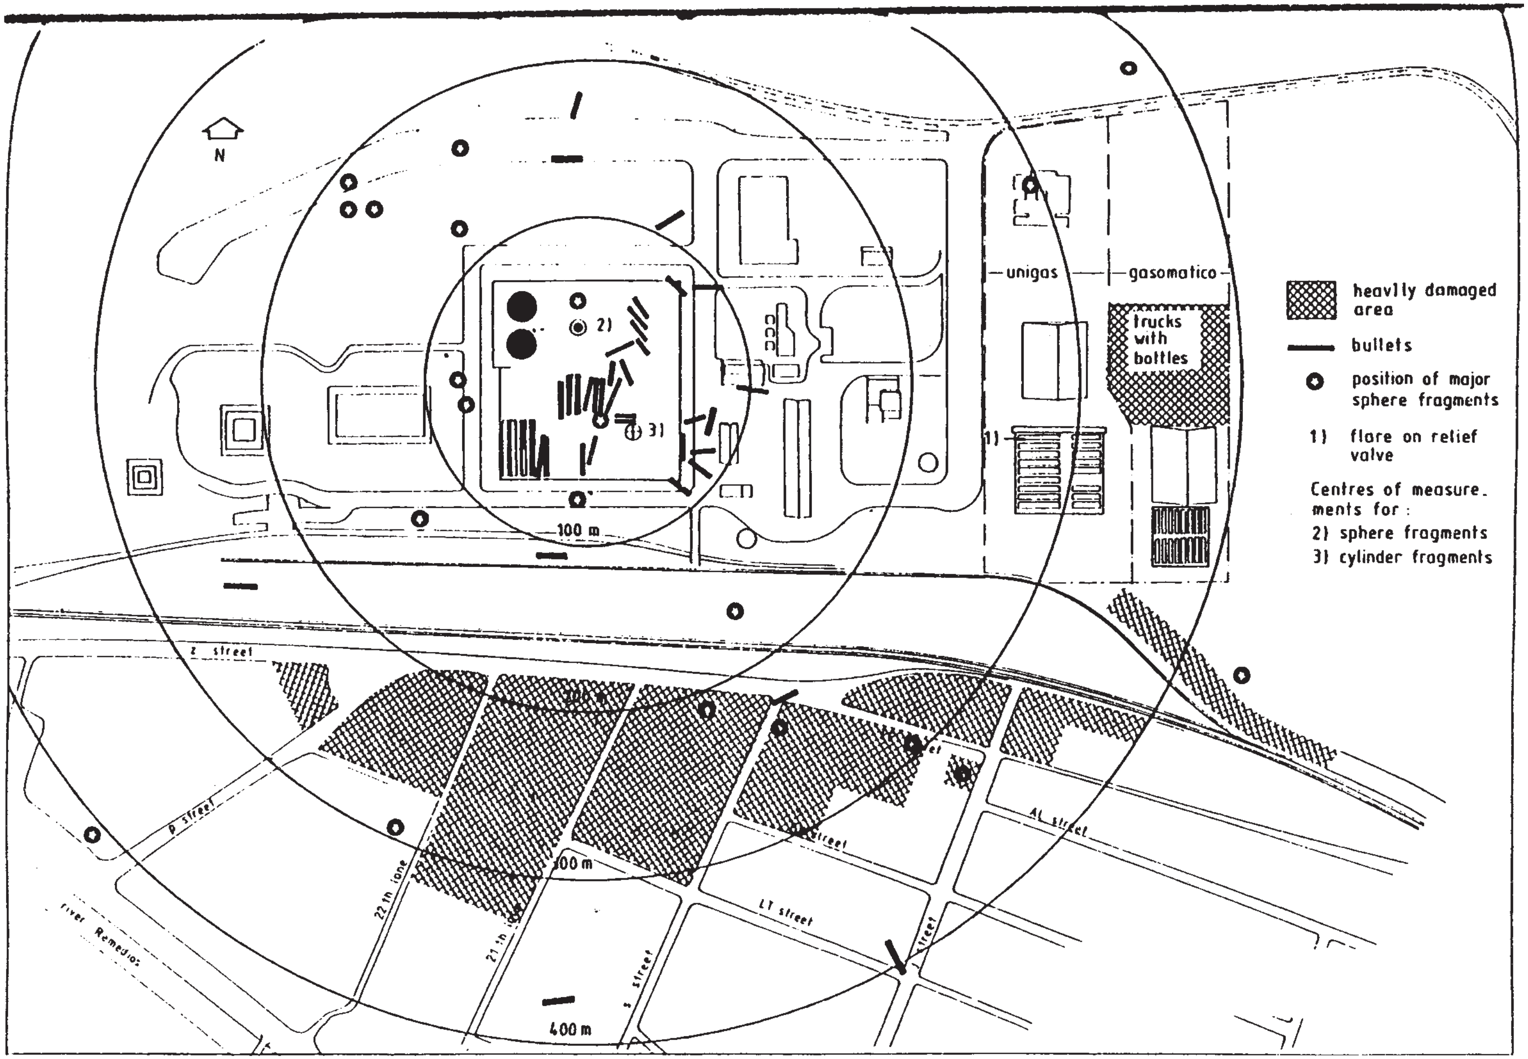

Figure A4.5 *Area plan of the PEMEX site at Mexico City, showing damage to housing area and fall of missiles (Pietersen 1985) (Courtesy to TNO)*

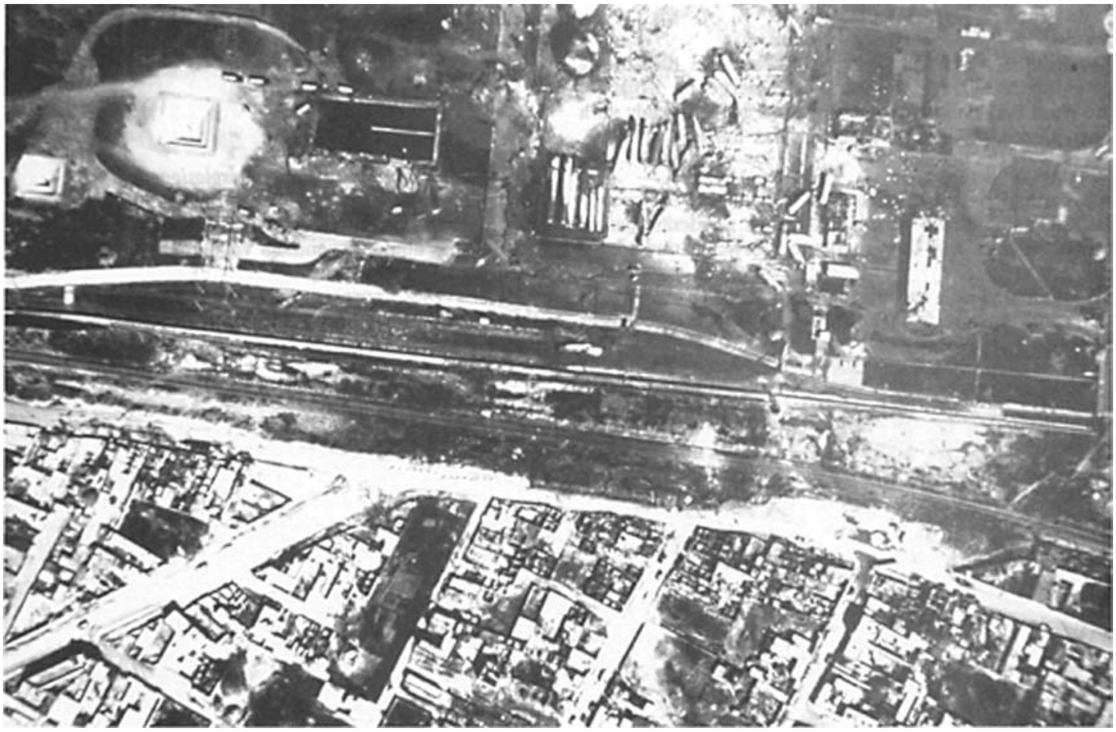

Figure A4.6 *PEMEX site at Mexico City after the accident (Skandia, 1985) (Photograph: State of Mexico)*

missiles. An aerial photograph of the plant after the disaster is shown in Figure A4.6.

Numerous missiles were generated by the bursting of the vessels. Many of these were large and travelled far. Twenty-five large fragments from the four smaller spheres weighing 10–40 te were found 100–890 m away. Fifteen of the 48 cylindrical vessels weighing 20 te became missiles and rocketed over 100 m, one travelling 1200 m. Four cylinders were not found at all. The missiles caused damage both by impact and by their temperature, which was high enough to set houses alight.

When the fire began, people were already on their way to work. Eyewitnesses spoke of a huge hot, red light, intense heat, smoke and lack of air, blast waves and missiles. The following account by Nicanor Santiago, a mason, is typical:

> Around 5.30 a.m. I went to work. It was still dark when I took my bicycle out of the house, when suddenly there was this huge light, red and hot. I could see nothing at all. The huge light blinded me. I could not feel anything except that everything was hot. Then I heard some explosions and a second blast. The walls of my house were rocking, it was an earthquake. I was lying on the pavement and close to me all sorts of matter came falling out of the sky. There was a lot of broken glass, chairs and flower pots were flying all over the place. I suddenly remembered the PEMEX gas plant and I saw a big tongue of fire and a very big orange mushroom, and then a felt another explosion. Pieces of molten metal were dropping out of the sky and I felt intense heat waves burning my clothes and my hair. I ran into the bedroom, everything was dark inside and there was plenty of smoke. I could not see anything. I could not breathe for the gas. I noticed something huge fell on top of the house and a rush of air threw me out of the house into the street. By then I was really frightened and I started to run as fast as I could. I do not know where my wife and children got to. They may even be unidentified in a mass grave.

A timetable of events during the disaster is given in Table A4.2, Section B.

A4.3 The Emergency

Accounts of the emergency give little information about the response of the on-site management in the emergency and deal mainly with the rescue and firefighting.

The site became the scene of a major rescue operation which reached a climax in the period 8.00–10.00 a.m. Some 4000 people participated in rescue and medical activities, including 985 medics, 1780 paramedics and 1332 volunteers. At one point there were some 3000 people in the area. There were 363 ambulances and five helicopters involved.

The rescuers were at risk from a large BLEVE. The Skandia report states: 'If a BLEVE had occurred during the later morning, a large number of those 3,000 people who were engaged in rescue and guarding would have been killed.'

The fire services were called by surrounding plants and by individual members of the public about 5.45 a.m. They went into the plant area only 3 h after the start of the incident. Initially, they moved towards the Gasomatico site, where a sphere fragment had landed and started a fire, which caused the domestic gas cylinders to explode.

The fire brigade also fought the fire on the two larger spheres, which had not exploded. They were at appreciable risk from BLEVE of the spheres. In the event, however, these burnt themselves out. The last flames on the spheres went out about 11.00 p.m. Some 200 firemen attended the site.

A4.4 The Fire and Explosion – 2

The TNO report gives much technical information on the course of the disaster and on the fire and explosion phenomena which occurred during it.

It discusses the effects of explosions, including vapour cloud explosions, BLEVEs and physical explosions; the effects of fire engulfment and heat radiation; and the effects of missiles, including fragments from bullet tanks and spheres.

The report gives estimates of the overpressure from BLEVE of the principal vessels. It states that the degree of blast damage to housing was not great; that the vapour cloud explosion effects were not responsible for major damage; that the second explosion, a BLEVE, was the most violent and did damage houses; that the worst explosion damage was probably from gases which had accumulated in houses; and that much of the damage was done by fire.

Films were available for many of the BLEVEs, though not for the second, violent explosion. From this evidence, the BLEVEs had diameters of 200–300 m and durations of some 20 s. Heavy direct fire damage was done at distances up to about 300 m, which agrees reasonably well with the estimates of fireball size.

A very large fire burned on the site for about an hour and a half, punctuated by BLEVEs. Details are given of the number, size and range of fragments from spheres and bullet tanks. Information on BLEVEs and missiles in the TNO report is given in Chapters 16 and 17.

A4.5 Some Lessons of Mexico City

Some of the lessons to be learned from Mexico City are listed in Table A4.3.

Table A4.3 *Some lessons of Mexico City*

Siting of major hazard installations
Layout of large LPG storages
Gas detection and emergency isolation
Planning for emergencies
Fire fighting in BLEVE situations
Boiling liquid expanding vapour explosions

Siting of major hazard installations

The high death toll at Mexico City occurred because the housing was too near to the plant. At the time the plant was constructed the area was undeveloped, but over the years the built-up area had gradually crept up to the site.

Layout and protection of large LPG storages

The total destruction of the facility occurred because there was a failure of the overall system of protection, which includes layout, emergency isolation and water spray systems.

Gas detection and emergency isolation

One feature which might have averted the disaster is more effective gas detection and emergency isolation. The plant had no gas detector system and, probably as a consequence, emergency isolation was too late.

Planning for emergencies

One particularly unsatisfactory aspect of the emergency was the traffic chaos which built up as residents sought to flee the area and the emergency services tried to get in.

Another was risk run by the large number of rescuers who came on site from a BLEVE of one of the larger spheres.

Fire fighting in BLEVE hazard situations

The fire services appear to have taken a considerable a risk in trying to fight the fire on the two larger spheres. The potential death toll if a BLEVE had occurred was high.

Boiling liquid expanding vapour explosions

After Flixborough the problem of vapour cloud explosions received much attention. Mexico City demonstrates that boiling liquid expanding vapour explosions are an equally important hazard.

Mexico City represents the largest series of major BLEVEs which has occurred and provides much information on these.

Appendix 5 Bhopal

Contents

Early in the morning of 3 December 1984, a relief valve lifted on a storage tank containing highly toxic methyl isocyanate (MIC) at the Union Carbide India Ltd (UCIL) works at Bhopal, India. A cloud of MIC gas was released onto housing, including shantytowns, adjoining the site.

Close on 2000 people died within a short period and tens of thousands were injured. The casualty figures are discussed further in Section A5.9.

The accident at Bhopal is by far the worst disaster which has ever occurred in the chemical industry. Its impact has been felt worldwide, but particularly in India and the United States.

Following the accident the Government of India (GoI) set up an inquiry which reported at the end of 1985 (Varadarajan, 1985). An investigation was conducted by the US parent company the Union Carbide Corporation (UCC), which issued its own report (the *Union Carbide Report*) (Union Carbide, 1975). Another investigation was carried out by the ICFTU-ICEF (1985). In its initial investigation, Union Carbide had limited access to documents and personnel, and it subsequently caused to be published further findings (Kalelkar, 1988). These investigations are described in Section A5.8.

Besides the investigations mentioned, other accounts have been given in Bhopal. *Anatomy of a Crisis* by Shrivastava (1987) and by Badhwar and Trehan (1984), Bhushan and Subramanian (1985), Bowonder (1985, 1987, 1988), Bowonder and Miyake (1988), Kalelkar (1988), Kletz (1988h), van Mynen (1990) and Bowonder, Arvind and Miyake (1991).

Selected references on Bhopal and MIC are given in Table A5.1.

A5.1 The Company and the Management

Union Carbide began operations in India in 1904 and by 1983 had 14 plants operating in the country. Its Indian interests were held by UCIL. UCIL was owned 50.9% by the American parent company UCC and 49.1% by Indian investors. UCC thus retained a majority share, having persuaded the Indian government to waive its usual requirement for Indian majority shareholding, on the basis of the technological sophistication of the plant and the export potential.

Methyl isocyanate
Kimmerle and Eben (1964); ten Berge (1985)

UCIL began operations at Bhopal in 1969. Initially, the plant formulated carbamate pesticides from concentrates imported from the United States. In 1975, UCIL was licensed to manufacture its own carbaryl with the trade name Sevin. The process selected was the same as at the UCC plant at W. Virginia, but initially the MIC intermediate was imported from the latter source. Production began in 1979. The plant had a capacity of 5250 te/y, but the market was less than expected. Production peaked at 2704 te in 1981 and fell to 1657 te in 1983. At these levels of sales the plant had problems of profitability.

Prior to the accident, the management structure of UCIL changed and the Bhopal pesticides plant was put under the direction of the Union Carbide battery division in India.

A5.2 The Site and the Works

The location of the UCIL works at Bhopal is shown in Figure A5.1. The works was in a heavily populated area. Much of the housing development closest to the works had occurred since the site began operations in 1969, including the growth of the J.P. Nagar shantytown. Although these settlements were originally illegal, in 1984 the government gave the squatters rights of ownership on the land to avoid having to evict them. Other residential areas which were affected by the gas cloud had been inhabited for over 100 years.

A5.3 The Process and the Plant

In the process used at Bhopal, MIC was made using the reaction scheme shown in Figure A5.2. The process itself is shown in Figure A5.3. Monomethylamine (MMA) is reacted with excess phosgene in the vapour phase to produce methylcarbamoyl chloride (MCC) and hydrogen chloride and the reaction products are quenched in chloroform. The unreacted phosgene is separated by distillation from the quench liquid and recycled to the reactor. The liquid from the still is fed to the pyrolysis section where MIC is formed. The stream from the pyrolyser condenser passes as feed to the MIC refining still (MRS). MIC is obtained as the top product from the still. The MIC is then run to storage.

Phosgene was produced on site by reacting chlorine and carbon monoxide. The carbon monoxide was also produced on site.

The MIC storage system (MSS) consisted of three storage tanks, two for normal use (Tanks 610 and 611) and one for emergency use (Tank 619). The tanks were 8 ft diameter × 40 ft long with a nominal capacity of 15,000 USgal. They were made of 304 stainless steel with a design pressure of 40 psig at 121°C and with hydrostatic test pressure of 60 psig. A diagram of the storage tank system is shown in Figure A5.4.

A 30 ton refrigeration system was provided to keep the tank contents at 0°C by circulating the liquid through an external heat exchanger.

There was on each storage tank a pressure controller which controlled the pressure in the tank by manipulating two diaphragm motor valves (DMVs), a make-up valve to admit nitrogen and a blowdown valve to vent vapour. Each tank had a safety relief valve (SRV) protected by a bursting disc. It also had a high temperature alarm and low and high level alarms.

A vent gas scrubber (VGS) and a flare were provided to handle vented gases. The VGS was a packed column 5 ft 6 in.

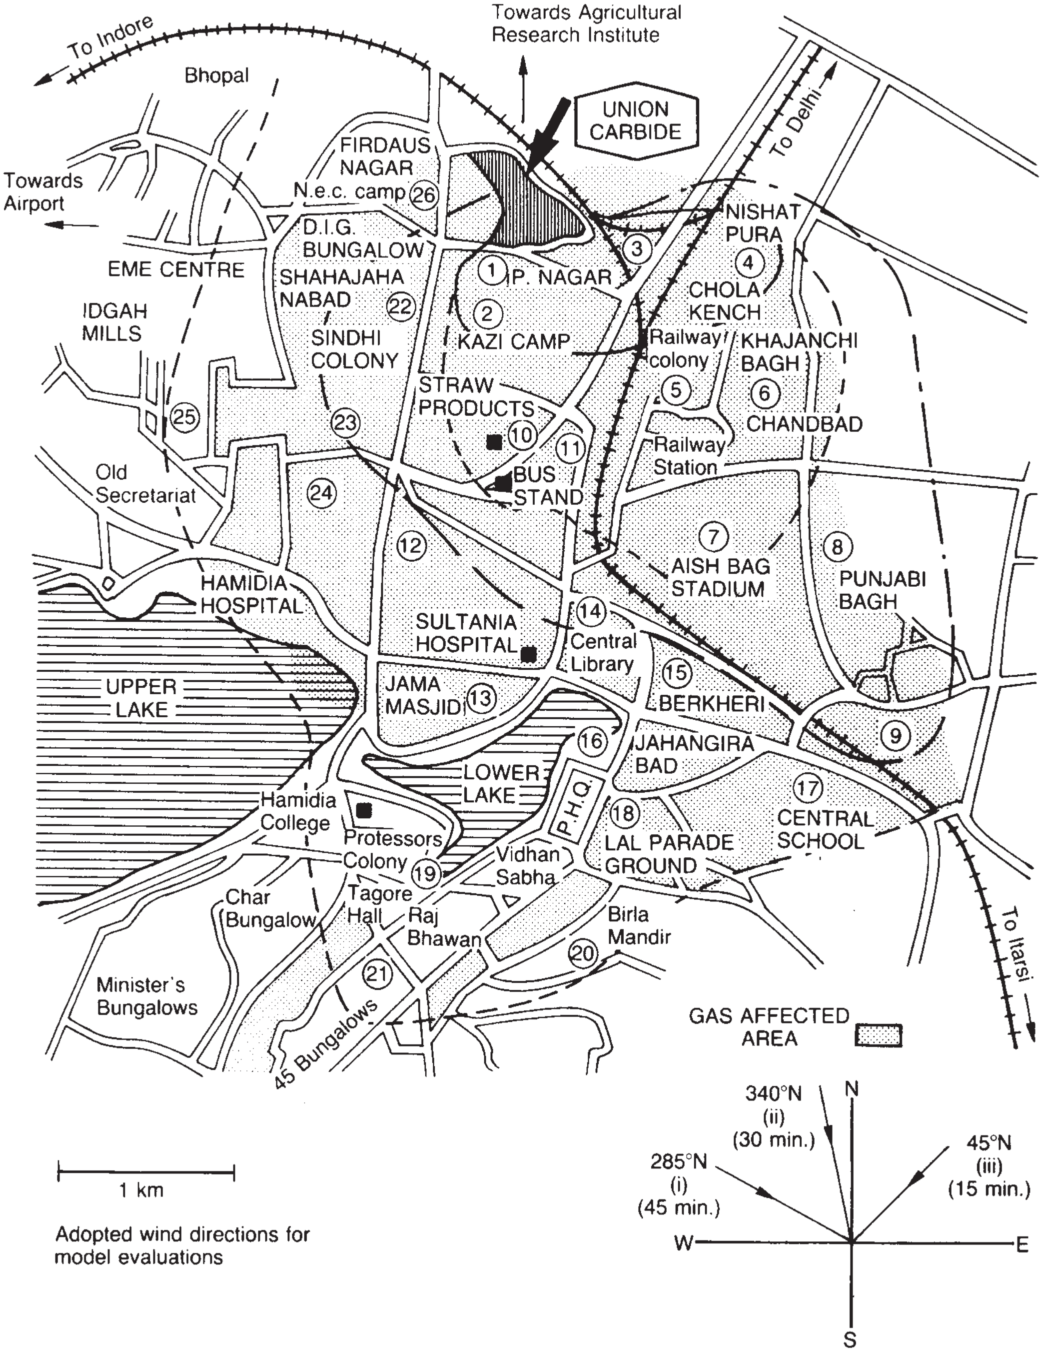

Figure A5.1 Simplified plan of the area near the Union Carbide India Ltd works at Bhopal (M.P. Singh and Ghosh, 1987). The diagram also shows the estimated dimensions of the gas cloud (Courtesy of Elsevier Science Publishers)

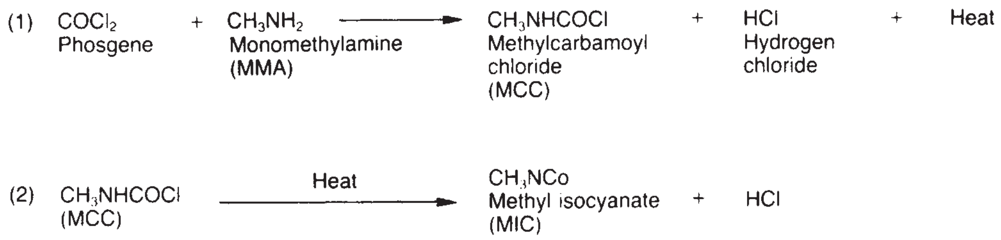
diameter in which the vent gases were scrubbed with caustic soda. There were two vent headers going into the column: the process vent header (PVH), which collected the MIC system vents, and the relief valve vent header (RVVH), which collected the safety valve discharges. Each vent header was connected both to the VGS and the flare and could be routed to either. The vent stack after the VGS was 100 ft (33 m) high. A diagram of the VGS is shown in Figure A5.5.



$$\text{(1)}\quad COCl_2 + CH_3NH_2 \longrightarrow CH_3NHCOCl + HCl + \text{Heat}$$

$$\text{(2)}\quad CH_3NHCOCl \xrightarrow{\text{Heat}} CH_3NCo + HCl$$

Figure A5.2 *Reaction scheme (Union Carbide, 1985. Reproduced by permission.)*

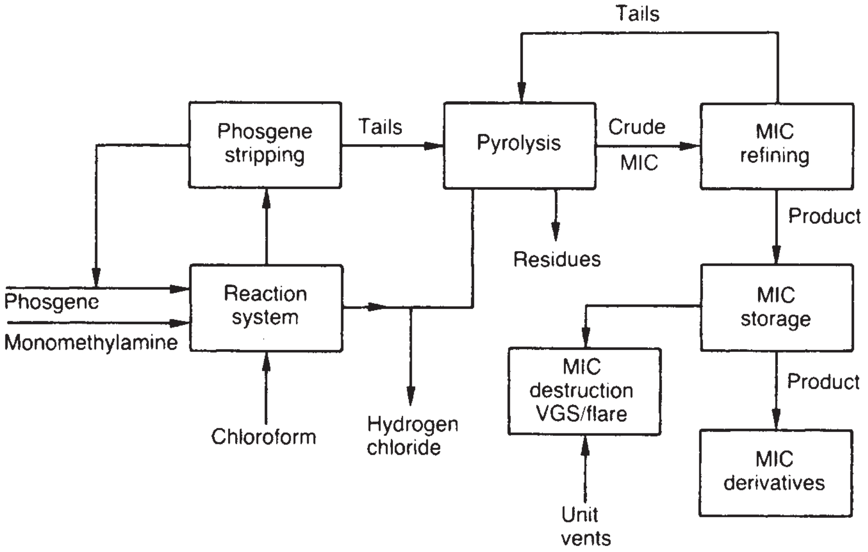


Figure A5.3 *Process for production of MIC (Union Carbide, 1985. Reproduced by permission.)*

The VGS had the function of handling process vents from the PVH and of receiving contaminated MIC, in either vapour or liquid form, and destroying it in a controlled manner.

The function of the flare was to handle vent gases from the carbon monoxide unit and the MMA vaporizer safety valve and also vent gas from the MIC storage tanks, the MRS and the VGS.

In the two years preceding, the number of personnel on site were reduced, 300 temporary workers being laid off and 150 permanent workers pooled and assigned as needed to jobs, some of which they said when interviewed they felt unqualified to do. The production team on the MIC facility was cut from 12 to 6.

A5.4 MIC and Its Properties

MIC is a colourless liquid with a normal boiling point of 39°C. It has a low solubility in water. It is relatively stable when dry, but is highly reactive and in particular can polymerize and will react with water. It is flammable and has a flashpoint of –18°C and a lower flammability limit of 6% v/v. It is biologically active and highly toxic.

The high toxicity of MIC is indicated by the fact that its TLV at the time was 0.02 ppm. This is very low relative to most typical compounds handled in industry.

MIC is an irritant gas and can cause lung oedema, but it also breaks down in the body to form cyanide. The cyanide suppresses the cytochrome oxidase necessary for oxygenation of the cells and causes cellular asphyxiation.

Information on the inhalation toxicity of MIC is given by Kimmerle and Eben (1964) and ten Berge (1985).

MIC can undergo exothermic polymerization to the trimer, the reaction being catalysed by hydrochloric acid and inhibited by phosgene. It also reacts with water, iron being a catalyst for this reaction. This reaction is strongly exothermic.

A5.5 Events Prior to the Release

In 1982, a UCC safety team visited the Bhopal plant. Their report gave a generally favourable summary of the visit, but listed ten safety concerns, including

3. Potentials for release of toxic materials in the phosgene/MIC unit areas and storage areas, either due to equipment failure, operating problems, or maintenance problems.
4. Lack of fixed water spray protection in several areas of the plant.
7. Deficiencies in safety valve and instrument maintenance program.

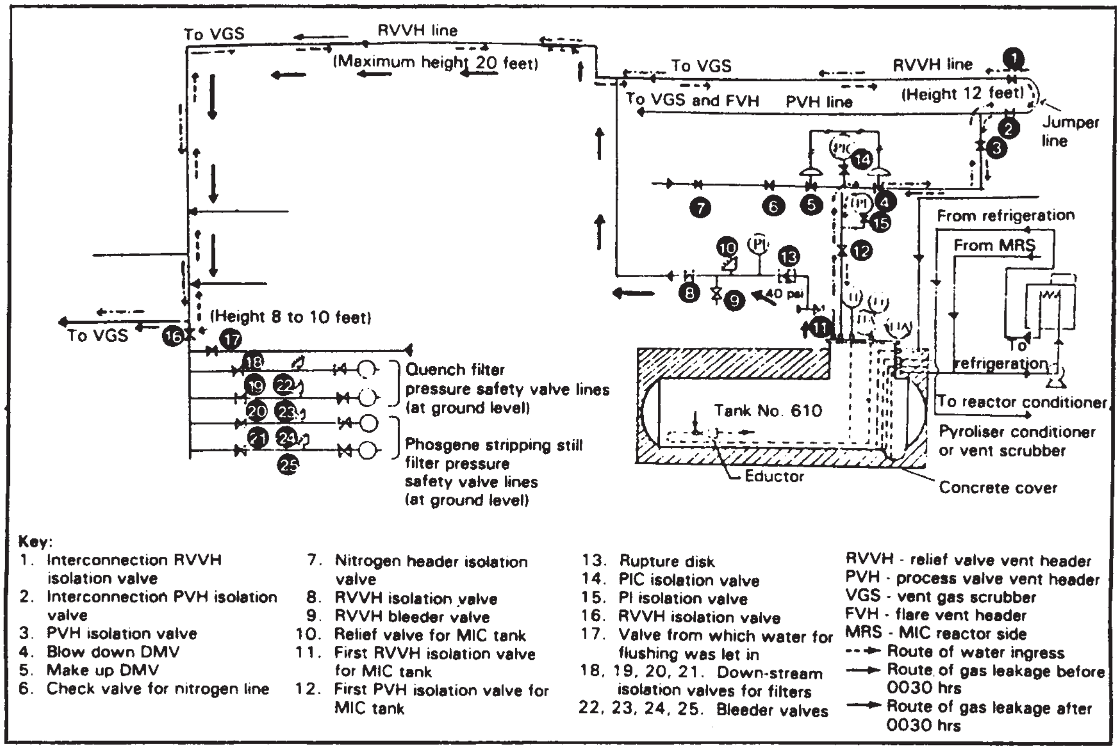

Figure A5.4 *Flow diagram of Tank 610 system (Bhushan and Subramanian, 1985) (Courtesy of Business India.)*

8. Deficiencies in Master Tag/Lockout procedure application.
10. Problems created by high personnel turnover at the plant, particularly in operations.

Following this visit valves on the MIC plant were replaced, but degraded again. At the time of the accident, the instruments on Tank 610 had been malfunctioning for over a year.

Between 1981 and 1984, there were several serious accidents on the plant. In December 1981, three workers were gassed by phosgene and one died. Two weeks later 24 workers were overcome by another phosgene leak. In February 1982, 18 people were affected by an MIC leak. In October 1982, three workers were injured and nearby residents affected by a leak of hydrochloric acid and chloroform.

Following this latter accident workers from the plant posted a notice in Hindi which read: 'Beware of fatal accidents . . . lives of thousands of workers and citizens in danger because of poison gas . . . Spurt of accidents in the factory, safety measures deficient'. These posters were also distributed in the community.

About a year before the accident, a 'jumper line' was connected between the PVH and the RVVH. Figure A5.4 shows the MIC storage tank and pipework arrangements. The jumper line is between Valves 1 and 2. The object of the modification was to allow gas to be routed to the VGS if repairs had to be done on one of the vent headers.

In June 1984 the 30 ton refrigeration unit cooling the MIC storage tanks was shut down. The charge of Freon refrigerant was drained from the system.

In October the VGS was turned off, apparently because it was thought unnecessary when MIC was only being stored not manufactured. In the same month, the flare tower was taken out of service, a section of corroded pipe leading to it being removed so that it could be replaced.

Another feature was that difficulty was being experienced in pressurizing MIC storage Tank 610. It appeared that since nitrogen was passing through the make-up valve satisfactorily, the blowdown valve was leaking and preventing pressurization.

According to plant workers there were other instrumentation faults. The high temperature alarm had long been faulty. There were also faults on the pressure controller and the level indicator.

The plant had a toxic gas alarm system. This consisted of a loud siren to warn the public and a muted siren to warn the plant. These two sirens were linked and could be activated from a plant toxic alarm box. The loud siren could be stopped from the control room by delinking the two. A procedure had been introduced according to which after delinking, the loud siren could be turned on only by the plant superintendent.

Plant workers stated that on the morning of 2 December washing operations were undertaken. Orders were given to flush out the downstream sections of four filter pressure safety valves lines. These lines are shown in Figure A5.4. In order to carry out this operation Valve 16 on the diagram

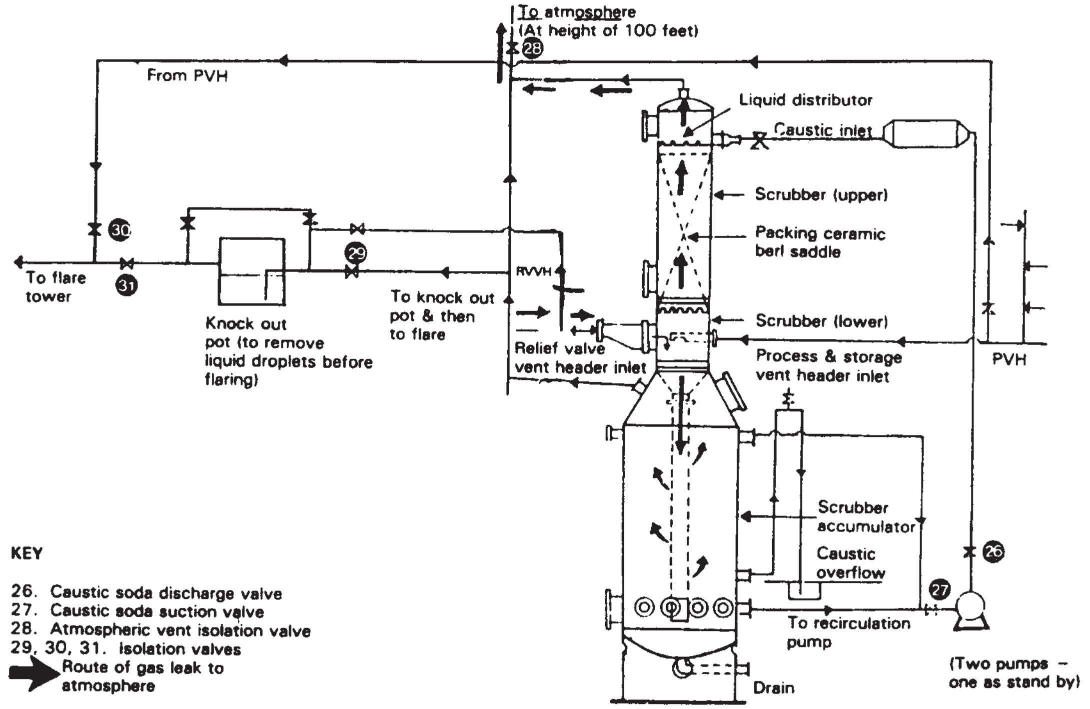

Figure A5.5 *Flow diagram of the vent gas scrubber system (Bhushan and Subramanian, 1985) (Courtesy of Business India)*

was shut, Valves 18–21 and 22–25 opened and then Valve 17 opened to admit water.

It was suggested water might have entered MIC storage Tank 610 as a result of this operation – the water washing theory. On this hypothesis, water evidently leaked through Valve 16, into the RVVH and passed through the jumper line into the PVH and thence into Tank 610. This would require that Valves 3 and 12 were open to connect the tank to the PVH and Valves 1 and 2 open to connect the RVVH to the PVH via the jumper line.

A5.6 The Release

On the evening of 2 December, a shift change took place on the plant at 22.45. At 23.00, the control room operator noticed that the pressure in Tank 610 was 10 psig. This was higher than normal but within the 2–25 psig operating pressure of the tank. At the same time the field operator reported a leak of MIC near the VGS. At 00.15, the field operator reported an MIC release in the process area and the control room operator saw that the pressure on Tank 610 was now 30 psig and rising rapidly. He called the supervisor and ran outside to the tank. He heard rumbling sounds coming from the tank and a screeching noise from the safety valve and felt heat from the tank. He returned to the control room and turned the switch to activate the VGS, but this was not in operational mode, the circulating pump not being on.

At 00.20, the production supervisor informed the plant superintendent of the release. At 00.45 operations in the derivative unit were suspended due to the high concentration of MIC.

At 01.00, an operator in this unit turned on the toxic gas alarm siren. After 5 min the loud siren was switched off leaving the muted siren on.

At about the same time the plant superintendent and control room operator verified that MIC was being emitted from the VGS stack to atmosphere and turned on and directed at the stack fixed fire water monitors to knock down the vapour.

Water was also directed at the MIC tank mound and at the vent header to the VGS. Steam issued from the cracks in the concrete showing that the tank was hot.

One plant supervisor tried to climb the structure to plug the gas leak but was overcome, falling and breaking both legs.

Some time between 01.30 and 02.30, the safety valve on Tank 610 reseated and the release of MIC ceased.

At about 02.30, the loud siren was switched on again.

The cloud of MIC gas spread from the plant towards the populated areas to the south. There was a light wind and inversion conditions.

People in the housing around the plant felt the irritant effect of the gas. Many ran out of their houses, some towards the plant. Within a short period, animals and people began to die.

At Railway Colony some 2 km from the plant, where nearly 10,000 people lived, it was reported that within 4 min 150 died, 200 were paralysed and 600 rendered unconscious and that 5000 were severely affected.

People tried to telephone the plant but were unable to get through. At 01.45, a magistrate contacted the plant superintendent.

The cloud of toxic gas hung around the area for the whole of 3 December. During the day, it stopped moving towards the city, but resumed its movement in that direction during the night.

A5.7 The Emergency and the Immediate Aftermath

Large numbers of people were affected by the toxic gas and very large numbers fled their homes.

The two hospitals principally concerned, the Hamidia and the Javaprakas Hospitals, were overwhelmed with casualties.

The difficulties were compounded by the fact that it was not known what the gas was or what its effects were. Speculation about the gas, including suggestions that it was phosgene, continued in the world press for some days.

The company provided little advice. Initially, it stated that MIC causes eye irritation but is not lethal.

As early as noon on 3 December, doctors at the Gandhi Memorial College carried out post-mortems which gave strong evidence of cyanide poisoning. Victims had died of respiratory arrest, but there was no evidence of the cyanosis due to the deoxygenation of the blood which normally accompanies pulmonary asphyxiation and there were cases where there was no evidence of pulmonary oedema.

There developed a conflict of views on the appropriate treatment. The standard treatment for cyanide poisoning is sodium thiosulfate. One group took the view that this should not be given until cyanide poisoning was established by analyses, another argued that it was well known that in cyanide poisoning the cyanide may be metabolized, leaving little trace. There followed a period in which the advice given was not clear. It was not until 3 February that an authoritative and unambiguous recommendation that sodium thiosulfate be used was issued by the Indian Council for Medical Research.

The Indian Central Bureau of Investigation (CBI) took control of the site and began a criminal investigation.

A5.8 The Investigations

A5.8.1 Government of India investigation

An investigation of the incident was undertaken by the GoI. It issued in December 1985, the *Report on Scientific Studies on the Factors Related to Bhopal Toxic Gas Leakage* by a team chaired by Varadarajan (1985).

The report refers to the fact that it was reported that about 21.30 on 2 December an operator was clearing a possible choke in the RVVH lines downstream of the phosgene stripping still filters by water flushing, without inserting a blind. The 6 in. isolation valve on the RVVH would presumably be closed but if it had not been leak-tight, water could enter the RVVH. This water could have found its way into the Tank 610 via the blowdown DMV or through the SRV and bursting disc.

A5.8.2 Union Carbide investigation – 1

A team from UCC arrived in Bhopal on 6 December charged with the tasks of assisting in the safe disposal of the remaining MIC and investigating the accident. The first task was completed on 22 December and the team returned home on 2 January.

The investigation was severely constrained by the CBI control of the site and by the criminal investigation. The team were allowed only limited access to plant records and personnel. They were permitted to talk to certain persons, but not to interview staff directly involved in the incident. They were allowed to take samples from Tank 610, but not to open and inspect the tank and its piping or to take samples from elsewhere on the plant. An account of the situation is given by Kalelkar (1988b).

On their return home, the investigators carried out a programme of some 500 experiments to establish what had occurred. The most abundant component in the residues was MIC trimer, others present in significant quantities being the components conveniently referred to as DMI, DMU, TMU, TMB and TRMB. There were also iron, chromium and nickel in approximately their proportions in 304 stainless steel and some 5% chloride.

Trimerization had obviously occurred, but it was unclear what other reactions had taken place. The investigators carried out experiments in which the principal materials believed to have been in the tank, namely MIC, chloroform, water and iron, were heated at 200°C and developed a reaction scheme which accounted for the production, starting from these materials, of the components found in the residue with the exception of TRMB, which they considered they could account for.

From plant records, Tank 610 contained prior to the incident 41 te (90,400 lb; 11,290 USgal) of liquid. The team estimated that Tank 610 had originally contained 1000–2000 lb (120–240 USgal) water and 1500–3000 lb chloroform. The source of the water was uncertain. The chloroform could be accounted for by the fact that the MRS had been operated at a temperature higher than normal and in preparation for shutdown MIC with a high chloroform content has been sent to Tank 610 rather than Tank 619. The iron could have come from corrosion, given high chloroform and water contents and high temperature.

The scenario which the investigators invoked to explain the events is as follows. The contents of Tank 610 were initially at 15–20°C. Some 1000–2000 lb water entered the tank in a manner unknown. The exothermic reaction between MIC and water led to an increase in temperature and also in pressure due to evolution of carbon dioxide. The higher temperature and presence of chloroform caused accelerated corrosion. The iron thus produced catalysed the exothermic trimerization of MIC.

Calculations showed that reaction of some 40% of the MIC would generate enough heat to vaporize the rest. This would give some 36,000 lb of solids in the tank, but only an estimated 10,000 lb were found. There may have been appreciable loss of solids and liquid through the relief vent.

The period during which the relief valve was open was reported to have been about 2 h. It was calculated that in order to vent most of the tank contents in this time the discharge rate would have had to be 40,000 lb/h, of which 29,000 lb/h were vapour and 11,000 lb/h solids/liquid mixture and that this would have required a pressure averaging 180 psig. The temperature reached was estimated as in excess of 200°C. These conditions would have been attained during the course of the venting. With the safety valve lifting at 40 psig the initial discharge would have been 10,000 lb/h.

The report puts forward the hypothesis that the water was directly introduced into Tank 610, either inadvertently or deliberately through the process vent line, nitrogen line or other piping. It refers to the washing operation on the filter pressure safety valve lines and states that this section of line had not been isolated using a blind, but that passage of water to Tank 610 through several reportedly closed valves is unlikely.

The report draws attention to a number of factors which contributed to the accident. These include the facts that refrigeration had been discontinued, that a blind was not used to isolate the lines being washed out, that the MRS was operated at a higher than normal temperature, that the VSG did not work and that the flare was out of commission.

At the press conference held to present the report, the UCC spokesman suggested that the water may have come from a nearby utility station which supplied water and nitrogen to the area: 'If someone had connected tubing to the water line instead of the nitrogen line, either deliberately or intending to introduce nitrogen into the tank, this could account for the presence of the water. . .'. The press interpreted this as a suggestion by UCC that the cause of the accident was sabotage. Subsequently UCC agreed that there was no direct evidence for this hypothesis.

A5.8.3 Union Carbide investigation – 2

Following the involvement of the Indian Government in litigation in the US courts, UCC was allowed access to personnel who had been involved on the plant and was able to gather evidence in support of its original hypothesis. An account of this extension of the UCC investigation is given by Kalelkar (1988b).

Against the water washing hypothesis he makes the following points. First, the water was introduced through a $\frac{1}{2}$ in. inlet (Valve 17). The difference in head between this point and the inlet to Tank 610 was some 10.4 ft. There were three open bleeder valves close to the inlet point which would limit the backpressure of water to 0.7 ft. Second, there were a number of valves between the inlet point and the tank and for water to pass these would have had to be open or not leak-tight. One of these valves, close to the inlet point, had been shut since 29 November 1984. It was given a one-hour test during which no water leaked through it. Third, for water to reach Tank 610 it would have had to fill the 6 in. diameter connecting pipe, 65 ft of 8 in. RVVH, with numerous branches running off, and then some 340 ft of 4 in. RVVH. The amount of water to do this was estimated as 4500 lb. On 8 February 1985, the CBI ordered a hole to be drilled in the lowest point of the PVH. For the hypothesis to hold this section, which had no bleeders or flanged joints, should have been full of water; it was completely dry.

In support of the hypothesis of direct entry of water into Tank 610 the arguments presented by Kalelkar may be summarized as follows. First, an instrument supervisor, not on duty that night, stated that he had found the local pressure indicator on the tank missing; this was one of the few points to which a water hose could be connected. Second, a water hose was found nearby. Third, there was evidence that the operators had become aware earlier in the evening that water had entered Tank 610 and had taken steps to deal with the situation. Fourth, the plant logs showed evidence of extensive tampering and alteration.

The plant could be supplied with MIC from Tank 610 or Tank 611, the MIC being passed to a one ton tank, the Sevin charge pot. There were difficulties with the pressure in Tank 610 and the transfers had been made from Tank 611. However, investigation showed that the MIC in the Sevin charge pot contained water. It had evidently come from Tank 610. Water is heavier than MIC and Tank 610 had a bottom offtake. The hypothesis is that the operators, aware that water had got into Tank 610 and wishing to remove it, on this occasion drew the MIC from that tank rather than from Tank 611.

Kalelkar suggests that the addition of water to Tank 610 may have been the act of a disgruntled employee.

A5.9 The Late Aftermath

The precise numbers of the dead and injured at Bhopal are uncertain. The scale of the accident was such that it led to much confusion. People have continued to die of the effects over a period of years. The official Indian Government estimate of the death toll about 2 years after the event was 1754. By 1989, this had risen to 3150 and by 1994 to 4000. Other figures given are 30,000 permanently or totally disabled; 20,000 temporary cases; and 50,000 with minor injury.

The ICFTU-ICEF report in 1985 states that the number of people treated in the state hospitals had been given by Dr Nagu, the Director of Health Services for Madhya Pradesh, as approximately 170,000. Some 130,000 were treated in Bhopal hospitals, mainly for lung and eye injuries, and some 40,000 in 22 other districts. Some 12,000 of the 170,000 were in a critical condition and 484 died. He estimated the total number of dead as 2000.

The disaster led to various sets of court proceedings. The GoI instituted criminal proceedings against UCC, which at the time of writing remain extant. The GoI also became a party to proceedings in the US courts. In 1987, UCC made a 'final settlement' with the GoI of $470 million. Victims tried to challenge this in the US courts, but the US Supreme Court ruled that they lacked legal standing to do so.

A5.10 Some Lessons of Bhopal

A5.10.1 Some lessons

The lessons to be learnt from Bhopal are numerous. A list of some of them is given in Table A5.2. They combine many of the lessons of Flixborough and Seveso.

Some of these lessons are now considered:

Public control of major hazard installations

The disaster at Bhopal received intense publicity for an extended period and put major hazards on the public agenda worldwide, but particularly in India and the United States, which had not reacted so strongly to Flixborough and Seveso, whose impact had been felt most in Europe.

Table A5.2 *Some lessons of Bhopal*

Public control of major hazard installations
Siting of and development control at major hazard installations
Management of major hazard installations
Highly toxic substances
Runaway reactions in storage
Water hazard in plants
Relative hazards of materials in process and in storage
Relative priority of safety and production
Limitation of inventory in the plant
Set pressure of relief valves
Disabling of protective systems
Maintenance of plant equipment and instrumentation
Isolation procedures for maintenance
Control of plant and process modifications
Information for authorities and public
Planning for emergencies

Siting of and development control at major hazard installations

Very large numbers of people were at risk from the plant at Bhopal. This situation was due in large part to the encroachment of the shantytowns, which came up to the site boundary. Although these settlements were illegal, the Indian authorities had acquiesced in them.

In this instance, however, this was not the whole story. The accident showed that site was close enough to areas populated before the plant was built to present a hazard when used for the production of a chemical as toxic as MIC. If the manufacture of such a chemical was envisaged from the start, the problem may be regarded as one of siting. If not, it may be viewed as one of intensification of the hazard on the site.

Management of major hazard installations

The plant at Bhopal was by any standards a major hazard and needed to be operated by a suitable competent management. The standards of operation and maintenance do not give confidence that this was so.

There had been recent changes in the responsibility for the plant which suggest that the new management may not have been familiar with the exigencies of major hazards operation. However, many of the problems on the plant appear to have antedated these changes.

Highly toxic substances

MIC is a highly toxic substance, much more toxic than substances such as chlorine which are routinely handled in the chemical industry. The hazard from such highly toxic substances has perhaps been insufficiently appreciated.

This hazard will only be realized if there is a mechanism for dispersion. At Bhopal, this mechanism was the occurrence of exothermic reactions in the storage tank.

Runaway reaction in storage

The hazard of a runaway reaction in a chemical reactor is well understood, but that of such a reaction in a storage tank had received little very attention. At Bhopal, this occurred due to ingress of water. Where such a reaction could act as the mechanism of dispersion for a large inventory of a hazardous substance, the possibility of its occurrence should be carefully reviewed.

Water hazard in plants

In general terms, the hazard of water ingress into plants is well known. In particular, water may contact hot oil and vaporize with explosive force or may cause a frothover, it may corrode the equipment and it may cause a blockage by freezing. Bhopal illustrates the hazard of an exothermic reaction between a process fluid and water.

Relative hazard of materials in process and in storage

There has been a tendency to argue that the risks from materials in storage are less than from materials in process, since, although usually the inventories in storage are larger, the probability of a release is much less. The release at Bhopal was from a storage tank, albeit from one associated with a process.

The relative hazard of materials in process and in storage is discussed Chapter 22.

Relative priority of safety and production

The features which led to the accident have been described above. As indicated, the *Union Carbide Report* itself refers to a number of these.

The ICFTU-ICEF report states that at the time of the accident the plant was losing money and lists a number measures which had been taken, apparently to cut costs. These include the manning cuts and the cessation of refrigeration.

Limitation of inventory in the plant

The hazard at Bhopal was the large inventory of highly toxic MIC. The process was the same as that used at UCC's W. Virginia plant. UCIL had stated that it regarded this inventory as undesirable, but was overruled by the parent company, which wished to operate the same process at both plants.

Processes are available for the manufacture of MIC which require only small inventories of the material. Moreover, carbaryl can be made by a route which does not involve MIC. The alternatives to the use of MIC are discussed by Kletz (1988h).

Set pressure of relief devices

It is desirable from the operational viewpoint for the set pressure of a relief valve to be such that the valve opens when the pressure rise threatens the integrity of the vessel but not when normal minor operating pressure deviations occur. Where the cause of potential pressure rise is a runaway reaction, however, there is a penalty in setting a high set pressure in that this may allow the reaction to reach a higher temperature and to proceed more rapidly before venting starts, so that there is a need to balance these two factors.

Disabling of protective systems

It was evidently not appreciated that the flare system was a critical component for the protection of the plant, since it was allowed to remain out of commission for the 3 months prior to the accident. It is essential that there be strict procedures for the disabling of any item which is critical for protection and that the time for which the item is out of action be kept to a minimum.

Maintenance of plant equipment and instrumentation

The 1982 UCC safety team drew attention to the problems in the maintenance of the plant. The *Union Carbide Report* gives several examples of poor maintenance of plant equipment and instrumentation and the ICFTU-ICEF report gives further details. Workers stated that leaking valves and malfunctioning instruments were common throughout the plant.

Maintenance was also very slow. The flare system, which was a critical protective system, had been out of commission for three months before the accident.

Isolation procedures for maintenance

A particular deficiency in the maintenance procedures was the failure to isolate properly the section of plant being flushed out by positive isolation using a slip plate or equivalent means. The fact that the water may not have entered in this way does not detract from this lesson.

Control of plant and process modifications

A principal hypothesis to explain the entry of water into Tank 610 is that the water passed through the jumper line. The installation of this jumper line was a plant modification. Company procedures called for plant modifications

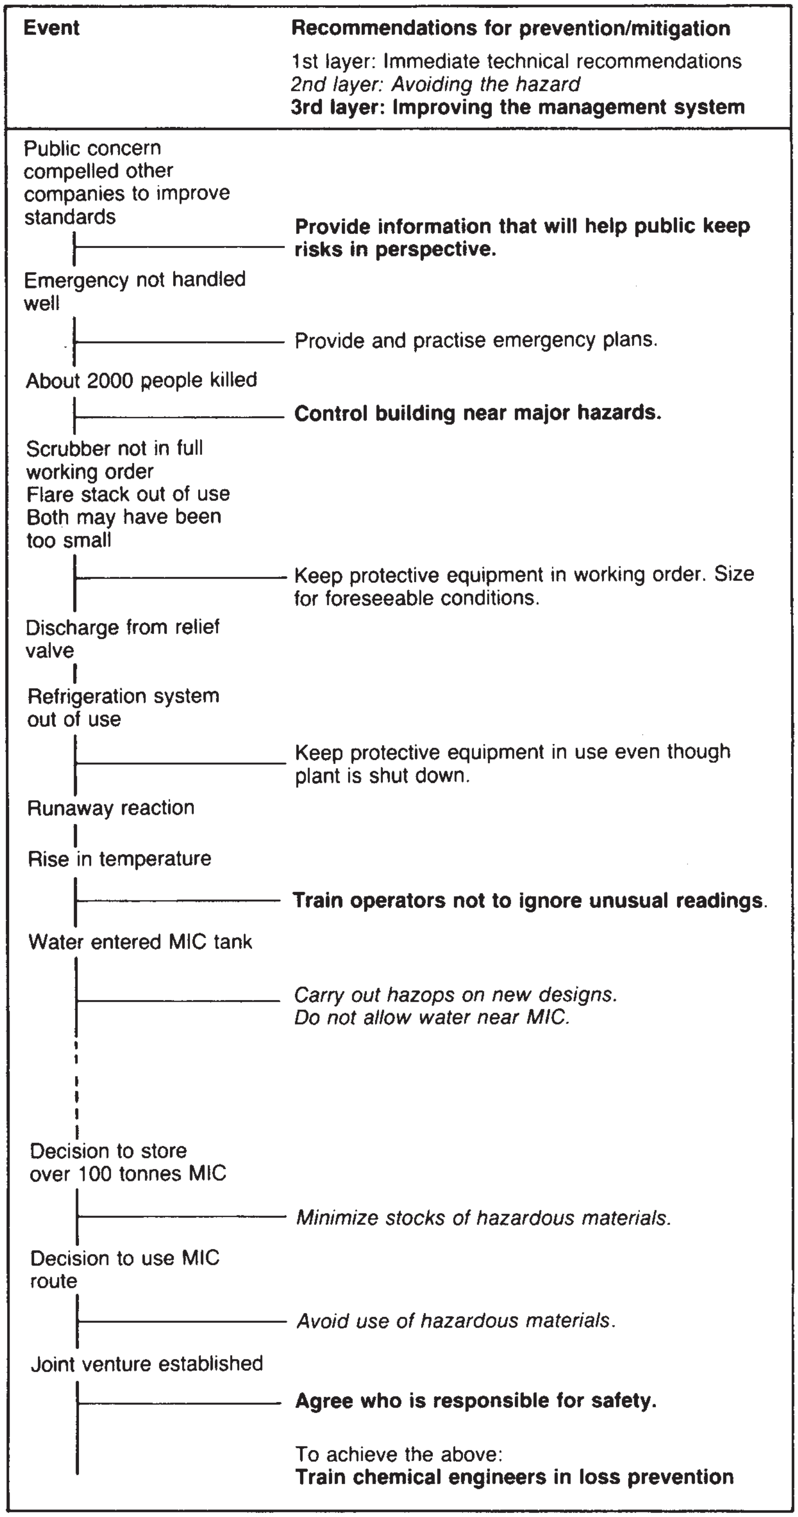

Figure A5.6 *An accident model for Bhopal, showing critical events and recommendations (Kletz, 1988h) (Courtesy of Butterworths)* to be checked by the main office engineers, but were evidently disregarded.

There was also a process modification which more certainly contributed to the accident. This is the decommissioning of the refrigeration system, so that the temperature in Tank 610 was higher than the 0°C for which the system was designed.

Information for authorities and public

UCIL had not provided full information on the substances on site to the authorities, emergency services, workers or members of the public exposed to the hazards. Many workers interviewed said they had had no information or training about the chemicals.

Planning for emergencies

The response of the company and the authorities to the emergency suggests that there was no effective emergency plan.

Within the works, defects revealed by the emergency include the hesitation about the use of the siren system and the lack of escape routes.

The preliminary condition for emergency planning to protect the public outside the works is provision to the authorities of full information about the hazards. This was not done. In consequence the people exposed did not know what the siren meant or what action to take, the hospitals did not know what they might be called on to handle, and so on.

Likewise, the essential action in an actual emergency is to inform the authorities what has happened and what the hazards are. On the morning of the accident, the hospitals were in the dark about the nature and effects of the toxic chemical whose victims they were trying to treat.

A5.10.2 An accident model

An accident model for Bhopal given by Kletz (1988h) is shown in Figure A5.6.

Appendix 6

Pasadena

Contents

Shortly after 1.00 p.m. on 23 October 1989, a release occurred on a polyethylene plant at the Phillips 66 Company's chemical complex at Pasadena, near Houston, Texas. A vapour cloud formed and ignited, giving rise to a massive vapour cloud explosion. There followed a series of further explosions and a fire. Twenty-two people on the site were killed and one later died from injuries, making a death toll of 23. The number injured are variously given as 130 and 300.

A report on the investigation of the accident has been issued by OSHA (1990a). Other accounts include those of Mahoney (1990), T. Richardson (1991) and J.N. Scott (1992).

Selected references on Pasadena are given in Table A6.1.

A6.1 The Site and the Plant

The Phillips works was sited in the Houston Chemical Complex along the Ship Channel, the location of a number of process companies.

The plant on which the release occurred was Plant V, one of the two active polyethylene plants in the complex. The plant operated at high pressure (700 psi) and high temperature. The process involved the polymerization of ethylene in isobutane, the catalyst carrier. Particles of polyethylene settled out and were removed from settling legs.

A6.2 Events Prior to the Explosion

On the previous day work began to clear three of the six settling legs on Reactor No. 6, which were plugged. The three legs were prepared by a company operator and were handed over to the specialist maintenance contractors, Fish Engineering. The configuration of a typical leg is shown in Figure A6.1.

At 8.00 a.m. on Monday, 23 October, work began on the second of the three blocked legs, Leg No. 4. The isolation procedure was to close the DEMCO ball valve and disconnect the air lines to it.

The maintenance team partially disassembled the leg and were able to remove part of the plug, but part remained lodged in the pipe 12–18 in. below the ball valve. One of the team was sent to the control room to seek assistance. Shortly after, at 1.00 p.m., the release occurred.

Although both industry practice and Phillips corporate safety procedures require isolation by means of a double block system or a blind flange, at local plant level a procedure had been adopted which did not conform to this.

It was subsequently established that the DEMCO ball valve was open at the time of the release. The air hoses to the valve had been cross-connected so that the supply which should have closed it actually opened it. The hose connectors for the 'open' and 'close' sides of the valve were identical, thus allowing this cross-connection to be made. Although procedures laid down that the air hoses should not be connected during maintenance, there was no physical barrier to the making of such a connection. The ball valve had a lockout system but it was inadequate to prevent the valve being inadvertently or intentionally opened during maintenance.

A6.3 The Explosion

The mass of gas released was estimated as some 85,200 lb of a mixture of ethylene, isobutane, hexene and hydrogen, which escaped within seconds. The release was observed by five eyewitnesses. A massive vapour cloud formed and moved rapidly downwind.

Within 90–120 s the vapour cloud found a source of ignition. Possible ignition sources were a gas-fired catalyst activator with an open flame; welding and cutting operations; an operating forklift truck; electrical gear in the control building and the finishing building; 11 vehicles parked near the polyethylene plant office; and a small diesel crane, although this was not operating.

The TNT equivalent of the explosion was estimated in the OSHA report as 2.4 tons. An alternative estimate from seismograph records is 10 tons.

There followed two other major explosions, one when two 20,000 USgal isobutane storage tanks exploded and the other when another polyethylene plant reactor failed catastrophically, the timings being some 10–15 min and some 25–45 min, respectively, after the initial explosion. One witness reported hearing 10 separate explosions over a 2-h period.

Debris from the explosion was found 6 miles from the site.

All 22 of those who died at the scene were within 250 ft of the point of release and 15 of them were within 150 ft.

Injuries which occurred outside the site were mainly due to debris from the explosion.

The explosion resulted in the destruction of two HOPE plants.

A6.4 The Emergency and the Aftermath

People in the immediate area of the release began running away as soon as they realized that gas was escaping. The alarm siren was activated, but the level of noise in the finishing building was such that there was a question whether some employees there failed to hear it.

The immediate response to the emergency was provided by the site fire brigade, which undertook rescue and care of the injured and began fighting the fire. Twenty-three persons were unaccounted for, but for an extended period the area of the explosion remained dangerous to enter.

Severe difficulties were experienced in fighting the fires resulting from the explosion. There was no dedicated fire water system, water for firefighting being drawn from the process water system. The latter suffered severe rupture in the explosion so that water pressure was too low for firefighting purposes. Fire hydrants were sheared off by the blast. Fire water had to be brought by hose from remote sources such as settling ponds, a cooling tower, a water treatment plant and a water main on a neighbouring plant. These difficulties were compounded by failures of the fire pumps. The electrical cables supplying power to the regular fire pumps were damaged by the fire so that these pumps were put out of action. Further, of the three backup diesel fire pumps one was down for maintenance and one quickly ran out of fuel. Despite these problems the fire was brought under control within some 10 h.

The handling of the emergency was handicapped by the facts that the intended command centre had been damaged and that telephone communications were disrupted. Telephone lines were jammed for some hours following the accident.

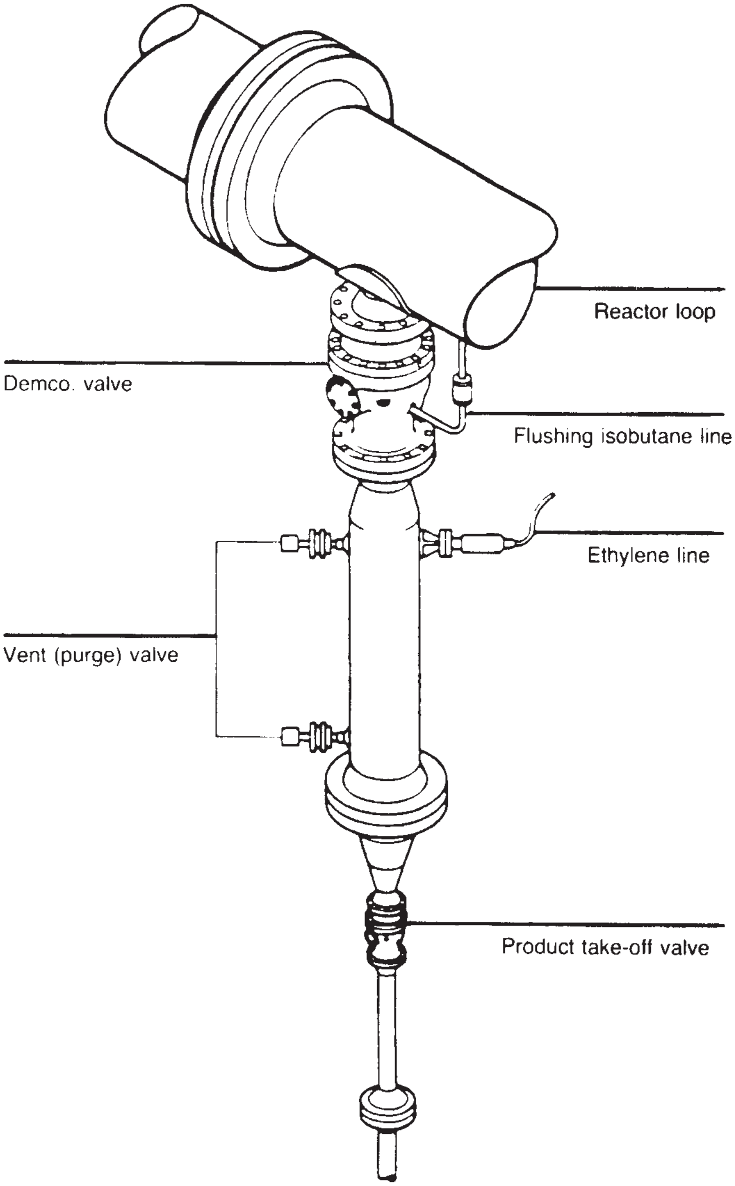

Figure A6.1 *Typical piping settling leg arrangement on reactor (Occupational Safety and Health Administration, 1990a)*

The emergency response was co-ordinated by the site chief fire officer and involved the local Channel Industries Mutual Aid (CIMA) organization, a co-operative of some 106 members in the Houston area.

More than 100 people were evacuated from the administration building across the Houston Ship Channel by the US Coast Guard and by Houston fireboats; they would otherwise have had to cross the area of the explosion to reach safety.

The media were quickly aware of the explosion and within an hour there were on site 150 media personnel from 40 different organizations.

The financial loss in this accident is comparable with, and may exceed, that of the Piper Alpha disaster. Redmond (1990) has quoted a figure of $1400 million, divided almost equally between property damage and business interruption losses.

On the basis of a review of company reports and of the defects found during the investigation of the disaster, OSHA issued a citation to the company for wilful violations of the 'general duty' clause. The citation covered the lack of hazard analysis; plant layout and separation distances; flammable gas detection; ignition sources; building ventilation intakes; and the fire water system; the permit system; isolation for maintenance.

A6.5 Some Lessons of Pasadena

Some of the lessons to be learned from Pasadena are listed in Table A6.2.

Management of major hazard installations
The OSHA report details numerous defects in the management of the installation. Some of these are described below.

Hazard assessment of major hazard installations
According to the report, the company had made no use of hazard analysis or an equivalent method to identify and assess the hazards of the installation.

Plant layout and separation distances
The report was critical of the separation distances in the plant in several respects. It stated that the separation distances between process equipment plant did not accord with accepted engineering practice and did not allow time for personnel to leave the polyethylene plant safely during the initial vapour release; and that the separation distance between the control room and the reactors was insufficient to allow emergency shut-down procedures to be carried out.

Location of control room
As just mentioned, the control room was too close to the plant. It was destroyed in the initial explosion.

Building ventilation intakes
The ventilation intakes of buildings close to or downwind of the hydrocarbon processing plants were not arranged so as to prevent intake of gas in the event of a release.

Minimization of exposure of personnel
Closely related to this, there was a failure to minimize the exposure of personnel. Not only the control room but the finishing building had relatively high occupancy.

Table A6.2 *Some lessons of Pasadena*

Management of major hazard installations
Hazard assessment of major hazard installations
Plant layout and separation distances
Location of control room
Building ventilation intakes
Minimization of exposure of personnel
Escape and escape routes
Gas detection system
Control of ignition sources
Permit-to-work systems
Isolation procedures for maintenance
Integrity of fire water system
Dependability of fire pumps
Audibility of emergency alarm
Follow-up of audits
Planning for emergencies

Escape and escape routes
As already stated, the separation distances were not such as to allow personnel on the polyethylene plant to escape safely. Further, the only escape route available to people in the administration block (other than across the ship channel) was across the area of the explosion.

Gas detection system
Despite the fact that the plant had a large inventory of flammable materials held at high pressure and temperature, there was no fixed flammable gas detection system.

Control of ignition sources
The control of ignition sources around the plant was another feature criticized in the OSHA report.

Permit-to-work systems
The OSHA report stated that an effective permit system was not enforced for the control of the maintenance activities either of the company's employees or of contractors.

Isolation procedures for maintenance
In this incident the sole isolation was a ball valve, which was meant to be closed but was in fact open. There was no double block system or blind flange.

The practice of not providing positive isolation was a local one and violated corporate procedures. The implication is that it had not been brought to light by any safety audits conducted.

Integrity of fire water system
The practice of relying for fire water on the process water system and the failure to provide a dedicated fire water system meant that the fire water system was vulnerable to an explosion.

Dependability of fire pumps
The electrical cables to the regular fire pumps were not laid underground and were therefore vulnerable to damage by explosion and fire. One of the back-up diesel pumps had insufficient fuel and one had been taken out for maintenance without informing the chief fire officer.

Audibility of emergency alarm
As described, the level of noise in some areas was such that the employees might not have been able to hear the siren.

Follow-up of audits
The OSHA report criticized the company's failure to act upon reports issued previously by the company's own safety personnel and by external consultants, which drew attention to unsafe conditions.

Planning for emergencies
The disaster highlighted a number of features of emergency planning. The company had put a good deal of effort into planning and creating personal relationships with the emergency services, by means such as joint exercises, and these paid off. The value of planning, training and personal relations was one of the most positive lessons drawn.

Another area in which a proactive approach proved beneficial was in relations with the media. Senior personnel made themselves available, and the company evidently felt it received fair treatment.

One weakness of the emergency planning identified was that it had not envisaged a disaster of the scale which actually occurred.

The incident brought out the need to be able to respond clearly to calls from those liable to be affected about the toxicity of the fumes and smoke generated in such an event.

The behaviour of rescue helicopters posed a problem. Personnel on the ground had no means of communication with them and the craft tended to come in low, creating the danger of blowing flames or toxic fume onto those below. A need was identified for altitude and distance guidelines for helicopters.

Appendix 7

Canvey Reports

Contents

The most comprehensive hazard assessment of non-nuclear installations in the United Kingdom is the Canvey study carried out for the HSE by SRD.

The first phase of the work is described in *Canvey: An Investigation of Potential Hazards from Operations in the Canvey Island/Thurrock Area* (the First *Canvey Report*) (HSE, 1978b). The report is in two parts: Part 1 is an introduction by the HSE and Part 2 the SRD study.

The origin of the investigation was a proposal to withdraw planning permission for the construction of an additional refinery in the area. Two oil companies, Occidental Refineries Ltd and United Refineries Ltd, had been granted planning permission for the construction of oil refineries. The construction of the Occidental refinery was begun in 1972, but was halted in 1973 pending a major design study review. United Refineries had valid planning consents, but had not started construction. It was a public inquiry into the possible revocation of the planning permission for the United Refineries development which gave rise to the investigation.

Responses to the First *Canvey Report* centred mainly on two aspects: the methodology used and the magnitude of the assessed risks. The HSE commissioned further work, leading to the Second *Canvey Report* (HSE, 1981a), in which the methodology used is revised and the assessed risks are rather lower.

An account of the first report is given in Sections A7.1–A7.6, of the response to that report in Section A7.7 and of the second report in Sections A7.8–A7.10.

A map of the Canvey/Thurrock area showing the principal installations and populated areas is given in Figure A7.1.

Selected references on the *Canvey Reports* are given in Table A7.1.

A7.1 First *Canvey Report*

The terms of reference of the investigation were

> In the light of the proposal by United Refineries Limited to construct an additional refinery on Canvey Island, to investigate and determine the overall risks to health and safety arising from any possible major interactions between existing or proposed installations in the area, where significant quantities of dangerous substances are manufactured, stored, handled, processed and transported or used, including the loading and unloading of such substances to and from vessels moored at jetties; to assess the risk; and to report to the Commission.

The members of the investigating team were appointed as inspectors of the HSE under the provisions of the Health and Safety at Work etc. Act 1974 and were given specified powers to enable them to make the necessary inquiries. The overall approach taken in the investigation was

(1) To identify any potentially hazardous materials, their location and the quantities stored and in process.
(2) To obtain and review the relevant material properties such as flammability and toxicity.
(3) To identify the possible ways in which failure of plants might present a hazard to the community.
(4) To identify possible routes leading to selected failures. Typically, the factors examined included operator errors, fatigue or aging of plant, corrosion, loss of process control, overfilling, impurities, fire, explosion, missiles and flooding.
(5) To quantify the probability of the selected failures occurring and their consequences.

The investigation involved the identification of the principal hazards of the installations and activities in the area, the assessment of the associated risks to society and to individuals, and the proposal of modifications intended to reduce these risks.

Some 30 engineers were engaged in the investigation, which cost about £400,000.

A7.2 First *Canvey Report:* Installations and Activities

The principal hazardous installations and activities identified in the investigation are summarized in Table A7.2. These installations are now briefly described.

A7.2.1 British Gas Corporation

The British Gas Corporation operates on Canvey Island, a methane terminal that is used for the importation and storage of LNG from Algeria. There are some 50 shipments of LNG a year made by two specially designed ships each with a cargo capacity of about 12,000 t. The LNG is pumped ashore from a single jetty into above-ground and in-ground fully refrigerated storage tanks with a combined total capacity of approximately 100,000 t. The natural gas is sent out as vapour by pipeline except for a small amount that goes out by road.

The terminal is also used for the fully refrigerated storage of liquid butane. A pipeline from the butane tanks crosses the area.

In addition, new LNG ships are commissioned at the terminal by using the LNG from the storage tanks to cool down the ships' cargo tanks.

A7.2.2 Texaco Ltd

Texaco Ltd operates on Canvey Island storage for petroleum products, but not LPG, with a total capacity of more than 80,000 t. The petroleum products are brought in by sea via two jetties and are sent out by sea, road and pipeline.

A7.2.3 London and Coastal Wharves Ltd

London and Coastal Wharves Ltd also operates on Canvey Island storage for a wide range of substances, including petroleum products and other flammable and toxic materials, with a total capacity of more than 300,000 t. Part of the site is leased to Texaco. The materials are brought in mainly by sea via a single jetty and also by road and are sent out not only by road but also by sea. Oil is sent out by Texaco by pipeline.

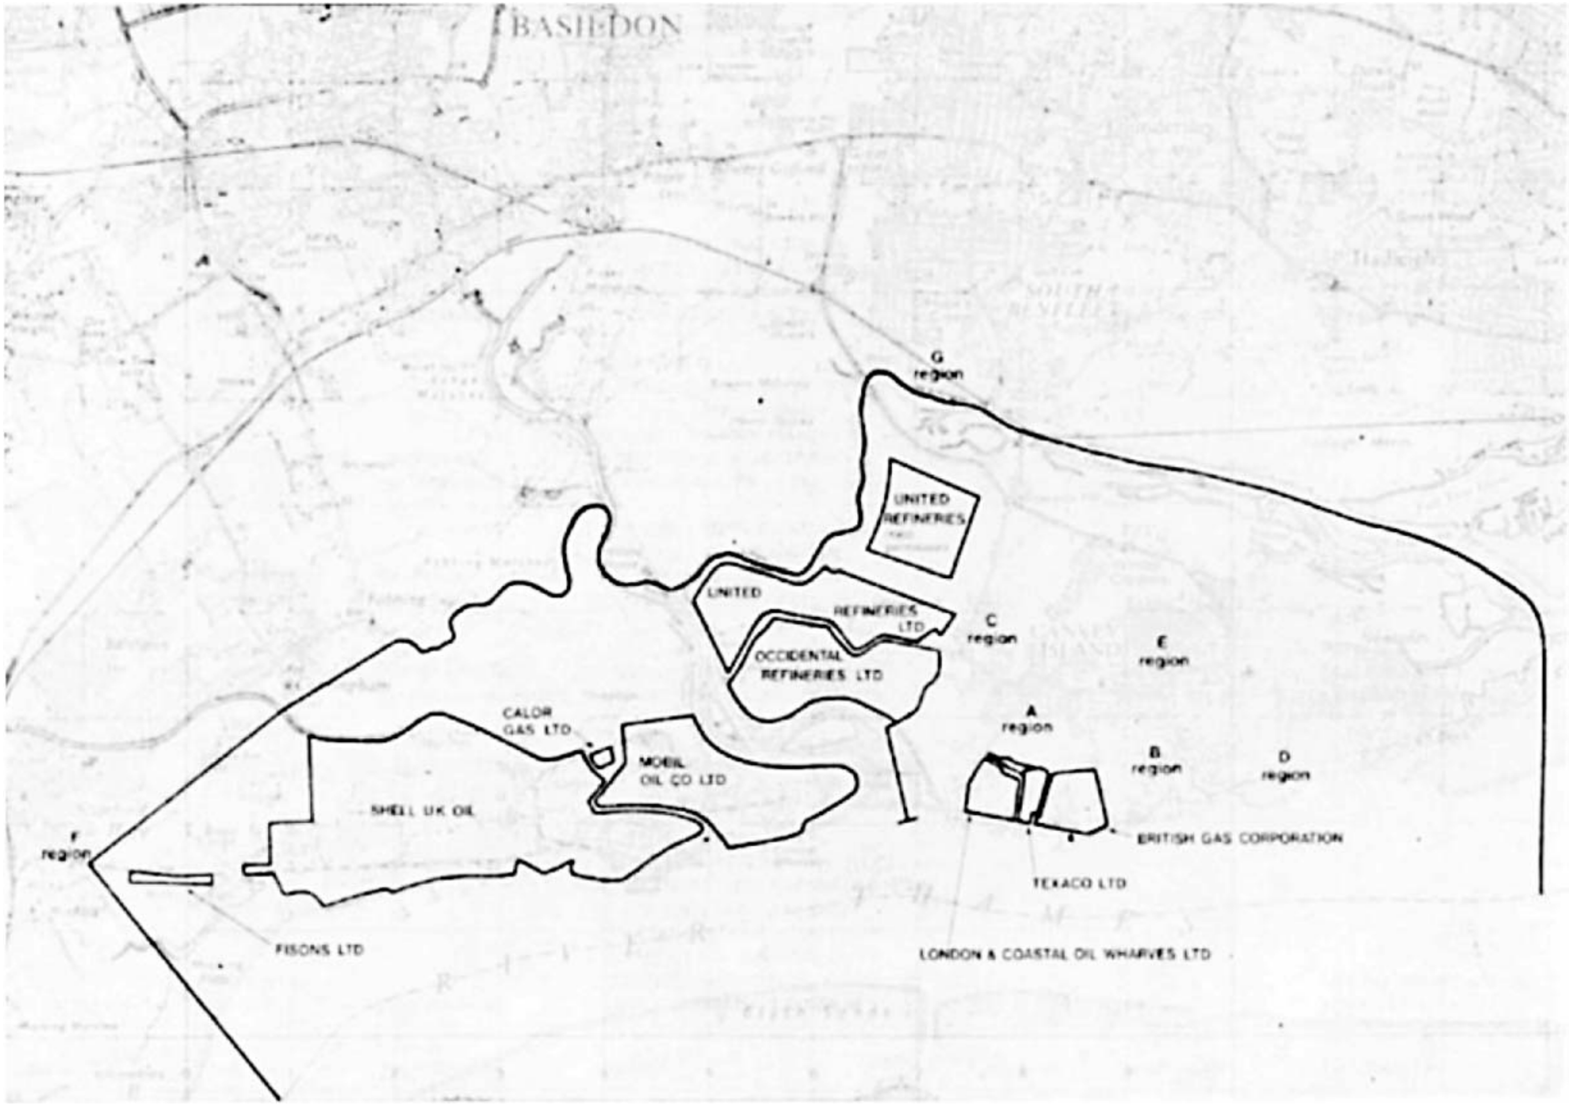

Figure A7.1 *First Canvey Report: map of the Canvey/Thurrock area, showing principal installations and populated areas (Health and Safety Executive, 1978b) (Courtesy of HM Stationery Office)*

Table A7.2 *First Canvey Report: principal hazardous installations and activities at Canvey*

Location	*Company*	*Installation or activity*	*Storage*	*Employees*	*Transport in*	*Transport out*
Canvey Island	British Gas Corporation	LNG terminal	Fully refrigerated storage of LNG (atmospheric pressure, <−162°C) 6 × 4000 t above-ground tanks 2 × 1000 t above-ground tanks 4 × 20,000 t in-ground tanks. Fully refrigerated storage of butane (atmospheric pressure, <10°C) 1 × 10,000 t tank 2 × 5000 t tanks	200	Sea	Mainly pipeline (as vapour) but some road
	Texaco Ltd	Petroleum products storage	Atmospheric storage of petroleum products >80,000 t total capacity	130	Sea	Pipeline, road, sea
	London and Coastal Wharves Ltd	Flammable and toxic liquids storage	Atmospheric storage of liquids >300, 000 t total capacity	50	Mainly sea but some road	Pipeline (Texaco oil). Rest mainly road but some sea
	Occidental Refineries Ltd	Oil refinery (proposed)	Pressure storage of LPG (atmospheric temperature) 2 × 750 t propane spheres 2 × 400 t butane spheres			
	United Refineries Ltd	Oil refinery (proposed)	Pressure storage of LPG (atmospheric temperature) 4 × 200 t propane spheres 3 × 900 t butane spheres. Process and storage containing hydrogen fluoride			
Coryton	Mobil Oil Co. Ltd	Oil refinery	Pressure storage of LPG (atmospheric temperature) 1 × 1000 t+14 other vessels, giving 4000 t total capacity	800	LPG produced on site	Pipeline, road, rail, sea
		Oil refinery (extension)	Pressure storage of LPG (atmospheric temperature) 4 × 1000 t LPG spheres. Fully refrigerated storage of LPG (atmospheric pressure) 1 × 5000 t tank. Process and storage containing hydrogen fluoride		LPG produced on site	Pipeline, road, rail, sea

	Calor Gas Ltd	LPG terminal	Pressure storage of LPG (atmospheric temperature) 3 × 60 t propane vessels 2 × 60 t butane vessels + cylinders, giving 500 t total inventory	100	Pipeline (from oil refineries)	Road (cylinders, bulk tankers)
Shell Haven	Shell Oil U.K. Ltd	Oil refinery	Pressure storage of LPG (atmospheric temperature) 1 × 1700 t butane sphere + 3 other butane spheres, giving 3200 t total butane capacity 4 × 400 t propane spheres 3 × 135t LPG horizontal vessels	1900	LPG produced on site	Pipeline, road, rail, sea
			Fully refrigerated storage of liquid anhydrous ammonia (atmospheric pressure, −33°C) 1 × 14,000 t tank. Process and storage containing hydrogen fluoride 2 × 40 t vessels		Sea	Sea, road, occasionally rail
Stanford-le-Hope	Fisons Ltd	Ammonium nitrate plant	Storage of 92% aqueous ammonium nitrate solution 1 × 5000 t tank 1 × 2000 t tank	80	Ammonium nitrate produced on site	Road
		Ammonia storage	Semi-refrigerated pressure storage of liquid anhydrous ammonia (pressure above atmospheric, 6°C) 1 × 2000 t sphere		Rail	Ammonia used on site
Canvey/ Thurrock area	General	Transport of hazardous Materials by river, road, rail and pipeline				

A7.2.4 Mobil Oil Co. Ltd

Mobil Oil Co. Ltd operates at Coryton, an oil refinery as well as a bulk distribution depot and a large research and technical services laboratory. Oil is brought in by sea into storage tanks and is drawn off from these as required by the refinery. LPG is produced on site. The total storage capacity is more than 1,500,000 t. Products are sent out by sea, road, rail and pipeline.

In addition, at the time of the investigation Mobil was undertaking a major extension of the refinery.

A7.2.5 Calor Gas Ltd

Calor Gas Ltd operates at Coryton, an LPG terminal for the filling of gas cylinders. The gas is supplied by pipeline from both the nearby refineries and is held in storage vessels with a total capacity of 350 t. The gas cylinders bring the total inventory on site to 500 t. LPG is sent out by road in cylinders and in bulk tankers.

A7.2.6. Shell Oil UK Ltd

Shell Oil UK Ltd operates at Shell Haven, an oil refinery. Oil is brought in by sea into storage tanks and is drawn off from these as required to the refinery. LPG is produced on site. The total storage capacity is more than 3,500,000 t. Products are sent out by sea, road, rail and pipeline.

There is also on site a large fully refrigerated storage tank for liquid anhydrous ammonia with a capacity of 14,000 t. Ammonia is brought in by sea and sent out by sea and road, and occasionally by rail.

A7.2.7 Fisons Ltd

Fisons Ltd operates at Stanford-le-Hope, an ammonium nitrate plant in which strong ammonium nitrate solution is produced by reacting together ammonia and nitric acid, the latter itself being made on site from ammonia. The ammonium nitrate is stored in two large heated tanks with a total capacity of 7000 t and is sent out by road. Liquefied anhydrous ammonia for the process is brought in by rail and is stored in a large semi-refrigerated pressure storage sphere with a capacity of 2000 t.

A7.2.8 Other activities

Explosives are trans-shipped at Chapmans Anchorage at the eastern end of Canvey Island, while there is a specified anchorage for explosives ships at the other end of the area.

Ships passing up and down the river are obliged to travel fairly close to the sea walls and jetties within the area.

A7.3 First *Canvey Report:* Identified Hazards

The investigation identified several principal hazards in the area. These are;

(1) oil spillage over bund;
(2) LNG vapour cloud release (1000 t);
(3) LPG vapour cloud release (1000 t);
(4) ammonium nitrate explosion (4500 t of 92% solution);
(5) ammonia vapour cloud release (1000 t);
(6) hydrogen fluoride cloud release (1000 t).

The figures in parentheses indicate standard cases considered in the study.

A severe fire might occur if there is an escape of flammable liquids from storage so that large quantities flow down into the residential area. This hazard is presented by the large storages of flammable liquids at London and Coastal Wharves and Texaco and at the proposed refineries of Occidental and United Refineries, and also by the large butane storage at British Gas.

A severe vapour cloud fire and/or explosion might occur if there is a spillage of LNG so that a vapour cloud forms and ignites. This hazard is presented by the large LNG terminal and storage at British Gas. The spillage might occur at sea or on land.

Similarly, a severe vapour cloud fire and/or explosion might occur if there is a spillage of LPG so that a vapour cloud forms and ignites. This hazard is presented by the LPG terminals and storages at British Gas, Shell and Mobil and by those at the proposed refineries of Occidental and United Refineries.

A severe explosion might occur if there is a rupture of an ammonium nitrate storage tank. This hazard is presented by the storage of ammonium nitrate at Fisons.

A severe toxic release might occur if there is a spillage of ammonia. This hazard is presented by the large terminals and storages at Fisons and at Shell. The spillage might occur at sea or on land.

A severe toxic release might also occur if there is a rupture of storage or process plant containing hydrogen fluoride. This hazard is presented by the alkylation facilities at Shell, at the Mobil extension and at the proposed Occidental refinery.

The investigators also identified and assessed other hazards, but these are not considered here.

A7.4 First *Canvey Report:* Failure and Event Data

The investigation required the estimation of the probabilities of various occurrences and of their consequences.

Some of the sources of information on such probabilities used in the study were

(1) UK industries, including oil, chemical and other process industries and transport;
(2) government organizations such as those concerned with fire, and road, rail and sea and air transport;
(3) professional institutions, for example, Institution of Chemical Engineers, Institution of Civil Engineers, American Institute of Chemical Engineers;
(4) international safety conference proceedings, for example, loss prevention in the process industries, ammonia plant safety and hazardous materials spills;
(5) industry-based associations, for example, Chemical Industries Association, Institute of Petroleum, American Petroleum Institute, Liquefied Petroleum Gas Industry Technical Association;
(6) international insurance interests, for example, Lloyds, Det Norsk Veritas, and industrial risk insurers, Fire Protection Association;
(7) overseas government and international agencies, for example, US Coast Guard, US Department of Transportation, OECD and EEC;
(8) specialized research laboratories;
(9) individual subject specialists known or recommended to the investigating team.

Selected references used in the *Canvey Report* are given in Table A7.3.

The degree of uncertainty associated with the probability estimates is indicated by the following code:

(a) assessed statistically from historical data – this method is analogous to the use of aggregate estimates in economic forecasting;
(b) based on statistics as far as possible but with some missing figures supplied by judgement;
(c) estimated by comparison with previous cases for which fault tree assessments have been made;
(d) 'dummy' figures – likely always to be uncertain, a subjective judgement must be made;
(e) not used;
(f) fault tree synthesis, an analytically based figure which can be independently arrived at by others.

The coding (a) denotes a value based on historical failure or event data. The coding (b) indicates that the value is again based on historical data as far as possible, although with some exercise of judgement, but also that given more effort a firmer value would probably be obtained. The coding (d) indicates that the value is based on judgement and the prospects of ever reducing the uncertainty are poor. Category (d) factors are effectively dummy values. Conclusions should not be drawn from these without testing for sensitivity. The value of a (d) category factor is generally not very small: it is typically 0.3 and exceptionally 0.1. The coding (f) denotes a value synthesized by fault tree methods. This category is in fact very little used in the study. Instead use is made of (c) category factors. The coding (c) indicates that the value is based on a value previously obtained for a similar situation using fault tree methods. The *Canvey Report* contains much useful information on failure and event data. Some of these data are given in Section A7.5 and in Table A7.4. It is emphasized that these data are given here for illustrative purposes and that the report itself should be consulted for the description of the background to and the application of these data.

A7.5 First *Canvey Report:* Hazard Models and Risk Estimates

The investigation involved the study of a wide range of hazards and scenarios.

The projects that were initiated as part of the investigation were

(1) consideration of known history of identified storage tanks and their possibility of failure;
(2) probability of particular storage tanks or process vessels being hit by missiles caused by fires or explosions on site or adjacent sites, by fragmentation of rotating machines or pressure vessels, or transport accidents;
(3) effects of vapour cloud explosions on people, houses, engineering structures, etc.;
(4) evaporation of LNG from within a containment area on land or from a spill on water;
(5) special problems of frozen earth storage tanks for LNG and the effect of flooding;
(6) study of possible failures in handling operations;
(7) consideration of the possible benefits and practicality of evacuation;
(8) civil engineering aspects of the sea-wall – the chance of it being breached by subsidence, explosion or impact of ships, consideration of the timing of improved defences, consideration of the time for floods to rise;
(9) statistics of ship collisions and their severity, groundings, etc., applying extensive world experience to the Canvey Island area;
(10) reliability and analysis of fluid handling practices, ship to shore, and store to road vehicles and pipelines;
(11) toxicology of identified hazardous substances;
(12) studies to determine the lethal ranges for various releases of toxic or explosive materials leading to a number of special studies such as
    (a) the behaviour of ammonia spilt on water or land, and
    (b) an assessment of the relative importance of explosion or conflagration from a cloud of methane or liquefied petroleum gas.

The subjects that are considered in appendices to the report are

(1) a review of current information on the causes and effects of explosions of unconfined vapour clouds (F. Briscoe);
(2) fires in bunds – calculations of plume rise and position of downwind concentration maximum (R. Griffiths);
(3) a quantitative study of factors tending to reduce the hazards from airborne toxic clouds (Q.R. Beattie);
(4) the dispersal of ammonia vapour in the atmosphere with particular reference to the dependence on the conditions of emission (F. Abbey, R.F. Griffiths, S.R. Haddock, G.D. Kaiser, R.J. Williams and B.C.Walker);

Table A7.4 *First Canvey Report: some failure and event data used (after Health and safety Executive, 1978b)*

Installation or activity[a]			*Canvey Report page(s)*
Pressure vessels (LPG, ammonia, HF)	Frequency of spontaneous failure of pressure vessel	10^{-5}/year–10^{-4}/year	57, 59, 69
Pressure circuit (HF)	Frequency of spontaneous failure of pressure circuit	10^{-4}/year	59
	Frequency of release due to operational fault	10^{-4}/year	59
	Frequency of penetration of pressure circuit by missile	10^{-4}/year	59
High speed rotating machine	Frequency of disintegration of rotor	10^{-4}/year–10^{-3}/year	58
Pipework (LPG)	Frequency of failure of pipework (whole refinery installation)	5×10^{-3}/year	56
Pump(LPG)	Frequency of catastrophic failure of pump	10^{-4}/year	56
LPG filling point	Frequency of large vapour release	5×10^{-3}/year	58, 81
LNG tank (above ground)	Frequency of serious fatigue failure	2×10^{-4}/year	63
	Frequency of overpressurization by overfilling	10^{-5}/year–10^{-4}/year	63, 95
	Frequency of rollover involving structural damage	10^{-5}/year–10^{-4}/year	63, 95
Jetty pipework (LNG)	Frequency of catastrophic failure of jetty pipework	10^{-4}/year–10^{-3}/year	63
Fire	Frequency of major fire in a refinery	0.1/year	55, 130
Explosion	Probability of refinery explosion, given major refinery fire	0.5	130
Missiles	Probability of missile generation, given refinery explosion	0.1	130
	Frequency of missile-generating explosion in refinery	5×10^{-3}/year	130
	Average number of missiles generated per explosion	*c.* 6	130
	Probability of missile hitting large storage sphere at 300 m	10^{-3}/year	55

Unconfined vapour cloud explosion	Frequency of unconfined vapour cloud explosion in a refinery	10^{-3}/year	69, 130
Pipeline (butane)	Frequency of failure of pipeline (15/20 cm diameter)	3×10^{-4}/km y	85
Rail transport	Frequency of derailment of rail tank car	1×10^{-6}/train km travelled	79
	Probability of overturning given derailment	0.2	79
Road transport	Frequency of accident of road tanker involving spillage	1.6×10^{-8}/km travelled	84
Sea transport (Port of London)	Frequency of ship–ship collision of moderate severity due to harbour movements	0.5×10^{-4}/harbour movement	146
	Frequency of berthing contact	1.5×10^{-4}/harbour movement	146
	Frequency of grounding	0.3×10^{-4}/harbour movement	146
	Frequency of spillage due to harbour movements: ammonia carrier	3.1×10^{-5}/harbour movement	149
	Frequency of fire	0.5×10^{-4}/harbour movement	146
	Frequency of ship–ship collision of moderate severity in transit in estuary	2.3×10^{-5}/movement	147
	Frequency of spillage due to ship–ship collision intransit: ammonia carrier	5×10^{-6}/movement	150
Jetty incidents	Frequency of shipboard explosion at jetty: ammonia ship, Shell jetty	10^{-4}/harbour movement	96
	Frequency of fire or explosion at jetty: LPG, Occidental, Mobil jetty	4×10^{-5}/harbour movement	96
Aircraft movements	*See* Section A.5.5 of this Appendix		139–140
Helicopter movements	Frequency of helicopter accident – total accidents	3×10^{-7}/km flown	141
	– Fatal accidents	8×10^{-8}/km flown	141

---

[a] The data given in this table are in most cases heavily qualified and the original report should be consulted for the description of the background to and the application of them.

(5) statistics on fires and explosions at refineries Q.H. Bowen);
(6) missiles – penetration capability (EA White);
(7) discussion of data base for pressure vessel failure rate (TA Smith);
(8) risk of aircraft impacts on industrial installations in the vicinity of Canvey Island (LS. Fryer);
(9) the dispersion of gases that are denser than air, with LNG vapour as a particular example (G.D. Kaiser);
(10) not used;
(11) the risk of a liquefied gas spill to the estuary (D.F. Norsworthy);
(12) the toxic and airborne dispersal characteristics of hydrogen fluoride (Q.R. Beattie, F. Abbey, S.R. Haddock, G.D. Kaiser);
(13) transient variation of the wall temperature of an LNG above-ground storage tank during exposure to an LNG fire in an adjacent bund (I.R. Fothergill);
(14) the escape of 1000 t of anhydrous ammonia from a pressurized storage tank (L.S. Fryer, G.D. Kaiser and B.C. Walker);
(15) graphical calculation of toxic ranges for a release of 1000 t of ammonia vapour (J.H. Bowen);
(16) effect of unbunded spill of hydrocarbon liquid from refinery at Canvey Island (A.N. Kinkead);
(17) estimated risk of missile damage causing a vapour cloud release from existing and proposed LPG storage vessels at the Mobil refinery, Coryton (D.F. Norsworthy);
(18) risks of accidents involving road tankers carrying hazardous materials (L.S. Fryer);
(19) toxicology of lead additives (S.R. Haddock);
(20) compatibility of materials stored at London and Coastal Wharves Ltd (S.R. Haddock);
(21) blast loading on a spherical storage vessel (Q. Wall);
(22) statistical comment on data on distribution of cracks found on inspection of steel vessel (Q.C. Moore);
(23) calculation of resistance of ship hull to collision (A.N. Kinkead);
(24) reduction of apparent risk by shared experience (Q.H. Bowen).

The treatment of some of the topics which is given in the report is now described. These topics are

(1) failure of pressure vessels;
(2) failure of pressure piping;
(3) failure of pipelines;
(4) generation of and rupture by missiles;
(5) crash of and rupture by aircraft;
(6) ship collision and other accidents;
(7) flow of a large release of oil;
(8) temperature of the wall of an LNG tank exposed to an LNG fire in an adjacent bund;
(9) evaporation of LNG and ammonia on water;
(10) dispersion of an LNG vapour cloud;
(11) unconfined vapour cloud fire and explosion;
(12) ammonium nitrate explosion;
(13) toxicity of chlorine, ammonia, hydrogen fluoride and lead additives;
(14) dispersion of ammonia and hydrogen fluoride vapour clouds;
(15) factors mitigating casualties from a toxic release;
(16) road tanker hazards;
(17) evacuation.

It is emphasized that the following summary of the methods used in the report is necessarily highly compressed and that the report itself should be consulted for a fuller discussion of the methods themselves and of the background to and application of the methods.

A7.5.1 Failure of pressure vessels

Spontaneous failure of pressure vessels is considered as a possible initiating event for releases of LPG, ammonia and hydrogen fluoride. The report discusses spontaneous failure of pressure vessels in Part 2, Section 5.3.2. and in Appendix 7 and the sensitivity of the results for LPG, ammonia and hydrogen fluoride releases in Part 2, Sections 17.14–17.16.

It reviews the surveys of pressure vessel failures available at that date, as described in Chapter 12, and concludes that the UK survey data are broadly applicable to LPG storage vessels.

For vessels covered by the surveys the frequency of a fault requiring repair or withdrawal from service was about 3×10^{-4}/y. If it can be assumed that the critical defect length is less than the wall thickness, so that detection is easier, and that there is an effective inspection system, a reasonable estimate of the probability of detection is 90%. The frequency of an undetected fault would then be about 3×10^{-5}/y. A catastrophic failure rate of pressure vessels of 10^{-5}/y is used in the study.

In addition, however, the sensitivity of the results to errors in the assumed failure rate was calculated taking a failure rate of 10^{-4}/y instead of 10^{-5}/y. The effect of this change is almost to double the risk from LPG operations for the existing installations after the proposed modifications. Thus for an incident involving >1500 casualties the frequency is 264×10^{-6}/y with a contribution of $20-10^{-6}$/y for spontaneous failure of pressure vessels, but the latter rises to 200×10^{-6}/y if the spontaneous failure rate of pressure vessels is increased from 10^{-5}/y to 10^{-4}/y.

It is concluded that a high standard of inspection of the LPG pressure vessels is necessary.

External threats to pressure vessels were also considered. An event tree for the derailment involving overturning of a rail tank car with possible threat to a sphere containing 2000 t of anhydrous ammonia is shown in Figure A7.2.

Missile threats are described in Section A7.5.4.

A7.5.2 Failure of pressure piping

Failure of pressure piping is considered as a possible initiating event for releases of LPG and LNG. The report discusses the failure of LPG pressure piping in Part 2, Section 5.3.1.

LPG is piped around the refineries in pressure piping. The pipes mainly contain liquid, but there are some vapour return lines. It was considered that probably if a large pipe were to fail, there would be a vapour plume, the plume would find a source of ignition and would burn back to the pipe and there form a burning jet. In burning back there would be the possibility of semi-confined vapour explosions. If on a 25 cm diameter LPG pipe the fluid burned as a jet, the latter could be over 50 m long, while if, due to obstruction, it burned rather as a hemisphere, the radius of the latter could be over 10 m.

Various effects of such fires and explosions from LPG pipe failure are reviewed. An LPG sphere should withstand a semi-confined explosion beneath it; a horizontal cylinder

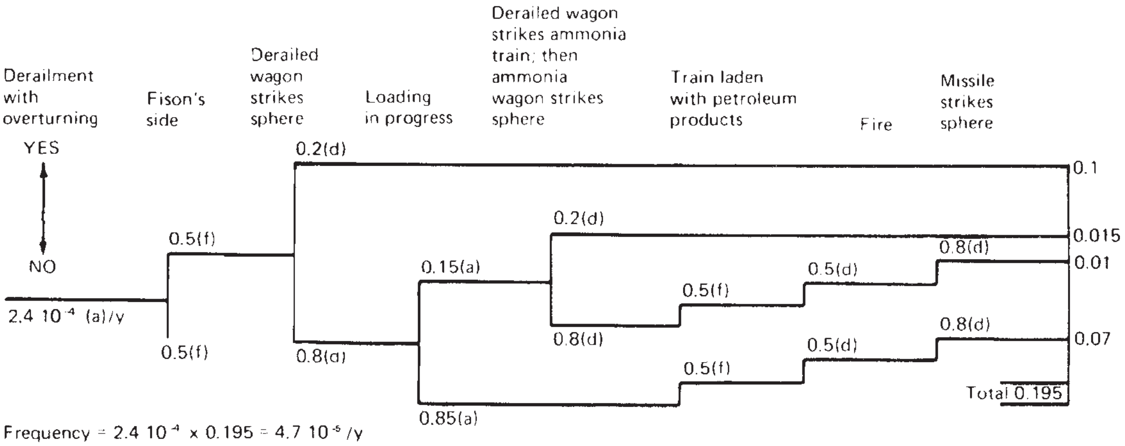

Figure A7.2 *First Canvey Report: event tree for derailment involving overturning of a rail tank car with possible threat to a sphere containing 2000 te of anhydrous ammonia (Health and Safety Executive, 1978b) (Courtesy of HM Stationery Office)*

could be lifted up some tens of centimetres. The principal hazard foreseen, however, is burn back under an LPG storage sphere.

Three cases are treated: (1) failure of a pipe, (2) failure of a pump and (3) failure of a suction line within about 10 m of a storage sphere. The smallest pipe size considered was 15 cm diameter.

It was estimated that the area of a typical refinery is about 3 km^2 and that the length of LPG pipe of diameter $\geq$15 cm in such a refinery is about 3 km, of which about 10% is 25 cm diameter pipe. The total frequency of pipe fracture for this length of pipe was assessed from data in the SRS data bank as 5×10^{-4}/y. For a pipe to affect the storage it must be sufficiently near. The hazard ranges of 15 and 25 cm diameter pipe were taken as 150 and 500 m, respectively. The width of a plume would be of the order of 20°, so that the possibility of the plume lying in any particular direction is 5%. Then the frequencies of involvement of an LPG storage vessel due to pipe failures are

Frequency for 15 cm pipe
$$= 2 \times 10^{-2} \times 5 \times 10^{-3} \times 5 \times 10^{-2} = 5 \times 10^{-6}/\mathrm{y}$$

Frequency for 25 cm pipe
$$= 1 \times 0^{-1} \times 2 \times 10^{-1} \times 5 \times 10^{-3} \times 5 \times 10^{-2} = 5 \times 10^{-6}/\mathrm{y}$$

Total frequency for all large pipes $= 10^{-5}$/y.

The number of LPG pumps in a typical refinery was estimated at about 20. The frequency of catastrophic rupture of such pumps was assessed from data in the SRS data bank as 10^{-4}/y. As before, the probability of the plume in any particular direction is 5%. Then the frequency of involvement of an LPG storage vessel due to a pump rupture is

$$\text{Frequency for pumps} = 20 \times 10^{-4} \times 5 \times 10^{-2} = 10^{-4}/\mathrm{y}$$

In addition, there is the possibility that if the pumps are close together (<20 m spacing), a fire at one pump would involve other pumps and would create a large fire regardless of plume direction. Then the frequency for this event is 2×10^{-3}/y.

The proportion of 25 cm diameter LPG pipe within 10 m of a storage vessel was estimated as about 10%. Then the frequency of involvement of an LPG storage vessel due to failure of such pipe is

Frequency for 25 cm pipe beneath vessels
$$= 10^{-1} \times 10^{-6} \times 5 \times 10^{-3} = 5 \times 10^{-5}/\mathrm{y}$$

Thus the frequency of failure of an LPG vessel due to failure of a large LPG pipe or a pump is 1.6×10^{-4}/y. If interaction between pumps can occur as described above, this figure rises to 2.1×10^{-3}/y.

The report also discusses the failure of the pipes that carry LNG from the jetty head to the storage tanks in Part 2, Section 6.5.2.

The frequency of failure of these pipes was assessed as 10^{-4}–10^{-3}/y. The lower rate is more likely during actual transfer pumping and the higher rate during warm-up and cool-down when the pumps are not in use.

A7.5.3 Failure of pipelines

Failure of a pipeline is considered as a possible initiating event for LNG and LPG. The report discusses failure of pipelines in Part 2, Section 15.

There are four methane pipelines leaving the British Gas terminal. One of these is a 35 cm diameter line passing close to the built-up area. A serious failure of this line would lead to a large release of methane, but the gas would be highly buoyant and would undergo turbulent mixing with air, so that there is no chance of the formation of a large vapour cloud heavier than air.

The frequency of a serious failure of the 35 cm pipeline in the built-up area was estimated as not greater than 10^{-4}/y.

There is a liquid butane pipeline from the British Gas terminal to a point near the Shell refinery. The line is 20 cm diameter for 4 km leaving the terminal and then reduces to 15 cm diameter. The line is not used, but contains some 585 t of liquid butane at a pressure of 4–6 atm. A serious failure of this line could give an initial liquid release rate of 20–30 t/min. If the pressure were sustained by flashing off of propane some 50–100 t could be released in a few minutes. Unless there is a limit on the amount of propane or other volatile component present, the flashing off of the discharging mixture could form a vapour cloud.

The frequency of a serious failure was estimated from data for similar pipelines in the SRS data bank as 3×10^{-4}/km y. The distance travelled by the pipeline through populated terrain is 1.5 km. Thus the frequency of a serious failure causing casualties was estimated as 4.5×10^{-4}/y.

A7.5.4 Generation of and rupture by missiles

Rupture by a missile is considered as a possible initiating event for releases of LPG, ammonia and hydrogen fluoride. The report discusses the generation of missiles in Appendix 5 and the penetration capability of missiles in Appendix 6.

Some scenarios considered are shown in Table A7.5.

The frequency of a large fire in an oil refinery is, for the United States of America, 0.2/y obtained from API data and, for the United Kingdom, 0.25/y obtained from FRS data. The API figures indicate that the proportion of these fires that are very large is about one-third. Thus the frequency of a very large fire in a refinery was taken as 0.1/y.

The proportion of such very large fires that involves explosion was estimated from IRI data as 0.5. The proportion of such explosions that generate missiles was estimated as 0.1.

The frequency of a very large fire that involves an explosion and generates missiles was thus estimated as 5×10^{-3} y.

It was estimated also that on average such a missile-generating explosion generates some half-dozen missiles.

The frequency of disintegration of the rotor of a rotating machine was estimated as 5×10^{-4}/y from data in the SRS data bank.

The report gives in Appendix 6 methods for the estimation of the probability of a missile landing in a given area at a known distance from the source and methods for determining whether the missile will penetrate a vessel.

Missiles particularly considered are fragments from process plant and gas cylinders. With regard to the former a case is quoted in the United Kingdom in which a fractured vessel produced at least seven missiles of 1 t capacity. Reference is also made to the explosion at Whiting, Indiana, where an exploding hydroformer generated some tens of missiles, one of 60 t, with a velocity of 600 ft/s.

Various empirical formulae for penetration by missiles are given. There is considerable variation in the results obtained from these formulae. When used to determine the penetration thickness for a missile with a velocity of 300 ft/s, the penetration thicknesses given by the formulae ranged from 0.25 to 2.75 in. One reason for the variation is that some of the formulae are applicable to clamped flat plates rather than spherical or cylindrical vessels.

It is concluded that

(1) LPG spheres in excess of $1\frac{1}{4}$ in. thick will not be penetrated by flying gas cylinders even at velocities of 300 ft/s, which is a pessimistic upper limit;
(2) spheres and cyinders 0.75 in. thick could be penetrated by flying gas cylinders;
(3) process missiles can be considerably larger than a gas cylinder and can impact with substantially greater energy – these could penetrate LPG spheres and cylinders.

The report also discusses missile threat to the LNG tanks in Part 2, Section 6.5.4.

A7.5.5 Crash of and rupture by aircraft

Rupture by aircraft crash is considered a possible initiating event for release of all the hazardous materials. The report discusses aircraft crash and vessel rupture in Appendix 8.

The frequency of a fixed wing aircraft crash at Canvey was assumed to be that for the United Kingdom in general and not that for an area near the airport. Canvey is within the Special Rules Zone of Southend airport, but is neither close to the main runway nor beneath the airspace of an aircraft waiting to land.

The frequency of an aircraft crash was obtained from UK aircraft accident data. Two alternative equations are given for the frequency of an aircraft crash on a target. They are:

Method 1 $$F = A_H F_H + A'_V F_H \qquad \text{[A7.5.1a]}$$

Method 2 $$F = A_H F_H + A_V F_H \qquad \text{[A7.5.1b]}$$

where A_H is the horizontal area of the target, A'_V is the vertical area of the target, A_V is the horizontal projection of the vertical area of target; F the frequency of aircraft crash on the target area; F_H is the frequency of aircraft crash per unit of ground area and F_V is the frequency of aircraft crash per unit of vertical area.

In Equation A7.5.1a the value of A'_V was calculated assuming that the impact angle is 15°. In Equation A7.5.1b the value of F_V was calculated from data on the frequency with which aircraft crash into the National Grid system. The latter frequency was taken as 0.1/y.

Results obtained for the frequency of crashes of aircraft of all types on the total target area at Canvey for each type of hazard were identical by both methods except that, for the refrigerated LPG at British Gas, Method 1 gave

Table A7.5 *First Canvey Report: some potential missile accidents at Canvey (after Health and Safety Executive, 1978b)*

Site	*Installation*	*Missile*
Shell	LPG vessel	Missile from storage area
Mobil (including extension)	LPG vessel	Missile from process area
Fisons	Ammonia sphere	Missile from rotating machine
Shell	Hydrogen fluoride plant	Missile from neighbouring plant
Mobil (extension)	Hydrogen fluoride plant	Missile from neighbouring plant

Table A7.6 First Canvey Report: some potential aircraft crash accidents at Canvey (after Health and Safety Executive, 1978b)

Site	*Installation*	*Frequency of impact* (impacts/y)
Shell, Mobil, UR, Occidental	LPG	1×10^{-6}
British Gas	Methane	1×10^{-6}
Calor Gas	LPG	2×10^{-6}
London and Coastal Wharves	Oil	7×10^{-6}
Fisons	Ammonia	1×10^{-7}
Shell	Ammonia	1×10^{-7}
Shell, Mobil, UR, Occidental	Process area	2×10^{-5}

a frequency of impact of 6×10^{-7}/y and Method 2 one of 4×10^{-7}/y. Other results were as given in Table A7.6.

The frequency of a helicopter crash was also considered. Helicopters are used to survey pipelines in the area. It was assumed that data on the frequency of helicopter crashes obtained from NTSB publications are applicable to these helicopters. The frequency of crash obtained from these data is 3×10^{-7}/km flown. In such crashes descent is almost vertical.

Frequencies of crash estimated were 2.4×10^{-5}/y, 1.4×10^{-5}/y and 3.6×10^{-6}/y for the Occidental, Shell and Texaco sites. These are not, however, the frequencies of impact on vulnerable targets. These latter frequencies should be very much less, provided the helicopter routes are chosen to avoid such targets.

Helicopters are used by British Gas to survey its gas pipelines. There are about 26 inspection flights per year. The pilots are instructed to avoid flying over industrial complexes and to skirt such locations by about 500 yd.

A7.5.6 Ship collision and other accidents

Ship collision is considered as a possible initiating event for release of LNG, LPG and ammonia. The report discusses ship collision in Appendices 11 and 23.

Ship collision may occur while the ship is at sea, is stationary in mid-channel or is moored at a jetty. At the time of the survey the Port of London Authority (PLA) had just imposed on ships a new speed restriction of 8 knot.

Data on the frequency of ship collisions were obtained from the PLA. These data show that over the 12-year period 1965–76, there were within the scheduled area 592,250 harbour movements and 121 accidents, of which 91 were classed as minor. Thus this gives for collisions of at least moderate severity a frequency of 0.5×10^{-4}/harbour movement.

Other PLA data were analysed to obtain the frequencies of berthing contact, grounding and fire. Thus the frequencies for collision and for these other accidents are

Frequency of ship–ship collision (moderate severity) $= 0.5 \times 10^{-4}$/harbour movement

Frequency of berthing contact $= 1.5 \times 10^{-4}$/harbour movement

Frequency of grounding $= 0.3 \times 10^{-4}$/harbour movement

Frequency of fire $= 0.5 \times 10^{-4}$/harbour movement

Further PLA data were analysed to obtain the frequency of ship–ship collision for ships in transit in the estuary. Thus the frequency of collision in transit is

Frequency of ship–ship collision (moderate severity) in transit $= 2.3 \times 10^{-5}$/movement

The vulnerability of ships to collision damage varies. The LNG carriers are double-hulled ships, whereas the LPG and ammonia carriers were not considered as of comparable strength. The former have much greater cargo protection.

An investigation of the resistance of ships to impact was carried out in 1959 by Minorsky, who correlated his results in terms of the critical impact speed vs the loaded displacement of the striking ship, and the Minorsky curve method is widely used as a means of assessing impact resistance of ships.

For a typical LPG carrier, data on the relation of the critical impact speed vs loaded displacement of the striking ship were obtained from Lloyds Register. These data were interpreted as meaning that a striking ship with a loaded displacement of about 4000 t (2000 GRT) could penetrate an LPG carrier and cause spillage if there is no speed restriction, but that a loaded displacement of about 15,000 t (7500 GRT) would be necessary if the speed of the striking ship is limited to 8 knot.

Data for another typical LPG carrier were obtained from Norsk Veritas. These data differ from the Lloyds data and indicate that this is an area of uncertainty.

The frequencies of spillage for an ammonia carrier, which in this context is broadly similar to an LPG carrier, were estimated by using the historical data in conjunction with the following assumed probabilities:

Probability of spillage from ship–ship collision $= 0.2$

Probability of spillage from berthing contact $= 0.1$

Probability of spillage from grounding $= 0.2$

Thus for an ammonia carrier the frequencies of spillage due to harbour movements are

Frequency of spillage due to ship–ship collision $= 1 \times 10^{-5}$/harbour movement

Frequency of spillage due to berthing contact $= 1.5 \times 10^{-5}$/harbour movement

Frequency of spillage due to grounding $= 0.6 \times 10^{-5}$/harbour movement

Total frequency of spillage due to harbour movements $= 3.1 \times 10^{-5}$/harbour movement

An alternative calculation of the frequency of spillage due to harbour movement based on world data gave a value of 1.45×10^{-5}/harbour movement.

It is concluded that for an ammonia carrier a reasonable estimate of frequency of spillage due to harbour movements is unlikely to exceed.

Frequency of spillage due to harbour movements $= 2 \times 10^{-5}$/harbour movement

but that this estimate might be significantly reduced if more information were available on cargo protection.

The frequency of spillage for an ammonia carrier due to collision in transit in the estuary was estimated using an assumed probability of spillage due to ship–ship collision of 0.2. Thus for an ammonia carrier frequency of spillage in transit is unlikely to exceed

Frequency of spillage due to ship–ship collision in transit $= 5 \times 10^{-6}$/movement

This estimate might be significantly reduced if more information were available on cargo protection.

The frequency of spillage for an LPG carrier was taken as similar to that for an ammonia carrier. Thus for an LPG carrier the frequency of spillage is unlikely to exceed

Frequency of spillage $= 2 \times 10^{-5}$/movement

Again this estimate might be significantly reduced given more information on cargo protection.

For an LNG carrier, the situation is different because the vessel is double-hulled. This case was the subject of a special study. From this study a relation was obtained for an LNG carrier between the critical impact speed and the loaded displacement of the striking ship. This relation for an LNG carrier differs considerably from that for an LPG carrier, since the former, being double-hulled, has much greater protection. The relation shows that for an LNG ship stationary in mid-channel a striking ship with a loaded displacement of 100,000 t (50,000 GRT) would need to have a speed of 9 knot to effect penetration at a 90° impact angle, and that for an LNG ship moored at a jetting striking ships with loaded displacements of 100,000 t (50,000 GRT) and 20,000 t (10,000 GRT) would need to have speeds of 7 and 13.5 knot, respectively, to effect penetration at a 45° impact angle.

It was assumed, therefore, that only ships with a loaded displacement greater than about 20,000 t (10,000 GRT) have the potential to cause a spillage from an LNG carrier. This does not include allowance for the new PLA speed restrictions.

It was also concluded that for an LNG carrier spillage due to berthing contact could be disregarded.

The frequency of spillage for an LNG carrier was estimated from the historical data in conjunction with the following assumed probabilities:

Probability of striking ship $>$ 20,000 t (10,000 GRT) $= 0.1$

Probability of strike in vulnerable section $= 0.5$

Then for an LNG carrier the frequency of spillage is

Frequency of spillage $= 2.5 \times 10^{-6}$/movement

This assessment is based on only four incidents over the 12-year period.

An alternative calculation of the frequency of spillage for LNG carriers based on world data gave a value of 1×10^{-6}/movement.

It is concluded that for an LNG carrier a reasonable estimate for frequency of spillage is

Frequency of spillage $= 2 \times 10^{-6}$/movement

A7.5.7 Flow of a large release of oil

A large release of oil from storage and flow of this oil towards housing is one of the hazard situations considered. The report discusses the methods of calculating the flow of a large release of oil from the catastrophic failure of a storage tank in Appendix 16.

Equations are given for the flow of a slumping fluid derived from those of van Ulden (1974) assuming that his constants c and A have the value of unity. It is assumed that the liquid is initially held in a vertical cylindrical source. The equations are

$$r = [r_s^2 + 2t(gV_s/\pi)^{1/2}]^{1/2} \qquad \text{[A7.5.2]}$$

$$h_f = \frac{V_s}{\pi r^2} \qquad \text{[A7.5.3]}$$

$$u_f = (gh_f)^{1/2} \qquad \text{[A7.5.4]}$$

where g is the acceleration due to gravity (m/s^2); h_f the slumped liquid depth (m); r the radius of the flooded zone (m); r_s the radius of the source cylinder (m); t the time after initiation of slumping (s); u_f the slumped liquid velocity (m/s); and V_s the volume of the source cylinder (m^3).

A7.5.8 Temperature of the wall of an LNG tank exposed to an LNG fire in an adjacent bund

The rupture of an LNG tank due to an LNG fire in an adjacent bund is one of the hazard situations considered. The report discusses the effect of an LNG fire in an adjacent bund on the temperature of an LNG tank wall in Appendix 13.

The LNG tanks considered are cylindrical in shape and are 30 m diameter and 20 m high. They stand in a bund of 60 m diameter.

The temperature of the tank wall is determined by the heat balance on the wall. It was assumed that the wall gains heat by radiation and loses it both by radiation and by convection.

For the heat gained by the tank wall use was made of the experimental work of L.E. Brown, Wesson and Welker (1974b). It was assumed that the heat flux from the fire is 44,000 BTU/h ft^2, which is the maximum average value obtained by these workers for liquid pools of up to 30 m diameter. This value is considered reasonably conservative for bund fires with an effective diameter up to 60 m. The flame height calculated from the empirical formula given by these workers is 75 m. The fraction of the radiated heat received by the tank was then calculated by dividing both the flame and tank surfaces into smaller subsurfaces and determining view factors. The total radiated heat Q_i received by the tank wall was calculated as 3.11×10^7 W.

For the heat loss by the tank wall the equation used for radiation is

$$Q_r = \varepsilon\sigma(A_V + A_H)\theta_T^4 \qquad \text{[A7.5.5]}$$

where A_H is the area of the tank roof (m^2); A_V the exposed area of the tank vertical sides (m^2); Q_r the heat loss by radiation (W); ε the emissivity of the tank wall; θ_T the absolute temperature of the tank wall (K); and σ the Stefan–Boltzmann constant (W/m^2 K^4). The equation used for convection is

$$Q_n = (1.76A_V + 2.25A_H)(\Delta\theta)^{1.25} \qquad \text{[A7.5.6]}$$

with

$$\Delta\theta = \theta_T - \theta_A \qquad \text{[A7.5.7]}$$

where Q_n is the heat loss by convection (W); $\Delta\theta$ the temperature difference between the tank wall and ambient air (°C); and θ_A the absolute temperature of ambient air (K).

The areas A_V and A_H of tank surface are the exposed areas and since the whole of the roof but only part of the walls is exposed, A_H is based on the whole of the roof surface, but A_V is based on only part of the vertical wall surface.

The equilibrium tank wall temperature θ_T was found to be 647 K assuming an emissivity ε of 0.5 and did not differ by more than 40°C even assuming an emissivity of unity. The tank wall temperature is therefore relatively insensitive to estimates of the emissivity.

The heat loss by radiation is over three times greater than that lost by convection at a tank wall temperature of 650 K.

The time for the temperature of the tank wall to reach steady state was calculated from the unsteady-state equation

$$mc_p \frac{d\theta_T}{dt} = Q_i - (Q_n + Q_r) \qquad [A7.5.8]$$

where c_p is the specific heat of the tank wall (J/kg °C); m the mass of the exposed tank wall (kg); and t the time (s).

The thermal capacity mc_v of the exposed tank wall was taken to include half that of the associated perlite insulation.

Equation A7.5.8 is non-linear and is solved numerically. It was calculated that the time for the temperature of the wall to reach 95% of its equilibrium value is about 42 min.

A7.5.9 Evaporation of LNG and ammonia on water

The spillage and evaporation of LNG and ammonia on water is one of the hazard situations considered. The report discusses the evaporation rates of LNG and of ammonia spilled on water in Part 2, Sections 6 and 7, respectively.

It is stated that for a rapid spill of LNG on water the evaporation time is short and a puff dispersion model is applicable. But for a continuous spill the evaporation rate rapidly reaches the spill rate and this evaporation rate then determines the pool diameter reached. The evaporation rate has been determined by a number of investigators as about 0.19 kg/m^{2}s, which corresponds to a liquid regression rate of 4.7×10^{-4} m/s.

Similarly, it is stated that for a rapid spill of ammonia on water the evaporation time is short and that all the ammonia will evaporate, except for about 20% which dissolves in the water.

A7.5.10 Dispersion of an LNG vapour cloud

The dispersion of an LNG vapour cloud is one of the hazard situations considered. The report discusses the dispersion of an LNG vapour cloud in Appendix 9.

A cloud of cold LNG vapour tends to behave as a heavy gas cloud. The following elements are identified as particularly important in describing the behaviour of such a cloud: (1) specification of the source, (2) description of the gravitational slumping, (3) description of the air entrainment, and (4) description of the thermal effects.

The model of the source that is assumed can have a significant effect on the results. The release may be instantaneous or continuous. The source may be of fixed size or of increasing size, as with LNG spilled on to water. The process of release may or may not involve the entrainment of large amounts of air.

The differences between the various models currently available for the gravitational slumping phase are discussed and it is suggested that these may be due in large part to the extent to which air entrainment is taken into account. The model of R.A. Cox and Roe (1977) is instanced as representative of the new generation of models that take into account air entrainment.

Information is presented on the distance travelled by an LNG cloud before it is diluted to the lower flammability limit, that is, the hazard range. Experimental work described includes

Source	*Release*	*Weather conditions*
API	1/3–10 t on sea	Stable (Pasquill stability category E)
Shell	5–50 t on sea	Relatively stable
AGA	Spillages in bunds giving vapour releases up to 25 kg/s	

Theoretical work mentioned is that of Cox and Roe of Cremer and Warner.

Hazard ranges derived from these sources are shown in Figures A7.3(a) and A7.3(b) for continuous and instantaneous releases, respectively. Models for both instantaneous and continuous releases may be derived from the experimental work described by estimating values of the dispersion coefficients in the Pasquill–Gifford model for an instantaneous release and assuming that these coefficients are the same for a continuous release. This is the basis for the curves shown in Figures A7.3(a) and A7.3(b), except for the API 2.5% case, which is based on the work of Feldbauer *et al.* (1972). The lower flammability limit of methane is approximately 5% and most of the data shown in the figures are for this concentration, but some data are shown for a concentration of 2.5%, which allows for localized short-term concentrations up to the lower flammability limit (LFL).

The weather conditions on which the graphs are based are neutral conditions (Pasquill stability category D) or stable conditions (Pasquill stability category E). For less stable conditions the hazard range is less or at worst no greater. For Canvey more stable conditions (Pasquill stability categories F and G) were not considered, because Canvey Island is an urban site and it has been shown that over such an area the dispersion of a plume in very stable conditions is unlikely to produce airborne concentrations greater than those obtained over open country for neutral and stable conditions (Pasquill stability categories D and E).

The quantities of LNG involved in the releases in Figures A7.3(a) and A7.3(b) are relatively small. The warning is given, therefore, that the use of these graphs for a continuous release of, say, 10 t/s or an instantaneous release of, say, 1000 t involves scaling up by two orders of magnitude with all the uncertainties attendant on such a procedure.

Mention is also made of methods for the prediction of LNG vapour dispersion based on wind tunnel simulations, but it is concluded that the results obtained are subject to too great a range of uncertainty to be useful.

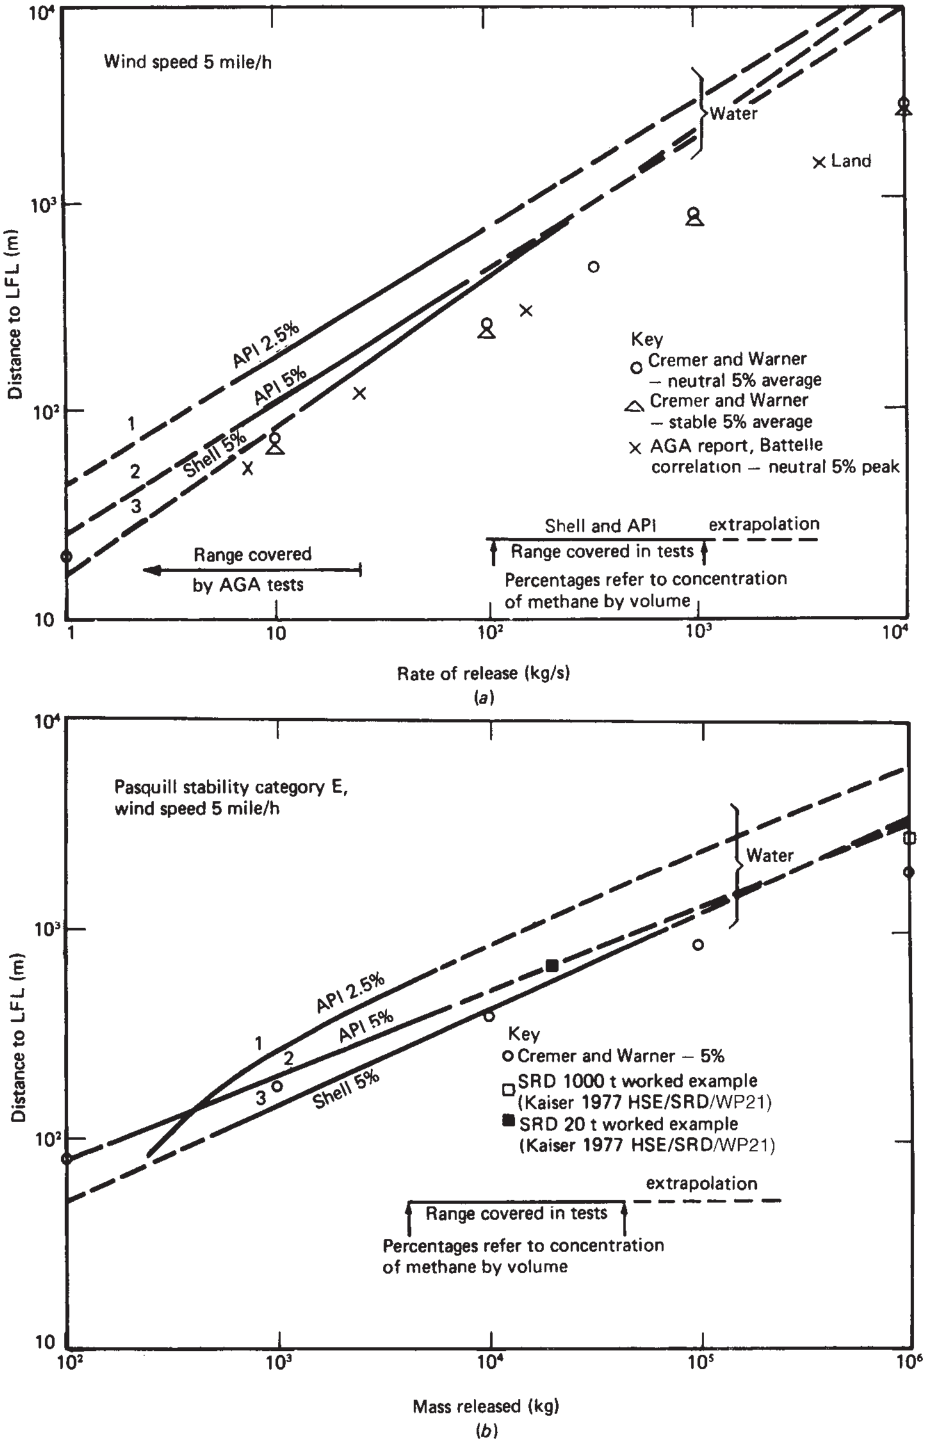

Figure A7.3 *First Canvey Report: hazard ranges for releases of LNG vapour in neutral and stable weather conditions (Health and Safety Executive, 1978b): (a) continuous releases – curve 1 API tests model, 2.5% average, stable condition; curve 2 API tests model, 5% average, stable condition; curve 3 Shell tests model, 5% average, stable condition; (b) instantaneous releases – curve 1 API tests model, 2.5% average, stable condition (Feldbauer et al., 1972); curve 2 API tests model, 5% average, stable condition; curve 3 Shell tests model, 5% average, stable condition (Courtesy of HM Stationery Office)*

For the purpose of the hazard assessment, however, it was necessary to make estimates of the possible range of vapour clouds from marine spillages of LNG. The distances obtained by scaling up the small spillage data were considered too conservative and the following estimates were used:

Spillage (t)	*Maximim range to LFL* (km)	
	average	peak
10	0.54	0.7
100	1.4	1.8
1,000	3.8	5.2
10,000	10	10

The average concentration corresponds to 5% and the peak concentration to 2.5% that, as explained above, allows for localized short-term concentrations of double the latter value.

A7.5.11 Unconfined vapour cloud fire and explosion

An unconfined vapour cloud fire or explosion is considered as one of the possible accidents that could be the cause of fatalities. The report discusses unconfined vapour cloud fire and explosion in Part 2, Sections 4 and 6, and in Appendix 1. The treatment given of unconfined vapour cloud fire and explosion is broadly as follows.

Two standard vapour clouds are considered. The first contains 100 t and the second 1000 t of hydrocarbons.

Ignition of an unconfined vapour cloud may result in fire or in explosion. The fire and explosion characteristics are given for the two standard vapour clouds just mentioned.

Both complex explosion models and a modified TNT equivalent model were used to estimate the damage effects from an unconfined vapour cloud explosion.

Only the modified TNT equivalent model is described here. This is similar to the usual model, except that the relation between peak overpressure and scaled distance is modified to allow for the fact that the explosion is that of a vapour cloud rather than that of TNT.

For the energy of explosion an equivalence factor α is defined such that the explosion of a flammable gas cloud of W t of hydrocarbons with a combustion energy release H kcal produces the same damage effects as a TNT explosion with an energy release of αH kcal. The value of α used is 0.1. In other words, it is assumed that 10% of the hydrocarbons takes part in the explosion.

For the peak overpressure Δp_m and the peak dynamic pressure q_m at radial distance r and scaled distance $r/H^{1/3}$ the relations used are shown in Figure A7.4. Separate curves of Δp_m are given for TNT explosion, for hydrocarbon detonation and for hydrocarbon deflagration with a deflagration velocity of 170 m/s. Figure A7.4 is for spherical symmetry. Results for explosions with hemispherical symmetry may be obtained by doubling the energy release.

Thus, for example, for a hydrocarbon vapour cloud explosion with an energy release αH where

$$H = 11.1 \times 10^6 \text{ W kcal}$$

$$\alpha = 0.1$$

Figure A7.4 gives for hemispherical symmetry

Δp_m		r (m)
(psi)	(bar)	
3	0.2	$69.1\,W^{1/3}$
1	0.07	$196\,W^{1/3}$

For the two standard hydrocarbon vapour clouds considered the fire and explosion characteristics used are shown in Section A of Table A7.7. The ranges quoted for dilution to the LFL are for weather conditions of Pasquill stability category D. The overpressures quoted apply only to the cases where an explosion occurs.

The foregoing indicates for the standard hydrocarbon vapour clouds considered the estimated hazard ranges of fire and of explosion, that is, overpressure effects, where these effects occur.

The probability of ignition of a vapour cloud was taken as 0.1 or 1, depending on whether ignition was regarded as improbable or probable, taking into account the ignition sources between the point of release and the population group.

The probability of deflagration with overpressure in a vapour cloud, given ignition, was taken as 1 for large clouds (>100 t) of flammable gas, as 0.1 for smaller clouds of flammable gas other than methane, and as 0.01 for smaller clouds of methane, reflecting the significantly lower probability of explosion of a cloud of methane compared with one of other hydrocarbons.

For the 1000 t hydrocarbon vapour cloud it was assumed that the whole cloud burns with a fireball approximately equal in volume to that of the cloud formed by the stoichiometric gas–air mixture and further that, where overpressure occurs, the proportion of hydrocarbon taking part in the explosion is 10%.

If the vapour cloud is ignited *in situ*, the hazard to the public for the situations considered is that of explosion. In accordance with the data given in Table A7.7 it was assumed that the overpressure at the site boundary would not exceed 0.2 atm.

An incidence of 1½% is quoted for casualties among the population in the areas subject to an overpressure between 0.2 and 0.05 atm, which is approximately the level of overpressure corresponding to the Explosives Acts recommendations.

If the vapour cloud drifts and is ignited off-site, the hazards to the public for the situations considered are those of fireball and explosion. For this case, where the cloud is ignited and burns fully over the populated region, it was assumed that the whole population engulfed in the fireball is killed. For the 1000 t hydrocarbon cloud burning fully over a populated region with the average population density of the area, the number of fatalities would be 2000. In addition, it was assumed that in this situation there would be 100 further fatalities and 2000 serious injuries caused by explosion effects out to a radius where the overpressure is 0.075 atm.

The more probable case, however, is ignition when the leading edge of the cloud is just beginning to encroach on the populated region.

It was assumed that if for ignition of the cloud on the edge of the populated region, the number of casualties is N and

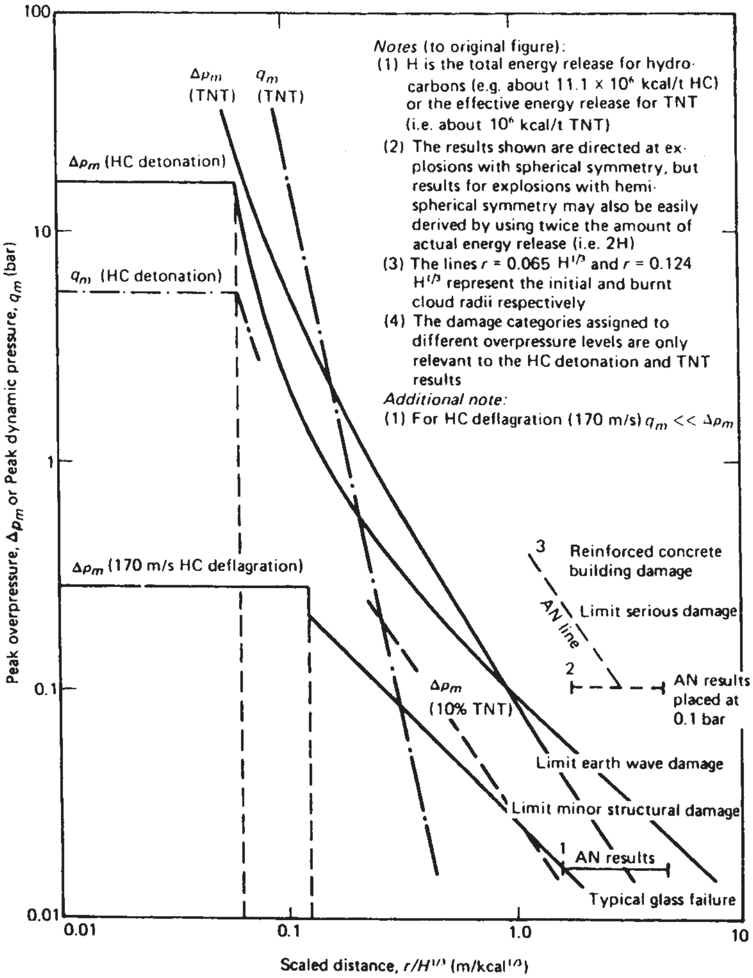

Figure A7.4 *First Canvey Report: peak overpressure and peak dynamic pressure vs scaled distance for various types of explosion (Health and Safety Executive, 1978b) (Courtesy of HM Stationery Office)*

the probability is P, then for ignition right over the populated region the number of casualties is $4N$ and the probability is $0.25P$. It was also assumed that the range of probabilities may be represented by a linear probability distribution function. The corresponding relationships between the numbers of casualties and the probability of these numbers are given in Section B of Table A7.7. The number of fatalities is taken as half the number of casualties.

For a hydrocarbon vapour cloud greater than 1000 t it was assumed that the number of casualties would vary with the mass of vapour according to a 2/3 power law.

The report discusses unconfined LNG vapour cloud fire and explosion in Part 2, Section 6. The following scenarios are among those considered:

Case 1a Release from storage tank (25 cm diameter hole) – vapour cloud of up to 100 t
1b Release from ship's cargo tank at jetty (25 cm diameter hole) – vapour cloud of 100 t
2 Failure of storage tank – vapour cloud of 200 t
3 Failure of ship's cargo tank – vapour cloud of 1000 t

The fire and explosion characteristics of the vapour clouds for these cases are given in Section C of Table A7.7.

The probability of explosion, that is, overpressure in the vapour cloud, was taken as unity only for the larger clouds. The explosion effects were again calculated assuming that 10% of the hydrocarbons take part in the explosion.

A7.5.12 Ammonium nitrate explosion

An ammonium nitrate (AN) explosion is considered as one of the possible accidents that could be the cause of fatalities. The report discusses ammonium nitrate explosions in Part 2, Sections 4.1.2 and 11, and in Appendix 1.

The ammonium nitrate considered is the storage of 92.5% aqueous solution in two tanks of 5000 and 2000 t capacity, respectively. A large spillage from this storage would probably give a mushy heap of ammonium nitrate

Table A7.7 *First Canvey Report: vapour cloud fire, explosion and casualty characteristics used (after Health and Safety Executive, 1978b)*

A Fire an explosion characteristics of hydrocarbon vapour clouds

Mass of hydrocarbon (t)	*Diameter of stoichiometric hemispherical cloud* (m)		*Range of stated overpressure* (km)		*Range for dilution to lower flammability limit* (km)
	Before burning	*After burning*	*0.2 atm* (3 psi)	*0.07 atm* (1 psi)	
100	169	323	0.321	0.910	2
1000	364	696	0.691	1.960	5

B Casualty characteristics of a 1000 t hydrocarbon vapour cloud fire and explosion

Upper limit				
No. of casualty	0	1500	3000	4500
No. of fatalities	0	750	1500	2250
Cumulative probability	1	0.64	0.35	0.14

C Fire and explosion characteristics of an LNG vapour cloud

Case	*Mass of hydrocarbon* (t)	*Burnt cloud radius* (m)	*Radius of stated overpressure* (m)		*Probability of overpressure*
			0.2 atm (3 psi)	*0.07 atm* (1 psi)	
1	100	162	321	910	0.01
2	200	204	404	1147	1
3	1000	348	691	1960	1

crystals near the point of release. An escape of 4500 t of 92.5% solution was considered as the standard case.

If ammonium nitrate is ignited, the result is normally a fire rather than explosion. The latter is likely to occur only if conditions are favourable for transition from a fire to an explosion.

These conditions have been investigated theoretically and experimentally by van Dolah *et al.* (BM 1966 RI 6773) and this work is discussed. It is concluded that the work indicates that transition to explosion would be impossible for quantities of ammonium nitrate of tens of tonnes and probably hundreds of tonnes, but that it might occur at the thousands of tonnes level.

The historical record of ammonium nitrate explosions is reviewed and explosions of prilled ammonium nitrate in transport are quoted, one in rail tank cars at Traskwood, Arkansas, in 1960 and one in road tankers in Queensland in 1972.

The only significant possibility foreseen for the occurrence of an ammonium nitrate explosion was the derailment of a train carrying petroleum products that could cause simultaneously the rupture of an ammonium nitrate tank and a liquid petroleum fire.

The frequency of a derailment and overturning was calculated as follows:

Frequency of derailment of rail tank car $= 1 \times 10^{-6}$/train km

Number of trains with petroleum products $= 3000$/y

Length of track opposite tanks ≈ 300 m

Probability of derailment leading to overturning $= 0.2$

Probability of overturning on tank side of track $= 0.5$

Frequency of derailment and overturning on tank side of track $= 8.5 \times 10^{-5}$/y

In view of the many uncertainties and of the omission of other possible accident modes this latter value was also taken as the frequency of an ammonium nitrate explosion. Thus

Frequency of ammonium nitrate explosion $= 8.5 \times 10^{-5}$/y

The effect of an ammonium nitrate explosion was assessed by reference to the data on such explosions given by M.A. Cook (1958) and shown in Table A7.8.

These results were interpreted as follows. It was assumed that the predominant reaction in the explosion of ammonium nitrate is

$$2NH_4NO_3 = 2N_2 + 4H_2O + O_2$$

for which the heat of reaction is 0.35×10^6 k cal/t. Then using this heat of reaction the values obtained for the group $r/H^{1/3}$ (m/(kcal)$^{1/3}$) corrected for spherical symmetry for the distance for major damage in the four explosions listed lie in the range 1.72–4.8. This spread indicates a lack of agreement with the 1/3 power scaling relation, which is reduced but not eliminated if a 1/2 power scaling relation

Table A7.8 *First Canvey Report: some major ammonium nitrate explosions (after Health and Safety Executive, 1978b)*

Date	*Location*	*Mass of ammonium nitrate* (t)	*Distance for major damage* (m)	*Fatalities*
1918	Morgan, NJ	500	1600	64
1923	Oppau, Germany	4500	7000	1100[a]
1947	Brest, France	3000	5000	21
1947	Texas City, TX	3500	2300	560

[a] This value differs from that given by Commentz *et al.* (1921).

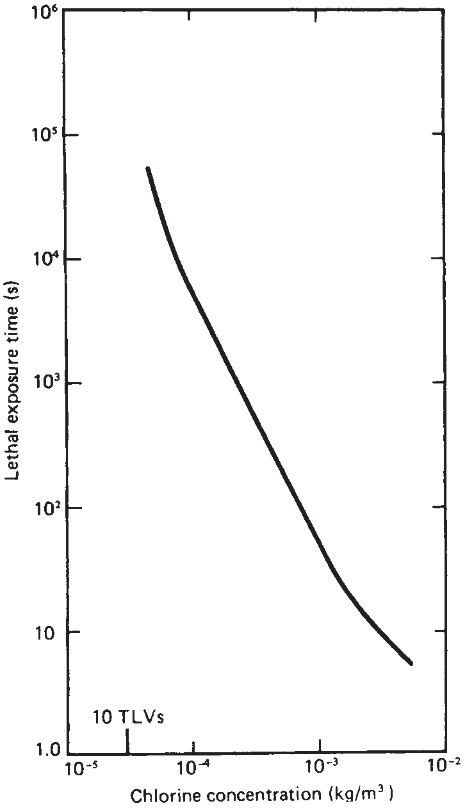

Figure A7.5 *First Canvey Report: lethal exposure time vs concentration for chlorine (Health and Safety Executive, 1978b) (Courtesy of HM Stationery Office)*

is used. The disagreement may be due in part to the relative lack of precision in the term 'serious damage'. If these results are located on the curve for overpressure Δp_m (TNT) in Figure A7.4, then, as shown by the full line (line 1) in this figure, they correspond to an overpressure of 0.02 bar. This is an extremely low overpressure to cause serious damage. In view of this dilemma, it was decided to locate the ammonium nitrate results at an overpressure of 0.1 bar, as shown by the dotted line (line 2) in Figure A7.4, although they then lie above the TNT curve. It is the further dotted line (line 3) which is used to calculate the damage ranges for explosions of 2250 and 4500 t of ammonium nitrate in the report.

A7.5.13 Toxicity of chlorine, ammonia, hydrogen fluoride and lead additives

The toxicity of chlorine, ammonia, hydrogen fluoride and lead additives is considered. The report discusses the toxicity of chlorine in Appendices 3 and 12, that of ammonia in Appendix 15, that of hydrogen fluoride in Appendix 12 and that of lead additives in Appendix 19.

There is considerable uncertainty about the lethal dosages for all these chemicals and it was necessary, therefore, to make approximate estimates.

Chlorine was not one of the chemicals considered in the study to constitute a hazard at Canvey, but its toxicity is discussed in relation to factors that mitigate casualties from a toxic release and in relation to the toxicity of hydrogen fluoride.

For chlorine the relation between the lethal concentration and the time of exposure shown in Figure A7.5 was used. This graph is derived from data given by Dicken (1974, 1975).

For ammonia a probit equation was used

$$\mathrm{Pr} = a + b \ln D \qquad \text{[A7.5.9]}$$

with

$$D = \int_0^t C^{2.75}\,\mathrm{d}t \qquad \text{[A7.5.10]}$$

where C is the concentration (g/m^3); D the dosage ((g/m^3)$^{2.75}$min); Pr the probit; t the time (min); and a, b are constants.

Precise information on the lethal dosage of ammonia is lacking. Two cases were considered. For case A it was assumed that a concentration of 1.75 g/m^3 (2500 ppm) is lethal to 50% of the exposed population in 30 min, while for case B it was assumed that the same concentration is 50% lethal in 60 min. Then the values of the constants are

	a	*b*
Case A	1.14	0.782
B	−7.41	2.205

For hydrogen fluoride it is necessary to take care with the units in which concentration is expressed on account of the high degree of association in the vapour phase. Concentrations are therefore expressed in units of mg/m^3 rather than of ppm.

Precise information on the lethal dosage of hydrogen fluoride is again lacking. Insofar as it is an irritant gas it appears to have effects similar to chlorine at similar concentrations. The toxicity of hydrogen fluoride was therefore assumed for the purpose of the study to be similar to that of chlorine at a similar concentration, where the concentration units are mg/m^3.

In addition, however, hydrogen fluoride in large but sublethal dosages may also have other injurious long-term effects.

The lead additives are the alkyl lead compounds, particularly the methyl and ethyl derivatives.

For lead additives precise information on the lethal dosage is again lacking. The medical evidence is reviewed in some detail. It is concluded that there is a significant probability of fatality at a concentration of 500 mg/m^3 for an exposure of 1 h. It is also considered that total dosage is more important than concentration so that the concentration can be scaled inversely with the exposure time for exposure times in the range 15–60 min.

A7.5.14 Dispersion of ammonia and hydrogen fluoride vapour clouds

The dispersion of anhydrous ammonia and hydrogen fluoride gas clouds is one of the hazard situations considered. The report discusses the dispersion of an ammonia gas cloud in Part 2, Section 7, and in Appendices 4 and 14 and that of a hydrogen fluoride gas cloud in Part 2, Section 5.5, and in Appendix 12.

The dispersion of an anhydrous ammonia cloud depends on whether it is lighter or heavier than air. The following conclusions are reached. If an initial fraction of the ammonia released is in the form of suspended droplets, the cloud may become denser than air as it is diluted. There will be a critical value for the initial fraction of droplets such that if the fraction is below this value the cloud will be less dense than air regardless of the humidity of the air. There will be a second critical value such that if the fraction is above this value the cloud will be more dense than air regardless of the humidity of the air. These two critical values are given, respectively, as 4–8% and 16–20% of the total mass of ammonia. Between these critical values the density of the cloud is determined by the degree of dilution and humidity of the air. High values of the air humidity favour low cloud densities and vice versa, since water in the atmosphere will tend to freeze and so liberate latent heat.

The possible chemical reactions of anhydrous ammonia with the water and the carbon dioxide in the air to give ammonium hydroxide and ammonium bicarbonate and carbonate are also reviewed, but it is concluded that it seems unlikely that any such reaction will be a significant effect, although in foggy or rainy conditions it may convert some ammonia to a less toxic form and so effect some reduction in the hazard.

The historical record of anhydrous ammonia releases is reviewed and those at Blair, Conway, Potchefstroo and Houston are quoted. In all these cases the ammonia cloud appears to have behaved as denser than air.

The emission and dispersion of a release of 1000 t of anhydrous ammonia from pressurized storage at 6°C in weather conditions of Pasquill stability category D and wind speed of 3 m/s were calculated.

For emission it was assumed that the whole mass of 1000 t of ammonia is released virtually instantaneously, that 20% of the ammonia forms vapour and that the remaining 80% forms liquid droplets, so that the whole amount spilled is airborne.

The escaping ammonia will entrain air. There is little information available on this aspect, although the Potchefstroom accident provides some evidence. There some 40 t of ammonia were released and eyewitness accounts stated that 'the *immediate* resulting gas cloud was about 150 m in diameter and nearly 20 m in depth'. This corresponds approximately to an air–ammonia mass ratio of about 10 if all the ammonia was airborne and visible. If it is assumed that in the scenario considered enough dry air is mixed with the ammonia to vaporize all the liquid ammonia, leaving an air–ammonia mixture at the boiling point of ammonia, the corresponding air–ammonia mass ratio is about 20.

The following conditions were taken, therefore, as the source for the dispersion model. The release is 1000 t of anhydrous ammonia. This forms a vapour cloud with an air–ammonia mass ratio of 20 at a temperature of −33°C and with a density of 1.42 kg/m^3. This density is greater than that of air at 20°C by a factor of 1.18 so that the cloud is denser than air. Both the radius and height of the cloud are 167 m.

For dispersion it was assumed that the behaviour of the vapour cloud is described initially by a heavy gas slumping model and then by a neutral gas dispersion model. This follows the approach developed by van Ulden (1974).

For slumping, van Ulden's model is used

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \left(\frac{(\rho_0 - \rho_\mathrm{a})gh}{\rho_0}\right)^{1/2} \qquad [\mathrm{A7.5.11}]$$

with

$$h = V_0/\pi r^2 \qquad [\mathrm{A7.5.12}]$$

and

$$r^2 - r_0^2 = 2\left[\left(\frac{(\rho_0 - \rho_\mathrm{a})gV_0}{\pi\rho_0}\right)t\right]^{1/2} \qquad [\mathrm{A7.5.13}]$$

where g is the acceleration due to gravity; h the height of the cloud; r the radius of the cloud; r_a the initial radius of the cylinder; t the time; V_O the initial volume of the cylinder; ρ_a the density of air; and ρ_o the initial density of the cloud.

The termination of slumping depends in this model on the turbulent energy density and hence on the surface roughness length. For a roughness length z_o of 10 cm the predicted height h at termination of slumping is 0.15 m. For the purposes of this approximate calculation the height h at termination of slumping was taken as 1 m.

The state of the cloud at termination of slumping is then as follows. The radius is 2170 m, the height is 1 m, the density is 1.42 kg/m^3. The time taken is about 12 min and the distance travelled with the wind speed of 3m/s is about 2.6 km.

This model predicts, therefore, that the cloud radius becomes very large and that the cloud travels far downwind. The cloud travel distance is regarded as pessimistic, because it is to be expected that at a height of 1 m the cloud will be slowed down by various obstacles.

For further dispersion the Pasquill–Gifford model for a neutral buoyancy gas was used

$$\chi(x;y;t) = \frac{2Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z} \times \exp\left[-\frac{1}{2}\left(\frac{(x-ut)^2}{\sigma_x^2}+\frac{y^2}{\sigma_y^2}\right)\right] \qquad [A7.5.14]$$

with

$$\sigma_x = \sigma_y \qquad [A7.5.15]$$

where x y and z are the distances in the downwind, crosswind and vertical directions (m); Q^* the mass released instantaneously (kg); t the time (s); u the wind speed (m/s); σ_x, σ_y and σ_z the standard deviations, or dispersion coefficients, in the downwind, crosswind and vertical *(x,y,z)* directions (m); and χ the concentration (kg/m^3). The downwind distance x is measured from the source. At the termination of slumping it was assumed that the cloud has a Gaussian concentration distribution with the 10% edges of the cloud equal to the edges of the slumped cloud. Then at transition

$$r = 2.14\sigma_y \qquad [A7.5.16]$$

$$h = 2.14\sigma_z \qquad [A7.5.17]$$

The maximum concentration on the axis at a downwind distance x occurs when the centre of the cloud is at that point so that

$$x = ut \qquad [A7.5.18]$$

and hence

$$\chi_{\max}(x) = \frac{2Q^*}{(2\pi)^{3/2}\sigma_x\sigma_y\sigma_z} \qquad [A7.5.19]$$

The mean concentration $\chi_{\mathrm{av}}(x)$ along the axis is related to the maximum concentration $\chi_{\max}(x)$ as follows:

$$\chi_{\mathrm{av}}(x) = 0.585\ \chi_{\max}(x) \qquad [A7.5.20]$$

The mean concentrations calculated for the release considered are given in Figure A7.6. Figure A7.6(a) shows the mean concentration as a function of downwind distance and Figure A7.6(b) the mean concentration as a function of exposure time.

The distance at which the ammonia cloud is potentially lethal is obtained from Figure A7.6. If it is assumed that the ammonia is potentially lethal at a concentration of 0.002 kg/m^3 for a period of 30–50 min, the range of potential lethality of the cloud is 5 km from the point at which slumping is terminated. This point is itself 2.6 km from the source.

Cloud behaviour was also investigated for other weather conditions.

The approximate area within which people are at risk from an instantaneous release of 1000 t of anhydrous ammonia in weather conditions of Pasquill stability category D and wind speed of 6 m/s is shown in Figure A7.7.

The model just described is a relatively crude one. Further, more sophisticated models were derived which took into account (1) the heating of the cloud and (2) the entrainment of air during the slumping phase. These models indicated that the overall behaviour of the cloud is not greatly altered by these effects and that the original model gave a sufficient representation for approximate calculations.

The dispersion of a hydrogen fluoride gas cloud also depends on whether it is lighter or heavier than air. Hydrogen fluoride monomer has a molecular weight of 20, which suggests that the gas should be lighter than air. But hydrogen fluoride gas is highly associated, forming in particular the hexamer. Although dissociation takes place as the gas is diluted, the process is endothermic so that cooling occurs. Thus the behaviour of a hydrogen fluoride gas cloud is in some ways analogous to that of an ammonia gas cloud.

The approach adopted was to treat the hydrogen fluoride cloud as denser than air.

A7.5.15 Factors mitigating casualties from a toxic release

Large toxic releases are considered as one of the possible accidents which could be the cause of fatalities. Theoretical estimates of large toxic releases tend, however, to give rather large numbers of fatalities and to appear pessimistic compared with the historical record. Consideration was therefore given to the factors mitigating casualties from a toxic release.

The report discusses mitigating factors for a toxic release in Appendix 3.

The historical record of chlorine releases is reviewed. The releases listed by Simmons, Erdmann and Naft (1974) are quoted, as are the releases at Zarnesti, Roumania, in 1939 and at Baton Rouge, Louisiana, in 1976.

The following features are adduced as factors that may mitigate the effects of a chlorine release:

(1) low population density downwind of the source, particularly within the first kilometre or so;
(2) favourable weather conditions;
(3) low rate of release;
(4) escape;
(5) shelter.

It is possible to make a quantitative estimate of the effect of these factors. There are other factors such as

(6) topography

which may also be important, but which in the present state of knowledge cannot be readily assessed.

A series of calculations was done for a 20 t chlorine release over periods of 6 s, 10 min and 6h in weather conditions of Pasquill stability category D and with a wind speed of 5 m/s.

The calculations were based on the Pasquill model for short continuous releases, as given in Equation 15.16.31,

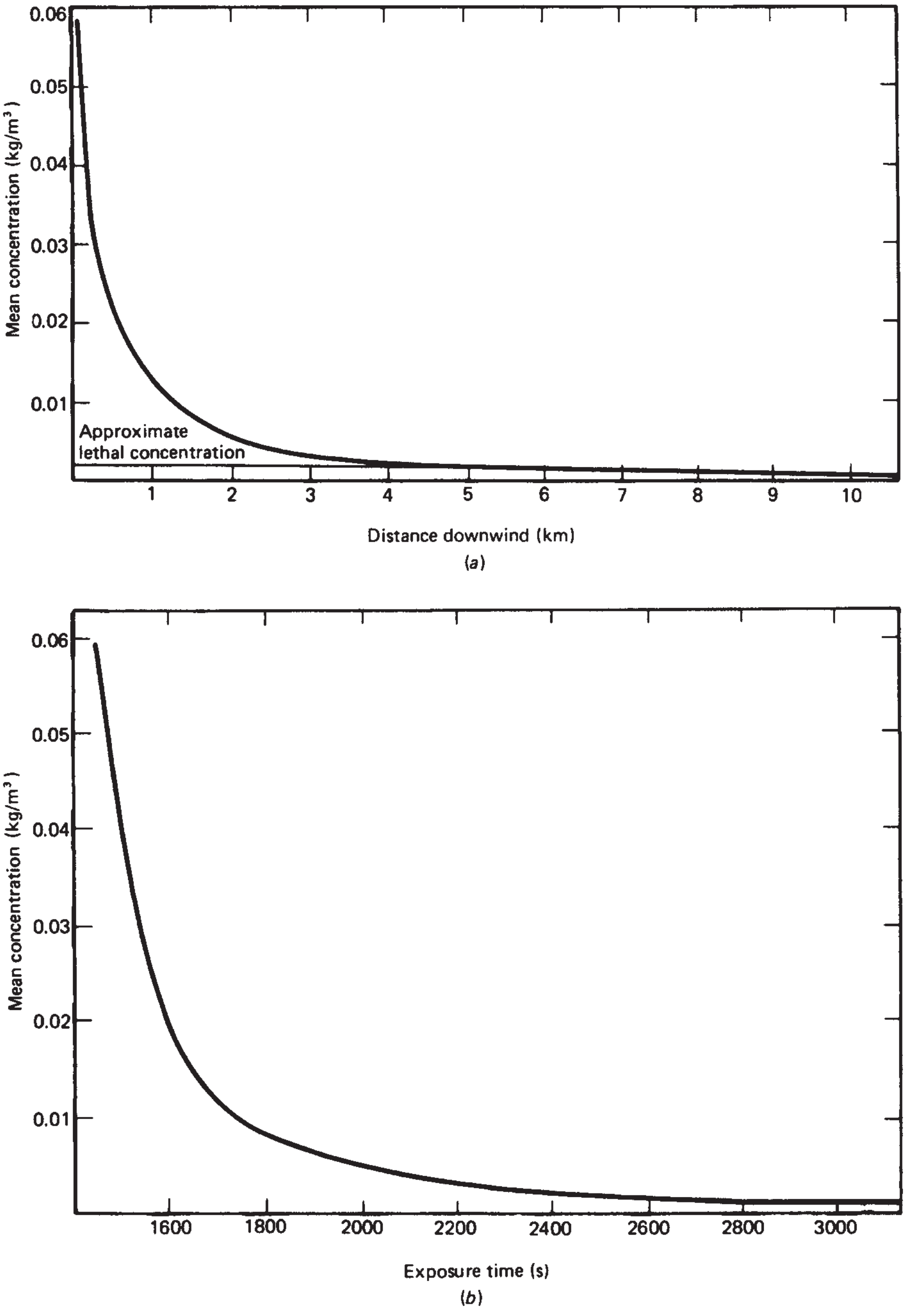

Figure A7.6 *First Canvey Report: mean concentration vs distance and exposure time for an instantaneous release of WOO te of anhydrous ammonia (Health and Safety Executive, 1978b): (a) mean concentration vs distance and (b) mean concentration vs exposure time (Courtesy of HM Stationery Office)*

using the graphs presented by Bryant (1964 UKAEA AHSB(RP) R42 Figure 4). This model may be adapted to the determination of the time of passage and the dosage from a nearly instantaneous release, as follows. The time of passage for an instantaneous release is obtained as the times between the concentration rising to, and subsequently falling back to, one-tenth of its maximum value. This time of passage is corrected for a nearly instantaneous release

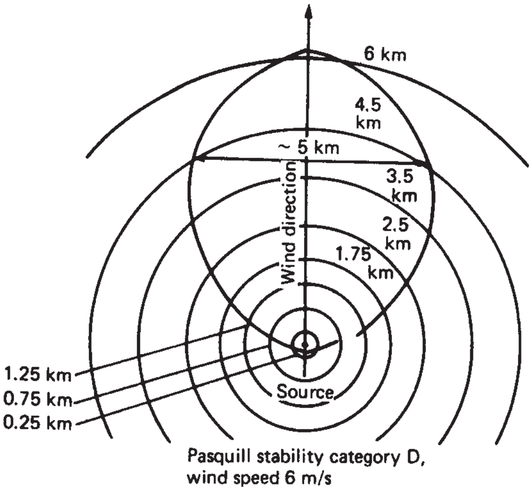

Figure A7.7 *First Canvey Report: approximate area within which people are at risk from an instantaneous release of 1000 te of anhydrous ammonia (Health and Safety Executive, 1978b) (Courtesy of HM Stationery Office)*

by adding to it the time of release. For the dosage use is made of the fact that Equation 15.16.31 gives the total dosage for an instantaneous release, as described in Chapter 15. The model applies strictly to short releases of approximately 3 min duration. No account was taken, therefore, of plume broadening with duration of release, but it was believed that this effect would be small for the stability condition considered.

For various points on the downwind axis of the cloud, calculations were made of the dosage and of the time of passage, and by dividing the former by the latter, of the mean concentration. The chlorine toxicity data given in Figure A7.5 were used to determine for each mean concentration the corresponding lethal exposure time. If the lethal exposure time was less than the time of passage, then the cloud was assumed to be fatal to a person remaining in the open air at that point.

The results of the calculations are summarized in Figures A7.8(a–c), which show the mean concentration, the time of passage and the lethal exposure time vs distance for the three releases studied.

The distances at which the time of passage and lethal exposure time cross over are the lethal distances, or hazard ranges, of the clouds. These distances are 2.7, 1.9 and 0.6 km for release times of 6 s, 10 min and 6 h, respectively. The variation of the lethal range is due entirely to the slope of the line of lethal concentration vs exposure time in Figure A7.5, which is a log–log plot. If the slope were –1 instead of approximately –2, there would be no variation of distance.

The effects of the mitigating factors are discussed in the light of these results.

For population density the effect of low population density is as follows. In a UK urban area with a population density of about 5000/km^2 the numbers in a 15° sector would be about 650, 2650 and 6000, while in a UK rural area with a population density of about 100/km^2 the corresponding numbers would be 13, 53 and 120 within distances of 1, 2 and 3 km, respectively. Thus it is estimated that a rapid release of 20 t of chlorine gas could kill up to 6000 in an urban area and up to 120 in a rural area.

The effect of more favourable weather conditions was not calculated. It was considered that, in view of the uncertainties in gas dispersion estimates, calculations for other weather conditions were not justified.

The effect of a lower rate of release is to reduce the estimated number of fatalities. The values may be calculated from the data given.

The effect of escape was estimated by calculating the time for a man to walk out of the cloud. It was assumed that if the axial concentration is lethal for the time of passage of the cloud, the concentration halfway out of the cloud may be considered only injurious and that at the edge of the cloud, defined as 10% of that of the centre, relatively harmless. It was assumed that the man would walk out of the cloud across wind at a speed of 3 mile/h (1.34 m/s). Escape was assumed if the time to walk from the cloud centre to the cloud edge was less than the lethal exposure time at the axial concentration. The times to walk out are shown in Figures A7.8(a–c). The distances at which the time to walk out and the lethal exposure time curves cross are the lethal distances of the clouds allowing for escape. For the release time of 6 s the lethal range remains 2.7 km, but for the release times of 10 min and 6 h it is reduced to 1.1 km and less than 100 m, respectively.

The effect of shelter was estimated using the equation

$$C = C_0[1 - \exp(-\lambda t)] \qquad \text{[A7.5.21]}$$

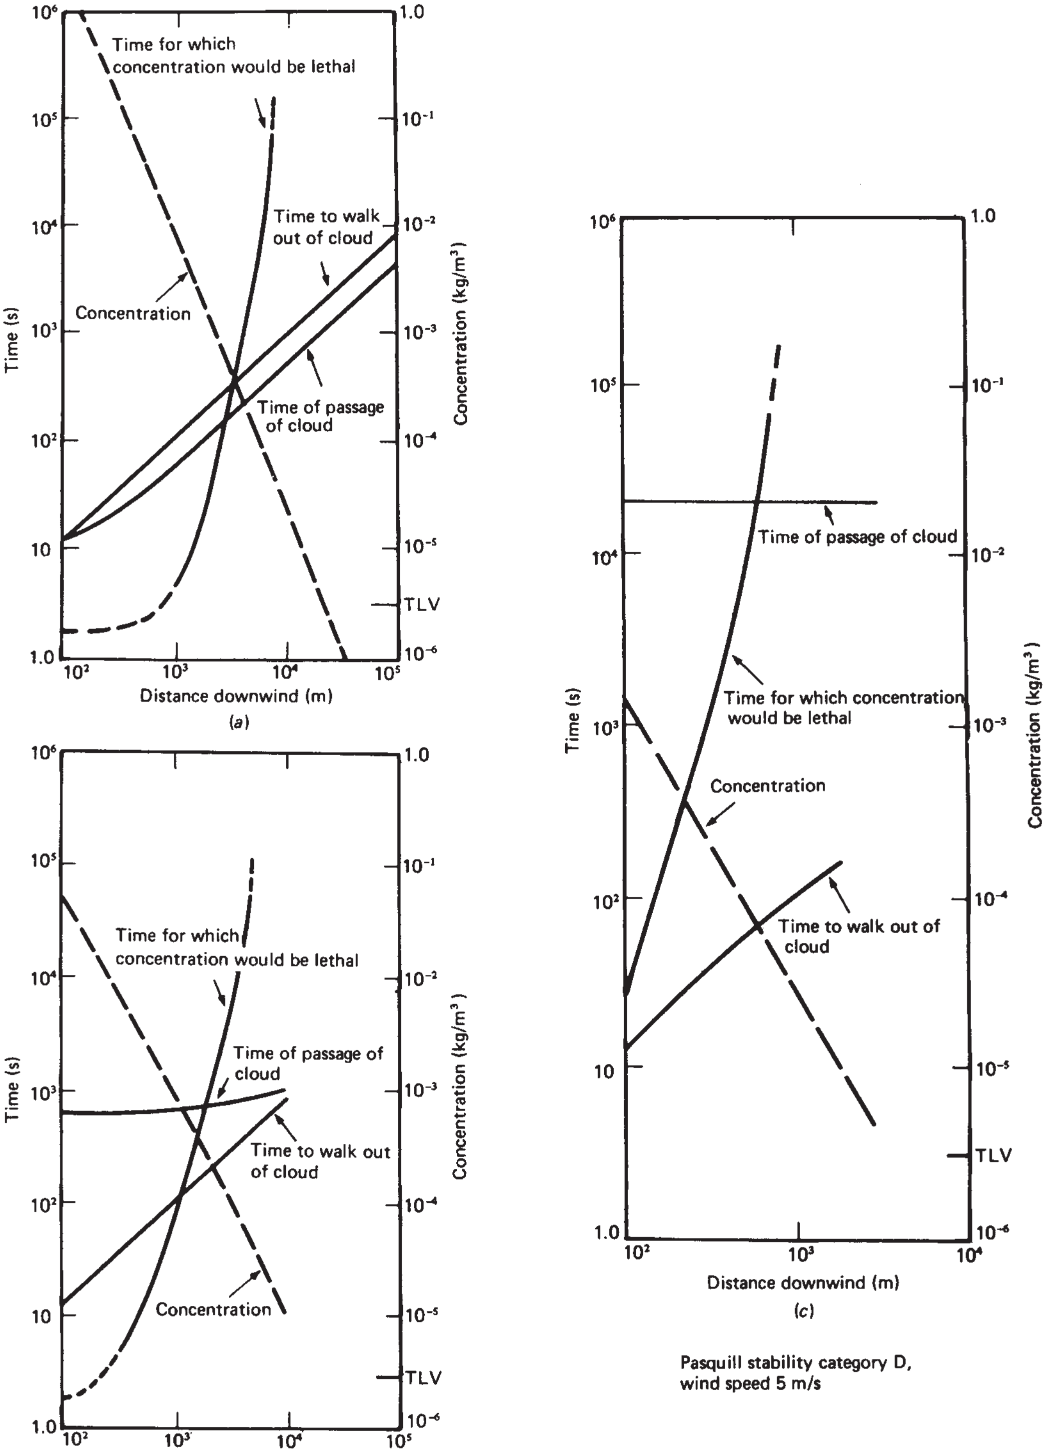
where C is the concentration indoors; C_0 the concentration outdoors; t the time; and λ the number of air changes per unit time.

The value of λ is about one change per hour for a modern centrally heated building, but in general can be two or three changes per hour, particularly if doors or windows are open. Assuming that shelter with one air change per hour is used, for a 6 s release the cloud is lethal at 100 m, but not at 200 m, and for a 10 min release it is lethal at 300 m, but not at 500 m. For a 6 h release the concentration in the building rises to that outside it after 1 h and the cloud is lethal at 0.6 km as before. Thus shelter is very effective for the release time of 6 s and quite effective for the release time of 10 min, but is ineffective for the release time of 6 h. In the latter case, however, escape is relatively easy.

A7.5.16 Road tanker hazards

A road tanker accident is considered as a possible initiating event for release of flammable and toxic materials. The report discusses road tanker accidents in Part 2, Section 14, and in Appendix 18.

The nature of the hazard from a road tanker accident is not discussed in as much detail as that from some of the other hazards. Mention is made of the possibility of a 10 t spillage of flammable material which could give rise to a fire (p. 96) and of spillage of LPG which could give rise to a 14 t cloud which could travel 200 m and still remain flammable (p. 178).



Pasquill stability category D, wind speed 5 m/s

Figure A7.8 *First Canvey Report: mean concentration, lethal exposure time, time of passage and time to walk out vs distance for a 201 release of chlorine with various release times (Health and Safety Executive, 1978b): (a) release time of 6 s; (b) release time of Wmin and (c) release time of 6 h (Courtesy of HM Stationery Office)*

The frequency of spillage is estimated from data recorded by HM Inspector of Explosives on accidents resulting in loss of life and personal injury and involving the contents of petrol tankers. These records indicated that over the past 5 years there were on average five accidents per year that led to a spillage. But from statistics published by the DoE (1976) the quantity of petroleum products moved by road is 4.3×10^9 t km. Then since the average tanker load is 14 t

Frequency of petrol tanker accident involving spillage
$= 1.6 \times 10^{-8}$/km

Tankers carrying LPG are stronger than petrol tankers, but the conservative assumption was made that the frequency of accidents involving spillage is the same for LPG tankers as for petrol tankers.

The frequency of spillage from all hazardous materials transported by road from the British Gas Corporation, London and Coastal Wharves, and Texaco was then estimated as 1.4×10^{-3}. The contribution of flammables to this figure is the largest, that of toxics being relatively small.

A7.5.17 Evacuation

The mitigating effect of evacuation was also considered. The report discusses evacuation in Part 1, Section 10, and in Part 2, Section 16.

There are two respects in which the evacuation situation at Canvey Island is unusual. There are only two roads leading off the island, and these converge at a single roundabout, and there exist already plans for evacuation in the event of flooding by the sea.

The need for an additional road off the island has been the subject of debate in the area.

The evacuation process was modelled. An exponential model was used in which it was assumed that half the population is moved to safety in the first 2 h, half of the remainder in the next 2 h and so on.

Evacuation was found to be possibly beneficial in one or two types of emergency. In particular, consideration was given to evacuation in the event of a large release of ammonia from a ship collision or jetty incident. For the majority of emergencies, however, it is suggested that it would be better to remain indoors rather than to attempt evacuation.

Such evacuation would require prior planning. The existing arrangements for evacuation for flooding would not necessarily suffice, since the advance warning from a chemical emergency is likely to be less.

Similarly, the provision of an additional road was seen as beneficial for the same types of incident, but it was considered that the construction of such a road could not be recommended solely for evacuation without further discussion.

A7.6 First *Canvey Report*: Assessed Risks and Actions

The hazards described in Section A7.3 were assessed using appropriate failure and event data as described in Section A7.4 and hazard models and risk estimates, including those described in Section A7.5. The accidents that might occur, the nature and frequency of the initiating events and the frequency–number relations for casualties, or societal risks, are shown in Table A7.9.

The results of the risk assessments are presented by the investigators as risks of causing casualties, that is, severe hospitalized casualties or worse. This is in accordance with established practice (e.g. Department of Defense, n.d.; Glasstone, 1964). It was considered misleading to attempt to distinguish between severe injury and death.

These results have several interesting features. The hazards may be ranked for societal risks in order of descending frequency for accidents of different magnitude as shown in Table A7.9.

The hazard arising from the very large quantities of LNG stored is a serious one, but is no worse than that from the considerably smaller quantities of LPG.

The obvious hazards of LNG, LPG and ammonia are equalled by others, such as oil and hydrogen fluoride, which are perhaps less well appreciated.

The relative importance of the hazards changes with the scale of the accident. For the smaller scale accidents oil spillage, flammable vapour clouds and toxic gas clouds are all important. As the scale increases, it is the toxic gas clouds that dominate.

There are a number of interactions identified both within sites and between sites. These include the threat to LPG storage at Mobil from the Calor Gas site, to the oil storage at Texaco from explosives barges, to the ammonia sphere at Fisons from rotating machinery and from the ammonium nitrate plant at Fisons, to various installations from process and jetty explosions, and possibly to the ammonia storage tank at Shell from explosion in the Shell refinery.

The relative hazard of the pressure storage of anhydrous ammonia at Fisons is much greater than that of the refrigerated storage of the same chemical at Shell. The risk for the latter was assessed as negligible with the possible exception of rupture by an explosion.

The assessed societal risks are shown in Table A7.9 and in Figure A7.9. Figure A7.9(a) gives the societal risks for all the existing installations. It shows that the risk of an accident causing more than 10 casualties is 31×10^{-4}/y. Figure A7.9(b) gives the societal risks for all the proposed developments. It shows that the risk of an accident causing more than 10 casualties is 16×10^{-4}/y.

The assessed individual risks are given for all the existing installations. These range from 13×10^{-4}/y in region A to less than 1×10^{-4}/y in region G of the area. The individual risks are also given for all the existing installations and proposed developments. These range from 26.3×10^{-4}/y in region A to less than 2×10^{-4}/y in region G (Table A7.10).

The investigators made a number of recommendations for the reduction of the hazards. These included

(1) oil spillage – construction of a simple containing wall around the London and Coastal Wharves and Texaco sites and the proposed Occidental and UR refinery sites;
(2) LNG tank flooding – construction of a dike;
(3) spontaneous failure of LPG spheres – high standard of inspection;
(4) LPG vessel rupture by missile (Mobil) – measures including fitting of pressure relief valves on cylinders at Calor Gas depot;
(5) LPG tank failure at BG jetty – improvement of bund;
(6) LPG pipeline failure (BG) – removal of pipeline;
(7) spontaneous failure of ammonia sphere – high standard of inspection, control of ammonia purity;
(8) ammonia release at Shell jetty – provision of water sprays at jetty;

Table A7.9 *First Canvey Report: principal hazards identified at Canvey and associated societal risks (after Health and Safety Executive, 1978b)*

Hazardous material	*Company*	*Initiating event*	*Type of accident*	*Frequencies in units of 10^{-6}/year*

		Missiles from neighbouring plant		100							
		Subtotal			464	343	284	246	214	139	100

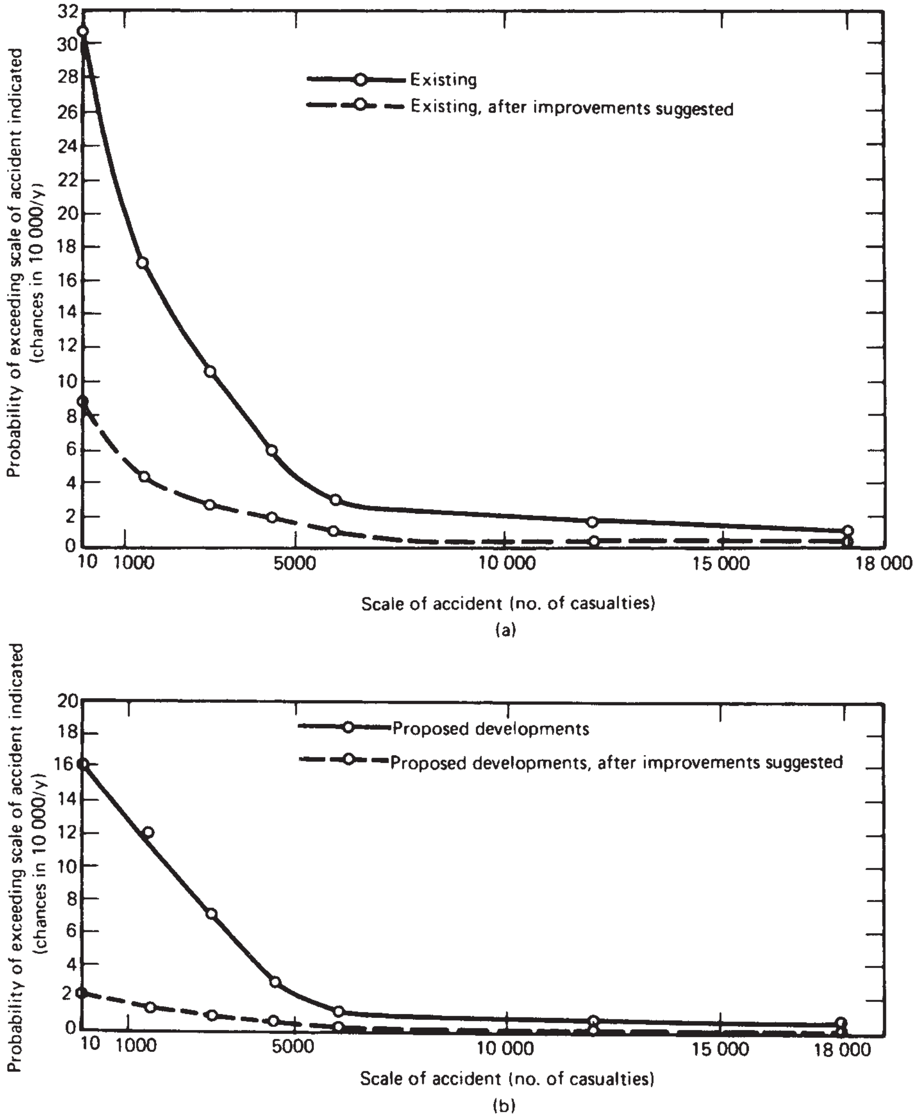

Figure A7.9 *First Canvey Report: societal risks for existing installations and proposed developments (Health and Safety Executive, 1978b): (a) all existing installations and (b) all proposed developments (Courtesy of HM Stationery Office)*

(9) HF plant rupture (Mobil, Occidental) – provision of water sprays;
(10) ship collision – strict enforcement of the speed restriction of 8 knot;
(11) road tanker hazards – road tanker traffic restriction to new road only (if road built).

The assessed effect of the proposed modifications is to eliminate the hazards from oil spillage, from LPG vapour cloud due to explosion at the jetty and pipeline failure at British Gas, and from vessel rupture at Mobil due to missiles from Calor Gas, and to reduce greatly many of the other hazards.

The rank order for societal risk of the hazards assuming that the proposed modifications are carried out is then as shown in Table A7.11. Oil spillage and LPG vapour cloud (BG) are eliminated.

There are some hazards, however, which remain relatively difficult to eliminate. In particular, spontaneous failure of storage vessels, jetty incidents and ship collisions make large contributions to the residual risks.

The effect of the proposed modifications on the societal risks for the existing and proposed installations is given in Figure A7.9. This shows that the risk of an accident causing more than 10 casualties is 9×10^{-4}/y for the existing installations and 2×10^{-4}/y for the proposed developments.

Table A7.10 *First Canvey Report: rank order of societal risks for some principal hazards of existing and proposed installations at Canvey (after Health and Safety Executive, 1978b)*

Frequencies in units of 10^{-6}*/year*								
>10 casualties			*>4,500 casualties*			*>18,000 casualties*		
1	Oil spillage	1366	1	Ammonia vapour cloud	258	1	HF vapour cloud	100
2	LPG vapour cloud (BG)	970	2	HF vapour cloud	246	2	ammonia vapour cloud	73
3	Ammonia vapour cloud	735	3	Oil spillage	150	3	LNG vapour cloud	7
4	LPG vapour cloud (others)	637	4	LPG vapour cloud (other)	96			
5	LNG vapour cloud	497	=5	LNG vapour cloud	80			
6	HF vapour cloud	464	=5	LPG vapour cloud (BG)	80			
7	AN explosion	85	7	AN explosion	17			

Table A7.11 *First Canvey Report: rank order of societal risks for some principal hazards of existing and proposed installations at Canvey, after improvements suggested (after Health and Safety Executive, 1978b)*

Frequencies in units of 10^{-6}*/year*								
>10 casualties			*>4,500 casualties*			*>18,000 casualties*		
1	LPG vapour cloud (other)	421	1	Ammonia vapour cloud	71	1	HF vapour cloud	24
2	LNG vapour cloud	396	2	HF vapour cloud	67	2	Ammonia vapour cloud	18
3	Ammonia vapour cloud	240	3	LNG vapour cloud	66	3	LNG vapour cloud	7
4	HF vapour cloud	115	4	LPG vapour cloud (other)	63			
5	AN explosion	8	5	AN explosion	2			

The assessed individual risks are given for all the existing installations after the proposed modifications. These range from 6×10^{-4}/y in region A to less than 1×10^{-4}/y in region G. The individual risks are also given for all the existing installations and proposed developments, after the proposed modifications. These range from 9×10^{-4}/y in region C to less than 1×10^{-4}/y in Region G.

The risk to an individual member of the public at Canvey may be compared with the average risk to workers in British industry. For the latter the fatal accident rate (FAR) per 10^8 exposed hours, is 4. If it is assumed that a man works 2000 h per year, then the FAR is equivalent to an individual risk of 0.8×10^{-4}/y.

A7.7 First *Canvey Report:* Responses to Report

A7.7.1 Response of HSE

The HSE accepted the report as a significant step forward in quantitative risk assessment, while acknowledging that there were some deficiencies.

It concluded that provided certain improvements were carried out, none of the existing installations need cease operations and the proposed developments could take place.

A7.7.2 Response of other parties

An account of some of the other responses to the report is given by the HSE in the Second *Canvey Report*, described below.

Publication of the report led to a surge of interest both locally and at national and international levels. HSE attended a public meeting at Canvey and explained the report. While the determination of the risks was welcomed, there was criticism of HSE's decision to allow continued operation of the existing installations, subject to the modifications.

The HSE gave a summary of some criticisms made of the report by various parties. One was that the report overestimates the risks. The assessors were required by HSE not to err on the side of optimism. Many in the industry, however, considered that it is preferable to adopt a 'best estimate' approach and that a conservative method which involves making a pessimistic estimate at each stage where there is doubt is liable to give a gross overestimate of the risks.

The HSE was also criticized in appearing to acquiesce in risks, some of which had been assessed as relatively high. On this the HSE draws attention to its requirement that improvements be made. It goes on.

HSE strongly believes that it has a duty, as the body charged with enforcing health and safety legislation, to express opinions about what may be required by that legislation. In HSE's view it is not sufficient merely to identify the risk to health and safety without also recommending a course of action.

A critique of the First *Canvey Report* was published by Cremer and Warner (1980).

A7.7.3 General comments

An investigation of the kind described has perhaps an inevitable tendency to suggest that the hazards revealed were previously unappreciated. In fact companies involved in such a survey are generally very well aware of the hazards and have taken the measures that they consider appropriate.

The report itself expresses some reservations on the risk estimates and states: 'Practical people dealing with industrial hazards tend to feel in their bones that something is wrong with risk estimates as developed in the body of the report'.

At the time, the industry in the United Kingdom was conscious particularly of the Flixborough explosion. This has been dwarfed by subsequent disasters such as those at Mexico City, Bhopal, Ufa and Piper Alpha.

A7.8 Second *Canvey Report*

In 1981 there appeared the Second *Canvey Report* entitled *Canvey: A Review of Potential Hazards from Operations in the Canvey Island/Thurrock Area Three Years after Publication of the Canvey Report* (HSE, 1981a). This again was in two parts, with Part 1 an introduction by the HSE and Part 2 the SRD study.

In Part 1 HSE outlines the criticism of the first report, as just described, and gives its conclusions concerning the reviewed assessment.

In the next two sections, accounts are given of the reassessed risks and actions and of some technical aspects of the second report.

A7.9 Second *Canvey Report:* Reassessed Risks and Actions

The risks assessed in the Second *Canvey Report* are generally less than those in the first report. Thus, for example, at Stanford-le-Hope the individual fatality risk is given as 0.6×10^{4}/y, as opposed to 5×10^{-4}/y in the first report, a reduction by a factor of 8.

The HSE in Part 1 adduce the following reasons for this: (1) physical improvements already carried out; (2) changes in operation; (3) detailed studies by companies; (4) changes in assessment techniques; (5) correction of errors and (6) further changes firmly agreed but yet to be made.

One major change in operation was the cessation of ammonia storage at Shell.

In a number of cases in the first report, estimates of the risks had to be made without benefit of detailed studies. Subsequent studies by the companies involved showed that in some cases the risks had been overestimated. A case in point was the limited ammonia spill at Fisons.

In a large proportion of cases the effect of the use of improved models for heavy gas dispersion was to reduce the travel distance of the cloud and hence the risks.

The HSE describe a number of further actions taken or pending to reduce the risks.

A7.10 Second *Canvey Report:* Technical Aspects

The Second *Canvey Report* revisits some of the frequency estimates and gives a revised set of hazard models and injury relations, covering the following aspects: (1) emission; (2) gas dispersion; (3) ignition; (4) fire events (5) vapour cloud explosions and (6) toxic release.

A7.10.1 Pressure vessel failure

The report reviews the frequency of spontaneous failure of pressure vessels, in the light of a further survey of the failure rate of such vessels by T.A. Smith and Warwick (1978) (see also Smith and Warwick 1981 SRD R203). The use of a failure rate of 10^{5}/y is reaffirmed.

A7.10.2 Emission models

The set of emission models given covers the following cases:

(1) rupture of a pressure vessel;
(2) flow from a pipe:
  (a) non-flashing liquid;
  (b) flashing liquid;
  (c) gas.

The model for emission following rupture of a pressure vessel containing liquefied gas is the adiabatic flash.

A7.10.3 Vaporization model

Vaporization of a pool of liquefied gas is treated using the SRD code SPILL, which can be applied to instantaneous or continuous releases.

A7.10.4 Gas dispersion models

Most of the liquefied gases studied exhibit heavy gas behaviour on release. For these use is made of the SRD codes DENZ and CRUNCH for instantaneous and continuous releases, respectively.

The report gives some results from these models in the form of tables of distance to the LFL and ½LFL for releases of propane and butane. As described in Chapter 15, a correlation model for heavy gas dispersion based on such tables has been developed by Considine and Grint (1985).

A7.10.5 Ignition models

The report gives several sets of ignition probabilities. It distinguishes three distinct cases of gas cloud

Delay before ignition	*Cloud composition*	*Likely consequence*
Seconds	Droplets entrained, cloud likely to be rich	Fire burning around edge of cloud (possibly leading to a fireball)
Minutes	Gas well mixed with air, likely to be in flammable range	Flash fire or explosion
An hour	Gas well diluted with air, likely to be lean	Hazard unlikely, though some flammable gas pockets possible

Table A7.12 *Second Canvey Report: some ignition probabilities for a flammable vapour cloud (after Health and Safety Executive, 1981a)*

A Ignition on site

Sources of ignition	*Ignition probability*
None	0.1
Very few	0.2
Few	0.5
Many	0.9

B Ignition at jetty

Delay before ignition	*Probability of ignition following*	
	Fire/explosion	*Collision*
Immediate ignition (within 30 seconds)	0.6	0.33
Delayed ignition (delay ½ to several minutes)	0.3	0.33
No ignition (within a few minutes)	0.1	0.33

C Ignition in transit

Terrain	*Ignition probability*
Open land	0
Industrial site	0.9

D Ignition over populated area

Type of ignition	*Ignition probability*
Edge/edge: edge of unignited cloud just reaches edge of populated area when ignition occurs	0.7
Central: unignited cloud right over population when ignition occurs	0.2
No ignition	0.1

dispersion: ignition may occur (1) at source, which may be (a) on site or (b) at a jetty; (2) in transit or (3) over a populated area. Table A7.12 shows some of the ignition probabilities given for a flammable gas cloud in these situations. The values are based partly on data on the proportion of releases ignited given by Science Applications Inc. (SAI) (1974) and D.C.Wilson (1980) and partly on judgement.

A7.10.6 Fire models and injury relations

The report gives a set of models for the following fire events: (1) pool fires; (2) fireballs; (3) BLEVEs; (4) flash fires.

Delay before ignition	*Liquefied gas release*	
	Refrigerated	*Pressurized*
Immediate ignition (within seconds)	Pool fire	Fireball
Slight delay (up to 30 s)	Diffusion flash fire	Premixed flash fire/explosion
Longer delay (min)	Premixed flash fire/explosion	Premixed flash fire/explosion

The event that occurs will depend on the delay before ignition. The behaviour assumed is as follows: For the various fire models the report refers to work by Considine (1981), evidently an early version of the paper by Considine and Grint (1985), which gives a similar set of models, as described in Chapter 16.

A7.10.7 Vapour cloud explosion model and injury relations

The vapour cloud explosion model covers both the probability that an explosion occurs given ignition and the effects of such an explosion. For the former the probabilities used are

Size of cloud (te)	*Explosion probability*
<10	0
100–100	0.1 (LNG = 0.01)
>100	1

For the effects of such an explosion use is made of the following relations based on the work of the ACHM:

$$p_o = kM^{1/3} \qquad [A7.10.1]$$

$$R = 30M^{1/3} \qquad [A7.10.2]$$

hence

$$p_a = k'R \qquad [A7.10.3]$$

where M is the mass released (te), p_a the peak side-on overpressure (kPa), R the radius of the cloud (m) and k, k' are constants. Relationships are given as follows:

Overpressure (kPa)	*Hazard range* (m)	*Casualty probability*
0<7	>4.25R	0
7–21	(2–4.25)R	0.1
21–34	(1.35–2)R	0.25
34–48	(1.1–1.35)R	0.70
>48	<1.1R	0.95

Further the authors quote the estimates of the ACMH that the overpressure at the centre of the cloud is likely to be about 103 kPa and at the edge about 69 kPa.

A7.10.8 Toxic injury relations

Injury relations are given for ammonia and for hydrogen fluoride. For these gases the authors state that the best information available to them on the LC_{50}, the concentration lethal at the 50% level, is as follows:

Time t (min)	*Lethal concentration LC_{50}*	
	Ammonia (kg/m^3)	*Hydrogen fluoride* (kg/m^3)
1		1.5×10^{-3}
5	7×10^{-3}	4×10^{-4}
10	3.5×10^{-3}	
30	1.2×10^{-3}	
60	5×10^{-4}	4×10^{-5}

They further state that these data may be fitted to the relation

$$LCt_{50} = kCt^{0.9} \qquad [A7.10.4]$$

where C is the concentration, LCt_{50} the dose lethal at the 50% level and t time.

A7.11 Notation

Section A7.5

Subsection A7.5.5

A_H	horizontal area of target
A_V	vertical area of target
A'_V	horizontal projection of vertical area of target
F	frequency of aircraft crash on target area
F_H	frequency of aircraft crash per unit of ground area
F_V	frequency of aircraft crash per unit of vertical area

Subsection A7.5.7

g	acceleration due to gravity (m/s^2)
h_f	slumped liquid depth (m)
r	radius of flooded zone (m)
r_s	radius of source cylinder (m)
t	time after initiation of slumping (s)
u_f	slumped liquid velocity (m/s)
V_s	volume of source cylinder (m^3)

Subsection A7.5.8

A_H	area of tank roof (m^2)
A_V	exposed area of tank vertical sides (m^2)
c_p	specific heat of tank wall (J/kg°C)
m	mass of exposed tank wall (kg)
Q_i	heat input to tank (W)
Q_n	heat loss by convection (W)
Q_r	heat loss by radiation (W)
t	time (s)
ε	emissivity of tank wall
θ_A	absolute temperature of ambient air (K)
θ_T	absolute temperature of tank wall (K)
$\Delta\theta$	temperature difference between tank and ambient air (°C)
α	Stefan–Boltzmann constant (W/m^2 K^4)

Subsection A7.5.11

H	heat of combustion of hydrocarbons (kcal)
Δp_m	peak overpressure (bar)
q	peak dynamic pressure (bar)
r	distance (m)
W	mass of hydrocarbons (t)
α	equivalence factor

Subsection A7.5.13

a, b	constants
C	concentration (g/m^3)
D	dosage ((g/m^3)$^{2.75}$ min)
P_r	probit

Appendix Rijnmond Report

8

Contents

Another comprehensive hazard assessment is the Rijnmond study carried out for the Rijnmond Public Authority by Cremer and Warner.

This work is described in *Risk Analysis of Six Potentially Hazardous Industrial Objects in the Rijnmond Area*, a Pilot Study issued by the Rijnmond Public Authority (1982) (the Rijnmond Report).

The Rijnmond is the part of the Rhine delta between Rotterdam and the North Sea. Within the Rijnmond area of 15×40 km^2 are located some one million people and a vast complex of oil, petrochemical and chemical industries as well as the largest harbour in the world. A description of the industrial complex at Rijnmond has been given by Molle and Wever (1984). A map of the Rijnmond showing the principal plant areas is given in Figure A8.1 and a diagram of the petrochemical complex in Figure A8.2. There are five oil refineries with a refining capacity of some 81 Mt/year, including the large refineries of Shell at Pernis and BP near Rozenburg, and major petrochemicals complexes operated by Shell, Gulf and Esso. Some of the other plants are described below.

A first note on the industrial hazards issued in 1976 by the Rijnmond Authority was strongly criticized by industry. Accordingly a commission, COVO, was set up with representatives of the Labour Inspectorate of the Ministry of Social Affairs, the Rijnmond Authority and industry. COVO decided to carry out a pilot study of six industrial installations in the Rijnmond in order to evaluate the applicability of risk assessment to decision-making on safety and commissioned Cremer and Warner to carry out the study. A steering committee was formed and the work was done to the requirements of this committee.

A8.1 The Investigation

The aim of the work was to evaluate the methods of risk assessment for industrial installations and to obtain experience in the practical application of these methods. Such evaluation was considered to be essential before any decision could be made on the role of such methods in the formulation of safety policy.

The objectives of the study were formulated so as to give an answer to the following questions:

(1) What is the reliability of the assessment of the consequences and probabilities of possible accidents with industrial installations when the procedures and methodology of risk analysis are carried out to their full extent?
(2) What problems and gaps in knowledge exist in the field of risk analysis?
(3) How can the results of a risk analysis be presented conveniently, without losing important details, so that it may be used for safety policy decisions?
(4) How well can the influence of risk reducing measures on the consequences and probabilities be calculated?
(5) What resources are required, in time and money, to assess the risk with sufficient accuracy to be useful for safety policy decisions?

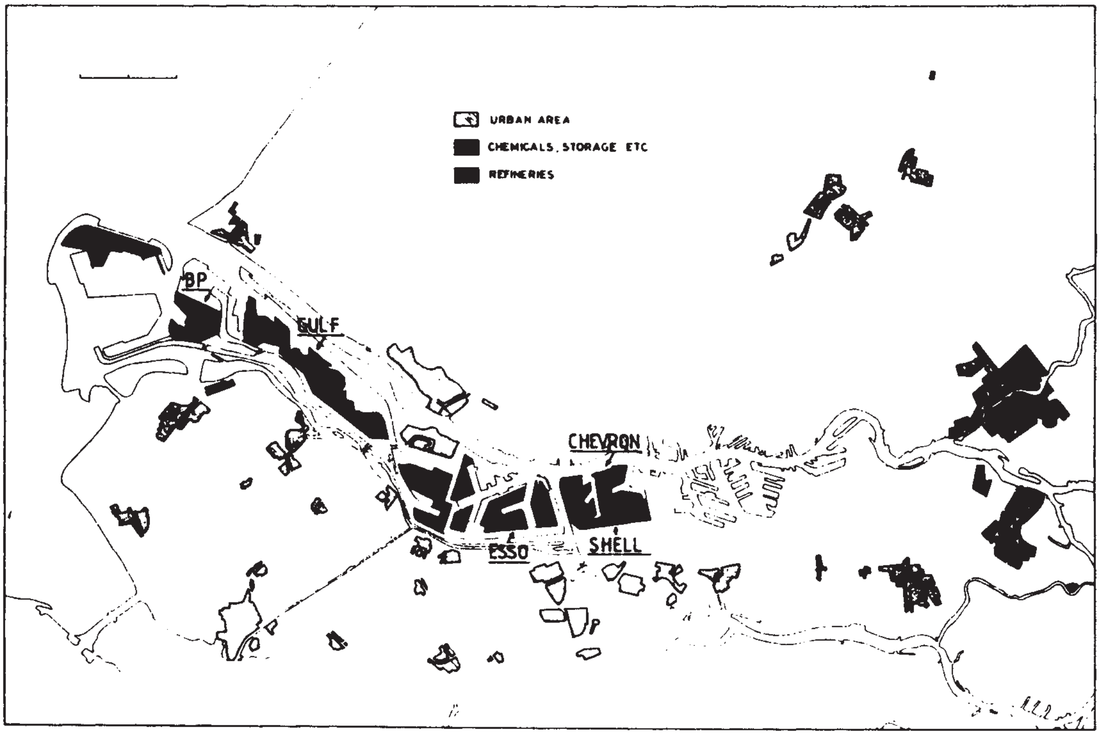

Figure A8.1 *Rijnmond harbour area (Molle and Wever, 1984)*

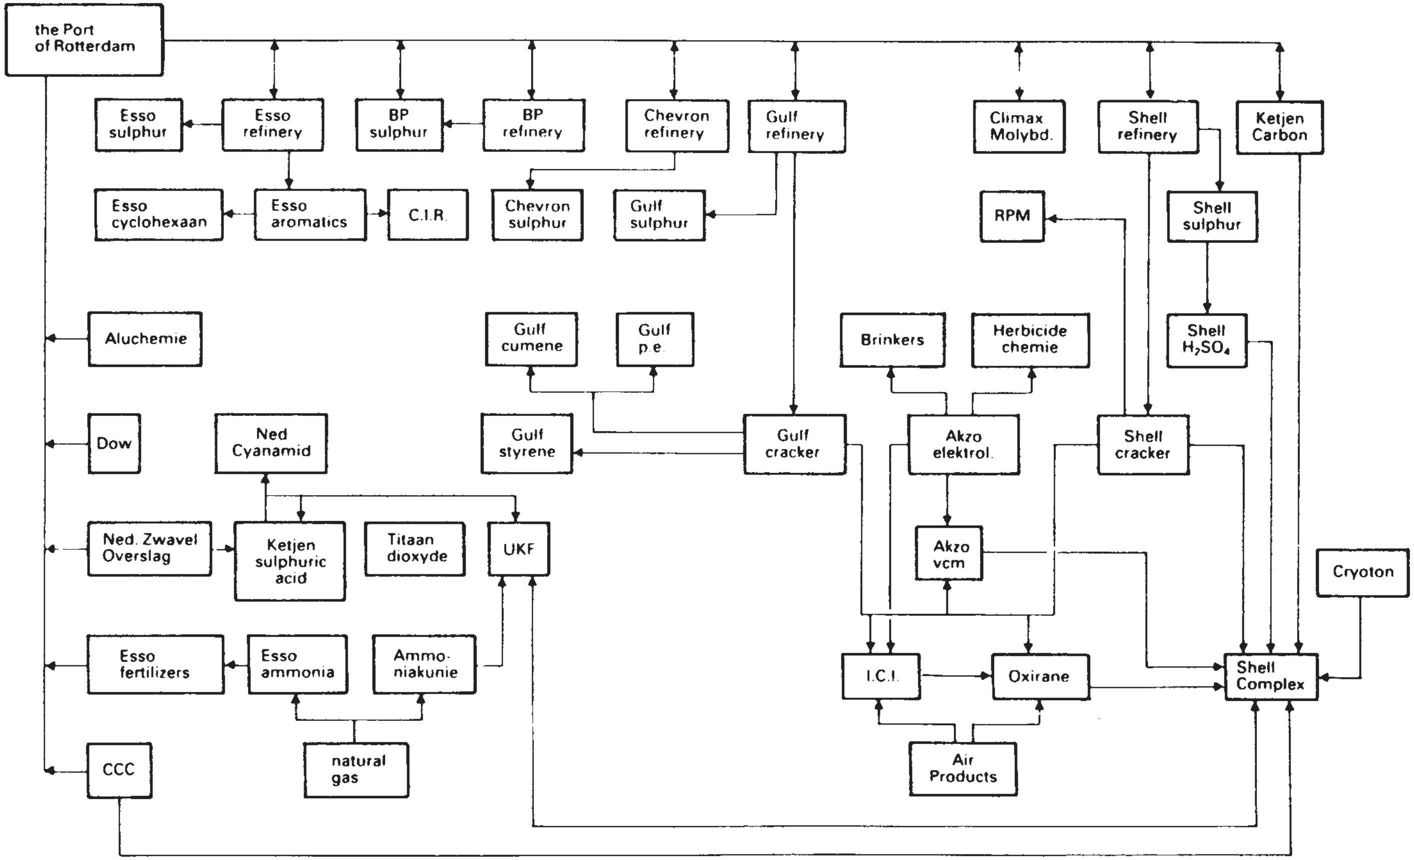

Figure A8.2 *Petrochemical complex in the Rijnmond harbour area (Molle and Wever, 1984)*

The COVO steering committee was reinforced with experts from industry. The committee also included representatives of the Battelle Institute who were charged with the task of scrutinizing the methodology and models used. The overall approach taken in the investigation was:

(1) to collect basic data and define the boundary limits of the installation;
(2) to identify the potential failure scenarios;
(3) to select and apply the best available calculation models for physical phenomena;
(4) to collect and apply the best available basic data and models to calculate the probabilities of such events;
(5) to choose and develop different forms of presentation of the final results;
(6) to investigate the sensitivity of the results for variations in the assumptions used and to estimate the accuracy and reliability of these results;
(7) to investigate the influence of risk reducing measures.

The investigation involved the identification of the principal hazards of the installations in the area, the assessment of the associated individual and societal risks and the proposal of remedial measures to reduce the risks.

The project was planned to last one year but in fact took two-and-a-half years and it cost some 2.5 m guilders. A supplementary contract was placed with the consultants to study methods of presenting the results. The report was published in 1982. It is in five parts. Part 1 is the report of the steering committee, Part 2 is the main Cremer and Warner study, Part 3 the supplementary Cremer and Warner study, Part 4 is the Battelle review and Part 5 contains the industrial and other comments.

A8.2 Installations and Activities

The six installations studied were as follows:

(1) Acrylonitrile storage (Paktank);
(2) Ammonia storage (UKF);
(3) Chlorine storage (AKZO);
(4) LNG storage (Gasunie);
(5) Propylene storage (Oxirane);
(6) Hydrodesulfurizer (Shell).

The storages of acrylonitrile and LNG were at atmospheric pressure and those of ammonia, chlorine and propylene were all liquids under pressure. The acrylonitrile, ammonia and chlorine represented toxic materials and the LNG and propylene flammable materials. The hydrodesulfurizer represented part of a process plant, the section studied being the diethanolamine stripper.

The context of these installations is described by Molle and Wever and accounts of the individual installations are given below.

The report is organized partly by installation and partly by themes and material on a particular installation is therefore given dispersed. Table A8.1 gives a summary of the entries for each installation.

A8.3 Event Data

The event data used in the study were a mixture of generic data, plant data and estimates. Some failure and event data and some external event data used are given in Tables A8.2 and A8.3, respectively. Other data are given in the sections on particular installations.

A8.4 Hazard Models

The principal hazard models used are given in Table A8.4 and their application is described in the sections on particular installations.

A8.5 Injury Relations

The injury relations used are given in Table A8.5 and their application is described in the sections on particular installations.

A8.6 Population Characteristics

The study covered the risks both to employees and to the public. For the off-site population a grid was used showing the number of people over an area of some 75 km^2, which covered the whole of the Rijnmond. Populations were estimated for each 500 m^2 square using data from the 1971 census, updated in 1975.

Both day and night time populations were determined, day being defined as the working week of 45 h and night as the remaining 123 h.

Outside the population grid average population densities were used. These were required only in cases where an exceptionally large cloud occurred.

For the particular installations studied data were obtained on the numbers of employees present during day and night and on their locations. The on-site population N_e was estimated from the relation

$$N_e = \frac{(5N_d + 16N_n) \times 52}{((5 \times (52 - n_h))} \qquad [A8.6.1]$$

where n_h is the number of weeks off for holidays, sickness, etc., N_d the numbers present during the working day and N_n the numbers present at all other times.

For toxic gas hazard it was assumed that 1% of the population are outdoors. This estimate includes an allowance for people taking shelter. For explosion hazard it was assumed that 10% are outdoors.

A8.7 Mitigation of Exposure

The principal mitigations of exposure considered were evacuation and shelter. For evacuation the estimate of the proportion evacuated is taken as a function of the warning time. In some cases the proportion is estimated as 90–100%.

For the effect of shelter from toxic gas the single-exponential stage model of ventilation is used.

A8.8 Individual Assessments

A8.8.1 Acrylonitrile storage (Paktank)

The acrylonitrile (AN) storage is one of a number of storages at the Botlek terminal of Paktank, a tank storage company providing bulk storage and associated services to the oil and chemical industries.

There are normally two or three tanks containing AN. The study was confined to a single tank and associated transfer systems which had been dedicated to handling AN for some years. This AN tank is one of a number of fixed roof tanks located in a tank bund which is at the centre of the site. The tank has a capacity of 3700 m^3. It is designed to withstand small variations of internal pressure, the breather valves being designed to open at an overpressure of 200 mmHg and a vacuum of 50 mmHg.

Operation at the site is flexible, but in the preceding two years only six modes of transfer had been recorded, these being loading of coastal barges, loading of road tankers, loading of rail tank cars, filling from coastal barges and chemical tankers, filling from sample tanks, and transfer between this tank and others at the site.

A summary of the risk assessment for the AN storage is given in Table A8.6. Section A of the table lists the undesired events considered, section B the hazard scenarios and section C the main fault trees.

An escape from the tank into the bund, though instantaneous, gives rise to a constant evaporation rate and hence acts as a continuous source. Releases from the pipework are also continuous sources.

The frequency of the releases is estimated using the seven fault trees listed as shown in Figure A8.3. The table giving the frequency and event data for these trees contains 81 entries. Of these some 30 are derived from the generic data given in Tables A8.2 and A8.3 and the rest from other sources, mainly company data, meteorological data or judgement.

For fire hazard it was assumed that 10% of all major spillages or resulting vapour clouds and 5% of significant spillages ignite and that an operator present at the release or ignition source receives fatal burns in 80% of cases. The hazard distances obtained are shown in the table as <10 m.

For toxic gas hazard the exposure is continuous. In most cases only employees were at risk. A 10-min exposure was assumed for employees, who are alert to the hazard.

It was found, however, that serious toxic effects were possible to the public from a major spill (PI) if the exposure time was 30 min. For the public credit was given for evacuation, usually 90–100%, depending on the warning time.

Typical hazard distances to the LTL_{50} of 76 m are given in Table A8.6. The distances are greater for adverse weather conditions, being on the centreline for 2.0/F and 1.5/D conditions 575 and 260 m to the LTL_{50} and 879 and 365 m to the LTL_{05}, respectively.

A8.8.2 Ammonia storage (UKF)

The ammonia storage is part of a complex of plants producing ammonia, nitric acid, ammonium nitrate, urea and other fertilizers at the Pernis site of UKF.

The ammonia is stored in a sphere under pressure at atmospheric temperature. The capacity of the sphere is 1000 m^3, but the average inventory is only 40% of this. The ambient temperature was taken in the study as 15°C that corresponds to a pressure of 7.1 bar.

Ammonia is transferred to the sphere from rail tank cars or from the ammonia plant. Transfer of the liquid ammonia from the rail tank car is effected by pressurizing the tank

View factor	McGuire (1953)

Table A8.5 *Rijnmond Report: some injury relations used*

A Fire: Steady state

Incident thermal radiation (kW/m^2)	*Effect*
1.6	Level insufficient to cause discomfort for long exposures
4.5	Level sufficient to cause pain if subject does not reach cover in 20 s; blistering of skin likely (first degree burns)
12.5	Minimum level for piloted ignition of wood, melting of plastic tubing, etc.
25	Minimum level for unpiloted ignition of wood at infinitely long exposures
37.5	Level sufficient to damage process equipment

B Fire: Unsteady state

Incident thermal radiation dose threshold (kJ/m^2)	*Effect*
65	Threshold of pain: no reddening or blistering of skin
125	First degree burns
250	Second degree burns
375	Third degree burns

Table A8.5 *(continued)*

C Explosion

Blast overpressure (bar)	*Effect*
0.03	Window breakage, possibly causing some injuries
0.1	Repairable damage; light structures collapse; pressure vessels remain intact
0.3	Major structural damage (assumed fatal to people inside buildings or other structures)

D Toxic effects

Data given in terms of constants in probit equation for fatalities
$Y = k_1 + k_2 \ln \Sigma C^n T$

Gas	*Constants n*	k_1	k_2	LTL_{50} ($\mathrm{ppm}^n\cdot\mathrm{min}$)
Acrylonitrile	1			8.15×10^3
Ammonia	2.5	−30.57	1.385	1.22×10^{10}
Chlorine	2.75	−17.1	1.69	5.46×10^4
Hydrogen sulfide	2.75			1.6×10^8

Table A8.6 *Rijnmond Report: summary of assessment of acrylonitrile storage (Paktank) (after Rijnmond public Authority, 1982)*

A Undesired events

Event[a]		*Frequency* (events/year)	*Mass flow or mass* (kg/s or kg)	*Duration* (s)	*Average no. of fatalities to public*[b,c] (deaths/year)
P1	Major rupture of tank	4.3×10^{-5}	1.85×10^6		7.6×10^{-6}
P2	Split in tank bottom/shell	2.0×10^{-4}	1.85×10^6		
P3	Rupture of tank roof	1.8×10^{-4}			
P4	Open drain valve on tank	1.0×10^{-4}		1800	
P5	Overfilling of tank	1.5×10^{-3}	200 m^3/h[d]		
P6	Internal explosion	5×10^{-6}			
P7	Unauthorized entry into tank	2×10^{-5}			
P8	Transfer line rupture	9×10^{-7}	1.85×10^6		3.2×10^{-7}
P9	Transfer line leakage	5.2×10^{-5}		1800	
P10	Hose rupture	2.6×10^{-3}		900	
P11	Catastrophic rupture of transfer line	8.8×10^{-6}		900	
P13	Transfer hose rupture	4×10^{-3}		600	
P14	Transfer hose rupture	4×10^{-3}		600	7.9×10^{-6}
Total					

B Hazard scenarios

Spillage into bund
Evaporation from bund
Gas dispersion (from continuous source)
Pool fire in bund
Flash fire in vapour cloud

C Fault trees

P1 Catastrophic rupture of tank
  P1.1 Severe overpressurization of tank
    P1.1.1 Pressurization of tank with nitrogen
    Pl.1.2 Severe polymerization within tank
  Pl.2 Severe tank depressurization

Table A8.6 *(continued)*

- P1.4 Severe polymerization in tank
- P5 Tank overfilled up to breather valve level
    - P5.1 High level detected, incorrect action taken

---

[a] There are 15 further events:

P12 Transfer line leakage
P15 Transfer hose leakage
P16 Transfer line rupture
P17 Transfer hose rupture
P18 Transfer line/hose rupture
P19 Transfer line/hose rupture
P20 Transfer line/hose leakage
P21 AN transfer line/hose leakage
P22 Line leakage
P23 Sampling hose/line rupture
P24 Transfer line/hose rupture
P25 Sample tank leakage
P26 Explosion with pre-pump sample
P27 Hose rupture
P28 Flash fire or explosion within AN system during maintenance

None of these events causes an average number of fatalities to the public $>10^{-5}$/year.

[b] For both cases P1 and P8 the typical hazard distances to the LTL_{50} are 76 m *and to the* LTL_{05} 126 m. These are the greatest hazard distances quoted.

[c] For all cases the typical hazard distances for fatal effects from fire are <10 m. No hazard distances for fatal effects from explosion are quoted.

[d] Maximum rate (pump rate).

car with ammonia vapour from the sphere and from the ammonia plant by pumps. Ammonia is transferred from the sphere to the downstream plants by pumps.

An escape from a sphere may constitute an instantaneous or a continuous source. Catastrophic rupture of a sphere was taken as equivalent to an instantaneous release, other escapes to continuous releases.

A summary of the risk assessment for the ammonia storage is given in Table A8.7. Sections A–C list the undesired events, the hazard scenarios and the main fault trees.

Ammonia constitutes both a flammable and toxic hazard, but since the toxic effects can occur at concentrations 100 fold less than the flammable effect, only the former were considered.

A8.8.3 Chlorine storage (AKZO)

The chlorine storage consists of five spheres associated with chlorine cellrooms at the Botlek site of AKZO.

The chlorine is stored in the spheres under pressure at atmospheric temperature. Each sphere has a capacity of 90 m^3 and can therefore hold 100 te, but at any given time one of the spheres is used as a dump tank, so that the capacity of the storage is 400 te. At ambient temperature the sphere pressure is 6.5 bar, but pressure is taken up to 9 bar when the sphere is discharging to consumer plants. The spheres are located in a bund.

Chlorine is received only from the associated production plant, but is sent out to a variety of consumers. There is a chlorine gas disposal plant consisting of caustic soda scrubbers.

An escape from a sphere may constitute an instantaneous or a continuous source. Catastrophic rupture of a sphere was taken as equivalent to an instantaneous release, other escapes to continuous releases or mixed releases.

A summary of the risk assessment for the chlorine storage is given in Table A8.8. Sections A–C list the undesired events, the hazard scenarios and the main fault trees.

A8.8.4 LNG storage (Gasunie)

The LNG storage consists of two tanks and associated equipment at the peak shaving plant of Gasunie at Maasvlakte.

The LNG is contained in an inner tank of 9% nickel steel and an outer tank of carbon steel. This whole container is surrounded by a further containment consisting of a reinforced concrete floor and a pre-stressed concrete wall. The capacity of each tank is 57,000 m^3.

An escape from a tank may constitute an instantaneous or a continuous source. Catastrophic failure of a tank was taken as equivalent to an instantaneous release, other escapes to continuous releases or mixed releases.

A summary of the risk assessment for the LNG storage is given in Table A8.9. Sections A–C list the undesired events, the hazard scenarios and the main fault trees.

A8.8.5 Propylene storage (Oxirane)

The propylene storage is associated with the propylene oxide plant of Oxirane at Seinehaven. There are two spheres each with a capacity of 600 te. The ambient temperature was taken in the study as 15°C, that corresponds to a gauge pressure of 8 bar.

Propylene is transferred to the spheres by pipeline, ship and rail tank cars. It is transferred from the spheres to the downstream plants.

An escape from a sphere may constitute an instantaneous or a continuous source. Catastrophic rupture of a sphere was taken as equivalent to an instantaneous release, other escapes to continuous releases.

A summary of the risk assessment for the propylene storage is given in Table A8.10. Sections A–C list the undesired events, the hazard scenarios and the main fault trees.

A8.8.6 Hydrodesulfurizer (Shell)

The section of the hydrodesulfurizer studied is the diethanolamine (DEA) regenerator. The latter is part of an absorber–regenerator unit which removes hydrogen sulfide from sour gas. The hydrogen sulfide is absorbed into DEA in the absorber and the fat DEA passes to the regenerator where a reversible reaction occurs releasing the hydrogen sulfide again.

The escapes that can occur from this unit are of two types. There may be a direct release of hydrogen sulfide gas. Alternatively, the release may be by evolution of the gas from the fat DEA liquid.

Hydrogen sulfide presents both a flammable and a toxic gas hazard. On review the flammable hazard was discounted. However, the flammability of the gas remains relevant in that in a proportion of cases the gas cloud would burn and would then not constitute a toxic hazard.

A summary of the risk assessment for the regenerator section of the hydrosulfurizer is shown in Table A8.11. Section A lists the undesired events and Section B the hazard scenarios. As indicated in section C there are no fault trees.

B Hazard scenarios

Pipework failure:
continuous release
Gas dispersion

C Fault trees

None

[a] For these 7 cases the typical hazard distances to the LTL_{50} are 0, 19, 59, 81, 144, 153, and 64 m and to the LTL_{05} 0, 85, 96, 99, 173, 181 and 81 m, respectively.

Table A8.12 Rijnmond Report: individual and average annual risk for six installations (Rijnmond Public Authority, 1982)

Installation	*Average annual fatalities*		*Individual risk employees*
	Employees	*Public*	
Acrylonitrile	2.1×10^{-3}	7.9×10^{-6}	6.6×10^{-6}
Ammonia	2.1×10^{-3}	2.0×10^{-4}	20×10^{-6}
Chlorine	1.1×10^{-2}	3.6×10^{-3}	5.1×10^{-5}
LNG	1.5×10^{-7}	6.8×10^{-10}	5.7×10^{-9}
Propylene	1.1×10^{-4}	3.7×10^{-5}	7.7×10^{-7}
Hydrodesulfurizer	1.0×10^{-6}	0	2.1×10^{-9}

For cases S1–S2, which involve direct release of hydrogen sulfide, it was found that the inventory of gas, which is at a gauge pressure 0.5 bar, was too small to sustain a release of any significant duration and that for these cases the limiting flow was determined by the rate of evolution of the gas, which was 4370 kg/h. This is equivalent to discharge from hole of a 75 mm diameter.

All the emissions are continuous sources.

An ignition probability of 0.2 on release was assumed.

For toxic gas hazard, therefore, the exposure is continuous. In all cases only employees were at risk.

Typical hazard distances to the LTL_{50} are given in Table A8.11, the greatest distance there quoted being 153 m. The distances are greater for adverse weather conditions, being for case S2.3 on the centreline for 2.0/F conditions 395 m.

A8.9 Assessed Risks

The results of the assessment are presented in a number of ways. These include

Risk contours
Risk to employees:
  Individual risk
Risk to public:
  Individual risk
  Societal risk
  FN tables
  FN curves
Average annual fatalities

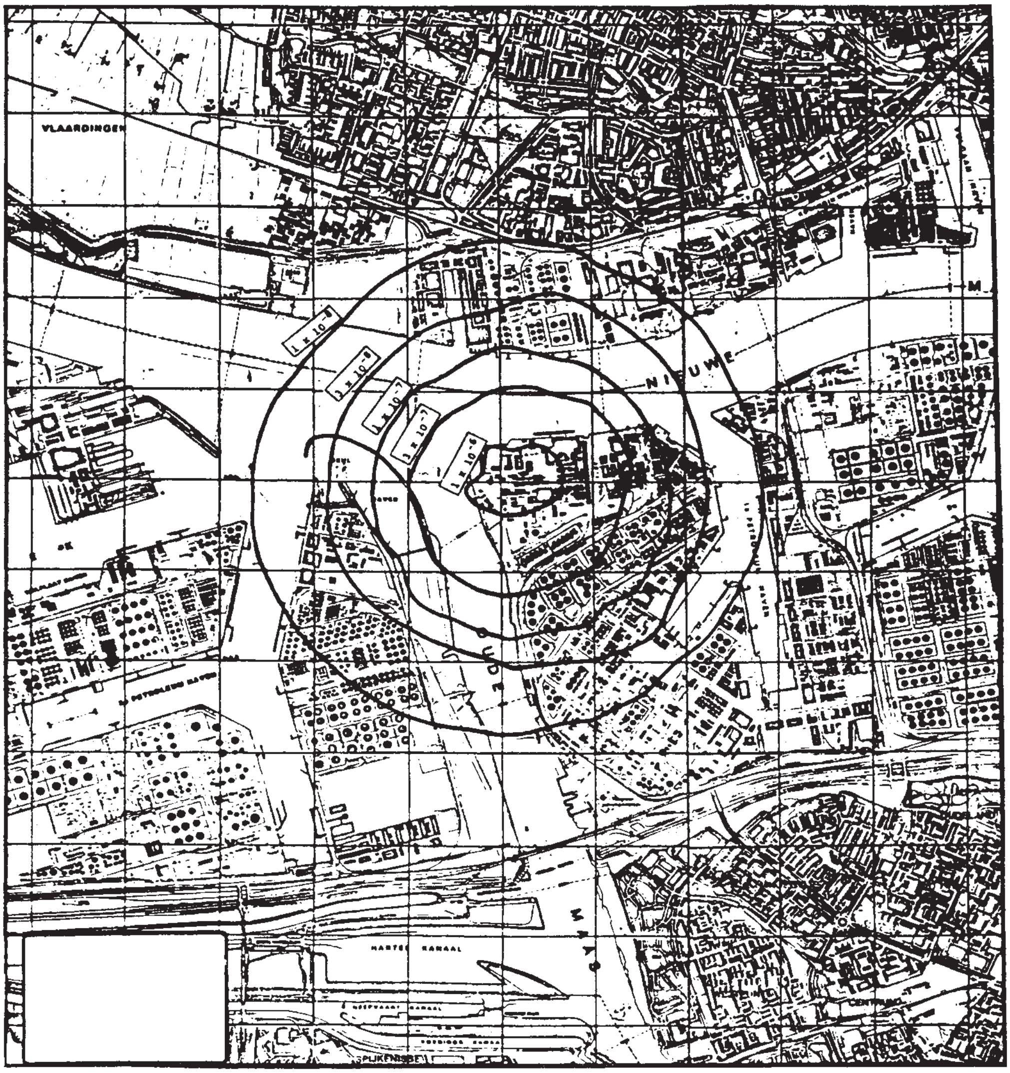

Figure A8.4 *Rijnmond Report: risk contours for ammonia storage (Rijnmond Public Authority, 1982. Reproduced by permission)*

Table A8.13 *FN table for public for chlorine storage in Rijnmond Report (after Rijnmond Public Authority, 1982)*

No. of deaths	*Cumulative frequency*	*No. of deaths*	*Cumulative frequency*
1	4.00×10^{-4}	125	2.09×10^{-6}
10	1.07	151	1.62
20	3.70×10^{-5}	200	9.86×10^{-7}
30	1.50	304	3.06
40	9.46×10^{-6}	404	2.34
50	7.32	518	1.26
60	6.34	738	4.85×10^{-8}
70	5.23	1027	3.40
80	4.31	1697	7.50×10^{-10}
90	3.23		
100	2.87		

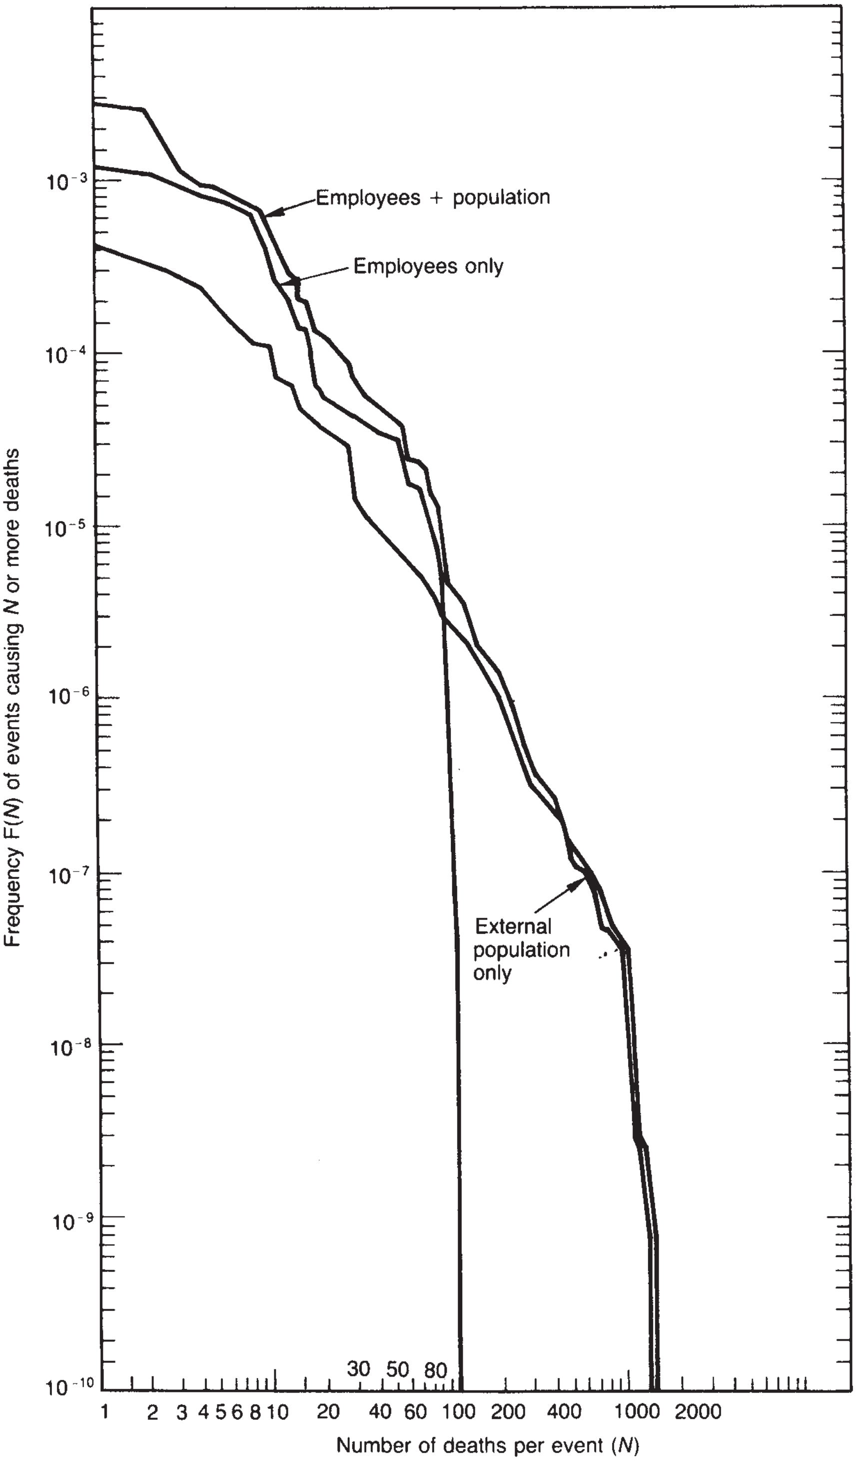

Figure A8.5 *Rijnmond Report: FN curve for chlorine storage (Rijnmond Public Authority, 1982. Reproduced by permission)*

The individual risks and average annual fatalities are shown in Table A8.12.

The use of risk contours is illustrated here by one of those for the ammonia storage shown in Figure A8.4, while that of FN tables and of FN curves is illustrated by those for the chlorine storage shown in Table A8.13 and Figure A8.5, respectively.

A8.10 Remedial Measures

For each installation recommendations were made for remedial measures to reduce the risks. In accordance with the remit of the study the proposals made were illustrative rather than exhaustive and are suggestions for further evaluation.

For the AN storage the main measure proposed is nitrogen blanketing to prevent internal explosion. It is recognized, however, that there is a contrary view that lack of oxygen may make spontaneous reaction more likely. It was estimated that inciting would reduce the frequencies of events P1 and P3 to 0.1×10^5 and 0.4×10^5/year, respectively. Some 17 other measures are also listed, including hose support, tanker earthing and changes to sampling methods.

For the ammonia storage the principal measure suggested is the provision of a bund. This would do little to retain material released in a catastrophic failure of the sphere, but it might well mitigate the effect of failure of a bottom connection.

Another proposal made is the provision of an emergency air supply at the control room to allow the operators time to close emergency isolation valves.

For the chlorine storage the main recommendations are directed to reduction of the size of escapes from pipework by the use of excess flow valves.

For the LNG storage the main measure proposed is directed towards the prevention of escalation due to brittle fracture of carbon steel from a small release of cold liquefied gas. It is suggested that baffles on the tank roof would reduce this risk. It was estimated that this would reduce the total risk by 5.6%.

For the propylene storage the installation of remote isolation valves is the principal measure proposed. It was estimated that this would reduce the total risk by half. Proposals are also made for modifications to the vapour return system.

For the hydrodesulfurizer the measures proposed are minor. It is suggested that there should be monitoring of hydrogen sulfide in the control room and that the hazard of spread of DEA through the drain system be investigated.

A8.11 Critiques

As indicated, the *Rijnmond Report* itself contains its own critique in the form of a review by outside consultants and industrial comment. Much of this relates to the failure and event data, the hazard models and the injury relations and particularly to the models.

A8.12 Notation

n_h	number of weeks off for holidays, sickness, etc.
N_d	number of persons on site during day
N_e	number of persons on site
N_n	number of persons on site at other times

Appendix 9 Laboratories

Contents

Laboratories are an integral part of the activities of the process industries. They include not only analytical laboratories and laboratories carrying out research and development work in industry but also university teaching laboratories where future industrial managers are trained. Pilot plants are considered in Appendix 10.

Accounts of laboratories and of laboratory safety are given in *Safety in the Chemical Laboratory* by Pieters and Creighton (1957), *Safety in University Laboratories* by the AUT (1967), *Hazards in the Chemical Laboratory* by Muir (1971) and later Bretherick (1999, 2000), *Handbook of Laboratory Safety* by Steere (1971), *A Guide to Laboratory Design* by Everett and Hughes (1975), *Prudent Practices for Handling Hazardous Chemicals in Laboratories* by NRC Staff (1981), *Introduction to Safety in the Chemical Laboratory* by N.T. Freeman and Whitehead (1982), *Handbook of Laboratory Waste Disposal* by Pitt and Pitt (1985), *Improving Safety in the Chemical Laboratory* by J.A. Young (1987a) and *Safety in Chemical Engineering Research and Development* by V.C. Marshall and Townsend (1991) (the IChemE *Laboratories Guide*).

A *Code of Practice for Chemical Laboratories* (the RIC *Laboratories Code*) has been published by the Royal Institute of Chemistry (RIC) (1976).

Activities in a chemical laboratory are distinguished from those on an industrial plant, above all, by their small scale. The smaller quantities of species in the laboratory can reduce the overall consequence of an event. In addition, heat losses are relatively greater at the laboratory scale. This certainly reduces the hazards. There are, however, factors which may increase the risk of a hazardous initial event, such as the use of inexperienced and untrained personnel, and of escalation of that event, such as the enclosed space and the close proximity of personnel. Further, if the small scale of the hazard leads to general complacency and poor practice, the risk that it will be realized is augmented.

Despite the lesser scale of the hazard, the approach to hazard control used for full-scale plants is applicable in large part to activities in the chemical laboratory. An accident in the laboratory can give rise to considerable personal injury or loss of life and direct damage loss, because the density of personnel and of expensive equipment which are at risk is relatively high. There may also be serious consequential loss due to interruption of the facilities which the laboratory provides for production plants or of research and development activities.

Moreover, where a laboratory, whether in the university, government, or industry, has a training function, it is essential to adhere to, and instill, good practice in hazard control.

Many of these topics touched on here have already been discussed, albeit not specifically in relation to laboratories, in previous chapters, in particular those on legislation (Chapter 3), management and management systems (Chapter 6), hazard identification (Chapter 8), reactive hazards (Chapter 33), process design (Chapter 11), fire, explosion and toxic release (Chapters 16–18), personal safety (Chapter 25) and safety systems (Chapter 28).

Selected references on laboratory safety are given in Table A9.1.

A9.1 Legal Requirements

In the United Kingdom the Factories Act 1961 covers industrial workplaces, including laboratories, while the HSWA 1974 applies to all places of work and thus extends coverage to university as well as industrial laboratories.

Chapter 3 gives an account of these acts and also of other legislation relevant to laboratories such as that on the workplace, including management, work equipment and incident reporting; pressure systems; toxic substances and occupational hygiene; flammable and explosive materials; fire; ionizing radiations; electricity; and personal safety, including safety signs, machine guarding, compressed air and compressed gases, manual handling, protective equipment, eye protection and first aid.

A review of legislation applicable to chemical engineering laboratories is given in the IChemE *Laboratories Guide*.

A9.2 Laboratory Management Systems

The management approach used for the control of hazards in industry is in large part applicable in chemical laboratories. In particular, use should be made of formal systems and procedures as described in Chapter 6.

The laboratory should have a management system with suitable organization and competent people, systems and procedures, standards and codes of practice, and documentation. There should be a clear chain of command and separation of executive from advisory, or staff functions. There should be a safety officer and a safety committee, and safety audits should be conducted.

Some principal systems are described below, and others in later sections.

A9.2.1 Hazard reviews

There should be a system of hazard reviews for experimental work. A review should give a statement of the hazards involved and of the means by which they will be controlled.

A9.2.2 Permit systems

Hazardous activities should be covered by a permit system. Permits may be required for general maintenance activities, for hot work and for vessel entry. The IChemE *Guide* gives example permit forms.

A9.2.3 Incident reporting

There should be a system for the reporting of incidents. As a minimum this should meet the legal requirements given in RIDDOR (1985), but in addition there should be a general requirement for the reporting of unintended events.

A9.2.4 Safety audits

The system of safety audits should cover the management systems for the laboratory, the equipment, the services, storage and waste disposal, and the operations.

The conduct of safety audits is discussed in the IChemE *Guide* and by Bretherick (2000) and J.A. Young (1987b).

A9.3 Laboratory Personnel

There tend to be wide variations in the capability of the personnel who work in laboratories, ranging from well-trained and experienced permanent staff to relatively inexperienced research workers and students. A discussion of people in laboratories is given by Buttolph (1980 LPB 32).

A9.3.1 Training

It follows from the above that for laboratory personnel training assumes particular importance. This training needs to cover the hazards, the equipment, the procedures and the systems. As with all training, it should aim to motivate as well as to inform.

Personnel who use the laboratory should be trained in good laboratory practice. The training should include such aspects as action to take in case of fire and other accidents, methods of eye irrigation and use of fire extinguishers.

The laboratory should have the appropriate number of persons trained in first aid.

Where the personnel concerned are prospective managers of industrial plants, experience in a well-conducted laboratory provides a good foundation.

Accounts of the content of, and techniques for, laboratory training are given by Bretherick (2000), Armour (1987) and Redden (1987).

A9.4 Laboratory Codes

A9.4.1 RIC *Laboratories Code*

The RIC *Laboratories Code* covers the following aspects:

(1) Laboratory services
  (a) electricity
  (b) gas for heating
  (c) water
  (d) steam
  (e) ventilation
  (f) compressed air
  (g) brine circulation
  (h) hot plates, ovens and furnaces
  (i) drainage
(2) Hazardous chemicals
  (a) flammable substances
  (b) explosive substances and mixtures
  (c) corrosive chemicals
  (d) irritant chemicals, dusts, gases and vapours
  (e) toxic chemicals
  (f) radiation and radioactive materials
  (g) cylindered gases
  (h) cryogenic fluids and systems
(3) Hazardous techniques
  (a) pressure reactions
  (b) vacuum techniques
  (c) glass handling
  (d) heating of chemical apparatus
  (e) centrifugation
(4) Organization
  (a) safety officers and safety committees
  (b) appointment and functions of a safety committee
  (c) fire prevention
  (d) personal protection
  (e) rescue
  (f) first aid and medical services
  (g) housekeeping and safety audits
  (h) labelling
  (i) storage
  (j) waste disposal
  (k) noise
  (l) unattended experiments and working alone
  (m) documentation of procedures
(5) Legal responsibility
  (a) legal responsibility
  (b) legislation

A9.4.2 NFPA 45

Guidance on fire protection is available in NFPA 45: 1986 *Fire Protection for Laboratories using Chemicals*.

The standard covers (1) general topics, (2) laboratory unit hazard classification, (3) laboratory unit design and construction, (4) fire protection, (5) explosion hazard protection, (6) laboratory ventilating systems and hood requirements, (7) chemical storage, handling and waste disposal, (8) compressed and liquefied gases, (9) laboratory operations and apparatus and (10) hazard identification.

The classification divides laboratories into high, intermediate and low hazard according to the maximum densities of materials held. For flammable or combustible liquids Class I, II or IIIA, these densities are

Laboratory unit class	*Flammable or combustible liquid class*	*Maximum quantity/ $100ft^2$ of unit* (US gal)	
		Excluding storage	*Including storage [format]*
A High hazard	I	10	20
	I, II and IIIA	20	40
B Intermediate hazard	I	5	10
	I, II and IIIA	10	20
C Low hazard	I	2	4
	I, II and IIIA	4	8

The storage referred to is storage in cabinets and cans. The standard states that Class A laboratory units should not be used as instructional laboratories and that for Class B and C instructional laboratories the maximum quantities should be half those given above.

An account of the use of NFPA 45 in laboratory design is given by Le, Santay and Zabrenski (1988).

A9.4.3 IChemE *Laboratories Guide*

The IChemE *Laboratories Guide* has the following coverage: (1) introduction, (2) safety management of laboratories, (3) the law and process laboratories, (4) hazards in chemical engineering laboratories, (5) designing process research and development facilities, (6) services, (7) storage of materials and disposal of waste, (8) design of experiments, (9) operating procedures and safety, (10) emergency procedures, (11) maintenance and modifications and (12) relevant publications.

A9.5 Laboratory Hazards

Reviews of hazards in chemical laboratories are given in the RIC *Code* and the IChemE *Guide* and in most texts of laboratory safety such as those of Steere (1971), Bretherick (2000) and J.A. Young (1987a). The list quoted from the RIC *Code* in Section A9.4 is typical.

In addition to the specific treatments mentioned below, a general account of the handling of hazardous research chemicals is given by Prokopetz and Walters (1987) and one of hazards other than those from chemicals by Bulloff (1987).

Further treatments of the hazards of flammable substances are given in Chapter 16, of toxic substances in Chapter 18 and of others such as radiation, electrical and mechanical hazards in Chapter 25.

A review of the causes of incidents in laboratories is given by J.A. Young (1987c), who utilizes the following headings: (1) management responsibilities inadequate, (2) lack of communication, (3) lack of personal responsibility, (4) lack of proper ventilation, (5) lack of protective equipment, (6) personal hygiene problems, (7) electrical hazards, (8) storage problems and (9) inadequate emergency procedures and equipment.

A9.5.1 Reactive substances

Where reactive substances are handled or processed, every effort should be made to obtain the fullest information on their behaviour. Texts such as *Handbook of Reactive Chemical Hazards* by Bretherick (2000) , Sax's *Dangerous Properties of Industrial Materials* (2000), and *Hazardous Chemicals Handbook* by Carson and Mumford (1994) are an essential point of departure.

Bretherick (2000) has also provided a review of chemical reactivity in the laboratory context.

A9.5.2 Flammable substances

Many of the liquids and gases handled in laboratories are flammable. Each phase presents its characteristic hazards.

Accounts of the hazards of flammable and combustible materials are given in the various NFPA codes, including for laboratories NFPA 45 and by Steere (1971), Bretherick (2000) and Gerlach (1987).

Where flammable liquids are handled, one hazard is release followed by ignition. Factors which need to be considered are the integrity of the containment, the flow of liquid if it does escape and any sources of ignition.

Another hazard is overheating of the liquid, leading to its escape, either as a liquid following failure of the containment or as vapour from an open vent.

A frequent cause of bench fires is loss, or under-circulation, of cooling water.

Flammable liquids should not be handled near, or heated on, naked flames and should also be kept away from arcing/sparking devices.

Where flammable gases or vapours are handled, the most common hazard is a leak which allows a flammable atmosphere to build up in the enclosed laboratory space. Unless there is a high level of ventilation, this can occur even with a relatively small leak rate.

Another cause of bench fires is contact between water and reactive metals such as sodium.

Oxygen should not be used in such a way as to create the hazard of an oxygen-enriched atmosphere. Oxygen is liable to oxidize and then rupture rubber tubing. There is also the possibility of an 'oxygen fire' in which the metal can be ignited (arising, for example, from adiabatic compression, particularly in non oil-free lines as described in NFPA 53).

A9.5.3 Toxic substances

Where toxic substances are handled, it is necessary to consider all three modes of entry into the body and both short- and long-term toxic effects.

For entry, inhalation may well be the principal mode, but in laboratory work in which chemicals are 'handled' to a much greater extent the ingestion and skin modes may be more significant than is usually the case. High standards of hygiene therefore assume greater importance.

With regard to inhalation, there may be a hazardous short-term effect if the substance is highly toxic and circumstances can be foreseen in which a concentration sufficiently high to cause acute poisoning can occur. This is rather more likely in the enclosed space of a laboratory.

More commonly, however, the hazard arises from exposure to low concentrations over a relatively long period.

Where a toxic hazard exists, the requirements of the Control of Substance Hazardous to Health (COSHH) Regulations 1988 apply.

The design countermeasures are primarily a high standard of containment. Other measures are described in the next section.

Accounts of the effects of toxic chemicals in the laboratory context are given by Steere (1971), Bretherick (2000) and Springer (1987).

A9.5.4 Radiation hazards

There are a variety of radiation hazards, most of which may be found on occasion in laboratories. They include both ionizing and non-ionizing radiations as described in Chapter 25.

With regard to ionizing radiation, some devices containing radioactive sources instanced in the IChemE *Guide* are certain liquid level gauges, gas chromatograph detectors, leakage detectors, anti-static devices on balances, and fire detectors.

Certain apparatus producing voltages above 5 kV may be a source of X-rays.

Non-ionizing radiation sources include lasers, microwaves and UV and IR devices.

A9.5.5 Electrical hazards

The electrical hazards are little different from those in industrial situations generally, but unless good practice is observed a laboratory tends to be especially vulnerable to them.

Personnel may be at risk of electrocution from temporary lashups and repairs, defective and damaged cabling, unearthed components and poor earthing. This may be aggravated by handling equipment with wet hands.

Short circuits due to worn cabling, wrong wiring or over-rated fuses can lead to a fire.

A9.5.6 Mechanical hazards

The mechanical hazards likewise are such as may be found in other industrial situations, but again laboratory personnel may be especially vulnerable unless strict controls are observed.

These mechanical hazards include those associated with rig equipment, workshop machinery, hand and power tools, lifting equipment, rotating equipment, and pinching equipment.

Accidents are liable to occur where laboratory personnel use equipment with which they are unfamiliar in order to progress the job.

A9.5.7 Operating condition hazards

Equipment operating at high or low temperature constitutes a contact hazard. Contact with a very cold surface can cause a ‘cold burn’ not unlike the burn from a very hot surface.

A cryogenic fluid also involves the hazard that it will vaporize by heat transfer from the atmosphere unless this is positively prevented. Depending on the nature of the fluid, such vaporization may give rise to an atmosphere enriched with a flammable or toxic material or oxygen.

A laboratory usually contains a number of sources of high pressure such as compressed air, steam, compressed gas in cylinders and so on. Water also may act as a high pressure source. Rupture of equipment may occur either because the pressure to which it is subjected is above the design conditions, or because the equipment is weaker than designed. Overpressure can occur if a valve is open or fails, weakening if metal equipment is exposed to extremes of heat, cold or thermal cycling.

Failure may also be caused by vacuum, which may occur not just by connection to a vacuum supply but by rapid cooling of a vapour in the apparatus.

Rupture by a pressurized vapour/gas or by a superheated liquid, however, would have more severe consequences than by a subcooled liquid.

A9.5.8 Water release hazards

Another hazard is the escape of water, particularly in the form of a jet. Some potential effects of such a jet are short circuiting, thermal shock, extinction of gas jets and reaction with water-reactive chemicals.

A9.6 Laboratory Design

Laboratory design and layout is discussed in the IChemE *Guide* and by Steere (1971), Everett and Hughes (1975) and Baum and Diberardinis (1987).

A checklist for laboratory design is given by Everett (1980 LPB 32) and a case study in such design by Martin (1980 LPB 32).

A9.6.1 Laboratory layout

The design and layout of a laboratory should proceed on principles broadly similar to those described in Chapter 10. This is the approach taken in the IChemE *Guide*.

The method described in the guide is to analyse the needs of the experimental activities using a flow diagram showing the flow of materials between the experimental rigs, the workshops, stores, analytical services, waste disposal facilities, etc., and to develop layout diagrams in which the low and high hazard features are separated, with minimization of exposure near the latter.

A9.6.2 Toxic chemicals

The hazard from toxic chemicals has been described in the previous section.

Where toxic chemicals are handled, the design should aim to keep the concentrations in the laboratory environment below the relevant exposure limits. The prime means of ensuring this is to prevent leaks through a high standard of containment.

For toxic chemicals the COSHH Regulations 1988 apply as described in Chapter 25. These regulations include provisions for monitoring the workplace atmosphere.

Means of keeping down the concentration of contaminants which do escape include use of ventilation and of fume hoods.

A9.6.3 Ventilation

The most common method of controlling the concentration of contaminants in the workplace is ventilation. The basic methods are local exhaust ventilation and general ventilation. Ventilation of the workplace is described in Chapter 25.

The exhaust from the ventilation should pass to a safe place (e.g. away from air intakes).

A9.6.4 Fume hoods

For some toxic or noxious chemicals use is made of a fume cupboard. An account of fume hoods is given in Chapter 25.

The resort to fume hoods has been criticized, however, by V.C. Marshall (1981 LPB 37) as outmoded. He argues that in the laboratory the release of noxious chemicals has become too readily accepted. The proper approach is higher standards of containment which avoid such emissions.

A9.6.5 Laboratory support

There are a number of facilities which may be needed to support the laboratory. They include (1) workshop, (2) stores, (3) receipt bays, (4) analytical services and (5) staff facilities. These are essentially self-explanatory.

The storage needs should be examined to identify the extent to which segregation is required. It is normal to devote one store to the materials required for the fabrication of rigs and another to process materials such as flammable and toxic liquids, but further segregation may be required.

The IChemE *Guide* suggests, for example, that separate stores are normally required for solvents, different classes of chemicals, explosives, gas cylinders and cryogenic materials.

Eating and drinking should not be permitted in laboratories. There need to be adequate staff facilities provided.

A9.7 Laboratory Equipment

A9.7.1 Glassware

Much laboratory apparatus is constructed in glass. Glass has a number of advantages such as resistance to corrosion, flexibility in use and visibility of contents. It can be used with a high degree of safety. For this it is necessary that its limitations be respected, that it be used only in suitable applications and that manufacturers guidance be consulted.

A9.7.2 Hotplates, ovens and furnaces

Hotplates, ovens and furnaces involve the hazard that an item being heated, or the heating element itself, becomes overheated.

The use of ovens is frequently not subject to the same degree of formal control as other apparatus, and different people may put in items which are incompatible or may alter the controls, with undesirable results.

A9.7.3 Centrifuges

Laboratory centrifuges are a recognized hazard. They are the subject of BS 4402: 1982 *Specification for Safety Requirements for Laboratory Centrifuges* and are treated in Appendix 6 of the IChemE *Guide*. This is in addition to BS 767 and a further IChemE guide both of which apply to industrial centrifuges.

A laboratory centrifuge should be properly balanced. The buckets should be well fitting and with rubber pads in place. The machine should be cleaned and dried after use to prevent corrosion which is a common cause of mechanical failure.

In use the lid should be closed and locking devices secured before start-up. The machine should be brought up to speed gradually. It should be stopped using the controls, not simply switched off. The lid should not be opened until the machine has come to rest.

Centrifuges are discussed further in Chapter 11.

A9.8 Laboratory Services

Laboratories use a wide range of services. The most common are (1) water, (2) steam, (3) compressed air, (4) fuel gas and (5) electrical power. Others include refrigerated coolants, vacuum, oxygen and other piped gases.

A9.8.1 Water

Water is used as process water and as coolant.

Where the cooling load is larger enough to justify it, an external cooling water system may be provided which is a smaller-scale version of an industrial system with the water pumped through cooling towers.

The use of water in laboratories involves several hazards. The first is the potential for reverse flow of liquid from a laboratory process into a water supply main. Where such a possibility exists, some safeguard is required. A break tank provides a barrier more dependable than a non-return valve.

Another hazard is loss of cooling water. Generally this occurs on a single rig due to a leak at that point.

A third hazard is the escape of water into the laboratory. A typical situation might be failure of a cooling water connection on apparatus in a fume hood where the drains are blocked, so that the water flows into the laboratory. If the equipment is running unattended, a large quantity of water can escape, perhaps damaging equipment such as computers on the floor below.

There is often a requirement for demineralized water, which is supplied by a stand-alone unit.

A9.8.2 Steam

Steam is required in the laboratory for heating on larger rigs. It is typically provided by an external boiler system, but for small quantities may be generated by a small electrically heated, or less commonly, gas-fired, unit.

The pressure of steam for laboratories is typically in the range 4–10 barg. Measures should be taken to ensure that equipment supplied with such steam cannot be overpressured and that, where loss of coolant with steam still on could be hazardous, steam is shut off.

The use of steam implies the use of steam traps. These devices need regular maintenance.

A9.8.3 Compressed air

Compressed air for laboratories is generally provided by a fixed piped system supplied from an external air receiver charged by a compressor.

The air should be free of oil, which may be achieved either by use of an oil-free compressor or by oil-removal equipment. Regular maintenance is required for the latter.

Compressed air is potentially hazardous and the supply pressure should be limited to that required for the purposes of the laboratory.

Like steam, compressed air is a potential source of overpressure and measures are needed to safeguard against this.

A9.8.4 Fuel gas

Fuel gas is another service which is usually provided in a laboratory by a fixed pipe system.

A9.8.5 Refrigerated coolants

Cooling to lower temperature that can be achieved by cooling water may be provided using refrigeration, either by circulation of a refrigerant or by the use of an intermediate fluid such as brine or ethylene glycol.

The normal practice is to house the refrigeration set in a separate room.

A9.8.6 Vacuum

In some laboratories a piped system is provided to supply vacuum. Collapse of equipment under vacuum is not unlike an explosion and may generate missiles. Measures are required to ensure that equipment connected to vacuum is not under pressure. Also, backflow prevention should be installed.

A9.8.7 Oxygen

Another gas which may be provided as a fixed piped supply is oxygen, but where this is done special care is needed.

Hazards arising from the use of oxygen are attack and rupture of rubber tubing and creation of an oxygen-enriched atmosphere, which can result in a dramatic enhancement of the flammability of clothing.

A9.8.8 Other piped gases

Laboratory requirements for gases other than air vary greatly. In principle, where the usage is high, a fixed piped system has the very considerable advantage of eliminating the use of temporary facilities. However, frequently what is required is moderate quantities of a relatively large number of gases, so that a piped supply for any one is difficult to justify. In some instances pipes are used for different gases, with suitable precautions.

Where a piped supply is installed, the gas is usually piped from gas cylinders located at a protected shelter on the outside of the building.

Piped systems for hydrogen require special care.

Lines should be carefully labelled and flow restrictors should be installed.

A9.8.9 Compressed gas cylinders

For the reasons just given, supply of many of the gases used is often taken from gas cylinders brought into the laboratory. The use of gas cylinders requires a number of precautions.

The contents of the cylinder should be identified by labelling and colour coding. In use the cylinder should be fitted with a regulator and both valve and regulator should be kept clean and free of grease and oil. The valve should be closed when the cylinder is not in use. The cylinder should be transported in a wheeled carrier and when in use supported in a vertical position.

A more detailed treatment of precautions in the use of gas cylinders is given in Appendix 4 of the IChemE *Guide*.

Cylinders should be secured (e.g. with chains) when in use or transported.

A9.9 Laboratory Storage and Waste Disposal

A9.9.1 Materials storage

The storage of materials for the laboratory is discussed in the IChemE *Guide* and by Steere (1971), Bretherick (2000) and Williamson and Kingsley (1987).

The main inventory of hazardous chemicals is, or should be, in the chemical storage locations. General principles governing such storage concern (1) segregation of incompatible materials, (2) types of containers, (3) receipt points, (4) acquisition, stock-taking and disposal, (5) minimization of inventory and (6) identification, ownership, safety and health information and labelling.

With regard to segregation, some relevant categories of chemical are (1) flammables, (2) toxics, (3) oxidizing agents, (4) corrosive substances, including strong acids and alkalis, (5) cryogenic substances and (6) pyrophoric substances. Toxics should be segregated from flammables and oxidizing agents from flammables, organic chemicals, reducing or dehydrating agents. Categories which should be held in separate stores include corrosive substances, cryogenic substances and pyrophoric substances.

Types of container used are small containers, large containers, bulk containers and gas cylinders. Aspects of good practice with small containers include the use of bottle carriers, non-spill containers and controlled dispensing. Good practice in the storage of large containers, essentially drums, and bulk containers is discussed in Chapter 22.

The receipt points for chemicals should be designed to facilitate handling of incoming loads. Vehicles carrying gas cylinders generally have their own lifting gear, but those carrying drums often do not.

The control of materials in storage is exercised through the processes of acquisition, stock-taking and disposal. It is common for an experimenter to order an appreciable quantity of a chemical, use only a portion of it and then forget about it. Unless close control is exercised, there can build up in the stores, a large quantity of chemicals, much without ‘ownership’. It is necessary to keep the situation under control by taking stock periodically and by disposal of unwanted material.

Closely connected with this is the minimization of inventory. The inventory held in the laboratory itself and in storage should be the minimum necessary.

The number of chemicals used in a laboratory can be large and the conditions of use very varied. It is essential to ensure that all materials are identified and labelled. There should be a materials safety data sheet for each chemical. Reale and Young (1987) give an account of labelling and MSDSs in the laboratory context.

The Poison Rules 1982 give in Schedule 1 a list of substances which must be stored in a locked cupboard under the supervision of a registered keeper and the usage of which must be entered in a register.

A9.9.2 Waste disposal

A laboratory usually generates gaseous, liquid and solid wastes, all of which need to be disposed of. The problems of waste disposal are not trivial and have become increasingly severe as environmental standards have risen.

Accounts of this aspect are given in *Handbook of Laboratory Waste Disposal* by Pitt and Pitt (1985), in the IChemE *Guide* and by Steere (1971), Bretherick (2000) and Varnerin (1987).

A distinction is generally made between domestic and chemical wastes. The former category includes paper and broken glass. The latter should be segregated both from paper and from unbroken bottles.

Flammable solvents generally constitute a large proportion of the chemical wastes. Other liquids which are incompatible with such solvents should be collected separately. Separate collection is also required for oil-soaked rags. On no account should chemical wastes be put down the drains.

Separate, clearly labelled receptacles are required for each category of waste. For some categories, such as for flammable solvents, receptacles with appropriate safety features should be used.

Options for the disposal of laboratory wastes are listed by Pitt and Pitt, who give some 13 choices, although many are applicable only to small quantities.

The disposal of wastes has to be formally managed by identifying disposals and obtaining the necessary licenses.

Specialist contractors are used by most laboratories for disposal of at least some of their wastes. This is one of the options discussed by Pitt and Pitt.

A9.10 Laboratory Operation

A9.10.1 Information requirements

It is essential to have the fullest information on the chemicals being handled and on the associated hazards. This applies particularly to chemicals which are highly reactive or which have toxic effects at low concentrations over long periods. Sources of such information are discussed in Chapter 33.

A9.10.2 Design of experiments

Laboratory experiments are undertaken for different purposes and these necessarily influence their design.

In all cases inherently safer design should be a prime aim, but the extent to which it can be achieved will vary. Facets of inherent safety include scale, operating conditions and materials. Where the objective is the pedagogical one of demonstrating a principle, it may be possible to operate on a small scale, at atmospheric pressure and temperature and using less hazardous materials such as air, water and inert solids.

The purpose of the experiment should be well defined. The experiment should not be too ambitious, and if necessary should progress in stages. Information on the materials handled and their potential hazards should be as complete as practical. The basis of safety should be defined. The design should cover the equipment and its operation, and should meet applicable standards and codes.

The design should be subject to a hazard review, utilizing hazard identification techniques such as checklists and hazop studies (covered in A9.10.3.).

Laboratory equipment should be fit for purpose. The standard of construction of the apparatus should match the degree of hazard and its expected life.

It is not uncommon to build a 'temporary' rig with connections made to certain services by hose rather than by fixed piping. If this is accepted in certain applications, care is still needed to ensure that the practice does not extend to unsuitable cases or to operation over extended periods.

Another common practice is the use in a new experiment of a rig 'inherited' from an earlier one. The suitability of the equipment for the new purpose needs careful scrutiny.

For critical features consideration should be given to the provision of automatic protective devices. Trips may be required to guard against loss of cooling, excessive heating, and deviations of pressure, temperature, flow, level and composition.

Full instructions should be prepared for operating procedures and emergency procedures. Consideration should be given to the requirements of unattended operation if this is planned.

Certain activities require special enclosures. These include the use of a fume hood where the materials are toxic and of explosion cubicles where the process involves hazardous reactions or high pressures.

The planning of safe experiments is discussed by Fowler (1989 LPB 32).

A9.10.3 Hazard assessment

If an experiment has the potential to cause serious injury, it is important to carry out a hazard assessment. Case studies of the application of hazard assessment in the laboratory have been described by Le, Santay and Zabrenski (1988).

One example given is a review of the situations involving release of toxic gas sufficient to pose an acute toxic threat. The gases in question were arsine, diborane and phosphine, all in hydrogen. A tabulation was made of the various release scenarios, showing the expected toxic loads and candidate scenarios were then investigated. Fault tree analysis was used to determine the failure paths.

Another case study described by these authors involved fault tree analysis where the top event considered was the formation of a detonable hydrogen–air mixture from a gas phase reactor system.

A9.10.4 COSHH assessment

A COSHH assessment should be made for any laboratory activity which attracts such an assessment under the COSHH Regulations 1988, as described in Chapter 18.

A9.10.5 Operating procedures

Operating procedures may be classified in two ways. One distinction is between general laboratory procedures and procedures specific to a particular rig. Another is between those which concern safety and those which do not.

For the laboratory as a whole, general operating instructions relating to safety are usually set down in a laboratory safety manual.

For the particular rig, it is advisable to separate the procedures which have safety implications from those which do not. Where operating instructions are imported, as with equipment bought from a manufacturer, it may be necessary to rewrite them, abstracting the safety-related parts.

The operating instructions for a rig should cover start-up, running and shut-down, and should indicate the hazards and the countermeasures to be taken. They should not duplicate the general instructions. They should be clear and simple, and should be as concise as possible.

A9.10.6 Emergency procedures

The operating procedures for each rig should cover action to be taken in the event of an emergency (1) on that rig and (2) in the laboratory as a whole.

It is an accepted principle that a laboratory fire should be fought if it can be done without undue risk. The same principle may be extended to other actions in an emergency which threatens to escalate.

Emergency planning is discussed in Section A9.12.

A9.10.7 Equipment maintenance

The general approach to maintenance of equipment in a laboratory is similar to that in a plant. It involves identification of the equipment to be worked on; planning of the work and shut-down of the equipment; electrical and mechanical isolation of the equipment and preparation for the work by removing fluids and solids and by cleaning. The principles are as outlined in Chapter 21.

A9.10.8 Equipment and procedure modification

Similarly, control should be exercised over modifications to the equipment or the activities, analogous to those over equipment and process modification in a full-scale plant described in Chapter 21.

The IChemE *Laboratories Guide* gives detailed guidance on what, in a laboratory context, constitutes a modification and contains in Appendix 14 a specimen form for control of modifications.

A9.10.9 Permit systems

The scope of the permit system, defining which activities need to be so covered and which do not, should generally be agreed between the laboratory superintendent and the rig supervisor.

The activities which require permits and the parties responsible for issuing and receiving them should be listed in the general laboratory instructions or the rig instructions.

Hazardous activities such as maintenance and vessel entry should be covered by a permit system. The principles are similar to those for an industrial plant as described in Chapter 21 .

One of these principles is formal handover from operations to maintenance personnel and then handback in the reverse direction. In a laboratory these responsibilities may sometimes be less clear than in a plant and, as just stated, they need therefore to be clearly defined. The effectiveness of the permit system depends on formal observance of such handovers.

A9.10.10 Housekeeping

There should be a high standard of housekeeping. Facilities should be provided for disposal of broken glass and of waste materials. Equipment not in use should be removed or arranged tidily. Spillages should be cleaned up at once. Orderly sample storage with minimal retention should be maintained; glassware/equipment cleaning should be carried out.

A9.10.11 Out-of-hours working

Personnel working out of normal work hours should be required to sign in and sign out.

Working alone in the laboratory should be permitted only where the hazard is low and is best kept to a minimum. Anyone who does work alone should be in contact with, or should be visited by, the security guard at regular intervals.

A9.10.12 Unattended operation

Unattended operation of equipment may present a hazard, especially if flammable or toxic materials are involved. There will be some experiments where such operation is not permissible. When unattended operation is practiced, arrangements should be made for the apparatus to be visited by a trained security guard, who should be given full instructions on the action to be taken in case of accident or doubt and should be able to make telephone contact with the experimenter.

A9.10.13 Access

Access to the laboratory should be subject to control and unauthorized persons should be excluded. The extent of the measures necessary depends on the nature of the hazards and the confidentiality of the work.

A9.11 Laboratory Fire and Explosion Protection

A9.11.1 Fire protection

The laboratory should be designed for fire protection, in accordance with building and fire protection codes and with advice from the fire authorities.

Some basic elements of design for fire protection include the fire resistance of the laboratory envelope, including doors; internal layout; hazardous area classification; mechanical ventilation and a fire alarm system.

It is desirable that there be constructional features with a minimum fire resistance between the laboratory and any adjoining section of the building and that the doors meet a fire resistant standard. Measures should be taken to prevent fire spread through openings in walls and voids in the roof.

It should be a principal aim of the laboratory layout to minimize both the occurrence and escalation of fire.

Hazardous area classification should be applied to effect control of ignition sources. It is suggested in the IChemE *Guide* that for a well-ventilated laboratory classification as Zone 2 should be sufficient. The guide states that ideally the whole space should be so classified, but if this is not practical, the Zone 2 should extend at least 2 m around any potential leak source.

The risk of buildup of a flammable atmosphere may be minimized by the use of mechanical ventilation. The guide recommends that where flammable liquids are in use, the ventilation fan should be operated for the period of use and for 5 min thereafter. (Use of a flammable storage cabinet may be appropriate. Also, labs with fire risk may need to require workers/visitors to use Flame Retardant Clothing.)

There should be a fire alarm system with alarm points inside the exits and at other strategic points.

A9.11.2 Fire fighting

The laboratory should be equipped with suitable fire extinguishers, fire blankets, etc. An account of fire extinguishers in general is given in Chapter 16 and in the laboratory context in the IChemE *Guide*.

A9.11.3 Explosion protection

Where there is to be operation of equipment such as an experimental reactor with a significant risk of vessel rupture, a separate cubicle should be provided in which the work can be conducted. Such arrangements are perhaps more commonly found in pilot plants, but may find place in a laboratory.

The cubicle should be designed to contain both blast and missiles. Accounts of such explosion-proof cells are given in Chapter 17 and Appendix 10.

A9.12 Emergency Planning

Emergency planning should be undertaken to identify the potential causes and types of emergencies and their consequences, and the countermeasures required. The principles are similar to those outlined in Chapter 24.

Planning should cover not only the laboratory and the rigs but also storages and services. The plan should be formulated by conducting audits during design and at commissioning and should be updated by audits at regular intervals thereafter.

The purposes of emergency planning are to protect life and property. They are achieved by early recognition of the problem, rapid raising of the alarm and prompt action to bring the incident under control and to separate the people from the hazard.

Functions which need to be performed in an emergency are to deal with the emergency, to evacuate people and to liaise with the emergency services. The personnel who will perform these functions should be identified and their tasks defined.

The range of situations in laboratories tends to be particularly wide and the emergency plan should aim for flexibility.

Laboratory personnel responsible for emergency response should understand the statutory duties and likely priorities and needs of the external services.

There are certain typical problems faced by the external fire services coming into laboratory situations. Steps should be taken to find out what information the fire brigade is likely to need and to ensure as far as is practical that it can be provided. This means having the information available and appointing someone to communicate it in the actual event. Frequently fire brigades are hampered by hazards from gas cylinders and radioactive materials and by lack of information on the chemicals present and their hazards.

There should be regular fire drills, including joint exercises with the external services.

A detailed account of laboratory emergency planning is given in the IChemE *Guide*.

Appendix 10

Pilot Plants

Contents

Pilot plants are intermediate in scale between the laboratory bench and the full-scale plant. They are used for a variety of purposes, essentially to obtain information on process design and operation and on products, including information relevant to safety. Some hazards are liable to show up first at the pilot plant stage and the pilot plant is therefore an important tool for hazard identification, as described in Chapter 8. Here consideration is given to the more general aspects of pilot plants and particularly to their characteristic features and hazards, and to safety in pilot plants.

Accounts of pilot plants are given in *Pilot Plants, Models and Scale-Up Methods in Chemical Engineering* by Johnstone and Thring (1957), *The Chemical Plant from Process Selection to Commercial Operation* by Landau (1967), *Chemical Process Development* by D.G. Jordan (1968) and *Pilot Plant Design, Construction and Operation* by Palluzzi (1992) and by Constan (1984), Carr (1988), Dore (1988), Palluzzi (1989, 1990, 1991), Lesins and Moritz (1991), J. Jones *et al.* (1993a,b) and Lo and Oakes (1993). Safety is treated in the *Pilot Plant Safety Manual* by the AIChE (1972/33) and by Kohlbrand (1985), Siminski (1987), Carr (1988), Dore (1988), Capraro and Strickland (1989), Carson and Mumford (1989 LPB 89, 90), Constan, Herman and Moeller (1992) and Palluzzi (1992).

A number of authors on pilot plants give checklists, often as tables. These checklists include the following: justification for use (J. Jones *et al.,* 1993b); overall programme (Lesins and Moritz, 1991; J. Jones *et al.,* 1993a); chemical and process information (Dore, 1988); scale-up issues (Lo and Oakes, 1993); project review (J. Jones *et al.,* 1993a); flowsheet review (Lesins and Moritz, 1991); hazards (Dore, 1988); hazard identification—what-if review (Lesins and Moritz, 1991); plant construction (Dore, 1988); staffing requirements (J. Jones *et al.,* 1993a); operating and safety aspects (Dore, 1988); operating manual (J. Jones *et al.,* 1993a); operator training manual (Chaty, 1985) and computer control systems (J. Jones *et al.,* 1993a). Many of the entries in the AIChE *Pilot Plant Safety Manual* may be used as checklists for pilot plant safety.

In general, the principles of laboratory safety, discussed in Appendix 9, are applicable to pilot plants also.

Selected references on pilot plants are given in Table A10.1.

A10.1 Pilot Plant Uses, Types and Strategies

A10.1.1 Uses of pilot plants

The purposes for which pilot plants are built are the development of (1) a new product, (2) a new process or (3) an existing process. For a new product small quantities may be required for testing and for market development. For a new process information is required to prove feasibility, specify operating conditions, resolve scale-up issues, provide design data, identify problems, develop operating procedures and provide experience and training. For an existing process work may be required to check the suitability of different raw materials, improve product quality, explore modified operating conditions, improve the treatment of the effluents and effect cost reductions and other optimizations.

Frequently it is information on reaction kinetics and yield which is lacking and which the pilot plant is required to provide. Other information typically obtained from a pilot plant is data on heat and mass transfer and pressure drops; on mixing effects; on impurities, foams and emulsions; and on fouling and corrosion.

The justification for pilot plants is discussed by J. Jones *et al.* (1993a). They discuss the following situations, in increasing order of difficulty:

Process	*Product*	*Customer*
New	Existing	Existing
New	New	Existing
New	New	New

A10.1.2 Types of pilot plant

Pilot plants differ in both type and scale. There are three principal types: (1) the general-purpose pilot plant; (2) the specific-purpose pilot plant; and (3) the multi-purpose pilot plant. The merits of these different types of pilot plant are discussed by Palluzzi (1991, 1992).

Representative capacities for different scales of operation are given by J. Jones *et al.* (1993b) as follows:

Scale	*Capacity*	
	Batch	*Continuous*
Laboratory bench	0.1–1000 g	10–100 g/h
Mini-pilot plant	1–100 kg	0.1–10 kg/h
Pilot plant	100–1000 kg	10–100 kg/h
Semi-works	1000–10,000 kg	100–1000 kg/h

Some pilot plants currently in use are quite old and over the years have been modified and adapted.

Accounts of particular pilot plants include those of Chaty (1985), P. Dawson (1986), Siminski (1987), Carr (1988), Capraro and Strickland (1989) and Lesin and Moritz (1991).

A10.1.3 Strategies for development utilizing pilot plants

It need not be assumed that a pilot plant necessarily has to be designed and located in-house; there are other options. The main options are (1) design and location in-house; (2) location in-house but with design by a design contractor; (3) hiring of outside pilot plant facilities and (4) contracting out of the pilot plant work. The merits of these options are discussed by Palluzzi (1991).

A10.2 Pilot Plant Features and Hazards

While the hazards encountered on pilot plants are essentially similar to those on full-scale plants, the characteristics of pilot plants are such that the hazard profile is somewhat different. The specific features and hazards of pilot plants are discussed by a number of authors, including Carr (1988) and Capraro and Strickland (1989).

Some features characteristic of pilot plants include (1) gaps in knowledge; (2) novelty of chemicals, process, equipment and operations; (3) scale effects; (4) extent of manual activities; (5) frequency of modification; (6) multiplicity of tasks; (7) materials storage and transfer; (8) flow features; (9) recycles; (10) utilities features; (11) frangible elements; (12) plant layout features; (13) location in a building and (14) research staff involvement.

The process reaction may involve a number of potential hazards. Most frequently mentioned is the unidentified reaction exotherm, which could lead to a reaction runaway. There should be a formal system of screening to identify any exotherms. However, this is by no means the only hazard which may be present. The raw materials may contain impurities. The ratio and flow rate of the reactants may vary. There may be inhomogeneities due to poor mixing which affect reaction rate and temperature measurement. Features of the reaction such as induction time may assume greater significance. The handling of the catalyst may pose problems.

There are a number of equipment problems which can occur on pilot plants. One is the use of unfamiliar equipment. Another is the reactivation of idled equipment. When this is in prospect, a check on the integrity of the equipment is advisable; it may have been 'cannibalized'. Another problem can be the use of equipment which differs from that used on the full scale and for which, in consequence, operating procedures may be deficient. An example is an oven used by a number of different users with no formal control over its contents and settings.

A principal reason for building a pilot plant is to fill the gaps in the information necessary for the design and operation of the full-scale plant. This implies that there will be gaps also in the information which ideally would be available for the design of the pilot plant.

A pilot plant is on a scale intermediate between those of the laboratory and of the full-size plant. Relative to the laboratory, the larger scale of the pilot plant means that hazards may become apparent which were obscured at the laboratory scale. Operation on the laboratory scale has some of the features of an inherently safer design. The most obvious is the limited inventory, but there are also others such as good ventilation. In some cases the problem may be that the change in scale is accompanied by other changes, such as the use of less pure raw materials. In others it may simply be that features always present become more obvious with scale such as the need to dispose of noxious effluents. Moreover, the pilot plant is the stage at which the process is first carried out in process plant as opposed to laboratory equipment and thus the stage at which difficulties of processing, of equipment or of measurement will show up.

Relative to the full-scale plant, the smaller scale of the pilot plant is beneficial in reducing the scale of the hazard, but can lead to problems of flow control, blockage and so on.

The balance between manual and automatic functions tends to be different in a pilot plant from that on the full scale. There are several reasons for this. Foremost reasons are economics and flexibility; others include factors such as measurement problems.

It is a normal, and expected, feature of pilot plant operation that both the process and the plant are subject to frequent modification. A system for the control and documentation of modifications of both types is required, both as a record of the learning process and to assure safety.

Work in a pilot plant is liable to involve tasks which are more numerous, varied and novel features, which can increase the probability of error.

The problems of containers for materials and the identification of the materials and containers can be a significant problem in pilot plants. The number of materials used may be appreciable, creating much greater scope for error than on a regular plant. It is necessary, therefore, that raw materials, intermediates, products and effluents be fully identified. Where common containers are used, as sometimes with effluents, controls need to be established to prevent mixing of incompatible materials.

Flow problems associated with features such as highly viscous fluids, gas locks, lutes, siphons, water hammer, cavitation and so on are features commonly encountered on process plants, but it is on the pilot plant that they may be first experienced and will have to be solved.

Another feature which may well be novel at the pilot stage is recycling with its characteristic problems of positive feedback and build-up of impurities.

Some pilot plants, particularly the larger ones, are on a works site and are served by the works utilities. It is normal practice to give advance warning to the main production plants of an expected change in the status of such utilities, but the Cinderella status of the pilot plant may result in its being overlooked, and suffering unexpected loss of a utility.

Frangible pipework and vessels made of glass or plastic and other features, such as rotameters and sightglasses are common in pilot plants, and make the plant more vulnerable to damage and leaks.

Plant layout in pilot plants tends to be more congested. Such congestion can increase the risk of damage to plant or inadvertent movement of controls. An example of the latter is movement of a control such as a valve as an operator brushes against it. This danger is increased by the fact that the valve is much lighter and more readily moved than its equivalent on the full scale. Similar points apply to damage to plant, which is more vulnerable on the small scale.

In contrast to most large-scale plants, which are in the open, many pilot plants are in buildings, and this has a number of implications. There is often a more congested layout. There is an increased hazard from accumulation of gases or vapours. These may be flammable or toxic vapours, whether from open vessels or from leaks and spillages. Or they may be asphyxiant gas, such as nitrogen, or flammability-enhancing gas, such as oxygen. Likewise, there may be occupational hygiene problems because fugitive emissions disperse less readily.

Research staff involved in pilot plant work are likely to be less attuned than those familiar with plant operation to the disciplines necessary, and specific steps may need to be taken to rectify this.

A10.3 Pilot Plant Scale-up

Historically, a basic reason for the use of a pilot plant has been the difficulty of scaling up from the laboratory bench to the full scale. To a considerable extent, such scale-up is what chemical engineering is all about, and progress in the discipline has made this reason seem rather less cogent.

Despite this, operation on the pilot scale may still be desirable even in respect of fundamental features such as reactor heat transfer, mixing, runaway and venting.

However, even in terms of scale-up, there is more to pilot plant operation than the scale effects typically expressed in terms of dimensionless numbers and engineering models. As already indicated, there are other effects of scaling up such as the use of less pure raw materials; the occurrence of poor mixing; the build-up of impurities due to recycling; the need to dispose of noxious effluents; and so on.

The process of scale-up is frequently envisaged as a linear one, progressing to successively larger scales. An alternative model, however, is one in which the process is iterative, passing to and fro between the smaller and large scales.

The pilot plant stage is the first at which the process is operated in the form of a plant. It therefore provides the first opportunity to examine all those features which are new in passing from laboratory bench to plant. This is so whether the pilot plant is small or large.

A10.4 Pilot Plant Design

There are a number of features which are characteristic of, or tend to bulk large in, the design of pilot plants. Some of these are now considered.

A10.4.1 Some design objectives

The pilot plant should be utilized to design the full-scale plant using recognized engineering methods of scale-up.

The design should accommodate a sufficiently wide range of operating variables, such as pressure and temperature, to allow the effect of these variables to be determined with some confidence.

The purpose of the pilot plant is to provide information for the design of the full-scale plant. The plant should be designed and operated so as to yield information in which confidence can be placed and which is conformable to established design methods. As far as practicable, the process should be modelled and the experimental results compared with the model as they are obtained. Important features of such a model are the mass and heat balance and pressure drop relations, the reaction kinetics and the unit operations models.

A10.4.2 Design standards and codes

A particular problem in pilot plant design is the application of standards and codes. In general, these are formulated with full-scale plant in mind, and can sometimes pose difficulties for the pilot plant designer.

The standards to be applied should be declared at an early stage and any potential conflict identified, whether between different standards or between a standard and the design.

The application of standards to pilot plants is discussed by Siminski (1987), who describes the particular case of the standards covering an engine test facility. The approach which he describes is to assess the impact of standards on the safety, industrial hygiene and environmental aspects of the plant, to assess the risks and develop alternative strategies, to seek independent review and to test design concepts early on, to examine the specification to check whether features causing conflict with standards are strictly necessary, and to negotiate with the parties to achieve solutions.

A10.4.3 Flexibility and multiple use

Since the purpose of a pilot plant is to extend knowledge and deal with novel issues, it needs to be flexible. Methods of providing such flexibility are discussed by P. Dawson (1986). They include the provision of inherently flexible equipment, a range of equipments and materials of construction and a layout which groups together items which most frequently need to be connected, thus avoiding long pipe runs.

A10.4.4 Plant layout

The basic principles of plant layout apply to pilot plants also, but some features assume particular importance.

One feature just mentioned is layout to minimize the length of pipework and to ensure a convenient arrangement of principal items of equipment.

Another feature is to ensure good access, which includes both access to items of equipment but also minimization of the likelihood of inadvertent damage to plant or operation of controls as personnel move about congested passages. Closely related is minimization of damage by dropped objects.

Another feature is clear identification of equipment. One aspect is the labelling of tanks and vessels holding process materials, since misidentification of materials is an error characteristic of pilot plant operation. Another aspect is labelling and coding of equipment which may need to be worked on and which may contain noxious materials.

Another feature is provision for collecting and disposing of liquid leaks.

A fifth feature is the provision of protective barricades against missiles. In some cases this leads to a design in which the pilot plant space is divided up into separate cells.

A10.4.5 Protective barricades

If the process carried out involves high pressures, and particularly high-pressure reactions, protective barricades may be provided.

Some practical aspects of barricades are discussed by Carr, who describes methods of protection against missiles such as valve stems and reactor fragments, as well as high-pressure steam jets, which can be almost as damaging.

Missiles from an exploding reactor may be stopped by a barricade in the form of a sand bath protected by a pressure relief valve. This reduces the need to house the whole plant in a barricade.

For barricade design in general, design case missiles are specified and the barricade is designed to withstand these missiles, using methods such as those outlined in Chapter 17. It is on pilot plants that the provision of such barricades is most common, and thus where most of the expertise resides.

A10.4.6 Pressure systems

The combination of the facts that a pilot plant is usually in a building and that it is subject to continuous experimentation and modification means that it is necessary to give particular attention to the integrity of the pressure system. Procedures should be laid down for the proof testing and leak testing of the plant.

A10.4.7 Pressure relief

It is common practice in pilot plants to put a safety valve on a vessel. The lines to and from such valves tend to be small diameter and liable to fill with liquid which then solidifies. Countermeasures include design of lines so that the liquid drains away and use of heated lines.

A10.4.8 Frangible elements

Pilot plants are frequently constructed in part or in whole in glass or plastic. They also tend to contain vulnerable features such as rotameters and sightglasses.

The protection of the latter devices is described by Carr. Use is made of protective shields with adequate pressure-relief space between the shield and the device. Specific designs have been developed and tested for most types of device used.

A10.4.9 Gas cylinders

Another hazard discussed by Carr is gas cylinders. Rupture of a line supplied by a high pressure cylinder can result in a large jet of gas. He describes arrangements involving the use of a limiting orifice just downstream of the regulator.

A10.4.10 Ignition source control

Another aspect of the design is the control of ignition sources. The importance of this is enhanced in a pilot plant by the facts that the probability of a leak tends to be higher, that in a building gas or vapour accumulates more readily and that the probability of personnel being present is relatively high.

Since it is necessary to exclude all ignition sources, the proper approach is to make a formal examination of the plant to identify possible sources of release. These sources include activities, both operations and maintenance, as well as fixed plant. Such ignition hazard identification provides a basis for the design both of layout and equipment and of operating controls.

The application of the methods of hazardous area classification is one necessary aspect of this. The principal options are classification as Zone 1 or as Zone 2. Classification as Zone 1 puts constraints on the equipment, particularly instrumentation, which can be used, while classification as Zone 2 requires the elimination of leaks and a good level of ventilation.

An account of practical measures for an area classified as Class 1, Division 2, in the US system is given by Carr.

Other features typically include liquid catchment and disposal arrangements, gas detectors and mechanical ventilation.

Multipurpose plant places particularly severe requirements on ignition control.

These hardware measures need to be complemented by a system of operational controls to eliminate ignition sources. Failure to do this largely negates the value of the hardware.

A10.4.11 Plant classification

A systematic approach to the design of pilot plants is to use a formal method of classification.

Carr describes the method which is used in one company for classifying pilot plants for the purposes of design and operation and of personnel protection and which utilizes four operating categories:

Category	*Hazard potential*
1. Detonation reactions	High potential for detonation or massive rupture and large, extremely rapid release
2. Rupture and fires	High potential for large rupture and large fire
3. Leaks and small fires	Low potential for leaks and, at worst, only leaks and fires of limited size
4. Low hazard operations	Near ambient temperatures and low pressures with very low potential for either ruptures or fires

The corresponding protection requirements are given in Table A10.2.

A10.4.12 Extent of automation and protective systems

The operations to be performed on a pilot plant are on a small scale and are required for a limited period, relative to the equivalent operations on the full-scale plant. Further, their automation may well require the development of measuring instrumentation. Hence it will generally not be appropriate to seek to automate these operations to the extent that will pertain on the full-scale plant.

Somewhat similar considerations apply to the provision of protective systems such as trips and interlocks. These definitely have their place in pilot as in full-scale plants, but the particular mix appropriate to the full scale may not suit the pilot scale.

A10.4.13 Control systems

The pilot plant should be provided with instrumentation sufficient not only to obtain design data but to ensure safety. The same principles should be applied as to the design of full-scale plant, such as the use of trips and interlocks, subject to the comments made above on the extent of automation and of protective systems.

The use of computers, mainly PCs, for data acquisition and control of experiments is routine in pilot plants. In some cases the flexibility of such computers has also been exploited to provide alarms and trips.

Table A10.2 *Protection requirements scheme for pilot plants (after Carr, 1988) (Courtesy of the American Institute of Chemical Engineers)*

Typical hazard	*Category 1* *Detonating reactions*		*Category 2* *Rupture and fire hazards*		*Category 3* *Leaks and small fires*		*Category 4* *Low hazards*	
	Hazard potential	*Protection device*	*Hazard potential*	*Protection device*	*Hazard potential*	*Protection device*	*Hazard potential*	*Protection device*
Detonation (internal)	High	Barricade Blast relief	Negligible		Negligible		Negligible	
Shrapnel	High	Barricade Shrapnel stop	Negligible		Negligible		Negligible	
Explosive atm. (external)	High	Barricade Blast relief Ventilation Min. cubicle size	Moderate	Baffle Ventilation Cubicle size	Nelgligible		Negligible	
Fire	High	Baffle	High	Baffle	Moderate	Baffle	Negligible	
Pressure leaks	Possible	Baffle (barricade)	Possible	Baffle	Possible	Baffle	Negligible	
Skin toxic	Possible	Baffle (barricade)	Possible	Baffle	Possible	Baffle	Possible	Baffle
Lung toxic	Possible	Ventilation	Possible	Ventilation	Possible	Ventilation	Possible	Ventilation
Permitted access to operating areas		Exculded		Limited		Limited		Unlimited
Summary of protective devices		Barricade Blast relief Shrapnel stop Ventilation Min. cubicle size		Baffle Ventilation Cubicle size		Baffle Ventilation Required if: lung toxic chemicals		Baffle required if: skin toxic chemicals or adjacent operations (see baffle design) Ventilation required if: lung toxic chemicals

Control schemes for pilot plants are discussed by Uitenham and Munjal (1991) and Palluzzi (1992).

The effectiveness of any protective systems depends on the training of the operators.

A10.4.14 High-pressure plants

Some pilot plants involve high-pressure equipment. The AIChE *Pilot Plant Safety Manual* contains sections on the design of pilot plants for high-pressure and for high-temperature operation. For the former further guidance is given in the *High Pressure Safety Code* by E.G. Cox and Savffle (1975) and by E.L. Clark (1963), W.G. High (1967), Jercinovic (1984) and Mehne (1984).

At the pilot plant scale it is quite common to provide blast-proof cubicles and barricades against missiles, which tend to be impractical on the full-scale plant.

A10.5 Pilot Plant Operation

A10.5.1 Suitability of plant

If the pilot plant is a multipurpose one and is thus used to investigate a number of different processes, a particularly careful check should be made that it is fully suitable for the proposed process.

A10.5.2 Personnel and training

The magnitude of the hazard on a pilot plant is less than on the full scale, but in other respects the operations tend to be more demanding. The materials, the process, the equipment, the plant and the procedures are all relatively unfamiliar. The operating team needs strong leadership and experienced personnel.

As with plant operation generally, training is critical. Many of the topics mentioned in this appendix imply the need for training.

Training is required for management and research personnel also. The latter may well be used to laboratory rather than plant situations, and need to become familiar with plant disciplines.

A10.5.3 Operating and emergency procedures

The operations to be performed should be identified and for each a suitable operating procedure should be developed, and examined from the safety viewpoint. Operations which are likely to bulk large in pilot plant work include manual operations, reactor operations, sampling and measurement activities. There also needs to be suitable emergency procedures.

A10.5.4 Specifications and documentation

Despite the small scale, it is desirable to adhere to a certain formality in pilot plant operation. Some aspects of this are discussed by J. Jones *et al.* (1993a).

There should be formal specification for the raw materials, intermediate and products, for yield and throughput, for cost targets and for the completion date.

Records should be kept of the progress of the project during the pilot plant stage, of problems and hazards encountered, and of the steps taken to solve the problems and to eliminate or control the hazards.

The data needed for the design of the full-scale plant should be documented and the information gathered and recorded.

The operating procedures evolved, including the emergency procedures should be properly documented. Again, this should include any problems and hazards encountered and the response made.

A10.5.5 Mothballing

By its nature a pilot plant is liable to be subject to intermittent operation, with periods when it is not in use. Often a pilot plant is shut-down and 'mothballed' for an extended period. If this is a possibility, it should be taken into account in the design. At the start of such a shut-down measures should be taken to prevent deterioration, including cleaning and flushing of the plant. On recommissioning care should be taken to identify hazards which may arise from the prolonged shut-down.

A10.6 Pilot Plant Safety

An accident in a pilot plant, like one in a laboratory, is generally on a much smaller scale than one on a full-scale plant, but again it can give rise to considerable direct and consequential loss.

Safety in pilot plants is treated in the AlChE *Pilot Plant Safety Manual*. This deals with procedures, including transfer of information from the chemist, hazard identification, process design, mechanical design and design review; scale-up from pilot to full scale; engineering standards for flammable, explosive, corrosive and toxic materials and for radiation protection; maintenance procedures; and high-pressure and high-temperature processes.

In general, the same approach should be taken to the design and operation of a pilot plant as is adopted for a full-scale plant. Many of the topics already discussed are equally relevant to pilot plants, including management and management systems (Chapter 6), hazard identification (Chapter 8), reactive hazards (Chapter 3), process, pressure system and control system design (Chapters 11–13), fire, explosion and toxic release (Chapters 16–18), plant operation and maintenance (Chapters 20 and 21), personal safety (Chapter 25) and safety systems (Chapter 28). On the other hand there are certain features which are characteristic of pilot plants.

A10.6.1 Project safety reviews

There should be a system of project safety reviews adapted to pilot plant design and operation. These should be the subject of a formal requirement and should be documented.

The general methods of hazard identification should be used to discover potential hazards in plant design and operation. In addition, there are hazard identification procedures which are particularly relevant to pilot plants.

The information on the chemicals handled, the reactions involved, and the materials of construction for the plant should be as complete and as well documented as practical.

The transfer of information from the chemist to the engineer should be regulated by formal procedures. The chemist should give a full description of the process, including the reaction kinetics and heats of reaction, limits of operating parameters such as pressure and temperature, and procedures and precautions adopted. The engineer should study the research reports to envision problems which may arise in scale-up to the pilot plant.

The process reaction(s) should be screened to identify any reaction exotherm which might lead to a runaway reaction as described in Chapter 33.

A10.7 Pilot Plant Programmes

Accounts of pilot plant programmes emphasize a number of themes. They include keeping attention focused on the basic chemistry; keeping the programme simple, first establishing feasibility, before getting involved in matters such as yield, effluents, etc., applying lateral thinking and seeking alternative approaches; being prepared to take the calculated risk that the process may not work, although taking no risks with safety; and making use of expert advice from other sources.

A10.7.1 Handover and decommissioning

The pilot plant operation must recognize the point at which the baton should be handed over to the next stage. However, it is advisable not to be in too much of a hurry to decommission a pilot plant. The purpose of the plant is to provide information and/or products to other users. Once they have received these, they too will have to undergo a learning process, and are likely to come back with queries, some of which may require further plant trials. This is true particularly with new products, where the queries may be directed to improving quality or reducing cost and meeting regulatory requirements and environmental restraints.

Appendix 11

Safety, Health and the Environment

Contents

Although the problems of environmental protection (EP) are basically beyond the scope of this book, they cannot be completely neglected, because there are a number of ways in which they are closely linked to safety and loss prevention (SLP).

Selected references on the environment and pollution are given in Table A11.1.

Safety, Health and the Environment

These links are recognized in the common practice of coupling health, safety and environment (HSE) or safety, health and environment (SHE). In the following the latter acronym is preferred, the former already having an established meaning.

A11.1 Common Responsibilities

A11.1.1 Professional responsibilities

The professional engineer has responsibilities both for safety and for environmental matters, which are very similar in nature.

These responsibilities are outlined in the Engineering Council codes *A Code of Professional Practice on Risk Issues (1992) and A Code of Professional Practice on Engineers and the Environment* (1993) described in Chapter 3.

A11.1.2 Legislation

The detailed legislative requirements for safety and environment naturally vary between countries but the worldwide trend is clear. It is towards higher standards both inside and outside the factory; more formal management systems for identification, assessment and control; inherently safer/cleaner designs; and greater legislative and public pressures.

Legislation is described in Sections A11.4–A11.6.

A11.1.3 Professional education

The education of professional engineers should provide a firm grounding in both safety and environmental matters, creating awareness, instilling responsibility and introducing the appropriate engineering approaches.

A11.1.4 Job descriptions

Safety and environmental issues have both grown progressively in importance for industry and government at all levels. In industry there has been an increasing tendency for job titles and descriptions to assign responsibilities which cover both safety and environment.

A11.2 Common Elements

A11.2.1 Economic factors

Both SLP and EP have a fundamental influence on the design of the plant. Each imposes constraints which may well be decisive in the economics of the design.

A poor design is more likely to require the addition of numerous protective devices and the installation of much pollution control equipment and to involve more last-minute modifications to meet legislative and other safety and environmental standards.

A11.2.2 Inherently safer/cleaner design

The concept of inherently safer design, discussed in Chapter 11 and Chapter 32, has its counterpart in that of inherently cleaner design, or, more broadly, waste minimization.

The philosophy of inherently cleaner design is to avoid the generation of noxious effluents. As with inherently safer design, this is easier said than done, but progress has been made and the pressures to operate cleaner processes continue to grow.

A11.2.3 Intermediate storage

A prime theme in inherently safer design is the elimination of intermediate storage. It transpires that the elimination of storage tanks is also a significant feature of waste minimization programmes. In the first case the motivation is to reduce the inventory of hazardous materials, while in the second it is to reduce the quantities of tank residues and wash liquids.

A11.2.4 Hazard identification

The general approach to hazard identification developed in SLP is also applicable to EP.

The hazop method, for example, is increasingly being adapted or enlarged to cover the environment.

A11.2.5 Hazard assessment

Likewise, hazard assessment is finding application in EP as well as in SLP.

Although much of the methodology of hazard assessment used in SLP is applicable to environmental problems, there are also some significant differences. The treatment of the events leading up to a release uses an essentially common methodology, but the modelling of the consequences of a release naturally differs more significantly.

Thus whereas for SLP hazard assessment involves estimating and evaluating the consequences in terms of injury to people and damage to property, for EP the consequences to be considered are the fate of chemicals in the environment, and their ultimate effects on plant and animal life.

A11.2.6 Hazard models

Many of the models used in hazard assessment for SLP are applicable also to EP, and indeed it was for the latter that some were first developed.

Thus the treatment of emission, vaporization and dispersion largely shares a common methodology, although there are some differences of emphasis. In gas dispersion, for example, heavy gas dispersion is of particular significance in SLP, while for EP passive dispersion, including dispersion over much greater distances, plays a more significant role.

A11.2.7 Fugitive emissions

A problem common to SHE and EP is that of low level, or fugitive, emissions from a plant. Such emissions have an impact on the health of workers in the plant and on the population and environment outside.

In SLP the need for stricter controls on emissions within the plant was evidenced by the vinyl chloride problem in 1975, while in EP pressure for emission controls arose from studies of the causes of air pollution in cities such as Los Angeles in the later 1970s, which implicated emissions from nearby refineries.

A11.2.8 Environmental impact assessments

There has been a general trend to require that an industrial activity make an environmental impact assessment (EIA) or environmental impact statement (EIS), also referred to, respectively, as an environmental assessment (EA) and an environmental statement (ES). Such environmental impact assessments and statements include safety issues, although mainly in respect of hazards to the public.

A11.2.9 Safety cases

Closely related is the requirement in European legislation for preparation of a safety case. The requirement to address hazards to the environment as well as humans has received increasing emphasis.

A11.2.10 Communication with public

Process plants and hazardous waste facilities are both liable to generate opposition, prior to creation or in the course of operation. The need to communicate with the public, and the approach required, are very similar in both cases.

A11.3 Some Conflicts

Another link between SLP and EP is that in some cases a degree of conflict arises. In some cases the preferred solution to a safety problem may be ruled out, or at least discouraged, on environmental grounds; in others stricter environmental controls may push the designer towards solutions which would not otherwise be adopted for safety reasons.

Accounts of such conflicts have been given by Elphick (1972), R.Y. Levine (1972b), Bodurtha (1976) and Kletz (1993e).

Some of the practices which are so affected are now considered.

A11.3.1 Reactor venting

The normal method of protection for a chemical reactor has been the provision of a bursting disc with a short, straight pipe discharging to atmosphere at a safe place.

If such discharge is not permitted but this basic method of protection is retained, it becomes necessary to pipe each bursting disc into a vent header leading to a disposal system such as a scrubber or flare. Some of the problems which this creates have been described by Levine.

It is largely for this reason that the alternative approach of using instrumented protective systems on reactors has become increasingly attractive, as described in Chapter 11.

A11.3.2 Pressure relief valve discharge

An essentially similar conflict and similar problems arise over the practice of fitting pressure relief valves which discharge directly to atmosphere.

Some of the problems of vent collection systems are described by Kletz.

Avoidance of discharge to atmosphere is one of the main arguments for the use of trip systems to protect against overpressure, as described in Chapter 13.

A11.3.3 Flaring

A flare radiates intense heat and light and may be smoky and noisy. These are all aspects of pollution which have become increasingly unacceptable.

In contrast to the oil industry, which has continuous flaring, the chemical industry often makes use of an intermittent flare. The flare may be used to burn small quantities of smelly materials. But since very small quantities are sometimes not ignited by the flare pilot burner, it is sometimes necessary to operate the flare continuously, using fuel gas which could otherwise be used more productively.

A11.3.4 Bleeding

The build-up of impurities in plants is avoided by taking off a bleed. If this practice is inhibited by environmental considerations, the impurity can accumulate and may create a hazard. Levine describes a multimillion dollar loss which occurred due to the build-up of the explosive impurity azomethane.

A11.3.5 Leakages

The degree of leakage which has been tolerated in the past is now frequently unacceptable. The problems which can then arise are illustrated by the leakage of hydrogen from mercury cell chlorine plants. The hydrogen stream is one of the carriers of mercury vapour from the cells. Therefore mercury escapes in the hydrogen leakages. One possible solution is to run with the hydrogen under a slight negative pressure, but this creates the risk of air ingress leading to an explosion.

A11.3.6 Incineration

Burning in open pits has been widely used as method of disposing of waste solvents on chemical plants. Closed incinerators eliminate this pollution, but present hazards of their own.

A11.3.7 Ventilation

The hazard from flammable leaks in a compressor house can be reduced if the building is of open construction such that ventilation is much enhanced. This solution runs into the difficulty, however, that the noise of the machinery carries further.

A11.3.8 Combustion processes

The attempt to reduce the emission of nitrogen oxides from combustion processes can increase the risk of explosion. A marked decrease in nitrogen oxides formation occurs as excess air is reduced. But reduction of excess air increases the probability of an explosion due to unburned fuel in the gas leaving the combustion chamber.

A11.3.9 Pollution control equipment

Equipment for the removal of flammable dust from gases can present another hazard. Although this can be minimized by the use of wet scrubbers, these run into difficulties from water pollution controls.

A11.3.10 Halons

Halons have found a distinctive role in the process industries as fire extinguishants and explosion suppressants. The banning of chlorofluorohydrocarbons (CFCs) creates a gap which for fire extinguishants is not yet fully filled.

Pollution of the Environment

Awareness of the seriousness of environmental pollution grew rapidly in the 1960s. The publication of *Silent Spring* by Carson (1963) was a landmark. Other warnings have followed such as *Bitter Harvest* by Egginton (1980).

Accounts of pollution and environment include *Handbook of Environmental Control by* Bond and Straub (1973–), *The Pollution Handbook* by Mabey (1974), Introduction to Environmental Science by Strahler and Strahler (1974), *A Dictionary of the Environment by* Allaby (1977), *Topics and Terms in Environmental Problems* by Holum (1977), *The Protection Handbook of Pollution Control by* P. Sutton (1977b), *Environmental Education by* Bakshi and Naveh (1980), Britain, Europe and the Environment by MacRory (1983) and *Environmental Pollution and Control* by Veselind, Peirce and Weiner (1990).

Also relevant are the reports of the Royal Commission on Environmental Pollution.

A11.4 Legislation

Although there are significant differences between gaseous effluents, liquid effluents and solid wastes, some of the legislation addresses more than one of these, and it is convenient therefore to take all three together.

A11.4.1 Air pollution

The Alkali etc. Works Regulation Act 1906 was for many years the principal act governing air pollution.

The philosophy of enforcement of the act has been the use of best practicable means (BPM) to minimize emissions.

The HSWA 1974 states in Section 1(1) (d) that its provisions are made with a view to controlling emissions of noxious substances and it contains in Section 5 a general duty to use best practicable means to prevent such emission.

The Health and Safety (Emissions into the Atmosphere) Regulations 1983, amended 1989, create in Section 3 prescribed classes of premises for the purposes of Section 1(1) (d) of the HSWA, listed in Schedule 1, and specify under Section 4 substances prescribed as noxious. These premises and substances are listed in Schedules 1 and 2, respectively.

A11.4.2 Control of Pollution Act 1974

The Control of Pollution Act 1974 (COPA) has four main parts: Part I, Waste on Land; Part II, Pollution of Water; Part III, Noise; and Part IV, Pollution of the Atmosphere.

Part I of the act states requirements for the disposal authority to control waste disposal by a system of licensing. It prohibits the unlicensed disposal of controlled waste.

In Part II the act lays down the duties of the Water Authorities to operate a system of consents for discharges and prohibits noxious discharges.

The provisions of Part IV on atmospheric pollution are limited and deal mainly with pollution by certain fuels and with information about air pollution.

A11.4.3 Environmental Protection Act 1990

The Environmental Protection Act 1990 (EPA) has nine parts, those of principal relevance here being Part I, Integrated Pollution Control and Air Pollution Control by Local Authorities; Part II, Waste on Land; and Part III, Statutory Nuisances and Clean Air.

Part I of the act establishes a system of integrated pollution control (IPC) enforced by HM Inspectorate of Pollution (HMIP) and one of air pollution control (APC) administered by the local authorities (LAAPC).

Section 1 of Part I gives definitions of environment, pollution and harm which read as follows:

> (2) The 'environment' consists of all, or any, of the following media, namely the air, water and land; and the medium of air includes the air within buildings and the air within other natural or man-made structures above or below ground.
> (3) 'Pollution of the environment' means pollution of the environment due to the release (into any environmental medium) from a process of substances which are capable of causing harm to man or any other living organisms supported by the environment.
> (4) 'Harm' means harm to the health of living organisms or other interference with the ecological systems of which they form part and, in the case of man, includes offence caused to any of his senses or harm to his property; and 'harmless' has a corresponding meaning.

Section 2 creates a system of prescribed processes and substances and Section 3 allows regulations to be made for their control. Subsection 2 of Section 3 allows the prescription of standard limits for the concentration, the amount or the amount in any period to be released; of standard requirements for measurement; and of standards or requirements for the process. Subsection 5 allows the making of plans for establishing limits for the total amount or total amount in any period to be released in any area; for quotas for operators; and for establishing or reducing limits so as progressively to reduce pollution.

Sections 6–12 create a system of authorizations to operate a prescribed process. Section 7 deals with the conditions of such an authorization. It requires that in carrying on such a process use should be made of the best available technology not entailing excessive cost (BATNEEC) to prevent release of prescribed substances or to render harmless any other potentially harmful substances.

Section 4 establishes the enforcing authorities and Sections 13–19 deal with enforcement. Section 13 gives powers to make an enforcement notice and Section 14 a prohibition notice.

Section 23 gives a list of offences and penalties. Section 27 gives powers such that where an offence causes any harm which it is possible to remedy the inspectorate may arrange for any reasonable steps to be taken to remedy the harm and may recover the cost from any person convicted.

The EPA covers discharges into all environmental media. Some processes have the potential to make significant discharges into more than one medium, in some cases as a result of transfer from one medium to another. An example is removal of substances from a gas stream which then ends up in a liquid effluent. In such situations the EPA requires the selection of the best practical environmental option (BPEO) and the operator is required to demonstrate that its process meets the BPEO criterion.

Part II of the act creates a duty of care in respect of wastes and a system of waste management licences.

Part III defines a number of statutory nuisances which are 'prejudicial to health or a nuisance' and which include emissions such as smoke; fumes and gases; dust, steam, smell and other effluvia; accumulations or deposits; and noise. It lays on a local authority a duty to inspect its area to detect such nuisances and to act on them.

The prescribed processes and substances are given in the Environmental Protection (Prescribed Processes and Substances) Regulations 1991. Schedule 1 contains a number of chapters, each of which deals with a particular industry. The chemical industry is covered in Chapter 4 of the schedule.

A distinction is made between those processes which are subject to control by local authorities in respect of air pollution only and those which have the potential for pollution of more than one environmental medium, which require an IPC authorization from the HMIP – the Part B and Part A processes, respectively.

A11.4.4 Clean Air Act 1993

The Clean Air Act 1993 covers pollution by smoke, grit, dust and fumes from industrial processes not required to be registered under the HSWA 1974 and the Health and Safety (Emissions into the Atmosphere) Regulations 1983.

The act prohibits the emission of 'dark' smoke from any chimney or industrial premises.

A11.4.5 Water pollution

Until 1973 local authorities had the duty of providing sewerage and sewerage treatment not only to domestic but also as far as possible to industrial users. Controls on effluents from industrial premises to the public sewerage system were established by the Public Health (Drainage of Trade Premises) Act 1937.

The Water Act 1973 transferred the responsibilities for industrial effluents to the public Water Authorities (WAs). The operation and maintenance of the sewerage system continued to be done by the local authorities on an agency basis.

The Control of Pollution Act 1974 strengthened the controls on water pollution.

The development of controls on water pollution has been influenced by the apparent deterioration of water quality in the North Sea and by a series of North Sea Conferences of the states concerned, the first being held in 1984.

Substances identified as particularly harmful to the aquatic environment by reason of their toxicity, persistence and bioaccumulation are identified in the 'Red list'.

Control of water pollution is now governed by the Water Act 1989, described below, and the EPA 1990.

The system being developed under these acts is one of integrated pollution control based on environmental quality objectives (EQOs) and environmental quality standards (EQSs) utilizing the BATNEEC criterion.

A11.4.6 Water Act 1989

The Water Act 1989 defines the waters which are subject to control, establishes the powers of control and creates the National Rivers Authority (NRA).

Prior to privatization the WAs were responsible both for the supply of water and for control of pollution of water. In other words, they were both poacher and gamekeeper. The need to separate these functions led to the creation of the NRA, which is now responsible for protecting the aquatic environment.

Section 103 of the Act defines the various waters subject to controls, which are essentially inland waters, including rivers and watercourses; groundwaters; coastal waters; and territorial waters out to a 3 mile limit.

Part III of the Act gives the NRA powers to improve water quality and to control effluent discharges.

Discharge of liquid effluent is governed by a system of discharge consents. The discharge consent procedures are given in Schedule 12 of the Act.

Public participation is allowed by arrangements for advertising a discharge application in the local press and by a duty on the authority to consider representations made.

A11.4.7 Hazardous wastes

Control of hazardous wastes is exercised under the Deposit of Poisonous Waste Act 1972 and the Deposit of Poisonous Waste (Notification of Removal or Deposit) Regulations 1972.

Hazardous waste controls are also major elements of the Control of Pollution Act 1974, Part I and the EPA 1990, Part II, as already described. The EPA 1990 creates a system of waste management licences.

A11.4.8 Environmental impact assessment

EC Directive 85/337/EEC on the assessment of the effect of certain public and private projects on the environment creates for certain projects requirements for an environmental assessment.

In the United Kingdom, implementation of these requirements is largely covered by the Town and Country Planning (Assessment of Environmental Effects) Regulations 1988 (the EA Regulations).

The regulations specify that a developer provide information on the impact of the project in the form of an environmental statement.

A11.4.9 Advisory bodies

There is a standing Royal Commission on Environmental Pollution (RCEP). The reports of the commission are listed in Appendix 28.

Among the topics addressed are coastal water pollution (1972, *Third Report*), integrated air pollution control (1976, *Fifth Report*), sea pollution (1981, *Eighth Report*), waste management (1985, *Eleventh Report*), best practical environmental option (1988, *Twelfth Report*), freshwater quality (1992, *Sixteenth Report*) and waste incineration (1993, *Seventeenth Report*).

A11.4.10 Safety cases

EC Directive 82/501/EEC on major accident hazards creates controls on certain installations which include the submission of a safety report. There have been two subsequent modifying directives, the second 88/610/EEC containing requirements in response to the Rhine pollution incident at Schweizerhalle in 1986.

The initial directive is implemented in the United Kingdom by the CIMAH Regulations 1984 and the two later directives by amendments of these regulations. In the second set of amendments in 1990 the requirement for the safety case is contained in Regulation 7 and its contents are specified in Schedule 6.

Schedule 6 refers to information on the consequences of a major accident without specifically mentioning those to the environment, but guidance given in HS(R) 21 by the HSE (1990) states that in relation to the environment information should include the routes by which harm may be brought about and the effect on the exposed environment including persistence of the substance in the environment.

A11.5 EC Directives

There are a considerable number of EC Directives concerned with the environment. Some of the principal directives are listed in Chapter 3.

An information service on EC legislation is given in *European Environment Law for Industry* by Agra Europe (1994a).

Directive 76/464/EEC gives a list of substances dangerous to the environment. 80/68/EEC addresses groundwater protection. Discharge of certain substances listed in 76/464/EEC is covered by 86/280/EEC. There are directives on discharge of metals such as mercury and cadmium. Directive 84/360/EEC deals with air pollution from industrial plants and 88/609/EEC with large combustion plants. There are directives on ozone, sulfur dioxide, nitrogen dioxide and carbon dioxide. Other specific pollutants covered by directives include lead, asbestos and PCBs. Toxic and dangerous wastes are the subject of Directives 78/319/EEC and 91/689/ EEC, while 84/631/EEC deals with transfrontier shipment of wastes.

Directive 85/337/EEC requires for certain activities the production of an environmental impact assessment.

A11.6 US Legislation

Accounts of US legislation on the environment and on pollution control are given by Lipton and Lynch (1987), E.J. Martin and Johnson (1987), Nemerow and Dasgupta (1991) and Veselind, Peirce and Weiner (1991).

The account given below complements that given in Chapter 3.

A11.6.1 Air pollution

In the United States, air pollution legislation includes the Air Pollution Control Act 1975, the Clean Air Act 1963 (CAA) and the Clean Air Act Amendments 1970, 1977 and 1990 (CAAA).

The CAAA 1970 required the EPA to establish National Ambient Air Quality Standards (NAAQSs). The CAAA 1977 brought in requirements for the NAAQSs to be regularly up-dated and for the 'prevention of significant deterioration' (PSD) in regions with air cleaner than the NAAQS. A system of New Source Reviews (NSRs) was instituted with New Source Performance Standards (NSPSs). Best available control technology (BACT) is required for compliance.

Title III of the CAAA 1990 gives a list of 189 air toxics and requires the EPA to publish a list of source categories emitting 10 ton/year of any one toxic or 25 ton/year of a combination and to issue for such toxics maximum achievable control technology (MACT) standards.

A11.6.2 Water pollution

Water quality in the United States is protected by legislation on effluent discharges to streams and on drinking water quality. The Federal Water Pollution Control Act 1972 envisaged a nationwide policy of zero discharge of pollutants by 1985. The EPA introduced a discharge permit system in the form of the National Pollutant Discharge Elimination System (NPDES). The Clean Water Act Amendments 1977 backed away from zero discharge and introduced a system requiring instead that in due course discharges be treated with the best conventional pollutant control technology. In addition, the EPA is now charged with setting limits for some 100 toxic substances in effluents.

Advisory standards for drinking water in the United states have long been set by the US Public Health Service (USPHS). The Safe Drinking Water Act 1974 authorizes the EPA to set minimum national drinking water standards.

A11.6.3 Hazardous wastes

Hazardous wastes in the United states, governed previously by the Solid Waste Disposal Act 1965, are now are subject to the Resource Conservation and Recovery Act 1976 (RCRA). The act seeks to ensure proper land disposal of defined hazardous wastes and to fill certain loopholes in control on air and water pollution. Under it the Office of Solid Waste (OSW) of the EPA promulgates regulations defining hazardous wastes and standards applicable to it. In implementation of the Act, the EPA classified waste disposal sites as landfills, lagoons or landspreading operations, defined eight categories of impact which such sites might have and stated the operational and performance standards to be met to minimize such impacts.

Hazardous wastes attract further controls. For these the EPA has set up what is in effect a 'cradle-to-grave' system covering hazardous waste generation, transport and treatment, storage and disposal facilities, imposing duties on the generator, the transporter and the facility operator and involving tracking by a system of identification numbers and control by a system of permits.

The problem of the large number of hazardous waste sites in unsatisfactory condition, or worse, is addressed by the Comprehensive Environmental Resource Conservation and Liability Act 1980 (CERCLA), or Superfund. The act creates controls on such facilities and provides for the EPA to supervise the clean-up of existing and abandoned sites. The EPA seeks to identify Potentially Responsible Persons (PRPs) and, where such parties are not found, it initiates a clean-up paid for from the Superfund.

The Superfund Amendments and Reauthorization Act 1986 (SARA) renews the Superfund. The part known as SARA Title III extends its application to accidental releases.

The numerous other items of legislation which have some bearing on hazardous waste are reviewed by Edelman (1987).

A11.6.4 Fugitive emissions

Standards governing fugitive emissions have been promulgated by the EPA under the CAA. These are the Standards of Performance of New Stationary Sources Equipment Leaks of VOC, Petroleum Refineries and Synthetic Organic Chemical Manufacturing Industry 1983, amended 1984, also referred to as the New Source Performance Standards (NSPSs), the NSPS Regulations or the VOC (SOCMI) Regulations. These set standards for emissions permissible from items of equipment.

In addition to these controls on VOCs, the EPA has also issued National Exposure Standards for Hazardous Air Pollutants (NESHAPs) for certain specific substances. These too give equipment emission standards.

The NSPSs apply to new equipment but also have application to reconstructed and modified equipment, and guidance has been given on determining how far they affect existing equipment. In addition, existing equipment is affected by the assimilation into EPA controls of state requirements on monitoring and maintenance (M&M).

A11.6.5 Environmental impact assessment

The National Environmental Policy Act 1969 (NEPA) contains in Section 102 the far-reaching provision that where the action of a federal agency may have significant consequences for the human environment, an environmental impact statement should be given. The practice is to prepare a draft statement, which is put out for consultation, and then to issue the final statement.

A11.7 Environmental Management

11.7.1 Environmental management systems

The environment needs to be protected by an approach to management and management systems similar to that developed for safety and loss prevention, which has been described in Chapter 6. There should be an environmental management system (EMS) which parallels the safety management system.

A11.7.2 BS7750

Environmental management is the subject of BS 7750: 1992 Specification for Environmental Management Systems. The standard may be regarded as applying in this field the principles of quality systems given in BS 5750. An overview is given by Shillito (1991).

Requirements of BS 7750 include (1) documentation of the environmental management and management systems; (2) collation of regulatory requirements on the environment; (3) inventory of raw materials and energy usage and of wastes and releases; (4) formulation of environmental objectives; (5) an environmental management plan; (6) a system of environmental audits; (7) a system of environmental controls with verification and testing; and (8) personnel qualified and trained in environmental matters.

A11.7.3 Process environmental reviews

The EMS should require a system of process environmental reviews akin to the process safety reviews described in Chapters 6 and 8.

This review system should include formal systems for the identification and assessment of environmental hazards.

The hazop study method is now applied to identify potential problems with the environment as well as with safety and operability. Accounts are given by Isalski *et al.* (1992) and Ormond and Isherwood (1992).

A11.7.4 Environmental audits

Another essential feature of an EMS is a system of environmental audits. Environmental auditing stands in essentially the same relation to EP as safety auditing does to SLP.

Accounts of environmental audits are given by Baumer (1982), Keene (1982), D.L Russell (1985) and Petts and Eduljee (1994).

A11.7.5 Environmental planning

The essential concern of planning is with the environment as broadly defined, including amenity as well as hazards and pollution.

The planning arrangements vary from country to country. Accounts of planning in the United Kingdom in relation to major hazard installations have been given by Petts (1988b, 1989, 1992).

Accounts of planning in relation to pollution are given by D.C. Wilson (1981) and Petts and Eduljee (1994), both dealing with hazardous wastes.

To a considerable extent planning centres around the EIS, discussed in Section A11.9.

A11.7.6 Environmental emergency planning

Environmental emergency planning is needed to cover both fixed installations and transport. The treatment in Chapter 24, which covers both aspects as far as safety is concerned, is in large part applicable to planning for environmental emergencies.

Further treatments relevant to the environment specifically are given in *Hazardous Materials Emergency Response and Control* by Cashman (1988) and by G.F. Bennett, Feates and Wilder (1982).

As stated earlier, the CIMAH safety case is required to cover environmental as well as safety aspects of emergency planning.

A11.8 Environmental Hazard Assessment

There is now an increasing activity in environmental hazard assessment. In large part this has been driven by the threat to the environment from hazardous waste sites.

In the United states, the pollution arising from the hazardous wastes dumped at Love Canal, described in Section A11.22, and the resultant arrangements for clearing up waste sites under Superfund have stimulated assessment of such sites to determine the extent of the risks and to set priorities for clean-up.

Hazard assessment is undertaken both for existing or proposed hazardous waste treatment, storage and disposal facilities (TSDFs) and for abandoned hazardous waste dumps.

Accounts of environmental hazard assessment are given in *Risk Assessment of Hazardous Waste Sites* by Long and Schweitzer (1982), *Hazardous Waste Risk Assessment* by Asante-Duah (1993) and *Standard Handbook for Solid and Hazardous Waste Facility Assessments* by Sara (1994) and by H. Bradford (1986a), B.P. Smith (1987), Kemp and Gerrard (1991), Kolluru (1991), Welsh (1992, 1993) and Rouhiainen (1993).

A11.8.1 EPA guidance

Guidance on hazard assessment of hazardous waste sites, in the context of Superfund, is given in *Risk Assessment Guidance for Superfund: I, Human Health Evaluation Manual* and in *Risk Assessment Guidance for Superfund: II, Environmental Evaluation Manual* both by the EPA (1989a,b). EPA philosophy is also described by B.P. Smith (1987).

The process outlined by the EPA involves the following steps: (1) hazard identification, (2) toxicity assessment, (3) exposure assessment and (4) risk characterization.

A brief description of the assessment process is given by Kolluru (1991) and a more detailed account by Asante-Duah (1993).

These stages in the assessment are now outlined.

A11.8.2 Hazard identification

Hazard identification is the first stage and, in this context, means the identification of those chemicals which pose the greatest risks, the so-called indicator chemicals.

Since this identification involves the inventory, mobility, persistence and toxicity of the chemicals, some degree of iteration back from the subsequent stages may be necessary.

A11.8.3 Toxicity assessment

Toxicity assessment requires consideration of toxicity both for carcinogens and for non-carcinogens.

For carcinogens the assumption made by the EPA is that there is no threshold below which a dose is harmless. The probability of harm is then obtained from the slope of the dose-response curve, the so-called cancer slope factor (CSF) or potency factor. The EPA also recognizes a weight of evidence factor. Carcinogens are divided into four categories: (1) human carcinogens, (2) probable human carcinogens, (3) probable human carcinogens but with inadequate human data and (4) possible human carcinogens.

For non-carcinogens a threshold is admitted. For the dose of such a chemicals there is therefore a no observable adverse effect level (NOAEL). A reference dose (RfD) is defined which is one hundredth of the NOAEL and which thus incorporates a substantial safety factor. The reference dose is also termed the acceptable daily intake (ADI).

A11.8.4 Exposure assessment

Exposure assessment involves determining the persons exposed and their intake of toxic chemicals.

The EPA has issued standard assumptions for exposure. For adults these include the following:

Air inhaled (m^3/d)	20
Water ingested (1/d)	2

Soil ingested (mg/d)	100
Fish consumption (g/d)	6.5
Lifetime exposure (year)	70

The assessment required is for a reasonable maximum exposure (RME) under present and future land use conditions.

A11.8.5 Risk characterization

Risk characterization involves combining the toxicity and exposure estimates to obtain an assessment of risk to human health and making an assessment of the risks to the environment.

Cancer risks are expressed as the probability of contracting cancer from exposure to the chemicals over a lifetime. Non-cancer risks are expressed for a single substance in terms of a hazard quotient (HQ) or for a set of substances in terms of a hazard index (HI), the sum of the hazard quotients. The hazard quotient is the ratio of the daily intake to the RfD. If the HQ is less than unity, the chemical is not regarded as a threat to public health.

A11.8.6 Source terms and transport models

A full hazard assessment of a hazardous waste TSDF requires the modelling of source terms and of the transport and transformation of chemicals in the atmosphere and the ground. These aspects are discussed in Section A11.12.

A11.9 Environmental Impact Assessment

A11.9.1 Environmental assessments

An EA presented in an ES is for some projects a regulatory requirement under the Environmental Assessment Regulations 1988.

Accounts of ES are given in *Environmental Impact Assessment of Waste Treatment and Disposal Facilities* by Petts and Eduljee (1994) and by E.J. Martin and Johnson (1987) and Veselind, Peirce and Weiner (1990).

The treatment by Petts and Eduljee is comprehensive and although concerned with hazardous waste facilities its general approach is of much wider application.

The authors describe the regulatory requirements for, the purposes of and practice in respect of an EA and they relate the EA to the requirement to select the best practicable environmental option (BPEO) with its implication that alternatives must be considered.

They outline the process of scoping. Following Elkin and Smith (1988), identification of the crucial concerns should cover (1) geographic boundaries, (2) administrative boundaries, (3) project timing and duration, (4) key stakeholders, (5) key resources and land uses, (6) key activities, (7) key policies and (8) interactions. They describe the scoping techniques of consultation and identification of impacts and their significance and indicate other techniques such as checklists, matrix and network methods, and cause–effect diagrams. They then deal specifically with the scoping of landfill and incineration.

For each feature subject to impact, Petts and Eduljee describe the feature itself, the scoping, the baseline conditions and survey, the prediction and evaluation of impacts, and the mitigation of impacts. They apply this treatment to (1) flora and fauna, (2) geology and soils, (3) ground and surface water, (4) air quality and climate, (5) public health, (6) landscape and visual amenity, (7) transport, (8) social and economic features, (9) land use and heritage and (10) residuals. In addition to the usual impact factors they consider acute events, noise and vibration, and landfill gas.

As a case study, the authors consider the Seal Sands incinerator.

A US perspective is given by Veselind, Peirce and Weiner (1990). They describe an EIS as consisting of three distinct parts: (1) inventory, (2) assessment and (3) evaluation. The relevant factors are broadly similar to those just mentioned. They also outline a scoring scheme in which impacts are rated using scales of importance and magnitude.

In some instances, particularly in the early days, the EIS has constituted a major exercise. For the trans-Alaska pipeline the draft EIS, the comments and the final EIS ran to 30 volumes.

A11.9.2 Safety cases

For major hazard installations the CIMAH Regulations 1984 require the submission of a safety case which covers the consequences of a major accident not only for human but for the environment. This aspect of the safety case is discussed by Singleton (1989) and Cassidy (1990).

The safety case is concerned with acute events and it may be regarded as complementing the regulatory controls dealing with long-term pollution and environmental impact.

Cassidy advises that the safety case should give information on the land uses around the site, the environmental hazards of the substances stored or processed and the potential impact on flora and fauna and on the balance of nature. Where there is potential to contaminate water, it should give comprehensive information on the local watercourses and their uses. Particular attention should be paid to the potential for harm to targets which are rare or unique, to persistence of noxious substances in the environment and to long-term damage. The author gives decision trees for assessing land and water impacts.

He also draws attention to the need to address the environmental aspects in the emergency planning required under the regulations.

Singleton deals with the assessment of the consequences to the environment of an accident involving an ultratoxic substance. He considers the cases of copper–chrome–arsenate (CCA) wood preservatives and of pesticides.

A11.9.3 Waste facility assessments

A hazardous waste facility needs to be assessed to determine the hazard which it poses to the environment and to humans.

Petts and Eduljee (1994) describe two approaches to such assessment. One is to undertake a full environmental hazard assessment, as described in the previous section.

The other approach is the use of a structured checklist. This is the method used in the project on hazard assessment of landfill (HALO) described by Kemp and Gerard (1991).

A somewhat similar approach is taken in the Hazard Ranking Scheme (HRS) of the EPA (1982a), which utilizes a scoring system.

A11.9.4 Spill impact assessment

A more specific form of impact assessment is the assessment of the effects of a spill of hazardous material.

Typically this might be a liquid spill occurring in road or rail transport or from a pipeline.

Methods of assessing the impact of a spill which has already occurred are given in the literature as one aspect of spill control, as described in Section A11.20, but assessment of the impact of potential spills in advance receives little mention.

A11.10 Environmental Economics

The costs to the process industries of environmental protection are high, but experience indicates that, as with safety, good practice is also good business.

Costs and savings may be computed at national or company level. At the national level costs in the United states have been given in *Environmental Investments: The Costs of a Clean Environment* by the EPA (1991) (Chementator 1991 Mar., 25). In 1972, expenditure on pollution control was some \$30 billion (≈1% of GDP). By 1987, it had risen to \$98 billion (≈2% GDP) and by 1990 to \$115 billion (≈2.1% GDP); the projection for the year 2000 is \$140–160 billion (≈3% GDP); the values are all in 1990 dollars. The 1987, figures include \$28.9 billion for air and \$42.9 billion for water pollution control. The process industries account for a large proportion of this expenditure.

Savings at the national level are inevitably less easy to obtain.

However, as described in Section All.13, the efforts now devoted to waste minimization are testimony to the fact that there are economic benefits.

A11.11 Environmentally Noxious Chemicals

There are a number of substances which figure particularly prominently as pollutants. Some of the principal ones are mentioned briefly in this section.

Many of these substances appear in gaseous or liquid effluent streams. To this extent, their release is controlled one. The hazard from others may arise from an accident. A pesticide is a case in point, as described below.

A11.11.1 Sulfur dioxide and acid rain

A major pollutant from combustion processes is sulfur dioxide, which is responsible for acid rain.

Acid rain pollution is described in *Sulphur Emissions and the Environment* by the SCI (1981b), *Energy and the Environment: Acid Rain* by Keith (1982), *Acid Rain Information Book* by Record, Bubenick and Kindya (1982) and *Acid Deposition* by Adams and Page (1986) and by Ireland (1987). Control technologies are detailed in *Add Emissions Abatement Techniques* by the DoE (1991–).

A11.11.2 Nitrogen oxides

Nitrogen oxides NO_x arise from combustion processes. Both industrial combustion and cars are major contributors.

The NO_x problem and control technologies are discussed by Marzo and Fernandez (1980), Niess (1980), Redman (1989a) and R. Smith and Petala (1991–).

A11.11.3 Pesticides

Pesticides are highly active chemicals. The expose in *Silent Spring* by Carson (1963) rendered their use controversial.

The production, storage and handling of pesticides creates the potential for release in an event such as a fire, or with the fire water used.

The pesticide problem is discussed in *Persistent Pesticides in the Environment* by C.A. Edwards (1974) and by the SCI (1978).

A11.11.4 Polychlorinated biphenyls

For many years, until their extreme toxicity came to be appreciated, polychlorinated biphenyls (PCBs) were used as electrical transformer fluids. The main concern now is prevention of escape from such equipment and safe methods of disposal. This is discussed by Berry (1981) and Motter (1991). A guide to EPA-approved methods of disposal is given by Kokozska and Flood (1985).

A11.11.5 Toxic metals

Toxic metals which occur in trace quantities in effluents, including those from incinerators, can be very harmful to the environment.

Treatments of toxic trace metals are given in *Control and Fate of Atmospheric Trace Metals* by Pagna and Ottar (1989) and by Barton, Clark and Seeker (1990).

A11.11.6 Mercury

Certain processes, notably traditional processes for chloralkali production, discharge mercury, albeit in very low concentrations. Accumulation of mercury, especially in the form of methyl mercury, is very noxious to the environment.

A11.11.7 Dioxins

TCDD and other dioxins exhibit toxic effects in minute concentrations, and rank as ultratoxic substances. The toxicity of TCDD is discussed in Appendix 3 in the context of Seveso.

TCDD is produced in very low concentrations in combustion processes and can be produced in a chemical reactor.

The dioxin problem and methods of dealing with it are discussed in *Human and Environmental Risks of Chlorinated Dioxins and Related Compounds* by R.E. Tucker, Young and Gray (1983) and *Dioxin Containing Wastes: Treatment Technologies* by Arienti *et al.* (1988) and by Ayres (1981), Rice (1982), Short *et al.* (1984) and Beychok (1987a).

A11.11.8 Nitrates

Nitrates are another significant pollutant, but arise mainly from the use of fertilizers, and are outside the present scope. An account is given by Nicolson (1979).

A11.11.9 Health effects

Threats to health may arise from the use, or more often abuse, of chemicals or from their release to the environment.

Health effects of chemicals in the environment are treated in *Health Effects of Environmental Pollutants* by Waldbott (1973), *Environmental Industrial Health Hazards* by Trevethick (1976), *Air Pollution and Human Health* by Lave and Seskin (1977a), *Long-Term Hazards of Environmental Chemicals* by Doll and McLean (1979) and *Hazardous Waste and Human Health* by the BMA (1991) and by McLean (1981) and Asante-Duah (1993), as well as in texts on environmental hazard assessment.

A11.12 Chemicals Transport, Transformation, Fate and Loading

A fundamental approach to hazard assessment in EP involves tracing the dispersion and determining the fate of chemicals in the environment.

In principle, a full treatment therefore involves study of the dispersion of gaseous effluents in the atmosphere and of the deposition of particulate matter; the transmission of chemicals through waters and soils of all types; and their passage through the food chain.

A great deal of work has been and continues to be done in all these areas. In some cases the prime concern is with potential airborne releases from nuclear power plants or leaks from nuclear waste stores into watercourses, in others it is with the effects of pesticides and other chemicals already in use.

Accounts of the transport, transformation and fate of chemicals in the environment include *Environmental Pollution* by Chemicals Walker (1971), *Persistent Pesticides in the Environment* by C.A. Edwards (1974), *Pollution Criteria for Estuaries* by Helliwell and Bossanyi (1975), *Principles for Evaluating Chemicals in the Environment* by the NAS (1975), *Safety of Chemicals in the Environment* by Harwell (1979), *Chemical Concepts in Pollutant Behaviour* by Tinsley (1979), *Hydrocarbons and Halogenated Hydrocarbons in the Aquatic Environment* by Afghan and Mackay (1980), *Dynamics, Exposure and Hazard Assessment of Toxic Chemicals* by Haque (1980b), *Chemicals in the Environment* by Neely (1981), *Physico-Chemical Behaviour of Atmospheric Pollutants* by Versino and Ott (1982), *Environmental Exposure to Chemicals* by Neely and Blau (1985), *Pollutant Transport and Fate in Ecosystems* by Coughtrey, Martin and Unsworth (1987), *Control and Fate of Atmospheric Trace Metals* by Pagna and Ottar (1989), *Reaction Mechanisms in Environmental Organic Chemistry* by Larson and Weber (1994), *Hazardous Waste Risk Assessment* by Asante-Duah (1993) and *Standard Handbook for Solid and Hazardous Waste Facility Assessment* by Sara (1994). Worldwide limit values are given in *World-wide Limits for Toxic and Hazardous Chemicals in Air, Water and Soil* by Sittig (1994).

A11.12.1 Source terms

The starting point for the modelling of transport through environmental media is the definition of the source terms.

Three principal types of source terms are (1) gaseous emissions from a hazardous waste TSDF, (2) leachate seepage from a TSDF and (3) liquid spill into a watercourse in a transport accident.

A review of gaseous emission source terms at a TSDF is given by B.P. Smith (1987). Models quoted by this author are for surface impoundments, that of Thibodeau, Parker and Heck; for aerated tanks, that of R.A. Freeman (1980); for storage tanks, the usual relations for 'breathing' losses; for landfill, that of W.J. Farmer, Yang and Letey (1980), as modified by Hwang (1980) and Shen (1981); and for land treatment, that of Thibodeaux and Hwang (1982).

For liquid seepage the source term is highly site specific. Seepage from landfill is treated in accounts of landfill and of leachate.

A liquid spill from a transport vehicle is a relatively well-defined source. Another form of transport spills is a pipeline leak, where the issues are the location and the flow rate.

A11.12.2 Transport of chemicals

Chemicals are transported through the environment by atmospheric dispersion and by movement through waters.

A review of air, surface water, groundwater, soil and multimedia transport models applicable in this context is given by McBean (1993).

For transport of gaseous emissions use is made of atmospheric dispersion models. These include the passive gas dispersion models familiar in hazard assessment, but also in some cases models for transport over much greater distances and periods and in more complex meteorological conditions.

The ISC model of the EPA is widely used, both in its short-term version ISCST and its long-term version ISCLT.

For transport through water the review by McBean may be supplemented by the exhaustive treatment of transport through soil and groundwater, based on fundamental geology and hydrology, given by Sara (1994).

Transport through water is typically modelled using compartment, or control volume, models. For movement in surface water a widely used model is EXAMS of Burns, Cline and Lassiter (1982).

The modelling of the dispersion of a chemical spilled into a stream is discussed by Kontaxis and Nusser (1982).

There is no obvious preferred model for movement through groundwater.

The TOX-SCREEN model of the EPA (1984c), which assesses the potential fate of chemicals released to air, surface water or soil, may be used to screen for substances which even on conservative assumptions are unlikely to pose a threat to the environment.

In the United kingdom, as described by Welsh (1993), the HSE is developing a risk assessment tool for pollution risk from accidental influxes into rivers and estuaries (PRAIRIE), which incorporates a family of river dispersion models DYNUT.

A11.12.3 Transformation of chemicals

Chemicals moving through the environment may undergo a number of transformations, including reactions, among which are (1) hydrolysis, (2) chemical oxidation, (3) photolysis and photo-oxidation, (4) biodegradation, (5) absorption, (6) adsorption, (7) volatilization and (8) sedimentation.

Some of these transformation processes are described by Welsh (1993).

A11.12.4 Fate of chemicals

The determination of the fate of chemicals in the environment is an extremely complex matter. In part it has to do with the transport and transformation processes just outlined and in part with the assimilative capacity of environmental media and with the effects of the take-up of chemicals into food chains. The concept of an ultimate fate appears to imply some eventual steady state, although the associated timescales may well be rather long.

A11.12.5 Capacity of the environment

To a greater or lesser degree, environmental media have the capacity to tolerate a certain chemical burden. The assumption that this is so is frequently implicit in industry practices.

In certain instances this assimilative capacity is estimated and the loading is adjusted accordingly. Two such cases are the limiting chemical load in land treatment and the oxygen demand load on watercourses.

An example of calculated loading occurs in land treatment, where the quantity of liquid waste applied to an area of land may be estimated by identifying the soil contaminant control and removal mechanisms and estimating the assimilative capacity.

A11.12.6 Loading of watercourses

Another example of loading occurs when a chemical is spilled into a watercourse, either by accidental discharge from a works or as a result of a transport accident.

The health of a watercourse such as a stream or river depends on the maintenance of sufficient dissolved oxygen (DO).

Industrial wastewater discharged into a watercourse tends to use up the oxygen in the latter, its propensity to do so being measured by its oxygen demand (OD), or more specifically its biological oxygen demand (BOD), described below. If the wastewater is hot, it also tends to raise the temperature of the watercourse. Discharge of wastewater therefore tends to deplete the oxygen in the watercourse both by virtue of its OD demand and its temperature. Reaeration processes operate to make up the dissolved oxygen deficit caused by these deoxygenation processes.

There are a number of models, described by Nemerow and Dasgupta (1991), of the effect of wastewater discharge. They include the formulation of Streeter and Phelps (1925), the method of H.A. Thomas (1948) and the correlation of Churchill and Buckingham (1956). The latter found that they were able to correlate the DO as a function of the BOD, the temperature and the flow.

A11.12.7 Biological oxygen demand

A standard method of expressing the oxygen demand is as the BOD measured under specified conditions over 5 days and at 20°C.

The solubility of oxygen in water at 20°C is 9.2 mg/l. The BOD of domestic sewage is about 200 mg/l, whilst that of some industrial wastes can be as high as 30,000 mg/l.

Another measure is the chemical oxygen demand (COD). The test for COD is quicker than that for BOD, but since in this case all the organics are oxidized, this test gives a higher reading.

A11.13 Waste Minimization

The development of loss prevention is paralleled by that of waste minimization. A large part of the latter is by inherently cleaner design (ICD), which stands in much the same relationship to the environment as inherently safer design does to safety. But in so far as waste minimization involves management commitment and management systems to deliver a systematic approach, the closer parallel is with loss prevention. Another term commonly used is clean technology.

Accounts of waste minimization are given in *Hazardous Waste Minimization Handbook* by Higgins (1989), *Hazardous Waste Minimization* by R.A Freeman (1990), *Waste Minimization Guide* by Crittenden and Kolaczkowski (1992) and by Redman (1989c), Hethcoat (1990), R. Smith and Petela (1991–), Curran (1992), Chadha and Parmele (1993) and Rossiter, Spriggs and Klee (1993).

In the United States, the waste minimization approach is actively promoted by the EPA, relevant publications being *Waste Minimization, Environmental Quality with Economic Benefits* (EPA, 1987b) and *Waste Minimization Opportunity Assessment Manual* (EPA, 1988).

A11.13.1 Waste minimization management systems

The waste minimization philosophy has been widely adopted in the process industries. As with loss prevention, success has been achieved as management has become convinced and committed and has developed effective strategies, put in place formal systems, allocated the necessary resources, including people, and created a self-reinforcing waste minimization culture.

An account of developments in the United States and elsewhere, is given by Redman (1989c), together with numerous examples of case studies and cost savings.

Basic approaches to waste minimization are to modify (1) the chemicals, (2) the process, (3) the equipment and (4) the effluent treatment. Chemicals which tend to be troublesome include toxic metals and halogenated hydrocarbons. Process modifications which may prove fruitful are replacement of (1) chemical by mechanical processes and (2) single pass processes, including rinse operations, with closed processes. Effluent treatment may be modified to recycle or recover materials.

Approaches to waste minimization are outlined in Figure A11.1. On an existing plant the first step is a waste audit.

The ways in which waste minimization may be effected are very varied. This comes across clearly from the examples quoted by Redman. They include minimization of plant washdowns, squeezing of sludges to remove water and reduce mass, design of drums which leave less residue, and so on.

Redman cites a case, described by Huisingh, in which installation of equipment to recover wastes from film development at a cost of $120,000 made annual savings of $2.6 million on silver and on developing, fixing and bleach solutions, a payback time of one month.

An account of a waste minimization programme in one company is given by Koenigsberger (1986).

A11.13.2 Process plant wastes

A review of the application of waste minimization in the process industries covering (1) the basic problem, (2) reactors, (3) separation and recycle systems, (4) process operations and (5) utilities is given by R. Smith and Petala (1991–).

In a reactor five main sources of waste are (1) low conversion, (2) unwanted by-products from the primary reaction, (3) unwanted by-products from the secondary reaction, (4) unwanted by-products from feed impurities and (5) degraded catalyst. There is often scope for reduction of such waste by the application of reaction engineering principles.

In separation processes there may be scope for waste minimization by (1) elimination of feed impurities, (2) elimination of extraneous materials used for separation, (3) recycling of waste streams and (4) additional separation of such streams.

As an illustration of the benefits of eliminating a feed impurity the authors instance the elimination of nitrogen by the use of oxygen rather than air in the oxychlorination stage of ethylene dichloride production. They describe a design of ethylene dichloride reactor which avoids carryover of the ferric chloride catalyst and thus eliminates the need for washing and neutralization stages.

Under process operations they cover (1) start-up and shut-down, (2) product changeover, (3) equipment maintenance, (4) tank filling, (5) accidental spillages and (6) fugitive emissions. During transient operations such as start-up and shut-down product may be off specification, additional by-products may be made and recycles may not be possible. Product changeover and equipment cleaning give rise to cleaning wastes. Tank filling causes losses as vapours are forced out.

In the utilities wastes are associated particularly with combustion processes, steam generation and cooling water. All these wastes can be reduced by a design which promotes energy efficiency. In combustion methods are discussed of minimizing or dealing with oxides of sulfur and nitrogen. Other wastes to be minimized are boiler and cooling tower blowdowns.

A11.13.3 Refinery wastes

The application of waste minimization to refinery operations has been described by Hethcoat (1990) and Curran (1992).

Whereas originally waste minimization was applied mainly to the conservation of hydrocarbons, it now finds much wider application. The overall strategy involves (1) source reduction and (2) recycling as well as (3) treatment.

Some principal wastes are (1) oily materials, (2) catalyst residues, (3) spent caustic and (4) wastewaters.

Oily residues are oil-coated solids, mainly from oil—water separators, dissolved air filtration (DAF) units, heat exchanger cleanings and tank bottoms. Residues also arise in sewers from road dust materials carried in with runoff water. Waste catalysts arise from processes such as catalytic cracking, conversion of heavier products to lighter ones, reforming of gases to liquid products, and sulfur removal. Spent caustics occur as phenolic or sulfide caustics.

The incidence of wastes is highly variable from one refinery to another. Curran states that quantities of oil residues and usage of water can vary by almost two orders of magnitude.

Measures to reduce refinery wastes include use of mixers in crude oil tanks to keep solids suspended, elimination of intermediate storage tanks between units, elimination of blending tanks by use of in-line blending, minimization of surfactants which cause emulsions and promote sludges, preskimming of oil at the separators, use of pressurized air at the dissolved air flotation unit to give a more concentrated sludge, reprocessing of oily residues in suitable refinery units such as a coker, paving of process areas to reduce dust and sweeping of roads for the same purpose.

At the utilities measures taken include maximization of air cooling, use of a closed cooling water system and reduction of solids in the boiler blowdown water.

Segregation also has a part to play. Curran describes segregation of phenolic and sulfide spent caustics, Hethcoat provision of three separate sewer systems for non-oily liquids and one for oily ones.

Hethcoat discusses the identification of options for waste minimization, under the source reduction, recycling and treatment heads, giving as illustrations oily wastewater from separator bottoms and wastes from empty drums.

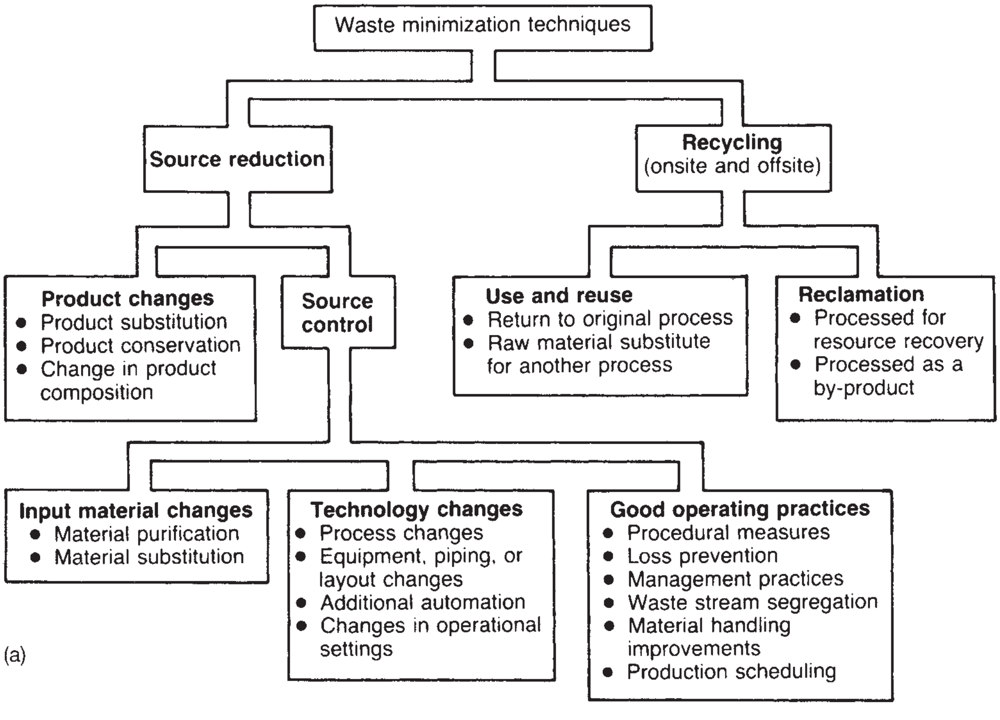

Figure A11.1 *Waste minimization: (a) techniques; and (b) assessment procedure (Environmental Protection Agency; reproduced by permission of Gower Press)*

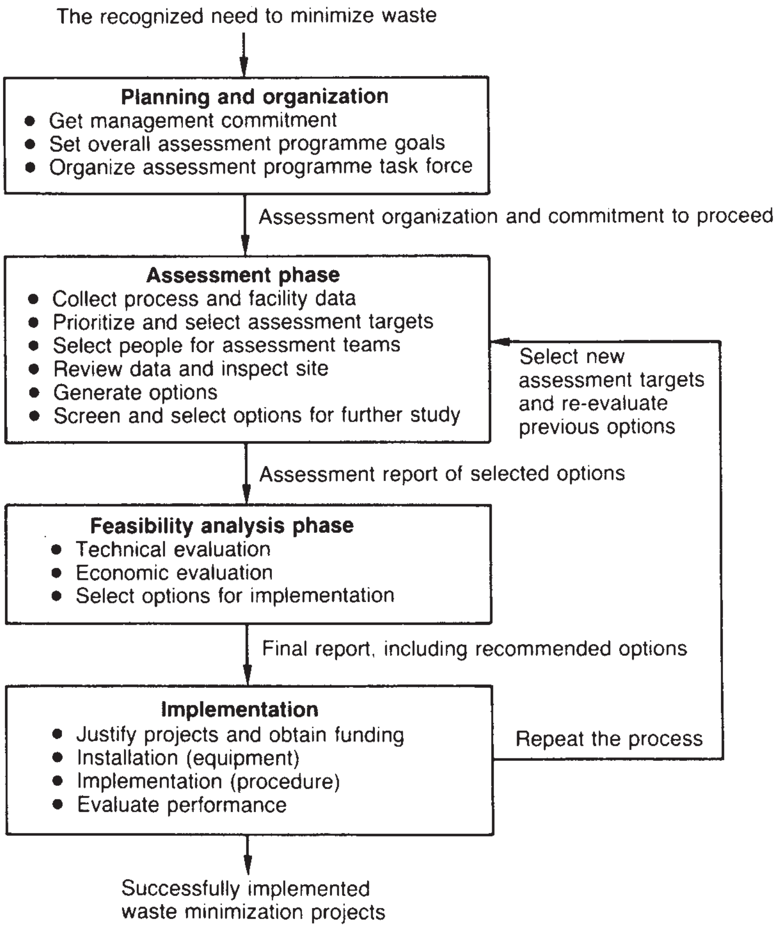

(b)

Figure A11.1 *Continued*

A11.13.4 Process integration

Waste minimization may be addressed in terms of process integration. The treatment by R. Smith and Petala (1991), just described, approaches the problem from this viewpoint. Another account is that of Rossiter, Spriggs and Kell (1993).

A11.13.5 Center for Waste Reduction Technology

The AlChE has set up the Center for Waste Reduction Technology (CWRT), a sister centre to the CCPS. It is described by L.L Ross (1991).

A11.14 Gaseous Effluents

Processes tend to generate a number of gaseous effluents which include impurities entering in the feeds, notably nitrogen in process air and air dissolved in liquid feeds; unwanted gaseous products from reactions; gases from purges such as that in the flare stack; and gaseous products of combustion.

Accounts of gaseous effluents, and the technologies of dealing with them, are given in *Air Pollution Handbook* by Magill, Holden and Ackley (1956), *Atmospheric Pollution* by Meetham (1968), *Air Pollution* by Scorer (1968), *Air Pollution Control* by Strauss (1971–), *Gas Purification Processes for Air Pollution Control* by Nonhebel (1972), *Pollution in the Air* by Scorer (1973), *Compilation of Air Pollutant Emission Factors* by the EPA (1978a), *Fundamentals of Air Pollution* by Stern *et al.* (1973), *Dust Control and Air Cleaning* by Dorman (1974), *Gas Cleaning for Air Quality* by Marchello and Kelly (1975), *Air Pollution* by the Open University (1975a), *Air Pollution* by Seinfeld (1976), *Air Pollution Control Equipment* by Theodore and Buonicore (1976), *Approaches to Controlling Air Pollution* by Friedlander (1978), *Reference Book* by the National Society for Clean Air (NSCA) (1978), *Industrial Air Pollution Handbook* by A. Parker (1978), *Air Pollution Impacts and Control* by Downey and Ni Uid (1979), *Air Pollution Control* by Hesketh (1979), *Air Pollution Control Engineering* by Licht (1980), *Paniculate Air Pollution* by Theodore, Sosa and Fajardo (1980), *Air Pollution* by E. Weber (1982), *Hazardous Air*

Emissions from Incineration by Brunner (1985), *Environmental Pollution and Control* by Veselind, Peirce and Weiner (1990), *Process Engineering and Design for Air Pollution Control* by Benitez (1993) and *Gas Processing: Environmental Aspects and Methods* by Speight (1993).

A11.14.1 Types of gaseous effluent

A gas effluent stream may consist of a gas which is itself noxious or of a non-noxious carrier gas which contains noxious impurities. The impurities may be gases or vapours, liquid droplets or solid particles.

Some principal gaseous effluents which require to be treated are (1) hydrogen sulfide, (2) carbon dioxide, (3) sulfur-containing gases SO_x and (4) nitrogen-containing gases NO_x. Hydrogen sulfide and carbon dioxide are commonly referred to as acid gases.

Hydrogen sulfide figures prominently in oil handling and refining. Carbon dioxide is the main acid gas product of combustion and also arises from oil refining and chemical operations. Sulfur oxides SO_x, essentially SO_2, are generated in combustion of fuel containing sulfur and in oil refining and chemical operations. Nitrogen oxides NO_x, essentially NO and NO_2, arise as so-called fuel-bound NO_x and thermal NO_x from combustion processes.

A11.14.2 Gaseous effluent control

Waste minimization may be applied to reduce the quantities of the gaseous effluents to be treated and the concentration of noxious components in these effluents, and to facilitate any treatment necessary.

A principal application of this approach which has long been practised is desulfurization of coal prior to combustion, as described below.

A11.14.3 Gas cleaning

The main methods of removing noxious gases or vapours from a gas stream are absorption, adsorption, reaction to a solid product and reaction with solids.

Absorption processes for removal of hydrogen sulfide and carbon dioxide are the amine family of processes, including the Girbitol process using ethanolamine, and the carbonate family, including the Benfield process using potassium carbonate, and for removal of hydrogen sulfide the Stretford process using sodium carbonate.

Hydrogen sulfide is removed in the Claus process by thermal and then catalytic reaction to sulfur. Hydrogen sulfide is also removed by reaction with iron oxide, a traditional gasworks process.

Processes for removal by absorption of sulfur dioxide include the Battersea process. Prior to combustion sulfur dioxide may be removed by fuel desulfurization. In its application to coal, this approach is also known as clean coal technology. In the process sulfur dioxide may be removed by reaction with limestone.

Absorption in oil is a traditional method of removing acid gas and hydrocarbons.

Flue gas desulfurization (FGD) comprises a group of techniques. One option is desulfurization of the fuel prior to combustion. A traditional post-combustion method is the removal of sulfur dioxide by the use of lime or limestone in 'wet scrubbers'. Advanced post-combustion methods involve contacting the gas with a sorbent such as lime either by in-stack injection or by injection into separate in-line vessels.

There are also combined processes for removal of both sulfur dioxide and nitrogen oxides, in which FGD is combined with a denitrification step. One method of removing nitrogen oxides is catalytic reaction with injected ammonia.

There are a large number of other gas cleaning processes. Outlines of about 80 are given by Speight (1993). Process flow diagrams are given periodically in *Hydrocarbon Processing*.

Removal of gaseous components may also be effected by the use of membrane processes.

Principal methods for the removal of particles include cyclones, fabric filters and electrostatic precipitators.

A review of technologies for acid gas removal in support of the UK programme is given in *Acid Emissions Abatement Technologies* by the DoE (1991).

A11.14.4 Smog reduction

A number of industrialized countries have suffered from serious air pollution in the form of smog. An account of the 'killer smog' in London in 1952 is given below.

In the United Kingdom, considerable progress has been made in reducing this form of air pollution. Thus in the City of London between 1955 and 1974, for example, the annual average concentrations of smoke and sulfur dioxide near the ground were reduced as follows (Warner, 1976):

	Concentration of smoke ($\mu g/m^3$)	*Concentration of SO_2* ($\mu g/m^3$)
1955	≈195	230
1974	≈40	110

A11.14.5 Tall chimneys

The use of tall chimneys for avoidance of pollution in the immediate vicinity of a plant is a traditional practice. The drawback is that noxious effluents may be spread, albeit in dilute form, further afield.

An account of the practice of the Alkali Inspectorate in relation to tall chimneys has been given by Ireland (1984).

The topic has also been discussed by Perriman (1986).

A11.14.6 Emission bubble

An approach to air pollution control which in principle allows a company to adopt the most economic trade-offs is that of the 'bubble', in which all emissions from sources within the bubble are treated as if they were from a single controllable source. A formal statement of such a policy is that alternative methods of control are allowed provided it can be demonstrated that they are substantially equivalent, the criterion being the equivalence of the emissions leaving the bubble. The bubble concept was adopted by the EPA in 1979. It had a mixed reception, being welcomed in some cases by industry, but not always by the states. An account is given by Weismantel and Parkinson (1980).

A11.15 Liquid Effluents

The liquid effluents from a process plant include not just those shown as such on the flowsheet for the basic process, but a variety of other liquid flows ranging from washwater to rainwater runoff.

Accounts of liquid effluents, and the technologies of dealing with them, are given in *Biological Waste Treatment* by Eckenfelder and O'Connor (1961), *Industrial Wastewater Control* by Gurnham (1965), *Industrial Water Pollution* by Eckenfelder (1966), *Water and Waste Water Engineering* by Fair, Geyer and Okun (1966), *Aqueous Wastes from Petroleum and Petrochemical Plants* by Beychok (1967), *Liquid Waste of Industry* by Nemerow (1971), *Water Pollution* by Newsom and Sherratt (1972), *Waste Water Systems Engineering* by H.W. Parker (1972), *Clean and Dirty Water* by the Open University (1975b), *Handbook of Advanced Wastewater Treatment* by Gulp, Webster and Gulp (1978), *Wastewater Treatment* by Sundstrom and Klei (1979), *Wastewater Treatment and Disposal* by Arceivala (1981), *Biological Treatment of Waste Water* by Winkler (1981), *Handbook of Wasterwater Treatment Processes* by Vernick and Walker (1982), *Removal of Metals from Wastewater* by Cushie (1984), *Hazardous Waste Management Engineering* by E.J. Martin and Johnson (1987), *Environmental Pollution and Control* by Vesilind, Peirce and Weiner (1990), *Wastewater Engineering* by Metcalf and Eddy Inc. (1991) and *Industrial and Hazardous Waste Treatment* by Nemerow and Dasgupta (1991).

The modelling of the hydraulics of, and dispersion in, rivers, estuaries, etc. is described in *Hydraulic Behaviour of Estuaries* by McDowell and O'Connor (1977); *Groundwater* by Freeze and Cherry (1979); *The Mathematics of Hydrology and Water Resources* by Lloyd, O'Donnell and Wilkinson (1979); *Practical Aspects of Computational River Hydraulics* by Cunge, Holly and Verwey (1980); *Hydraulic Modelling* by Kobus (1981); *Models in Hydraulic Engineering* by Noak and Cabelka (1981); and also in certain texts of computational fluid dynamics.

A11.15.1 Types of liquid effluent

Liquid effluents from process plants are fluids from (1) the process, (2) the cooling system, (3) the process ancillary operations, (4) the sanitary system and (5) the rainwater runoff. The process ancillary operations are those such as cleaning and washing.

A proportion of the fluids from the process are liquids which are either non-aqueous or high concentration aqueous wastes. The rest are wastewaters containing oils and chemicals at lower concentrations.

A detailed review of liquid wastes from different industries, including the oil and chemical industries, is given by Nemerow and Dasgupta (1991). They cover organic chemicals; toxic chemicals; acid and chloralkali wastes; formaldehyde wastes; pesticides wastes; and wastes from the energy, fertilizer, phosphates, plastics and rubber, soap and detergent and explosives industries.

A11.15.2 Wastewater control

Wastewater requires a degree of treatment before it is discharged to receivers such as municipal systems or watercourses. There are a number of prior measures which may be taken to minimize the extent of the treatment required. These measures include (1) volume reduction, (2) strength reduction and (3) flow equalization and proportioning.

Waste minimization may be applied to reduce the volume of wastewater either by generating less in the first place or by reusing it. It may also be applied to keep down the concentration of contaminants in the wastewater. Segregation of wastewaters also has a role to play in reducing the volume to be treated or facilitating treatment.

Flow equalization involves the control of flows discharged to smooth out plant flow fluctuations and flow proportioning the control of discharge flows to match those in the municipal system or the watercourse.

A11.15.3 Wastewater treatment

Complete treatment of wastewater is typically classified as follows: (1) wastewater pretreatment, or conditioning, (2) primary treatment, (3), secondary treatment, (4) tertiary treatment, (5) sludge treatment and (6) liquid and sludge disposal.

Wastewater pretreatment processes are screening and grit removal and neutralization.

Primary treatment of wastewater involves removal of suspended solids by (1) sedimentation and (2) flotation. Either process may be operated with chemical addition. Removal of oil droplets can be effected by gravity separation.

Solids also occur in colloidal form, and the methods of dealing with them are often termed intermediate treatment. They include (1) chemical coagulation, (2) charge neutralization coagulation and (3) adsorption. The second of these involves coagulation by neutralization of the electric charge.

Secondary treatment processes deal with dissolved organic materials and comprise a range of mainly biological treatments. These processes are (1) aerobic or (2) anaerobic.

There is a wide variety of aerobic processes including (1) lagooning, (2) activated sludge, (3) modified aeration, (4) dispersed growth aeration, (5) high rate aerobic treatment, (6) contact stabilization, (7) trickling filtration, (8) biological discs, (9) mechanical aeration, (10) wet combustion and (11) spray irrigation. Holding in lagoons is used to effect biological degradation. Activated sludge involves oxidation by floes from suspended and colloidal solids, the sludge concentration being controlled by a recycle. Modified aeration is a modification of the activated sludge method. Dispersed growth aeration is a variant, which does not involve the use of floes. Contact stablization, or biosorption, is another modification of the activated sludge method. High rate aerobic treatment, or total oxidation, is another sludge process but with a higher sludge return rate. Trickle filtration and biological discs involve oxidation by slimes, the substrate being in the one case a packed bed and in the other rotating discs. Mechanical aeration involves sparging air into the liquid. Wet combustion, or wet air oxidation, is described below. In spray irrigation the liquid is sprayed onto land with aerobic conditions maintained to a certain depth, and is thus both a treatment and a disposal.

Anaerobic digestion takes place in closed vessels in the absence of air. Loadings are low and residence times long. It is most suited to small throughputs of liquids with high concentrations of readily oxidized organics and is used mainly for sludges rather than liquid wastes.

Other methods of removing organics include steam stripping and solvent extraction.

Tertiary treatment processes remove dissolved inorganic materials. They involve both chemical treatments and physical separation using a variety of unit operations. Chemical methods include (1) coagulation and precipitation and (2) oxidation and reduction reactions. Unit operations utilized are (1) evaporation, (2) adsorption,

(3) ion exchange, (4) reverse osmosis and (5) electrodialysis. Adsorbents used are activated carbon and polymers.

Sludge treatment methods include (1) digestion, (2) conditioning, (3) thickening, (4) dewatering and (5) drying. Digestion may be aerobic or anaerobic, utilizing some of the methods already described. Conditioning is effected using chemical and thermal methods. Thickening may be done in (1) gravity, (2) flotation or (3) centrifugal thickeners. Methods of dewatering are (1) vacuum filtration, (2) filter press dewatering, (3) belt filter dewatering and (4) centrifugal dewatering.

A11.15.4 Wet air oxidation

For water contaminated by small amounts of organic compounds a method of treatment which is often attractive is the wet air oxidation (WAO) process, also referred to as wet combustion. Accounts are given by Flynn (1979), Wilhelmi and Knopp (1979), Laughlin, Gallo and Robey (1983), Baillod, Lamparter and Barna (1985), Heimbuch and Wilhelmi (1985), E.J. Martin and Johnson (1987) and Nemerow and Dasgupta (1991).

The aqueous effluent to be treated is pumped to a high pressure, passed through a heater to heat it part way to the reaction temperature, then into a reactor vessel where compressed air is blown in and where the resultant exothermic reaction raises the liquid to its reaction temperature, finally out through a cooler to a separator where the oxidized liquid is taken off the bottom and nitrogen, carbon dioxide, steam, etc., off the top. Typical reaction temperatures are in the range 275–320°C. There are numerous variations on this basic process, including the use of a catalyst.

Wet air oxidation can degrade most industrial organic compounds. The reduction, or dilution, factors obtainable are generally good, though higher in some cases than others. Wilhelmi and Knopp list factors in the range 12–4200.

A11.15.5 Wastewater receivers

Wastewater treated to a suitable quality may be discharged to the municipal sewage system, to watercourses such as streams or rivers, or to land.

Some options available in principle are discharge of (1) raw industrial and sanitary wastes to the municipal system, (2) partially treated industrial and sanitary wastes to the municipal system, (3) completely treated industrial and sanitary wastes to the municipal system, partially treated industrial wastes to a watercourse, completely treated industrial wastes to a watercourse, and (6) completely treated industrial wastes to land. These options are discussed in detail by Nemerow and Dasgupta (1991).

A11.15.6 Deep well disposal

A quite different option for dealing with liquid wastes is deep well injection. Accounts are given by M.E. Smith (1979) and Nemerow and Dasgupta (1991).

This form of disposal has been used particularly in the United States, subject to strict controls and permitted only if no better method is available.

The formation selected to receive the waste is one below the levels holding potable water. The basic technology used derives from oil and gas production. The receiving formation may first be given a conditioning treatment. In order to eliminate solids, the waste is pretreated to remove suspended solids. In addition, a buffer solution such as dilute salt water may first be injected to prevent precipitation from the waste liquid.

A11.15.7 Sludge disposal

Methods of disposal of sludge from wastewater treatment include lagooning, landfill, incineration and sludge barging.

Lagooning involves digestion and is in effect a treatment process which shades into storage or disposal. Landfill may take the form of area landfill or trench landfill. Incineration is considered below.

Sludge barging has been used but tends to involve problems of sludge rising to the surface or being washed ashore, and in many cases has been discontinued.

A11.16 Hazardous and Solid Wastes

In addition to gaseous and liquid effluents, it is also necessary to deal with hazardous and solid wastes, including sludges and residues.

Accounts of hazardous wastes and solid wastes, and the methods of waste disposal, are given in *Disposal of Solid Toxic Wastes* by Key (1970), *Solid Wastes* by Mantell (1975), *Waste Recycling and Pollution Control* by Bridgewater and Mumford (1979), *Toxic and Hazardous Waste Disposal* by Pojasek (1979), *Handbook of Industrial Waste Disposal* by Conway and Ross (1980), *Design of Land Treatment Systems for Industrial Waste* by Overcash and Pal (1980), *Waste Management* by Woolfe (1981), *Hazardous Material Spills Handbook* by G.F. Bennett, Feates and Wilder (1982), *Hazardous Waste Processing Technology* by Kiang and Metry (1982), *Risk Assessment of Hazardous Waste Sites* by Long and Schweitzer (1982), *The Scientific Management of Hazardous Wastes* by Cope, Fuller and Willetts (1983), *Handbook of Industrial Residues* by Dyer and Mignone (1984), *Hazardous Air Emissions from Incineration* by Brunner (1985), *Handbook of Laboratory Waste Disposal* by Pitt and Pitt (1985), *Hazardous Waste Management* by Dawson and Mercer (1986), *The Solid Waste Handbook* by W.F. Robinson (1986). *Hazardous Waste Management Engineering* by E.J. Martin and Johnson (1987), *Handbook of Hazardous Waste Incineration* by Brunner (1989), *Environmental Impacts of Hazardous Waste Treatment, Storage and Disposal Facilities* by Salcedo, Cross and Chrismon (1989), *Emerging Technologies in Hazardous Waste Management* by Tedder and Pohland (1990), *Environmental Pollution and Control* by Veselind, Peirce and Weiner (1990), *Hazardous Waste Treatment Technologies* by Jackman and Powell (1991), *Industrial and Hazardous Waste Treatment* by Nemerow and Dasgupta (1991), *Environmental Impact Assessment for Waste Treatment and Disposal Facilities* by Petts and Eduljee (1994) and *Standard Handbook for Solid and Hazardous Waste Facility Assessment* by Sara (1994).

A11.16.1 Types of hazardous and solid waste

Hazardous and solid wastes fall into three categories (1) hazardous liquid wastes, (2) hazardous solid wastes and (3) non-hazardous solid wastes. The main concern here is with the first two of these.

A11.16.2 Hazardous waste control

The principles of waste minimization should be applied to minimize the quantity of hazardous waste and to ease the problems of handling it in treatment, storage and disposal facilities.

A11.16.3 Hazardous waste treatment, storage and disposal

Hazardous wastes may be stored or sent to ultimate disposal, either with or without prior treatment.

Methods of dealing with solid hazardous wastes include the use of (1) incineration, (2) landfill, (3) waste piles and (4) storage. Incineration, landfill and land treatment, which are usually treated as methods of ultimate disposal, are discussed further below.

A waste pile, or tip, may be regarded as storage or disposal, depending on the acceptability of its being permanent. Storage proper is typically in drums.

There are a number of methods of stabilization, fixation, solidification and encapsulation available for the treatment of residues and sludges, many developed originally for radioactive wastes. An account is given in E.J. Martin and Johnson (1987).

For liquid hazardous wastes methods include the use of (1) incineration, (2) surface impoundment, (3) land treatment and storage. Incineration and land treatment are both methods of ultimate disposal.

Surface impoundment (SI) or lagooning, has been discussed above. The liquid may be aerated or non-aerated. As stated, a lagoon may be regarded as a form intermediate between treatment, storage and ultimate disposal.

Storage is mainly in storage tanks, which may be open, open with external floating roof, closed with fixed roof and closed with internal floating roof. The vapour space may be inerted.

A11.16.4 Incineration

A prime method of dealing with hazardous waste is incineration. It is used for solid, liquid and sludge or residue wastes.

Treatments of incineration are given in *Handbook on Incineration* by Cross (1972), Incineration by Brunner (1987) and *Handbook of Hazardous Waste Incineration* by Brunner (1989) and by Novak and Pfrommer (1982), Grumpier and Martin (1987), Wiley (1987), Vervalin (1990), Veselind, Peirce and Weiner (1990) and Nemerow and Dasgupta (1991). Particular aspects of incineration discussed are the decision whether or not to use incineration by Haseltine (1992), testing of incinerators by Monroe (1983b), off-normal emissions from incinerators by Zeng and Okrent (1991), problems with incinerators by Ready and Schwab (1980), role of incineration in remedial actions by H.M. Freeman (1984) and dioxin problems by Beychok (1987). Plasma arc incineration is described by Ondrey and Fouhy (1991).

Incineration is a preferred method of the EPA.

Incineration is commonly carried out in dedicated equipment. Types of incineration equipment are described by Novak and Pfrommer (1982) and Brunner (1989). Alternatively, in some instances items of process plant may be used as incinerators. Feeley (1984) describes the use of boilers for this purpose.

Incineration of solid wastes is done in open pits, rotary kilns and multiple hearth furnaces.

Ideally, the products of combustion from an incinerator are carbon dioxide and water vapour. In practice, the gaseous effluents may contain more noxious gases due to (1) incomplete combustion and (2) components in the waste. Some effluents which are troublesome in incinerators include sulfur and nitrogen oxides, metals and dioxins.

There are three main factors which determine the completeness of combustion: time, turbulence and temperature – the three Ts. The first two are set by the design of the system, leaving only the temperature as an operating variable. The temperature is controlled by adjusting the air/fuel ratio.

If the effluent gas falls below the concentration at which it can sustain combustion before destruction is sufficiently complete, one option may be to use an afterburn by injecting additional fuel gas. Alternatively, it may be necessary to pass the effluent gas through a scrubber. Thus an incinerator produces both gaseous effluent and ash, and may produce a liquid effluent also.

Combustion products which have proved particularly troublesome are the dioxins, notably TCDD. TCDD is a product in virtually all combustion processes, including barbecues. The production of TCDD at incinerators has been the subject of much concern. Controls are such that operators are required to keep the concentration of TCDD measured in the adjacent area vanishingly small.

Incineration has the advantages that it is an established process, can handle a wide range of wastes, can accept high throughputs and is economical in its requirement for land, especially relative to landfill. Disadvantages are the comparatively high cost and the effluents generated.

Hazardous wastes in sludge form are incinerated in rotary kilns, fluidized beds and multiple hearth furnaces.

Incineration is also practised for liquid wastes, provided they are at least partially combustible. A liquid waste may be categorized as combustible, partially combustible or non-combustible. A waste with a calorific value below about 18,500 kJ/kg is regarded as only partially combustible. Where the properties allow, liquid wastes are generally injected through an atomizer.

A11.16.5 Landfill

Another principal method of disposing of hazardous waste is landfill (LF). This involves depositing the hazardous waste on land which is then covered over. Both area and trench systems are used.

Accounts of the landfill option are given in *Landfill Technology* by Crawford and Smith (1985) and by A. Parker (1982), G.W. Dawson (1983), J.B. Cook (1984), Loehr (1987), Veselind, Peirce and Weiner (1990) and Nemerow and Dasgupta (1991).

The main problem with landfill is the leaching out of hazardous substances and transport of these into watercourses. Leachate management is therefore essential if landfill is used.

This aspect is discussed in *Groundwater Contamination from Hazardous Wastes* by E.F. Wood (1984) and by Hoppe (1984a), Shuckrow, Touhill and Pajak (1987), Ahlert and Kosson (1990) and Batchelor (1990).

There are a number of options for dealing with leachates. The first should be the application of waste minimization to eliminate or reduce potential leachates. The site can be designed to minimize the generation and escape of leachates, which includes diversion of surface waters and provision of barriers such a liners and trenches. Leaching may be reduced and/or leachate treatment simplified by segregation of wastes. Stabilization methods may be used to minimize leaching. The leachates may be collected and treated.

Economic estimates generally show landfill to be appreciably cheaper than incineration but the potential for migration of leachates into watercourses can be a serious problem which may well alter the balance of advantage.

A description of an landfill project associated with the chemical industry is given by Anon. (1988k).

A11.16.6 Land treatment

Land treatment involves spraying the liquid on land, exploiting the assimilative capacity of the soil.

Accounts are given in *Design of Land Treatment Systems for Industrial Wastes* by Overcash and Pal (1980) and by Loehr (1987) and Nemerow and Dasgupta (1991).

A11.16.7 Contract disposal

The producer of hazardous wastes often has the option of having them removed by a specialist contractor. Given the number and severity of problems often arising with such wastes, this can be an attractive option.

The main point to be made here is that regulatory controls are now such that there is a responsibility of the producer to ensure that the wastes are properly disposed of. The producer who hands over the wastes to a 'cowboy' contractor can expect trouble.

A11.16.8 Hazardous waste facility siting

A hazardous waste treatment, storage and disposal facility is liable to pose a more serious siting problem than the generality of process activities. In the United States more than half the applications for such developments fail. An account of the siting problem of TSDFs, with emphasis on the public consultation process, is given by Barclay (1987).

A11.16.9 Hazardous waste facility management

A hazardous waste facility needs to be managed. Incineration, landfill and storage all involve their characteristic management problems.

Active management is required of the basic activity and of the monitoring of effluents from the treatment processes, of spills and other escapes, and of the concentrations of chemicals in the immediate environment.

For landfill, leachate management assumes particular importance. An account is given by Shuckrow, Touhill and Pajak (1987).

A11.16.10 Hazardous waste facility reclamation

In the past hazardous waste was frequently deposited in an uncontrolled manner, with the consequence that many countries have a large number of waste disposal sites, which present major problems in establishing ownership and responsibility, reasserting control and effecting reclamation.

Accounts of land decontamination and reclamation are given in *Reclamation of Contaminated Land* by the SCI (1980), *Remedial Action Technology for Waste Disposal Sites* by Rogoshenski, Boyson and Wagner (1983) and by Wagner *et al.* (1986), *Evaluation of Remedial Action Unit Operations at Hazardous Waste Disposal Sites* by Ehrenfeld and Bass (1984), *Contaminated Land: Reclamation and Treatment* by M.A. Smith (1985), *Dioxin Containing Wastes: Treatment Technologies* by Arienti *et al.* (1988), *Environmental Remediation* by Vandegrift, *Reed and Tasker* (1992) and *Remedial Processes for Contaminated Land by Pratt* (1993).

As described earlier, under CERCLA 1980, or Superfund, the EPA is charged with supervision of site clean-up and federal funds are available for this. An account is given in *Superfund Handbook* by Sidley and Austin (1987).

A11.16.11 Ocean dumping and incineration

A quite different solution to the waste disposal problem is to dump or incinerate the waste at sea.

Accounts of these options are given in *Ocean Dumping of Industrial Wastes* by Ketchum, Kester and Park (1981) and *Ocean Disposal Systems for Sewage Sludge and Effluent* by the NRC (1984) and by Finnecy (1982), Remirez (1982), Crumpler and Martin (1987), Ditz (1988) and Nemerow and Dasgupta (1991).

Essential safeguards in any system of ocean dumping are those substances which are highly toxic and persistent and do not disperse sufficiently are not dumped and that for those materials which are the assimilative capacity of the area should not be overloaded.

Vessels used for ocean incineration include *Matthias I, II* and *III*, Vesta and Vulcanus. Of these the MT Vulcanus, a cargo ship converted in 1972 into a chemical tanker with two large incinerators, is perhaps the best known and documented. These incinerator vessels are described by Finnecy (1982).

Both ocean dumping and ocean incineration are governed by the marine pollution conventions. The Convention for the Prevention of Marine Pollution by Dumping of Wastes and Other Matter 1972 (the London Dumping Convention (LDC)) governs ocean dumping, and provisions on ocean incineration have been added to this.

A review of the operation of this convention is given by the IMO (1991 IMO-532). The unregulated dumping which used to take place has largely stopped, the dumping of certain wastes has been eliminated altogether or is being phased out and stringent programmes are in place to assess the need for and impact of ocean disposal.

A11.16.12 Underground storage tanks

It is convenient at this point to mention briefly the problem of leaking underground storage tanks (USTs) and pipework. The use of underground storage is widespread but in recent years there has been growing concern, particularly in the United States, over leaks from such installations. Accounts are given by G. Parkinson (1987) and Stone (1987).

Underground storage tanks are considered in Chapter 22.

A11.17 Fugitive Emissions

Fugitive emissions occur on process plants from diffuse continuous sources such as valves, seals and flanges; from equipment which operates intermittently such as pressure relief valves; from the 'breathing' of storage tanks; and from activities such as draining and sampling and the opening up of equipment during operations or for maintenance.

Accounts of fugitive emissions are given in *Fugitive Emissions of Vapour from Process Plant Equipment* by the BOHS (1984 TG3) and *Health Hazard Control in the Process Industries* by Lipton and Lynch (1987).

The topic of fugitive emissions can be considered under the following heads: (1) emission sources, (2) emission control, (3) occupational health effects and (4) environmental effects.

Fugitive emission sources, emission control and occupational health aspects are discussed in Chapters 15, 12 and 18, respectively.

The environmental effect which initiated concern over fugitive emissions was smog, originally in Los Angeles.

The EPA has been active to reduce fugitive emissions, as instanced by *Compilation of Air Pollutant Emission Factors* (EPA, 1973), *VOC Fugitive Emissions in Synthetic Organic Chemical Manufacturing Industry – Background Information for Promulgated Standards* (EPA, 1982) and *Standards of Performance for New Stationery Sources Equipment Leaks of VOC, Petroleum Refineries and Synthetic Organic Chemical Manufacturing Industry* (EPA, 1984).

A11.18 Odours

Another form of pollution is noxious odours. The concentration at which a substance can cause an odour can be very low, and certainly well below the levels of the air quality standards set to prevent air pollution.

Accounts of odours and their control are given in *Methods of Air Deodorisation* by Summer (1963), *Odour Pollution of Air* by Summer (1971), *Human Response to Environmental Odors* by Turk, Johnston and Moulton (1974) and *Odour Control* by Valentin and North (1980) and by Oelert and Florian (1972), Amoore and Hautala (1983), Ruth (1986), Langenhove, Lootens and Schamp (1988), Miedema and Ham (1988), Valentin (1990), Nagy (1991), A.M. Martin *et al.* (1992) and Sober and Paul (1992).

A11.18.1 Regulatory controls

Regulatory controls on odours are at present fairlyrudimentary. In the UK, odours are statutory nuisances under the EPA 1990 and subject to control by the local authorities.

In the USA the Clean Air Amendments 1990 provide a framework within which controls on industrial odours may develop.

In the Netherlands, the authorities have taken initiatives, described below, aimed at putting odour control on a more scientific basis.

A11.18.2 Odour-generating activities

Many of the activities which give rise to noxious odours lie outside the mainstream process industries, being such as agricultural activities; animal waste rendering and leather tanning; fishmeal processing; sewage and effluent treatment and sludge disposal; brickmaking; and so on. However, petroleum refining and chemical manufacture do generate odours as do coke ovens and tar distillation; pulp and paper processing; plastics and rubber processing; soap and detergent manufacture; and fermentation processes associated with brewing or pharmaceutical manufacture.

A11.18.3 Odour measurement

A fundamental approach to odour measurement would appear to require that (1) the components responsible for the annoyance are identified, (2) their concentrations are measured and (3) their contributions, severally and possibly in combination, are quantified. This is a tall order. It is not surprising therefore that the most practical way of measuring an odour is still the human nose.

The method commonly used is to assemble an odour panel of suitably selected individuals and to use the technique of dynamic dilution. This involves diluting the original sample containing the odour with progressively larger quantities of clean air until 50% of the panel can no longer detect the odour. The results obtained are sensitive to the experimental conditions and can vary by a factor of 10 or more.

The concentration at which the odour is no longer detectable to 50% of the panel is designated as one odour unit (ou). The number D of dilutions required to get down to this concentration is a measure of the odour concentration of the original sample. Thus if dilution by a factor of 2000 is required ($D = 2000$), the odour concentration of the sample is 2000 ou.

A11.18.4 Odour thresholds

There are available a number of compilations of odour thresholds. They include the collections in Standardised Human Olfactory Thresholds by Devis (1990) and by Leonardos, Kendall and Barnard (1969), Amoore and Hautala (1983) and Ruth (1986).

A11.18.5 Odour sources

Odour sources may take the form of point sources, area sources, line sources or fugitive emissions. An area source is exemplified by an open tank containing liquid and a line source by a works transport route. A discussion of such sources is given by Sober and Paul (1992).

Fugitive emission sources, with typical emission rates, are listed in EPA AP-42 Compilation of Air Pollutant Emission Factors (1985).

A11.18.6 Odour dispersion

The dispersion of an odour may be modelled using passive gas dispersion models, which are described in Chapter 15.

The use of such models is discussed by Sober and Paul (1992). They refer in particular to the various EPA models such as ISC and Inpuff.

Models specific to odours, developed at Warren Spring Laboratory (WSL), have been described by Valentin and North (1980) and Valentin (1990). For short-range dispersion from a ground level source, the following simplified relation provides a rough guide:

$$Dr = 7E/UX^2 \qquad [A11.18.1]$$

with

$$E = D_e F \qquad [A11.18.2]$$

where D_e is the odour concentration at the emission point (ou), D_r is the odour concentration at the receptor point (ou), E the contaminant, or odour, emission flow (m^3/s), F the total emission flow (m^3/s), U the wind speed (m/s) and X the distance between the emission and receptor points (m).

Other WSL models relate to the distance at which complaints can be expected. For ground level emissions

$$d_{\max} = (\phi E)^{0.6} \qquad [A11.18.3]$$

with

$$E = DF \qquad [A11.18.4]$$

where $d_{\max}$ is the maximum distance at which complaints can be expected (m), D the dilution factor (ou) and ϕ a factor. The value of ϕ is 2.2, which is the geometric mean of the uncertainty range 0.7–7. The equation can be used for emissions for chimneys provided that $d_{\max}$ is 40–50 times the effective chimney height.

An equation is also given for the effective chimney height for nuisance-free dispersion:

$$H_e = (\psi E)^{9.5} \qquad [A11.18.5]$$

where H_e is the effective chimney height (m) and ψ a factor. The value of ψ is 0.1, which is close to the geometric mean of the uncertainty range 0.05–0.15. The actual chimney height is obtained by subtracting the plume rise from the effective chimney height.

The last two equations encompass not just dispersion but also human response. The ability to correlate the complaints distance, albeit with a wide uncertainty range, by extrapolation from panel experiments to field assessments on the basis of the dilution factor D is encouraging for the development of a generalized approach.

A11.18.7 Odour control strategy

The outline of an odour control strategy is given by Valentin (1990). A necessary preliminary is to establish that it really is your plant which is the source of the problem. The odour sources should be identified. If practical, an odour source should be eliminated. For those which are not eliminated, ventilation, local where possible, should be used to remove and collect the contaminated air. If the air stream contains mist or dust, these should be removed. This air should then be treated using one of the methods described below.

A11.18.8 Odour control techniques

There are a number of methods available for treating air containing air contaminated with odours. Accounts are given by Valentin (1990) and A.M. Martin *et al.* (1992).

Martin *et al.* describe a wide range of techniques, including (1) incineration, (2) adsorption, (3) absorption, (4) condensation, (5) advanced oxidation and (6) biological treatment. Incineration may be carried out in a thermal incinerator, a catalytic incinerator, a flare, a boiler or a process heater. Adsorption is commonly by carbon. Advanced oxidation involves treatment with an oxidizing agent such as ozone using UV radiation to effect photochemical stimulation of the reaction. Biological treatment may be by a biological scrubber or a biological filter. The authors give examples of the efficiencies obtained with the different methods and guidance on selection of a method.

The options available are also discussed by Valentin, who deals in particular with thermal and catalytic incineration, adsorption, absorption and biological filters.

A11.18.9 Odour impact on community

Studies of the impact of odours on the neighbouring community have been described by van Langenhove, Lootens and Schamp (1988) and Miedema and Ham (1988).

The former study involved the investigation of odour from an animal rendering plant. A questionnaire was used to assess the proportion of persons annoyed by the odour at different distances. The effective limit of the nuisance was found at about 600 m. The authors then used a passive gas dispersion model to work back to the effective strength of the source, which they assessed as 68×10^6 ou/h.

Miedema and Ham describe field studies conducted by TNO in support of Dutch government plans for odour control. The authors emphasize the importance of the method used to assess the dilution factor D. They describe and advocate the use of the TNO 'sniffing car' method.

These authors too made use of a questionnaire to determine the relation between the distance and the proportion of persons annoyed by the odour. They correlate their results in terms of the C_{98} value, or the 1 hour average concentration which is exceeded only 2% of the year, and of the probability of being annoyed, expressed as a Z score, from the normal distribution, and obtain the relation

$$Z = 1.19 \log C_{98} - 2.16 \qquad [A11.18.6]$$

They suggest that a correlation of this type has potential as the basis for standards for odour control.

A11.19 Transport

A proportion of the chemicals produced are consumed on site, but a large proportion are transported from the site.

The transport of chemicals is discussed in Chapter 23 and emergency planning for such transport in Chapter 24.

Such transport, whether by vehicle or a pipeline, has the potential for an accident resulting in a spill. Spills are discussed in the following section.

A11.19.1 Transport of hazardous wastes

There is also the separate question of the transport of hazardous wastes. This has been a severe problem area due to the prevalence of illicit practices in transport and disposal, described in *Laying Waste* by M. Brown (1981). The transport of hazardous wastes, and of material from spill incidents, is discussed by R.J. Buchanan (1982), Bromley and Finnecy (1985) and Colen (1987b).

A11.20 Spills

Another way in which pollution can occur is by a liquid spill, either at a fixed site or during transport, including by pipeline.

Spills are treated in *Hazardous Chemicals – Spills and Waterborne Transportation* by Weidenbaum (1980) and *Hazardous Material Spills Handbook* by G.F. Bennett, Feates and Wilder (1982) and by Lindsey (1975) and Feates (1978).

The variety of situations which can occur and of the responses are illustrated in the numerous case histories described in the conference series *National Conference on Hazardous Materials Spills* in the United States.

In the United States, hazardous materials spills involve several agencies, including the DOT, the EPA and the FEMA, as reflected in the guidance published for the EPA in *Manual for the Control of Hazardous Material Spills* by Huibregtse *et al.* (1977), in *Emergency Guide for Selected Hazardous Materials* by the DOT (1978) and for FEMA in *Planning Guide and Checklist for Hazardous Materials Contingency Planning* by Gunderloy and Stone (1980).

A11.20.1 Types of spill

Some principal types of spill are those from (1) process plant or storage, (2) pipeline, (3) road tanker, (3) rail tank car, (5) barge, (6) ship and (7) drilling rig or fixed production platform.

A spill within the works occurs in a relatively controlled environment, but this is less true of one in transport.

A liquid spillage on land poses a threat to land and to watercourses. It is characterized by the facts that the release is transient and generally relatively limited in volume but often noxious.

Liquid spilled into a stream can cause a degree of pollution which kills off much of the aquatic life so that a long period elapses before recovery can occur.

A11.20.2 Response to spills onto land

If a spill occurs on land, there are a variety of measures which can be taken. A review is given by Scholz (1982), who considers the problem under the heads of (1) termination of discharge, (2) containment to prevent entry into watercourses and (3) recovery and treatment.

Chemical and physical measures are discussed by Eckenfelder (1982) who covers (1) neutralization, (2) sedimentation, (3) coagulation, (4) precipitation, (5) carbon adsorprtion, (6) ion exchange, (7) oxidation–reduction reactions and (8) biodegradation. A fuller account of biological measures is given by Armstrong (1982).

The EPA has developed a number of items of equipment for dealing with spills, including a portable foam diking system, a mobile physical–chemical treatment unit, a portable sedimentation tank, a mobile incineration system and a mobile soil decontamination system. The foam diking system can be used to restrict the flow of a liquid over asphalt or concrete or to plug drains to prevent liquid from entering. These and other devices are described Freestone and Brugger (1982), in an account of EPA development work on spill control technology, and also by Scholz.

Accounts of specific techniques and devices for dealing with hazardous material spills include those on physical barriers by Friel, Hiltz and Marshall (1973), sorbents by Melvoid and Gibson (1988), a mobile treatment system by M.K. Gupta (1976), a mobile incineration system by Tenzer *et al.* (1979), groundwater protection by Huibregtse and Kastman (1981), *in situ* detoxification of soil by Huibregtse, Lafornara and Kastman (1978) and soil reclamation by Wentzel *et al.* (1981).

A11.20.3 Response to spills into streams

If a spill occurs which threatens a stream may be possible to prevent it from entering the stream, but once it does the measures which can be taken are generally limited.

Strategies for dealing with spills into streams have been described by G.W. Dawson and co-workers (Dawson, Shuckrow and Mercer, 1972; Dawson, 1975; Dawson and Parkhurst, 1976; Dawson and McNeese, 1978).

One approach is stream diversion. The EPA has developed a portable stream diversion system capable of bypassing 0.35 m^3/s a distance of 300 m.

Accounts are given by Lafornara (1982) of stream sampling and analysis, by Nadeau (1982) of bioassay and by Kontaxis and Nusser (1982) of dispersion modelling.

A11.20.4 Response to oil spills

Methods for the control of oil spills have been published by CONCAWE. They include a manual on inland oil spill cleanup (CONCAWE 1981 7/81), disposal techniques for spilt oil (CONCAWE 1980 9/80), protection of ground-water from oil pollution (CONCAWE 1979 3/79), strategies for the assessment of biological impacts of large oil spills on European coasts (CONCAWE 1985 5/85), and field guides to inland oil clean-up (CONCAWE 1983 10/83), coastal waters clean-up (CONCAWE 1981 9/81) and oil spill dispersal (CONCAWE 1988 2/88).

A11.20.5 Ultimate disposal of spilled material

Ultimate disposal of spilled material is considered by Lindsey (1975), R.J. Buchanan (1982), Novak and Pfrommer (1982) and A. Parker (1982). The options described by these authors are primarily incineration and landfill.

A11.21 Marine Pollution

Pollution of the seas occurs by discharges made following cleaning of tanks of oil tankers and as a result of accidental spillages from oil tankers and chemical carriers.

Pollution may occur as the result of illicit discharges or as the result of an accident. Most of the incidents which have hit the headlines have occurred after the ship has run aground.

Accounts of sea pollution are given in *Oil Pollution of the Sea and Shore* by WSL (1972), *Accidental Oil Pollution of the Sea* by the DoE (1976), *Marine Pollution* by R. Johnston (1977) and *Pollutant Transfer and Transport in the Sea* by Kullenberg (1982), *Poisoners of the Sea* by Goudray (1988) and *Marine Pollution* by R.B. Clark (1993) and of pollution criteria in *Pollution Criteria for Estuaries* by Helliwell and Bossanyi (1975).

The WSL publication records experience gained as a result of the pollution mitigation activities following the Torrey Canyon disaster.

A11.22 Pollution Incidents

Incidents involving pollution occur both from fixed installations and in transport and over varying timescales.

A11.22.1 Incident databases

The SRD operates the Environmental Data Service EnvIDAS which complements its other databases MHIDAS for major hazard incidents and EIDAS for explosion incidents.

In addition, the account of an incident in a hazards database frequently includes some information on environmental effects.

A11.22.2 Air pollution

Air pollution incidents tend to take the form of (1) a sudden large release, (2) a regular lower level release which is aggravated by an unusual weather condition or (3) a regular practice of lower level release which is found to be damaging the environment.

An example of a sudden large release is that at Seveso, described in Appendix 3.

A11.22.3 Smog incidents

At the end of October 1948, a heavy smog developed in inversion conditions in the industrial town of Donora, Pennsylvania. After several days conditions became such that 17 died within one day; a further 4 succumbed before the smog abated.

The worst smog incident recorded was the 'killer smog' in London in 1952. Again a heavy smog developed in inversion conditions. The concentration of sulfur dioxide rose to some seven times its normal level. The maximum mean daily concentration of the gas in Central London reached 3500$\mu g/m^3$. Two days into the incident the death rate began to soar. The number of excess deaths was estimated at about 4000.

A11.22.4 Bonnybridge

An example of the problems attendant on incineration is provided by the travails of Rechem, a company involved in the incineration of hazardous wastes. During the 1980s, the incinerators which it operated included one at Bonnybridge in Scotland and one at Pontypool in Wales. At Bonnybridge there were complaints from the public and cattle nearby suffered from an unexplained sickness. Tests did not confirm excessive levels of contamination, but the plant was closed. The company had further troubles in its relations at Pontypool, though again numerous independent surveys failed to find concentrations of contaminants above the background levels.

A11.22.5 Watercourse pollution

Watercourse pollution incidents tend to take the form of (1) a sudden large release, (2) a temporary but appreciable increase in the quantity or concentration of a regular release or (3) a regular practice of lower level release which is found to be damaging the environment.

A11.22.6 Schweizerhalle

On 1 November 1986, a fire in a agrochemical warehouse at Schweizerhalle in Basel, Switzerland, broke out and was extinguished with large quantities of fire water, which became contaminated and then found its way into the Rhine, causing serious pollution. The incident is described in Case History A113.

A11.22.7 Minimata

Discharge of mercury compounds in Minimata Bay in Japan led to severe pollution and to the Minimata mercury poisoning disaster. For some 15 years prior to 1953, the Chisso Chemical Company had been discharging mercury catalyst into the bay. People fell ill, at first in small and then in increasing numbers. In 1957, a ban was placed on fishing in the bay. Of 116 officially recorded cases in 1958, 43 had died. By 1972, the official list of victims was almost 300.

A11.22.8 Hazardous waste pollution

Hazardous waste tends to give rise to developing problems at hazardous waste facilities rather than to incidents as such. However, incidents can arise such as those due to serious malpractice in transport of such wastes.

Accounts of hazardous waste problems and incidents are given in *Laying Waste* by M. Brown (1981) and *World of Waste* by Goudray (1992).

A11.22.9 Love Canal

The scale of the environmental disaster which may result from waste disposal is illustrated by the case of Love Canal. In 1953, this site was sold by the Hooker Chemical Company to the Niagara Falls education authority for a nominal sum. For over a decade the site had been used to dump chemical wastes. In 1976, local residents began to complain of odours and other nuisance. Concern escalated, leading to the relocation of 238 families and causing the President to declare the site a national environmental emergency, making it thereby eligible for federal clean-up funds.

There were numerous damage suits. In support of its suit against the company, the Justice Department commissioned a chromosome study of 36 residents; the study proved controversial.

The engineering measures taken to render the site safe are described by Glaubinger, Kohn and Remirez (1979).

A11.22.10 Land spill pollution

Incidents involving PCBs are described by A.J. Smith (1982), others involving pesticides by Frisbie (1982) and one involving phenol by A. Shepherd (1982a).

The Seveso incident, in which a large area of land was contaminated with TCDD, is described in Appendix 3.

A11.22.11 Sea pollution

Sea pollution incidents which tend to have particularly serious consequences are groundings of tankers on coasts. The three cases given below are all of this kind. Pollution of the sea also occurs from oil production activities, as described in Appendix 18.

A11.22.12 Torrey Canyon

On 18 March 1967, the tanker Torrey Canyon, carrying 114,000 tons of crude oil, ran aground on the coast of Cornwall, releasing 30,000 tons of oil. Over the next 7 days a further 20,000 tons escaped. On 26 March the ship broke its back with release of another 50,000 tons. Following this, the ship was bombed to burn the remaining 20,000 tons and the oil slick was sprayed with detergent to disperse it.

A11.22.13 Amoco Cadiz

On 16 March 1978, the oil tanker Amoco Cadiz lost its steering and ran aground at Portsall on the Brittany coast. The resulting oil spill polluted some 200 km of coastline, causing an incident which at the time was the worst to have occurred.

A11.22.14 Exxon Valdez

On 24 March 1989, the tanker Exxon Valdez ran aground near Valdez, Alaska, rupturing eight cargo tanks and releasing some 258,000 bbl of oil. The result was a major environmental disaster.

A11.23 Notation

Section A11.18

C_{98}	1-h average concentration exceeded only 2% of the year
$d_{\max}$	maximum distance at which complaints can be expected (m)
D	dilution factor (ou)
D_e	odour concentration at emission point (ou)
D_r	odour concentration at reception point (ou)
E	contaminant, or odour, emission flow (m^3/s)
F	total emission flow (m^3/s)
H_e	effective chimney height (m)
U	wind speed (m/s)
X	distance between emission point and reception point (m)
Z	score value
ϕ	factor
ψ	factor

Appendix 12

Noise

Contents

The environment may be degraded not only by chemical pollution but also by noise. Process plant contains a variety of noise sources covering rotating equipment, piping, combustion equipment and vents to atmosphere. Noise from process plant sources may affect workers from the perspective of noise induced hearing loss and the general public through environmental or community noise impacts. The control of noise from process plants needs to be controlled and noise control design needs to be an integral part of the engineering and planning for any process facility.

Accounts of noise, noise effects on humans and noise control are given in the following references:

- *Handbook of Noise Control* by C.M. Harris (1957),
- *Handbook of Noise Measurement* by A. Peterson and Gross (1967),
- *Noise and Vibration Control* by Beranek (1971),
- *Noise and Hearing Conservation Manual* by Berger *et al.* (1986 AIHA/11),
- *Engineering Noise Control* by Bies and Hansen (1988),
- *Woods Practical Guide to Noise Control* by Sharland (1990),
- *Noise and Health* by Fay (1991 ACGIH/70) and
- *Noise and Vibration Control Engineering* by Beranek and Ver (1992).
- *Code of Practice for Reducing the Exposure of Employed Persons to Noise* by the DoE (1972/1) (the DoE Noise Code).

A12.1 Regulatory Controls

Regulations applicable to noise levels within an industrial facility are intended to protect employees from noise-induced hearing loss. The regulations are usually based on an employee noise exposure limits (e.g. 85 dB(A) averaged over 8 h). The regulations normally allow for exposure to higher noise levels for reduced time periods and mandate the use of hearing protection if necessary. This allows the employees' averaged noise exposure level to remain below the safe limits.

Applicable regulations for the UK/EEC and USA would include the following:

- EEC Machinery Directive – 'Noise at Work Directive', 86/188/EEC and 'Machinery Directive', 89/392/EEC.
- UK Noise at Work Regulations 1989.
- USA OSHA regulation – USA Code of Federal Regulations Title 29 Part 1910.95

Typically these regulations set a series of action levels based on employee noise exposure levels as follows:

(1) First Action Level – daily personal noise exposure exceeds 85 dB(A)
  - Employer is responsible for initiating a hearing conservation programme and having noise assessment made by a competent person.
  - Employer is required to reduce the risk of hearing damage from exposure to noise to the lowest level reasonably practicable.
  - Appropriate hearing protection should be available to the employee on request.

(2) Second Action Level – daily personal noise exposure of 90 dB(A)
  - Appropriate hearing protection must be made available to all persons exposed.
  - Employer must reduce noise as far as reasonably practicable.
  - Other requirements include assessment records and audiograms, designated ear protection zones, training on maintenance and use of equipment and provision of information to employees and information to employees.

The following International Institute of Noise Control Engineering (I-INCE) Publication summarizes and compares employee noise exposure regulations for a range of countries worldwide: 'Technical Assessment of Upper Limits on Noise in the Workplace' I-INCE Publication 94-1.

Community or environmental noise impact must also be considered in plant noise control design. Noise limits set to control noise emissions outside of the plant are primarily intended to protect plant neighbours from noise-related annoyance or interference. In setting community noise limits, local regulations need to be considered together with assessments of likely community reaction to the increased noise levels. These issues also need to be considered in the context of the Environmental Impact Assessment (EIA) for the project.

Government regulations to control environmental noise vary greatly from country to country. Typically regulations apply to particularly zoning areas or land use classifications with different noise limits defined for specified daytime and night-time noise levels (e.g. residential, mixed residential/commercial, industrial etc.). These limits are forced to be generic and may not meet the specific requirements of a plant location. An important point, which is often overlooked, is that compliance with community noise regulations does not ensure against community complaints. People will complain because they find the noise disturbing or annoying, not because it exceeds a government regulation.

An EIA for a project would require the evaluation of the existing ambient noise levels in the proposed plant location and the predicted operational noise levels from the facility to assess the noise impact of the new plant.

Applicable standards and references for environmental noise would include the following:

- World Bank – '*Pollution Prevention and Abatement Handbook*' of 1998.
- US Export Import Bank – *'Environmental Procedures'* 1998.
- ISO 1996-1:1982 *'Acoustics Description and Measurement of Environmental Noise – Part 1: Basic Quantities and Procedures'.*
- ISO 1996-2:1987 *'Acoustics – Description and Measurement of Environmental Noise – Part 2: Acquisition of Data Pertinent to Land Use'.*
- ISO 1996-3:1987 *'Acoustics – Description and Measurement of Environmental Noise – Part 3: Application to Noise Limits'.*
- UK Control of Pollution Act 1974.
- UK Environmental Protection Act 1990.

A12.2 Process Plant Noise

The following organizations have a series of useful standards and guidelines relevant to Process Plant Noise:

- Engineering Equipment Material Users Association (EEMUA), 14-15 Belgrave Square, London, England SW1X 8PS UK; Phone: 071-235-5316

- CONCAWE, Madouplein 1, Brussels B-1030, Belgium; Phone: 32-2-220-3111
- American Petroleum Institute, 1220 L Street, NW, Washington, DC 20005-4070; Phone 202-682-8000

A12.3 Noise Control Terminology

A summary of widely used noise control terminology is given below:

- Audible Frequency Range
  The range of sound frequencies normally heard by the human ear. The audible range spans from 20 Hz to 20 kHz, but for most engineering investigations only frequencies between 40 Hz and 11 kHz (i.e. 63 Hz to 8 kHz octave bands) are considered.
- Background Noise
  The sound pressure levels in a given environment from all sources excluding a specific sound source being investigated or measured.
- Decibels (dB)
  Ten times the logarithm (to the base 10) of the ratio of two mean square values of sound pressure, voltage or current.
- Sound Pressure
  A dynamic variation in atmospheric pressure. The pressure at a point minus the static atmospheric pressure at that point (N/m^2).
- Sound Pressure Level (L_p)
  The ratio, expressed in decibels, of the mean square pressure to a reference mean square pressure which by convention has been selected to be equal to the assumed threshold of hearing.

$$L_p = 10 \log_{10}\left(\frac{P}{P_{\text{ref}}}\right)^2$$

where P = RMS sound pressure (N/m^2); $P_{\text{ref}} = 2 \times 10^{-5}$ N/m^2.

- Sound Intensity
  The rate of sound energy transmission per unit area in a specified direction (W/m^2).
- Sound Intensity Level (L_I)
  The rate of sound energy transmission per unit area in a specified direction related to a reference intensity level.

$$L_I = 10 \log_{10}\left(\frac{I}{I_{\text{ref}}}\right)$$

where I = RMS value sound intensity (W/m^2); $I_{\text{ref}} = 1 \times 10^{-12}$ watts/m^2.

- Sound Power
  The total sound energy radiated by a source per unit time (W).
- Sound Power Level (L_w)
  The acoustic power radiated from a given sound source as related to a reference power level, expressed in decibels.

$$L_w = 10 \log_{10}\left(\frac{W}{W_{\text{ref}}}\right)$$

where W = RMS value sound power (W); $W_{\text{ref}} = 1 \times 10^{-12}$ watts.

- Octave Bands
  Frequency ranges in which the upper limit of each band is twice the lower limit. Octave bands are identified by their geometric mean frequency (center frequency). The table below shows the octave band upper/lower frequency limits.

Octave band cut-off frequencies (Hz)

Octave band center frequency	*Lower band limit*	*Upper band limit*
31.5	22	44
63	44	88
125	88	177
250	177	355
500	355	710
1,000	710	1,420
2,000	1,420	2,840
4,000	2,840	5,680
8,000	5,680	11,360
16,000	11,360	22,720

- 1/3 Octave Bands
  Frequency ranges where each octave is divided into one-third octaves with the upper frequency limit being 1.26 times the lower frequency. Identified by the center frequency of each band.
- A-Weighted Sound Pressure Level (dBA)
  The sound pressure level measured using an electronic filter that approximates the frequency response of the human ear. The table below shows octave band A-weighting correction factors.

Octave band A-weighting correction factors

Octave band center freq (Hz)	*A-weighting correction* (dB)
63	−26.2
125	−16.1
250	−8.6
500	−3.2
1000	0
2000	+1.2
4000	+1.0
8000	−1.1

- L_{Aeq} – Equivalent Continuous Sound Level
  The A-weighted energy mean of the noise level averaged over the measurement period. It can be considered as the continuous steady noise level which would have the same total A-weighted acoustic energy as the real fluctuating noise measured over the same time period.

$$L_{\text{Aeq}} = 10 \log_{10} \frac{1}{T} \int_0^T \left(\frac{p_A(t)}{p_o}\right)^2 \mathrm{d}t$$

where T = total measurement time; $P_A(t)$ = A-weighted instantaneous sound pressure; $P_{\text{ref}} = 2 \times 10^{-5}$ N/m^2

L_{Aeq} is, therefore, an important number for the evaluation of a fluctuating noise level, because it reflects the actual energy content of the time varying noise. L_{Aeq} is used in its own right in many national and international standards for rating some forms of community noise.

- L_{N} – Percentile Level
  The A-weighted sound level equalled or exceeded by a fluctuating sound level × percent of the measurement time period. For example:c

  L_{A10} – the A-weighted sound pressure level exceeded for 10% of the measurement period
  L_{A50} – the A-weighted sound pressure level exceeded for 50% of the measurement period
  L_{A90} – the A-weighted sound pressure level exceeded for 90% of the measurement period

  The various L_{N} levels over a measurement period are important in the evaluation of the temporal nature of the sound. A widely varying sound level over a measurement period will tend to have large differences between the various L_{N} levels than a more constant steady noise.

- Daily Personal Exposure
  The daily personal exposure of an employee is defined in the schedule to the HSE *Noise Guide 1* as follows:

$$L_{\mathrm{EP,d}} = 10\log_{10}\left[\frac{1}{T_o}\int_0^{T_e}\left(\frac{pA(t)}{p_{\mathrm{o}}}\right)^2 \mathrm{d}t\right]$$

  where $L_{\mathrm{EP,d}}$ is the daily personal exposure (dB(A)); $p_{\mathrm{A}}(t)$ is the time-varying value of the A-weighted instantaneous sound pressure in the undisturbed field (Pa); t is the time (h); p_{o} is the base value of the sound pressure (Pa); T_{e} is the duration of the exposure (h); T_{o} a period of 8 h. As before, the value of p_{o} is 2×10^{-5} Pa.

A12.4 Noise Control

Noise control is generally considered under four heads: (1) at source, (2) in transmission, (3) on emission and (4) on receipt.

Noise can be generated only if there is a vibrating source, which may take the form of a vibrating surface or of fluctuation in fluid flow. The topic of noise is therefore inextricably bound up with that of vibration, as attested by the titles quoted earlier.

- Control at Source
  Control of noise at source should be the first option considered. The approach is analogous to inherently safer design. The approach to noise control at source is to identify potential sources and to either eliminate them altogether or to reduce their level of vibration by one or more of the following: the surface, the amplitude, the frequency and, in the case of a fluid, the flow velocity. A number of specific methods for control of noise, such as impact reduction, clamping, damping, acoustic panels and silencers can be considered.
- Control in Transmission
  In principle, noise associated with transmission through pipes and ducts may be structure-borne or fluid-borne. For gas or vapour pipes the sound is predominantly fluid borne as evidenced by the effectiveness of control by the use of in-line silencers. Such silencers are used, for example, on the intakes and exhausts of internal combustion engines and on the intake/exhaust of fans.
- Control on Emission
  Control on emission involves modification of the route by which the noise reaches the worker. Devices used include sound-absorbing materials on the workroom walls, sound-absorbing screens, total or partial enclosure of machines and cabins serving as 'noise refuges'. Another approach is to increase the distance between the worker and the noise source. Distance may be increased by segregation of noisy machines, use of remote controls and siting of exhausts.
- Control at Receiver
  Control at the receiver involves the use of ear protection. Types and selection of ear protectors are discussed in HSE *Noise Guide 5*.

  Limiting the time for which the person is exposed to the noise may effect some reduction in the noise burden, but to be effective the proportion of time exposed has to be cut drastically. Complete removal for half a shift, for example, reduces the daily exposure by only 3 dB(A).

The importance of addressing noise control issues as early as possible in a process plant engineering project cannot be over emphasized. The earlier noise control design issues are identified and resolved on a project, the more effective is the noise control design. That is effectiveness as measured in terms of overall project costs, impact on project schedule and compliance with the project noise requirements.

Effective noise control design for refining or petrochemical projects requires careful planning during the initial stages of the project, with equally careful and prudent execution through the various phases of the project. Before addressing specific project noise control design issues it will be useful to place some perspective on the noise control challenges faced on process plant projects. Any metric, from the capital cost, which can run in hundreds of millions, if not billions, of US dollars to the thousands of individual equipment items and bulk quantities of piping demonstrates the scale and complexity of these projects. The projects can be completely new 'grass-roots' plants or expansions to existing facilities. Often times a large project is further complicated by the need to divide the engineering in to manageable packages, with different engineering contractors responsible for different process units.

The sections below highlight the key noise control design activities from the initial front end engineering design (FEED) phase of the project through Detailed Design to Commissioning and Start-up:

- Front End Engineering Design (FEED)
  Noise control must be executed as early as possible in a project to minimize the effect on project costs layout and schedule. The major noise control activities on a project, therefore, tend to focus towards the FEED phase of the project. During these initial stages of a project, baseline noise surveys may be required to establish existing noise levels at the plant site. For a 'grass-roots' project the primary focus of the baseline survey will be on community noise levels. For an expansion project at

an existing facility the survey must consider both in-plant and community noise levels.

The key noise control task during the early stages of a project is the FEED Noise Study. This study evaluates the potential noise sources within the plant and establishes, through plant noise modelling, the predicted noise levels (in-plant and community) for the new facility. The initial modelling will be based on standard equipment with no special provision for noise control. The modelling will establish a baseline noise control position for the overall plant. This will identify potentially high noise equipment and high noise areas of the plant and will allow noise control design options to be readily included and evaluated in the plant noise model. This 'what if' analysis will allow the noise control design to be optimized to meet the plant owner's overall project noise control requirements.

Effective and accurate plant noise modelling is critical to this evaluation process. The plant noise modelling must be based on international and industry accepted standards (e.g. EEMUA, CONCAWE, ISO 9613). Noise model input data must be based on reliable and verifiable equipment and field noise data. Only with a solid background of field experience on comparable equipment in similar service can the noise control engineer speak with authority on predicted plant noise levels.

The findings of the FEED Noise Study will provide the data to define definite and unambiguous noise limits and requirements for the Detailed Design phase of the project. This will apply to the designation of in-plant noise limits and the definition of 'Restricted Areas' (i.e. hearing protection areas) together with property line noise requirements and overall sound power level limits. The goal must be to define and specify noise control requirements so that they meet the project requirements and can be effectively managed and enforced during the Detailed Design phase of the project.

- Detailed Design.
  Noise control for the detailed design phase of a project will involve the engineering contractor, or contractors, executing the noise control design for the project in compliance with the noise limits defined during the FEED phase of the project. Primary areas of noise control activity during the Detailed Design phase of the project would include:

  - Equipment requisition and design/data review process
  - Piping noise and control valve noise control
    - Acoustic insulation definition
    - Low noise control valve selection
    - Vent and in-line silencers
  - Acoustic enclosures
  - Acoustic insulation for rotating equipment
  - Equipment shop noise testing (only in appropriate situations when good measurements are possible)

- Commissioning and Start-up.
  The main noise control activities during commissioning and start-up will be noise surveys to demonstrate/verify compliance with the project noise limits. Depending on the results of the noise surveys corrective action may need to be initiated to reduce operation noise levels.Depending on the project type, long-term environmental noise monitoring in the community or on the plant property may be worthwhile during commissioning/start-up. This type of monitoring would provide data on upset and startup venting operating conditions (e.g. flaring). Obtaining reliable data on these difficult to reproduce operating conditions may prove valuable.

Noise control issues associated with typical classes of process plant equipment area discussed below:

- Rotating Machinery
  A major source of noise in process plant is rotating machinery. Centrifugal compressors can produce noise levels of up to 100 dB(A) at 1 m from the equipment surface, often with dominant tonal content at the blade passing frequency. The casing is usually sufficiently massive to prevent transmission of aerodynamic vibration. There are also other noise sources such as motors, turbines, gear units, lube oil pumps and control valves. Full acoustic enclosure is usually unnecessary and it is more common to use a combination of acoustic insulation and spring support for the pipework together with low noise valves.Another source of noise on rotating machinery is electric motors. Large medium voltage motors can produce a noise level above 90 dB(A), due principally to the cooling air fan and also sometimes to magnetically induced vibration. The problem is generally soluble using smaller, more efficient cooling air fans but on occasion increased frame size and/or cooling air silencers may be required.
- Fluid Flow in Pipes
  Another main source of plant noise is the flow of fluids in pipes. Noise control of individual plant items may not be sufficient to attain the noise target and it may be necessary to address the noise in the pipework also.

  Noise from gas pipes is the subject of studies by CONCAWE described by Marsh *et al.* (1985), Pinder (1985) and van de Loo (1988). The CONCAWE piping model is an essentially empirical one and is somewhat similar to that in VDI 3733. With regard to noise control, Pinder outlines four methods, which relate to: pipewall thickness, plant layout, in-line silencers and acoustic insulation.

  Noise due to flow through valves is discussed in ISA S75.17-1989 *Control Valve Aerodynamic Noise Prediction.*
- Combustion Processes
  Combustion processes are also a significant source of plant noise. On furnaces with induced or naturally induced air flow the air inlet and combustion noise can exceed 90 dB(A) @ 1 m per burner unless adequate acoustic absorption is included in the design of the burner plenums. With forced draft systems the sound levels are much less, noise in this case coming mainly from the fan intake, casing and motor. Noise can be transmitted by furnace wall and by duct vibration, the solution in this case being adequate stiffness.
- Flares
  A particular type of combustion process that is liable to generate a high level of noise, including noise affecting the public, is a flare.

  The noise generated by a flare is a function of the energy release in the flame. Swithenbank (1972) has defined a noise generation efficiency equal to the fraction of the net heat release which is given off as noise power, and has correlated it with mass velocity at the flare tip. Ohiwa, Tanaka and Yamaguchi (1993) describe fundamental studies on the noise from a turbulent diffusion flame.

As he points out, proprietary flare tips are available to overcome the noise problem. Effective designs are based on the Coanda effect plus other utilizing mufflers or baffles for steam assist flares. A ground flare design also offers benefits for reduced noise due to flaring.

- Pressure Relief

  An alternative method of disposal that also generates noise is venting to atmosphere. A method of estimating the noise from a high pressure relief discharging to atmosphere through a vent stack is given in API RP 521: 1990.

A12.5 Notation

f	fractional exposure
f_{tot}	total fractional exposure
H	sound power level (dB)
L	sound pressure level (dB(A))
L_{eq}	equivalent continuous sound level (dB(A))
$L_{EP,d}$	daily personal exposure (dB(A))
L_T	sound pressure level at distance r (dB)
N	number of decibels (dB)
$p_A(t)$	time-varying value of A-weighted instantaneous sound pressure in the undisturbed field (Pa)
p_o	base value of sound pressure (Pa)
P	pressure disturbance (Pa)
r	distance (m)
t	time (h)
T_e	duration of exposure (h)
T_o	8-h period
W	source power (W)

Subscript

o	reference level

Appendix 13

Safety Factors for Simple Relief Systems

Contents

A13.1 Comments on Safety Factors to be Applied when Sizing a Simple Relief System

It is recommended that a safety factor be applied to take account of both uncertainty in the data and inaccuracy in the calculation methods.

It is assumed in the following discussion that (1) the designer has chosen a method appropriate to the application, intended to tend towards oversizing the relief system rather than the reverse, and (2) the relief system consists at most of a safety valve or bursting disc preceded by a constant diameter pipe and followed by a constant diameter pipe to atmosphere. It is also assumed that the flow through any safety valve has been checked against the manufacturer's data; under no circumstances should the mass flow be assumed to exceed the value so calculated.

The safe case is that which corresponds with the highest estimate of the required relief rate(s) and the lowest estimate of the actual flow(s).

The overall safety factor can be applied in one of two ways:

(1) by sizing the relief system to pass a flow equal to the required mass flow multiplied by the safety factor; or
(2) in cases where the vent capacity is determined by one particular cross-sectional area, by multiplying the calculated required vent area by the safety factor. However, it is important then to check that the capacity remains determined by this area.

The overall safety factor F_O may be represented as the product of a number of sub-factors, each taking account of particular features:

$$F_o = \prod_{i=1}^{n} F_i \qquad \text{[A13.1]}$$

where F_i is the sub-factor for feature i. Some of the sub-factors which may be appropriate are

(1) A sub-factor ($\geqslant 1$) to reflect any features of the method, unless included in other specific sub-factors such as those suggested below, which might lead to undersizing of the relief system for the application concerned. These might be features of the methods used to calculate the required relief rate(s) or vent area, although in most cases the methods will have been chosen so as to tend to overestimate those. They may also be features of the approach to assessment of the relief system flow capacity not covered below, for example the method may have neglected the presence of solids in the flow. The designer must himself establish the required value for this sub-factor.
(2) A sub-factor ($\geqslant 1$) to take account of uncertainty in the data. The magnitude and direction of any errors arising from the data assumptions should be assessed. For reactors particular attention should be paid to any errors affecting the rate of reaction including its dependence on temperature.
(3) A sub-factor ($\geqslant 1$) to allow for the inaccuracy in the fluid flow calculation methods which is present even for incompressible liquid and/or ideal gas. In this discussion it is assumed that the largest realistic pipe roughness has been assumed, otherwise a larger sub-factor will be necessary.

Some recognized wide-applicability two-phase gas/vapour-liquid flow methods, when used for lines in which friction and/or static head are significant, may be accurate only to a factor of ±2 (i.e. the actual flow is in the range half to two times the calculated value), and would thus correspond to a sub-factor of 2. For poorer methods, a larger sub-factor may be needed, while for methods more targeted at the specific application a lower sub-factor may suffice; expert advice should be sought. For two-phase gas/vapour-liquid flow with negligible friction and no changes in static head, for example through a safety valve alone, lower sub-factor values in the range 1.2–1.5 may sometimes be sufficient; expert advice should be sought.

For vapour-only flow when friction is significant a reasonable value for this sub-factor will usually lie in the range 1.2–1.5, while if only momentum changes are significant, a lower sub-factor may be allowable; expert advice should be sought.

(4) A subfactor to allow for the effects of gas/vapour-phase nonideality if these have not been taken into account in the mass flow capacity calculation.

For critical (choked) frictionless gas/vapour-only flow (e.g. through a safety valve alone) the factor may be estimated from the work of Leung and Epstein (1988) using their figures 2, 4–6. These figures show the ratio of real-gas critical mass flow to ideal $(Z = 1)$ critical mass flow (our sub-factor is the inverse of this ratio) as a function of the ratio (stagnation (inlet reservoir) pressure/thermodynamic critical pressure), for various values of the ideal (zero pressure) ratio of specific heats. The figures are based on the applicability of the Redlich–Kwong equation of state, but give a useful indication of the magnitude of the effects of non-ideality on critical flow. It can be seen that a sub-factor is needed for pressures exceeding about 20 times the critical pressure. At lower pressures the real critical flow is seen to be greater than the ideal critical flow, but caution should be exercised before adopting a sub-factor <1. It should be noted that non-ideality cannot be fully compensated for by assuming a constant Z value or using an adjusted fictitious molecular weight; this is discussed below.

For gas/vapour-only flow with friction, and for non-choked flow with or without friction, the author is unaware of any treatment analogous to that of Leung and Epstein. For given inlet reservoir conditions and back pressure and assumed constant Z, the adiabatic or isothermal mass flow of a gas through a perfect nozzle, and from a reservoir via a perfect rounded inlet into and through a straight pipe, is proportional to $1/Z^{1/2}$ (Lapple, 1943). This suggests an approximate value for this sub-factor given by

$$F_4 = \frac{\text{Real gas mass flow}}{\text{Ideal gas } (Z = 1) \text{ massflow}} = \frac{1}{Z_{\max}^{1/2}} \qquad \text{[A13.2]}$$

where $Z_{\max}$ is the maximum value of Z occurring in the flow. Clearly this sub-factor will be inaccurate when Z varies significantly (e.g. near the thermodynamic critical point, and near choking conditions); this can be seen by comparing this sub-factor (which if Z were constant would apply equally to critical frictionless flow) with the sub-factor obtained from the work of Leung and Epstein for critical frictionless flow (and also from their figure 9). It would seem prudent to adopt a sub-factor at least as large as the larger of these two estimated sub-factors (but again, care should be exercised before adopting any value <1). If the non-ideality is severe and such as to reduce the flow, then ideally the relief system should be sized using a method which takes full account of non-ideality; the other sub-factors would still be required. If the non-ideality is severe but (as is more likely) is such as to increase the flow, then a sub-factor of 1 may be prudent.

It should be noted that the above sub-factors based on the work of Leung and Epstein and of Lapple are for application to the mass flow calculated on the basis of fully ideal ($Z=1$) flow. If the flow has been calculated as semi-ideal with an assumed constant Z, or with an adjusted fictitious molecular weight, to give partial compensation for the departure from ideality, then this corresponds to the prior application of a sub-factor of $Z^{1/2}_{\text{assumed}}$ or $(\text{MW}_{\text{actual}}/\text{MW}_{\text{assumed}})^{1/2}$.

It seems likely that the effects of gas/vapour-phase non-ideality in two-phase gas/vapour-liquid flow, will be less, but the author is not aware of any studies to validate this. It is suggested that this sub-factor be taken as the same as for gas/vapour-only flow.

(5) A sub-factor ($\geqslant 1$) to take account of errors in the flow calculation for two-phase gas/vapour-liquid flow resulting from neglecting the variation in liquid density, liquid specific heat and latent heat along the pipe. The variation in these quantities can be judged from the calculated conditions along the pipe and thermodynamic charts. Then either a value can be assigned to this sub-factor or safe values can be assigned to those properties and the sub-factor set to 1. For calculation of mass flow capacity, safe values (giving a low mass flow) are low density, high specific heat and low latent heat. For gas-only or vapour-only flow, this sub-factor is irrelevant.

Finally the designer must check that there are no further sub-factors to be included, and decide whether to accept the calculated overall safety factor F_0. There is little published advice on typical factors. It would be surprising if the overall factor were to be less than 1.2 in any event, and significantly larger factors would be likely for reactors. For polymerization reactors Boyle (1967) said that the specified relief area should be two to three times the area indicated by design calculation (but note that this was before the preparation of the DIERS methods). Boyle's recommendation is consistent with typical overall factors obtained using the approach described above for two-phase vapour/liquid venting.

Caution

It is emphasized that the above comments are offered only to assist the designer in his consideration of what might be an appropriate overall safety factor. The designer must decide whether the advice is relevant to his application (bearing in mind the restrictions defined in the second paragraph of this note) and what sub-factors and overall factor are adequate.

Appendix 14

Failure and Event Data

Contents

Many of the methods described in this volume require the use of data for failure and other events. This appendix gives a brief account of such data and a selection of references, which have been published in the open literature.

The data are given in summary form and primarily for illustrative purposes only. It is emphasized that there are many factors that determine the failure rates of equipment and the range of failure rates observed can be quite wide. It should be borne in mind that the same data are often quoted by a number of references. The existence of several sets of data that are in agreement is not necessarily evidence of the validity of the data. For industrial reliability work, therefore, it is necessary to consult the original literature and to make appropriate use of data banks and plant data.

Selected references on event and failure data are :

A14.1 Type of Data

There are several types of data that may be required. The first type is accident and incident data including the recording of system malfunctions, accident reports and databanks established to store accident information. The second type is event and failure rates data that involve all the abnormal events and the performance of equipment. For equipment, these data include:

(1) Failure frequency, probability
(2) Repair time
(3) Unavailability

and for events:

(4) Event frequency.

Failure rate data are usually given as frequencies or mean time to failure (MTTF). Two types of failure rate data are typically used: time-related and demand-related. Time-related failure rates are established for equipment that is continuously in use while demand-related failure rates are for equipment that is normally dormant and required to operate on demand.

A14.2 Definition and Regimes of Failure

The failure rate recorded for equipment necessarily depends on the definition of failure. The importance of this may vary. Failure of a pump to start on demand would appear relatively unambiguous, but failure of a pressure relief valve may refer either to failure of the set pressure to stay within prescribed limits when removed from the plant and tested in the workshop or to failure to relieve pressure during plant operation. An equipment failure can be catastrophic, degraded or incipient. It is essential to have a uniform definition and classification of failure for data collection, selection and verification.

It is usually assumed that the failure rate of a component, or strictly the hazard rate z, is constant, but this may not necessarily be the case, especially at the burn-in and wear-out stages of its life cycle. Consideration may be given to the effect of time-dependent failure characteristics for the equipment and processes perceived critical to plant operation. Bathtub and Weibull distribution have been used to represent a wide range of failure data. The hazard rate may be decreasing, constant or increasing, corresponding to the regimes of early failure, constant failure or wearout failure and characterized by values of the Weibull shape parameter $\beta < 1, 1, > 1$, respectively. A number of workers have found an early failure regime, corresponding to $1 < \beta$. Some typical results are

Equipment	β	*Reference*
Pump,		
type A	0.74–1.07	de la Mare (1976) Berg (1977)
type B	0.69–0.87	de la Mare (1976)
Valves	0.70–1.02	de la Mare (1976)
Pumps	as low as 0.5	Aird (1977b)

A further account of the Weibull method is given in Chapter 7.

A14.3 Influence Factors

The failure rate of equipment is influenced by a large number of factors, including design, specification, manufacture, application, operating conditions, maintenance, and environment. Process equipment is used in a wide variety of operating conditions and environments, and it is desirable to account for these influencing factors.

For some types of device, the effect of certain influencing or environmental factors can be quite well defined. An environment factor K, which is a multiplier to the nominal failure rate, is widely used for the effect of temperature on items of electrical equipment such as resistors. Some values of environment factors are given by A.E. Green and Bourne (1972). Base failure rate, quality factor, learning factor, and environment factor are defined in MIL-HDBK-217F (1991) to predict failure rates for some electronic equipment. It is more difficult to define the effect of such factors on mechanical equipment, but a few examples may be mentioned. Several authors have given correlations for the effect of particular influencing factors on equipment. Moss (1977 NCSR R11) has given data on the failure rates of mechanical valves in two nuclear power stations. The overall failure rates λ of the valve were

Steam valves	$\lambda = 0.1$ faults/year
Water valves	$\lambda = 0.01$ faults/year

The variation of the failure rate with the severity of the operating conditions pressure and temperature was correlated by an equation of the form

$$\lambda = \lambda_0 \exp\left[\frac{D}{D_0} - 1\right] \qquad \text{[A14.3.1]}$$

with

$$D = p + t \qquad \text{[A14.3.2]}$$

where D is the severity parameter, p is pressure (psi), t is temperature (°C) and subscript 0 indicates base case.

C.F. King and Rudd (1972) have expressed the hazard rate for pumps as function of the form

$$z = At^{-1/2} + B + Ct^3 \qquad \text{[A14.3.3]}$$

where t is time and A, B and C are functions of temperature, motor power and pump utilization. An environment factor for instruments has been given by Anyakora, Engel and Lees (1971), as described in Chapter 13. Similarly, a severity index for instruments has been given by Barbin (1973).

A14.4 Collection of Data

Any reliability work would not be successful without an efficient data collection and analysis system, and collection of data is receiving more and more attention of engineers. Failure rate data are characterized by complex interactions of components, specifications, maintenance procedures, operating environments, etc. Each company should examine the sources of data carefully and take full advantages of the available information, internal and external.

The most desirable information for reliability and risk analysis is to have sufficient plant specific data. In general, failure of plant equipment needs to be recorded and investigated, both in order to identify types of failure so that failure rates can be reduced by better engineering, and to obtain failure data for reliability calculations.

It is normal practice to record for production management the downtime of the plant together with its cause. Frequently the cause assigned is the failure of the particular equipment. This system may yield useful data, particularly on plant availability. Likewise, it is normal practice to record for maintenance management failures of plant equipment. Useful data on failure rates may be generated by this system.

Most chemical plants have a wealth of data in their operating and maintenance records. Frequently, the data yielded by the existing production and maintenance management systems are not directly usable for reliability work. It is then necessary to make certain adjustment the records to obtain the desired data. Usually this involves some additional work by the operating and maintenance personnel. It is essential, therefore, to design the data collection system appropriately. Realizing this, CCPS (1991) devoted a whole chapter discussing locating raw plant data and converting them into reliability data.

If data collection is to be instituted for reliability work, it is necessary to define the system carefully. This includes (1) data requirement, (2) data capture, (3) data classification (4) data retrieval, and (5) data utilization. The system should be appropriate in scale and in duration. In some cases the aim is to monitor continuously features such as equipment failure and/or unit availability. In this case continuous collection is clearly necessary. On the other hand if the aim is simply to obtain data for reliability engineering or hazard assessment purposes, it may be sufficient to collect certain data over a limited period on a 'campaign' basis.

One pitfall is to embark upon too ambitious a scheme that is then not fully exploited and soon falls into disuse. A better policy is to start with a more modest system and to put effort at an early stage into utilizing the data and demonstrating their usefulness to those involved in collecting them. At the other extreme, the desire to avoid this error can lead to the converse mistake of seeking so little modification to the existing system that usable data are not obtained. It is desirable, therefore, both to design the system so that it matches the use to be made of it and, once the system is operating, to begin as soon as possible to utilize the data which flow so that those participating can see that use their efforts are not being wasted.

Particular attention should be paid to the point of generation of the data. In some cases the quality of information on documents such as job tickets is sufficiently good for the purpose. But in other cases some form of specific debriefing may be preferable in order to ensure that the data obtained are meaningful.

Further discussions of data collection are given by D.J. Smith and Babb (1973), Wingender (1991), Davidson (1994), Ireson, Coombs and Moss (1996) and Dhillon (1999).

A14.5 Sources of Data

Failure data may be obtained from external sources such as the literature and data banks. Alternatively, they may be collected within the works. The sources available depend on the user. A company operating plant has access to data from its own works that are not available to other parties, unless supplied to an accessible database. The possible sources may include warranty claims, previous experience with similar or identical equipment, repair facility records, factory acceptance testing, records generated during the development phase, customers' failure reporting systems, test, and inspection records generated by quality control/manufacturing group.

Failure rates depend on many factors, including the function of the equipment in the system and the definition of failure; the process environment and the maintenance practices; and the type of equipment and its manufacturer. The ideal situation is to have sufficient in-house data from identical equipment in the same application. On the other hand, internal collection may not be appropriate, or for new plant designs there is apparently no in-house failure data.

Generic data are often used in reliability work, especially at design stage. However, there are available in the literature a number of collections of data, it requires the knowledge of the background and data origin to choose the appropriate generic failure rate data. Table A14.1 is the cross reference between principal data sources prepared by the Data Acquisition Working Party of the Mechanical Reliability Committee of the Institution of Mechanical Engineering (Davidson, 1994), and Table A14.2 is the equipment category associated with Table A14.1.

A selection of data on equipment failure rates obtained by the UKAEA and given by A.E. Green and Bourne are shown in Table A14.3 and Figure A14.1. These data derive from the work of the UKAEA initially in the nuclear field but subsequently in non-nuclear applications also.

Figure A14.2 and Figure A14.3 gives the operating ranges of critical failure rates of some equipment from nuclear plants and EIReDA data.

Further selected failure rate data given in the *Rasmussen Report* are shown in Table A14.4. The failure data in this table include both failure rate per unit time and failure probability on demand and are quoted as a median value together with a range. These data were obtained from both nuclear and non-nuclear sources, but were collected for use in nuclear hazard assessment, in particular on the critical loss of coolant accident (LOCA). The report, which is described more fully in Appendix 23, gives extensive documentation qualifying the data presented.

Table A14.2 Equipment category code for Table A14.1 (reproduced from The Reliability of Mechanical Systems edited by J. Davidson (technical editor C. Hunsley), 1994, with the permission from Professional Engineering Publishing Ltd)

Equipment category	*Typical component*
1 Rotating equipment	Pumps, compressors, turbines, motors
2 Static equipment	Pipes, pipelines, flowlines, valves, vessels
3 Instrumentation	Sensor (temperature, pressure, level etc.) and controllers
4 Safety	Fire pumps, safety valves, fire/gas/smoke detectors
5 Process	Pumps, compressors, valves vessels, piping
6 Electrical	Cables, motors, circuit boards lamps

[a] This table should be used in conjunction with the above table.
[b] Note that the categories are not intended to be mutually exclusive. For example, pumps can be categorized as bother 'rotating' and 'process'.

Another set of failure rate data are those given by D.J. Smith (1985) and a selection is shown in Table A14.5. In this case the failure rate is given as a single value, a range or a single value and a range.

A synthesis table generated by EIReDA is shown in Table A14.6. The data set are originally from nuclear plants.

Failure rate data for offshore have been given in the collections by OREDA (1984, 1992, 1997, 2002). These data include not only overall failure rates but also failure rates in some failure modes. The number of failures, which determines the confidence bounds on the values, is also given.

In the cases there is no applicable internal or external failure data, careful engineering estimation has to be made. Usually, the final data set to be used is a judicious mixture of data from all these sources.

A14.6 Status of Data

In hazard assessment it is a good practice to indicate the status of the data. Some relevant distinctions are:

(1) Value based on historical data:
  (a) value based on large number of events (narrow confidence limits);
  (b) value based on small number of events (wide confidence limits);
  (c) value based on number of event-free years or occasions;
(2) Value based on judgment of a number of experts.
(3) Value synthesized using fault tree methods.
(4) Value based partly on data and partly on judgment of analyst.
(5) Value entirely on judgement of analyst.

A similar classification is given in the *First Canvey Report* described in Appendix 7.

The status of data is discussed by Andow (1989) and Holloway (1989).

A14.7 Processing of Data

Using failure rate data requires thorough understanding and judicious judgements. The quality of the data from different sources will be varying. For a particular

Table A14.3 *Some data on equipment failure rates published by the UKAEA, (data from Reliability Technology by A.E. Green and J.R. Bourne, Copyright ©, 1972, reproduced with permission of John Wiley and Sons, Inc.)*

	Failure rate (failures/10^6 h)
Electric motors (general)	10.0
Transformers (< 15 kV)	0.6

(lightly stressed)	0.2
Hair springs	1.0
Calibration springs: creep	2.0
breakage	0.2
Vibration mounts	9.0
Mechanical joints	0.2
Grub screws	0.5
Pins	15.0
Pivots	1.0
Nuts	0.02
Bolts	0.02
Boilers (all types)	1.1
Boiler feed pumps	1012.5
Cranes	7.8

Sources: F.R. Farmer (1971); A.E. Green and Bourne (1972).
Note: Further failure data on electronic, mechanical, pneumatic and hydraulic components are given by A.E. Green and Bourne (1972).

reliability study, it is essential to consult the original data sources and identify appropriate data sources to reach a better estimation of the equipment failure rates. EsReDA (1999) offers a summary of the collection, analysis and quality assurance of reliability data.

Mean failure rate is appropriate for failure rates obtained from testing a large population of samples under controlled environment, typically for electronic components. On the other hand, for mechanical equipment, we may want to look into the plant operation to select the appropriate data and apply some adjustment.

A14.8 Uncertainty of Data

Reliability data can deviate by a factor of three or four, and a factor of 10 is not unusual, as suggested by Trevor Kletz (1999). However, not much information exists in the open literature regarding the uncertainty of data. Since the uncertainty is quite large, it is inappropriate to report failure rate data or calculations using failure rate data to more than two significant figures. A serious implication of precision is suggested when more than two significant figures are reported.

A14.9 Databases

Database and data bank are sometimes referred to in the literature exchangeably. However, a database is a collection of data managed through computer programs for specified applications while a data bank is a collection of data in a specific area of knowledge, such as a handbook. An account of data banks and databases is given in *Reliability Data Banks* by Cannon and Bendell (1991). Fragola (1996) reviewed reliability databases from a historical aspect and suggested the possible improvements of reliability database development.

The two main kinds of database are the incident database and the reliability database. An incident database does not have an inventory of items at risk and concentrates on the attributes and development of the incidents. The information available is often limited to whatever was recorded at the time. A variety of databases have been established to store and share this type of information. Among them are FACTS, WOAD (Worldwide Offshore Accident Database), MARS (the European Union Major Accident Reporting System), etc. A reliability database may well record incidents, but treats them primarily as events from which statistical information on reliability, availability and maintainability are to be derived. Reliability data can be overall failure rates or values separated into failure modes and causes.

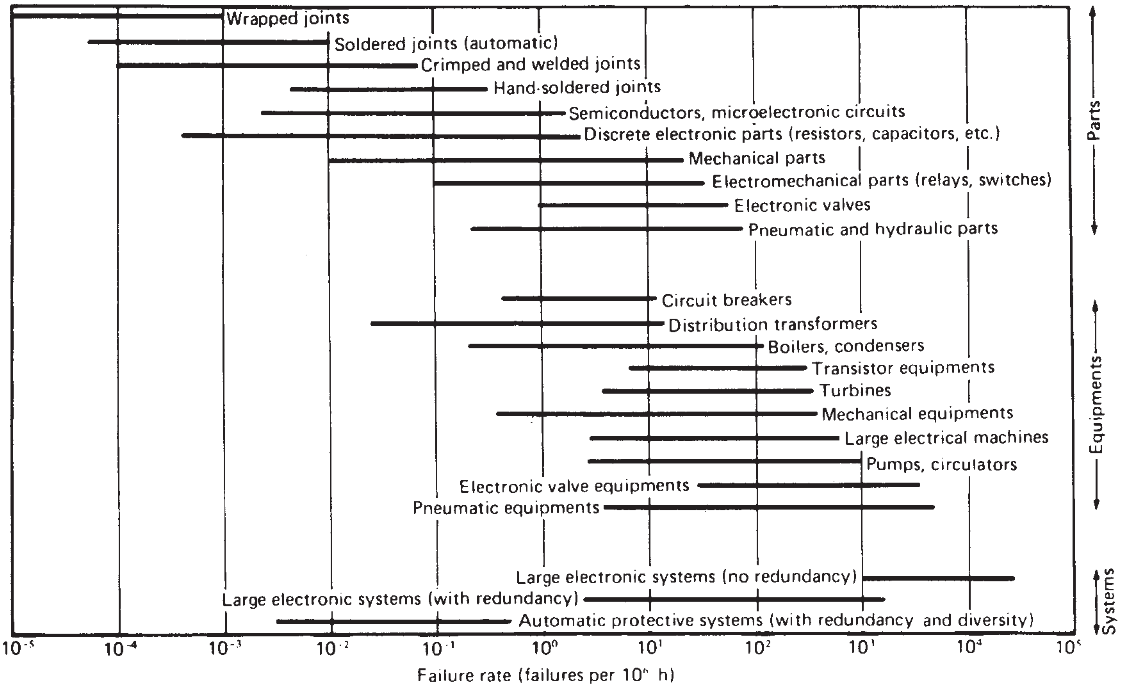

Figure A14.1 *Typical ranges of failure rates for parts, equipments and systems (A.E. Green and Bourne, 1972) (reproduced with permission from Reliability Technology by A.E. Green and J.R. Bourne, Copyright ©, 1972, John Wiley and Sons, Inc.)*

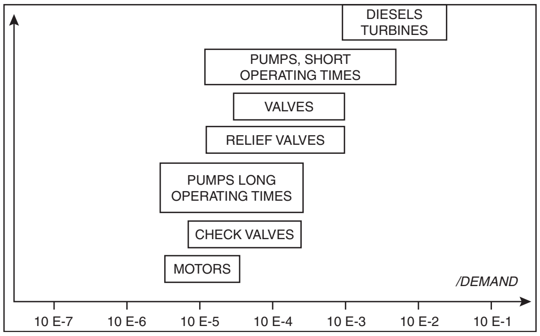

Figure A14.2 *Demand critical failure rate ranges of some equipment at French nuclear plants (sample = 80–170 unit-years depending on equipment) (Lannoy and Procaccia, 1996; reproduced with permission from Elsevier)*

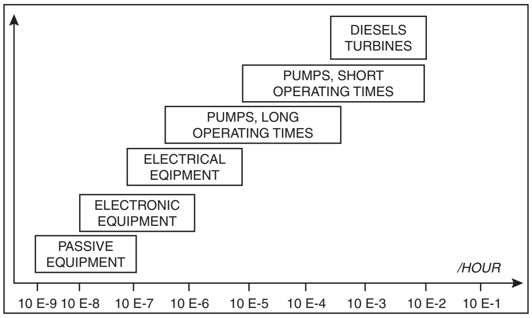

Figure A14.3 *Operating critical failure rate ranges of some equipment at French nuclear plants (sample = 80–170 unit-years depending on equipment) (Lannoy and Procaccia, 1996; reproduced with permission from Elsevier)*

Reliability databases are created by different users for somewhat different purposes. They range from the database created by a single individual through those at company level to those operated by specialist organizations. High quality reliability data are expensive to collect and often require a long time or a large sample to be statistically viable. The investment of effort in creating and operating a reliability database is appreciable and the exercise is not one to be undertaken lightly. It is essential to define clearly the data to be held, the means by which they will be acquired, and the uses to which they will be put.

Most serious reliability databases are part of the activities of an organization that is involved in other aspects of reliability work also. The organization thus has an interest in the database as a user, which is likely to make it more friendly to other users. There are a variety of reliability databases, such as the reliability databank operated by AEA Technology, ERDS, OREDA, etc. CCPS (1991) provides a review of the available databases. CCPS is also conducting a reliability project with selected companies, but the results of this effort are not publically available.

Table A14.4 *Some failure data used in the Rasmussen Report (AEC, 1975)*

		Failure rate	
		Median	*Range*
Diesels (complete plant)	Failure to start, Q_d[a]	3×10^{-2}/d	1×10^{-2}–1×10^{-1}/d
	Failure to run, given start, in emergency conditions, λ_0	3×10^{-3}/h	3×10^{-4}–3×10^{-2}/h
Diesels (engine only)	Failure to run, given start, in emergency conditions, λ_0	3×10^{-4}/h	3×10^{-5}–3×10^{-3}/h
Battery power systems (wet cell)	Failure to provide proper output λ_s	3×10^{-6}/h	1×10^{-6}–1×10^{-5}/h
Electric motors	Failure to start, Q_d[b]	3×10^{-4}/d	1×10^{-4}–1×10^{-3}/d
	Failure to run, given start, in normal environment, λ_0	1×10^{-5}/h	3×10^{-6}–3×10^{-5}/h
	Failure to run, given start, in extreme environment, λ_0	1×10^{-3}/h	1×10^{-4}–1×10^{-2}/h
Transformers	Open circuit, primary or secondary, λ_0	1×10^{-6}/h	3×10^{-7}–3×10^{-6}/h
	Short, primary to secondary λ_0	1×10^{-6}/h	3×10^{-7}–3×10^{-6}/h
Solid state devices (low power application)	Failure to function, λ_0	1×10^{-6}/h	1×10^{-7}–1×10^{-5}/h
	Failure by short, λ_0	1×10^{-7}/h	1×10^{-8}–1×10^{-6}/h
Circuit breakers	Failure to transfer, Q_d[b]	1×10^{-3}/d	3×10^{-4}–3×10^{-3}/d
	Premature transfer, λ_0	1×10^{-6}/h	3×10^{-7}–3×10^{-6}/h
Fuses	Failure to open, Q_d	1×10^{-5}/d	3×10^{-6}–3×10^{-5}/d
	Premature open, λ_0	1×10^{-6}/h	3×10^{-7}–3×10^{-6}/h
Relays	Failure to energize, Q_d[b]	1×10^{-4}/d	3×10^{-5}–5×10^{-4}/d
	Failure of NO contacts to close, given energization, λ_0	3×10^{-7}/h	1×10^{-7}–1×10^{-6}/h
	Failure of NC contacts by opening, given no energization, λ_0	1×10^{-7}/h	3×10^{-8}–3×10^{-7}/h
	Short across NO/NC contacts, λ_0	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
	Coil open, λ_0	1×10^{-7}/h	1×10^{-8}–1×10^{-6}/h
	Coil short to power, λ_0	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Terminal boards	Open connection, λ_0	1×10^{-7}/h	1×10^{-8}–1×10^{-6}/h
	Short to adjacent circuit, λ_0	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Wires (typical circuit, several joints)	Open circuit, λ_0	3×10^{-6}/h	1×10^{-6}–1×10^{-5}/h
	Short to ground, λ_0	3×10^{-7}/h	3×10^{-8}–3×10^{-6}/h
	Short to power, λ_0	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Instrumentation (amplification annunciators transducers, combination)	Failure to operate, λ_0	1×10^{-6}/h	1×10^{-7}–1×10^{-5}/h
	Shift in calibration, λ_0	3×10^{-5}/h	3×10^{-6}–3×10^{-4}/h
Pressure switches	Failure to operate, Q_d	1×10^{-4}/d	3×10^{-5}–3×10^{-4}/d
Limit switches	Failure to operate, Q_d	3×10^{-4}/d	1×10^{-4}–1×10^{-3}/d
Valves (manual)	Failure to remain open (plug), Q_d	1×10^{-4}/d	3×10^{-5}–3×10^{-4}/d
	Rupture, λ_s	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Valves (air-fluid operated)	Failure to operate, Q_d[b]	3×10^{-4}/d	1×10^{-4}– 1×10^{-3}/d
	Failure to remain open (plug)[c]		
	Q_d	1×10^{-4}/d	3×10^{-5}–3×10^{-4}/d
	λ_s	3×10^{-7}/h	1×10^{-7}–1×10^{-6}/h
	Rupture, λ_s	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Valves (motor operated, includes driver)	Failure to operate, Q_d[b]	1×10^{-3}/d	3×10^{-4}–3×10^{-3}/d
	Failure to remain open (plug)[c]		
	Q_d	1×10^{-4}/d	3×10^{-5}–3×10^{-4}/d
	λ_s	3×10^{-7}/h	1×10^{-7}–1×10^{-6}/h
	Rupture, λ_s	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Valves (solenoid operated)	Failure to operate, Q_d[b]	1×10^{-3}/d	3×10^{-4}–3×10^{-3}/d
	Failure to remain open (plug), Q_d	1×10^{-4}/d	3×10^{-5}–3×10^{-4}/d
	Rupture, λ_s	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Relief valves	Failure to open, Q_d	1×10^{-5}/d	3×10^{-6}–3×10^{-5}/d
	Premature open, λ_0	1×10^{-5}/h	3×10^{-6}–3×10^{-5}/h

Table A14.4 *(continued)*

		Failure rate	
		Median	*Range*
Check valves	Failure to open, Q_d	1×10^{-4}/d	3×10^{-5}–3×10^{-4}/d
	Internal leak (severe), λ_0	3×10^{-7}/h	1×10^{-7}–1×10^{-6}/h
	Rupture, λ_s	1×10^{-8}/h	1×10^{-9}–1×10^{-7}/h
Pumps (including driver)[d]	Failure to start, Q_d	1×10^{-3}/d	3×10^{-4}–3×10^{-3}/d
	Failure to run, given start, in normal environment, λ_0	3×10^{-5}/h	3×10^{-6}–3×10^{-4}/h
	Failure to run, given start, in extreme post-accident environment inside containment, λ_0	1×10^{-3}/h	1×10^{-2}–1×10^{-4}/h
Pipes $\leq$ 3 in. (per section)	Rupture/plug, λ_s, λ_0	1×10^{-9}/h	3×10^{-11}–3×10^{-8}/h
$>$ 3 in. (per section)	Rupture/plug, λ_s, λ_0[b]	1×10^{-10}/h	3×10^{-12}–3×10^{-9}/h
Gaskets (containment quality)	Leak (serious) in post-accident situation, λ_0	3×10^{-6}/h	1×10^{-7}–1×10^{-4}/h
Elbows, flanges, expansion joints (containment quality)	Leak (serious) in post-accident situation, λ_0	3×10^{-7}/h	1×10^{-8}–1×10^{-5}/h
Welds (containment quality)	Leak (serious) in post-accident situation, λ_0	3×10^{-9}/h	1×10^{-10}–1×10^{-7}/h
Clutches (mechanical)	Failure to operate, Q_d[b]	3×10^{-4}/d	1×10^{-4}–1×10^{-3}/d

[a] Q_d = failure/demand; λ_0 = failure/h in operational mode; λ_s = failure/h in standby mode. The unit d in this table stands for demand.

[b] Demand probabilities are based on the presence of proper input control signals.

[c] Plug probabilities are given as probabilities per demand and as rates per hour, since the plug is generally time-dependent but may only be detected upon a demand on the system.

[d] Turbine-driven pump system may have significantly higher failure rates.

In the following, brief descriptions are given of six principal databases: the NCSR, ERDS, FACTS EIREDA, OREDA, and GIDEP databases. Other databases include the EOF database (Procaccia, 1991); the IAEA database (Tomic and Lederman, 1991); the CREDO database at ORNL (Knee, 1991); the Dante database (Mizuta *et al.*, 1991), the SRDF database (AUPIED and PROCACCIA, 1984), the SKI-PIPE database (Lydell 2000), and the database operated for SRD Association by AEA Technology etc.

A14.9.1 Design of database

As to its definition, a database is first of all a computer system, which may have billions of data collections. The construction of a database involves the translation of the-logical data model, giving the relationships between the data field into the physical database embodied in the computer. This is ensured by the database management system (DBMS). Many software companies have developed very effective database management programs that can be tailored for any specific needs. Four main architecture models of the database management system are the hierarchical, network, relational and object models. The characteristics and merits of these different approaches for reliability databases are discussed in EsReDA (1999).

Information about components held in the database comes under two main heads: the component inventory and the component history. The component inventory contains a description of each component on which information is held. The component history gives the detailed failure and maintenance history of each component. Both for component inventory and component history the design of the data set to be held is not a trivial question. For inventory it is first necessary to define the component boundary. A valve actuator, for example, may not remain permanently on the same valve.

It is then necessary to specify the attributes of the components. This involves deciding the degree of subdivision or, alternatively, the level of aggregation. Excessive subdivision results in samples which are too small, while excessive aggregation lumps together items that differ significantly.

For component history, information is typically recorded on failure mode and failure cause. Here the problem is the tendency toward excessive subdivision by creation of additional failure mode and cause categories. This problem is aggravated if numbers of persons are authorized to extend these categories.

It is also desirable to have a plain language fault descriptor. Experience suggests that a set of pre-specified descriptors is on some occasions too detailed and on others not detailed enough, and that there is value in a facility to use free text.

In general, it is desirable to store the data in their 'original' form rather than in an abstracted form, which involves loss of information. For this reason, the data in a reliability data bank may be stored as a set of events from which statistical data may then be obtained.

Early reliability databases tried to account for environments and other conditions via K or π factors, such as MIL-HDBK 217F and Green and Bourne (1972). Most of them give point estimates of failure rates without indicating the bound and confidence level. Modern reliability databases provide failure rates on categorized failure modes, like IEEE-Std-500 (1984), OREDA (1984, 1992, 1997, 2002), EIREDA (1991) and CCPS (1991). IEEE-Std-500, OREDA (1984, 1992, 1997, 2002) and CCPS (1991) provide upper and lower values on failure rates and EIREDA (1991) provides confidence level with error factors.

Many efforts have been carried out to standardize database design. Further discussion on database design can be found in Ireson, Coombs, and Moss (1996), Cooke and Bedford (2002) and the vol. 51, num. 2 of *Reliability Engineering and System Safety* which is specially devoted to reliability database design.

Table A14.5 *Some data on equipment failure rates (D.J. Smith, 1985; reproduced by permission of Macmillan)*

Equipment	*Failure rate*[a] (failure/10^6 h)		
Compressor			
Centrifugal, turbine driven	150		
Reciprocating, turbine driven	500		
Electric motor driven	100	300	
Diesel generator	125 (0.97 start)	4000	
Electricity supply	110		
Gaskets	0.02	1	
Heat exchanger	1	40	
Pipe joint	0.5		
Pumps			
Centrifugal	10	**30**	80
Boiler	100	500	
Fire[b]	100	150	
Fuel	6	50	
Oil lubrication	10	30	100
Vacuum	20		
Turbine, steam	30	80	
Valves			
Ball	1	3.5	
Butterfly	1	**20**	30
Gate	1.5	15	
Relief	4	9	
Non-return	2	5	
Slam shut	10	30	
Solenoid	1.5	**10**	30
Valve actuators[c]			
Fail open	0.1	4	
Spurious close	5	40	

[a] Entries are given in three formats: a single value, where the various references are in good agreement; two values, indicating a range; and three values with one in bold, indicating a range with the value in bold predominating. Bold is also used for one end of a range, where that value predominates.

[b] Approximately 800 for a complete fire pump and priming system.

[c] Depends on the complexity of the pneumatic circuit; requieres FMEA.

A14.9.2 Operation of database

The operator of a reliability database has to maintain a sufficient flow of data from the data suppliers, synthesize the data from different sources, and satisfy the needs of the data users in a manner which is cost effective. This is no easy task.

Fresh data are the lifeblood of a reliability data bank. There must be a sufficient incentive for an organization to supply them, either by collecting them itself or by allowing access for their collection. Typically it will be one that is also a user of the database.

The data user will have a set of requirements, which often can be met only in part. Ideally the user would like data from which to obtain failure and repair time distributions, and so on. Often these will simply not be available, the best on offer being perhaps failure or repair rates based on a constant rate assumption. There may also be problems of sample size. The data bank operator has to balance the often-conflicting requirements of user demand, data supply and economy in handling.

A14.9.3 Data acquisition

Information on equipment for the component inventory is obtained from the plant documentation, which includes equipment records and equipment and plant drawings. Acquisition of the inventory data for a plant may not be straightforward. Records and drawings may be incomplete from the outset, and it is even more common that modifications made are not entered. There can be confusing identifications, with the same item allocated several quite different code numbers.

There can be a corruption of the component design parameters, with differences between the item as designed and as purchased and installed being quite common. As Cross and Stevens comment: 'It is incredible how poor the average plant inventory records are'.

For information on equipment failure and repair a basic source of information is the job card or ticket. Typically this gives as a minimum the identity of the equipment, the failure notified or diagnosed and the repair work done. Other documentation such as logbooks, permits-to-work and stores requisitions are generally useful as cross-checks rather than prime sources. Sometimes, vendors' test data can also be used as a supplement source.

To the extent practical, the failure data should be such as to permit analysis to obtain failure distributions as well as average values. This implies that the data should give the times to failure for individual equipment rather than just the total number of failures. This greatly enhances the value of the data to the data analyst.

Some data require a degree of reinterpretation or filtering. One common problem is the failure that presents as a cluster of events arising over a short time interval. This may take several forms, each of which involves events that are in some sense dependent. One is the repair that is unsatisfactory so that failure recurs almost immediately and the work has to be done again. Somewhat similar is the repair that is made in several passes such as a leaking valve which is first tightened, then repacked and finally replaced. A third situation is the nearly simultaneous failure of a number of items due to a common cause.

A14.9.4 NCSR database

The NCSR Reliability Data Bank is a major database system which has been in operation for over twenty years serving the nuclear, aerospace, electronics, oil, chemical and other industries. Accounts of the early database and SYREL data bank have been given by Barnes (1967 UKAEA AHSB(S) R138), Ablitt (1973 SRS/GR/14) and Fothergffl (1973 SS/GR/22). The mature database has been described by Cannon (1991a,b). An account of further developments in the database is given by Cross and Stevens (1991).

As described by Cannon (1991a) the data bank about the mid-1980s consisted of data stores for (1) generic reliability, (2) events, (3) accidents, (4) human reliability, and (5) maloperation. Much of the data collection was carried out by placement of students in cooperating companies. Cannon gives examples of the use of the data bank, including cases where application of the data resulted in reductions in the observed failure rates.

Cross and Stevens (1991), writing from the perspective of the user as well as the operator of a data bank, describe the transition of the NCSR system from a system which was based originally on 1960s technology, using mainframe

***Table A14.6** Example of best-estimated reliability parameters from some equipment (Lannoy and Procaccia, 1996; reproduced with permission from Elsevier)*

Equipment	*Main Character*	*Mean failure rate* (10^{-}6/h)	*Range* (10^{-6}/h)	*Failure on demand* (10^{-3}/d)	*Range* (10^{-3}/d)	*MMTR* (h)
Accumulator, nitrogen driven						
Pressurized	$P < 50$ bar; $T < 50°C$	0.52	0.2–0.8	0.03	–	2.6
Compressor, motor driven						
Centrifugal	P: 6–40 bar; kW: 360	81	60–104	0.18	0.09–0.25	2.6
Reciprocating	$P \cong 10$ bar; kW: 5–85	782	506–1108	0.3	0.2–0.38	5
Water filter (paper)	P: 10–190 bar	2.3	1.5–3.1	–	–	6
Heat exchanger						
Plate	P: 7–155 bar T: 30–220°C	20.7	19–22	0.01	–	9
Shell/tube		0.55	0.08–0.9	–	–	25
Shell/tube	P: 155 bar; T: 200–300°C	0.31	0.005–0.5	0.02	–	25
Shell/tube	P: 7–50 bar; T: 50–220°C	0.83	0.2–1.3	–	–	25
Pump, centrifugal multistage						
Motor/turbine driven[a]	kW: 300/400 head: 900 m flow: 80 m^3/h	174	125–228	0.2	0.1–0.3	34
Turbine driven	kW: 2200/5300 head: 570 m flow ≤ 3300 m^3/h	10	7–14	0.15	0.11–0.27	13

[a] Standby pump.

computers, large in size and not readily modified, to one utilizing modern database methods and implemented on PCs.

Of the two basic formats for storage of information, summary and complete record, the NCSR system utilizes the latter, so that complete details of each event are held. From these complete records statistical data can then be abstracted as required.

A14.9.5 ERDS database

The European Reliability Data System (ERDS) is an EC database operated by the JRC at Ispra. It is described by Capobianchi (1991).

ERDS acquires its data from European and other databases, and is therefore in effect a database of databases. It is oriented particularly to serve the nuclear industry.

The data are rendered homogeneous by conversion to a uniform format. This format is specified in a detailed system of classification – the Common European Reference Classifications, which is thus by way of being a European standard.

ERDS has four main data subsystems: (1) the Component Event Data Bank (CEDB), (2) the Abnormal Occurrences Reporting System, (3) the Operating Unit Status Report and (4) the Reliability Parameter Data Bank. Among them, the CEDB stores the component characteristics, historical information, and failure information and is the central subsystem, which serves and is connected to the other three subsystems.

A14.9.6 FACTS database

The Failure and Accident Technical Information System (FACTS) is an incident data bank operated by TNO in the Netherlands. It is described by Koehorst and Bockholts (1991).

FACTS gathered the information about near-misses, minor accidents and major accidents associated with hazardous materials. Nuclear materials and military activity are excluded for its scope. The information is derived from the literature; from companies; from inspectorates, fire services, etc.; and from FACTS agencies in other countries, respecting anonymity. Press reports serve as triggers to acquire information.

Features of the database are a schedule of accident attributes and values and a hierarchical keyword structure. Another structure is the cause classification in which the course of the accident is translated into a sequence of occurrences.

This makes it possible to trace back from an event down the causal chain. The original plain text accounts are held on microfiche.

Applications of the system described by the authors include (1) analysis of the role of instrumentation in accidents; (2) analysis of incorrect human response and (3) compilation of a reference book to trace incident causes (the Cause Book), giving a survey of incident causes which can occur in a large number of systems and operations.

Further analysis is given in *An Analysis of Accidents with Casualties in the Chemical Industry Based on Historical Facts* by Koehorst (1989).

Developments of the system include an expert system front end.

A14.9.7 OREDA database

The Offshore Reliability Data (OREDA) project is an offshore reliability database described in the handbook by OREDA (1984, 1992, 1997, 2002). It gives failure rates, failure mode distribution and repair data for offshore installations, mainly in the UK and Norwegian sectors of the North Sea.

A substantial effort was devoted to the design of the system to ensure as far as possible that the components, their boundaries and environment, are well defined and that the data obtained are high quality and statistically meaningful. The database is fully explained in the OREDA handbook, which describes the system, gives the data and outlines the statistical treatment. Some discussion about the data collection and application of this project can be found in Groenendijk (1995), Sandtorv, Hokstad and Thompson (1996), Rausand and Øien (1996), Haugen, Hokstad and Sandtorv (1997), Langseth, Haugen and Sandtorv (1998).

The project therefore serves as a good illustration of a reliability database and is widely recognized as a standard information source for risk analysis.

The project is supported by ten major oil and gas companies: AGIP, BP, Elf, Esso, Norsk Hydro, SAGA, Shell, Statoil and Total. The data cover (1) process systems, (2) control and safety systems, (3) electrical systems, (4) utility systems, (5) crane systems and (6) subsea equipment and drilling systems.

The component inventory gives the following information: (1) brief description, (2) application, (3) operational mode (continuous, standby, protective, etc.), (4) internal environment (fluids handled), (5) external environment and (6) boundary specification, including a sketch. The operating data include (1) population at risk, (2) number of installations supplying data, (3) total calendar and operational times and (4) number of demands (where applicable). The failures are broken down into four different categories of severity: (1) critical, (2) degraded, (3) incipient and (4) unknown severity; there may be a number of modes in each category. The failure and repair data comprise (1) number of failures, (2) failure modes, (3) failure rates for each failure mode, (4) active repair time and (5) repair time. Mean and lower and upper bound values are given for the failure rates and mean, minimum and maximum values for the repair times. The active repair time is the average time required to analyse and repair the item and return it to service, excluding time to detect the fault and isolate the equipment and any delay due to tools or spares. The repair time is the number of manhours required for the repair. The failure and repair data are given for each mode and for the equipment overall.

Some of the events recorded in the OREDA as failures are those such as failure to start and spurious trip.

The number of installations participating, the number of components at risk and the number of failures experienced are very variable. In many cases the population at risk is 10 or less.

The handbook states that data in the form of times between failures are collected, but that confidence in the statistical data varies between the different generic groups and that for most purposes time-independent failure rates are a relevant approximation. It does not give data on times between failures.

A14.9.8 EIReDA database

The EIReDA (European Industry Reliability Data Bank) is operated by ESReDA, which is established in 1992 by EuReDATA (European Reliability Data Bank Association) and ESReDA (European Safety and Reliability Research and Development Association) jointly. The original data were collected from 50 nuclear power plants operated by Electricite de France from 1978 to 1995 and analysed using Bayesian methodology. The data bank contains failure rates (for critical failure modes only) and mean repair time data for mechanical components, electrical components and instrumentation and control equipment. A full description of the data bank is provided in EsReDA (1998), which describes the scope, the choice of components, the definition of boundaries, and the statistical treatment.

Engineering and operational characteristics are provided in detail for each item of equipment, as well as a color photograph, a general drawing and the boundaries. Background information such as inventory and service year is also provided. Comparable data are listed in a separate table, compiled from other published sources (mainly WASH 1400, IEEE 500, RKS 85-25; EuReDATA and ESReDA project reports and publications, and other power plant, modern petrochemical and processing plants). The methodological application to other industries is included in the appendix.

A14.9.9 GIDEP database

GIDEP (Government Industry Data Exchange Program) was established in 1959 as the Inter-service Data Exchange Program (IDEP) by the US government to reduce expenditures of resources in the life cycle of systems facilities and equipment through share of data among government agencies and industry organizations.

To make use of GIDEP database, an agency or company has to be a full or partial participant of GIDEP program. GIDEP is currently participated by thousands of agencies and industries.

Information on parts, processes and materials they use or manufacture is submitted to the GIDEP Operations Center by government and industry participants.

The program maintains six major types of data: (1) engineering data; (2) failure experience data; (3) metrology data; (4) product information data; (5) reliability– maintainability data and (6) urgent data requests. GIDEP is DOD's centralized database for Diminishing Manufacturing Sources and Material Shortages (DMSMS).

A14.10 Inventory

A14.10.1 Inventory of plants

Information is sometimes required on the number of plants at risk, either nationally or world-widely. This is needed, for example, in order to convert data on the number of a particular type of event, for example, vapour cloud explosions, into a frequency per plant.

Data on the number and capacity of chemical and petrochemical plants in various countries are given in the publications by SRI International which include Directory of Chemical Producers – United States 1988 and Directory of Chemical Producers – Western Europe 1988 (SRI Int., 1988b,c).

From the SRI data for the United States (US) and Western Europe (WE):

	US	*WE*	*UK*
No. of chemical/petrochemical plants	1420	1455	185

The following ratios apply for the number of plants and for the plant capacity:

	US/WE	*UK/WE*
No. of plants	0.92	0.12
Plant capacity	1.08	0.12

For petroleum refineries similar data are given in the *International Petroleum Encyclopaedia 2002* (IPE, 2002).

From IPE data

Region	Africa	Asia	East Europe	Middle East	North America	South America	West Europe
No. of refineries	46	203	94	46	170	68	105

The countries having over 10 refineries from IPE (2002) data are listed below.

	No. of refineries
United States	143
China	95
Russia	42
Japan	35
Canada	21
Germany	17
India	17
Italy	17
France	13
Brazil	13
United Kingdom	11
Argentina	10
Australia	10
Romania	10
World total	732

A refinery contains a number of major units and this number varies. Information given in periodic surveys (e.g. Anon., 1985dd) suggests an average value of about five such units per refinery.

Information is also available on the number of installations that attract certain regulatory controls. In the United Kingdom, the number of installations notifiable under the NIHHS Regulations 1982 has been given by Pape and Nussey (1985) and by Pape (1989) as

LPG	600
Natural gas	400
Chlorine	120
Total	1600

Of the LPG installations 450 are storage installations and 130 gas cylinder storages.

In a discussion of the CIMAH Regulations 1984 (later superseded by COMAH) Welsh (1993) states that over 400 safety reports have been submitted. In interpreting this figure, it should be borne in mind that the number of reports is necessarily be equated to the number of CIMAH installations. CIMAH Regulation 1984 was later replaced by COMAH Regulation in the United Kingdom, which is stricter and came into force in the February of 1999. A total of 3–5000 top-tier major hazard plants in Europe are expected to submit safety, of which the United Kingdom has 438 with a further 843 lower tier installations.

A14.10.2 Ammonia plants

Estimates of the number of ammonia installations and carriers have been given by Baldock (1980) and are shown in Table A14.7.

A14.11 Inventory of equipment in plants

Another estimate that may be required is the number of potential leak sources on a plant. Information on the number of fittings and valves on pipework of different diameters has been given by Hooper (1982) in the context of cost estimation and is shown in Table A14.8.

Numbers of potential leak sources on various types of plant have been given, mainly in the context of fugitive emissions. Table A14.9 shows the numbers given by T.W. Hughes, Tierney and Khan (1979) for some potential leak sources in four petrochemical plants and Table A14.10 those given by D.P. Wallace (1979) for some sources in a single medium sized plant. Table A14.11 shows data given by Lipton and Lynch (1987) on the number of some sources in a large refinery. Table A14.12 after Wetherold (1983) gives the number of valves in a refinery and in two other plants.

Using such data, it is possible to construct a profile of the potential leak sources on a typical plant.

In a study of fugitive emissions from the ethylene oxide production industry, equipment containing more than 1 wt % ethylene oxide is surveyed in 13 major EO plants by Berglund, Romano, and Randall (1990).

A14.12 Vessel and Tanks

The failure rates of pressure vessels are discussed in Chapter 12.

Table A14.7 *Estimated number of ammonia installations and carriers*

	Estimated no. world-wide
Plants	2,000
Storage areas	1,000
Vessels	10,000
Refrigeration plants	100,000
Transfer points	1,000
Road tankers	1,000
Rail tankers	5,000
Ammonia ships	20
Pipeline miles	2,000

Source: Baldock (1980), table 2.

Table A14.8 *Pipework fittings and valves*

Nominal pipe diameter (in.)	*Total length of pipe* (ft)	*Number of fittings*	
		Flanges	*Valves*
$\frac{1}{2}$	33,990	1,818	11,589
$\frac{3}{4}$	33,123	2,973	7,551

Table A14.12 *Inventory of potential leak sources: number of valves in a refinery and two other plants*

A No. of valves in three plants

	No. of valves
Large integrated refinery	21, 800
Large olefins plant	15,000
Cumene process unit	1,179

B No. of valves on different duties in large refinery

Leak source	No. of items
Valves	
Gas and light liquid only	13,334
All	21,776

Source: Wetherold (1983), tables 1 and 3.

Estimated failure rates of storage tanks quoted by Batstone and Tomi (1980) are shown in Table A14.13.

Data on the failure rates of storage tanks in ammonia and LNG are given in Sections A14.25.2 and A14.24, respectively.

Data on storage tank fires are given in Section A14.28.5.

A14.13 Pipework

The failure rates of pipes are discussed in Chapter 12.

De la mare and his coworkers developed pipeline inventory and pipeline failure and repair history databanks for the North Sea area. Some of their statistic results are shown in Tables A14.14–A14.18.

Data on the failure rates of gaskets are given in Tables A14.3–14.5 and by Pape and Nussey (1985).

Comparison of these values gives for the failure frequency of gaskets:

	Failure frequency (failures/year)
Smith: Lower limit	0.00018
Upper limit	0.0088
UKAEA	0.0044
Rasmussen Report	0.026
Pape and Nussey	4×10^{-5} (average)

A14.13.1 Bellows

There is a potential ambiguity in the term bellows, which may refer to bellows used in instrumentation or to those used in pipework.

The UKAEA data on the failure rate of bellows in Table A14.3 gives a failure frequency of 5×10^{-6} failures/year. D.J. Smith (1985) gives a failure rate of 4×10^{-6} failures/year.

A14.14 Heat Exchangers

Data on the failure rates of heat exchangers are given in Table A14.5.

Some information on the failure rate of heat exchangers has been given by C.F. King and Rudd (1972) in a reliability study of a heavy water plant. With some 21 heat exchangers, the MTTF ranged from 677 to 7865 h.

For offshore shell and tube heat exchangers, the data given by OREDA (1997) include the following (all failure modes included):

	Population	*No. of failures*	*Failure rate* (per 10^6 h)	*Mean repair time* (manhours)
Crude oil →> sea water (1000–3000 kW)	2	0	35.14 (upper limit)	
Crude oil →> sea water (1000–10,000 kW)	10	29	94.42	145.0
Gas →> gas (1000–10,000 kW)	4	5	75.02	48.2
Gas →> gas (10,000–30,000 kW)	1	5	142.60	3.4
Gas →> sea water (100–1000 kW)	4	3	31.16	14.7
Gas →> sea water (1000–10,000 kW)	4	12	85.62	53.2
Gas →> water/glycol (1000–3000 kW)	3	5	79.61	47.4
Gas →> water/glycol (1000–10,000 kW)	5	13	120.24	45.0
Gas →> water/glycol (10,000–30,000 kW)	12	38	121.64	64.4

A14.15 Rotating Machinery

A14.15.1 Compressors

Data on the failure rates of compressors are given in Table A14.5.

For offshore compressors the data given by OREDA (1997) include the following (all failure modes included):

	Population	*No. of failures*	*Failure rate* (per 10^6 h)			*Mean repair time* (manhours)
			Lower	*Mean*	*Upper*	
Centrifugal, electric motor driven						
100–1000 kW	5	58	2.64	550.66	2106.50	20.6
1000–3000 kW	14	204	174.54	880.21	2033.05	25.1
3000–10,000 kW	9	398	1157.79	2433.02	4088.47	48.2
Centrifugal, turbine driven						
	9	586	122.28	2449.88	7341.37	29.6
Reciprocating, electrical motor driven						
1000–3000 kW	4	352	2293.78	2509.70	2741.16	9.6
3000–10,000 kW	4	317	4029.38	5388.42	6909.82	98.6

The Power Reliability Enhancement Program (PREP) of the US Army corps of Engineers conducted a study of the operational and maintenance data on 204 power generation, power distribution and HVAC components (Hale and Arno, 2001). Efforts focused on the equipment installed after 1971. To be statically justifiable, minimums of 3,500,000 calendar hours were established for each component. They reported 0.07601 failures/year for electric air compressor and 0.01033 failures/year for fuel air compressor (Hale and Arno, 2001).

A14.15.2 Fans

Data on the failure rates of fans are given in Table A14.45.

A14.15.3 Pumps

There are wide variations in the type, duty and environment, and hence in the failure rate, of pumps. However, many pumps have a failure rate of some 1–5 failures/year. Data on the failure rates of pumps are given in Tables A14.3–A14.5.

D.J. Smith (1985) gives the failure modes of pumps as about 50% leakage and 50% no transmission.

Some information on the failure rate of pumps has been given by C.F. King and Rudd (1972) in a reliability study of a heavy water plant. MTTFs for four auxiliary pumps ranged from 51 to 398 days according to maintenance data, but from 12.5 to 439 days according to production data.

An account has been given by R. James (1976) of a pump maintenance program on 880 major process pumps, mainly centrifugal pumps, aimed at eliminating premature wearout failures, in which the MTBF of the pumps was raised from 8.7 to 12.2 months.

In accounts of pump reliability improvements by a particular manufacturer (Anon., 1985x; Bloch and Johnson, 1985) it is stated that for pumps the industry average MTBF is some 6 months, corresponding to a failure rate of 2 failures/year. Bloch and Johnson state that ANSI standard pumps have an MTBF of 13 months, or failure rate of 0.9 failures/year. It is claimed, however, by Anon. (1985x) that specified improvements have resulted in the achievement of an MTBF of some 25 months, or failure rate of 0.48 failures/year. For individual features improvements are said to have extended the lives of the ball bearings, the mechanical seal system, the shaft and the coupling to 5, 2.5, 15 and 7 years, respectively.

A study of 85 ethylene plant pumps has been reported by Sherwin (1983). There were 243 failures and the failure rate was 1.8 failures/year. The failure modes are shown in Table A14.19

Data on the failure rates of pumps in LNG plants are given in Table A14.44.

A study of feedwater pumps in French nuclear power stations has been made by Aupied, Le Coguiec and Procaccia (1983). The overall failure rate was Failure rate of feedwater pumps $= 5.6 \times 10^{-4}$ failures/h $= 4.9$ failures/year

The failure modes of the pumps are shown in Table A14.20.

A survey of pump mechanical seals by BHRA has been reported by Flitney (1987) in which pumps were surveyed in three refineries and five chemical plants, a sample of some 200–300 pumps being taken at each site. The two principal reasons for seal removal were

Leakage	66%
Bearing replacement	12%

Mechanical seals are also the subject of a study at Esso reported by N.M. Wallace and David (1985). They give a table of seal lives for some 17 cases, the lives varying from 2 to 12 months. For catastrophic failure of a pump the Rijnmond Report uses a value of 1×10^{-4} failures/year.

Operational data of 505 primary coolant pumps of steam supply systems in 146 nuclear power plants were analysed and an average failure rate of 1×10^{-5} was suggested (Milivojevic and Riznic, 1989).

Data from 320 electric submersible pumps gathered over a 13-year period in Milne Point Field, Alaska were analysed and the mean time to failure is estimated to be 330 days (Sawaryn, Grames, and Whelehan, 2002).

Some data on pumps given out by EIReDA is shown in Table A14.21.

[a] Overhauls were not at regular intervals but as a result of conditions found on opening up following a failure.

[b] Leaks other than those due to seals/glands.

A14.15.4 Turbines

Data on the failure rates of turbines are given in Table A14.5.

A study of steam turbine failure with particular reference to catastrophic failure and the generation of missiles has been described by Bush (1973). He quotes data from six major suppliers of steam turbines. The accumulated

operating experience is 12,330 years prior to 1950 and 57,950 years in the period 1950–72. There were no failures in the earlier period and 10 in the later period. All four failures after 1959 were due to over-speed. Of the ten incidents seven generated missiles. His analysis indicates that the failure frequency was slowly decreasing. His estimates of the then current failure frequencies are

$$\text{Frequency of failure} = 9 \times 10^{-5}/\text{year}$$

$$\text{Frequency failure resulting in missile generation} = 8 \times 10^{-5}/\text{year}$$

For offshore gas turbines failure data are given by OREDA (1992, 1997, 2002).

A14.16 Valves

A14.16.1 General

A study of valves in French nuclear power stations has been carried out by Aupied, Le Coguiec and Procaccia (1983). Some of the more critical valves are classified as primary valves and the others as secondary valves. Some of the failure rates obtained in this work are shown in Table A14.22, while failure modes are given in Table A14.23.

A survey designed to identify significant and common valve problems such as leakage and jamming and to relate them to valve type, service and manufacturer has been described by Vivian (1985). The survey was conducted in a major oil company and covered 10 businesses involving 17 facilities, of which a significant proportion are in the North Sea. Some quarter of a million valves were covered, of which almost 10% were reported as giving significant problems. The numbers of each type of valve are shown in Figure A14.4(a) and the associated problems in Figure A14.4(b).

The UKAEA data in Table A14.3 gives for control valves a failure rate of 0.25 failures/year and for manual valves 0.13 failures/year. The values used in the *Rijnmond Report* are 0.3 and 0.1 failures/year for control and manual valves, respectively.

Further values for valve failure rates obtained by Moss (1977 NCSR Rll) are discussed in Section A14.25. These values are 0.1 and 0.01 failures/year for valves on steam and water service, respectively. The latter value in particular is a lower than the others quoted here.

For valve rupture the *Rasmussen Report* gives a failure frequency of 1×10^{-8}/h (0.9×10^{-4}/year). For valves in offshore operation, failure data are given by OREDA (1992, 1997, 2002).

A14.16.2 Control valves

Data on the failure rates of control valves are given in Tables A14.3–A14.5. Further data are given in various parts of this appendix.

A14.16.3 Pressure relief valves

For pressure relief valves (PRVs) the definition of failure is particularly important. Definitions of failure that may be used include failure of any kind, failure to lift within a certain proportion of the set pressure and failure to open on demand. The failure rates for these different types of failure are quite different.

Data on the failure rates of PRVs are given in Tables A14.3–A14.5, A14.22 and A14.23.

The following data are for the failure rates of PRVs are given by Kletz (1972a, 1974a) and by Lawley and Kletz (1975):

	Failure rate (faults/year)
Valve fails shut	0.001
Valve lifts heavy	0.004
Total fail danger	0.005 (later modified to 0.01)
Valve fails open or lifts light	0.02
Total fail safe	0.02

A survey of PRV inspections in a large chemical company has been reported by Aird (1983). Failure was defined as lifting 10% outside the set pressure when put under test. The number of useful tests was 866. The proportion of failures was 44.5%.

The failure rate showed no discernible trend with operating time and it was concluded that PRVs may be subject to changes that occur relatively rapidly. One cause often quoted is spring relaxation.

A study of controlled safety valves in power stations has been made by Oberender and Bung (1984). The valves were either intrinsically controlled by the vented fluid or externally controlled by a control fluid (pneumatic or hydraulic). Two basic events were considered: faultless functioning and failure to open on demand. Some 1378 tests were conducted. The proportion of valves giving faultless functioning was approximately:

Intrinsic control	40%
External control	
Pneumatic	80%
Hydraulic	85%

The proportion giving failure on demand was approximately:

Intrinsic control	
Load principle	2%
Relief principle	4.5%
External control	
Pneumatic	0.3%
Hydraulic	0.8%

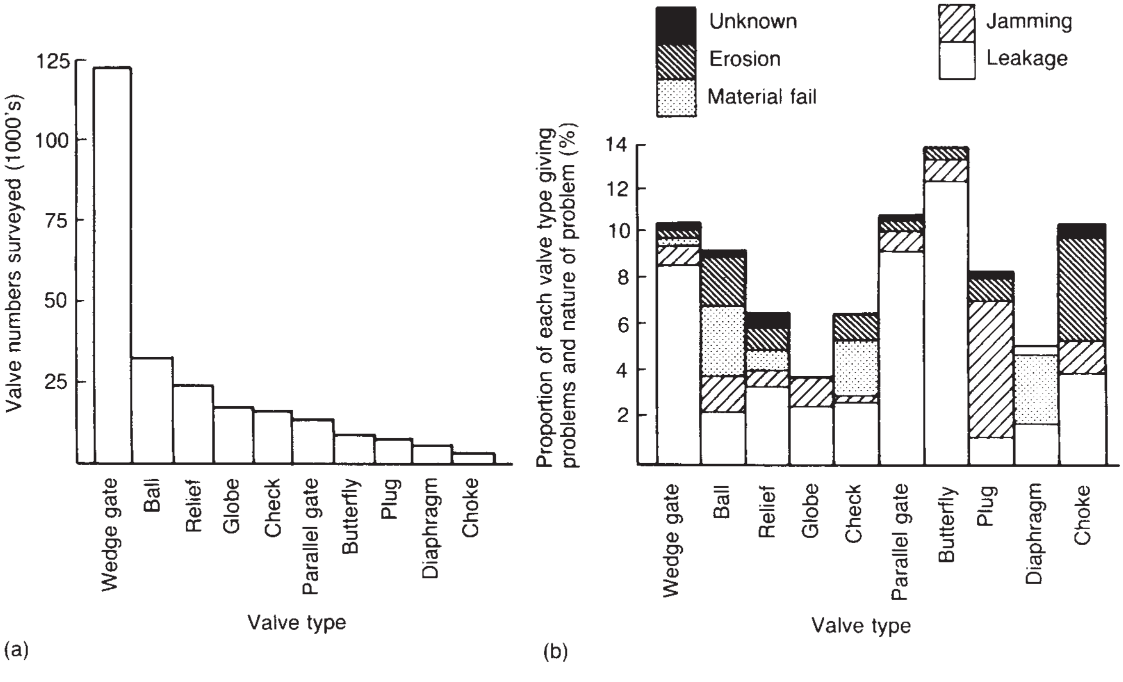

Figure A14.4 *Number and failure modes of valves in a large oil company survey (after Vivian, 1985): (a) number of valves; and (b) failure modes of valves (Reproduced by permission of Gower Press)*

For the intrinsically controlled valves, however, there was an improvement over time, the failure rate falling from some 10% in the initial period to $<1\%$ in the final period.

Estimates of the success rate of PRVs in particular applications have been given by Prugh (1981) as follows:

Venting of vapour/air explosion	1%
Venting of runaway reaction	95%
Venting of excessive nitrogen purge	99%

Historical data on a 10% random sample (240 valves) out of 2416 relief valves in a petrochemical plant were collected and analysed (Alfares 1999). Figure A14.5 shows the composition of the sample and valves in the plant, and Table A14.24 shows the average time between failure by valve pressure, service, size, temperature and type.

Failure data of relief valves for offshore operations are given by OREDA (1992, 1997, 2002). The following data are extracted from OREDA (1997):

Type	*Population*	*No. of failures*	*Mean failure rate* (per 10^6 h)	*Mean repair time* (manhours)
Globe (0.1–1.0 in.)	7	6	22.08	1.0
Globe (1.1–5.0 in.)	21	9	12.30	3.4
Globe (5.1–10.0 in.)	8	4	15.99	3.5

A14.16.4 Non-return valves

ORNL (Oak Ridge National Laboratory) and NIC (Nuclear Industry Check Valve Group) jointly conducted a study of check valve failures recorded between 1991 and 1992 in the INPO (Institute of Nuclear Power Operations) Nuclear Plant Reliability Data System (NPRDS) (McElhaney 2000). This study characterized check valve failures by valve type, and correlations between failure modes, failure causes, failure area, failure discovery method, extent of degradation with valve types were developed. Figures A14.6(a) and (b) are the distribution of 1991–92 check valve failures and 1991 check valve population by valve type respectively. Tables A14.25 and A14.26 are number of failures by valve type and failure mode and by valve type and failure cause specifically. Figure A14.7 is the relative failure rate by valve type and different system.

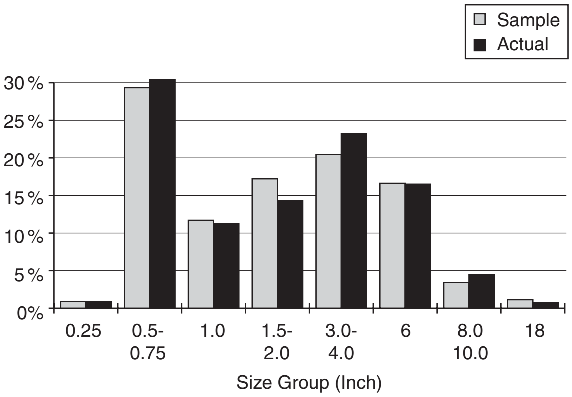

***Figure A14.5** The composition of the sample and relief valves in a petrochemical plant (Alfares, 1999; with permission from Elsevier)*

Additional data on the failure rates of non-return, or check, valves are given in Tables A14.4, A14.5, A14.22 and A14.23.

A14.16.5 Emergency isolation valves

Failure data for safety shut-down valves from OREDA (1992) has been analysed by Haugen, Hokstad and Sandtorv (1997). The safety shut-down valves included are mainly gate valves of approximately 6 in. handling oil, gas or water in offshore installations. The data are divided into two groups based on the test intervals (6 months or 12 months) as shown in Tables A14.27–A14.30.

OREDA (1997) gives failure rate data for shutoff valves in offshore operations as follows:

Type	*Population*	*No. of critical failures*	*Mean failure rate* (critical failures per 10^6 h)	*Mean repair time* (manhours)
Gate (1.1–5.0 in.)	104	13	2.10	0.3
Gate (20.1–30.0 in.)	1	1	28.54	3.0
Globe	8	1	5.19	4.0

Data on the failure rates of emergency isolation valves, also called slam shut or shut-off valves, are given in Table A14.5. Data on the failure rates of manual isolation valves are given in Tables A14.3 and A14.4.

A14.17 Instruments

For instruments the definition of failure is particularly important. This was discussed in detail in Chapter 13.

The importance of the definition of failure has been studied by Kortland (1983) for differential pressure transmitters. For transmitters required to maintain their calibration within 2% the failure rate observed was 0.1 failures/year. For transmitters with a required calibration within 5%, a less severe specification, the observed failure rate was a function of the calibration interval, being about 0.01 failures/year with a calibration interval of 1 year, but increasing for longer calibration intervals.

Some data on the failure rates of instruments are given in Chapter 13. The data given there refer mainly to instrumentation in the early and mid-1970s. The data given in this section supplement those given in Chapter 13 and include more recent data.

Data on the failure rates of instruments are given in Tables A14.3 and A14.4.

A study of control system failure sequences in ammonia plants has been described by Prijatel (1984). A comparison is given between predicted and actual failure sequences. Information on actual failure sequences was obtained from the work of G.P. Williams and Hoehing (1983). Some 95% of

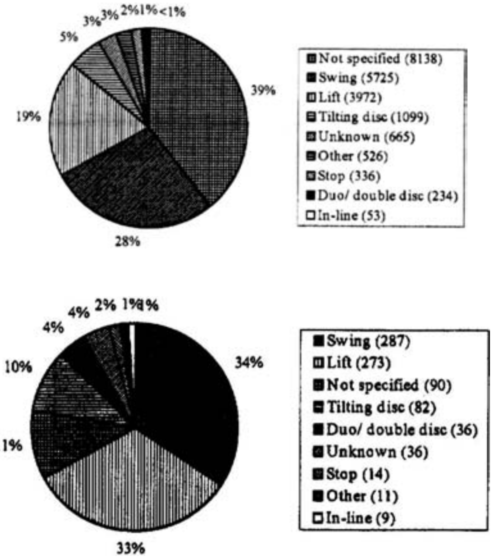

Fig A14.6 *(a) Distribution of 1991–92 check valve failure by valve type. (b) Distribution of 1991 check valve population by valve type (McElhaney, 2000; reproduced with permission from Elsevier)*

the actual failure sequences were single event failures. Data on instrument failure were obtained from plant records and from the literature. Some of the data used in the study are given in Table A14.31.

For control failure sequences the actual shut-down frequencies of particular units such as compressors were some two to four times as high as the predicted frequencies. The ranking of the instruments as a cause of shut-down was in descending order of importance controllers, switches, solenoid valves, control valves and uninterruptible power supply (UPS) system, the contribution of these items to shut-downs being 41.2, 36.7, 7.5, 4.6 and 4.3%, respectively. Thus two items, controllers and switches, accounted for 78% of shut-downs.

Data on the failure rates of process chromatographs and other analytical instruments have been given by Huyten (1979). Some 870 instruments are considered in the survey. He gives the following availabilities:

Analysers	93.8%
Gas chromatographs	91.0%

He also gives for analysers failure modes that include the following:

Sampling system	39%
Analyser	18%
Non-availability of spares	16%
Plant upsets, start-up and shut-down	11%

A comparative study of the MTBF and maintenance time for controllers from five manufacturers has been described by H.S. Wilson (1978). He gives the following data:

Manufacturer	*type*	*MTBF* (year)	*Maintenance time* (h)
A	Electronic	1	0.5
B	Electronic	1	1.5
C	Pneumatic	5	3
D	Electronic	3	4
E	Pneumatic	15	5

He comments that the controller from manufacturer E failed so rarely that the maintenance time was greater due to unfamiliarity. From this comment the maintenance times are evidently times per failure.

Paula (1993) presented failure rates for programmable logic controllers (PLC) in three different processes: a US phenol plant, French nuclear plants and a Canadian nuclear power plant with data input from operation personnel and Electricite de France (EDF). His result is presented in Table A14.32. Rate of coverage, the probability of a PLC successfully switching to the redundant processor upon a single processor failure, is also estimated.

A good deal of the literature data for instrument failure is now quite old. In general, it is to be expected that the failure rates have fallen. The following is a comparison of the failures rates given for certain measuring instruments

Table A14.25 *Number of 1991–92 failures by valve design and failure modes (McElhaney, 2000; reproduced with permission from Elsevier)*

8.2		2	1			1				4
Total	1	4	13	5	1	21	1	1	0	47

by Anyakora, Engel and Lees (1971) and for sensors in process alarm systems by OREDA (1992):

	Failure rate (failures/year)	
	Anyakora, Engel and Lees	*OREDA*
Pressure	1.41	
(p) (< 1500 psig)		0.019
(e)		0.37
Flow	1.73	
(p) (gas)		0.25
(e) (gas)		0.75
Level	1.71	
(e)		0.096
Temperature	0.88	
(e)		0.1

The first authors refer for pressure to 'pressure measurement', for flow and level to differential pressure transducers and for temperature transducers, but do not distinguish between transducers with pneumatic (p) or electronic (e) output. The instruments selected from the OREDA collection are all transducers with specified type of output. In comparing the figures, allowance needs to be made for the effects on failure rate of environment and calibration requirements. Nevertheless, the data do suggest an improvement in reliability.

Table A14.30 *Number of critical failures for various failure modes, $\tau = 12$ months (Haugen, Hokstad and Sandtorv, 1997; reproduced with permission from Elsevier)*

Code	*EXL*	*FTC*	*FTO*	*INL*	*LCP*	*SPO*	*· · ·*	*Total*
1.0			1					1
1.2		1	2					3
1.4		1	1		1			3
2.0	1			3	2			6
2.1	16		1	15	8			40
2.2		1						1
3.0		8						8
3.1		6				1		7
3.2		1						1
7.0			1					1
8.2	1	1		2				4
Total	18	19	6	20	11	1	0	75

The codes system used for the failure modes are shown as follows:

DOP	Delayed operation
EXL	External leak
FTC	Fail to close
FTO	Fail to open
INL	Internal leak
LCP	Leakage in closed position
PLU	Plugged
SPO	Spurious operation

For process sensors used in offshore operations, OREDA (1997) gives the following data:

Application	*Population*	*No. of failures*	*Mean failure rate* (/10^6 h)	*Mean repair time* (manhours)
Flow	72	92	26.41	0.4
Level	73	57	32.93	10.4
Pressure	282	137	18.06	6.4
Temperature	8	7	56.36	0.5

A14.18 Process Computers

The reliability of process computer systems is discussed in Chapter 13.

Data on the failure rates of 12 process computer systems in the paper industry given by Hubbe (1970) are shown in Table A14.33.

Data by E. Johnson (1983) on the failure rates of several different process computer configurations are summarized in Table A14.34. The data refer to total system failure, rather than failure of individual items such as printers. Johnson gives full details of the fault and downtime incidents. He states that for the total system an MTBF of 5000 h with a combined availability of about 99.9%, corresponding to no more than 8 h downtime per year, is about the level which may be found acceptable.

A14.19 Relief Systems

Some information is available on the failure rates of the individual elements of a pressure relief system, such as pressure relief valves, bursting discs and vent systems. Data on the failure of these items is given in this section. For chemical reactors, information on the failure rate of pressure relief systems has been given by Marrs and Lees (1989) as described in Chapter 11.

A14.19.1 Pressure relief valves

Data on the failure rate of PRVs are given in Section A14.16.3.

A14.19.2 Bursting discs

Data for the failure rate of bursting discs are given by Lawley (1974b) as follows:

Frequency of disc rupture at normal pressure
= 0.2 failures/year.

Table A14.31 *Failure of instruments in ammonia plants (after Prijatel, 1984)*

	Failure rate (failures/year)
Control valves	0.028
Controllers[a]	0.25
Switches[b]	0.22
Redundant switch systems[c]	1.68×10^{-4}
Solenoid valves	0.046
UPS system	0.026

[a] For flow, pressure, level.

[b] For flow, pressure, temperature, level.

[c] An alternative figure of 2.9×10^{-3} failures/year is also given.

Table A14.32 *Failure and coverage rates of PLC in an US phenol plant, French-design nuclear power plants, and a Canadian nuclear power plant (Paula, 1993; reproduced with permission from Elsevier)*

PLC application	*Single processor failure rate (per PLC year)*	*Total PLC failure rate (per PLC year)*		*Coverage*	
US phenol plant	2	0.0082[b]	0.016[c]	0.9918–0.9959[b]	0.9837–0.9918[c]
French-design nuclear power plants	–[a]	0.011[d]	0.021[e]		
Canadian nuclear power plant	–[a]	0.025			

[a] Information not available.
[b] Excluding early failures.
[c] Including early failures.
[d] Excluding power supply failures.
[e] Including power supply failures.

Table A14.33 *Failure data for 12 process computer systems in the paper industry (Hubbe, 1970)*

	MTBF		*Availability*	
	Hardware faults (h)	*Software faults* (h)	*Hardware faults* (%)	*Software faults* (%)
Composite average	550	1365	99.1	99.80
Best case	1633	8163	99.94	99.97

Table A14.34 *Failure data for some process computer systems in the chemical industry (after E. Johnson, 1983; reproduced by permission of Elsevier Science Publishers)*

System	*Operating time* (h)	*No. of failures*	*Downtime*		*Availability* (%)
			Failure (h)	*Planned* (h)	
Single computer system with analogue standby	66,528	13	65	300	99.9
Twin computer system with analogue standby[a]	35,040	8	30.5	38	99.91
Twin computer system with shared critical loops – 1	78,888	21	172	48	99.78
Twin computer system with shared critical loops – 2	78,888	37	388	73	99.5
Twin computer system with analogue standby[a]	13,848	6	54	17	99.61

[a] Different configurations.

For chemical reactors the failure rate of bursting discs in a single company has been investigated by Marrs and Lees (1989). The estimates obtained refer to the bursting disc itself, including blockage before the disc, but not to the vent pipework after the disc. There were during the period of investigation 11 successful ventings and no failures. The estimated probability of failure from these data is 0.083 failures/demand. An alternative, and less pessimistic, estimate was obtained from the fact that there were four unrevealed fail-to-danger failures in 164 reactor-years with an inspection interval of 1 year, giving an estimated probability of failure of 0.012. The authors' best estimate of the probability of failure is 0.01 failures/demand, but the confidence bounds are relatively wide.

A14.19.3 Vent systems

For chemical reactors and vented vessels, the failure rate of vent systems, excluding bursting discs, in a single company has been investigated by Marrs and Lees (1989). There were 28 successful ventings and no failures during the period of investigation.

The estimated probability of failure from these data is 0.034 failures/demand. An alternative, and less pessimistic, estimate was obtained from the fact that there was one unrevealed fail-to-danger failure in 262 vessel-years with an inspection interval of one year, giving an estimated probability of failure of 0.0019. The authors' best estimate of the probability of failure is 0.002 failures/demand, but the confidence bounds are relatively wide.

A14.20 Fire and Gas Detection Systems

A study of fire detection systems with particular reference to false alarms has been described by Peacock, Kamath and Keller (1982). Some data from this study are shown in Table A14.35. Section A of the table shows the event rates for fire detection systems as assessed for chemical plant by safety officers from a single company. Section B gives the event rates for each type of detector.

Hanks (1983) has described a study of the fire and gas detection system at the gas terminal at St Fergus. The results reported for failure rates are confined to those for the gas detectors, which were mainly in compressor cabs

Table A14.35 Some event rates in fire detection systems (after Peacock, Kamath and Keller, 1982; reproduced by the permission of the American Institute of Chemical Engineers)

A Events by location

	Event rate (events/10^3 detector-year)			
	Real alarms	*False alarms*	*Failure to operate*	*Real alarms/false alarm*
Plant in buildings	4.7	3.4	0.15	1 : 0.7
Plant in open	60	273	27	1 : 4.6
All locations	2.1	7.2	0.16	1 : 3.4

B Events by type of detector

Smoke	5.9	40	0.5	1 : 6.8
Heat	1.5	5.3	0.3	1 : 3.5
Smoke and heat	16	38	0	1 : 2.4
Flame (UV, IR)	108	622	108	1 : 5.8

and emergency generator rooms. Hanks gives the following failure rates:

	Failure rate (failures/10^6 h)	
	Compressor cab	*Other installation*
Gas detector	48	8
Gas detector and module	75	35

Y.P. Gupta (1985) describes a survey of automatic fire detection systems at six sites. His account includes estimates of the failure rates of ionization-type smoke detectors synthesized from data on the reliability of electronic components. For detectors in a first class, or non-adverse, environment, the overall failure rate was assessed as 0.057 faults/year, of which 0.04 faults/year were classed as fail-safe and 0.017 faults/year as dangerous. Most adverse environments result in a much higher failure rate. For such environments the failure rate was assessed as 0.46 faults/year. For control units the failure rate was assessed for false alarms as 0.044 faults/year and for unrevealed dangerous faults as 0.06 faults/year.

The US Navy Program, Damage Control Automation for Reduced Manning (DC-ARM) tested the performance of 20 sensors to 120 scenarios (82 fire, 38 nuisance sources and 120 non-fire events) (Rose-Pehrsson *et al.*, 2000). These sensors include electrochemical cell sensors (most of the gas detectors), solid state metal sensor (general hydrocarbon sensor), non-dispersive infrared sensor (carbon dioxide detector), photoelectric smoke detectors and ionization smoke detectors, which is shown in Table A14.36. The performance of smoke detectors is shown in Table A14.37. The data set were analysed with probabilistic neural network and par of the results is shown in Table A14.38.

For offshore fire and gas detection systems failure data are given by OREDA (1992, 1997, 2002). OREDA (1997) include failure rate data for fire and gas detectors as following (all failure modes included):

Type	*Population*	*No. of failures*	*Mean failure rate* (Per 10^6 h)	*Mean repair time* (man hours)
Flame				
Infrared	520	111	11.94	8.6
Combination IR/UV	132	31	7.36	0.4
Ultraviolet	358	150	48.84	6.1
Heat				
Rate compensated	666	46	2.30	17.4
Rate-of-rise	199	33	7.06	3.8
Smoke/combustion				
Ionization	1214	171	4.60	3.9
Photo electric	683	47	2.13	3.3
Hydrocarbon gas				
Catalytic	2044	1730	31.08	4.5
Infrared	2	19	309.97	10.5
H_2S gas	10	1	3.26	–

A14.21 Fire Protection Systems

Data on the failure rates of sprinkler systems are available from sources such as the Factory Mutual Research Corporation and the NFPA.

A review of failure rates of sprinkler systems that draws on these sources has been given by Rasbash (1975a). For fires in buildings in the United Kingdom in the period 1966–71, the breakdown of incidents given is

Type of incident	*No. of incidents*
Small fire, extinguished by other means	5,229
Sprinkler system installed and operated	
Fire controlled by other means	275
Fire controlled by sprinkler	3,180
Fire extinguished by sprinkler	651
Effect of sprinkler unknown	73
Sprinkler system installed but did not operate	676
Total	10,084

Thus, excluding the small fires, sprinkler performance was unsatisfactory in some 14% of cases. NPFA statistics for the period 1925–64 quoted by Rasbash indicate that in some 75,290 fires sprinkler performance was unsatisfactory in some 3.8% of cases.

Rasbash also quotes statistics from the Australian Fire Protection Association (AFPA). For some 5734 fires in the period 1886–1968 the proportion of sprinklers which gave unsatisfactory performance was 0.2%. For some 1250 fires in the period 1968–73 the proportion was 0.64%. These very low AFPA values are discussed by Rasbash, who refers to differences in the criteria for satisfactory operation.

Table A14.36 *Sensors used in the multicriteria detection test program (Rose-Pehrsson et al., 2000; reproduced with permission from Elsevier)*

Species	*Sensor range*	*Resolution*	*Instrument model number*	*Manufacturer*
Oxygen (O_2)	0–25%	0.1% O_2	6C	City Technology
Carbon monoxide with H_2 compensation (CO 4000 ppm)	0–4000 ppm	1 ppm	A3ME/F	City Technology
Carbon monoxide (CO 50 ppm)	0–50 ppm	0.5ppm	TB7E-1A	City Technology
Carbon dioxide (CO_2)	0–5000 ppm	Accuracy = greater than ±5% of reading or ±100 ppm	2001V	Telaire/Englehard
C_1–C_6 hydrocarbons (Ethyl)	0–50 ppm ethylene (C_2H_4)	±2.5 ppm	SM95-S2 with general hydrocarbons solid state sensor	International sensor technology
Hydrogen (H_2)	0–200 ppm	2 ppm	TE1G-1A	City Technology
Hydrogen chloride (HCl)	0–10 ppm	0.5 ppm	TL1B-1A	City Technology
Hydrogen cyanide (HCN)	0–25 ppm	0.1 ppm ± 2%F.S. accuracy	4664-40-1-1-1	EIT
Hydrogen sulfide (H_2S)	0–5 ppm	0.1 ppm	TC4A-1A	City Technology
Sulfur dioxide (SO_2)	0–10 ppm	0.5 ppm	TD2B-1A	City Technology
Nitric oxide (NO)	0–20 ppm	0.5 ppm	TF3C-1A	City Technology
Temperature (thermocouple or TC)	−200 to 1250°C	1°C or 0.75%	Type K, 0.127 mm bare bead TC	Omega
Temperature (Temp)	−20°C to 75°C	±0.6°C accuracy	HX93 transmitter (RTD)	Omega
Relative humidity (RH)	3–95%	±2%RH accuracy	HX93 transmitter	Omega
Photoelectric smoke detector (PHOTO)	0–19% obs./m		4098–9701	Simplex
Ionization smoke detector (ION)	1.6–10% obs./m		4098–9716	Simplex
Residential ionization smoke detector (RION)			83R	First Alert
Optical density meter (ODM)			VDM-2 670 nm, 2 mW laser	Meredith
Laser and photodiode with 0.965 m spacing			MRD 500 PIN silicon	Motorola
Measuring ionization chamber (MICX, MICY, MICY20)			EC-912	Photodiode Delta Electronics Testing

Table A14.37 *Summary of smoke detector performance (Rose-Pehrsson et al., 2000; reproduced with permission from Elsevier)*

Alarm level (%obs./m)	*Photoelectric*			*Ionization*		
	Fire source (%)	*Nuisance source* (%)	*Overall*[a] (%)	*Fire source* (%)	*Nuisance source* (%)	*Overall* (%)
Typical: 11 (Photo) 4.2 (Ion)	38	82	52 (76)	68	71	69 (85)
UL 268 minimum: 1.63	70	53	65 (83)	80	61	74 (87)
Half the UL 268 minimum 0.82	73	53	67 (83)	84	58	76 (88)

[a] Overall percent correct is based on 82 fires and 38 nuisance sources (120 for events). The parenthetical value is the percent correct based on 82 fires, 38 nuisance sources and 120 nonfire (background) events. The parenthetical value is the overall classification parameter that can be compared to the multivariate analysis results.

For the United Kingdom fires the two principal causes of unsatisfactory performance were that the heads were inaccessible to the fire and that the water was shut off, these occurring in 9.6 and 4.3% of the incidents, respectively.

The figures for unsatisfactory performance of sprinklers given by P. Nash and Young (1976) for the NPFA and Australian data are similar, but they give for the United Kingdom for the period 1965–69 a figure of 8.3% and quote a figure of 15% given by the Factory Mutual Corporation for the period 1970–72.

From the UK data, the causes of unsatisfactory performance are given as system shut off, defective system,

system frozen and unknown, these occurring in 4.6, 0.60, 0.07 and 3.0% of the incidents, respectively.

From the NFPA data some principal causes of unsatisfactory performance were valve shut, inadequate water supply and obstruction to distribution, these occurring in 36.0, 9.6 and 8.4% of the incidents, respectively. The causes for the valve being closed were closed for no known reason, closed too early in the fire, closed for system repair or modification and closed to prevent freezing, these occurring in 22, 21 and 20% of cases with a closed valve.

Nash and Young also give failure rates for the components of sprinkler systems as follows:

Component	*Failure rate* (failures/year)	
	Safe	*Dangerous*
Wet alarm valve	15×10^{-2}	0.4×10^{-4}
Alternate alarm valve	15×10^{-2}	0.8×10^{-4}
Alarm motor and gong	6×10^{-2}	1.6×10^{-2}
Accelerator	13×10^{-2}	7.9×10^{-3}
Main sprinkler stop valve	–	2×10^{-3}
Non-return valves	–	10×10^{-3}

Budnick (2001) reported an analysis of 16 published reliability data for automatic sprinkler systems and the mean value of reliability was estimated between 93 and 96% in his results. Further data on the effectiveness of fire protection systems have been given by M.J. Miller (1977), based on Factory Mutual experience in the period 1970–75. In presenting data, the author warns that an unknown number of system operations are not reported. He also points out that there is no standard definition of effectiveness so that there is an element of subjectivity. He states as rough guidance that the performance would be considered acceptable if the system is designed to FM/NFPA standards and is operated within the design conditions and if any loss does not exceed the estimated Normal Loss Expectancy. For sprinkler systems, the number of reported events by type of system, with the proportion effective in brackets, was as follows: wet 2102 (91%); dry 650 (86%); deluge 62 (76%) and non-freeze 16.

For special protection systems, the number of events with the proportion of successes, was as follows: water spray 49 (53%); dry chemical 22 (27%); carbon dioxide 100 (51%) and steam 30 (63%).

Information on failure rates of special protection systems is limited. For carbon dioxide systems in Germany, Miller quotes a success rate of some 76–78% over a 14-year period.

For Halon systems, he states that data are even scantier, but refers to a series of 300 tests of such systems by Dupont in which in some 23% of installations significant problems were identified and corrected.

Miller also gives data on the effectiveness of other active protection systems, namely: gas analyser; smoke detector; rate-of-rise detector; spray nozzles; foam water sprinkler; high expansion foam; low expansion foam; explosion suppression; halon (fire protection); halon (explosion suppression); vaporizing liquid; inert gas; in-rack sprinklers; standpipes. For only three of these is the number of reported events 10 or more, the numbers, with the number of successes, being as follows: gas analyser 13 (2); high expansion foam 10 (3) and low expansion foam 12 (5).

Reliability data of fire protection features from one boiling water reaction (BWR) sites and two pressurized water reaction (PWR) sites in German has been statistically analysed (Rowekamp and Berg, 2000). The study covers 7-year operation of BWR and 7 and 4 years of operation for the two PWRs. Failure rates and unavailability for the fire protection equipment were estimated and presented in Table A14.39.

A14.22 Emergency Shut-down Systems

Data on emergency isolation valves are given in Section A14.16.

For offshore emergency shutdown systems, failure data are given by OREDA (1997). It includes emergency shutdown valves as follows (all failure modes included):

	Population	*No. of failures*	*Mean failure rate* (failures/10^6 h)
Ball			
5.1–10.0 in.	14	29 (1)	61.61
10.1–20.0 in	13	15 (3)	32.93
20.1–30.0 in	2	0 (0)	6.04
Butterfly	1	1 (1)	28.54
Gate			
1.1–5.0 in.	39	24 (11)	20.13
5.1–10.0 in.	481	245 (105)	26.50
Plug	2	7 (1)	99.89

The values for number of failures in brackets refer to failure to close or to failure involving some degree of internal leakage.

For offshore platforms in the Gulf of Mexico, Forsth (1983) has reported that in 12 cases where the emergency shutdown system was mentioned in the fire or explosion incident report, the system operated properly in 11 but failed in one.

For programmable logic controllers used in the emergency shutdown systems, Mitchell and Williams (1993) analysed failure data from natural gas compressor stations. The failure rate of PLC (microprocessor failures only) was estimated to be 0.072 failures/PLC year while the overall PLC failure (all causes) was estimated 0.32 failures/PLC year.

A14.23 Utility Systems

A14.23.1 Electrical power

The failure rate of the outside power supply varies with the country concerned. In the United Kingdom, the National Grid system gives a high reliability supply and the failure rate is relatively low. In addition, chemical works often have their own power station. The failure rate of the power supply to a plant should normally be determined for the particular works.

For the United Status, the *Rasmussen Report* (figure III 6–5) gives data for outage times following a transmission line failure, as shown in Table A14.40.

A detailed study of the power supply to a plant making RDX explosive, on which it is critical that agitation should not stop, has been described by Ketron (1980). His analysis of the distribution of power failures by duration may be summarized as shown in Table A14.41. The dates quoted in the table run from December 1968 to January 1974 .

A study of probability of off-site power outage versus duration at three nuclear plants is published by Arul *et al.* (2003) with the probability of 1-h off-site power outage between 0.1 and 1.0.

Table A14.40 *Outage times of electrical power supply following a transmission line failure (after Atomic Energy Commission, 1975)*

Outage time (%)	*Proportion of outages* (%)
< 0.01	1.1
0.01–0.032	6.1
0.032–0.1	18.7
0.1–0.32	37.9
0.32–1.0	12.6
1.0–3.2	11.7
3.2–10	8.4

Table A14.41 *Duration of power failures in an explosives plant (after Ketron, 1980; reproduced by permission of the American Institute of Chemical Engineers)*

Duration of power failure t (min)	*No. of incidents*
Momentary	13
$t < 1$	3
$1 < t < 10$	2
$10 < t < 60$	4
$t > 60$	6
Total	28

Literature failure rates of equipment used in power supply systems given by Ketron are shown in Table A14.42. Weather-related features of power supplies have been considered by Jarrett (1983).

A14.23.2 Diesel generators

Information on the reliability of diesel generators is given in the *Raosmussen Report* (AEC, 1975). The study gives a probability of failing to start on demand of 3×10^{-2}.

Thus, if there are two diesel generators, but only one is required to provide the full emergency load, it might be calculated that the probability of both generators failing to start on demand is 9×10^{-4}. In fact, however, startup is treated in the study (p. III-72) as a single event that may trip both units. The probability of both generators failing to start on demand is assessed as 10^{-2}. The repair time for a diesel generator is given in the study (p. III-55/56) as a mean time of 21 h with a range of times of 2–300 h.

A survey of emergency generating equipment over the period 1977–82 has been reported by R. Stevens (1983). Much of the equipment was found to be in appalling condition. The failure modes are shown in Table A14.43.

Twenty-six years' operational data of 11 diesel generators of 125–250 kV A at Chalk River Nuclear Laboratory have been analysed presented by Winfield (1988), which gave a mean failure to start probability of 4.4×10^{-2} and failure to run probability between 5.6×10^{-3} and 1.2×10^{-2}.

Table A14.42 *Failure rates of electrical power supply equipment (after Ketron, 1980; reproduced by permission of the American Institute of Chemical Engineers)*

	Failure rate[a] (failures/d)
Diesel engine	0.008
Electric generator	0.0014
Electric motor	0.0014
Steam turbine	0.000057
Solenoid valves	0.0000063
Pneumatic valve	0.00011
Globe valve	0.0034

[a] Literature values.

Table A14.43 *Failure modes of emergency engines/generators (after B. Stevens, 1983; reproduced by permission of the American Institute of Chemical Engineers)*

	No. of cases	*Proportion* (%)
Cracking/overheating	36	26.1
Cracking/freezing	13	9.4
Mechanical breakage	6	4.4
Bearings and journals/scoring	18	13.0
Engine block/breakage	14	10.1
Pistons/breakage	9	6.5
Valves/breakage	7	5.1
General mechanical	20	14.5
Piston rings/breakage	7	5.1
Crankshaft/cracking–breaking	8	5.8
Total	138	100.0

Table A14.44 Mean probability of failure of emergency diesel generators at 63 nuclear plants from 1988–91 (Vesely, Uryasev, and Samanta,1994; reproduced with permission from Elsevier)

	For individual diesels	*Over station*	*Diesels or stations*
Failure to start	5.0×10^{-3}	5.2×10^{-5}	5.0×10^{-3}
Failure to load-run	9.6×10^{-3}	9.5×10^{-5}	9.3×10^{-3}

A total of 195 emergency diesel generators at 63 operating nuclear plants have been analysed from 1988 to 1991 (Vesely, Uryasev and Samanta, 1994). The mean probability of failure to start and failure to load-run is given in Table A14.44. Load-run failure is defined as diesel generator starts but does not run successfully. Estimation of standard deviation and variance is also provided in their paper.

For offshore diesel-driven pumps and emergency power generators, failure data are given by OREDA (1997) as follows.

	Population	*No. of failures*	*Mean failure rate* (per 10^6 h)	*Failure to start on demand*
Main power				
1–100 kW	2	82	731.62	–
100–1000 kW	8	174	479.80	–
Emergency power	7	142	685.44	0.018

A14.23.3 Instrument air

An estimate of the failure rate of the instrument air supply has been given Lawley and Kletz (1975). They give: failure frequency of instrument air supply = 0.05 failures/year.

This evidently refers to the instrument air supply rather than to the connections from the air supply to the instrument, for which separate failure rates are quoted.

A14.23.4 Cooling water

The arrangements for the supply of cooling water in a works vary somewhat. Generally, there is a works cooling water supply system, but use may also be made of other sources of supply such as wells.

A typical estimate of the failure rate of the cooling water supply of about 0.1 failures/year. This is for the supply itself and does not include failure of equipment such as cooling water pumps supplying a particular plant.

A14.23.5 Steam

Information on the failure rates of components of steam supply systems has been given by Coltharp *et al.* (1978), who carried out a study on the steam system of an automobile factory. Some of the data given by these authors is shown in Table A14.45.

Table A14.45 Failure rates of some components of a steam supply system (after Coltharp et al., 1979; reproduced by permission of the American Institute of Chemical Engineers)

Equipment	*Failure rate*[a] (failures/10^6 h)
Drives for spreader stoker:	
Electric drive	0.3
Steam drive	50
Boiler feedwater pump	0.9
Condensate collection and return	10
Waterwall tubes	57
Steam generating tubes	0.3
Superheater	0.4
Air preheater	1.1
Fans	
Overfire air	57
Induced draft	1.1
Drives for fans (forced draft, overfire air, induced draft)	
Electric drive	2
Steam drive	3
Ash conveyor	10

[a] Sources of data are Edison Electric Institute (EEI), Hartford Steam Boiler (HSE) and automobile company.

A14.24 LNG Plants

A survey of events on LNG plants has been reported by Welker and Schorr (1979). The data were obtained on 25 LNG peak-shaving plants in the United States ranging in age from 10 years to a few months. The survey covered nearly 35,000 h of vaporization experience, more than 400,000 h of liquefaction experience and more than 1.5 million hours of tank storage, as well as nearly 1.5 billion ft-h of pipe use and more than 1.3 million manhours of operating time.

The authors define a minor failure as one which results in an unscheduled shutdown of operating equipment where the repair period is less than 24 h, a major failure as one where the shutdown is more than 24 h and a safety-related failure as one which results in a fire or a large leak of gas or liquid.

Major leaks of gas are defined as those which could result in a release of the order of 100,000 ft^3 of gas. Major leaks of liquid involved primarily vaporizer tubes or pumps, with one major leak due to flange gasket failure.

The fires reported are confined to those involving LNG as gas or liquid. About half the fires were minor and half major. Vaporizers appeared to have a high risk of fire, because they have a relatively high failure rate and are located near fired equipment.

Some failure and event rates given in this survey are shown in Table A14.46.

A14.25 Leaks

A14.25.1 Leak sources

Information on the distribution of leak sources is available in several different classifications. The distribution of the place of origin for large fires in Great Britain 1971–73 has been given in Table 2.11.

The distribution of leak sources for process industry accidents reported to the HSE in the year 1987–88 has

Table A14.46 Failure and event rates on LNG plants (after Welker and Schorr, 1979; reproduced by permission of the American Gas Association)

A Failure rates

Plant section or equipment	*MTBF* (h)			
	Major failure	*Minor failure*	*Safety-related failure*	*Total failures*
Gas pretreatment	20,000	3000	$>350{,}000$[a]	3000
Liquefaction	6500	2500	$>420{,}000$[a]	1800
LNG vaporizers	8000	700	15,000	700
Compressors	3000	900	$>2 \times 10^{6}$[a]	700
LNG pumps	$>35{,}000$	3500	$>35{,}000$	3500
Cryogenic valves	$>4 \times 10^{7}$[a]	2×10^{7}	$>4 \times 10^{7}$[a]	2×10^{7}
Controls	15×10^{6}	700,000		

B Other events

	MTBF (h)
LNG tanks:	
Gas leaks	$>1.5 \times 10^{6}$ (no leaks)
Liquid leaks	$>1.5 \times 10^{6}$ (no leaks)
Cold spots	100,000
Pipelines (per ft):	
LNG pipelines	$>1.5 \times 10^{9}$ (no failures)[b]
Pipe insulation	$>1.5 \times 10^{9}$ (no failures)
Fire water mains	$>1.6 \times 10^{9}$
Hazard detection sensors:	
Gas	100,000[c]
Radiation	350,000[c]
High temperature	$>4 \times 10^{6}$ (no failures)
Smoke	1.4×10^{6}
Emergency systems:	
Water hydrants, monitors	4×10^{6}
Halon systems	100,000
Dry chemical systems	3×10^{6}
Human errors, leaks and fires:	
Human error incidents	50,000
Major gas leaks	300,000
Major liquid leaks	150,000
Major fires	200,000[d]

[a] No failures.
[b] Small leaks from gaskets not included.
[c] Excluding false alarms.
[d] Leaks only.

been analysed by A.W. Cox, Ang and Lees (1990). Separate analyses are given for normal, closed process plant and for plant and activities with open surfaces, etc., as shown in Tables A14.47 and A14.48, respectively.

For vapour cloud explosions the distribution of leak sources has been obtained by A.W. Cox, Ang and Lees (1990) from the case histories listed by Davenport (1977, 1983) as shown in Table A14.49.

For fires and explosions on offshore installations in the Gulf of Mexico and in the Norwegian North Sea the distribution of leak sources has been obtained by A.W. Cox, Ang and Lees (1990) from data given by Forsth (1981a,b) as shown in Tables A14.50 and A14.51.

Based on the API analysis of the SCAQMD refinery screening data, 90% of reducible fugitive emissions come from only about 0.13% of the piping components (API, 1997; Taback, Siegell, Martino, and Ritter, 2000).

A14.25.2 Leak frequency

Estimates of the frequency of leaks on ammonia installations and carriers have been made by Baldock (1980) and are given in Table A14.52.

In late 1987, 39 chemical plants and EPA jointly conduct a fugitive emission study including all domestic producers of ethylene oxide, phosgene and acrolein. Around 100,000 components were examined between 1988–1990, and the result is presented in Berglund (1992), and leak rate is also found to be a function of monitoring frequency and maintenance procedure.

Table A14.47 *Leak sources on closed process plant (after A.W. Cox, Ang and Lees, 1990; reproduced by permission of the Institution of Chemical Engineers)*

	No. of incidents	*Proportion of incidents* (%)
Plant	19	22.1
Reactor	8	9.3
Vessel	10	11.6
